where each $\kappa_{\vec{q}j\alpha}$ is a product of the phonon's mode-specific heat $C_{\vec{q}j} = n_{\vec{q}j}^0 \left(n_{\vec{q}j}^0 + 1 \right) \left(\hbar\omega_{\vec{q}j} \right)^2 / V_0 k_B T^2$ (here normalized by crystal volume V_0), velocity component in the transport direction $v_{\vec{q}j\alpha} = d\omega_{\vec{q}j}/dq_\alpha$, and lifetime $\tau_{\vec{q}j}$. Depending on crystal symmetry, this lifetime can vary with the direction of the temperature gradient and thus will sometimes be given a Cartesian subscript and called a transport lifetime $\tau_{\vec{q}j\alpha}$. This directional dependence will be disregarded here, but discussed later when relevant. $n_{\vec{q}j}^0 = 1/\left(e^{\hbar\omega_{\vec{q}j}/k_B T} - 1 \right)$ is the Bose-Einstein distribution that represents the phonon population in equilibrium, $\omega_{\vec{q}j}$ is the frequency, and k_B is Boltzmann's constant. $C_{\vec{q}j}$ and $\vec{v}_{\vec{q}j}$ are functions of the phonon frequencies alone and are thus described as harmonic properties as they arise from noninteracting harmonic phonons (Sect. 2.2). The intrinsic phonon lifetimes (Sect. 2.4) require a description of interacting phonons, thus including anharmonic terms in the interatomic potential (Sect. 2.3).

2.2 Phonons: Harmonic

A crystal is built from a base unit cell consisting of a small subset of atoms that is mapped out in space by a set of primitive lattice vectors $\vec{R}_l$ in a periodic pattern (one for each dimension of the system). Here l designates the lth unit cell and k will designate a particular atom in the unit cell. It is assumed that the atoms do not deviate significantly from their equilibrium positions (justification for the harmonic approximation) and the equations of motion are given by:

$$-\frac{\partial V_{\text{harm}}}{\partial u_{lk\alpha}} = m_k \frac{d^2 u_{lk\alpha}}{dt^2} \tag{3}$$

$u_{lk\alpha}$ is the displacement from equilibrium in the αth direction of the kth atom in the lth unit cell, m_k is the mass of this atom, and V_{harm} is the harmonic contribution to the interatomic potential energy $V = V_0 + V_1 + V_{\text{harm}} + V_{\text{anharm}}$ (lowest-order nontrivial term in a Taylor expansion of V) given by:

$$V_{\mathrm{harm}} = \frac{1}{2} \sum_{lk} \sum_{l'k'} \sum_{\alpha\beta} \Phi_{\alpha\beta}^{lkl'k'} u_{lk\alpha} u_{l'k'_\beta} \tag{4}$$

$\Phi_{\alpha\beta}^{lkl'k'} = \partial^2 V / \partial u_{lk\alpha} \partial u_{l'k'_\beta}$ are called the harmonic interatomic force constants (IFCs), and the derivatives are to be evaluated at equilibrium. Details of the calculation of these will be given in Sect. 3.1. Assuming a plane wave form for the atomic displacements $u_{lk\alpha} = \sum_{\vec{q}j} \varepsilon_{\vec{q}jk\alpha} e^{i\left(\vec{q}\cdot\vec{R}_l + \omega_{\vec{q}j}t\right)}$ (Srivastava 1990), substituting in Eqs. 3 and 4, and invoking translational invariance to eliminate the sum over unit cells, l gives an eigenvalue equation that is solved for $\omega_{\vec{q}j}$ and the eigenvectors $\varepsilon_{\vec{q}jk\alpha}$. In practice, these are determined by diagonalizing the so-called dynamical matrix for each $\vec{q}$:

$$\overline{D} = D_{\vec{q}\alpha\beta}^{kk'} = \frac{1}{\sqrt{m_k m_{k'}}} \sum_{l'} \Phi_{\alpha\beta}^{0kl'k'} e^{i\vec{q}\cdot\vec{R}_{l'}} \tag{5}$$

For polar materials, nonanalytic long-range Coulomb corrections to this dynamical matrix can play an important role in deriving optic mode frequencies, particularly longitudinal/transverse (LO/TO) splittings. An example of this is given in Fig. 2 for KCl where the LO and TO branches are highly separated at the Γ point. These long-range Coulomb corrections can be constructed from Ewald sums involving Born effective charges and high-frequency dielectric tensors from DFT calculations (Baroni et al. 2001). Not correcting for the LO/TO splitting can give artificially reduced scattering of heat-carrying acoustic modes interacting with these phonons and thus overestimation of the thermal conductivity.

Crystal periodicity reduces the calculations of all vibrational properties to the first Brillouin zone of the reciprocal lattice, in momentum space. Unit cells and symmetry are important considerations when taking on a transport calculation. The number of atoms in a typical unit cell can range from $n = 1$ (e.g., aluminum or lead) to n hundreds of atoms. This gives $3n$ phonon branches corresponding to three vibrational degrees of freedom for each unit cell atom and can be a limiting factor depending on computational resources. Figure 2 gives the phonon dispersion, relationship of $\omega_{\vec{q}j}$ and $\vec{q}$, within the first Brillouin zone and along high-symmetry directions for rock salt structure KCl. KCl has two atoms in its unit cell and thus six phonon branches – three acoustic branches with $\omega_{\vec{q}j} \to 0$ as $|\vec{q}| \to 0$ due to translational invariance of the crystal and three optic branches at higher frequencies.

Even at the simple harmonic level, various observables to compare with measurements can be determined: phonon frequencies (neutrons (Dorner 1982; Willis et al. 2009), x-rays (Burkel 2000; Rueff 2010), and Raman (Cardona 1975; Merlin et al. 2000) resonances), vibrational density of states (DOS), the volumetric-specific heat at low temperatures, elastic constants, and sound velocities. The phonon DOS is given by:
Fig. 2 Phonon dispersion along high-symmetry directions of rock salt structure KCl, black curves are calculations that employed density functional perturbation theory (Baroni et al. 2001) and red circles are from neutron scattering measurements (Copley et al. 1969)

$$\mathrm{DOS} = \sum_k \mathrm{DOS}_k = \sum_{\vec{q}jk} \left| \hat{\varepsilon}_{\vec{q}jk} \right|^2 \delta \left(E - \hbar \omega_{\vec{q}j} \right) = \sum_{\vec{q}jk} \left| \hat{\varepsilon}_{\vec{q}jk} \right|^2 \frac{\sigma}{\pi \left(\sigma^2 + \left(E - \hbar \omega_{\vec{q}j} \right)^2 \right)} \tag{6}$$

where E is the probe energy and the Dirac delta is represented by a Lorentzian distribution here (Byron and Fuller 1992). σ is an adjustable parameter, small enough to give a good representation of the Dirac delta, but large enough to smooth out unphysical variations in the DOS. The total DOS and that projected onto the separate vibrations of the constituent atoms DOS_k are given for KCl in Fig. 3.

Comparison of calculated specific heat with measurements is actually quite tricky. $C_V = \sum_{\vec{q}j} C_{\vec{q}j}$ is an easy calculation constructed from $\omega_{\vec{q}j}$ alone; however, it is an extremely hard property to measure as materials change volume with temperature. Measurements of C_P are more practical (Gaskell 2008):

$$C_P = C_V + \alpha_V^2 B V_{\mathrm{cell}} T \tag{7}$$

where α_V is the volume thermal expansion arising from anharmonicity and defined in the next section, V_{cell} is the equilibrium unit cell volume, and B is the isothermal bulk modulus. $C_V \approx C_P$ only at low temperatures, as shown in Fig. 4 for KCl.
Fig. 3 Projected and total phonon density of states (DOS) for rock salt structure KCl. The red curve gives the vibrational DOS contributions from the Cl atoms, while purple gives that from the K atoms. The K and Cl atoms have similar mass and thus give similar DOS features. When masses differ appreciably, the heavier atoms govern the low-frequency DOS, and the lighter atoms govern the higher-frequency DOS

Thus, more rigorous comparison with measurements at higher temperatures requires including the anharmonic contributions of Eq. 7, as also demonstrated in Fig. 4.

2.3   Phonons: Anharmonic

While non-interacting harmonic phonons can describe (for the most part) the low-temperature-specific heat of crystalline solids and resonances from neutron, x-ray, and Raman scattering experiments, going beyond this simple picture is required to describe and understand lattice thermal expansion and conduction (Debye 1914; Peierls 1929, 2001), linewidths, and lineshifts (Maradudin and Fein 1962; Cowley 1968) – all temperature-dependent behaviors. These require knowledge of the crystal anharmonicity or how phonons interact with one another via perturbations that arise from higher-order terms in the interatomic potential, V_{anharm}.

The lowest-order anharmonic term, and presumably the most relevant within quantum perturbation theory, is V_3 (Srivastava 1990; Ziman 2001):

$$V_3 = \frac{1}{3!} \sum_{lk} \sum_{l'k'} \sum_{l''k''} \sum_{\alpha\beta\gamma} \Phi_{\alpha\beta\gamma}^{lkl'k'l''k''} u_{lk\alpha} u_{l'k'\beta} u_{l''k''\gamma} \tag{8}$$
Fig. 4 Heat capacity of rock salt structure KCl. The blue curve gives C_V, while the black curve gives C_P from calculations. The red circles correspond to measured data of C_P (Southard and Nelson 1933). The measured $B = 19.7$ GPa for KCl (Norwood and Briscoe 1958) was used here

which gives rise to three-phonon interactions. $\Phi_{\alpha\beta\gamma}^{lkl'k'l''k''} = \partial^3 V/\partial u_{lk\alpha} \partial u_{l'k'\beta} \partial u_{l''k''\gamma}$ are third derivatives of the interatomic potential calculated at equilibrium, calculation of which is described in Sect. 3.1. From these, various anharmonic material properties can be constructed including mode Grüniesen parameters, which describe the frequency dependence with volume of each phonon mode (Fabian and Allen 1997):

$$\gamma_{\vec{q}j} = -\frac{V_0}{\omega_{\vec{q}j}} \frac{d\omega_{\vec{q}j}}{dV} = -\frac{1}{6\omega_{\vec{q}j}^2} \sum_k \sum_{l'k'} \sum_{l''k''} \sum_{\alpha\beta\gamma} \Phi_{\alpha\beta\gamma}^{0kl'k'l''k''} \frac{\varepsilon_{\vec{q}jk\alpha}^* \varepsilon_{\vec{q}jk'\beta}}{\sqrt{m_k m_{k'}}} r_{l''k''\gamma} \quad (9)$$

and the linear thermal expansion coefficient α (Fabian and Allen 1997; Ziman 2001):

$$\alpha = \frac{1}{3B} \sum_{\vec{q}j} C_{\vec{q}j} \gamma_{\vec{q}j} \quad (10)$$

$r_{lk\alpha}$ is the αth coordinate of the kth atom in the lth unit cell. For cubic systems like rock salt structure KCl $\alpha_V = 3\alpha$, which was used in the calculation of C_P for KCl in Fig. 4. Consideration of lattice thermal expansion is critical for effective device design as unlike materials expand and contract with temperature at different
Fig. 5 Linear thermal expansion coefficient α for KCl: black curve from DFT calculations and Eqs. 8, 9, and 10; red circles sampled from measured data in (Rapp and Merchant 1973)

rates leading to structural failure at their interface. Furthermore, it is important for understanding the fundamentals of optic phonon frequency shifts and other lattice dynamical nuances (Cardona 1975; Burke and Herman 1993). Figure 5 gives α for KCl as calculated from Eqs. 8, 9, and 10 and compared with measured data, also giving an example of the occasional failure of first-principles methods to accurately describe a measured data set.

At the core of this chapter is the effect of anharmonicity on lattice thermal conduction, as it gives rise to three-phonon interactions that govern the phonon lifetimes/linewidths and account for the dominant intrinsic thermal resistance in many materials.

2.4 Phonon Lifetimes: Relaxation Time Approximation (RTA)

Calculation of the phonon lifetimes $\tau_{\vec{q}j}$ in Eq. 2 is the core challenge to realistic thermal transport predictions. A phonon lifetime corresponds to the average time for a phonon to exist before scattering and is often related to its mean free path given by $\ell_{\vec{q}j} = |\vec{v}_{\vec{q}j}| \tau_{\vec{q}j}$. It may vary considerably among modes and materials and can be quite sensitive to extrinsic crystal defects –the motivation behind nanostructuring in thermoelectrics (Singh and Terasaki 2008; Kanatzidis 2010). The main focus of discussion in this subsection is the intrinsic resistance due to three-phonon interactions; ab initio defect resistance calculations will be discussed in Sect. 5.

The phonon lifetimes will not be fully derived here; certain aspects will be discussed in detail; others will simply be mentioned. Within the relaxation time approximation (RTA – discussed in more detail below), the intrinsic phonon lifetimes are given as the sum of all individual scattering probabilities $W = (2\pi/\hbar)|\langle f| V_3 |i\rangle|^2 \delta(E_f - E_i)$ (Shankar 1994) determined from Fermi's golden rule with the lowest-order anharmonic potential as the perturbation (Srivastava 1990; Ziman and John 2001):

$$\frac{1}{\tau_{\vec{q}j}} = \sum_{\vec{q}'j'} \sum_{\vec{q}''j''} \left(W^{\text{coalesce}}_{\vec{q}j\vec{q}'j'\vec{q}''j''} + \frac{1}{2} W^{\text{decay}}_{\vec{q}j\vec{q}'j'\vec{q}''j''} \right) \tag{11}$$

$$W^{\text{coalesce}}_{\vec{q}j\vec{q}'j'\vec{q}''j''} = \frac{\pi\hbar}{4N} \frac{\left| \Psi_{-\vec{q}j-\vec{q}'j'\vec{q}''j''} \right|^2}{\omega_{\vec{q}j}\omega_{\vec{q}'j'}\omega_{\vec{q}''j''}} \left(n^0_{\vec{q}'j'} - n^0_{\vec{q}''j''} \right) \delta \left(\omega_{\vec{q}j} + \omega_{\vec{q}'j'} - \omega_{\vec{q}''j''} \right)$$
$$\Delta \left(\vec{q} + \vec{q}' - \left(\vec{q}'' + \vec{G} \right) \right) \tag{12}$$

$$W^{\text{decay}}_{\vec{q}j\vec{q}'j'\vec{q}''j''} = \frac{\pi\hbar}{4N} \frac{\left| \Psi_{-\vec{q}j\vec{q}'j'\vec{q}''j''} \right|^2}{\omega_{\vec{q}j}\omega_{\vec{q}'j'}\omega_{\vec{q}''j''}} \left(n^0_{\vec{q}'j'} + n^0_{\vec{q}''j''} + 1 \right) \delta \left(\omega_{\vec{q}j} - \omega_{\vec{q}'j'} - \omega_{\vec{q}''j''} \right)$$
$$\Delta \left(\vec{q} - \vec{q}' - \left(\vec{q}'' + \vec{G} \right) \right) \tag{13}$$

$$\Psi_{\vec{q}j\vec{q}'j'\vec{q}''j''} = \sum_{k} \sum_{l'k'} \sum_{l''k''} \sum_{\alpha\beta\gamma} \frac{\Phi^{0kl'k'l''k''}_{\alpha\beta\gamma}}{\sqrt{m_k m_{k'} m_{k''}}} \varepsilon_{\vec{q}jk\alpha} \varepsilon_{\vec{q}'j'k'\beta} \varepsilon_{\vec{q}''j''k''\gamma} e^{i\vec{q}'\cdot\vec{R}_{l'}} e^{i\vec{q}''\cdot\vec{R}_{l''}} \tag{14}$$

for three phonons that conserve energy and momentum (within a reciprocal lattice vector $\vec{G}$):

$$\omega_{\vec{q}j} \pm \omega_{\vec{q}'j'} = \omega_{\vec{q}''j''} \qquad \vec{q} \pm \vec{q}' = \vec{q}'' + \vec{G} \tag{15}$$

The $\pm$ corresponds to coalescence and decay processes, respectively, as depicted in Fig. 6.

The form and terms of Eqs. 11, 12, 13, and 14 derive from the quantum mechanical description of the displacements of the harmonic oscillators $u_{lk\alpha} = \sqrt{\hbar/2m_k N} \sum_{\vec{q}j} \varepsilon_{\vec{q}jk\alpha} e^{i\vec{q}\cdot\vec{R}_l} \left(\hat{a}_{\vec{q}j} + \hat{a}^*_{-\vec{q}j} \right) / \sqrt{\omega_{\vec{q}j}}$ (Ashcroft and Mermin 1976), which build Eq. 8 and act on the phonon states via Fermi's golden rule. N is the number of unit cells in the crystal; $\hat{a}_{\vec{q}j}$ and $\hat{a}^*_{\vec{q}j}$ are phonon creation and
Fig. 6 Three-phonon processes allowed by energy conservation (three phonons cannot be simultaneously created nor destroyed). The left depicts a coalescence process; the right depicts a decay process

annihilation operators, respectively, such that $\hat{a}_{\vec{q}j} \left| n_{\vec{q}j} \right\rangle = \sqrt{n_{\vec{q}j} + 1} \left| n_{\vec{q}j} + 1 \right\rangle$ and $\hat{a}^*_{\vec{q}j} \left| n_{\vec{q}j} \right\rangle = \sqrt{n_{\vec{q}j}} \left| n_{\vec{q}j} - 1 \right\rangle$ (Ashcroft and Mermin 1976; Shankar 1994).

Scattering processes with $\vec{G} = 0$ are called normal scatterings as they conserve momentum; however, they cannot provide direct resistance to a flowing phonon distribution though treated as resistive within the RTA. Processes with $\vec{G} \neq 0$ are called Umklapp ("folding over") scatterings and are directly resistive (Ziman 2001; Peierls 2001). The main simplification presented by the RTA is that $1/\tau_{\vec{q}j}$ is independent of the distribution of the other modes. That is, the deviation from equilibrium induced by the temperature gradient of mode $\vec{q}j$ (from which $1/\tau_{\vec{q}j}$ is derived) does not depend on the distributions of the other phonon modes with which it interacts. Thus, equilibrium Bose distributions are given for phonons $\vec{q}'j'$ and $\vec{q}''j''$ in Eqs. 12 and 13 rather than the actual non-equilibrium distributions that arise in the presence of a temperature gradient. For many materials (particularly low κ materials), this approximation is valid (Lindsay et al. 2013a); however, for some cases (particularly high κ materials), this gives a bad representation of phonon interactions and transport (Lindsay et al. 2009, 2014; Cepellotti et al. 2015).

Figure 7 gives the calculated phonon scattering rates for KCl at $T = 300$ K (room temperature): normal, Umklapp, and phonon-isotope scatterings (Sect. 5). In this system at room temperature, the intrinsic scattering is dominant; however, as temperature decreases, the three-phonon scattering weakens via the Bose distribution factors in Eqs. 12 and 13, while phonon-isotope scattering (Eq. 27) is T independent.

Briefly summarizing, calculation of $\tau_{\vec{q}j}$ (and thus κ in Eq. 2) within the RTA requires a description of the phonons built from the harmonic IFCs, a description of the anharmonic IFCs (Sect. 3.1), and integrations over delta functions (Sect. 3.2). Up to this point, the Peierls-Boltzmann equation (PBE) (Boltzmann 1872; Peierls 1929, 2001) for describing phonon transport has been alluded, but not rigorously introduced or connected, to these lifetimes.

2.5 Peierls-Boltzmann Equation (PBE)

The Peierls-Boltzmann equation in its typical form (Ziman 2001; Peierls 2001):
Fig. 7 Phonon scattering rates of KCl as determined by Eqs. 11, 12, 13, and 14 (intrinsic anharmonic rates) and Eq. 27 in Sect. 5 (phonon-isotope scattering from natural isotopic variation, purple circles). The intrinsic scattering is separated into normal scatterings (red circles) and Umklapp scatterings (black circles)

$$\vec{v}_{\vec{q}j} \cdot \vec{\nabla}T \frac{\partial n_{\vec{q}j}}{\partial T} = \left. \frac{\partial n_{\vec{q}j}}{\partial t} \right|_{scatterings} \tag{16}$$

describes the dynamics of a homogenous (no spatial variation beyond that induced by a small temperature gradient), steady-state (no time variation) distribution of phonons flowing in a material driven out of equilibrium by a temperature gradient – a temperature-driven distribution balanced by scattering. The solution of Eq. 16 gives the non-equilibrium distribution $n_{\vec{q}j}$ of each phonon mode in the presence of a temperature gradient and dependent on the non-equilibrium distribution of all the other modes. $n_{\vec{q}j}$ is used to determine each phonon lifetime as discussed later. The "scattering" term on the right-hand side of Eq. 16 is built from scattering processes of a similar form to Eqs. 12 and 13; however, the distributions are considered as unknowns to solve for rather than the $n_{\vec{q}j}^0$ terms presented there.

A significant assumption when solving the PBE is that the non-equilibrium distribution is the Bose distribution with a small correction linear in the temperature gradient (linearization of the PBE): $n_{\vec{q}j} = n_{\vec{q}j}^0 + n_{\vec{q}j}^1$ with $n_{\vec{q}j}^1 = \vec{\nabla}T \Omega_{\vec{q}j} \partial n_{\vec{q}j}^0 / \partial T$ where $\Omega_{\vec{q}j}$ is an unknown measure for how far each mode is perturbed from equilibrium (Srivastava 1990; Ziman 2001). (A helpful note: $\partial n_{\vec{q}j}^0 / \partial T = n_{\vec{q}j}^0 \left(n_{\vec{q}j}^0 + 1 \right) \hbar \omega_{\vec{q}j} / k_B T^2$.) Inserting these non-equilibrium distri-

butions in the scattering rates that construct Eq. 16, accounting for like terms and indistinguishable transitions, enforcing the collisional term to be zero for the equilibrium distribution, choosing an orientation for the temperature gradient along α, and keeping only linear terms in it, the PBE becomes (Broido et al. 2007):

$$
\begin{aligned}
\frac{v_{\vec{q}j\alpha}k_B T}{n_{\vec{q}j}^0 \left(n_{\vec{q}j}^0 + 1\right)} \frac{\partial n_{\vec{q}j}^0}{\partial T} = & \sum_{\vec{q}'j'} \sum_{\vec{q}''j''} \Bigg[W_{\vec{q}j\vec{q}'j'\vec{q}''j''}^{\text{coalesce}} \left(\Omega_{\vec{q}j} + \Omega_{\vec{q}'j'} - \Omega_{\vec{q}''j''}\right) \\
& + \frac{1}{2} W_{\vec{q}j\vec{q}'j'\vec{q}''j''}^{\text{decay}} \left(\Omega_{\vec{q}j} - \Omega_{\vec{q}'j'} - \Omega_{\vec{q}''j''}\right) \Bigg] \\
& + \frac{\Omega_{\vec{q}j}}{\tau_{\text{extrinsic}}}
\end{aligned}
\tag{17}
$$

This linearized form is solved to determine the deviations from equilibrium $\Omega_{\vec{q}j}$ for each phonon. Note that an extra scattering term is included in Eq. 17 for extrinsic phonon scattering mechanisms (isotopes, defects, boundaries, etc.) that can be incorporated at the RTA level, though not restricted to this approximation.

There are different ways to construct a solution of the coupled set of integral equations, including self-consistent iterative methods (Omini and Sparavigna 1996) and variational approaches (Ziman 2001; Fugallo et al. 2013). Given the solution of the PBE for $\Omega_{\vec{q}j}$, the lifetimes are:

$$
\tau_{\vec{q}j\alpha} = \frac{\Omega_{\vec{q}j}T}{\hbar\omega_{\vec{q}j}v_{\vec{q}j\alpha}}
\tag{18}
$$

In this way the calculated lifetimes from full solution of the PBE depend on the orientation of the temperature gradient (technically the deviation terms may also depend on the gradient $\Omega_{\vec{q}j} \rightarrow \Omega_{\vec{q}j\alpha}$). The lifetimes and deviation terms are related by Eq. 18 so as to reconstruct Eq. 2. Going back, the thermal energy current from Eq. 1 can also be written as the product of the energy carried by each mode, its speed, and the number of modes: $J_\alpha = \sum_{\vec{q}j} \hbar\omega_{\vec{q}j}v_{\vec{q}j\alpha}n_{\vec{q}j}/V_0$ (Ashcroft and Mermin 1976). Putting the linear form for the distribution in this and equating it with Eq. 1 gives Eq. 18.

In summary, given a set of harmonic and anharmonic IFCs, κ can be determined from a linearized form of the PBE with no adjustable fitting parameters for the intrinsic resistance. Practically speaking, wavevector grids to perform sums over the phonons must be defined within the first Brillouin zone, harmonic properties ($\omega_{\vec{q}j}$, $C_{\vec{q}j}$, $\vec{v}_{\vec{q}j}$, $n_{\vec{q}j}^0$) calculated via Eq. 5 for each grid point, numerical representations of the Dirac delta functions in Eqs. 12 and 13 constructed, and sums performed over these (phase space for scattering); and, if going beyond the RTA, these are plugged into Eq. 17 and solved for lifetimes to determine κ. Important points for the numerical implementation of these calculations will be discussed in the following section.

3 Numerical Recipes

Numerical implementation of the above theoretical discussion requires some careful thought and creativity, particularly regarding efficient calculation of interatomic forces, determination of all possible scattering configurations, and integrations over delta functions. Several software packages (Li et al. 2014; Tadano et al. 2014; Chernatynskiy and Phillpot 2015; Togo et al. 2015) have recently become available to calculate κ coupled with IFCs from density functional theory (Hohenberg and Kohn 1964; Kohn and Sham 1965), and each has different methods for addressing numerical details, some of which are discussed here.

3.1 Interatomic Force Constants (IFCs)

The only input parameters into the theoretical PBE transport formalism above are the harmonic and anharmonic IFCs. Thus, an accurate physical description of these is critically important for obtaining reasonable κ predictions. Unfortunately, this is also one of the numerical bottlenecks of these calculations, particularly when using DFT methods to extract the IFCs. Likely the most popular method for calculating them is numerical differentiation in real space of an interatomic potential defined by the electronic structure of the crystal (Srivastava 1990). In practice, a large supercell is defined from the basis unit cell using $\vec{R}_l$, specific atoms are strategically displaced from equilibrium by a small distance Δ, and calculations of the electronic structure, energies, and forces on all the atoms are performed. Δ should be significantly less than the interatomic spacing, but not so small that energies and forces cannot be calculated to desired precision. Furthermore, supercells must be large enough so that periodic images do not interact strongly.

Discussion here describes the calculation of the third-order anharmonic IFCs $\Phi_{\alpha\beta\gamma}^{0kl'k'l''k''}$; however, much of it can be applied to the determination of harmonic and even higher-order IFCs. Typical electronic structure calculations can give the forces acting on the atoms (Hellmann 1937; Feynman 1939; Baroni et al. 2001) relatively cheaply so $\Phi_{\alpha\beta\gamma}^{0kl'k'l''k''}$ is rewritten as:

$$\Phi_{\alpha\beta\gamma}^{0kl'k'l''k''} = -\frac{\partial^2 F_{l''k''\gamma}}{\partial u_{0k\alpha}\partial u_{l'k'\beta}} \approx -\frac{F_{l''k''\gamma}^{+,+} - F_{l''k''\gamma}^{+,-} - F_{l''k''\gamma}^{-,+} + F_{l''k''\gamma}^{-,-}}{4\Delta^2} \qquad (19)$$

where $F_{l''k''\gamma}$ is the force acting in the γth direction on the k''th atom in the l''th unit cell, $F_{l''k''\gamma}^{+,+}$ is the same but with $0k$ and $l'k'$ atoms perturbed a distance Δ in the positive $(+)$ α and positive β directions, respectively. In principle, there are an infinite number of IFCs each requiring four (one for each force in the numerator of Eq. 19) electronic structure calculations with large supercells, numerically intractable. Fortunately, IFCs become weaker with increasing distance of the atoms so an interaction cutoff distance is chosen (a spatial distance or number of nearest neighbor shells of the unit cell atoms) which truncates the number of anharmonic

IFCs. This cutoff should be chosen wisely to give a balance of computational efficiency and converged accuracy. From this truncated set, symmetry operations are employed to reduce the IFCs to a smaller set of independent/irreducible IFCs from which the entire truncated set can be assembled (Esfarjani and Stokes 2008). Then the minimum number of perturbed supercells required to assemble this irreducible set are constructed and forces calculated. As each calculation gives information of the forces acting on all the atoms in the supercell, many irreducible IFCs can be constructed from the same calculations, and there is a significant amount of redundant information – multiple calculations of the same irreducible IFC. This information can be used to check the numerical accuracy of calculations and can be averaged.

Physically meaningful IFCs not only satisfy derivative permutation and space group symmetry operations of the crystal lattice (which are guaranteed by operating with the irreducible IFCs) but also must satisfy various translational and rotational invariance constraints (Leibfried and Ludwig 1961; Gazis and Wallis 1966; Born and Huang 1998). Due to truncation of the anharmonic IFCs to a particular neighbor shell and numerical accuracy, translational invariance constraints given by the acoustic sum rule (ASR) (Leibfried and Ludwig 1961):

$$\sum_{l'k'} \Phi_{\alpha\beta\gamma}^{0kl'k'l''k''} = 0 = \sum_{l''k''} \Phi_{\alpha\beta\gamma}^{0kl'k'l''k''} \tag{20}$$

are not satisfied by IFCs directly from DFT supercell calculations. It is important to enforce these constraints by applying small changes to the irreducible DFT IFCs to obtain physically meaningful ones (Carrete et al. 2016); otherwise scattering rates from Eq. 11 likely will not have the proper low-frequency behavior, and calculated κ may be significantly underestimated, as demonstrated in Fig. 8 (Ge figure) adapted from Lindsay et al. (Lindsay et al. 2013a). Various numerical methods have been devised to solve optimization problems similar to enforcing symmetry constraints (Press et al. 1992; Esfarjani and Stokes 2008; Lindsay et al. 2013a; Mingo et al. 2014). Enforcing symmetry constraints beyond simple ASR can also be important for obtaining quadratic dispersion of flexural acoustic branches in 2D systems (Carrete et al. 2016).

Often DFT calculations are considered free of input parameters; however, there are significant choices which need consideration when performing lattice dynamical calculations: basis sets, representations of core and valence electrons, exchange and correlations, etc. (Giannozzi et al. 2009). Typical phonon transport calculations employ the local density (Kohn and Sham 1965) or generalized gradient approximations (Perdew et al. 1996) (LDA or GGA) using projector augmented wave (Blöchl 1994) or plane wave basis sets, with pseudopotentials to represent core electrons (Bachelet et al. 1982; Troullier and Martins 1991). An important point to note here is that LDA tends to overbind atoms (gives smaller structural lattice constants), while GGA tends to underbind atoms (Haas et al. 2009). Thus, LDA calculations sometimes overestimate optic phonon frequencies and acoustic velocities, while GGA calculations underestimate them. This can play a significant
Fig. 8 Calculated thermal conductivity of Ge versus temperature adapted from Lindsay et al. (Lindsay et al. 2013a). Solid curves (calculated) and black circles (measured (Ozhogin et al. 1996)) for isotopically purified Ge, dashed curves (calculated) and black triangles (measured (Ozhogin et al. 1996)) for Ge with natural isotope variations. The black and red curves are derived from calculations that employed different techniques for applying translational invariance, point group, and derivative permutation symmetries simultaneously. The purple curves give calculations that employed a simple ASR, breaking other symmetry properties. The green curve gives calculations for which no translational invariance was enforced. (Adapted figure with permission from Lindsay L et al., PRB 87, 165,201 (2013) Copyright (2013) by the American Physical Society (Lindsay et al. 2013a))

role in κ calculations, especially if the phase space for phonon scatterings of heat-carrying acoustic phonons is not well-represented (Ziman 2001; Lindsay et al. 2012). If measured phonon frequencies are available from neutron, x-ray, or Raman spectroscopies, it is a good idea to make comparisons before undertaking full transport calculations. Another related consideration is that typical DFT calculations do not incorporate the effects of temperature, particularly thermal expansion and thermally induced disorder. Such features can be partially accounted for within quasiharmonic approximations (Srivastava 1990), and some work has presented more rigorous calculations of temperature effects related to vibrational behaviors and κ (Hellman and Broido 2014; Romero et al. 2015).

3.2 Integrations, Delta Functions, and Phase Space

Integrations over the various delta functions that arise from fundamental conservation conditions require careful consideration and give rise to significant variety

in the mechanics of different software packages for calculating κ. In terms of the scatterings in Eqs. 12 and 13, the challenge is to find all scattering processes that conserve (or come close to) energy and crystal momentum (Eq. 15). Examining more closely the scattering rates from Eq. 12 for normal coalescence processes, the Kronecker delta Δ eliminates the sum over $\vec{q}''$, and the sum over $\vec{q}'$ is converted to an integration over the first Brillouin zone that can make use of the Dirac delta for the energies δ:

$$
\frac{1}{\tau_{\vec{q}j}} = \sum_{j'j''} \frac{V_0}{(2\pi)^3} \int_{BZ} \frac{\pi\hbar}{4N} \frac{\left|\Psi_{-\vec{q}j-\vec{q}'j'(\vec{q}+\vec{q}')j''}\right|^2}{\omega_{\vec{q}j}\omega_{\vec{q}'j'}\omega_{(\vec{q}+\vec{q}')j''}} \left(n^0_{\vec{q}'j'} - n^0_{\vec{q}''j''}\right) d\vec{q}
$$

$$
\delta\left(\omega_{\vec{q}j} + \omega_{\vec{q}'j'} - \omega_{(\vec{q}+\vec{q}')j''}\right)
\tag{21}
$$

If a 2D integration, as with graphene or MoS_2, the density prefactor will be $A/(2\pi)^2$ (A = area of crystal), and if 1D integration as with nanotubes, it is $L/(2\pi)$ (L = length of crystal). In these lower dimensional cases, κ in Eq. 2 is scaled by the thickness chosen for the 2D sheet or nanotube wall, and care should be taken to use the same thickness factor when comparing with experiments or other calculations. The Dirac delta in Eq. 21 can be represented in a variety of forms, one being (Jackson 1999):

$$
\delta\left(\omega_{\vec{q}j} + \omega_{\vec{q}'j'} - \omega_{(\vec{q}+\vec{q}')j''}\right) = \sum_i \frac{\delta\left(q'_\alpha - q'_{\alpha i}\right)}{\left|v_{\vec{q}'j'\alpha} - v_{(\vec{q}+\vec{q}')j''\alpha}\right|_{q'_\alpha = q'_{\alpha i}}}
\tag{22}
$$

where the Dirac delta for energy conservation has been converted into a Dirac delta to eliminate one of the wavevector integrations. In this case, an algorithm must be employed to find all $q'_{\alpha i}$ for each set of $jj'j''\vec{q}q'_\beta q'_\gamma$ that satisfy energy conservation. Another popular form is an adaptive Gaussian smearing method (Yates et al. 2007; Li et al. 2014):

$$
\delta\left(\omega_{\vec{q}j} + \omega_{\vec{q}'j'} - \omega_{(\vec{q}+\vec{q}')j''}\right) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\left(\omega_{\vec{q}j} - \omega_{\vec{q}'j'} + \omega_{(\vec{q}+\vec{q}')j''}\right)^2/2\sigma^2}
\tag{23}
$$

where the smearing term $\sigma = a\left|\vec{v}_{\vec{q}'j'} - \vec{v}_{(\vec{q}+\vec{q}')j''}\right|\left|\Delta q'\right|$ is a function of the reciprocal grid spacing $\left|\Delta q'\right|$ and a is a parameter ~1 that can be adjusted to speed up convergence with increasing integration grid densities. The smaller σ is chosen, the better Eq. 23 represents a Dirac delta; however, if too small, no combination of grid points on a finite grid will provide contributions to the integral in Eq. 21. This method differs from Eq. 22 in two important ways: (1) all wavevector integrations must be made in Eq. 21 using the smearing method, while Eq. 22 reduces these by one (though with the addition of another sum); and (2) for Eq. 23, energy conservation never strictly occurs, only within a smearing parameter, while in Eq. 22 three-phonon processes are determined very near conservation conditions, within a predetermined accuracy. Another method for Brillouin zone integrations over

energy conserving delta functions is the tetrahedron method whose description can be found elsewhere (Lehmann and Taut 1972; Togo et al. 2015).

Inevitably, for numerical calculations of scattering rates and κ, sums and continuous integrations must be represented on finite grids, and clever choice of these may result in less computational effort for desired convergence accuracy. Monkhorst-Pack meshes (Monkhorst and Pack 1976) have the advantage of naturally coordinating with reciprocal lattice vectors of the crystal and being evenly spaced in reciprocal space. Thus, if $\vec{q}$ and $\vec{q}'$ are defined on the same mesh, then all $\vec{q}''$ determined from crystal momentum conservation also land on this mesh, and less frequency diagonalizations (Eq. 5) need to be made. Furthermore, if using Eq. 23 to represent the Dirac delta, then $\vec{q}$, $\vec{q}'$, and $\vec{q}''$ are all on the same mesh, and interpolation schemes to determine $\Omega_{\vec{q}'j'}$ and $\Omega_{\vec{q}''j''}$ for off-grid wavevectors are not necessary. However, such evenly spaced integration methods do not exploit fancier integration techniques (e.g., Gaussian quadratures (Press et al. 1992)) and do not rigorously enforce energy conservation.

The strength of each three-phonon scattering process (Eqs. 12 and 13) is dictated by a complicated combination of eigenvectors, frequencies, and anharmonic IFCs, varying for each mode involved. Another factor governing the overall scattering rate for each mode (Eq. 11) is the total number of processes allowed by the conservation conditions of Eq. 15 – scattering phase space (Ziman 2001). In fact, this phase space has been shown to be a leading indicator of a materials ability to conduct heat (Broido and Lindsay 2008; Lindsay 2016). The more scattering available in a system, the lower will be its κ. Thus, estimates of the available phase space for scattering provide important insights into the behaviors of lattice κ among various materials, without having to explicitly calculate anharmonic IFCs. Features of the phonon dispersions have been correlated with this phase space including bandgap between acoustic and optic phonon branches (Lindsay et al. 2012), relative closeness of the acoustic branches (Lindsay et al. 2013b), and bandwidth of the optic branches (Lee et al. 2014; Mukhopadhyay et al. 2016). Furthermore, it has been argued that in materials where this phase space is small, and thus three-phonon scattering weak, the effects of higher-order scattering may be more important as higher-order conservation conditions are less restrictive (Ziman 2001; Broido and Lindsay 2008; Feng and Ruan 2016; Feng et al. 2017).

4   Other Observables

The interplay of experiment and theory is critical to building basic insights and fundamental principles into physical phenomena, and yet comparison of measurement and calculations is not always straightforward in practice. Here we discuss the relationship of other measurement probes (Raman, neutrons, and x-rays) and first-principles calculations of lattice vibrations and anharmonicity beyond integrated conductivity values, getting at microscopic mode-dependent information.

A variety of interesting new ultrafast spectroscopic techniques have been developed recently toward gaining insights into thermal transport in materials. Raman thermometry is being employed to access transport in 2D materials (Balandin et al. 2008; Cai et al. 2010; Beechem et al. 2015), though with fairly large error bars due to determination of power absorption of different samples. Also, transient thermal grating (Johnson et al. 2013), time-domain (Cahill et al. 2014), and frequency-domain thermoreflectance (Schmidt et al. 2009) (TDTR and FDTR) techniques are being pioneered to examine κ in various bulk materials, some with capabilities to examine κ as a function of the mean free path of the heat carriers. To this end a discussion of thermal conductivity accumulation κ_L^{acc} with mean free path $\ell_{\vec{q}j} = |\vec{v}_{\vec{q}j}| \tau_{\vec{q}j}$ is given here.

κ_L^{acc} is defined as the contribution to the total κ from modes with $\ell_{\vec{q}j}$ less than some characteristic length L: $\kappa_L^{acc} = \sum_{\vec{q}j} \kappa_{\vec{q}j} \theta\left(L - \ell_{\vec{q}j}\right)$ where θ is the Heaviside step function. Note that the directional dependence of the conductivity terms are ignored here. L may be related to the film thickness, laser spot size, or grating period depending on the experiment. κ_L^{acc} provides information for how κ reduction might be achieved via micro- or nanostructuring in thermoelectric or barrier coating materials (Singh and Terasaki 2008; Kanatzidis 2010) and for quality single crystal sizes needed to achieve highest κ in materials for thermal management applications (Broido et al. 2013). Integration choices can play an important role in these calculations as low-frequency, long wavelength phonons with large $\ell_{\vec{q}j}$ are typically not sampled as well as smaller wavelength modes with smaller $\ell_{\vec{q}j}$, leading to unphysical "jumps" in the κ_L^{acc} (Minnich et al. 2011; Jiang et al. 2016) as seen in Fig. 9 (red symbols). In nearly isotropic materials, like prototypical zincblende compounds, integration grids based on polar or spherical coordinates provide significantly better sampling of the wavevector/frequency space and give more physically meaningful κ_L^{acc} curves as also demonstrated in Fig. 9 (blue symbols).

Inelastic x-ray and neutron scattering experiments provide key insights into phonon properties (particularly dispersions and lifetimes) throughout the Brillouin zone (Dorner 1982; Burkel 2000; Willis et al. 2009; Rueff 2010). Raman spectroscopy, though confined to optic modes near the Γ point, also provides important information of phonon behaviors, as well as insights into couplings with other material properties (Cardona 1975; Merlin et al. 2000). These techniques have guided our fundamental knowledge of materials properties and still bring to light novel vibrational, electronic, and magnetic behaviors. Figure 2 gives a comparison of the phonon dispersion of KCl as measured by inelastic neutron scattering and DFT calculations. Measured linewidths $\Gamma_{\vec{q}j}$ and lineshifts $\Delta_{\vec{q}j}$ as a function of temperature can also provide key benchmarking data for anharmonic calculations (Debernardi et al. 1995; Deinzer et al. 2003; Bonini et al. 2007). Comparisons of lifetimes and linewidths are often made with the simple expression $1/\tau_{\vec{q}j} = \Gamma_{\vec{q}j}/\hbar$ (Di Bartolo 1968; Kuball et al. 2000) where $\Gamma_{\vec{q}j}$ is determined from fitting Lorentzian or Cauchy distributions to measured data (Byron and Fuller 1992):
Fig. 9 Thermal conductivity accumulation with mean free path for Si at room temperature given by calculations using Cartesian integration (red points) and polar integration (blue points). Black squares (Jiang et al. 2016), green circles (Regner et al. 2013), and purple diamonds (Minnich et al. 2011; Ding et al. 2014) give measured data for comparison

$$\delta \left(E - \hbar \omega_{\vec{q} j} \right) = \frac{\Gamma_{\vec{q} j}}{\pi \left[\Gamma_{\vec{q} j}^2 + \left(E - \hbar \omega_{\vec{q} j} \right)^2 \right]} \tag{24}$$

again, E is the probe energy – in the case of neutron scattering, E is the neutron energy transfer. For strongly anharmonic materials, measured signals can deviate significantly from simple Lorentzian behavior, and calculation of lineshapes may be of interest. In this case, the phonon linewidth can be expressed explicitly as a function of the probe energy (Maradudin and Fein 1962; Cowley 1968):

$$\begin{aligned}
\Gamma_{\vec{q} j}(E) k = \frac{\pi \hbar}{16N} \sum_{\vec{q}' j'} \sum_{\vec{q}'' j''} & \frac{\left| \Psi_{\vec{q} j \vec{q}' j' \vec{q}'' j''} \right|^2}{\omega_{\vec{q} j} \omega_{\vec{q}' j'} \omega_{\vec{q}'' j''}} \\
& \times \left[\left(n_{\vec{q}' j'}^0 - n_{\vec{q}'' j''}^0 \right) \Delta \left(\vec{q} + \vec{q}' - \left(\vec{q}'' + \vec{G} \right) \right) \right. \\
& \left\{ \delta \left(\omega_{\vec{q}' j'} - \omega_{\vec{q}'' j''} + E \right) - \delta \left(\omega_{\vec{q}' j'} - \omega_{\vec{q}'' j''} - E \right) \right\} \\
& + \left(n_{\vec{q}' j'}^0 + n_{\vec{q}'' j''}^0 + 1 \right) \Delta \left(\vec{q} - \vec{q}' - \left(\vec{q}'' + \vec{G} \right) \right) \\
& \left. \left\{ \delta \left(\omega_{\vec{q}' j'} + \omega_{\vec{q}'' j''} - E \right) + \delta \left(\omega_{\vec{q}' j'} + \omega_{\vec{q}'' j''} + E \right) \right\} \right]
\end{aligned} \tag{25}$$

Note that this expression requires performing fairly complicated sums (very similar to κ calculations discussed above) for *each* probe energy. Furthermore,

taking into account frequency shifts $\Delta_{\vec{q}j}$ due to anharmonic interactions (Cowley 1968), the mode frequency itself may be a function of the probe energy. This may be of interest for calculating temperature- and pressure-dependent behaviors of Raman spectra (Cardona 1975; Burke and Herman 1993; Kuball et al. 2000).

For some materials where only small crystal sizes may be synthesized and powder samples are more accessible for neutron measurements, it is more convenient to measure the integrated phonon density of states (DOS), rather than obtain mode-specific information. For strongly anharmonic systems where representing the anharmonic lineshapes is important (Mukhopadhyay et al. 2016), this becomes challenging as Eq. 25 must be calculated and summed over every phonon mode in the first Brillouin zone.

5   Phonon-Defect Scattering

Inevitably, real materials are not perfect, infinite crystals; even the purest sample has boundaries and imperfections (point and extended). Many of these defects form during synthesis, when otherwise randomly oriented free atoms bind together to grow the crystal little by little. Defects can also be created within a material via external perturbations or particle irradiation. Phonon-defect scattering intimately depends on the nature of the defect, on the vibrational properties of the crystal and on the spatial distribution of these defects. Generally, this scattering becomes important at lower temperatures where intrinsic phonon-phonon scattering is weak. This section discusses different methods to describe phonon-defect scattering and κ from phenomenological models to recent parameter-free ab initio techniques.

Due to their simplicity, phenomenological models are the most widely used methods to incorporate phonon-defect scattering into the PBE. These models assume the phonon-defect scattering rates $1/\tau_{\vec{q}j}^{d}$ are proportional to some power n of the phonon frequency (Ziman 2001):

$$\frac{1}{\tau_{\vec{q}j}^{d}} = A\omega_{\vec{q}j}^{n} \tag{26}$$

The proportionality constant A is typically an adjustable parameter used to fit measurements, sometimes explicitly including T dependence, and n depends on the nature of the defect and the dimensions of the crystal. For a substitutional atom with mass or binding force variation, $n = 4$ (Klemens 1955); for strain due to dislocations, $n = 1$ (Klemens 1955; Carruthers 1959); for the core of dislocations, $n = 3$ (Klemens 1958); for dynamic dislocations "fluttering," $n = -1$ (Kneezel and Granato 1982); and for grain boundaries, $n = 2$ (Klemens 1955). The simplicity of Eq. 26 arises from several approximations that are compensated by the fitting parameter A. One of them assumes a linear phonon dispersion, which restricts the accuracy of those models to the limit of low temperature and frequency. In that limit,

Eq. 26 yields a well-defined temperature dependence of the thermal conductivity $\kappa \propto T^{3-n}$, with n the power of the frequency in Eq. 26 (Carruthers 1961; Ziman 2001).

At the next level of refinement, phonon-defect scattering is derived from first-order perturbation theory (Shankar 1994), and it is sometimes referred to as the Born approximation. In fact, many of the phenomenological expressions above were originally formulated from Fermi's golden rule in a similar way to the phonon lifetimes due to anharmonic perturbations in Sect. 2.4 (Klemens 1955, 1958; Carruthers 1961; Ratsifaritana and Klemens 1987). Consider a defective crystalline material whose total harmonic interatomic potential energy is described by $V_{\text{harm}} + V_d$, separated into contributions from the pure crystal V_{harm} and the defect V_d. If V_d is small relative to V_{harm}, the phonon-defect lifetimes $\tau_{\vec{q}j}^d$ are given as the sum of all individual scattering probabilities $W = (2\pi/\hbar)|\langle f|V_d|i\rangle|^2 \delta(E_f - E_i)$ (Shankar 1994) similar to Sect. 2.4. Applying this methodology to a system of randomly distributed independent mass defects (Tamura 1983, 1984) gives the standard phonon-isotope scattering included in ab initio calculations of κ:

$$\frac{1}{\tau_{\vec{q}j}^{\text{isotope}}} = \frac{\pi}{2N}\omega_{\vec{q}j}^2 \sum_k g_k \sum_{q'j'} \left|\hat{\varepsilon}_{\vec{q}jk} \cdot \varepsilon_{\vec{q}'j'k}^*\right|^2 \delta\left(\omega_{\vec{q}j} - \omega_{\vec{q}'j'}\right) \tag{27}$$

with $g_k = \sum_i f_{ik}(1 - m_{ik}/\overline{m}_k)^2$, f_{ik} and m_{ik} are the fraction and mass of the ith type of the kth atom, respectively, and $\overline{m}_k$ is the natural isotope average mass of this atom.

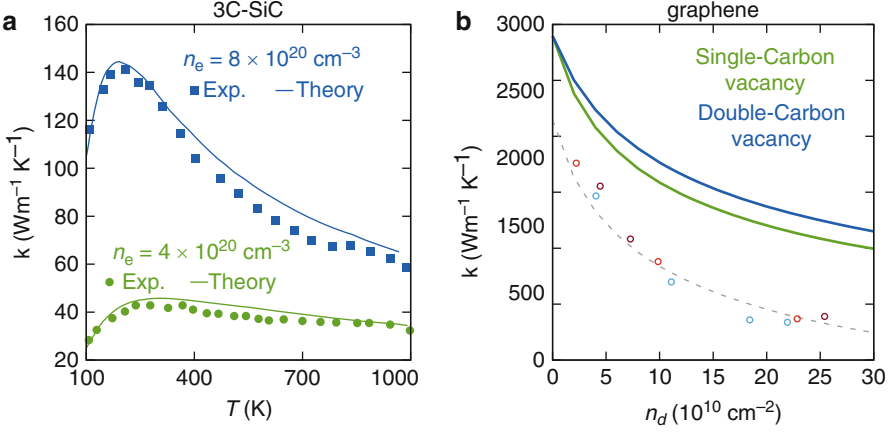
The major constraint of perturbative approaches – i.e., a *small* perturbation introduced by the defect in the host material – can be overcome using Green's function methodology. Calculations of phonon-defect scattering from this have demonstrated significant and important differences from those computed using perturbative approaches (Chen et al. 2013; Katcho et al. 2014; Katre et al. 2017; Kundu et al. 2011; Mingo et al. 2010; Protik et al. 2016; Wang et al. 2017, Polanco and Lindsay 2018). When only mass variation is considered, scattering rates from Eq. 27 are similar to those calculated using Green's function methodology at low frequencies, when the perturbation $V_d \propto \omega_{\vec{q}j}^2 (m_{ik} - \overline{m}_k)$ is small (Mingo et al. 2010; Kundu et al. 2011). However, structural and IFC variation around the defect can be more disruptive to phonon thermal transport. Phonon-vacancy scattering rates from Green's function methodologies for diamond, BAs, and SiC are nearly an order of magnitude larger than those from perturbative approaches, even in the low-frequency regime (Katcho et al. 2014; Protik et al. 2016; Katre et al. 2017). Green's function techniques have also been applied to extended defects (e.g., dislocations) (Wang et al. 2017), though computational effort increases significantly when going beyond localized defect structures. Figure 10 benchmarks the parameter-free calculations of κ from coupled phonon-defect scattering from Green's function methods with PBE transport, demonstrating reasonable agreement with measurements.


Fig. 10 Calculated κ via Peierls-Boltzmann transport and parameter-free phonon-defect scattering rates from the Green's function methodology. (Left) Calculations and measurements of κ for 3C-SiC doped with N_C substitutional defects (blue squares and blue curve) and codoped with N_C and B_C substitutional defects (green circles and green curve). The electron density n_e defines the defect density for the crystal doped with N_C and the difference between defect densities for the crystal codoped with N_C and B_C. (Adapted figure with permission from Katre A et al., PRL 119, 075902 (2017) Copyright (2017) by the American Physical Society (Katre et al. 2017)). (Right) Calculations (solid curves) and measurements (dots) of κ for graphene with single and double carbon vacancies. The qualitative trend of κ with defect density is in good agreement with measurements. (Reprinted figure with permission from Polanco C and Lindsay L, PRB 97, 014303 (2018) Copyright (2018) by the American Physical Society (Polanco and Lindsay 2018))

Green's function methodology is derived using the Lippmann-Schwinger equation (Lippmann and Schwinger 1950), which describes the exact probability of an initial state scattering into a final state due to a perturbation using an infinite recursive expansion. Considering all final states and applying the optical theorem (Economou 2006), the phonon scattering rates due to an independent distribution of point defects with defect density n_d can be expressed in terms of the scattering cross section $\sigma_{\vec{q}j}^d$ or the so-called T-matrix as (Economou 2006; Mingo et al. 2010):

$$\frac{1}{\tau_{\vec{q}j}^d} = n_d v_{\vec{q}j\alpha} \sigma_{\vec{q}j} = -n_d \frac{V_{\vec{q}j}}{\omega_{\vec{q}j}} \mathrm{Im} \left\{ \langle \vec{q}j | \, \tilde{T}_d \, | \vec{q}j \rangle \right\} \qquad (28)$$

Equation 28 is computed inside a small region with N_d atoms containing a single defect where the dynamical matrix deviates from that of the perfect crystal. This region will be referred as the device. The states $\vec{q}j$ are normalized vectors with $3N_d$ components, one per atomic degree of freedom of the device. The components associated to the unit cell l of the device are given by $\sqrt{1/N_d}\,\hat{\varepsilon}_{\vec{q}j}e^{i\vec{q}\cdot\vec{R}_l}$ assuming that $\hat{\varepsilon}_{\vec{q}j}$ is normalized. $V_{\vec{q}j}$ is the volume of the device, and $\tilde{T}_d$ is the T-matrix in the device, which has dimension $3N_d \times 3N_d$ and is given by a closed term or an equivalent infinite series (Economou 2006; Mingo et al. 2010):

$$\tilde{T}_d = \left[\tilde{I} - \tilde{D}_d \tilde{G}_0 \right]^{-1} \tilde{D}_d = \tilde{D}_d + \tilde{D}_d \tilde{G}_0 \tilde{D}_d + \tilde{D}_d \tilde{G}_0 \tilde{D}_d \tilde{G}_0 \tilde{D}_d + \dots \qquad (29)$$

Note that the tilde is used to represent $3N_d \times 3N_d$ matrices relating degrees of freedom inside the device. $\tilde{D}_d$ represents the contribution to the dynamical matrix from the defect so that the total dynamical matrix is split as $\tilde{D}_0 + \tilde{D}_d$, with $\tilde{D}_0$ the dynamical matrix of the pure crystal. $\tilde{I}$ is the identity matrix, and $\tilde{G}_0$ is the retarded Green function matrix for the perfect crystal inside the device region (Eq. 30).

For efficient computation of $\tilde{G}_0$, all but one Cartesian dimension are transformed to reciprocal space. In this way, the periodicity of the perfect crystal is used to decouple the system into independent "1D chains" that reduce the computational effort. In other words, the 3D crystal can be described as a 2D crystal in a plane, whose base unit cell is an infinite 1D atomic chain. The Green's function for the device of each chain is found using self-energy terms that account for the coupling of atoms inside the device to those outside it. Finally, $\tilde{G}_0$ results from transforming the matrices from reciprocal back to real space.

Transforming the xy plane to Fourier space (with the 1D chains along the z direction) turns the dynamical and Green's function matrices of the perfect crystal into block diagonal matrices labeled by the wavevector $\vec{q}_\perp$, which is defined inside a 2D Brillouin zone in the xy plane. We use the subscript $\perp$ to label these wavevectors because they are perpendicular to the 1D chains. This transformation simplifies the problem of finding Green's functions as each block can be dealt with separately from the others. Each block is associated with a 1D chain in reciprocal space along the z direction decoupled from the others. These chains will be labeled r-chains here to distinguish them from the chains in real space. After finding the device Green's function of each r-chain $\tilde{G}_{\vec{q}_\perp}$, $\tilde{G}_0$ is found using the inverse Fourier transform. The block of $\tilde{G}_0$ relating the degrees of freedom inside the device of the nth chain with those of the mth chain is given by (Zhang et al. 2006; Mingo et al. 2010):

$$\tilde{G}_0 (n, m) = \frac{1}{N_{\vec{q}_\perp}} \sum_{\vec{q}_\perp} \tilde{G}_{\vec{q}_\perp} e^{i \vec{q}_\perp \cdot (\vec{r}_{n\perp} - \vec{r}_{m\perp})} \qquad (30)$$

with $N_{\vec{q}_\perp}$ the number of wavevectors in the Brillouin zone of the 2D crystal and $\vec{r}_{n\perp}$ and $\vec{r}_{m\perp}$ the lattice position of the nth and mth chain, respectively. Each $\tilde{G}_{\vec{q}_\perp}$ is defined as (Zhang et al. 2006; Mingo et al. 2010):

$$\tilde{G}_{\vec{q}_\perp} = \left[\omega_{\vec{q}j}^2 \tilde{I} - \tilde{D}_{\vec{q}_\perp} - \tilde{\Sigma}_{\vec{q}_\perp}^{L} - \tilde{\Sigma}_{\vec{q}_\perp}^{R} \right]^{-1} \qquad (31)$$

All the matrices in Eq. 31 have dimension $3N_{cd} \times 3N_{cd}$, with N_{cd} the number of atoms inside the device region of a 1D chain or r-chain. $\tilde{D}_{\vec{q}_\perp}$ is the dynamical matrix of the r-chain labeled by $\vec{q}_\perp$, which is calculated by transforming the dynamical matrices of the 2D crystal to reciprocal space (Datta 2005; Zhang et al. 2006):

$$\tilde{D}_{\vec{q}\perp} = \sum_m \tilde{D}_{nm} e^{-i\vec{q}\perp \cdot (\vec{r}_{n\perp} - \vec{r}_{m\perp})} \tag{32}$$

$\tilde{D}_{nm}$ is the dynamical matrix relating device atoms of the nth chain with those of the mth chain, and m varies over all neighbor chains with non-zero interaction $\tilde{D}_{nm}$. $\tilde{\Sigma}^L_{\vec{q}\perp}$ and $\tilde{\Sigma}^R_{\vec{q}\perp}$ are the self-energy matrices accounting for the interaction of the device region of the r-chain with the regions to its left and right sides. The self-energy for the left (right) region $\tilde{\Sigma}^L_{\vec{q}\perp}$ $\left(\tilde{\Sigma}^R_{\vec{q}\perp} \right)$ is non-zero only on its top-left (bottom-right) corner, where the degrees of freedom of the device interact with those of the left (right) region. Those non-zero blocks are given by (Datta 2005; Zhang et al. 2007):

$$\text{top-left block of } \tilde{\Sigma}^L_{\vec{q}\perp} = \overline{C}^\dagger_{\vec{q}\perp} \overline{g}^L_{\vec{q}\perp} \overline{C}_{\vec{q}\perp} \tag{33}$$

$$\text{bottom-right block of } \tilde{\Sigma}^R_{\vec{q}\perp} = \overline{C}_{\vec{q}\perp} \overline{g}^R_{\vec{q}\perp} \overline{C}^\dagger_{\vec{q}\perp} \tag{34}$$

Quantities with a bar are matrices, usually with dimension smaller than that of the quantities with tilde. $\overline{g}^L_{\vec{q}\perp}$ and $\overline{g}^R_{\vec{q}\perp}$ are the surface Green's functions of the regions to the left and right of the device in the r-chain and are given by (Datta 2005):

$$\overline{g}^L_{\vec{q}\perp} = \left[\omega^2_{\vec{q}j} \overline{I} - \overline{B}_{\vec{q}\perp} + i\eta - \overline{C}^\dagger_{\vec{q}\perp} \overline{g}^L_{\vec{q}\perp} \overline{C}_{\vec{q}\perp} \right]^{-1} \tag{35}$$

$$\overline{g}^R_{\vec{q}\perp} = \left[\omega^2_{\vec{q}j} \overline{I} - \overline{B}_{\vec{q}\perp} + i\eta - \overline{C}_{\vec{q}\perp} \overline{g}^R_{\vec{q}\perp} \overline{C}^\dagger_{\vec{q}\perp} \right]^{-1} \tag{36}$$

with $i\eta$ an infinitesimal positive imaginary number that guarantees the causality of the Green's function (Datta 2005), hence termed "retarded." $\overline{B}_{\vec{q}\perp}$ and $\overline{C}_{\vec{q}\perp}$ are small matrices coming from the block tridiagonal nature of the dynamical matrix for each r-chain:

$$\overline{D}_{\vec{q}\perp} = \begin{pmatrix} \ddots & 0 & 0 & 0 & 0 \\ 0 & \overline{B}_{\vec{q}\perp} & \overline{C}_{\vec{q}\perp} & 0 & 0 \\ 0 & \overline{C}^\dagger_{\vec{q}\perp} & \overline{B}_{\vec{q}\perp} & \overline{C}_{\vec{q}\perp} & 0 \\ 0 & 0 & \overline{C}^\dagger_{\vec{q}\perp} & \overline{B}_{\vec{q}\perp} & 0 \\ 0 & 0 & 0 & 0 & \ddots \end{pmatrix} \tag{37}$$

The size of $\overline{B}_{\vec{q}\perp}$ and $\overline{C}_{\vec{q}\perp}$ depends on the longest interatomic interaction considered in the truncated set of harmonic IFCs that describe the perfect crystal. Similar to the discussion in Sect. 3.1, this truncated set should be the smallest possible that reproduces the phonon dispersion closely. This choice guarantees accuracy while keeping the computational load to a minimum. Assuming the size of $\overline{B}_{\vec{q}\perp}$ and $\overline{C}_{\vec{q}\perp}$ is

$s \times s$, the dimension of the surface Green's functions and non-zero blocks of the self-energies is $s \times s$. Note that for real material computations, efficient algorithms based on decimation or renormalization group techniques are used to find the surface Green's functions (Guinea et al. 1983; Rubio et al. 1984, 1985; Galperin et al. 2002).

To briefly summarize, the procedure to calculate the phonon-defect scattering rates from the Green's function methodology is the following: (1) Calculate the IFCs of the device without the defect and construct the dynamical matrix of the perfect device $\tilde{D}_0$ using Eq. 5. (2) Calculate the IFCs and corresponding dynamical matrix of the device with the defect. Then subtract this from $\tilde{D}_0$ to define the perturbation matrix $\tilde{D}_d$. (3) Describe the 3D crystal as a 2D crystal in a plane, whose base unit cell is an infinite 1D atomic chain. Then, using the IFCs for the perfect crystal, define the dynamical matrix $\tilde{D}_{nm}$ relating device atoms of the nth chain with those of the mth chain. (4) Define a set of wavevectors $\vec{q}_\perp$ inside the Brillouin zone of the 2D crystal, and use Eq. 32 to find the dynamical matrix of each r-chain $\tilde{D}_{\vec{q}_\perp}$. (5) Examine $\tilde{D}_{\vec{q}_\perp}$ and compare it with Eq. 37 to define $\overline{B}_{\vec{q}_\perp}$ and $\overline{C}_{\vec{q}_\perp}$. (6) Calculate the surface Green's functions from Eqs. 35 and 36 or using more efficient numerical techniques (Galperin et al. 2002). (7) Find the top-left and bottom-right blocks of the self-energies using Eqs. 33 and 34, and compute $\tilde{G}_{\vec{q}_\perp}$ for each $\vec{q}_\perp$. (8) Finally, build $\tilde{G}_0$ using Eq. 30, and calculate the T-matrix from Eq. 29 to determine the scattering rates using Eq. 28.

6   Summary

In summary, this chapter has presented details of the theoretical underpinnings of the phonon thermal transport capabilities that have recently become available for characterizing the flow of thermal energy in crystalline materials. More specifically, construction of intrinsic and extrinsic phonon scattering rates and other harmonic and anharmonic vibrational properties were discussed in terms of lattice thermal conductivity κ specifically in the context of the Peierls-Boltzmann equation. Discussion of integration methods, construction of interatomic force constants from density functional theory, and various numerical nuances were also presented, and first-principles phonon-defect scattering via Green's function methods was also discussed. Discussions of the calculations of vibrational properties and κ were set in the context of comparison with measured observables.

Abstract

The phonon Boltzmann transport equation is a reliable model for describing heat transfer in dielectric crystals and, coupled with first-principles methods, has shown to provide an accurate description of heat transport. Early solutions, based on simplifying assumptions, such as the single-mode relaxation-time approximation, have fostered the description of thermal transport as a kinetic theory of the phonon gas. In this chapter, we summarize some recent advances in the field of semiclassical transport. In particular, we show how the exact solutions of the linearized Boltzmann transport equations can be framed in terms of relaxons, collective excitations of phonon populations defined as the eigenvectors of the scattering operator. We show how an exact kinetic theory of heat transport can be constructed using relaxons, rather than phonons, as the relevant heat carriers. We showcase this change of perspective with a first-principles study of the transport properties of graphene. We discuss the relaxons' mean free paths, velocities, relaxation times, and their contributions to thermal conductivity. We contrast these results with those, approximate, obtained in the single-mode relaxation time approximation, and show how in this case the approximation fails qualitatively and quantitatively. Consequently, also Matthiessen's rule becomes invalid. Then, we discuss how surface or edge scattering can be properly recast in terms of friction, giving rise to heat profiles that resemble the hydrodynamic flow of liquids. Finally, we show how the Laplace transform of the linearized Boltzmann equation allows the definition of collective excitations, termed transport waves. These excitations are characterized by dispersion relations, and, in the context of lattice transport, they correspond to second-sound modes at finite wavelength, leading to relaxons in the long-wavelength limit.

1   Introduction

One of the first successful microscopic models for explaining the thermal conductivity of crystals has been the phonon Boltzmann Transport Equation (BTE), introduced in one of the first works of Peierls (1929). Today, almost 90 years later, the BTE remains a state-of-the-art method for modeling the thermal conductivity of crystals, striking a good balance between computational complexity, agreement with experiments, and range of applicability. With respect to earlier work, advancements in methods, theory, and algorithms have vastly improved the accuracy of BTE-based models, with a majority of efforts aimed at removing any additional approximation in the results. To this aim, notable contributions have been the introduction of first-principles parameters (Broido et al. 2007) and the development of methods to solve exactly the linearized BTE (LBTE) (Omini and Sparavigna 1997). As a result, it is now possible to solve exactly a first-principles LBTE and obtain excellent agreement with experiments (Broido et al. 2005, 2007; Garg et al. 2011; Fugallo et al. 2013; Esfarjani et al. 2011; Ward et al. 2009; Luckyanova et al. 2012; Cahill et al. 2014; Donadio and Galli 2009; McGaughey and Kaviany 2004; Volz and Chen 1999; Zhang and Li 2005).

Having access to exact solutions of the BTE is particularly interesting for evaluating the quality of certain approximations. In particular, the pioneering work of Peierls relied on the single-mode relaxation time approximation (SMA) – below we will discuss it in detail – introduced as a way to simplify the description of scattering between phonons. Loosely speaking, the SMA makes the hypothesis that each phonon mode can relax to equilibrium independently, without being affected by the relaxation of other phonons. Peierls himself was aware of the limitations of the SMA and noted that, for example, the SMA fails to describe crystals at cryogenic temperatures under the conditions of Umklapp freezing, because the conservation of energy and crystal momentum can only be ensured by considering the relaxation of the whole ensemble (i.e., conservation is a statistical property and not a mode-specific condition). This problem has gathered renewed interest because of the recent observations that two-dimensional or layered materials fall in these conditions of Umklapp freezing even at room temperature (Lindsay et al. 2010; Cepellotti et al. 2015; Lee and Lindsay 2017; Lindsay and Broido 2011; Jain and McGaughey 2015; Fugallo et al. 2014), so that the SMA doesn't apply.

Nowadays, we have the possibility of solving numerically the complete linearized BTE, thanks to iterative (Omini and Sparavigna 1996, 1997; Broido et al. 2005), variational (Ziman 2001; Hamilton and Parrot 1969; Srivastava 1976; Fugallo et al. 2013), or diagonalization (Guyer and Krumhansl 1966; Hardy 1970; Chaput 2013; Cepellotti and Marzari 2016) methods. These methods improve the estimates of thermal conductivity, but the interpretation of the results has been object of debate. Most of the common understanding is based on considerations derived within the SMA: for example, that the thermal conductivity of crystals can be interpreted with a kinetic theory of the phonon gas (Ziman 2001). Kinetic gas theory models thermal conductivity as $k = Cv\lambda = Cv^2\tau$, with C the specific heat, v the velocity, λ the mean free path, and τ the relaxation time of the particles forming the gas; Peierls introduced the notion of the phonon gas after noting that the SMA expression of thermal conductivity has a very similar form, with the relevant particles being phonons. When going beyond the SMA, it's not obvious anymore whether one can still define phonon relaxation times or mean free paths, and interpretations based on the phonon gas model become questionable. As an alternative explanation, it has been proposed that collective phonon excitations should be considered the correct heat carriers (Fugallo et al. 2014; Gill-Comeau and Lewis 2015; Cepellotti et al. 2015; Lee et al. 2015; Barbarino et al. 2015; de Tomas et al. 2014; Cepellotti and Marzari 2016).

Recently, we have formalized the construction of these collective phonon excitations and shown that the phonon gas theory does not correspond to an exact interpretation of the LBTE (Cepellotti and Marzari 2016). To interpret the exact solutions of the LBTE, we have introduced *relaxons*, i.e., collective phonon excitations defined as the eigenvectors of the scattering matrix. We found that it is still possible to describe thermal conductivity exactly with a kinetic gas theory, where the relevant gas doesn't consist of phonons, but of relaxons. The eigenvalues of the scattering matrix represent the exact relaxation times of the system and,

together with the relaxon velocities and mean free paths, redefine the relevant time, velocity, and length scales of thermal transport. Surface scattering is also reinterpreted in light of these considerations. Phonon gas theory suggests that the mean free path of heat carriers is limited by the size of the sample. Instead, surface scattering can be interpreted in hydrodynamic terms, with friction at the material's borders slowing down the heat flux (Cepellotti and Marzari 2017a). Finally, a dispersion relation for heat waves (and more generally, transport waves) can be derived (Cepellotti and Marzari 2017b), with frequencies, wavevectors, and relaxation times determined by the LBTE and tightly connected with the dispersion relations of second sound.

In this chapter, we aim at summarizing the current state of research on relaxons, presenting the topic comprehensively. We will assume that the reader is familiar with semiclassical transport theories and refer to classic textbooks for more detailed explanations of the semiclassical approximation and the derivation of the BTE. The manuscript is structured as follows: In the first section, we introduce the BTE and show how it can be written in terms of quantities computable from first-principles or microscopic models. The second section discusses the SMA, rederiving the expressions for the phonon gas model and underlining the limitations of such approach. The third section expresses the rationale for finding exact relaxation times from the LBTE and introduces the concept of relaxons. In the fourth section, we describe how to obtain bulk thermal conductivities with applications to silicon and graphene. The failure of Matthiessen rule when dealing with the exact LBTE is discussed in the fifth section. The sixth section extends the discussion of thermal conductivity to systems of finite size, dealing in particular with the example of a graphene ribbon. The dispersion relations of relaxons and their relation with second sound are presented in Section VIII. Last, we briefly discuss the limitations of the LBTE and our outlook for further studies and conclusions.

2 Fundamentals of Semiclassical Transport

Let's assume that the semiclassical approximation holds in a material. For each phonon mode, it is possible to construct a phonon wavepacket characterized by a well-defined wavevector $\boldsymbol{q}$, a branch index s and space-time coordinates $(\boldsymbol{r}, t)$. To simplify equations, we use the shorthand notation $\mu = (\boldsymbol{q}, s)$ to label each phonon mode (in this way, integrals over the Brillouin zone and summations over the branch index are replaced by a single summation on μ). Under these conditions, we can think that each phonon wavepacket behaves as a quasiparticle and that is also characterized by an energy $\hbar\omega_\mu$ and velocity $v_\mu = \frac{\partial \omega_\mu}{\partial \boldsymbol{q}}$. Within the semiclassical approximation, heat transport can be described by the linearized Boltzmann Transport Equation (Ziman 2001):

$$\frac{\partial n_\mu(\boldsymbol{r}, t)}{\partial t} + \boldsymbol{v}_\mu \cdot \nabla n_\mu(\boldsymbol{r}, t) = -\frac{1}{\mathscr{V}} \sum_{\mu'} \Omega_{\mu\mu'} \Delta n_{\mu'}(\boldsymbol{r}, t) \,. \tag{1}$$

where n_μ is the population number of the phonon μ, $\mathscr{V}$ is a normalization volume, and $\Omega_{\mu\mu'}$ is the scattering matrix.

The LBTE is a balance equation: the left-hand side – the Liouville or diffusion operator – describes how the phonon wavepacket moves in space and time with velocity $\boldsymbol{v}_\mu$. If phonon interactions are neglected, say at the level of the harmonic lattice approximation, the wavepacket would be able to proceed indefinitely and lead to an infinite thermal conductivity. Instead, anharmonic contributions cause the phonon to deviate from this perfect motion, and scattering events introduce a source of resistance. In the LBTE, scattering is described with a matrix $\Omega_{\mu\mu'}$ containing the total scattering rate for the transition $\mu \to \mu'$ due to any deviation of the true phonon Hamiltonian from the harmonic approximation. We recall that the scattering operator is nonlinear in its most generic form; however, one typically limits the discussion to small deviations from equilibrium (the same hypothesis under which the semiclassical approximation holds). Therefore, the operator can be linearized and assumes a matrix representation. As a consequence of this linearization, the scattering matrix doesn't act on the non-equilibrium phonon population n_μ; instead, it acts on the (small) difference $\Delta n_\mu = n_\mu - \bar{n}_\mu$ between n_μ and the thermal equilibrium population identified by the Bose-Einstein distribution function $\bar{n}_\mu(\boldsymbol{r}, t) = (e^{\hbar\omega_\mu/k_B T(\boldsymbol{r},t)} - 1)^{-1}$, with ω_μ being the phonon frequency and $T(\boldsymbol{r}, t)$ the local temperature.

The phonon frequency and group velocity are easily constructed by diagonalizing the dynamical matrix, i.e., the second derivative of the total energy with respect to ionic displacements. The scattering matrix is by far the most complex quantity entering the LBTE and must be built including all the phonon interactions. In practice, we limit the discussion to the inclusion of three-phonon processes and isotopic scattering events that lead to the scattering matrix (Ziman 2001; Fugallo et al. 2013):

$$
\begin{aligned}
\Omega_{\mu\mu'}\bar{n}_{\mu'}(\bar{n}_{\mu'} + 1) = &\left[\sum_{\mu'',\mu'''} \left(P^{\mu''}_{\mu\mu'''} + \frac{1}{2} P^{\mu}_{\mu''\mu'''} \right) + \sum_{\mu'} P^{\mathrm{isot}}_{\mu\mu'} \right]\delta_{\mu\mu'} \\
&- \sum_{\mu''}(P^{\mu'}_{\mu\mu''} - P^{\mu''}_{\mu\mu'} + P^{\mu}_{\mu'\mu''}) + P^{\mathrm{isot}}_{\mu\mu'} .
\end{aligned}
\tag{2}
$$

In Eq. 2, we split the matrix into a diagonal and an off-diagonal part, as it is convenient for the discussion of the SMA. The P coefficients indicate the transition rates for three-phonon and phonon-isotope scattering processes, which are obtained with the Fermi golden rule. In particular, the transition rate for three-phonon processes is (Fugallo et al. 2013; Paulatto et al. 2013; Ziman 2001; Vanderbilt et al. 1984; Debernardi et al. 1995; Lazzeri and de Gironcoli 2002):

$$
\begin{aligned}
P^{\mu''}_{\mu\mu'} = &\frac{2\pi}{N\hbar^2} \sum_{\boldsymbol{G}} |V^{(3)}(\mu, \mu', -\mu'')|^2 \\
&\times \bar{n}_\mu \bar{n}_{\mu'}(\bar{n}_{\mu''} + 1)\delta_{\boldsymbol{q}+\boldsymbol{q}'-\boldsymbol{q}'',\boldsymbol{G}} \\
&\times \delta(\hbar\omega_\mu + \hbar\omega_{\mu'} - \hbar\omega_{\mu''}) ,
\end{aligned}
\tag{3}
$$

where N is the number of phonon wavevectors $\boldsymbol{q}$, $\boldsymbol{G}$ is a reciprocal lattice vector, and $V^{(3)}$ is the third derivative of the unit cell energy $\mathscr{E}^{\text{cell}}$ with respect to atomic displacements

$$V^{(3)}(\mu, \mu', \mu") = \frac{\partial^3 \mathscr{E}^{\text{cell}}}{\partial X_\mu \partial X_{\mu'} \partial X_{\mu''}} \ , \tag{4}$$

with:

$$X_\mu = \frac{1}{N} \sum_{lb\alpha} \sqrt{\frac{2 M_b \omega_\mu}{\hbar}} z_\mu^{*b\alpha} u_{b\alpha}(\boldsymbol{R}_l) e^{-i\boldsymbol{q} \cdot \boldsymbol{R}_l} \ , \tag{5}$$

where b is an index running on the basis of atoms in the unit cell, $\boldsymbol{R}_l$ is a Bravais lattice vector identifying the lth unit cell inside the crystal, α is a cartesian index, M_b is the mass of atom b, z_μ is the phonon polarization vector, * indicates the complex conjugate, and u is the vector of atomic displacements. The scattering rate for a phonon-isotope scattering event is (Garg et al. 2011; Ziman 2001; Abeles 1963):

$$P_{\mu\mu'}^{\text{isot}} = \frac{\pi}{2N} \omega_\mu \omega_{\mu'} \left[\bar{n}_\mu \bar{n}_{\mu'} + \frac{\bar{n}_\mu + \bar{n}_{\mu'}}{2} \right]$$
$$\times \sum_b g_b \left| \sum_\alpha z_\mu^{*,b\alpha} z_{\mu'}^{b\alpha} \right|^2 \delta(\omega_\mu - \omega_{\mu'}) \ , \tag{6}$$

where $g_b = \frac{(M_b - \langle M_b \rangle)^2}{\langle M_b \rangle^2}$.

All of these quantities are needed to build the LBTE. In the examples that will be made in the following sections, we have obtained both the dynamical matrix and the anharmonic matrix $V^{(3)}$ from density-functional perturbation theory (Baroni et al. 1987, 2001; Giannozzi et al. 1991; Debernardi et al. 1995; Paulatto et al. 2013; Lazzeri and de Gironcoli 2002; Gonze and Vigneron 1989), with an implementation freely available in the open-source software distribution Quantum ESPRESSO (Giannozzi et al. 2009). As a result, the LBTE is free of adjustable parameters and can be used directly to compare with experimental results. We note in passing that the LBTE is not tied to first-principles simulations, and these parameters can be obtained with any other microscopic model (e.g., tight-binding methods, empirical potentials, etc.) capable of providing the total energy as a function of ionic positions.

As a last numerical point, we note that every numerical implementation of the theory needs to overcome the difficulty of the Dirac delta imposing the energy conservation. In the results shown here, we follow the prescription of Fugallo et al. (2013) and substitute the Dirac delta with a Gaussian smearing, chosen in such a way to best reproduce the numerical value of thermal conductivity in the limit of an infinite number of phonon wavevectors and zero smearing width.

For later convenience, we express the left-hand side of Eq. (1) in terms of $\Delta n_\mu = n_\mu - \bar{n}_\mu$:

$$\frac{\partial \bar{n}_\mu}{\partial T}\left(\frac{\partial T(\boldsymbol{r},t)}{\partial t} + \boldsymbol{v}_\mu \cdot \nabla T(\boldsymbol{r},t)\right) + \frac{\partial(\Delta n_\mu(\boldsymbol{r},t))}{\partial t} + \boldsymbol{v}_\mu \cdot \nabla(\Delta n_\mu(\boldsymbol{r},t)) =$$
$$= -\frac{1}{\mathscr{V}}\sum_{\mu'}\Omega_{\mu\mu'}\Delta n_{\mu'}(\boldsymbol{r},t) ; \tag{7}$$

where T is the reference temperature at which the scattering operator has been linearized. To write this equation, we used the fact that the Bose-Einstein distribution depends on space-time coordinates only through temperature. In this form, we have now explicitly put the equation in terms of the unknown Δn_μ and the parameter T; for each temperature, the LBTE needs to be solved to obtain Δn_μ. This complete expression shows that the LBTE becomes a set of coupled linear differential equations. Their solution has proven to be a daunting challenge, and the rest of the discussion will focus on finding solutions to a few simple problems. However, we note that the solution Δn_μ grants access to the out-of-equilibrium properties. In particular it can be shown, within the harmonic approximation (Hardy 1963), that each phonon transfers an energy flux equal to $\hbar\omega_\mu\boldsymbol{v}_\mu$; hence the total energy (heat) flux of the lattice is:

$$\boldsymbol{Q}(\boldsymbol{r},t) = \frac{1}{\mathscr{V}}\sum_\mu \hbar\omega_\mu\boldsymbol{v}_\mu n_\mu(\boldsymbol{r},t) . \tag{8}$$

Therefore, the knowledge of the out-of-equilibrium phonon population allows to compute the heat flux at each point of the material and to describe its evolution in time, all via microscopic degrees of freedom. Eventually, thermal conductivity is obtained from the relation $\boldsymbol{Q} = -k\nabla T$, connecting the heat flux generated in response to an applied temperature gradient ∇T. The great challenge, however, is the calculation of the deviation of phonon populations from equilibrium, and the simplest approximated way to find an expression for Δn_μ is by means of the SMA.

3   Single-Mode Relaxation Time Approximation

The first historical attempts at finding a solution of the LBTE have relied on the SMA, with the aim of simplifying the scattering matrix to a form such that the analytical solution of the LBTE becomes trivial. Mathematically, the SMA approximates to zero all the out-of-diagonal matrix elements of Ω, so that the right-hand side of the LBTE becomes:

$$\frac{1}{\mathscr{V}}\sum_{\mu'}\Omega_{\mu\mu'}\Delta n_{\mu'}(\boldsymbol{r},t) \approx \frac{\Delta n_\mu(\boldsymbol{r},t)}{\tau_\mu^{\text{SMA}}} , \tag{9}$$

where we label the diagonal terms of the scattering matrix as $\frac{1}{\tau_\mu^{\text{SMA}}} = \Omega_{\mu\mu}$.

To show that τ_μ^{SMA} is a relaxation time, we now suppose that the crystal is at thermal equilibrium ($T(\boldsymbol{r}, t) = T =$ const), so that the first two terms of Eq. 7 disappear. Every phonon at time t_0 is populated according to the Bose-Einstein distribution, except for one phonon mode μ, which we excite to a number $n_\mu(t_0)$ throughout space (in this way, there are no spatial gradients). The SMA-LBTE that describes this problem is simply:

$$\frac{\partial \Delta n_\mu(t)}{\partial t} = -\frac{\Delta n_\mu(t)}{\tau_\mu^{\text{SMA}}} , \qquad (10)$$

which describes how the system relaxes to equilibrium. Clearly, it will thermalize with an exponential decay of the excitation number $\Delta n_\mu(t) = \Delta n_\mu(t_0)e^{-t/\tau_\mu^{\text{SMA}}}$, where the relaxation time τ_μ^{SMA} gives the characteristic time of such decay and, if positive, ensures that at large-enough times the system will relax back to equilibrium ($\Delta n_\mu = 0$). Therefore, the diagonal matrix elements determine the characteristic time of such decay and have been identified as phonon relaxation times; we note though that this conclusion has to rely on the introduction of the SMA.

Since the SMA scattering matrix is diagonal, many problems can be tackled easily, such as the calculation of the bulk thermal conductivity. To characterize this property, we apply an infinitesimally small temperature gradient ∇T, which is spatially homogeneous and independent of time: $\nabla T(\boldsymbol{r}, t) = \nabla T =$ const. Since we limit the study to steady state, the distribution Δn_μ originated in response to this perturbation is independent of time. Moreover, we can expect Δn_μ to be independent from the spatial coordinates as well, thanks to the translational invariance of the bulk crystal. The SMA-LBTE to be solved becomes:

$$\frac{\partial \bar{n}_\mu}{\partial T} \boldsymbol{v}_\mu \cdot \nabla T = -\frac{\Delta n_\mu}{\tau_\mu^{\text{SMA}}} . \qquad (11)$$

Trivially, we can solve for Δn_μ by multiplying the equation by $-\tau_\mu^{\text{SMA}}$ (in fact, this simplicity is the main justification for this approximation). The thermal conductivity tensor k^{ij} follows and in the SMA is equal to:

$$k^{ij} = -(\nabla T)_j^{-1} Q_i = -(\nabla T)_j^{-1} \frac{1}{\mathcal{V}} \sum_\mu \hbar\omega_\mu v_\mu^i \Delta n_\mu$$

$$\approx \frac{1}{\mathcal{V}} \sum_\mu \frac{\partial \bar{n}_\mu}{\partial T} \hbar\omega_\mu v_\mu^i v_\mu^j \tau_\mu^{\text{SMA}} = \frac{1}{\mathcal{V}} \sum_\mu C_\mu v_\mu^i (\Lambda_\mu^j)^{\text{SMA}} , \qquad (12)$$

where i and j represent Cartesian coordinates, $C_\mu = \frac{1}{k_B T^2} \bar{n}_\mu(\bar{n}_\mu + 1)(\hbar\omega_\mu)^2 = \frac{\partial \bar{n}_\mu}{\partial T} \hbar\omega_\mu$ is the specific heat, and $(\Lambda_\mu^j)^{\text{SMA}} = v_\mu^j \tau_\mu^{\text{SMA}}$ is the mean free path of the phonons. This expression has the same structure of the thermal conductivity obtained from the kinetic gas theory ($k = Cv\Lambda$). Therefore, Peierls interpreted the

semiclassical thermal transport theory in terms of a phonon gas, where each phonon contributes to the heat flux with a heat capacity C_μ and travels for a distance Λ_μ^{SMA} at velocity v_μ before thermalizing to equilibrium by the action of scattering on a time scale set by τ_μ^{SMA}.

This conclusion is justified within the SMA, but we cannot blindly apply it to the general solution of the BTE. In the next section, we will extend the same reasoning to the complete scattering matrix, and we will see that exact relaxation times can be defined but are not given by the diagonal elements. In fact, in the present derivation, we neglected the out-of-diagonal matrix elements. Physically, these are necessary for an accurate description of the energy transfer between phonons. For example, consider the case of Eq. 10 where we studied the time evolution of a single excited phonon. The energy change from equilibrium is determined by the phonon excitation number and evolves in time as $\Delta E_\mu = \hbar \omega_\mu \Delta n_\mu(t_0) e^{-t/\tau_\mu^{\text{SMA}}}$. It must be noted that the energy is not conserved, contrary to the expectations and despite the fact that each transition in the scattering matrix conserves energy (through a number of Dirac deltas). While the diagonal matrix elements correctly describe the rate at which energy leaves a phonon mode, the out-of-diagonal matrix elements describe how energy is transferred to other phonons (Fugallo et al. 2013). Thus, the SMA is not able to describe the correct redistribution of energy upon scattering; to this aim, one has to include the out-of-diagonal matrix elements.

4   Relaxons

To find exact relaxation times, we simply proceed in the same way as shown above but retaining the full expression of the scattering matrix. We consider a crystal kept at constant temperature $T(\mathbf{r}, t) =$const and excite a phonon mode homogeneously in space – as we did for the SMA – such that the evolution of the phonon population only depends on time but not on space. The LBTE is simplified to the following differential equation (a generalization of Eq. 10):

$$\frac{\partial \Delta n_\mu(t)}{\partial t} = -\frac{1}{\mathcal{V}} \sum_{\mu'} \Omega_{\mu\mu'} \Delta n_{\mu'}(t) . \tag{13}$$

Obviously, the SMA solution $\Delta n_\mu(t) = \Delta n_\mu(t_0) e^{-t \Omega_{\mu\mu}}$ is not the correct solution of this more general case. Nevertheless, the problem is still a set of coupled linear differential equations that can be solved analytically.

To solve these, we have to diagonalize the scattering matrix. From Eq. 2, one can verify that the scattering matrix $\Omega_{\mu\mu'}$ is not symmetric, i.e., $\Omega_{\mu\mu'} \neq \Omega_{\mu'\mu}$, which is inconvenient for diagonalization. The asymmetry however is caused just by a factor $\bar{n}_\mu(\bar{n}_\mu + 1)$ and the following scaling transformations (Hardy 1965, 1970; Krumhansl 1965; Chaput 2013):

$$\tilde{\Omega}_{\mu\mu'} = \Omega_{\mu\mu'} \sqrt{\frac{\bar{n}_{\mu'}(\bar{n}_{\mu'} + 1)}{\bar{n}_{\mu}(\bar{n}_{\mu} + 1)}} \;, \tag{14}$$

$$\Delta\tilde{n}_{\mu} = (\bar{n}_{\mu}(\bar{n}_{\mu} + 1))^{-\frac{1}{2}} \Delta n_{\mu} \tag{15}$$

allow to recast Eq. 13 in terms of a symmetric matrix $\tilde{\Omega}_{\mu\mu'}$ and of $\Delta\tilde{n}_{\mu}$. We can thus diagonalize $\tilde{\Omega}_{\mu\mu'}$ and find its complete set of eigenvectors and eigenvalues:

$$\frac{1}{\mathcal{V}} \sum_{\mu'} \tilde{\Omega}_{\mu\mu'} \theta_{\mu'}^{\alpha} = \frac{1}{\tau_{\alpha}} \theta_{\mu}^{\alpha} \;, \tag{16}$$

where α is an eigenvalue index, θ_{μ}^{α} is an eigenvector, and τ_{α} its eigenvalue. To impose normalization of the eigenvectors, we also define a scalar product $\langle\alpha|\alpha'\rangle \equiv \frac{1}{\mathcal{V}} \sum_{\mu} \theta_{\mu}^{\alpha} \theta_{\mu}^{\alpha'}$ and note that the completeness relation ensures that $\langle\alpha|\alpha'\rangle = \delta_{\alpha\alpha'}$. As a technical note aside, we note that Fugallo et al. (2013) stressed that the calculation of scattering rates requires a numerical implementation of the Dirac delta that ensures the energy conservation: such implementation must be made so that the scattering matrix remains symmetric, or the results of the diagonalization may deviate from what we will discuss in the following.

At the present stage, we know very little about the eigenvalue spectrum of the scattering matrix, because the diagonalization of this large matrix hasn't been attempted until recently, and even then, it has been done only in a handful of materials (Chaput 2013; Cepellotti and Marzari 2016; Togo et al. 2015). However, since $\tilde{\Omega}_{\mu\mu'}$ is a real symmetric matrix, all its eigenvalues are real numbers (Hardy 1970). Moreover, $\tilde{\Omega}_{\mu\mu'}$ is also a semi-positive definite matrix (Hardy 1965, 1970; Fugallo et al. 2013), that is, the eigenvalues must be equal to either zero or any positive number. We further add that for the case of graphene and silicon, later discussed in detail, we find only strictly positive eigenvalues.

Returning to the problem of thermal relaxation, we can now take advantage of the complete basis set of eigenvectors of the scattering matrix. Any response $\Delta\tilde{n}_{\mu}$ can be written as a linear combination of the θ_{μ}^{α} eigenvectors (Hardy 1970):

$$\Delta\tilde{n}_{\mu}(\boldsymbol{r}, t) = \sum_{\alpha} f_{\alpha}(\boldsymbol{r}, t) \theta_{\mu}^{\alpha} \;, \tag{17}$$

where $f_{\alpha}(\boldsymbol{r}, t)$ are a set of real coefficients. If we write Eq. 13 in the symmetrized form and then rotate it in the basis of eigenvectors, the equation describing thermalization becomes:

$$\frac{\partial f_{\alpha}(\boldsymbol{r}, t)}{\partial t} = -\frac{f_{\alpha}(\boldsymbol{r}, t)}{\tau_{\alpha}} \;. \tag{18}$$

The LBTE in this set of coordinates has the same structure of the SMA (Eq. 10), and therefore the relaxation of the system toward equilibrium is described by $f_\alpha(t) = f_\alpha(t_0)e^{-t/\tau_\alpha}$. We now recognize that the eigenvalues τ_α describe the characteristic time scale of thermal relaxation. At variance with the SMA result, the scattering operator has not been approximated, and therefore τ_α are the exact time scales of the thermal relaxation as described by the LBTE. The semi-positiveness of the scattering matrix ensures that the exponential factor decays to zero or, in the case of zero eigenvalues, the component is a stationary solution.

At variance with the SMA, the quantities relaxing to equilibrium are not phonons anymore, but the factors f_α that project the phonon population onto the eigenvectors of the scattering matrix. To stress that phonons do not have a relaxation time, note that the solution of Eq. 18 can be rotated back into the phonon basis, finding $\Delta n_\mu(t) = \sum_\alpha f_\alpha(t_0)\theta_\mu^\alpha e^{-t/\tau_\alpha}$. The thermal relaxation of a phonon is characterized by N different exponential relaxation channels (N being the number of phonon states in the system, equal to the number of eigenvalues), and thus it's not possible to identify a single characteristic decay time for a phonon population (we stress that the LBTE abstract the microscopic dynamics of the phonons into that of phonon populations, and it's the time scale of these phonon populations that we are describing now). Since the eigenvectors θ_μ^α can have any sign, the phonon thermalization $\Delta n_\mu(t)$ can behave as any decaying curve and not simply as an exponential. As a result, phonon relaxation times do not make sense anymore when the complete LBTE is considered. We note in passing that this statement is in contrast with several others (e.g., Broido et al. (2005) and others citing it), that define an exact phonon relaxation time, however without proving any connection with the actual time evolution of the phonon populations.

Looking now more carefully at the eigenvectors θ_μ^α, we note that each eigenvector has been used to express the phonon populations in terms of the coefficients f_α; in other terms, each eigenvector at fixed α identifies a distribution function of phonon occupation numbers, i.e., a collective excitation of phonons. To simplify the discussion, we will refer to the eigenvectors of the scattering matrix as *relaxons*, this name indicating that these are entities characterized by exact relaxation times. By definition, relaxons are invariant under the action of the scattering operator: each is thus a collective excitation of phonons that interact/scatter with each other, but each relaxon does not interact/scatter with other relaxons. In addition, the coefficients f_α can be interpreted as relaxon populations, and the evolution described by Eq. 18 is the time evolution of the relaxon populations. Since the LBTE has been expressed in terms of deviations from equilibrium, a zero relaxon population corresponds to thermal equilibrium. This interpretation is schematically shown in Fig. 1: we define relaxons as collective phonon excitations, such that the scattering interactions become decoupled, and the problem of phonon scattering is recast into a formulation of noninteracting relaxons, which only exist in an out-of-equilibrium situation and disappear at long times when thermal equilibrium is restored.
Fig. 1 Graphical representation of relaxon thermalization. Each relaxon is a collective excitation of phonons: phonons interact among themselves by the action of scattering, but relaxons do not scatter against each other by construction. Each relaxon thermalizes decaying exponentially to equilibrium, at a rate given by its exact relaxation times. (Picture from Cepellotti and Marzari 2016)

An interesting property of relaxons is that they have a well-defined parity (Hardy 1970), a result that follows from the symmetry of the scattering matrix $\tilde{\Omega}_{\mu\mu'} = \tilde{\Omega}_{-\mu-\mu'}$, where $-\mu = (-\boldsymbol{q}, s)$, so that every relaxon is either even or odd, i.e., $\theta_\mu^\alpha = \pm\theta_{-\mu}^\alpha$. As a consequence, the parity distinguishes the contributions to the energy change ΔE:

$$\Delta E = \frac{1}{\mathscr{V}} \sum_\mu \hbar\omega_\mu \Delta n_\mu = \frac{1}{\mathscr{V}} \sum_\mu \hbar\omega_\mu \sqrt{\bar{n}_\mu(\bar{n}_\mu + 1)} \Delta\tilde{n}_\mu$$

$$= \frac{1}{\mathscr{V}} \sum_\mu \theta_\mu^0 \sqrt{k_B T^2 C} \sum_\alpha f_\alpha \theta_\mu^\alpha$$

$$= \sqrt{k_B T^2 C} \sum_\alpha f_\alpha \langle 0|\alpha\rangle \ , \tag{19}$$

where we introduced the total crystal heat capacity $C = \frac{1}{\mathscr{V}} \sum_\mu C_\mu$ and the auxiliary vector $|0\rangle$ as:

$$|0\rangle = \theta_\mu^0 = \frac{\sqrt{\bar{n}_\mu(\bar{n}_\mu + 1)}\hbar\omega_\mu}{\sqrt{k_B T^2 C}} \ . \tag{20}$$

The parity of the eigenvectors, together with the even parity of $\bar{n}_\mu$ and ω_μ, ensures that only relaxons that are even contribute to changes in energy, whereas relaxons that are odd conserve energy. The distribution θ_μ^0 introduced here can be obtained from the Bose-Einstein distribution: to do so, one must take the first-order term in the Taylor expansion of $\bar{n}_\mu(T + \delta T)$, symmetrize the distribution using Eq. (15), and normalize the distribution.

The heat flux can be expressed in terms of relaxons, finding:

$$\boldsymbol{Q} = \frac{1}{\mathcal{V}} \sum_{\mu} \hbar \omega_{\mu} v_{\mu}^{j} \Delta n_{\mu}$$

$$= \sqrt{k_{B} T^{2} C} \sum_{\alpha} \boldsymbol{V}_{\alpha} f_{\alpha} \,, \tag{21}$$

where we introduce a relaxon velocity $\boldsymbol{V}_{\alpha} = \boldsymbol{V}_{0\alpha} = \langle 0|v|\alpha\rangle = \frac{1}{\mathcal{V}} \sum_{\mu} \theta_{\mu}^{0} \boldsymbol{v}_{\mu} \theta_{\mu}^{\alpha}$. Here, only relaxons of odd parity have a non-zero contribution to heat flux; even relaxons do not contribute. Therefore, the parity of the spectrum distinguishes between excitations contributing to energy changes (even) and relaxons contributing to energy fluxes (odd).

Having now found that relaxons are conveniently characterized by the exact relaxation times of the system, it is natural to extend the study to a more complex case than the thermal relaxation of Eq. 13. For a more general case, we must start from the full LBTE of Eq. 7, symmetrize it with Eq. 15, and change the basis to relaxons using Eq. 17. After various algebraic manipulations, the LBTE in the relaxon basis becomes:

$$\sqrt{\frac{C}{k_{B} T^{2}}} \left(\frac{\partial T(\boldsymbol{r}, t)}{\partial t} \langle 0|\alpha\rangle + \nabla T(\boldsymbol{r}, t) \cdot \boldsymbol{V}_{\alpha} \right) + \frac{\partial f_{\alpha}(\boldsymbol{r}, t)}{\partial t} + \sum_{\alpha'} \boldsymbol{V}_{\alpha\alpha'} \cdot \nabla f_{\alpha'}(\boldsymbol{r}, t)$$

$$= -\frac{f_{\alpha}(\boldsymbol{r}, t)}{\tau_{\alpha}} \,, \tag{22}$$

where $\boldsymbol{V}_{\alpha\alpha'} = \frac{1}{\mathcal{V}} \sum_{\mu} \theta_{\mu}^{\alpha} \boldsymbol{v}_{\mu} \theta_{\mu}^{\alpha'} \equiv \langle \alpha|v|\alpha'\rangle$ and $\boldsymbol{V}_{\alpha} = \boldsymbol{V}_{0\alpha} = \langle 0|v|\alpha\rangle$. $\boldsymbol{V}_{\alpha\alpha'}$ derives from the action of the diffusion operator on the deviation from equilibrium, while $\boldsymbol{V}_{\alpha}$ derives from the action of the diffusion operator on the equilibrium distribution.

The LBTE in the relaxon basis is now expressed in terms of the unknown relaxon occupation number, which replaces the phonon occupation number. At a first glance, not much has been gained by this transformation. First of all, the basis change is just a rotation of coordinates that doesn't add or modify the information encoded in the LBTE. Moreover, while the scattering operator in the relaxon basis is, by construction, simply diagonal, the drifting operator is not diagonal anymore, as it was instead in the phonon basis. We will show however that the challenging aspects of the LBTE haven't simply been moved from the scattering to the diffusion operator but that this choice of basis allows for identifying analytical solutions of the LBTE and additional physical insights.

5 Bulk Conductivity

The steady-state thermal conductivity in the bulk crystal can be obtained readily from the LBTE in the relaxon basis. In full analogy with the way bulk conductivity

has been derived within the SMA, we apply a constant temperature gradient that doesn't depend in space and time. Equation 22 can be simplified by setting time derivatives to zero, as long as we limit to stationary conditions, and taking advantage of the translational periodicity of a lattice, we can set $f_\alpha(\mathbf{r}, t) = f_\alpha$, as the response of the system must be homogeneous in space. The resulting LBTE is simply:

$$\sqrt{\frac{C}{k_B T^2}} \nabla T \cdot \mathbf{V}_\alpha = -\frac{f_\alpha}{\tau_\alpha} . \tag{23}$$

This equation has the same formal structure of the SMA bulk problem (Eq. 11) and is trivially solved in terms of f_α, simply multiplying the equation by $-\tau_\alpha$. Using the definition of thermal conductivity and the expression of heat flux of Eq. 21, the bulk conductivity of the LBTE can be expressed exactly as:

$$k^{ij} = \frac{-1}{\mathcal{V} \nabla_i T} \sum_\mu \hbar \omega_\mu v_\mu^j \Delta n_\mu = -\sum_\alpha f_\alpha^i \sqrt{k_B T^2 C} V_\alpha^j$$

$$= \sum_\alpha C V_\alpha^i V_\alpha^j \tau_\alpha = \sum_\alpha C V_\alpha^i \Lambda_\alpha^j , \tag{24}$$

where Λ_α^j is the α relaxon mean free path in direction j. In the same way that the bulk LBTE hasn't formally changed from the SMA to the relaxon basis, the formal structure of thermal conductivity itself hasn't changed and is again reminiscent of a kinetic theory of gases. Therefore, this result prompts the interpretation of thermal transport in bulk crystals as a gas of relaxons that travel at velocity V_α for a distance Λ_α, after which they equilibrate. The specific heat indicates that each relaxon changes the local temperature by an amount δT after spending an amount of energy equal to $\delta E = C \delta T$. Therefore, the kinetic theory of gases still applies, but the objects forming the gas have been redefined.

One difference with respect to the SMA is the specific heat: while each phonon has its own specific heat C_μ, the present equations indicate that each relaxon is characterized by an identical specific heat C, equal to the specific heat of the whole crystal. The difference stems from the fact that temperature, being an equilibrium property, cannot be changed by a single phonon but by a distribution of them. In detail, in order to change temperature from T to $T + \delta T$, it is necessary that the phonon distribution changes from $\bar{n}(T)$ to $\bar{n}(T + \delta T)$: for this reason, the relevant velocity V_α describes the phonon group velocities of relaxon α projected into the deviation θ_μ^0 (recall the definition $V_\alpha = \langle 0|v|\alpha \rangle$), and the component relevant to thermal transport is the one that contributes to the phonon population change $\bar{n}(T + \delta T) - \bar{n}(T)$.

5.1   Examples: Graphene and Silicon

To showcase the model discussed above for bulk thermal conductivity, we present here, as also discussed in Cepellotti and Marzari (2016), the bulk thermal conductivity of silicon and graphene. These two materials have been chosen for two opposite reasons. Silicon is a well-known material, there aren't debates on the value of its thermal conductivity, and the SMA does a good job in predicting the bulk thermal conductivity from first principles (138 W/mK) with respect to the exact conductivity (141 W/mk from Eq. 24), which is close to the experimental value (144 W/mK). In contrast, there is still no wide consensus (neither between experiments nor between theoretical predictions) on the thermal conductivity of graphene, and more importantly the SMA dramatically underestimates the exact thermal conductivity (Lindsay et al. 2010), in our calculations $k^{SMA} = 495$ W/mK against an exact $k = 3894$ W/mK at room temperature.

The LBTE is built from first principles, calculating harmonic and anharmonic force constants using density-functional perturbation theory (Baroni et al. 1987, 2001; Giannozzi et al. 1991; Debernardi et al. 1995; Paulatto et al. 2013; Lazzeri and de Gironcoli 2002; Gonze and Vigneron 1989) as implemented in the Quantum ESPRESSO distribution (Giannozzi et al. 2009), the scattering matrix contains three-phonon and isotope-phonon interactions. Linear algebra operations require massively parallel linear algebra routines; in particular, we take advantage of the ScaLAPACK library (Blackford et al. 1997). For the rest of this section, all quantities are computed at a temperature of 300 K, and, taking advantage of the isotropy of the materials, by thermal conductivity we mean here the single irreducible component of the thermal conductivity tensor.

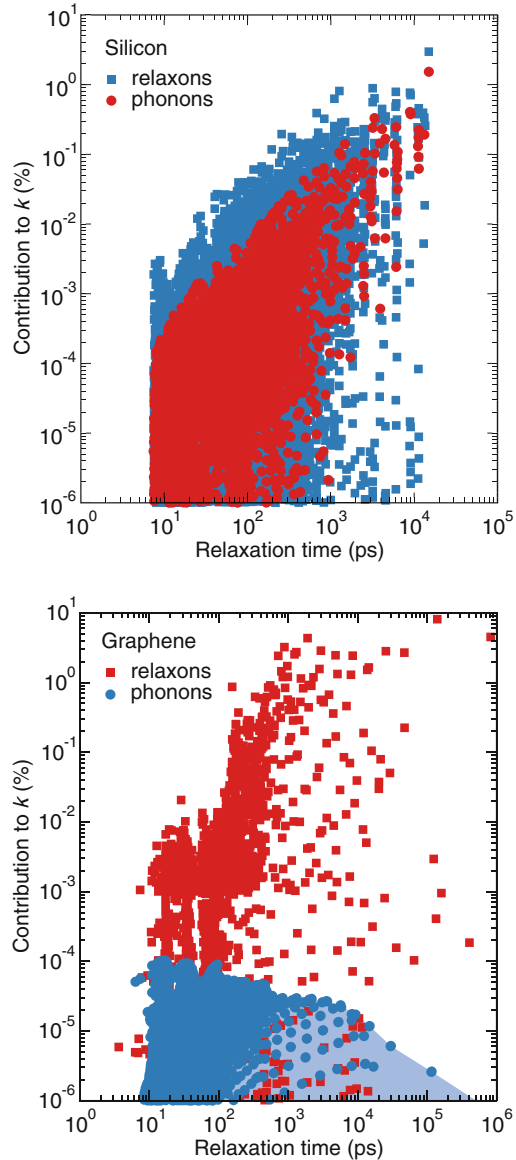
The diagonalization of Eq. (16) gives all the relaxons θ_μ^α. After desymmetrizing the eigenvectors with Eq. 15, they can be used to check the contributions of different phonon modes to a given relaxon. For example, in Fig. 2, we plot the longest-lived relaxon of graphene as a function of the phonon index $\mu = (\boldsymbol{q}, s)$. For the sake of simplicity, we only show the contribution to such relaxon from the three acoustic phonon branches (the optical contributions being much smaller). As the relaxon describes deviations of phonon populations from equilibrium, the picture shows that contributions to this specific relaxons come from deviations of long-wavelength ZA phonons and receives also contributions from LA and TA branches (with a much more complicated dependence on the Brillouin zone). It's important to note in this picture that, being a collective excitation, each relaxon receives contribution from most phonon modes, and the loci of phonon deviations do not seem to have a simple structure, except for the most relevant and dominant case of the ZA branch.

In Fig. 3, we illustrate the difference between the exact relaxation times (red dots) and phonon lifetimes (blue dots) for both materials. In particular, we plot the percentage contribution to thermal conductivity (k for relaxons, k^{SMA} for phonons) as a function of the exact/phonon relaxation time or lifetime.

In silicon, where the discrepancy between the SMA and the exact solution is small, we observe that the shape of the two distribution is rather similar,

Fig. 2 For graphene at room temperature, the relaxon θ_μ^α with the longest relaxation time ($\alpha=1$) is plotted against the phonon index $\mu = (\boldsymbol{q}, s)$, where we restrict the branch index s to the three out-of-plane/transverse/longitudinal acoustic modes (ZA, TA, and LA, respectively), among the six that are present. The hexagonal shape is the Brillouin zone of graphene, while height and colors indicate the difference of phonon population with respect to thermal equilibrium (red for overpopulated modes and blue for depopulated ones). It can be seen that contributions come from phonons across the whole Brillouin zone for different branches. The fine structure of the ridges is a numerical artifact due to discrete Brillouin zone sampling. (Picture from Cepellotti and Marzari 2016)
as well as the range of time scale covered by the two solutions. There are no lifetimes/relaxation times below 7–8 ps: this is the time scale set by the largest scattering rate available in the scattering matrix (limited to three-phonon and phonon-isotope processes). As the phonon/relaxon lives for a longer time, the more it contributes to thermal conductivity. Although the details of the distributions are different (and compressed in the picture by the logarithmic scale), the relaxon picture here doesn't change much the relevant time scale of the transport dynamics. We note in passing that we truncate in the picture several modes that have negligible contributions to the thermal conductivity.

The situation is radically different for graphene. Here, k^{SMA} is mostly determined by phonons of characteristic lifetimes of approximately 10–100 ps, while the largest

Fig. 3 Contribution to thermal conductivity as a function of relaxation times. Blue dots represent results at the level of the SMA phonon gas theory; red dots show results in terms of eigenvalues. Thermal conductivity is computed within the SMA for phonons, exactly for relaxons; to have comparable results, the contribution to thermal conductivity is plotted as a percentage. In silicon, the two theories give similar results. Relaxons in graphene instead show that the exact time scale of relaxation is much larger than what predicted at the SMA level. The peak of contributions to SMA thermal conductivity comes at a time scale of about 10–100 ps, whereas the largest exact contributions have a time scale larger than 1000 ps. The shaded area is a guide to the eyes, to recall that a finer integration of the Brillouin zone would lead to a continuous spectrum, whereas relaxon spectrum is discrete. (Picture from Cepellotti and Marzari 2016)


contributions to the exact thermal conductivity come from relaxons with lifetimes above $1\,\mu$s and up to $1\,$ms. As a consequence, we can see that the SMA fails to estimate the time scale of heat transport by orders of magnitude. The physical meaning of this large discrepancy is related with the role of the off-diagonal scattering matrix elements. The time scale at which energy leaves a phonon is of

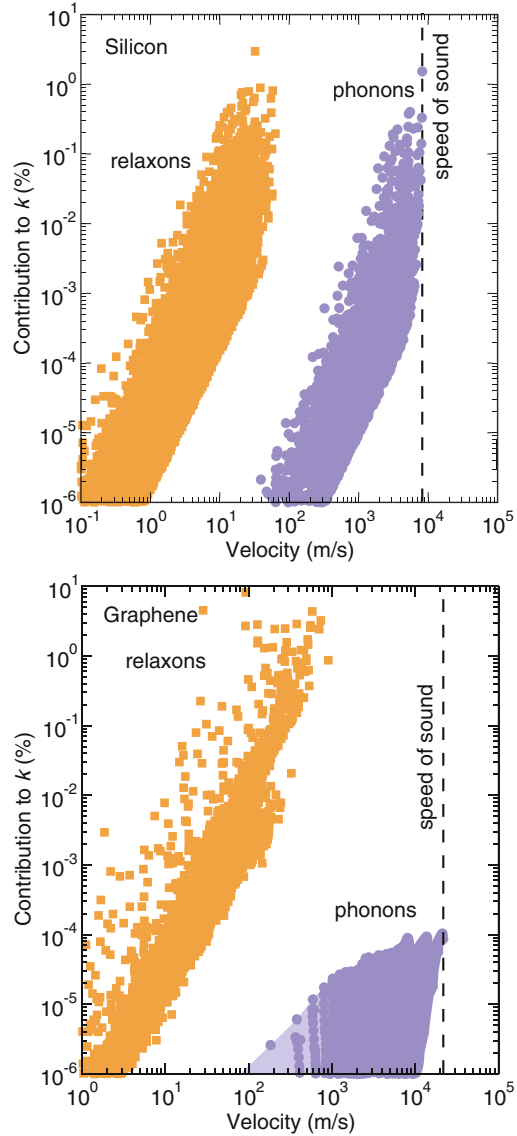
the order of 10–100 ps, but the heat flux is not thermalized after a single scattering event. Heat flux is instead transferred to other modes and can propagate over several scattering events on a much larger time scale than that of a single phonon scattering event. The exact time scale of this collective participation of phonon modes to the heat flux is set by the eigenvalues of the scattering matrix. In contrast, the similarity of the exact and SMA results for silicon suggests that in this material heat flux is quickly dissipated after a few scattering events.

As an artifact of the finite sampling of k-points in the Brillouin zone, the phonon lifetimes don't form a continuous distribution in the picture; however, by increasing the integration sampling, we would see the blue dots join together to form a continuous area. From the numerical results, it appears that relaxons do not necessarily form a continuous spectrum. In fact, our convergence studies on graphene indicate that the largest relaxation times form a discrete spectrum. It's not unusual in condensed matter physics that the eigenvalue spectrum of a continuous matrix can lead to a discrete eigenvalue spectrum, but we don't have yet a deeper insight of why it can happen here.

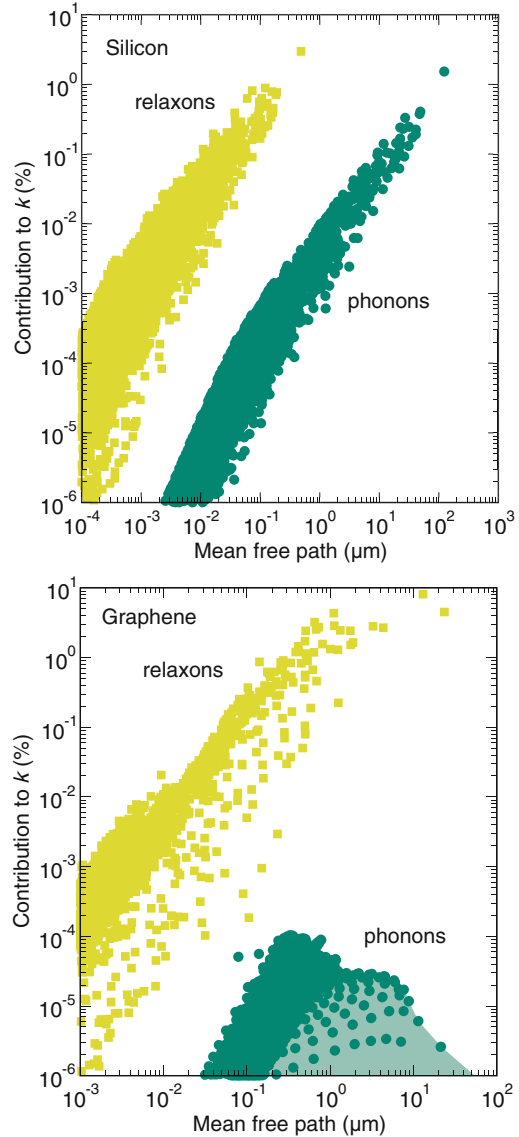
In Fig. 4, we study the percentage contribution to k or k^{SMA} for relaxons and phonons, respectively, as a function of the velocities $|V_\alpha^x|$ or $|v_\mu^x|$. For this property, both silicon and graphene (i.e., regardless of the effectiveness of the SMA) show notable differences between phonon group velocities and relaxon velocities. It appears therefore that the SMA overestimates the speed at which heat flux propagates through the material; in particular, the largest contributions come from phonons that have approximately the speed of sound. Instead, the relaxon velocity V_α is always much smaller than the speed of sound by one or two orders of magnitude. The result is interpreted by the fact that a relaxon couples together an ensemble of phonons that transfer heat flux. Since heat flux doesn't live on a single phonon, its average velocity will have to be averaged over several phonon modes; given that the speed of sound is typically the largest value, the resulting velocity will be smaller. In other words, the instantaneous velocity is the phonon group velocity, but the statistical velocity at which heat flux propagates in the bulk is much smaller.

Finally, the mean free paths shown in Fig. 5 combine the features of velocities and relaxation times of the previous figures, to illustrate the length scales at which heat flux dissipation occurs. In particular, the orders of magnitude of difference in the velocities and relaxation times are now propagated to the mean free paths. In silicon, the mean free paths Λ_α are much smaller than the SMA counterparts, but the distribution has a comparable shape. The differences between the two theories are more pronounced in graphene, where the distribution has also a different shape. In both cases, however, the contribution to the exact thermal conductivity is roughly proportional to the relaxon mean free path. Comparing the two materials, the exact mean free path shows that the heat flux dissipation takes place at a much larger value in graphene (10 microns) than in silicon (less than 1 micron).

It's worth noting that a typical tool to study the effect of nanostructuring is to plot the cumulative curve of conductivity as a function of the mean free path, as a direct postprocessing of the presented figure. The common understanding is that nanostructuring in a material will be effective to decrease thermal conductivity when

Fig. 4 Contribution to exact (SMA) thermal conductivity in percentage, as a function of the exact (phonon) relaxation time of the system at room temperature in graphene. Within the SMA, the velocity scale of thermal transport is well approximated by the group velocity of phonons, in particular, the largest contributions come from phonons at the speed of sound, i.e., about 20 (8) km/s in graphene (silicon). In the relaxon picture, heat flux is allowed to be shuttled through several phonon modes, resulting in an average velocity of heat flux that is on average much smaller than the speed of sound. (Picture from Cepellotti and Marzari 2016)


it has a length scale comparable with the mean free path. We stress however that these properties have been studied here only in the context of a bulk system, and in the next sections, we will see that the relation between surface scattering and mean free paths, while correct within the SMA, doesn't hold exactly.

Fig. 5 Analysis of phonon and relaxon mean free paths and their contributions to the thermal conductivity of graphene at room temperature. The relaxon mean free paths in silicon are a couple of orders of magnitude smaller than the values predicted by SMA phonon mean free paths. In graphene, the distribution of phonon and relaxon mean free paths are rather different, with the peak contribution from relaxon mean free paths at values of $10\,\mu$, larger than typical phonon mean free paths. This quantity estimates the distance that heat flux can propagate inside the material before dissipation. (Picture from Cepellotti and Marzari 2016)


6 Matthiessen Rule

In its original form, the Matthiessen rule states that the total resistivity ($\frac{1}{k}$) arising from two separate scattering mechanisms can be obtained as the sum of the resistivity of the two separate mechanisms, that is:

$$\frac{1}{k} = \frac{1}{k_1} + \frac{1}{k_2} \ . \tag{25}$$

The rule comes handy as it allows to separate the contribution to thermal conductivity from different scattering sources. However, it has long been known that the Matthiessen rule is only an approximation, the correct expression being (see Ziman (2001) and Cepellotti and Marzari (2016) for proofs):

$$\frac{1}{k} \leq \frac{1}{k_1} + \frac{1}{k_2} \ . \tag{26}$$

The historical relevance of this rule was much more important a few decades ago, when it was not unusual to approximate the whole scattering matrix with a single scalar quantity (the single relaxation time approximation, a further simplification of the single-mode relaxation time approximation). In the limit of the scattering matrix being approximated with a single scalar, the Matthiessen rule becomes exact. Nowadays the single relaxation time approximation sees less usage in numerical simulations but is nevertheless often used to obtain estimates (e.g., in experiments).

It is interesting to test, as shown in Fig. 6, the extent of the violation of the Matthiessen rule. In particular, we compare the exact conductivity with results in which we selectively turned off normal, Umklapp, or isotopic scattering events and add them separately with the Matthiessen rule. As granted by Eq. 26, the exact thermal conductivity is always smaller than all other curves. In most cases, the Matthiessen rule overestimates the total thermal conductivity of the system. The only case where the Matthiessen estimate gets closer to the exact result is when a kind of scattering event can be neglected. For example, the conductivity obtained splitting the isotopic from the three-phonon interactions ($k^{-1} = (k^{N+U})^{-1} + (k^I)^{-1}$) gets close to the exact answer only at large temperature when the isotopic scattering is negligible and $(k^I)^{-1} \approx 0$.

A common extension of the Matthiessen rule found in literature is the property:

$$\frac{1}{\tau_\mu^{\text{SMA}}} = \frac{1}{\tau_\mu^{\text{SMA}-1}} + \frac{1}{\tau_\mu^{\text{SMA}-2}} \ . \tag{27}$$

This equation reflects how the total phonon relaxation time of the system can be found as the inverse summation of different scattering mechanisms. Therefore, one can clearly distinguish the contribution to the phonon relaxation time coming from, say, three-phonon scattering and isotopic scattering events. This property derives from the fact that different scattering events are treated as independent processes (correlations are neglected); therefore the scattering rates can be summed in the scattering matrix. In the SMA limit, this relation holds exactly and allows for a clear-cut separation of contribution to thermal conductivity from different sources of scattering.

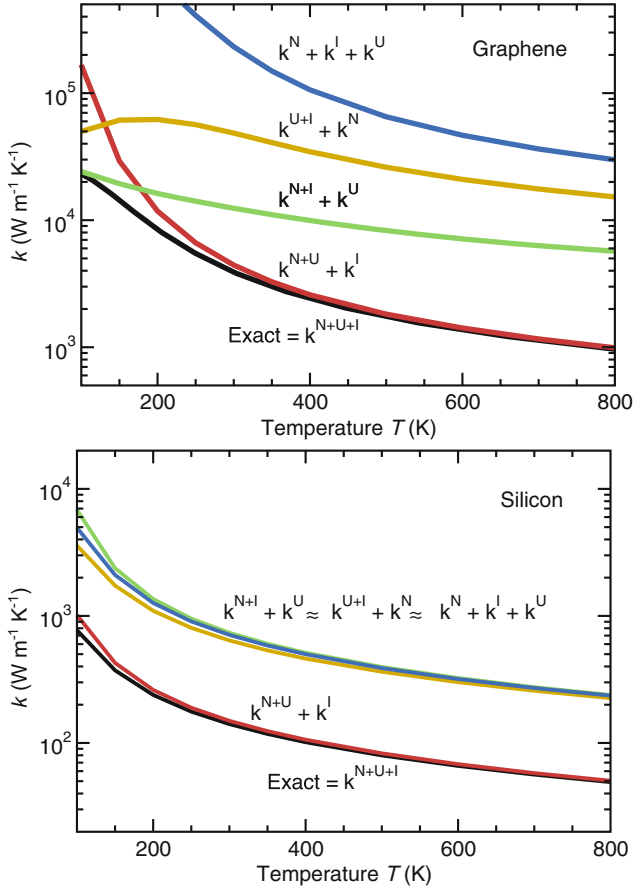
When dealing with exact relaxation times of the system, also this generalized Matthiessen rule doesn't hold anymore. In fact, the eigenvalues of the sum of two


Fig. 6 Study of the failure of Matthiessen rule in graphene and silicon. The total thermal conductivity (black line) is compared to conductivities computed through various Matthiessen sums, where the total sum is given by the sum of the reciprocals (by $k^N + k^U + k^I$ we mean $k^{-1} = (k^N)^{-1} + (k^U)^{-1} + (k^I)^{-1}$). Due to the correlation between scattering events, there is no decomposition for which the Matthiessen rule is obeyed at all temperatures. The only curve that approaches the exact thermal conductivity is the decomposition $(k^{N+U} + k^I)$, just when the effect of isotopic scattering is negligible

matrices are not equal to the sum of the eigenvalues of the two separate matrices (except in the SMA limit where the matrix is diagonal). Therefore, the exact solution of the LBTE doesn't have a case where the Matthiessen rule can be applied rigorously. As a result, it's not simple to define how much a single scattering process contributes to thermal conductivity, because the total thermal conductivity includes the interplay of the different scattering mechanisms. For example, the redistribution of phonon populations after, say, a normal scattering event indirectly affects the heat flux dissipation that takes place with an Umklapp or isotopic process.

From another perspective, however, Eq. 26 ensures that the inclusion of an additional scattering mechanism lowers the thermal conductivity. In fact, if we were to include the effect of four-phonon interactions, Eq. 26 guarantees that either (1) the thermal conductivity will be left unchanged if the interaction is negligible, or (2) the thermal conductivity will be smaller. Therefore, one should typically expect to overestimate the true thermal conductivity of a system.

7 Surface-Limited Conductivity

Nanostructuring a material provides an effective way to lower the thermal conductivity of a system. The most common understanding of such reduction is based on the idea that the heat carrier mean free path is limited by the size of the system (von De Haas and Biermasz 1938; Casimir 1938). In fact, one would argue naively that the heat carrier simply cannot travel over a distance that is larger than the sample size; therefore, adopting Matthiessen rule, the effective total relaxation time in a system of size L is:

$$\frac{1}{\tau^{\text{eff}}} = \frac{1}{\tau^{\text{intr}}} + \frac{v}{L} \, , \tag{28}$$

where the lifetimes may be referred to the phonon μ or the relaxon α and v is the carrier velocity along the thermal gradient. If L is much smaller than the intrinsic mean free path $v\tau^{\text{intr}}$, the thermal conductivity as given by Eqs. 12 or 24 will be linear in L and is therefore reduced. Within the SMA, one can indeed put this reasoning on solid grounds (see, e.g., Ziman 2001, Carruthers 1961, and Cepellotti and Marzari 2016) and thus agree with the intuition above. However, we will now show that the exact thermal conductivity in presence of a surface isn't explained by a relation of the form of Eq. 28. As argued in Cepellotti and Marzari (2017a), the impact of surfaces on thermal conductivity should be interpreted instead hydrodynamically, in terms of a viscous effect.

We note also that the majority of recent studies trying to describe surface-limited thermal conductivity with exact solvers of the LBTE (e.g., Li et al. 2014, Fugallo et al. 2013, 2014, and Omini and Sparavigna 1996) mix their results with concepts relying on the SMA. In particular, the following expression, that we will refer to as the Surf-RTA, has been used to model surface scattering:

$$\boldsymbol{v}_\mu \cdot \nabla T \frac{\partial \bar{n}_\mu}{\partial T} = -\frac{1}{\mathscr{V}} \sum_{\mu'} \left(\Omega_{\mu\mu'} + \frac{v_\mu}{L} \delta_{\mu\mu'} \right) \Delta n_{\mu'}(\boldsymbol{r}, t) \, . \tag{29}$$

Here, the BTE looks like a bulk problem but with a correction on the diagonal matrix elements. Note that the correction $\frac{v_\mu}{L}\delta_{\mu\mu'}$ also appears in various declinations, such as $\frac{|v_\mu|}{L}\delta_{\mu\mu'}$ or $\frac{v_\mu}{FL}\delta_{\mu\mu'}$. In any case, this expression is empirically justified by noting that (1) the diagonal matrix elements of the scattering matrix are phonon

lifetimes, (2) the SMA theory of surface scattering rigorously proves that the phonon relaxation time must be corrected with a factor $\frac{v_\mu}{L}$, and hence (3) an exact treatment of surface scattering should be achieved by adding the term $\frac{v_\mu}{L}\delta_{\mu\mu'}$. Unfortunately, the justification of this approach is only by analogy; we will see below that the results obtained from Eq. 29 strongly deviate from an exact description of surface scattering.

The main challenge for describing this phenomenon is that, in contrast with intrinsic events such as phonon-phonon interactions, the reflection/absorption of a phonon only takes place at the sample's surfaces. As argued by Ziman (2001) (who reports a few unsuccessful attempts of adding space-dependent scattering terms), one cannot describe this by adding a space-dependent term to the scattering matrix. Instead, the correct way to describe surface scattering (Ziman 2001; Carruthers 1961) is to solve the LBTE as a differential equation: after the integration on the spatial degrees of freedom, the integration constant is fixed by suitable boundary conditions. The following study is nothing but a generalization of the derivation of Eq. 28 made within the SMA by Carruther (1961) to the case beyond the SMA; the mathematical derivation is similar, but the analysis of the results differs notably.

We can start the derivation (Cepellotti and Marzari 2017a) from the LBTE in the relaxon basis (Eq. 22). Limiting the study to the steady state and a constant gradient of temperature, time derivatives are neglected and the LBTE becomes:

$$\sqrt{\frac{C}{k_B T^2}}\nabla T \cdot \boldsymbol{V}_\alpha + \sum_{\alpha'} \boldsymbol{V}_{\alpha\alpha'} \cdot \nabla f_{\alpha'}(\boldsymbol{r}) = -\frac{f_\alpha(\boldsymbol{r})}{\tau_\alpha} \ . \tag{30}$$

In contrast to the bulk problem, the periodicity of the lattice is broken by the surface, so that the relaxon population retains the dependence on spatial coordinates. The resulting LBTE is a set of coupled linear differential equations (rather than the linear algebra problem for the bulk). In general, it is hard to impose the boundary conditions for a material of a generic shape, and methods like finite-elements may be more suitable. Here, instead, we focus on a simple geometry that allows for a simple analytical solution and that illustrates the qualitative aspects of surface scattering treated exactly. In particular, we will focus on an infinitely long ribbon of graphene of width L. Cartesian coordinates are chosen such that x spans the length of the system and y the width, such that the surfaces are located on the lines $y = \pm\frac{L}{2}$. Finally, the temperature gradient is along the ribbon's length, so that the LBTE reduces to:

$$\sqrt{\frac{C}{k_B T^2}}V_\alpha^{(x)}\nabla T + \sum_{\alpha'} V_{\alpha\alpha'}^{(y)}\frac{\partial f_{\alpha'}(y)}{\partial y} = -\frac{f_\alpha(y)}{\tau_\alpha} \ . \tag{31}$$

To make progress, we multiply the LBTE by τ_α, to note that the derivative term has a factor $\tau_\alpha V_{\alpha\alpha'}$, which identifies an asymmetric matrix. To recast the problem

in a symmetrized form, we transform the relaxon populations as $f_\alpha = g_\alpha \sqrt{\tau_\alpha}$. The LBTE becomes:

$$\sum_{\alpha'} \Lambda_{\alpha\alpha'}^{(y)} \frac{\partial g_{\alpha'}}{\partial y} + g_\alpha = g_\alpha^\infty \tag{32}$$

where $\Lambda_{\alpha\alpha'}^{(y)} = \sqrt{\tau_\alpha} V_{\alpha\alpha'}^{(y)} \sqrt{\tau_{\alpha'}}$ and $g_\alpha^\infty = -\sqrt{\frac{C\tau_\alpha}{k_B T^2}} V_\alpha^{(x)} \nabla T$ is the solution of the bulk problem (save for a factor $\sqrt{\tau}_\alpha$, it's identical to Eq. 23). The matrix $\Lambda_{\alpha\alpha'}$ is symmetric (recall the definition $V_{\alpha\alpha'} = \frac{1}{\mathcal{V}} \sum_\mu \theta_\mu^\alpha v_\mu \theta_\mu^{\alpha'}$) and real, so that we can diagonalize it and write:

$$\sum_{\alpha'} \Lambda_{\alpha\alpha'}^{(y)} \psi_{\alpha' i} = \lambda_i^{(y)} \psi_{\alpha i} , \tag{33}$$

finding the eigenvalues $\lambda_i^{(y)}$ and the eigenvectors $\psi_{\alpha i}$ of the matrix $\Lambda_{\alpha\alpha'}^{(y)}$. Unlike the eigenvalues of the scattering matrix, the eigenvalues $\lambda_y^{(y)}$ can have any sign; in fact, note that the eigenvalues of $V_{\alpha\alpha'}$ are simply the phonon group velocities v_μ, which also can have any sign. In the numerical example we tested, we find a symmetry in the eigenvalue spectrum, such that both $\lambda_i^{(y)}$ and $-\lambda_i^{(y)}$ are eigenvalues. Since the eigenfunctions $\psi_{\alpha i}$ form a complete basis set, we can rotate the LBTE in this new basis and express the scaled relaxon populations g_α as a linear combination of the eigenvectors $\psi_{\alpha i}$:

$$g_\alpha = \sum_i \psi_{\alpha i} d_i , \tag{34}$$

with d_i a set of real coefficients. Like we did for relaxons, we interpret the eigenvectors $\psi_{\alpha i}$ as another kind of collective excitation and d_i as a population number. After a few algebraic manipulations, the LBTE can be rotated in this new basis, to find:

$$\lambda_i^{(y)} \frac{\partial d_i}{\partial y} + d_i = d_i^\infty , \tag{35}$$

with d_i^∞ such that $g_\alpha^\infty = \sum_\alpha \psi_{\alpha i} d_i^\infty$. Eventually, the LBTE has been recast into a simple form, using a new degree of freedom identified by the eigenvectors $\psi_{\alpha i}$ that decouple all terms and bring the LBTE to a diagonal form.

Since $\lambda_i^{(y)}$ is any real number, there are three classes of solutions. The simplest case is $\lambda_i^{(y)} = 0$, when the population d_i is identical to that of the bulk system. This suggests the interpretation that the mode $\psi_{\alpha i}$ is traveling parallel to the surface: as it never scatters against the surface, the ribbon will appear as a bulk to this mode. In the other two cases, when $\lambda_i^{(y)} > 0$ or < 0, the excitation $\psi_{\alpha i}$ scatters against

the surface and its population deviates from bulk as $d_i = d_i^{\infty} + c_i e^{-y/\lambda_i^{(y)}}$, where c_i is an integration constant to be determined from boundary conditions. To fix c_i, we must know the population d_i at one point.

Let's suppose that $\lambda_i^{(y)} > 0$: the mode $\psi_{\alpha i}$ is moving in the positive y-direction, suggesting that we should fix the boundary condition at the surface $y = -\frac{L}{2}$ where it last scattered. Ziman (2001) discusses a similar problem within the SMA and justifies his choice with arguments of causality, arguing that the phonon population must be determined only by events in the past. Moreover, there's also a more practical necessity: to fix the boundary condition on the opposite surface may cause an exponential divergence. In general, the boundary condition will look like $d_i(y = -\frac{L}{2}) = \delta_i$, so that the solution becomes:

$$d_i = d_i^{\infty} + (\delta_i - d_i^{\infty})e^{-(y+\frac{L}{2})/\lambda_i^{(y)}} . \tag{36}$$

The case of opposite sign $\lambda_i^{(y)} < 0$ is similar (but opposite) and leads to the expression:

$$d_i = d_i^{\infty} + (\delta_i - d_i^{\infty})e^{-(y-\frac{L}{2})/\lambda_i^{(y)}} . \tag{37}$$

Therefore, we formally obtained the solution of the LBTE, resorting to an additional change of basis set, which allowed us to find an analytical solution of the LBTE in a 2D ribbon. There exists collective excitations $\psi_{\alpha i}$ that travel parallel to the surface and behave as bulk, as well as modes that scatter against the border, and thermalize to the bulk limit after they traveled away from the surface for a characteristic distance $\lambda_i^{(y)}$.

We have however introduced an additional parameter δ_i that doesn't come from the LBTE itself. Ziman (2001), when discussing surface scattering within the SMA, proposed to associate this boundary condition with the phonon reflectivity at the boundary. In fact, one can construct a matrix $\mathscr{R}_{\mu}^{\mu'}$ describing how a phonon μ can be reflected into μ' after the impact on the surface. In principle, this matrix can describe any kind of surface scattering: for example, $\mathscr{R} = 0$ describes a perfectly absorbing surface, $\mathscr{R} = \text{constant}$ describes a diffusive phonon scattering, and specular scattering is identified by suitably selecting the angles between μ and μ'. Such reflection coefficients can be computed from microscopic models, such as molecular dynamics. However, the information on these quantities is scarce in the literature, and therefore, in order to avoid further complexity, we drastically simplify the discussion and make the simplest assumption possible, known as the Casimir limit: the surface is perfectly absorbing and therefore $\mathscr{R} = 0$ for any mode. To relate this coefficient with the boundary condition, Ziman wrote a balance equation so that the number of phonons leaving a surface is equal to the number of reflected phonons. Applying this same idea to the modes $\psi_{\alpha i}$, we first rotate the matrix of the phonon reflection coefficients in the basis of modes $\psi_{\alpha i}$ as $\mathscr{R}_i^j = \sum_{\mu\mu'\alpha\beta} \psi_{\alpha i} \theta_{\mu}^{\alpha} \mathscr{R}_{\mu}^{\mu'} \theta_{\mu'}^{\beta} \psi_{\beta i}$. Then, the balance equation is:

$$\delta_i = d_i\left(y = -\frac{W}{2}\right)\Bigg|_{\lambda_i^{(y)} > 0} = \sum_j \mathscr{R}_i^j d_j\left(y = -\frac{W}{2}\right)\Bigg|_{\lambda_j^{(y)} < 0}, \tag{38}$$

expressing the boundary condition in terms of microscopic quantities. In the Casimir limit, we simply have $\delta_i = 0$.

The thermal conductivity is obtained, as for the bulk case, as a by-product of the LBTE once the solution is known. In particular, the xx component of the thermal conductivity tensor is obtained by rotating Eq. 21 in the basis of modes $\psi_{\alpha i}$:

$$k(y) = -\frac{Q}{\nabla T} = \frac{-1}{\mathscr{V}\nabla T}\sum_\mu \hbar\omega_\mu v_\mu \Delta n_\mu = -\sum_\alpha f_\alpha(y)\sqrt{k_B T^2 C}\, V_\alpha^{(x)}$$

$$= -\sum_\alpha g_\alpha(y)\sqrt{\tau_\alpha k_B T^2 C}\, V_\alpha^{(x)}$$

$$= \sum_\alpha C V_\alpha^{(x)} \Lambda_\alpha^{(x)} - k_B T^2 \sum_{\alpha\beta}(\delta_\alpha - g_\alpha^\infty)\left(\sum_{\lambda_i^{(y)} > 0}\psi_{\alpha i}\, e^{-\frac{y+\frac{W}{2}}{\lambda_i^{(y)}}}\,\psi_{i\beta}^T + \right.$$

$$\left. \sum_{\lambda_i^{(y)} < 0}\psi_{\alpha i}\, e^{-\frac{y-\frac{W}{2}}{\lambda_i^{(y)}}}\,\psi_{i\beta}^T\right)(\delta_\beta - g_\beta^\infty) = k^\infty - \Delta k^{\text{surf}}(y), \tag{39}$$

where $\psi_{i\beta}^T$ is the matrix transpose of $\psi_{\beta i}$ and $\delta_\alpha = \sum_\alpha \psi_{\alpha i}\delta_i$. Hence we found the thermal conductivity of a 2D ribbon, consisting of a bulk contribution and a surface term, the latter decreasing thermal conductivity (as well as heat flux) by an amount that depends on the position inside the sample. The space dependency appears through a series of exponential factors: the largest suppression happens close to the surfaces and then relaxes to the bulk value when leaving the surface. In particular, there are two series of exponentials, each describing the suppression of thermal conductivity by one of the two ribbon surfaces. At large enough distance from both surfaces – that is, further than all the characteristic lengths $\lambda_\alpha^{(y)}$ – surface scattering becomes negligible, and the thermal conductivity approaches its bulk value.

First, we note that the length scale at which nanostructuring is effective in decreasing heat flux is given by the lengths $\lambda_\alpha^{(y)}$. In fact, if the ribbon is smaller than any of these characteristic lengths, there will be some non-negligible exponentials, and thus the thermal conductivity is suppressed. Otherwise, the surface scattering will decrease heat flux only on a small layer close to the surface, and the average conductivity will be as in the bulk.

This behavior of heat flux is reminiscent of the motion of fluids through a pipe in the laminar regime. Also for real fluids, the mass flux slows down in proximity of the surface and grows going further away from the surface. In that case, the underlying quantity for the suppression of mass flux is the liquid viscosity. Thus, we

suggest to interpret the eigenvalues $\lambda_i^{(y)}$ as *friction lengths* and the surface effects as a hydrodynamic slowdown of the heat flux by friction at the borders.

We can now note that Eq. 39 doesn't describe the reduction of thermal conductivity by surface scattering as a renormalization of the relaxation times or mean free paths, as predicted instead by the SMA (see Eq. 28). While relaxon mean free paths Λ_α describe the characteristic length of the decay of heat flux along the direction of the thermal gradient by action of intrinsic scattering events, the surface defines a decay of heat flux with respect to the position of the surface. Moreover, while the former case describes an exponential decay of the collective excitation θ_μ^α, the surface causes an exponential decay of the modes $\psi_{\alpha i}$. Due to the presence of a rotation between the two basis sets, it's not possible to interpret surface scattering by a simple rescaling of the relaxon mean free path. As a result, the interpretation of surface scattering based on the SMA doesn't apply anymore; by chance, the SMA allows to describe the problem as a renormalization of the mean free path, but this is only possible when the scattering matrix is diagonal and the correlation between phonons can be neglected (in fact, only the phonon basis is needed, and one doesn't have to introduce θ_μ^α or $\psi_{\alpha i}$). The interpretation of surface scattering in terms of friction instead encompasses both the full LBTE and the SMA limit, where in the latter, case friction lengths accidentally coincide with the phonon mean free paths.

We note in passing that the analogy of the heat flow with the Poiseuille flow of a real liquid is a tool to illustrate the case study but lacks a true one-to-one correspondence. Besides the obvious differences such as mass/heat and pressure/temperature, we note that the Poiseuille description is made on a single degree of freedom, the liquid density, whereas the LBTE has more microscopic information, given that it describes the population number of N phonons. Moreover, the underlying Navier-Stokes equations are quite different from the LBTE, so that even the detailed behavior of the profile of flux as a function of the distance from the surface is quantitatively different (a polynomial decay vs an exponential series). Therefore, one should think at the similarity with real fluid exclusively as a tool to gain some intuition on heat flux.

Before moving on to an example, we also argue against a limitation of this model of surface scattering. The LBTE written in Eq. 30 assumes that lattice properties such as force constants and anharmonic couplings do not change over the extent of the crystal. This assumption isn't correct for the first few layers of atoms at a surface, since the surface introduces new effects such as local relaxations, steps, defects, and oxidations that will modify surface lattice properties. To obtain a better description of these effects, which may be non-negligible for ribbon widths at the nano-scale, one should treat the system as a one-dimensional problem, compute force constants over the entire section of the ribbon, and study the details of surface phonons (e.g., using the insertion method Bungaro et al. 1996). This approach however can only be done for sufficiently small widths, due to computational constraints; if the ribbon is large and if the modification of the lattice properties is small compared to the bulk, then the model presented above might be preferable.

7.1 Examples

We will now apply the model of surface scattering to a ribbon of graphene. The computational parameters are the same used for the previous example on the bulk thermal conductivity of graphene; in addition, if not specified otherwise, we fix the ribbon width at $2\,\mu$m and the temperature at 300 K. We note that there is a remaining degree of freedom, consisting in the orientation of the surface with respect to the crystal lattice vectors. This choice doesn't modify the results for the bulk, because the symmetry of graphene guarantees that the bulk thermal conductivity tensor is isotropic. In the presence of a surface, and in particular for small sizes, some symmetries are broken, and one may expect anisotropies. Here, we will not investigate these effects any further and fix the x coordinate to be along the zig-zig direction of graphene, focusing instead on the qualitative aspects of the model.

In Fig. 7, we plot the average contribution of mode i to Δk^{surf}, i.e., the quantity

$$k_B T^2 \sum_{\alpha\beta} g_\alpha^\infty \psi_{\alpha i} \psi_{i\beta}^T g_\beta^\infty \frac{1}{W} \int e^{-(y \pm \frac{W}{2})/\lambda_i^{(y)}}\, dy \;,$$

as a function of the friction lengths $\lambda_\alpha^{(y)}$. In detail, we plot the contribution of mode i in percentage w.r.t. to the bulk conductivity, in order to compare with the percentage
Fig. 7 Friction lengths (see text for definition) on the horizontal axis in a graphene ribbon and their average contribution to thermal conductivity reduction (vertical axis) in a system of size $2\,\mu$m. All friction length contribute to a nonnegative reduction of the bulk conductivity (i.e., all values in the graph are positive). Friction lengths, determining the length scale at which the surfaces perturb the heat flux, are contrasted with the relaxon mean free paths, which describe the length scale at which heat flux is dissipated. Since the largest friction length is about $10\,\mu$m, one can expect nanostructuring in graphene to be effective at characteristic length scales of $10\,\mu$m or below

contribution to bulk thermal conductivity from relaxon α (red dots in Fig. 7 coincide with those in Fig. 5). Because friction lengths can have any sign and since we found a symmetry such that both $\lambda_\alpha^{(y)}$ and $-\lambda_\alpha^{(y)}$ are eigenvalues of $\Lambda_{\alpha\beta}$, we only plot the positive part of the spectrum of friction lengths.

The largest friction length is at $10\,\mu m$ approximately, indicating that the reduction of thermal conductivity happens within a distance of $10\,\mu m$ from the surface. A ribbon larger than $10\,\mu m$ may well be approximated by its bulk counterpart, neglecting the contribution from the surface layers. As a result, the spectrum of eigenvalues $\lambda_i^{(y)}$, and its largest eigenvalue in particular, provides at a glance the characteristic size at which nanostructuring is effective at reducing thermal conductivity. By contrasting the friction lengths with relaxon mean free paths, we intend to underline how the two quantities are not related. Not only is their physical meaning different – decay distance of heat flux along the thermal gradient vs the decay distance of heat flux from the surface – but also the distribution of these two quantities differs and does not need to coincide.

This similarity with the Poiseuille flow is best observed in Fig. 8, by looking at the profile of thermal conductivity along the ribbon section. The thermal conductivity of the ribbon (of width $2\,\mu m$ at $300\,K$) never quite reaches the bulk values, reported in figure for comparison. This is expected from the previous analysis of Fig. 7, since there are friction lengths between 2 and $10\,\mu m$ capable of disrupting heat flux. Thermal conductivity reaches a maximum at the ribbon center, the furthest distance from surfaces, with values about 10% smaller than the bulk value. Thermal conductivity (and thus heat flux) gets smaller when approaching the surfaces, similarly to the slowing of the mass flux of a real fluid in proximity of a wall, with most of the change happening within half a micron from the surface. We note how the minimum value of thermal conductivity at the surfaces is different from zero. In fact, Casimir's boundary condition – a perfectly absorbing surface – doesn't actually coincide with a nonslip condition: this is another departure from

Fig. 8 Profile of thermal conductivity along a section of a graphene ribbon (blue line) compared with the bulk conductivity (dashed red line). In a sample of finite size, thermal conductivity is not an intrinsic property of the material but depends on the sample shape and on the distance from the surface. Thermal conductivity reaches a maximum at the center of the ribbon (the furthest distance from surfaces) and decreases to a non-zero minimum at the surfaces
the hydrodynamics of the Navier-Stokes equations. The perfect absorption only guarantees that there won't be modes $\psi_{\alpha i}$ traveling away (rightward in the plot) from the surface at $y = -1\,\mu m$ (and vice versa for the opposite surface). This doesn't prevent modes $\psi_{\alpha i}$ traveling toward (leftward in the plot) the surface at $y = -1\,\mu m$ to conduct heat in proximity of that surface. Therefore, the model allows for a non-zero thermal conductivity at the surface; the nonslip condition can only be applied to a subset of modes $\psi_{\alpha i}$. Finally, we remark that the residual value of conductivity at the surface strongly depends on the boundary condition chosen. The case of the perfectly absorbing surface used here represents the case with the strongest reduction from the bulk value; a softer boundary condition that allows for reflection will instead increase thermal conductivity. In fact, the limiting case of a perfect mirror should leave the thermal conductivity equal to the bulk values at all points inside the ribbon.

It should be noted how thermal conductivity is not an intrinsic property of the material. Extrinsic properties now determine its value: here we have seen how the distance from the surface modifies the actual value of thermal conductivity; we have also shown in Cepellotti and Marzari (2017a) how a different shape (in that case, a trench) can also modify results, and we noted how even the orientation of crystal axis with respect to the surface affects the results and how the microscopic details of the surface modify the reflection of modes at the surface. Nevertheless, it is convenient to tag a nanostructure with an average thermal conductivity $\bar{k} = \frac{1}{W} \int k(y)\,dy$. This quantity is a good descriptor of the amount of heat flux that can travel through the ribbon at that specific size W; however, we are not allowed to use this in a different structure and cannot be used rigorously as a parameter entering heat diffusion equations. In fact, the thermal conductivity appearing in diffusion equations is an intrinsic constant property of the material and should not depend on extrinsic properties such as position. For small nanostructures therefore the correct approach is to avoid diffusion equations and use instead a microscopic model such as the LBTE.

In Fig. 9, we report the average thermal conductivity $\bar{k}$ as a function of the ribbon width at room temperature. We also contrast the results of this model with the Surf-RTA, i.e., the (incorrect) model of surface scattering where the scattering matrix is modified by adding a term $\frac{|v_{\mu}^{(y)}|}{L}\delta_{\mu\mu'}$ (similarly to Eq. 29). Results are unsurprising on the far right and far left of the graph: for small widths, thermal conductivity goes to zero, and for large widths the bulk value is recovered. The large difference appears in the region where the transition from the two limits takes place. For example, results from the two models differ by about 1000 W/mK in the range 0.1–10 μm, at length scales that are relevant for current experimental applications. Also, the Surf-RTA reaches the bulk value at a much slower rate than the exact solution. This has led a few – including us – to conclude that nanostructuring in graphene is relevant up to the millimeter length scale (or more) (Fugallo et al. 2014; Kuang et al. 2016); this result is more of an artifact of the model used. We remark that here we do not compare with experiments intentionally, the primary reason being that the geometry used here doesn't correspond to those of published experiments, i.e., Corbino disks (Balandin et al. 2008) or ribbons of comparable length and width (Xu et al. 2014).
Fig. 9 Average thermal conductivity of a graphene ribbon at room temperature as a function of the ribbon width. The results of the present model (solid lines) are compared with the Surf-RTA results (dotted lines): although the qualitative behavior is similar, the two theories give widely different results. In particular, the Surf-RTA overestimates the impact of nanostructuring on the thermal conductivity
Fig. 10 Average thermal conductivity $\bar{k}$ of a graphene ribbon (width $2\,\mu m$) as a function of temperature. For comparison, the red curve shows the conductivity of an infinite sheet and the dashed blue line shows the values obtained with the approximated Surf-RTA description of surface scattering. The model discussed here gives large improvements over the Surf-RTA, in particular at low temperatures where the surface gives the dominant contribution to thermal conductivity and the estimates are revised by an order of magnitude

Finally, we fix the width at $2\,\mu m$ and show in Fig. 10 how thermal conductivity varies as a function of temperature, comparing differences between the bulk conductivity, the ribbon, and the Surf-RTA conductivities. The bulk conductivity displays two distinct regimes: above $100\,K$ the thermal conductivity is driven by three-phonon interactions that give approximately a $1/T$ decrease of thermal conductivity (Ziman 2001). At lower temperatures, the bulk conductivity is dominated by phonon-isotope scatterings. The introduction of a surface causes a decrease of

thermal conductivity, especially in the low temperature regime, and one would expect the temperature dependence at low temperature to scale as T^3, i.e., the temperature dependence of the specific heat (Ziman 2001; Carruthers 1961). At high temperatures, friction lengths become smaller, and so the thermal conductivity of the ribbon approaches the bulk limit. Although also in this case results from the present model of surface scattering and the Surf-RTA are qualitatively similar, the differences are in the magnitude of the conductivity. In particular, the two estimates differ by an order of magnitude at low temperature, where surface scattering is dominant. Even at large temperatures, we can see how the Surf-RTA never achieves bulk values and systematically underestimates thermal conductivity, whereas the friction model quickly reaches the bulk values around room temperature. As a technical note, temperatures below 10 K have not been shown because of the difficulty in converging results which require a very dense sampling of the Brillouin zone.

To conclude, we note that the regime between 10 and 100 K isn't exactly a ballistic regime. A ballistic regime requires thermal conductivity to be completely determined by surface scattering: one can approximate the scattering matrix to zero, reduce the LBTE to the diffusion operator and compute the resulting thermal conductivity for the system of finite size. Here, as noted in Cepellotti et al. (2015) and Lee et al. (2015), the regime is not ballistic but of the Poiseuille kind. This means that, although surfaces reduce thermal conductivity, the existence of intrinsic scattering events cannot be neglected. In fact, and very notably, the thermal conductivity of the ribbon of graphene in presence of a surface is larger than the ballistic estimate and highlights how scattering between phonons can enhance the heat flux with respect to a system of noninteracting phonons.

8 Dispersion Relations for Relaxons and Second Sound

The derivation of relaxons given in Sect. 4 doesn't make it obvious whether relaxons are a mathematical tool to solve the LBTE or whether they can also lead to actual excitations of the crystal. Much of this question still needs to be answered, given the early stage of research on the topic. However, we will now show that we can define a dispersion relation for collective phonon excitations starting from the LBTE, as derived in Cepellotti and Marzari (2017b). We will see that relaxons, as introduced in Sect. 4, are the long-wavelength limit of these collective phonon excitations present in the LBTE. We will also see that such excitations are closely related with oscillations of energy and of temperature in a crystal, which sometimes has been experimentally observed as second sound.

To derive the dispersion relations, we must start again from the LBTE in the phonon basis (Eq. 7). We now limit the discussion to a system at thermal equilibrium, so that the temperature of the material is constant and equal to $T(\boldsymbol{r}, t) = T$. With this simplification, the LBTE reduces to:

$$\frac{\partial \Delta n_\mu(\mathbf{x}, t)}{\partial t} + \mathbf{v}_\mu \cdot \nabla(\Delta n_\mu(\mathbf{x}, t)) = -\frac{1}{\mathscr{V}} \sum_{\mu'} \Omega_{\mu\mu'} \Delta n_{\mu'}(\mathbf{x}, t) . \tag{40}$$

While in Sect. 4 we focused exclusively on the entities that are left invariant by the action of the scattering operator, we now seek to consider solutions that are stationary to the whole LBTE. In particular, we look for collective excitations in the form of a plane wave of phonon population numbers:

$$\Delta n_\mu(\mathbf{r}, t) = \text{Re}\left(I_\mu e^{i(\mathbf{k}\cdot\mathbf{r} - \omega t)}\right) , \tag{41}$$

where I_μ is the amplitude of the wave on mode μ, $\mathbf{k}$ is the wavevector, and ω is the frequency of such excitation (note the difference between ω and the phonon frequency ω_μ). To fix the value of the frequency and wavevector, we must substitute this ansatz in the LBTE – equivalent to taking the Laplace transform of the LBTE – obtaining:

$$-i\omega I_\mu + i I_\mu \mathbf{k} \cdot \mathbf{v}_\mu + \frac{1}{\mathscr{V}} \sum_{\mu'} \Omega_{\mu\mu'} I_{\mu'} = 0 . \tag{42}$$

Rearranging terms, we can cast Eq. 42 as an eigenvalue problem:

$$\sum_{\mu'} B_{\mu\mu'}(\mathbf{k}) I_{\mu'}^\alpha(\mathbf{k}) = \omega_\alpha(\mathbf{k}) I_\mu^\alpha(\mathbf{k}) , \tag{43}$$

where

$$B_{\mu\mu'} = \mathbf{k} \cdot \mathbf{v}_\mu \delta_{\mu\mu'} - \frac{i}{\mathscr{V}} \Omega_{\mu\mu'} , \tag{44}$$

with α a newly introduced eigenvalue index. For each wavevector $\mathbf{k}$, this equation identifies an eigenvalue problem that determines the allowed frequencies. In other terms, the Fourier transform of the LBTE fixes the dispersion relation of the collective phonon excitations.

To understand the connection with the relaxons introduced previously, we consider the long-wavelength limit $\mathbf{k} = 0$. In this case, the B matrix reduces (besides a phase factor) to the scattering matrix, and the equation becomes almost equivalent to the relaxon eigenvalue equation introduced in Eq. 16. The last difference to be fixed is to recast the problem in terms of symmetric matrices. To do so, we take the transformations of Eqs. 14 and 15: I and B transform like Δn and Ω, respectively, and re-express Eqs. 40, 41, 42, 43, and 44 in terms of symmetrized quantities. All quantities from now on refers to the symmetrized ones.

Looking at the mathematical aspects of the problem, the matrix B is symmetric, complex, and non-Hermitian; only in the long-wavelength limit the matrix is Hermitian. There is therefore a key difference with respect to the relaxon problem.

Here, the eigenvalues are a complex quantity and can be written as:

$$\omega_\alpha(\boldsymbol{k}) = \overline{\omega}_\alpha(\boldsymbol{k}) - \frac{i}{\tau_\alpha(\boldsymbol{k})} \ . \tag{45}$$

The real part $\overline{\omega}_\alpha(\boldsymbol{k})$ is the oscillation frequency of the collective excitation, and the imaginary part is the decay time $\tau_\alpha(\boldsymbol{k})$. This interpretation becomes apparent after rewriting the solution in terms of waves of phonon populations:

$$\Delta n_\mu^\alpha(\boldsymbol{k}) = |I_\mu^\alpha(\boldsymbol{k})| e^{-t/\tau_\alpha(\boldsymbol{k})} \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \overline{\omega}_\alpha(\boldsymbol{k})t + \phi) \ . \tag{46}$$

where ϕ is a phase.

It's easy to see that each of these solutions causes an oscillation of energy (i.e., heat). Note in fact that the energy of the crystal E is changed by an oscillation Δn_μ by an amount ΔE such that:

$$E(\boldsymbol{x}, t) = \frac{1}{\mathscr{V}} \sum_\mu \left(\bar{n}_\mu + \frac{1}{2}\right) \hbar\omega_\mu + \frac{1}{\mathscr{V}} \sum_\mu \Delta n_\mu(\boldsymbol{x}, t) \hbar\omega_\mu = E_0 + \Delta E(\boldsymbol{x}, t) \ ,$$

where E_0 is the energy at thermal equilibrium. Since changes of energy and temperature are related by the specific heat with $\delta E = C\delta T$, it follows that a damped wave of Δn_μ causes a damped wave of temperature. The emergence of temperature waves in a crystal is also known as second sound, with the relation $\omega(\boldsymbol{k})$ being its dispersion relation. Improving over earlier theoretical works (Guyer and Krumhansl 1964; Chester 1963; Hardy 1970; Enz 1968), this model gives an infinite number of second sound modes (in the thermodynamic limit) where at most three had been found, the full dispersion relation (often neglected), without approximations of the LBTE (in particular, avoiding the SMA).

We noted a number of properties in our numerical examples that lack an analytic proof. In particular, the stability of the solution requires $\tau_\alpha(\boldsymbol{k}) > 0$; otherwise the time evolution will cause a divergence in the phonon population number. We also found the symmetry $\overline{\omega}_\alpha(\boldsymbol{k}) - \frac{i}{\tau_\alpha(\boldsymbol{k})} = -\overline{\omega}_\alpha(-\boldsymbol{k}) - \frac{i}{\tau_\alpha(-\boldsymbol{k})}$. The non-Hermitian character of B implies that there is a distinction between left and right eigenvectors, which complicates both proofs and the calculation of group velocities for the collective excitation, since the Feynman theorem doesn't apply anymore.

Returning to the relaxon problem studied before, this can be understood as a special case where the eigenvalues are purely a decay time, with zero oscillation frequency and zero wavevector: it is for this reason that no dispersion relation appeared in the previous discussion. Now, by looking at a more general eigenvalue problem, we constructed a set of collective excitations that encompasses relaxons, as defined before, and all other forms of wavelike excitations of the system. Given the connection between collective phonon excitations and changes of temperature, it is now more intuitive to understand why the long-wavelength limit is the most convenient for the previous study of bulk conductivity. Excitations at finite

momentum determine a change in temperature of wavelike form that are more suitable to describe nonuniform temperature perturbations; in the limit of long-wavelengths, they become a constant gradient, which is the same temperature perturbation that was used in the previous sections.

8.1   Dispersion Relations in Graphene

We still use graphene to make a numerical example of the dispersion relation introduced above (Cepellotti and Marzari 2017b). Despite keeping the same computational parameters of the previous examples (same force constants, same number of k-points, etc.), the diagonalization of the non-Hermitian matrix is much more expensive than the diagonalization of a real and symmetric matrix. Nevertheless, current computational resources are powerful enough to diagonalize the B matrix along the high-symmetry lines of graphene. However, the computational costs prevented us to conduct, for the time being, a thorough convergence study of the spectrum, unlike the simpler case of the diagonalization of the scattering matrix. Therefore, the exact value of oscillating frequencies and decay times may not be well converged with respect to q-point sampling and the broadening of the energy-conserving Dirac delta function, but this shouldn't qualitatively alter the following analysis.

In Fig. 11, we plot the decay time versus the oscillation frequency for a few wavevectors along the line $\Gamma \rightarrow M$ in the Brillouin zone, computed at a temperature
Fig. 11 Eigenvalues $\omega = \bar{\omega} - \frac{i}{\tau}$ of graphene as a function of the oscillation frequency $\bar{\omega}$ (horizontal axis) and the relaxation time τ (vertical axis); colors identify different k-points in the Brillouin zone lying between Γ and the edge M. The allowed oscillation frequencies and decay times are both bounded. The change of wavevector affects more significantly the oscillation frequency: in the limit of $k = 0$, all frequencies must vanish, and the range of allowed frequencies is approximately linear in the wavevector. (Figure from Cepellotti and Marzari 2017b)

of 300 K. The first thing to note is that each wavevector identifies N collective excitations (N being equal to the number of phonon modes of the system), and therefore there is much more information to be analyzed than before.

As discussed above, the eigenvalues of B at $\boldsymbol{k} = \Gamma$ are characterized by a zero oscillation frequency and are pure decay times: this limit reproduces the eigenvalues of relaxons introduced in Sect. 4. The oscillation frequency is approximately linear in the wavevector $\boldsymbol{k}$ and tends to grow as the distance from Γ is increased. This result suggests that in Eq. 44, the contribution to B from scattering can be considered as a perturbation with respect to the diffusive term. Last, the frequency of oscillation can be comparable, at finite wavevectors, with the frequency of phonons. At the M point, these can be as large as $1100 \, \text{cm}^{-1}$, which compares with the largest frequency of phonons (about $1600 \, \text{cm}^{-1}$). The absolute value of the oscillating frequency of transport waves (at most $1100 \, \text{cm}^{-1}$) is comparable with the oscillation frequency of phonons, which range from 0 to $1600 \, \text{cm}^{-1}$. It must be noted however that results of this model at small wavevectors should not be trusted: the semiclassical approximation used to derive the LBTE requires a temperature perturbation to be slowly varying with respect to the interatomic distances. When the wavelength of the collective excitation is comparable to the lattice parameter (i.e., $q \approx M$), the semiclassical approximation fails and the predictions based on the LBTE may not be valid. Nevertheless, the semiclassical approximation holds for $q \to 0$, and results are reliable at large wavelengths.

The decay times of collective excitations span a range of values between a few picoseconds up to about 10^5 ps. This range of values is similar to that of phonon lifetimes which, as also analyzed in Fig. 4, mostly takes place at the range of values between 10 and 100 ps. Similarly, the largest portion of collective excitations have decay times in this region between 10 and 100 ps, which forms almost a continuum of points. There are however a few eigenvalues with extremely long decay times, which are reminiscent of the discrete part of spectrum of relaxation times discussed for graphene in Sect. 4. We also note that there are no relaxation times smaller than a few picoseconds; In fact, the smallest transition rates found in the scattering matrix for this example are of a few picoseconds; it is therefore impossible for collective phonon excitations to decay faster than these lower bounds.

In Fig. 12 we plot the eigenvalue spectrum along a high-symmetry path of the Brillouin zone. Since, at a fixed frequency, more than one eigenvalue may exist, the color code is used to map the largest relaxation time found at a certain wavevector and frequency. From this picture, we observe that the largest relaxation time is approximately linear with the modulus of the wavevector $\boldsymbol{k}$, that the wave frequency is comparable with the phonon frequency, and that the frequency can be well described by a linear dispersion. The waves with the largest decay times are primarily found in the small frequency region, with high frequencies being also characterized by a faster decay. The steplike features in the colored areas are numerical artifacts, due to the fact that only 25 wavevectors are computed along the high-symmetry path.

Since it has been put forward that second sound may exist in graphene (Cepellotti et al. 2015; Lee et al. 2015), it is reasonable to speculate that the longest-lived
Fig. 12 Continuum spectrum of dispersion relations for temperature waves in graphene at room temperature (shades of green); the red line marks the largest value for the allowed oscillation frequency, and all frequencies lying below are valid solutions. Phonon dispersions at zero temperature are also plotted (black lines). The different shades of green indicate the decay times of the temperature waves, showing how such modes can be longer lived, especially in the low-frequency region

modes will be the most likely candidates for experimental observation. If in fact a perturbation may excite collective excitations at a certain frequency or wavevector, it is likely that a continuum of collective excitations will be perturbed: therefore it may not be simple to observe a well-defined temperature wave. After a certain amount of time from the perturbation, the only surviving modes are those with the longest relaxation times, and it would be possible to recover a wavelike behavior of temperature. We stress however that at the present time, there is still no reported experimental observation of second sound in graphene.

9   Conclusions

In this chapter, we studied extensively the LBTE; while this is done in the context of heat transport, most or all of these concepts could find application to other quantities: electrons, spins, or other quasiparticles. The single-mode relaxation time approximation has been discussed, noting that it fails at describing the correct dynamics of energy fluxes, and in particular it doesn't guarantee energy conservation. A correct description can be achieved by solving the LBTE without approximations to the scattering operator. Thanks to computational advances, it is now possible to construct direct solutions of the LBTE. To this aim, we introduced relaxons, defined as the eigenvectors of the scattering matrix and that collective

phonon excitations are characterized by well-defined relaxation times. The exact bulk thermal conductivity can be expressed exactly in terms of a kinetic gas theory, but the relevant gas of excitations are the relaxons, not the phonons; in this sense, relaxons are the correct heat carriers in a crystal.

The direct approach to solving the LBTE also allows us to improve the description of surface scattering. Whereas conventional explanations interpret the presence of a surface as a way to limit the distance traveled by the heat carrier, the exact solution of the LBTE indicates that the surface slows down the heat flux hydrodynamically. In particular, friction at the materials' borders slows down heat flux to a minimum, and the bulk limit is recovered as the distance from the surface is increased. Heat flux is found to depend on the distance from the surface, in the form of a series of exponentials, with well-defined friction lengths that characterize the length scale at which nanostructuring is an effective tool to disrupt thermal conductivity.

Eventually, we have shown how it is possible to construct a dispersion relation of collective phonon excitations, such that each mode is characterized by a wavevector, a frequency, and a decay time. The long-wavelength, zero-frequency limit of such modes is found to coincide with the definition of relaxons. We find that the excitation of these collective excitations induces a wavelike change of temperature profile in the material, which suggests a link with the theory of second sound.

The theoretical modeling has been supported with first-principles simulations of the LBTE, illustrating how the revised theory can change the time, length, and velocity scale of thermal transport, discussed here for two prototypical materials such as silicon and graphene.

Before concluding, we stress that all the results reported here hold within the validity of the LBTE, limited in particular by the semiclassical approximation. There exist a number of cases where one should expect this hypothesis to fail. For example, the LBTE only holds for small perturbations out of equilibrium, but this may not necessarily be respected in presence of strong temperature differences. Moreover, we should not expect this approximation to hold in conditions where the phonon spectral function have features so broad that one cannot identify a phonon wavepacket of well-defined energy. Under all circumstances such that the semiclassical approximation doesn't hold, none of our conclusions hold rigorously, because our starting point, the LBTE, is not justified. Whether our conclusions hold beyond the semiclassical approximations remains to be understood and constitutes an exciting outlook for further studies. Despite this criticism, we believe that the semiclassical approximation has still great relevance in today's simulations, as proved by the excellent agreement between experimental results and first-principles LBTE studies and the insights that can give to our understanding on the physics of thermal transport.

Abstract

The Green-Kubo theory of thermal transport has long been considered incompatible with modern simulation methods based on electronic-structure theory, because it is based on such concepts as energy density and current, which are ill-defined at the quantum-mechanical level. Besides, experience with classical simulations indicates that the estimate of heat-transport coefficients requires analyzing molecular trajectories that are more than one order of magnitude longer than deemed feasible using ab initio molecular dynamics. In this paper we report on recent theoretical advances that are allowing one to overcome these two obstacles. First, a general gauge invariance principle has been established, stating that thermal conductivity is insensitive to many details of the microscopic expression for the energy density and current from which it is derived, thus permitting to establish a rigorous expression for the energy flux from Density-Functional Theory, from which the conductivity can be computed in practice. Second, a novel data analysis method based on the statistical theory of time series has been proposed, which allows one to considerably reduce the simulation time required to achieve a target accuracy on the computed conductivity. These concepts are illustrated in detail, starting from a pedagogical introduction to the Green-Kubo theory of linear response and transport, and demonstrated with a few applications done with both classical and quantum-mechanical simulation methods.

1   Introduction

Heat conduction in insulators is determined by the dynamics of the atomic nuclei, the electrons following adiabatically in their ground state: a regime that we will refer to as atomic or *adiabatic heat transport*. When a quasiparticle picture of the heat carriers (phonons) is adequate, a kinetic approach to heat conduction based on the Boltzmann transport equation (Peierls 1929) has been demonstrated (Broido et al. 2007) and successfully applied to crystalline insulators (Zhou et al. 2016), leveraging phonon frequencies and lifetimes from density-functional perturbation theory (Baroni et al. 1987, 2001; Giannozzi et al. 1991; Debernardi et al. 1995). As the temperature increases, anharmonic effects eventually make the quasiparticle picture break down well below melting (Turney et al. 2009), while the Boltzmann transport equation simply does not apply to glasses and liquids, where phonon dispersions are not even defined.

The simulation of thermal transport in glasses, liquids, and high-temperature crystalline solids thus requires the full deployment of the statistical mechanics of hydrodynamic fluctuations (Kadanoff and Martin 1963), started in the 1930s by Lars Onsager (1931a; 1931b) and culminated in the 1950s with the Green-Kubo (GK) theory of linear response (Green 1952, 1954; Kubo 1957; Kubo et al. 1957). According to this theory, the thermal conductivity, κ, can be expressed in terms of time correlations of the heat current, J, as:

$$\kappa \propto \int_0^\infty \langle J(t) J(0) \rangle \, dt, \tag{1}$$

where the brackets indicate ensemble averages over trajectories, which are accessible in principle to molecular dynamics (MD) simulations. In spite of the beauty, rigor, and broad scope of the GK theory, its adoption in the ab initio simulation of heat transport has stumbled at two seemingly insurmountable hurdles: first and foremost, the heat current entering Eq. (1) is ill-defined at the atomic scale, thus allegedly thwarting its implementation from first principles; second but not less important, experience in classical simulations, where a definition of the heat current is readily available in terms of suitably defined atomic energies (Irving and Kirkwood 1950), indicates that taming its statistical fluctuations requires so long MD simulations, as to be unaffordable using ab initio (AI) MD (Car and Parrinello 1985; Marx and Hutter 2009). As a matter of fact, no AIMD simulations of adiabatic heat transport based on GK theory have appeared until the spurious nature of these hurdles was recently revealed by Marcolongo et al. (2016) and Ercole et al. (2016, 2017).

The first difficulty was overcome by revealing a general *gauge invariance* principle for thermal transport, stemming from the hydrodynamic nature of energy fluctuations (see below), which makes transport coefficients independent of the microscopic expression of the energy density and current that are to a large extent ill-defined (Marcolongo et al. 2016; Ercole et al. 2016). Building on this principle, an expression for the energy current was derived from density-functional theory (Hohenberg and Kohn 1964; Kohn and Sham 1965), which allows simulating heat transport within the GK formalism, using equilibrium AIMD. The second difficulty was addressed using advanced statistical methods for the spectral analysis of stationary time series, which provide an asymptotically unbiased and consistent estimate of the power spectrum of the energy current, meaning that both the bias and the statistical error of the estimated conductivity can be made arbitrarily and controllably small in the limit of long simulation time (Ercole et al. 2017). The combination of these theoretical and methodological innovations makes the ab initio simulation of heat transport feasible in principle and affordable in practice. In this chapter, we review the efforts that have led to these achievements, starting with a brief review of the relevant theoretical concepts and illustrate them with relevant benchmarks and an application to a realistic model of liquid water.

2   Green-Kubo Theory of Heat Transport

2.1   Hydrodynamic Variables

The macroscopic processes occurring in condensed matter are often described in terms of *extensive variables*. By definition, the value that such a variable assumes for a system is the sum of the values it has for each of its subsystems. This property allows one to express an extensive variable, A, as the integral of a suitably defined density, $a(\mathbf{r})$, as:

$$A[\Omega] = \int_{\Omega} a(\mathbf{r}) d\mathbf{r}, \tag{2}$$

where Ω is the system volume. Here and in the following boldfaces indicate 3D vectors and Greek subscripts label Cartesian components: $\mathbf{u} = \{u_\alpha\} = \{u_1, u_2, u_3\}$. When an extensive quantity is locally conserved, a current density, $\boldsymbol{j}(\mathbf{r}, t)$, can be associated with its density in such a way that the two of them satisfy the continuity equation:

$$\frac{\partial a(\mathbf{r}, t)}{\partial t} = -\nabla \cdot \boldsymbol{j}(\mathbf{r}, t), \tag{3}$$

where $\nabla \cdot \boldsymbol{j}$ indicates partial differentiation and the middle dot a scalar product (a divergence in this case). In the following, the densities and current densities of conserved quantities will be called *conserved densities* and *conserved currents* for short. The space Fourier transform of Eq. (3) reads:

$$\dot{\tilde{a}}(\mathbf{q}, t) = -i\mathbf{q} \cdot \tilde{\boldsymbol{j}}(\mathbf{q}, t), \tag{4}$$

where the overdot indicates a time derivative and the tilde a Fourier transform, so that the longer the wavelength, the slower is the dynamics of a conserved density. We conclude that for long-enough wavelengths, conserved densities are adiabatically decoupled from all the other (zillions of) fast atomic degrees of freedom. Note that in this chapter, we are using the concept of *adiabatic decoupling* in two distinct senses, depending on the context, to indicate the decoupling of electronic from nuclear degrees of freedom and that of hydrodynamic variables from fast atomic ones.

The long-wavelength Fourier components of conserved densities are called *hydrodynamic variables*. In macroscopically homogeneous systems, different wavelengths are decoupled from each other, while, as we have seen, the long wavelengths are adiabatically decoupled from all the other degrees of freedom. Let us suppose there are Q conserved extensive variables. In the case of a mono-atomic fluid, for instance, $Q = 5$, corresponding to mass (or particle number), energy, and the three components of the momentum. In order to simplify the notation, we set the value of the conserved quantities equal to zero, $A^i = 0$, so that their densities, $a^i(\mathbf{r})$, directly refer to the departure from equilibrium, and we indicate by $\boldsymbol{j}^i(\mathbf{r}, t)$ the corresponding currents. At equilibrium, all the conserved densities and currents vanish. Off equilibrium, it will be assumed that the wavelength and the time scale of the disturbances are so long that thermal equilibrium still holds *locally*. That is to say, a local temperature, pressure, and chemical potential can be defined, such that, when combined with the densities of extensive variable, they satisfy a local equation of state.

For small-enough deviations from equilibrium, the time derivatives of conserved densities are linear combinations of the densities themselves. In the frequency/wavevector domains, this condition can be expressed as

$$-i\omega \tilde{a}^i(\mathbf{q}, \omega) = \sum_j \tilde{\Lambda}^{ij}(\mathbf{q}, \omega)\tilde{a}^j(\mathbf{q}, \omega), \tag{5}$$

where the tilde indicates now a space-time Fourier transform: $\tilde{a}(\mathbf{q}, \omega) = \int e^{-i(\mathbf{q}\cdot\mathbf{r}-\omega t)} a(\mathbf{r}, t) d\mathbf{r} dt$. By combining Eq. (5) with the time Fourier transform of Eq. (4), we obtain the so-called constitutive equations for the (longitudinal components of the) conserved currents:

$$\tilde{j}^i(\mathbf{q}, \omega) = i \frac{\mathbf{q}}{q^2} \sum_j \tilde{\Lambda}^{ij}(\mathbf{q}, \omega) \tilde{a}^j(\mathbf{q}, \omega). \tag{6}$$

In isotropic media, the $\tilde{\Lambda}$s are spherically symmetric functions of $\mathbf{q}$, whereas their value at $\mathbf{q} = 0$ vanishes, because a nonvanishing value would imply a nonphysical long-range dependence of the currents on density fluctuations, in contrast with our assumption of local thermodynamic equilibrium. The long-wavelength low-frequency limit of the coupling constants can thus be assumed to be $\tilde{\Lambda}^{ij}(\mathbf{q}, \omega) \sim q^2 \lambda^{ij}$, so that the macroscopic ($\mathbf{q} = 0$) stationary ($\omega = 0$) components of the currents, $\mathbf{J}^i = \frac{1}{\Omega} \int j^i(\mathbf{r}) d\mathbf{r}$, are related to the corresponding components of the density gradients, $\mathbf{D}^i = \frac{1}{\Omega} \int \nabla a^i(\mathbf{r}) d\mathbf{r}$, through the equation:

$$\mathbf{J}^i = \sum_j \lambda^{ij} \mathbf{D}^j. \tag{7}$$

In the following, the macroscopic component of a current will be indicated as a *flux*.

Let $x^i = \frac{\partial S}{\partial A^i}$ be the intensive variable conjugate to A^i, where S is the system's entropy and $\chi^{ij} = \frac{1}{\Omega} \frac{\partial A^i}{\partial x^j}$ the corresponding susceptibility. For instance, when A^i is the energy of the system, the corresponding conjugate variable is the inverse temperature, $x^i = 1/T$, while, when A^i represents the number of particles of a given species, one has $x^i = -\mu^i/T$, μ^i being the corresponding chemical potential. The hypothesis of local thermodynamic equilibrium allows defining local values of the intensive variables, and we define *thermodynamic forces* as their average gradients: $\mathbf{F}^i = \frac{1}{\Omega} \int \nabla x^i(\mathbf{r}) d\mathbf{r}$. The average density gradients are related to the thermodynamic forces through the susceptibility defined above, as:

$$\mathbf{D}^i = \sum_j \chi^{ij} \mathbf{F}^j. \tag{8}$$

By inserting this relation into Eq. (7), one gets:

$$\mathbf{J}^i = \sum_j L^{ij} \mathbf{F}^j, \tag{9}$$

where $L^{ij} = \sum_k \lambda^{ik} \chi^{kj}$. Equation (9) expresses the linear relation between fluxes, the $\mathbf{J}$'s, and thermodynamic affinities, the $\mathbf{F}$s, for which Onsager derived his celebrated reciprocity relations ($L^{ji} = L^{ij}$) from microscopic reversibility

(Onsager 1931a, b; Casimir 1945). Note that, according to our definition, both the **J**s and the **F**s in Eq. (9) do not depend on the size of the system.

2.2   Linear-Response Theory

In order to evaluate the L^{ij} phenomenological coefficients appearing in Eq. (9), we consider a classical system of N interacting atoms described by the Hamiltonian

$$H^\circ(\Gamma) = \sum_n \frac{1}{2M_n}(\mathbf{P}_n)^2 + V(\mathbf{R}_1, \mathbf{R}_2, \cdots \mathbf{R}_N),\qquad(10)$$

where M_n, $\mathbf{R}_n$, and $\mathbf{P}_n$ are the masses, coordinates, and momenta of the n-th particle, $\Gamma = \{\mathbf{R}_n, \mathbf{P}_n\}$ indicates the phase-space coordinates of the entire system, and V is a generic many-body potential. Let us now suppose that the system is subject to an external perturbation that can be described as a linear combination of the conserved densities, $\{a^i(\mathbf{r}; \Gamma)\}$, as:

$$V'(\Gamma, t) = \sum_i \int v^i(\mathbf{r}, t)a^i(\mathbf{r}; \Gamma)d\mathbf{r},\qquad(11)$$

where $a(\mathbf{r}; \Gamma)$ is a phase-space function whose ensemble average is the conserved density:

$$\begin{aligned} a(\mathbf{r}) &= \langle a(\mathbf{r}; \Gamma)\rangle \\ &= \int a(\mathbf{r}; \Gamma)\mathcal{P}^\circ(\Gamma)d\Gamma, \end{aligned}\qquad(12)$$

$\mathcal{P}^\circ(\Gamma) \propto e^{-\frac{H^\circ(\Gamma)}{k_B T}}$ is the equilibrium distribution, k_B the Boltzmann constant, and $\{v^i(\mathbf{r}, t)\}$ are time-dependent fields that couple to the conserved densities and vanish at $t = -\infty$, when the system is assumed to be in thermal equilibrium at some temperature T. Of course, conserved currents are also expected values of some phase-space functions, $\mathbf{j}(\mathbf{r}) = \langle \mathbf{j}(\mathbf{r}; \Gamma)\rangle$. The phase-space functions whose expected values are conserved densities/currents will be referred to as *phase-space samples* of the currents/densities. In the following, when the phase-space dependence of a conserved density/current is explicitly indicated, we will mean a phase-space sample; when it is not, a phase-space average will be implied. When a phase-space sample is evaluated along a dynamical trajectory, Γ_t, the sample function will depend on time and on the initial conditions of the trajectory. Averaging with respect to the initial conditions will result in a time-dependent expected value for the conserved densities (or currents):

$$\begin{aligned} a(\mathbf{r}, t) &= \langle a(\mathbf{r}; \Gamma'_t)\rangle_0 \\ &= \int a(\mathbf{r}; \Gamma'_t)\mathcal{P}^\circ(\Gamma_0)d\Gamma_0. \end{aligned}\qquad(13)$$

In Eq. (13), the notation Γ'_t denotes somewhat pedantically that the time evolution in phase space is driven by the perturbed Hamiltonian, $H° + V'$. If it were driven by $H°$, evidently the value of a would be time-independent. In the following, the notation Γ_t will indicate an unperturbed time evolution. As an example, the phase-space sample of the particle density can be assumed to be $n(\mathbf{r}; \Gamma) = \sum_n \delta(\mathbf{r} - \mathbf{R}_n)$, the corresponding current is $\mathbf{j}(\mathbf{r}, \Gamma) = \sum_n \delta(\mathbf{r} - \mathbf{R}_n)\mathbf{P}_n/M_n$, and a local external potential is described by $V'(\Gamma, t) = \sum_n v(\mathbf{R}_n, t) = \int v'(\mathbf{r}, t)n(\mathbf{r}; \Gamma)d\mathbf{r}$. Note that sample functions are not necessarily univocally defined. Different functions whose phase-space averages coincide in the long-wavelength limit sample the same hydrodynamical variable. More on this in Sect. 3.

According to Green (1954), Kubo (1957), and Kubo et al. (1957), the linear response of the i-th conserved current to the perturbation is:

$$j^i_\alpha(\mathbf{r}, t) = \frac{1}{k_B T} \sum_j \int_{-\infty}^t dt' \int d\mathbf{r}' \left\langle j^i_\alpha(\mathbf{r}, \Gamma_t)\dot{a}^j(\mathbf{r}', \Gamma_{t'})\right\rangle_0 v^j(\mathbf{r}', t'), \tag{14}$$

$$= \frac{-1}{k_B T} \sum_{j,\beta} \int_{-\infty}^t dt' \int d\mathbf{r}' \left\langle j^i_\alpha(\mathbf{r}, \Gamma_t)\partial'_\beta j^j_\beta(\mathbf{r}', \Gamma_{t'})\right\rangle_0 v^j(\mathbf{r}', t') \tag{15}$$

$$= \frac{1}{k_B T} \sum_{j,\beta} \int_{-\infty}^t dt' \int d\mathbf{r}' \left\langle j^i_\alpha(\mathbf{r}, \Gamma_t) j^j_\beta(\mathbf{r}', \Gamma_{t'})\right\rangle_0 \partial'_\beta v^j(\mathbf{r}', t'). \tag{16}$$

The second line follows from the first through the continuity equation, Eq. (3), while the third line follows after integrating by parts with respect to $\mathbf{r}'$. The notation $\partial'_\beta = \frac{\partial}{\partial r'_\beta}$ has been used.

By integrating Eq. (16) all over the space, and assuming space-time homogeneity as well as isotropy, one recovers Eq. (9) with:

$$J^i_\alpha(\Gamma) = \frac{1}{\Omega} \int j^i_\alpha(\mathbf{r}, \Gamma)d\mathbf{r} \tag{17}$$

$$F^i_\alpha(\Gamma) = \frac{1}{\Omega T} \int \partial_\alpha v^i(\mathbf{r}, \Gamma)d\mathbf{r} \tag{18}$$

$$L^{ij}_{\alpha\beta} = \frac{\Omega}{k_B} \int_0^\infty \left\langle J^i_\alpha(\Gamma_t) J^j_\beta(\Gamma_0)\right\rangle_0 dt. \tag{19}$$

This completes the derivation of the Green-Kubo formula for transport coefficients, Eq. (1), from classical linear-response theory. Onsager's reciprocity relations, $L^{ij} = L^{ji}$ (Onsager 1931a, b), follow from Eq. (19) leveraging time-translational invariance, $\langle J^i_\alpha(\Gamma_t)J^j_\beta(\Gamma_0)\rangle = \langle J^i_\alpha(\Gamma_0)J^j_\beta(\Gamma_{-t})\rangle$, and micro-reversibility, $\langle J^i_\alpha(\Gamma_t)J^j_\beta(\Gamma_0)\rangle = \langle J^i_\alpha(\Gamma_{-t})J^j_\beta(\Gamma_0)\rangle$.

2.2.1 Einstein-Helfand Expression for Transport Coefficients and the Wiener-Khintchine Theorem

The celebrated Einstein's relation between the mean-square displacement of a diffusing particle and its velocity autocorrelation function is easily generalized to an arbitrary stochastic process and has in fact been utilized by Helfand (1960) to provide an "Einstein-like" expression for transport coefficients.

Let X_t be a stationary stochastic process. One has:

$$\frac{1}{\mathcal{T}} \left\langle \left| \int_0^{\mathcal{T}} X_t dt \right|^2 \right\rangle = 2 \int_0^{\mathcal{T}} \langle X_t X_0 \rangle \, dt - \frac{2}{\mathcal{T}} \int_0^{\mathcal{T}} \langle X_t X_0 \rangle \, t \, dt. \tag{20}$$

In the large $\mathcal{T}$ limit, the second term on the right-hand side of Eq. (20) can be neglected.

When the stochastic process is the velocity of a Brownian particle, Eq. (20) allows one to establish a relation between the diffusion constant of the particle, temperature, and the autocorrelation time of the velocity. When X_t is the heat flux of a macroscopic body, Eq. (20) allows one to estimate the thermal conductivity, as given by Eq. (1), from the asymptotic behavior of the "energy displacement" $\mathcal{D}(\tau) = \int_0^{\tau} \mathbf{J}(\Gamma_t) dt$.

Equation (20) can be easily generalized to the finite-frequency regime, to get:

$$\begin{aligned} S_{\mathcal{T}}(\omega) &= \frac{1}{\mathcal{T}} \left\langle \left| \int_0^{\mathcal{T}} X_t e^{i\omega t} dt \right|^2 \right\rangle \\ &= 2\mathfrak{Re} \int_0^{\mathcal{T}} \langle X_t X_0 \rangle \, e^{i\omega t} dt + \mathcal{O}(\mathcal{T}^{-1}). \end{aligned} \tag{21}$$

This equation expresses the Wiener-Khintchine theorem (Wiener 1930; Khintchine 1934), which states that the expectation of the squared modulus of the Fourier transform of a stationary process is the Fourier transform of its time correlation function, which is usually referred to as the process *power spectral density*:

$$S(\omega) = \int_{-\infty}^{\infty} \langle X_t X_0 \rangle \, e^{i\omega t} dt, \tag{22}$$

aka the *power spectrum*. In the following, the subscript $\mathcal{T}$ will be neglected for simplicity and its value assumed to be sufficiently large as to be considered infinite. More generally, when several conserved currents interact with each other, one can define the *cross-spectrum* of the conserved fluxes as the Fourier transform of the cross-time correlation functions:

$$S^{kl}(\omega) = \int_{-\infty}^{\infty} \langle X_t^k X_0^l \rangle \, e^{i\omega t} dt,$$

$$= \frac{1}{\mathcal{T}} \Re\mathfrak{e} \left\langle \int_0^{\mathcal{T}} X_t^k e^{-i\omega t} dt \times \int_0^{\mathcal{T}} X_t^l e^{i\omega t} dt \right\rangle + \mathcal{O}(\mathcal{T}^{-1}) \tag{23}$$

Eqs. (20) and (21) indicate that the transport coefficients we are after essentially are the zero-frequency value of the (cross-)power spectrum of the corresponding current(s), a fact that will be instrumental in our approach to data analysis, as explained in Sect. 5. Therefore, Eq. (19) can be cast into the form:

$$L^{kl} = \frac{\Omega}{2k_B} S^{kl}(\omega = 0), \tag{24}$$

where the Cartesian indices have been omitted for clarity.

2.3 Heat Transport

The above treatment allows one to compute the linear response of a system at thermal equilibrium to a generic mechanical perturbation. Heat transport is determined by temperature gradients that cannot be described by any mechanical perturbation. The concept of temperature distribution implies that the system is locally at thermal equilibrium over lengths and times large with respect to atomic distances and relaxation times. Temperature affects the physical properties of a system through the Boltzmann distribution function. When the temperature is not constant, $T(\mathbf{r}) = T + \Delta T(\mathbf{r})$ ($|\Delta T| \ll T$), the effects of this inhomogeneity can be formally described by the distribution function:

$$\mathcal{P}(\Gamma) \propto e^{-\int \frac{e(\mathbf{r};\Gamma)}{k_B T(\mathbf{r})} d\mathbf{r}}, \tag{25}$$

$$= e^{-\frac{H^\circ(\Gamma)+V'(\Gamma)}{k_B T}}, \tag{26}$$

where $e(\mathbf{r}; \Gamma)$ is an energy (Hamiltonian) density, such that $\int e(\mathbf{r}; \Gamma) d\mathbf{r} = H^\circ(\Gamma)$. Equation (11) becomes:

$$V'(\Gamma) = -\frac{1}{T} \int \Delta T(\mathbf{r}) e(\mathbf{r}; \Gamma) d\mathbf{r} + \mathcal{O}(\Delta T^2). \tag{27}$$

Equation (27) shows that the effects of temperature inhomogeneities can be mimicked by a mechanical perturbation coupled to the temperature distribution. From Eqs. (9) and (17), (18), and (19), we conclude that in a system where the only nontrivial conserved quantity is the energy, the heat (energy) flow is coupled to temperature gradients through the constitutive equation:

$$\mathbf{J}^E = -\kappa \nabla T, \tag{28}$$

where the thermal conductivity $\kappa_{\alpha\beta} = L_{\alpha\beta}^{EE}/T^2$ (see Eq. (9)) can be expressed by a Green-Kubo relation in terms of the fluctuations of the energy flux as:

$$\kappa_{\alpha\beta} = \frac{\Omega}{k_B T^2} \int_0^\infty \left\langle J_\alpha^E(\Gamma_t) J_\beta^E(\Gamma_0) \right\rangle_0 dt, \tag{29}$$

and

$$\mathbf{J}^E(\Gamma) = \frac{1}{\Omega} \int \boldsymbol{j}^E(\mathbf{r}; \Gamma) d\mathbf{r}. \tag{30}$$

In order to obtain an explicit expression for the energy flux from a microscopic expression for the energy density, we multiply the continuity equation, Eq. (3), by $\mathbf{r}$ and integrate by parts to obtain:

$$\mathbf{J}^E(\Gamma_t) = \frac{1}{\Omega} \int \dot{e}(\mathbf{r}; \Gamma_t) \, \mathbf{r} \, d\mathbf{r} \tag{31}$$

$$= \frac{1}{\Omega} \int \left[\sum_n \left(\frac{\partial e(\mathbf{r}; \Gamma_t)}{\partial \mathbf{R}_n} \cdot \mathbf{V}_n + \frac{\partial e(\mathbf{r}; \Gamma_t)}{\partial \mathbf{P}_n} \cdot \mathbf{F}_n \right) \right] \mathbf{r} \, d\mathbf{r}, \tag{32}$$

where $\mathbf{F}_n$ is the force acting on the n-th atom and $\mathbf{V}_n = \frac{\mathbf{P}_n}{M_n}$ its velocity.

The manipulations leading from the continuity equation, Eq. (3), to Eq. (32) deserve some further comments, as they imply neglecting a boundary term, $\mathbf{J}_{\partial\Omega} = \frac{1}{\Omega} \int_{\partial\Omega} \left(\boldsymbol{j}(\mathbf{r}) \cdot \hat{\mathbf{n}} \right) \mathbf{r} \, d\mathbf{r}$ (where $\partial\Omega$ is the boundary of the integration volume and $\hat{\mathbf{n}}$ the normal to it), which in general does not vanish in the thermodynamic limit and is ill-defined in periodic boundary conditions (PBC). The correct way of addressing this problem is to work with the Taylor expansion of the space Fourier transform of the continuity equation, Eq. (4), and to perform the thermodynamic limit at finite wavelength. The leading nonvanishing term in the Taylor expansion yields Eq. (31) without any boundary term in the way.

2.3.1 Energy Flux from Classical Force Fields

When atoms interact through a classical force field, $V(\mathbf{R}_1, \mathbf{R}_2, \cdots \mathbf{R}_N)$, an energy density can be defined in terms of local atomic energies as:

$$e(\mathbf{r}, \Gamma) = \sum_n \delta(\mathbf{r} - \mathbf{R}_n) e_n(\Gamma), \tag{33}$$

$$e_n(\Gamma) = \frac{(\mathbf{P}_n)^2}{2M_n} + v_n(\{\mathbf{R}\}), \tag{34}$$

where the v_ns are a set of atomic potential energies whose sum is the total potential energy of the system, $\sum_n v_n = V$, with a short-range dependence on the coordinates of the other atoms. In the presence of long-range forces, this condition is effectively guaranteed by local charge neutrality, which we will assume throughout. By inserting Eq. (33) into Eq. (32), the energy flux can be cast into the form:

$$
\mathbf{J}^E(\Gamma) = \frac{1}{\Omega} \left[\sum_n \mathbf{V}_n e_n + \sum_n \mathbf{R}_n \left(\mathbf{F}_n \cdot \mathbf{V}_n + \sum_m \mathbf{V}_m \cdot \frac{\partial v_n}{\partial \mathbf{R}_m} \right) \right]
$$

$$
= \frac{1}{\Omega} \left[\sum_n \mathbf{V}_n e_n + \sum_{n,m} (\mathbf{R}_n - \mathbf{R}_m) \mathbf{F}_{nm} \cdot \mathbf{V}_n \right], \tag{35}
$$

where $\mathbf{F}_{nm} = -\frac{\partial v_m}{\partial \mathbf{R}_n}$ is the contribution of the m-th atom to the force acting on the n-th atom, $\sum_m \mathbf{F}_{nm} = \mathbf{F}_n$, and $\mathbf{F}_{nm} = -\mathbf{F}_{mn}$. When the interaction among atoms can be expressed in terms of two-body potentials, one has $v_m = \frac{1}{2} \sum_n v(\mathbf{R}_n - \mathbf{R}_m)$ and $\mathbf{F}_{nm} = -\frac{1}{2} \nabla_{\mathbf{R}_n} v(\mathbf{R}_n - \mathbf{R}_m)$. Here we implicitly assumed that the interaction energy is equally partitioned between atoms m and n. In Sect. 3, we shall see this is not the only possible choice, with far-reaching consequences on the theory of heat transport.

The first term on the right-hand side of Eq. (35) is often called *convective* and the second *virial*. We feel that the wording "convective" is somewhat misleading in this context, as the convective current, as well as its contribution to heat conductivity, may not vanish even in the absence of convection.

2.3.2   Multicomponent Fluids

In a multicomponent fluid, there is one conserved quantity (the particle number) per atomic species, plus the total energy and the three Cartesian components of the total momentum. The momentum densities are mass currents: the mass flux is therefore the total momentum, which vanishes in the center of mass reference frame. The transverse components of the momentum densities are decoupled from the other conserved densities (Foster 1975), while the longitudinal one can be assumed to coincide with the total momentum in the long-wavelength limit. Momentum conservation thus constrains the number of fluxes interacting with the energy flux in Eq. (9) to $Q - 1$, Q being the number of atomic species, so that the resulting dimension of the matrix of Onsager coefficients, L, is $Q \times Q$. The heat flux is defined as the non-convective component of the energy flux, i.e., the value of the latter in the absence of mass transport, that is to say when all the particle fluxes vanish. It is unfortunate, but inevitable due to common usage, that this definition of non-convective flux clashes with a different definition given above while commenting Eq. (35). By imposing this condition in Eq. (9), with $\mathbf{J}^1 \equiv \mathbf{J}^E$, and $\mathbf{J}^q$ ($q = 2, \dots Q$) being independent particle fluxes, the thermal conductivity, defined as the ratio of the heat flux over the temperature gradient, is given by:

$$\kappa = \frac{1}{T^2 \, (L^{-1})^{11}}. \tag{36}$$

This expression can be proved to be invariant under *any* non-singular linear transformation of the independent particle fluxes. For instance, in the case of a two-component liquid, energy and particle currents are coupled as in:

$$\mathbf{J}^E = L^{EE} \, \nabla \left(\frac{1}{T} \right) + L^{EQ} \, \nabla \left(\frac{\mu}{T} \right),$$

$$\mathbf{J}^Q = L^{EQ} \, \nabla \left(\frac{1}{T} \right) + L^{QQ} \, \nabla \left(\frac{\mu}{T} \right), \tag{37}$$

where $\mathbf{J}^Q$ is the particle current of one of the two species (say, the second) and μ the corresponding chemical potential (Sindzingre and Gillan 1990). By imposing that the particle current vanishes, the resulting thermal conductivity is:

$$\kappa = \frac{1}{T^2} \left(L^{EE} - \frac{(L^{EQ})^2}{L^{QQ}} \right). \tag{38}$$

3   Gauge Invariance of Heat Transport Coefficients

It is often implicitly assumed that the well-definiteness of thermal transport coefficients would stem from the uniqueness of the decomposition of the system's total energy into localized, atomic, contributions. This assumption is manifestly incorrect, as any decomposition leading to the same value for the total energy as Eq. (34) should be considered as legitimate. The difficulty of partitioning a system's energy into subsystems' contributions is illustrated in Fig. 1, which depicts a system made of two interacting subsystems. When defining the energy of each of the two subsystems, an arbitrary decision has to be made as to how the interaction energy is partitioned. In the case depicted in Fig. 1, for instance, the energy of each of the two subsystems can be defined as $\mathcal{E}(\Omega_i) = E(\Omega_i) + \frac{1}{2}(1 \pm \lambda) W_{12}$, where $E(\Omega_i)$ are the energies of the two isolated subsystems, W_{12} their interaction energy, and λ an arbitrary constant. In the thermodynamic limit, when all the subsystems' energies are much larger than the interaction between any pairs of them, the value of the λ constant is irrelevant. When it comes to defining energy densities (i.e., energies of infinitesimal portions of a system) or atomic energies, instead, the magnitude of the interaction between different subsystems is comparable to their energies, which become therefore intrinsically ill-defined.

Let us consider a mono-atomic fluid interacting through pair potentials, $v(|\mathbf{R}_n - \mathbf{R}_m|)$, and define the atomic energies as (Marcolongo 2014; Ercole et al. 2016):
Fig. 1 The energy of an isolated system is the sum of the energies of its subsystems (as defined when they are isolated as well) plus the interaction among them, W_{12}, whose magnitude scales as the area of the interface, depicted in red. When defining the energies of individual subsystems, $\mathcal{E}$, W_{12} has to be arbitrarily partitioned among them

$$e_{\gamma,n}(\Gamma) = \frac{1}{2M_n}(\mathbf{P}_n)^2 + \frac{1}{2}\sum_{m\neq n} v(|\mathbf{R}_n - \mathbf{R}_m|)(1 + \gamma_{nm}), \tag{39}$$

where $\gamma_{nm} = -\gamma_{mn}$ is *any* antisymmetric matrix. As the interatomic potential appearing in Eq. (39) is symmetric with respect to the atomic indices, it is clear that the sum of all the atomic energies does not depend on γ, thus making any choice of γ equally permissible. This trivial observation has deep consequences on the theory of thermal fluctuations and transport, because the value of the macroscopic energy flux, instead, depends explicitly on γ, thus making one fear that the resulting transport coefficients would depend on γ as well. Using the same manipulations that lead from Eqs. (33) and (34) to Eq. (35), for any choice of the γ matrix in Eq. (39), a corresponding expression for the macroscopic energy flux can be found, reading (Marcolongo 2014; Ercole et al. 2016):

$$\mathbf{J}_\gamma^E = \mathbf{J}^E + \frac{1}{2\Omega}\sum_{n,m\neq n} \gamma_{nm}\Big(v_{nm}\mathbf{V}_n + \big(\mathbf{V}_n \cdot \nabla_{\mathbf{R}_n}v_{nm}\big)(\mathbf{R}_n - \mathbf{R}_m)\Big), \tag{40}$$

where $v_{nm} = v(|\mathbf{R}_n - \mathbf{R}_m|)$.

As a specific example, Ercole et al. (2016) ran MD simulations for a Lennard-Jones monoatomic fluid described by the interatomic potential $v(r) = \epsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^6\right]$ at temperature $T = 1.86\frac{\epsilon}{k_B}$ and density $\rho = 0.925\sigma^{-3}$. In Fig. 2a, we display the resulting macroscopic energy-flux autocorrelation function corresponding to different choices of the γ matrix in Eqs. (39) and (40). Figure 2a clearly shows that the $\langle \mathbf{J}_\gamma^E(t) \cdot \mathbf{J}_\gamma^E(0)\rangle$ correlation functions dramatically depend on the γ matrices in Eqs. (39) and (40). Notwithstanding, the integrals of all these time correlation functions tend to the same limit at large integration times, as shown in Fig. 2b.

In order to get insight into this remarkable invariance property, let us inspect the difference between the generalized flux in Eq. (40) and the standard expression of Eq. (35):

$$\Delta\mathbf{J}_\gamma^E = \mathbf{J}_\gamma^E - \mathbf{J}^E = \frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{4\Omega}\sum_{n,m\neq n} \gamma_{nm}\, v(|\mathbf{R}_n - \mathbf{R}_m|)(\mathbf{R}_n - \mathbf{R}_m). \tag{41}$$
Fig. 2 (**a**) Time correlation functions of the modified macroscopic energy flux of a Lennard-Jones fluid, at the conditions described in the text, as defined in Eq. (40), for different definitions of the γ matrix. The "0" line refers to the standard definition ($\gamma = 0$), whereas the labels "1" and "2" correspond to two other (arbitrary) definitions of γ as described in Ercole et al. (2016). (**b**) Integral of the time correlation functions displayed in Fig. 2a, multiplied by the prefactor appearing in the GK relation, Eq. (29), as a function of the upper limit of integration. The barely visible shaded area surrounding each line is an indication of the error bars, as estimated by standard block analysis. Units are Lennard-Jones units ($M = \sigma = \varepsilon = 1$)

We see that the two different expressions for the macroscopic energy flux differ by a total time derivative of a bounded phase-space vector function. In the following, we show that this is a consequence of energy conservation and extensivity and a sufficient condition for the corresponding thermal conductivities to coincide.

The very possibility of defining an energy current density, from which the energy fluxes of Eqs. (35) and (40) ultimately depend, stems from energy extensivity. The considerations illustrated in Fig. 1 indicate that any two densities, $e'(\mathbf{r}, t)$ and $e(\mathbf{r}, t)$, whose integrals over a macroscopic volume differ by a quantity that scales as the volume boundary, should be considered as equivalent. This equivalence can be expressed by the condition that two equivalent densities differ by the divergence of a (bounded) vector field:

$$e'(\mathbf{r}, t) = e(\mathbf{r}, t) - \nabla \cdot \boldsymbol{p}(\mathbf{r}, t). \tag{42}$$

In a sense, two equivalent energy densities can be thought of as different *gauges* of the same scalar field. Energy is also conserved: because of this, for any given gauge of the energy density, $e(\mathbf{r}, t)$, an energy current density can be defined, $\boldsymbol{j}(\mathbf{r}, t)$, so as to satisfy the continuity equation, Eq. (3). By combining Eqs. (42) and (3), we see that energy current densities and macroscopic fluxes transform under a gauge transformation as:

$$\boldsymbol{j}'(\mathbf{r}, t) = \boldsymbol{j}(\mathbf{r}, t) + \dot{\boldsymbol{p}}(\mathbf{r}, t), \tag{43}$$

$$\mathbf{J}'(t) = \mathbf{J}(t) + \dot{\mathbf{P}}(t), \tag{44}$$

where $\mathbf{P}(t) = \frac{1}{\Omega} \int \boldsymbol{p}(\mathbf{r}, t) d\mathbf{r}$. We conclude that the macroscopic energy fluxes in two different energy gauges differ by the total time derivative of a bounded phase-space vector function.

We now show that the energy fluxes of the same system in two different energy gauges, e and e', differing by a bounded total time derivative, as in Eq. (44), result in the same heat conductivity, as given by the Green-Kubo formula, Eq. (29). More generally, the Onsager coefficients coupling two fluxes, $\mathbf{J}^1$ and $\mathbf{J}^2$, do not depend on the gauge of either one of them. In fact, let $(\mathbf{J}^1)' = \mathbf{J}^1 + \dot{\mathbf{P}}$; one has:

$$
\begin{aligned}
\left(L^{11}\right)' &= \frac{\Omega}{2k_B} \int_{-\infty}^{+\infty} \left\langle \left(\mathbf{J}^1(t) + \dot{\mathbf{P}}(t)\right) \cdot \left(\mathbf{J}^1(0) + \dot{\mathbf{P}}(0)\right) \right\rangle dt \\
&= L^{11} + \frac{\Omega}{2k_B} \left[\left\langle \mathbf{P}(t) \cdot \dot{\mathbf{P}}(0) \right\rangle \Big|_{-\infty}^{+\infty} + 2 \left\langle \mathbf{P}(t) \cdot \mathbf{J}^1(0) \right\rangle \Big|_{-\infty}^{+\infty} \right].
\end{aligned}
\tag{45}
$$

The expectation of the time-lagged products in Eq. (45) is equal to the products of two expectations at large time lag. As the equilibrium expectations of both a total time derivative and a current vanish, we conclude that $(L^{11})' = L^{11}$. A slight generalization of this argument, also using microscopic reversibility as in Onsager (1931a, b), allows us to conclude that $(L^{12})' = L^{12}$ and that, in general, $\kappa' = \kappa$.

3.1 Molecular Fluids

In a one-component molecular fluid such as liquid water or, say, ethanol, there are in general Q fluxes interacting with each other through Onsagers' Eq. (9), where Q is the number of atomic species in a molecule. The requirement that atoms are bound in molecules of fixed composition, however, sets a number of constraints that substantially simplify the treatment of heat transport, making the molecular case similar to the one-component one.

Let us consider a molecule of chemical formula $A_{N_A} B_{N_B} \cdots$, where $A, B, \cdots$ indicate atomic species and $N_A, N_B, \cdots$ the corresponding atomic stoichiometric indices. For each atomic species, we define the normalized number flux as:

$$\mathbf{J}^X = \frac{1}{N_X} \sum_{n \in X} \mathbf{V}_n. \tag{46}$$

If we indicate by M_X the atomic mass of species X, momentum conservation requires that $\sum_X M_X N_X \mathbf{J}^X = 0$ in the center-of-mass reference frame. The flux $\mathbf{J}^{XY} = \mathbf{J}^X - \mathbf{J}^Y$ is the total time derivative of a bounded vector, because its integral is the sum over all the molecules of the difference between the average atomic positions of either species within a same molecule, which is obviously bounded if molecules do not dissociate. As any number flux $\mathbf{J}^X$ can be expressed as a linear combination of the total momentum and of several $\mathbf{J}^{XY}$ fluxes, each of them is the total time derivative of a bounded vector. Therefore, the Onsager coefficient coupling any of these atomic fluxes with any other, or with the energy flux, vanishes. We conclude that energy is the only conserved quantity relevant for heat transport in a molecular fluid and that the energy-flux autocorrelation function directly yields the thermal conductivity, as in Eq. (1).

4   Density-Functional Theory of Adiabatic Heat Transport

Quantum simulation methods based on density-functional theory (DFT) have long been thought to be incompatible with the GK theory of thermal transport *because in first-principles calculations, it is impossible to uniquely decompose the total energy into individual contributions from each atom* (Stackhouse et al. 2010). For this reason, ab initio simulations of heat transport have often been performed using non-equilibrium approaches.

Stackhouse et al. (2010), for instance, computed the thermal conductivity of periclase MgO using a method devised by Müller-Plathe (1997). In this approach, a net heat flux, rather than a temperature gradient, is imposed to the simulated system, and the thermal conductivity is evaluated as the ratio between the heat flux and the resulting temperature gradient.

In the so-called *approach to equilibrium* methodology of Lampin et al. (2013), the system is first prepared in an out-of-equilibrium state characterized by an inhomogeneous temperature distribution, and the thermal conductivity is evaluated from the time it takes for the system to relax to equilibrium. This technique has been combined with AIMD to simulate thermal transport in a GeTe$_4$ glass by Bouzid et al. (2017) and further generalized and applied to crystalline and nanostructured MgO by Puligheddu et al. (2017).

Recently, there have been several attempts to combine the GK approach to heat transport with ab initio techniques based on electronic-structure theory, by adopting some ad hoc definitions for the energy flux. Kang and Wang (2017), for

instance, derived an expression for the energy flux from a (rather arbitrary) quantum-mechanical definition of the atomic energies and used a modified MD integration algorithm to cope with the difficulties ensuing from the implementation of their expression in PBC. Carbogno et al. (2017) gave a different expression for the energy flux, based on a normal-mode decomposition of the atomic coordinates and forces, which, while allowing to reduce the effects of thermal fluctuations, can only be applied to crystalline solids.

In spite of the undoubted ingenuity of these proposals, the problem still remains as of how it is possible that a rather arbitrary definition of the heat flux results in an allegedly well-defined value for the thermal conductivity. The gauge-invariance principle introduced in Sect. 3 not only provides a solution to this conundrum, but it also gives a rigorous way of deriving an expression for the energy flux directly from DFT, without introducing any ad hoc ingredients.

In order to derive such an expression for the adiabatic energy flux, we start with the standard DFT expression of the total energy in terms of the Kohn-Sham (KS) eigenvalues ε_v, eigenfunctions $\phi_v(\mathbf{r})$, and density $n(\mathbf{r}) = \sum_v |\phi_v(\mathbf{r})|^2$ (Martin 2008):

$$E_{DFT} = \frac{1}{2}\sum_n M_n V_n^2 + \frac{e^2}{2}\sum_{n,m\neq n}\frac{Z_n Z_m}{|\mathbf{R}_n - \mathbf{R}_m|}$$

$$+ \sum_v \varepsilon_v - \frac{e^2}{2}\int \frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}d\mathbf{r}d\mathbf{r}' + \int (\epsilon_{XC}[n](\mathbf{r}) - \mu_{XC}[n](\mathbf{r}))\,n(\mathbf{r})d\mathbf{r}, \qquad (47)$$

where e is the electron charge; $\epsilon_{XC}[n](\mathbf{r})$ is a local exchange-correlation (XC) energy per particle defined by the relation $\int \epsilon_{XC}[n](\mathbf{r})n(\mathbf{r})d\mathbf{r} = E_{XC}[n]$, the latter being the total XC energy of the system; and $\mu_{XC}(\mathbf{r}) = \frac{\delta E_{XC}}{\delta n(\mathbf{r})}$ is the XC potential. The DFT total energy can be readily written as the integral of a DFT energy density (Chetty and Martin 1992):

$$E_{DFT} = \int e_{DFT}(\mathbf{r})d\mathbf{r},$$

$$e_{DFT}(\mathbf{r}) = e_{el}(\mathbf{r}) + e_Z(\mathbf{r}), \qquad (48)$$

where:

$$e_{el}(\mathbf{r}) = \mathfrak{Re}\sum_v \phi_v^*(\mathbf{r})\big(H_{KS}\phi_n(\mathbf{r})\big)$$

$$- \frac{1}{2}n(\mathbf{r})v_H(\mathbf{r}) + (\epsilon_{XC}(\mathbf{r}) - \mu_{XC}(\mathbf{r}))\,n(\mathbf{r}), \qquad (49)$$

$$e_Z(\mathbf{r}) = \sum_n \delta(\mathbf{r} - \mathbf{R}_n)\left(\frac{1}{2}M_n V_n^2 + w_n\right), \qquad (50)$$

$$w_n = \frac{e^2}{2} \sum_{m \neq n} \frac{Z_n Z_m}{|\mathbf{R}_n - \mathbf{R}_m|}, \tag{51}$$

H_{KS} is the instantaneous self-consistent Kohn-Sham Hamiltonian and $v_H = e^2 \int d\mathbf{r}' \frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}$ is the Hartree potential. An explicit expression for the DFT energy flux is obtained by computing the first moment of the time derivative of the energy density, Eqs. (48), (49), (50), and (51), as indicated in Eq. (31), resulting in a number of terms, some of which are either infinite or ill-defined in PBC. Casting the result in a regular, boundary-insensitive, expression requires a careful breakup and refactoring of the various harmful terms, as explained by Marcolongo (2014) and in the online version of Marcolongo et al. (2016). The final result reads:

$$\mathbf{J}_{DFT}^E = \mathbf{J}^H + \mathbf{J}^Z + \mathbf{J}^0 + \mathbf{J}^{KS} + \mathbf{J}^{XC}, \tag{52}$$

$$\mathbf{J}^H = \frac{1}{4\pi \Omega e^2} \int \nabla v_H(\mathbf{r}) \dot{v}_H(\mathbf{r}) d\mathbf{r}, \tag{53}$$

$$\mathbf{J}^Z = \frac{1}{\Omega} \sum_n \left[\mathbf{V}_n \left(\frac{1}{2} M_n V_n^2 + w_n \right) + \sum_{m \neq n} (\mathbf{R}_n - \mathbf{R}_m) \left(\mathbf{V}_m \cdot \frac{\partial w_n}{\partial \mathbf{R}_m} \right) \right], \tag{54}$$

$$\mathbf{J}^0 = \frac{1}{\Omega} \sum_n \sum_v \left\langle \phi_v \left| (\mathbf{r} - \mathbf{R}_n) \left(\mathbf{V}_n \cdot \frac{\partial \hat{v}_0}{\partial \mathbf{R}_n} \right) \right| \phi_v \right\rangle, \tag{55}$$

$$\mathbf{J}^{KS} = \frac{1}{\Omega} \mathfrak{Re} \sum_v \langle \bar{\boldsymbol{\phi}}_v^c | H_{KS} + \varepsilon_v | \dot{\phi}_v^c \rangle, \tag{56}$$

$$J_\alpha^{XC} = \begin{cases} 0 & \text{(LDA)} \\ -\frac{1}{\Omega} \int n(\mathbf{r}) \dot{n}(\mathbf{r}) \frac{\partial \epsilon^{GGA}(\mathbf{r})}{\partial (\partial_\alpha n)} d\mathbf{r} & \text{(GGA)}, \end{cases} \tag{57}$$

where $\hat{v}_0$ is the bare, possibly nonlocal, (pseudo-)potential acting on the electrons and:

$$|\bar{\boldsymbol{\phi}}_v^c\rangle = \hat{P}_c \, \mathbf{r} \, |\phi_v\rangle, \tag{58}$$

$$|\dot{\phi}_v^c\rangle = \hat{\dot{P}}_v \, |\phi_v\rangle, \tag{59}$$

are the projections over the empty-state manifold of the action of the position operator over the v-th occupied orbital, Eq. (58), and of its adiabatic time derivative (Giannozzi et al. 2017), Eq. (59), $\hat{P}_v$ and $\hat{P}_c = 1 - \hat{P}_v$ being the projector operators over the occupied- and empty-states manifolds, respectively. Both these functions are well defined in PBC and can be computed, explicitly or implicitly, using standard density-functional perturbation theory (Baroni et al. 2001).

5 Data Analysis

The MD evaluation of the GK integral, Eq. (1), usually proceeds in two steps. One first evaluates the integrand as a running average of the time-lagged current products, $\langle J^i(\tau)J^j(0)\rangle \sim \frac{1}{\mathcal{T}-\tau}\int_0^{\mathcal{T}-\tau} J^i(t+\tau)J^j(t)dt$, where $\mathcal{T}$ is the length of the MD trajectory. The matrix defined in Eq. (19) is then estimated as a function of the upper limit of integration: $L^{ij}(\mathcal{T}) \propto \frac{\Omega}{k_B}\int_0^{\mathcal{T}}\langle J^i(\tau)J^j(0)\rangle\, d\tau$. One then recovers, via Eq. (36), an estimate for the thermal conductivity depending on $\mathcal{T}$: $\kappa(\mathcal{T}) \propto \frac{1}{(L^{-1}(\mathcal{T}))^{11}}$. This function is usually very noisy: in fact, at times greater than the correlation time between J^i and J^j, the correlation function $\langle J^i(\tau)J^j(0)\rangle$ approaches zero; hence $L^{ij}(\mathcal{T})$ starts integrating noise and behaves like the distance traveled by a random walk, whose variance grows linearly with the upper integration limit. The evaluation of transport coefficients thus requires averaging over multiple trajectories (possibly multiple segments of a same long trajectory) and estimating the resulting uncertainty as a function of both the length of each trajectory and the upper limit of integration. This is a cumbersome task that often leads to a poor estimate of the statistical and systematic errors on the computed conductivity, all the more so when the signal is inherently oscillatory, due to the existence of high-frequency features in the power spectrum of the energy flux, possibly due to intramolecular oscillations that meddle with the noise. Some authors try to overcome these problems by either fitting the autocorrelation function or the GK integral with a multi-exponential function (Schelling et al. 2002; Zhang et al. 2015) or by extrapolating the power spectrum of the energy flux to the zero-frequency limit (Volz and Chen 2000). Others have attempted an error analysis of the MD estimate of the GK integral, based on either heuristic or rigorous arguments (Jones and Mandadapu 2012; Wang et al. 2017; Oliveira and Greaney 2017), but they all require an estimate of an optimal value for the upper limit of integration, which determines a bias in the estimate and which is in general difficult to obtain. Different classes of systems require different approaches to error analysis, but it is widely believed that all of them always require so long simulation times as to be unaffordable with accurate but expensive AIMD techniques (Carbogno et al. 2017). In order to solve this problem, Ercole et al. (2017) considered it in the light of the statistical theory of stationary time series.

5.1 Solids and One-Component Fluids

In practice, MD gives access to a discrete sample of the flux process (a *time series*), $J_n = J(n\epsilon)$, $0 \leq n \leq N-1$, where ϵ is the sampling period of the flux and N the length of the time series, that we assume to be even. As was shown in Sect. 2.2.1, the Wiener-Khintchine theorem allows one to express the heat conductivity in terms of the zero-frequency value of the power spectrum of the energy flux (see Eqs. (21), (22), (23), and (24)):

$$\kappa = \frac{\Omega}{2k_B T^2} S(\omega = 0). \tag{60}$$

Let us define the discrete Fourier transform of the flux time series as:

$$\tilde{J}_k = \sum_{n=0}^{N-1} e^{2\pi i \frac{kn}{N}} J_n, \tag{61}$$

for $0 \le k \le N - 1$. Here, the convention for the sign in the exponential of the time-to-frequency Fourier transform is opposite to what is adopted in Ercole et al. (2017) and in most of the signal analysis literature, in order to comply with the convention for the space-time Fourier transforms usually adopted in the Physics literature and in Eqs. (4) and (5). The *sample spectrum* $\hat{S}_k$, aka *periodogram*, is defined as:

$$\hat{S}_k = \frac{\epsilon}{N} \left| \tilde{J}_k \right|^2, \tag{62}$$

and, for large N, it is an unbiased estimator of the power spectrum of the process, as defined in Eq. (21), evaluated at $\omega_k = 2\pi \frac{k}{N\epsilon}$, namely: $\langle \hat{S}_k \rangle = S(\omega_k)$. The reality of the $\hat{J}$s implies that $\tilde{J}_k = \tilde{J}_{N-k}^*$ and $\hat{S}_k = \hat{S}_{N-k}$, so that periodograms are usually reported for $0 \le k \le \frac{N}{2}$ and their Fourier transforms evaluated as discrete cosine transforms.

The space autocorrelations of conserved currents are usually short-ranged. Therefore, in the thermodynamic limit, the corresponding fluxes can be seen as sums of (almost) independent identically distributed stochastic variables, so that, according to the central-limit theorem, their equilibrium distribution is Gaussian. A slight generalization of this argument allows us to conclude that any conserved-flux process is Gaussian as well. The flux time series is in fact a multivariate stochastic variable that, in the thermodynamic limit, results from the sum of (almost) independent variables, thus tending to a multivariate normal deviate. This implies that at equilibrium, the real and imaginary parts of the $\tilde{J}_k$'s defined in Eq. (61) are zero-mean normal deviates that, in the large-N limit, are uncorrelated among themselves and have variances proportional to the power spectrum evaluated at ω_k. For $k = 0$ or $k = \frac{N}{2}$, $\tilde{J}_k$ is real and $\sim \mathcal{N}\left(0, \frac{N}{\epsilon} S(\omega_k)\right)$; for $k \notin \left\{0, \frac{N}{2}\right\}$, $\mathfrak{Re}\tilde{J}_k$ and $\mathfrak{Im}\tilde{J}_k$ are independent and both $\sim \mathcal{N}\left(0, \frac{N}{2\epsilon} S(\omega_k)\right)$, where $\mathcal{N}(\mu, \sigma^2)$ indicates a normal deviate with mean μ and variance σ^2. We conclude that in the large-N limit the sample spectrum of the heat flux time series reads:

$$\hat{S}_k = S(\omega_k) \xi_k, \tag{63}$$

where the ξs are independent random variables distributed as a χ_1^2 variate for $k = 0$ or $k = \frac{N}{2}$ and as one half a χ_2^2 variate, otherwise. Here and in the following χ_ν^2 indicates the chi-square distribution with ν degrees of freedom. For the sake of simplicity, we make as though all the ξs were identically distributed, $\xi_k \sim \frac{1}{2}\chi_2^2$

for all values of k, thus making an error of order $\mathcal{O}(1/N)$, which vanishes in the longtime limit that is being assumed throughout this section.

In many cases of practical interest, multiple time series are available to estimate the power spectrum of a same process, $\{^{p}J_{n}\}$, $p = 1, \cdots \ell$. For instance, in equilibrium MD, a same trajectory delivers one independent time series per Cartesian component of the heat flux, all of which are obviously equivalent in isotropic systems. In these cases, it is expedient to define a mean sample spectrum by averaging over the ℓ different realizations:

$$
\begin{aligned}
{}^{\ell}\hat{S}_{k} &= \frac{\epsilon}{\ell N} \sum_{p=1}^{\ell} \left| {}^{p}\tilde{J}_{k} \right|^{2} , \\
&= S\left(\omega_{k} \right) {}^{\ell}\xi_{k},
\end{aligned}
\tag{64}
$$

where the ${}^{\ell}\xi$s are $\chi_{2\ell}^{2}$ variates, divided by the number of degrees of freedom: ${}^{\ell}\xi_{k} \sim \frac{1}{2\ell}\chi_{2\ell}^{2}$ (for $k \notin \{0, \frac{N}{2}\}$).

Equations (63) and (64) show that ${}^{\ell}\hat{S}_{0}$ is an unbiased estimator of the zero-frequency value of the power spectrum, $\langle {}^{\ell}\hat{S}_{0} \rangle = S(0)$, and through Eq. (60), of the transport coefficients we are after. However, this estimator is not consistent, i.e., its variance does not vanish in the large-N limit. This is so because a longer time series increases the number of discrete frequencies at which the power spectrum is sampled, rather than its accuracy at any one of them.

Figure 3 displays the periodogram of water at ambient conditions, obtained from a 100 ps classical MD trajectory, showing the extremely noisy behavior of
Fig. 3 Periodogram of a classical flexible model of water obtained from a 100 ps MD trajectory. Gray: periodogram obtained directly from Eq. (64), with $\ell = 3$. Blue: periodogram filtered with a moving average window of width 1 THz, useful to reveal the main features of the spectrum (see text). The vertical dashed line delimits the low-frequency region used in the subsequent cepstral analysis

the periodogram as an estimator of the spectrum. Averaging over the values of the periodogram within a frequency window of given width (Weisstein MovingAverage) would consistently reduce the statistical noise, but the multiplicative nature of the latter in Eq. (63) makes it difficult to disentangle the noise from the signal and may introduce a bias. In order to cope with this problem, we had better transform the multiplicative noise into an additive one by defining the log-periodogram, ${}^{\ell}\hat{L}_k$, as:

$$
\begin{aligned}
{}^{\ell}\hat{L}_k &= \log\left({}^{\ell}\hat{S}_k\right) \\
&= \log\left(S(\omega_k)\right) + \log\left({}^{\ell}\hat{\xi}_k\right) \\
&= \log\left(S(\omega_k)\right) + {}^{\ell}\Lambda + {}^{\ell}\lambda_k,
\end{aligned}
\tag{65}
$$

where ${}^{\ell}\lambda_k = \log\left({}^{\ell}\hat{\xi}_k\right) - {}^{\ell}\Lambda$ are zero-mean identically distributed independent stochastic variables, ${}^{\ell}\Lambda = \left\langle\log\left({}^{\ell}\hat{\xi}\right)\right\rangle = \psi(\ell) - \log(\ell)$, and $\psi(z)$ is the digamma function (Weisstein PolyGamma). The variance of the ${}^{\ell}\lambda$ variables is $\sigma_{\ell}^2 = \psi'(\ell)$, where $\psi'(z)$ is the tri-gamma function (Weisstein PolyGamma).

Whenever the number of (inverse) Fourier components of the logarithm of the power spectrum is much smaller than the length of the time series, applying a low-pass filter to Eq. (65) would result in a reduction of the power of the noise, without affecting the signal. In order to exploit this idea, we define the "*cepstrum*" of the time series as the inverse Fourier transform of its sample log-spectrum (Childers et al. 1977):

$$
{}^{\ell}\hat{C}_n = \frac{1}{N}\sum_{k=0}^{N-1} {}^{\ell}\hat{L}_k e^{-2\pi i\frac{kn}{N}}.
\tag{66}
$$

A generalized central-limit theorem for Fourier transforms of stationary time series ensures that, in the large-N limit, these coefficients are a set of independent (almost) identically distributed zero-mean normal deviates (Anderson 1994; Peligrad and Wu 2010). It follows that:

$$
\begin{aligned}
{}^{\ell}\hat{C}_n &= \lambda_{\ell}\delta_{n0} + C_n + {}^{\ell}\mu_n, \\
C_n &= \frac{1}{N}\sum_{k=0}^{N-1}\log\left(S(\omega_k)\right)e^{-2\pi i\frac{kn}{N}},
\end{aligned}
\tag{67}
$$

where ${}^{\ell}\mu_n$ are independent zero-mean *normal* deviates with variances $\left\langle{}^{\ell}\mu_n^2\right\rangle = \frac{1}{N}\sigma_{\ell}$ for $n \notin \left\{0, \frac{N}{2}\right\}$ and $\left\langle{}^{\ell}\mu_n^2\right\rangle = \frac{2}{N}\sigma_{\ell}^2$ otherwise. Figure 4 displays the cepstral coefficients of the low-frequency region of the spectrum of water (marked in Fig. 3), showing that only the first few coefficients are substantially different from zero.
Fig. 4 Cepstral coefficients of water computed analyzing the low-frequency region of the periodogram (see Fig. 3), defined in Eq. (66)

Let us indicate by P^* the smallest integer such that $C_n \approx 0$ for $P^* \leq n \leq N - P^*$. By limiting the Fourier transform of the sample cepstrum, Eq. (66), to P^* coefficients, we obtain an efficient estimator of the zero-frequency component of the log-spectrum as:

$$
\begin{aligned}
{}^{\ell}\hat{L}_0^* &= {}^{\ell}\hat{C}_0 + 2 \sum_{n=1}^{P^*-1} {}^{\ell}\hat{C}_n \\
&= {}^{\ell}\Lambda + \log(S_0) + {}^{\ell}\mu_0 + 2 \sum_{n=1}^{P^*-1} {}^{\ell}\mu_n.
\end{aligned}
\tag{68}
$$

Inspection of Eq. (68) shows that ${}^{\ell}\hat{L}_0^*$ is a normal estimator whose expectation and variance are:

$$
\langle {}^{\ell}\hat{L}_0^* \rangle = \log(S_0) + {}^{\ell}\Lambda,
\tag{69}
$$

$$
\sigma_\ell^*(P^*, N)^2 = \sigma_\ell^2 \frac{4P^* - 2}{N}.
\tag{70}
$$

Using Eq. (60), we see that the logarithm of the conductivity can be estimated from the cepstral coefficients of the flux time series through Eqs. (68), (69), and (70) and that the resulting estimator is always normal with a variance that depends on the specific system *only* through the number of these coefficients, P^*. Notice that the absolute error on the logarithm of the conductivity directly and nicely yields the relative error on the conductivity itself.

The efficacy of this approach obviously depends on our ability to estimate the number of coefficients necessary to keep the bias introduced by the truncation to

a value smaller than the statistical error while maintaining the magnitude of the latter at a prescribed acceptable level. Ercole et al. (2017) proposed to estimate P^* using the Akaike's information criterion (Akaike 1974), but other more advanced *model selection* approaches (Claeskens and Hjort 2008) may be more effective. This method consists in choosing P^* as the one that minimizes the function:

$$\text{AIC}(P) = \frac{N}{\sigma_\ell^2} \sum_{n=P}^{\frac{N}{2}} \hat{C}_n^2 + 2P. \qquad (71)$$

In Fig. 5a, we report the low-frequency region of the spectrum of water obtained by limiting the number of cepstral coefficients to P^*:

$$^\ell \hat{S}_k^* = \exp\left[2 \sum_{n=1}^{P^*-1} {}^\ell \hat{C}_n e^{2\pi i \frac{kn}{N}} + {}^\ell \hat{C}_0 - {}^\ell \Lambda \right], \qquad (72)$$

thus showing the filtering effect of this choice. Finally, Fig. 5b shows the value of thermal conductivity of water obtained through Eqs. (68), (69), and (70).

5.2 Multicomponent Fluids

In Sect. 2.3.2, we have seen that in a fluid made of Q atomic species, there are in general Q macroscopic fluxes interacting with each other through Onsager's phenomenological equations, Eq. (9), not counting the different Cartesian components that do not interact among themselves because of space isotropy. A MD simulation thus samples Q stochastic processes, one for each interacting flux, that we suppose to be stationary. These processes can be thought of as different components of a same multivariate process (Bertossa et al. 2019). As in Sect. 5.1, for the sake of generality we suppose to have ℓ independent samples of such a process, described by a multivariate time series of length N: $\{{}^p J_n^i\}$; $p = 1, \ldots \ell$; $i = 1, \ldots Q$; $n = 0, \ldots N-1$. Stationarity implies that $\langle J_n^i \rangle$ does not depend on n and that $\langle J_n^i J_m^j \rangle$ only depends on $n - m$. We will further assume that $\langle J_n^i \rangle = 0$ and that $\langle J_n^i J_0^j \rangle$ is an even function of n, which is the case when J^i and J^j have the same signature under time-reversal. By combining Eq. (36) with Eq. (24), we see that in order to evaluate the thermal conductivity in the multicomponent case, we need an efficient estimator for $\left(S_0^{-1}\right)^{11}$, where $S_0^{kl} = S^{kl}(\omega = 0)$ is the zero-frequency cross-spectrum of the relevant fluxes, ordered in such a way that the energy one is the first.

Similarly to the one-component case, we define a mean sample cross-spectrum (or *cross-periodogram*) as:
Fig. 5 (**a**) Filtered low-frequency region of the power spectrum of water obtained by limiting the number of cepstral coefficients to various values of P^*, Eq. (72). $P^* = 7$ is the cutoff value suggested by the Akaike's information criterion, Eq. (71). Gray: the unfiltered periodogram obtained from Eq. (62). (**b**) Thermal conductivity of water estimated from Eqs. (68), (69), and (70) as a function of the cutoff, P^*. The colored bands indicate one standard deviation as estimated from theory. The vertical dashed line indicates the value suggested by the Akaike's information criterion, Eq. (71)

$$^{(\ell Q)}\hat{S}_k^{ij} = \frac{1}{\ell} \sum_{p=1}^{\ell} \frac{\epsilon}{N} \left(^{p}\tilde{J}_k^i\right)^* {}^{p}\tilde{J}_k^j. \tag{73}$$

By discretizing Eq. (23), we see that $^{(\ell Q)}\hat{S}_k^{ij}$ is an unbiased estimator of the cross-spectrum, $\left\langle ^{(\ell Q)}\hat{S}_k^{ij}\right\rangle = S^{ij}\left(\omega_k = \frac{2\pi k}{N\epsilon}\right)$. As it was the case for univariate processes, in the large N limit the real and imaginary parts of $\tilde{J}_k^i$ are normal deviates that are uncorrelated for $k \neq k'$. We conclude that the cross-periodogram is a random matrix distributed as a complex Wishart deviate (Goodman 1963a, b):

$$^{(\ell Q)}\hat{S}_k \sim \mathcal{CW}_Q\left(S(\omega_k), \ell\right). \tag{74}$$

The notation $\mathcal{CW}_Q(S, \ell)$ in Eq. (74) indicates the distribution of the $Q \times Q$ Hermitian matrix ${}^{(\ell Q)}\hat{S}^{ij} = \frac{1}{\ell} \sum_{p=1}^{\ell} {}^{p}X^i \, {}^{p}X^{j*}$, where $\{{}^{p}X^i\}$ ($p = 1, \cdots \ell$, $i = 1, \cdots Q$) are ℓ samples of an Q-dimensional zero-mean normal variate whose covariance is $S^{ij} = \langle X^i X^{j*} \rangle$.

Similarly to the real case, a Bartlett decomposition (Kshirsagar 1959) holds for complex Wishart matrices (Nagar and Gupta 2011), reading:

$$^{(\ell Q)}\hat{S} = \frac{1}{\ell} \mathcal{S} R R^\top \mathcal{S}^\dagger, \tag{75}$$

where "$\top$" and "$\dagger$" indicate the transpose and the adjoint of a real and complex matrix, respectively; $\mathcal{S}$ is the Cholesky factor of the covariance matrix, $S = \mathcal{S}\mathcal{S}^\dagger$; and R is a real lower triangular random matrix of the form:

$$R = \begin{pmatrix} c_1 & 0 & 0 & \cdots & 0 \\ n_{21} & c_2 & 0 & \cdots & 0 \\ n_{31} & n_{32} & c_3 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ n_{Q1} & n_{Q2} & n_{Q3} & \cdots & c_Q \end{pmatrix}, \tag{76}$$

where $c_i^2 \sim \chi^2_{2(\ell-i+1)}$ and $n_{ij} \sim \mathcal{N}(0, 1)$. We stress that R is independent of the specific covariance matrix and only depends upon ℓ and Q. In particular, it is independent of the ordering of the fluxes J^i. By expressing the QQ matrix element of the inverse of ${}^{(\ell Q)}\hat{S}$ in Eq. (75) as the ratio between the corresponding minor and the full determinant, and using some obvious properties of the determinants and of triangular matrices, we find that:

$$\frac{\ell}{\left({}^{(\ell Q)}\hat{S}_k^{-1}\right)^{QQ}} = \frac{1}{\left(S_k^{-1}\right)^{QQ}} c_Q^2, \tag{77}$$

As the ordering of the fluxes is arbitrary, a similar relation holds for all the diagonal elements of the inverse of the cross-periodogram. We conclude that the generalization of Eq. (64) for the multicomponent case is:

$$^{\ell}\underline{\hat{S}}_k \equiv \frac{\ell}{2(\ell - Q + 1)} \frac{1}{\left({}^{(\ell Q)}\hat{S}_k^{-1}\right)^{11}} = \frac{1}{\left(S_k^{-1}\right)^{11}} \xi_k, \tag{78}$$

where ξ_k are independent random (with respect to k) random variables, distributed as:

$$\xi_k \sim \begin{cases} \frac{1}{\ell-Q+1}\,\chi^2_{\ell-Q+1} & \text{for } k \in \{0, \frac{N}{2}\}, \\[2em] \frac{1}{2(\ell-Q+1)}\,\chi^2_{2(\ell-Q+1)} & \text{otherwise.} \end{cases} \qquad (79)$$

Starting from here we can apply the cepstral analysis as in the one-component case. The only difference is the number of degrees of freedom of the χ^2 distribution, that becomes $2(\ell - Q + 1)$, and a different factor in front of the result. Figure 6 shows an example of multi-component power spectrum for a solution of water and ethanol.

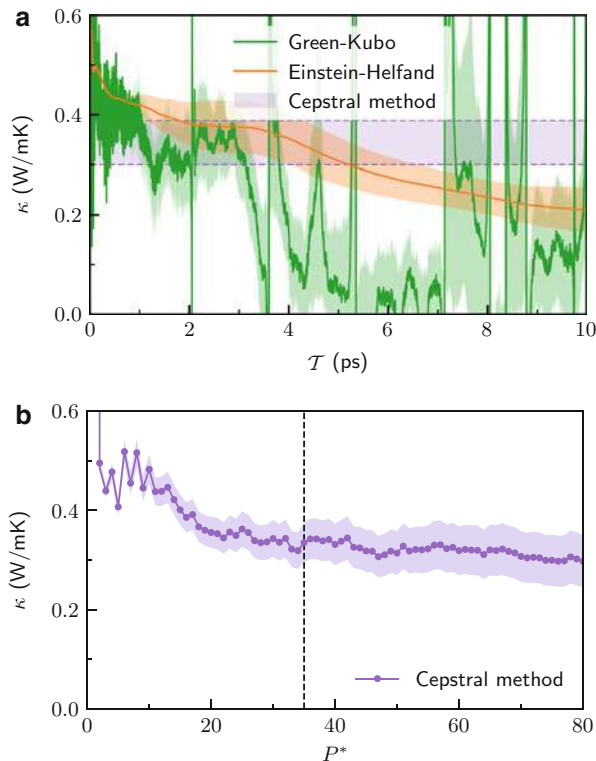
The method discussed so far shows a fundamental advantage with respect to a naïve implementation of direct time-integration approach. Figure 7 shows the two-component conductivity κ, obtained via Eq. (38), in the case of a water-ethanol solution, as a function of the upper time-integration limit $\mathcal{T}$ (Bertossa et al. 2019). Both the Green-Kubo and the Einstein-Helfand definitions of the finite-time expression of Onsager's coefficients (see Eq. (20)) are displayed. Due to thermal fluctuations, the integral of the correlation function becomes a random walk as soon as the latter vanishes, eventually assuming any value. Therefore, there will be a set of times (see Fig. 7) where the term L^{QQ} at the denominator in Eq. (38) vanishes, leading to divergences in the evaluation of κ; an issue not affecting the one-component case. Hence, in such a formulation of the multicomponent case, the mean value of the thermal conductivity estimator *in the time domain* does not exist. On the contrary, the multicomponent frequency-domain approach presented in this section, and built on sound statistical basis, provides a well-defined expression for the estimator of κ and its statistical error.
Fig. 6 Multicomponent power spectrum, as defined in Eq. (78), for a classical flexible model of a solution of water and ethanol 50 mol%, obtained from a 100 ps trajectory. Gray: $^\ell \hat{\underline{S}}_k$ obtained directly from Eq. (78), with $\ell = 3$ and $Q = 2$. Blue: $^\ell \hat{\underline{S}}_k$ filtered with a moving average window of width 1 THz in order to reveal its main features. The vertical dashed line delimits the low-frequency region used in the subsequent cepstral analysis (Bertossa et al. 2019)


Fig. 7 Convergence of the multicomponent thermal conductivity estimator κ using the direct time-integration approach and the cepstral method, for a classical flexible model of a solution of water and ethanol 50 mol%, obtained from a 100 ps trajectory. (**a**) Direct time-integration approach in its Green-Kubo (green, as obtained from the matrix $L^{ij}(\mathcal{T}) \propto \int_0^{\mathcal{T}} \langle J^i(t) J^j(0) \rangle dt$) and Einstein-Helfand (orange – obtained from the matrix $(L^{ij})'(\mathcal{T}) \propto \int_0^{\mathcal{T}} (1 - \frac{t}{\mathcal{T}}) \langle J^i(t) J^j(0) \rangle dt$) formulations. The horizontal purple band indicates the value obtained by the cepstral method. (**b**) Estimate of κ with the cepstral method as a function of the number of cepstral coefficients, P^*, see Eqs. (68), (69), and (70). The dashed vertical line indicates the value of P^* selected by the AIC, Eq. (71) (Bertossa et al. 2019)

5.3   Data Analysis Workflow

We summarize the steps leading to the estimation of thermal conductivity by the *cepstral analysis* method, in order to highlight the simplicity of its practical implementation.

1. From a MD simulation compute the heat flux time series J_n^1 and the independent particle fluxes J_n^q, $q = 2, \ldots, Q$.
2. Compute the discrete Fourier transform of the fluxes, $\tilde{J}_k^i$, and the element $1/(\hat{S}^{-1})^{11}$. In practice, only a selected low-frequency region shall be used (see

Ercole et al. (2017) for a detailed discussion). To lighten the notation, we drop the left superscripts of the variables in this subsection.

3. Calculate $\log\left[1/(\hat{S}^{-1})^{11}\right]$.
4. Compute the inverse discrete Fourier transform of the result to obtain the cepstral coefficients $\hat{C}_n$.
5. Apply the Akaike Information Criterion, Eq. (71), to estimate the number of cepstral coefficients to retain, P^*.
6. Finally apply Eq. (68) to obtain $\hat{L}_0^*$, and evaluate the thermal conductivity as

$$\kappa = \frac{\Omega}{2k_B T^2}\exp\left[\hat{L}_0^* - \psi(\ell - Q + 1) + \log(\ell - Q + 1)\right], \tag{80}$$

and its statistical error as:

$$\frac{\Delta\kappa}{\kappa} = \sqrt{\psi'(\ell - Q + 1)\frac{4P^* - 2}{N}}. \tag{81}$$

6   A Few Representative Results

Calculations of the thermal conductivity based on the Green-Kubo formalism combined with first-principles molecular dynamics are quite recent. The first benchmarks from Marcolongo et al. (2016) have been performed on liquid Argon and heavy water at ambient conditions, as reported below.

6.1   A Benchmark on a Model Mono-atomic Fluid

As a first test, liquid Argon was simulated by Marcolongo et al. (2016) using a local LDA functional neglecting dispersion forces. The resulting fictitious system, dubbed LDA-Argon, is a hard-core weakly interacting fluid whose dynamics is expected to be easily mimicked by a simple two-body potential, which can be engineered by standard force-matching techniques. This observation allows one to effectively test the ideas developed in Sect. 4: even if the energy density in LDA-Argon and in its fitted classical counterpart will likely be different, the resulting thermal conductivity is expected to coincide within the quality of the classical fit.

Simulations were performed in a cubic supercell of 108 atoms with an edge of 17.5 Å, corresponding to a density of 1.34 g cm^{-3}. Trajectories were sampled in the NVE ensemble for 100 ps, and the classical model was fitted with a pair potential of the form $V(r) = P_2(r)e^{-\alpha r}$, $P_2(r)$ being a second-order polynomial. In Fig. 8, we show the resulting autocorrelation functions at a representative temperature of 400 K. The DFT autocorrelation function shows a more structured behavior than that of the classical potential. Nevertheless, when considering the long time limit of the

a

Color coding common to the two panels. Blue: ab initio molecular dynamics (100 ps). Orange: classical molecular dynamics (100 ps). Green: classical molecular dynamics (1000 ps)

Green-Kubo integral, the thermal conductivities indeed coincide within statistical uncertainty, as predicted by theory.

6.2   Heavy Water at Ambient Conditions

Marcolongo et al. (2016) also computed the thermal conductivity of heavy water at ambient conditions. Simulations were performed using the PBE exchange correlation energy functional (Perdew et al. 1996), which is known to predict qualitatively the self-diffusion coefficient of water at ambient conditions only for a simulation temperature of about 400 K (Sit and Marzari 2005): the latter condition was imposed accordingly. A system of 64 heavy water molecules was sampled for 90 ps in the NVE ensemble using a cubic cell corresponding to the experimental density of $1.11 \, \mathrm{g\,cm}^{-3}$.

The ab initio treatment of heat transport in molecular fluids requires some care in order to eliminate non-diffusive components of the energy flux that, while not contributing to the conductivity, do increase the noise of the flux time series to a level that may compromise its analysis. To see where the problem comes from, let us split the potential energy of the system into the sum of non-interacting atomic energies plus an interaction energy as: $V(\{\mathbf{R}_n\}) = \sum_n \epsilon_n^\circ + V_{int}(\{\mathbf{R}_n\})$, where ϵ_n° is the energy of the n-th atom when it is isolated from the rest. In classical simulations, the energy of isolated atoms never enters the description of the system, and the ϵ_n°'s can be simply set to zero. In quantum simulations, instead, atomic and interaction energies enter on a same footing, and the former give a large and fluctuating contribution to the total energy flux, $\mathbf{J}^\circ = \sum_X \epsilon_X^\circ \mathbf{J}^X$, where $\mathbf{J}^X$ is the flux defined in Eq. (46). In a mono-atomic fluid, $\mathbf{J}^X$ is constant because of momentum conservation, and it is actually equal to zero in the center-of-mass reference frame. In molecular fluids, the $\mathbf{J}^X$ do not vanish, but, as we have seen in Sect. 3.1, they are non-diffusive and hence do not contribute to the heat conductivity while adding considerable noise

to the energy-flux time series. In order to remove them, instead of estimating $\mathbf{J}°$ from the noninteracting atomic energies, we prefer to implement a *decorrelation technique*, as described below.

Current decorrelation builds on a general inequality whose proof can be found in Marcolongo et al. (2016). Let $\mathbf{J}^1$ and $\mathbf{J}^2$ be two macroscopic fluxes and $\mathbf{J}^{12} = \mathbf{J}^1 + \mathbf{J}^2$ their sum. The corresponding conductivities κ^1, κ^2, and κ^{12} then satisfy $|\kappa^{12} - \kappa^1 - \kappa^2| \leq 2\sqrt{\kappa^1 \kappa^2}$. As a consequence, when κ^2 vanishes, κ^{12} coincides with κ^1. Let us now suppose that a set of fluxes $\{\mathbf{Y}^u\}$, $u = 1, \ldots U$ is known to exhibit a non-diffusive behavior. The above argument shows that the auxiliary flux defined as:

$$\mathbf{J}' \equiv \mathbf{J} - \sum_w \lambda^w \mathbf{Y}^w \tag{82}$$

will yield the same thermal conductivity as $\mathbf{J}$. Optimal values of the $\{\lambda^u\}$ coefficients can then be determined by imposing that the new time series $\mathbf{J}'$ is uncorrelated with respect to the non-diffusive ones, namely:

$$\langle \mathbf{J} \mathbf{Y}^u \rangle - \sum_w \lambda^w \langle \mathbf{Y}^w \mathbf{Y}^u \rangle = 0, \quad u = 1, \ldots U. \tag{83}$$

This procedure is particularly useful when the $\mathbf{Y}^u$ fluxes give a slowly converging contribution to the Green-Kubo integral, which is thus difficult to evaluate numerically.

The decorrelation technique has been applied to heavy water considering two non-diffusive number fluxes: $\mathbf{Y}^1 = \mathbf{J}^H + \mathbf{J}^O$, i.e., the sum of hydrogen and oxygen average velocities and $\mathbf{Y}^2 = \mathbf{J}^{el}$, the adiabatic electronic current. Note that the two time series $\mathbf{J}^H$ and $\mathbf{J}^O$ are trivially related, because of momentum conservation. Therefore $\mathbf{J}^H$, $\mathbf{J}^O$, or $\mathbf{J}^H + \mathbf{J}^O$ would all be equivalent choices. The latter is defined, following the same notation of Sect. 4, as:

$$\mathbf{J}^{el} = \frac{2}{\Omega} \mathfrak{Re} \sum_v \langle \bar{\boldsymbol{\phi}}_v^c | \dot{\boldsymbol{\phi}}_v^c \rangle, \tag{84}$$

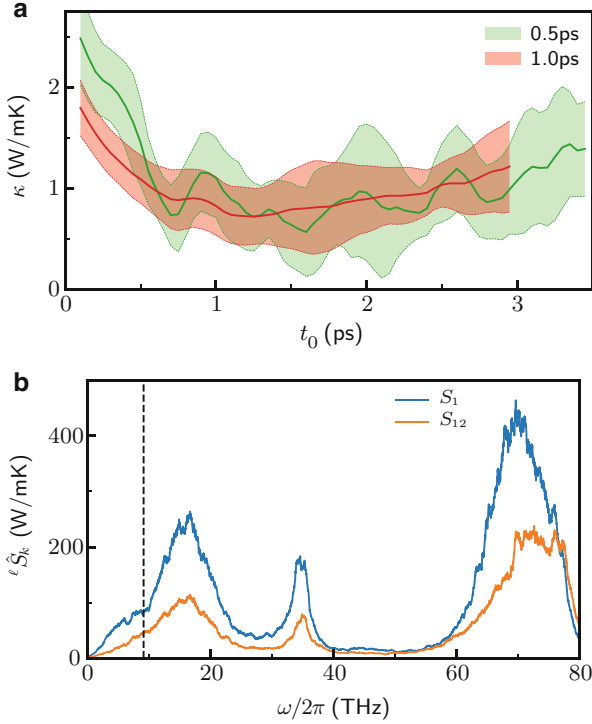
as can be derived from the continuity equation for the density: $\nabla \cdot \boldsymbol{j}^{el}(\boldsymbol{r}, t) = -\dot{n}^{el}(\boldsymbol{r}, t)$. In insulators $\mathbf{J}^{el}$ is non-diffusive and can thus be used to decorrelate the heat current. In the original paper the thermal conductivity was evaluated from the slope of the energy displacement $\mathcal{D}(\tau) = \int_0^\tau \mathbf{J}(t) dt$ (see Eq. (20)) and the corresponding error obtained from a standard block analysis, resulting in a nonoptimal estimate of both (see Fig. 9a). The same data have been reanalyzed with the novel cepstral technique presented in Sect. 5. We denote by $(\mathbf{J}^1)'$ and $(\mathbf{J}^{12})'$ the currents decorrelated with respect to $\mathbf{Y}^1$ alone and with respect to both $\mathbf{Y}^1$ and $\mathbf{Y}^2$, respectively. The power spectra of the two currents are plotted in Fig. 9b. Only the low-frequency region of the spectra (up to ~ 9.0 THz) was used for the cepstral analysis (see Ercole et al. (2017) for the technical details). The minimization


Fig. 9 (**a**) Value of thermal conductivity of heavy water obtained from a linear fitting of the energy displacement of $(\mathbf{J}^1)'$, $\mathcal{D}(\tau) = \int_0^\tau (\mathbf{J}^1)'(t)dt$. The two curves refer to different window widths used for the linear fit, of length 0.5 and 1.0 ps. The abscissa corresponds to the origin of the fitting window. (**b**) Periodogram of the $(\mathbf{J}^1)'$ and $(\mathbf{J}^{12})'$ currents, filtered with a moving average window in order to reveal the prominent features. The vertical dashed line delimits the low-frequency region used for cepstral analysis

of Eq. (71) suggests a cutoff $P_1^* = 17$ and $P_{12}^* = 15$, but a value 1.5 times larger was actually been used to reduce the bias possibly due to the fast variation of the spectrum at frequency close to zero. The resulting thermal conductivities are $\kappa^1 = 0.80 \pm 0.12$ W/mK for the $(\mathbf{J}^1)'$ flux and $\kappa^{12} = 0.93 \pm 0.14$ W/mK for $(\mathbf{J}^{12})'$, compatible with each other. By comparison, experiments give a value $\kappa \approx 0.6$ W/mK (Matsunaga and Nagashima 1983; Ramires et al. 1995). In this case, data analysis would not have yielded any meaningful results failing a proper decorrelation of the heat flux time series.

7 Outlook

We believe that the ideas presented in this chapter will pave the way to new developments and applications in the field of heat transport, particularly for strongly

anharmonic and/or disordered systems, where approaches based on the Boltzmann transport equation do not apply or are bound to fail. The general concept of gauge invariance of heat conductivity will likely apply to other transport properties as well, such as ionic conduction, viscosity, and many others, and/or simulation methodologies, such as those based on a neural-network representation of interatomic potentials, which hold the promise of a strong and long-lasting impact on molecular simulations. The applicability of this concept would not be as broad if not assisted by the powerful data-analysis methods which have also been described in this chapter. Here again, we believe that there is ample room for improvement, leveraging more general (possibly non-Fourier) representations of the log-spectrum of the currents to be analyzed and more advanced statistical-inference techniques to estimate the parameters of the spectral models resulting from these representations. From the applicative point of view, we expect that these methodological advances will have a strong impact in all those cases where heat, mass, and charge transport occurs in conditions that cannot be adequately described at the atomistic level by simple force fields, e.g., in complex materials; systems at extreme external conditions, such as those occurring in the planetary interiors; complex or reactive fluids; and many others.

Lattice Thermal Boundary Resistance

36

Aleandro Antidormi and Luciano Colombo

Contents

Abstract

Control and modelling of thermal transport at the nanoscale has emerged either as a key issue in modern nanoscience or as a compelling demand for the ever-increasing miniaturization process in information technologies: here the thermal budget of nanodevices is basically ruled over by heat exchanges across interfaces, and the relevant physics is cast in terms of a thermal boundary resistance. In this chapter, we present a unified discussion about the fundamental knowledge developed in this framework. Starting from the most general thermodynamical description of an interface, where the driving force for heat transport is identified together with the actual location and thickness of the interface itself, we define what the thermal boundary resistance is in fact. We then delve into the most successful modelling approaches, based either on the phonon picture or on

the atomistic picture. Adopting different assumptions and employing different implementation strategies, they offer a complementary description of the physical mechanisms underlying thermal boundary resistance, and they provide useful computational protocols to predict its value in realistic systems.

1   Introduction

Since the discovery of a thermal resistance at the interface between liquid helium and a solid (Kapitza 1941), the problem of thermal transport across interfaces has gradually gained interest, eventually reaching a key role in nanomaterials physics: robust advancements in the understanding of the mechanisms ruling over heat transport across boundaries have been made, with possible impact on many intriguing technological applications.

The study of thermal boundary resistance has naturally adopted the theoretical background of the most general field of thermal transport in bulk solid-state materials as a starting point: as a matter of fact, evaluation of a thermal boundary resistance requires, at least in principle, methodologies to calculate heat fluxes in non-equilibrium systems, similarly to the widely discussed problem of thermal conductivity. In particular, from the modelling point of view, the phonon picture (including the explicit treatment of the interface scattering) has been largely employed, although at different levels of sophistication, resulting in differently accurate models. Similarly, atomistic simulations have been fruitfully exploited to analyze transport in realistic systems.

It has been recognized that the key issue in the solution of the conundrum is represented by the interface, which ultimately represents the very unique and characterizing feature of thermal boundary resistance. A rigorous definition of what an interface is in fact (together with its corresponding description and modelling) has then become crucially important in order to properly understand its effects on the thermal transport across it. The most general definition of interface is provided by non-equilibrium thermodynamics which is able to identify the essential ingredients. Moreover, challenging questions exist about the role played by the interface structure, geometry, and bonding in the overall thermal resistance. Some traits of the effect of the interface have been clearly identified in the presence of interfacial scattering, ballistic transport, and wave effects (Cahill et al. 2003; Chen 2005; Hopkins 2013). These phenomena are believed to derive from new phonon-electron interaction mechanisms at the interface which are particularly hard to model and control.

The current interest in the thermal boundary resistance is driven not only by pure scientific curiosity but also by technological needs. In particular, as the ongoing miniaturization process taking place in the information technologies has led to the manufacturing of device at the nanoscale, new challenges in the management of thermal power have emerged (Balandin 2002; Maasilta and Minnich 2014). For example, power dissipation limits the performance of electronic systems from individual microprocessors to data centers. Silicon-based microprocessors with

clock frequencies larger than a few GHz cannot even work due to on-chip power densities exceeding $100\,\mathrm{W/cm}^{-2}$. Also in radio-frequency (RF) amplifier designs using III-V group compound semiconductors, thermal high power densities are sufficient to prevent a proper device operation. These huge power densities lead to device failure and to the need for better strategies of heat dissipation and control at the nanoscale.

Similar challenges are currently encountered in the field of thermoelectric applications: today solutions for thermal waste recovery suffer an extremely low efficiency, and the quest for good thermoelectric materials is consequently particularly intense. The most promising strategies adopted to date exploit materials nanostructuring to reduce the overall thermal conductivity without jeopardizing electron transport properties (Minnich et al. 2009; Dresselhaus et al. 2007).

In addition, the junction of two materials with different thermal properties represents the fundamental building block of the so-called phononic devices (Volz et al. 2016). In analogy with the electronic diodes, joining two materials with different thermal properties allows for the realization of thermal diodes (i.e., devices acting as thermal conductors or insulators depending on the sign of the temperature difference applied). This behavior, generally called "thermal rectification" (Dames 2009), is clearly due to the interface asymmetry which reflects into a different amount of thermal energy exchanged through it when the temperature difference is reversed. Starting from these simple elementary blocks, an entire information technology based on heat could be envisioned and developed.

It is then clear how an improved ability to control thermal transport at the nanoscale would represent a fundamental progress toward new smaller and more energy-efficient nanodevices. Such considerations are compelling motivations to address thermal transport across an interface by computer modelling. Two modelling strategies have been mostly exploited in the investigation on thermal boundary resistance, corresponding to fundamentally different physical pictures, namely, the phonon picture and the atomistic picture. The former represents a valid approach inspired by the theory of heat transport in crystalline materials, and it relies on the definition of phonons as energy carriers. Being collective lattice vibrations, the reciprocal space is the natural space in which thermal transport is more intuitively described and interpreted. However, due to some oversimplifying assumptions adopted (e.g., the absence of imperfections in the materials structures), its accuracy and predictivity is rather poor. A more sophisticated and accurate calculation of thermal boundary resistances is, on the contrary, provided by atomistic simulations. Within this picture, the thermal transport properties are calculated by simulating the trajectories of individual atoms for sufficiently long times. Hence, calculations are performed in the direct space. The extremely accurate atomic-scale description of the interface and the intrinsic properties of the materials allow to obtain values of thermal boundary resistance in excellent agreement with experiments. More importantly, the possibility of introducing realistic features in the system (e.g., atom vacancies, interface roughness, interdiffusion, etc.) offers the advantage of exploring the effect of non-idealities on the heat transport, which are generally ignored in the phonon picture. Both the modelling strategies will be separately discussed below.

The chapter is organized as follows. After outlining the basic thermodynamics of thermal transport in Sect. 2, the concept of thermal boundary resistance will be properly defined in Sect. 3. Here we express it as the ratio between the temperature drop across the interface and the corresponding heat flux passing through. The rest of the chapter will be devoted to the modelling efforts of thermal boundary resistance. In particular, Sect. 4 delves into the phonon picture of transport across interfaces: fundamental observables are identified as well as the assumptions necessary to get to the results. In Sect. 5, we finally describe the atomistic picture. Questions on how to correctly identify the interface and how to compute the heat flux passing through will be answered, hence offering a complete guide to a numerical evaluation of thermal boundary resistance in realistic systems. General conclusions will close this chapter.

2 Lattice Thermal Transport: Basics

A net flux of heat (e.g., the thermal energy amount crossing a unit of surface in a unit of time) in a condensed matter system can only be observed in non-equilibrium conditions, i.e., when a thermal bias – acting as a driving force – is applied across a specimen: the resulting current of thermal energy is in fact the response of the system to such a perturbation, in the attempt to recover the initial equilibrium configuration (Lienhard IV and Lienhard V 2017). In principle, there exist two kinds of microscopic heat carriers, namely, electrons and lattice vibrations. In case the system of interest is a crystalline material, these latter ones are referred to as phonons. When dealing with nonmetallic materials, as it is assumed throughout this chapter, the electron contribution is negligibly small with respect to the lattice one.

Any elementary theory of lattice heat transport is ruled over by two basic ingredients, namely, (i) a constitutive equation characterizing the thermal force-flux relationship and (ii) some transport coefficients, which depend on the actual material system and quantify its ability to transmit thermal energy. In order to elaborate a theory suitable for computer simulations, some simplifying assumptions must be adopted in order to proceed. First of all, we assume that no mass or charge transport phenomena, as well as no chemical reactions, occur (this can be done without any loss of generality since we are focussing on pure heat transport in solid-state materials). Next, we only consider a steady-state transport configuration, where the system response to the perturbation is stationary; this implies that either the applied thermal bias does not change in time and we follow the system after a long enough transient of time, i.e., after that the system has set up its own stationary response. This implies that, although a thermal bias is present, local equilibrium holds everywhere: accordingly, provided that all relevant quantities are given as the corresponding local density, the equations of equilibrium thermodynamics still hold in each selected material portion. Finally, and most importantly, we assume that the perturbation is small: the system will activate a linear response.

If we now consider a volume region of a homogeneous system subjected to a thermal bias under the above assumptions, we can write the entropy continuity equation as (Kjelstrup and Bedeaux 2008)

$$\frac{\partial s}{\partial t} = -\frac{\partial J_s}{\partial z} + \sigma_s \tag{1}$$

where $\partial s / \partial t$ is the change of entropy density within the selected volume element, $\partial J_s / \partial z$ is the net flow of entropy through it, and σ_s is the entropy density production term provided by any possible entropy source within the same volume element Hereafter z will be the direction of the heat current. By using the local Gibbs equation $du = T ds$ (where u is the internal energy density and T is the local temperature) and the energy balance equation $\partial u / \partial t = -\partial J_h / \partial z$ (we are assuming mechanical equilibrium, and, therefore, no mechanical work must be considered), Eq. 1 is easily transformed into

$$\frac{\partial s}{\partial t} = -\frac{\partial}{\partial z}\left(\frac{J_h}{T}\right) + J_h \frac{\partial}{\partial z}\left(\frac{1}{T}\right) \tag{2}$$

In this equation, J_h is the heat flux, i.e., the amount of thermal energy crossing a unit area in a unit of time. By comparing Eqs. 1 and 2, we can immediately identify the σ_s term which, in the present case of pure heat transport, can be expressed by the Onsager relation $\sigma_s = J_h X_h$ where X_h is the generalized force associated to J_h. This allows for identifying the actual force driving thermal transport as

$$X_h = \frac{\partial}{\partial z}\left(\frac{1}{T}\right) \tag{3}$$

Within the linear response regime we have assumed, we can further state $X_h = r J_h$, thus introducing the *Onsager resistivity coefficient r*: this is exactly the material-specific parameter that has been indicated as a basic ingredient of the present elementary transport theory. We can now identify the second ingredient by inserting the Onsager resistivity in Eq. 3 and getting the following force-flux equation

$$\frac{\partial}{\partial z}\left(\frac{1}{T}\right) = r J_h \tag{4}$$

corresponding to the *constitutive equation for heat transport*. We remark that according to Eq. 4 the actual *thermodynamic driving force for thermal transport is the gradient of an inverse temperature* (Kittel and Kroemer 1980). By developing the z-derivative of the inverse temperature, we get $\partial T / \partial z = -T^2 r J_h$ which can be recast in the form of the well-known *Fourier law*

$$J_h = -\kappa \frac{\partial T}{\partial z} \tag{5}$$

where the thermal conductivity κ (measured in $\mathrm{Wm^{-1}K^{-1}}$ units) is related to the inverse of the Onsager resistivity $\kappa = (T^2 r)^{-1}$. We remark that this latter relation establishes the link between the Onsager and the Fourier pictures: the former being rooted in robust non-equilibrium thermodynamics and the latter being fully phenomenological.

3   The Concept of Thermal Boundary Resistance

Let us now move to the case of two materials, with unlike thermal transport properties (i.e., with different thermal conductivity), meeting at an interface across which a thermal bias is applied. While for a homogeneous system a linear variation of temperature throughout the whole specimen occurs in steady-state condition, a sudden temperature drop ΔT is experimentally observed at the heterojunction in a similar condition: the situation is conceptualized in Fig. 1 where, at least for the moment, we do not need to specify the actual temperature profile in the interface region but, rather, we simply assign its average value hereafter referred to as *interface temperature* T_{int}. Furthermore, T_{left} and T_{right} are the local temperature just at the left and right boundary of the interface region.

In this situation Eq. 1 is recast in the form (Kjelstrup and Bedeaux 2008)

$$\frac{\partial s^{\mathrm{int}}}{\partial t} = -\left(J_{s,\mathrm{left}} - J_{s,\mathrm{right}}\right) + \sigma_s^{\mathrm{int}} \tag{6}$$
Fig. 1 Idealized scheme for the definition of the thermal boundary resistance concept. The bold black line represents the local temperature profile along the direction of heat flux. The interface region is marked by vertical light lines, while ΔT indicates the temperature drop occurring between the left and the right boundaries of the interface, respectively, at temperatures T_{left} and T_{right}

where the superscript "int" indicates an interface quantity, while $J_{s,\text{left}}$ and $J_{s,\text{left}}$ are the entropy density flux through the indicated interface boundaries. Similarly to the case treated in the previous section, we easily obtain σ_s^{int} as

$$\sigma_s^{\text{int}} = J_q \left(\frac{1}{T_{\text{int}}} - \frac{1}{T_{\text{left}}} \right) + J_q \left(\frac{1}{T_{\text{right}}} - \frac{1}{T_{\text{int}}} \right) \tag{7}$$

proving that *two flux-force equations are actually needed for the interface problem*, one for each boundary

$$\left(\frac{1}{T_{\text{int}}} - \frac{1}{T_{\text{left}}} \right) = r_{\text{left}} J_h \qquad \left(\frac{1}{T_{\text{right}}} - \frac{1}{T_{\text{int}}} \right) = r_{\text{right}} J_h \tag{8}$$

and each one defining its own Onsager resistivity coefficient.

This analysis allows to treat the *series of two Onsager resistances*

$$R_{\text{TBR}} = T_{\text{int}}^2 \left(r_{\text{left}} + r_{\text{right}} \right) = T_{\text{int}}^2 \frac{1}{J_h} \left(\frac{1}{T_{\text{right}}} - \frac{1}{T_{\text{left}}} \right) = \frac{T_{\text{int}}^2}{T_{\text{right}} T_{\text{left}}} \frac{T_{\text{left}} - T_{\text{right}}}{J_h} \tag{9}$$

as the net thermal boundary resistance (TBR) the heat current must pass through. The $(T_{\text{left}} - T_{\text{right}})/J_h$ factor on the right-hand side of the above equation is commonly called *Kapitza resistance* R_{Kapitza} (Pollack 1969; Swartz and Pohl 1989; Cahill et al. 2003, 2014; Kapitza 1941)

$$R_{\text{kapitza}} = \frac{T_{\text{left}} - T_{\text{right}}}{J_h} = \frac{\Delta T}{J_h} \tag{10}$$

and it is typically used to characterize interface thermal transport.

In summary, non-equilibrium thermodynamics provides the proper framework to define the Kapitza resistance, leaving us with problem of calculating the ratio between the temperature drop at the interface and the corresponding steady-state thermal current J_h. There exist basically two strategies to accomplish this task either based on calculations of lattice vibrational properties or on atomistic simulations. The former corresponds to a phonon picture of thermal boundary resistance; the latter offers an atomistic perspective for transport across the interface. The mentioned modelling pictures will be treated separately in the two following sections.

4 The Phonon Picture for the Thermal Boundary Resistance

In this section we present the phonon-based semiclassical formalism of thermal transport across an interface and retrace the main steps to predict the thermal boundary resistance. As commented above, we shall only consider the interfaces

between nonmetals, for which the electron contribution to heat flux can be neglected with respect to the lattice contribution.

The prototypical system on which we will focus is shown in Fig. 1. In the following, the materials involved will be assumed to be perfectly crystalline and the interface region small enough to be well approximated by the plane $z = 0$. The heat flux can be expressed in terms of quanta of vibrational energy, the phonons, on the left and right parts of the interface. The most simple and successful picture consists in attributing the onset of thermal resistance to phonon scattering at the interface: a phonon incident on the interface has a certain probability of being transmitted to the other side. Such a probability of transmission generally depends on the phonon mode, its polarization p, its wave vector $\mathbf{k}$, and its frequency $\omega_p(\mathbf{k})$. The net heat transfer across the interface is due to the net balance of incoming, transmitted, and reflected energy. Since energy is carried by phonons, this reflects into a balance for the incoming, transmitted, and reflected phonon flux (Swartz and Pohl 1989; Chen 2005). The mechanism of phonon transmission and reflection is illustrated in Fig. 2.

Under the simplifying assumptions of negligible inelastic scattering at the interface and no phonon-phonon interactions, the heat flux incident from the side α ($\alpha = 1, 2$) on the interface can be written as

$$J_\alpha = \sum_p \int_{\mathbf{k}'} \frac{1}{4\pi} \hbar \omega_p(\mathbf{k}) f_\alpha(\omega_p(\mathbf{k}), T) \, \mathbf{v}_p(\mathbf{k}) \cdot \mathbf{n} \, d\mathbf{k} \qquad (11)$$

where $\mathbf{n}$ is the unit vector normal to the interface, $\mathbf{v}_p(\mathbf{k})$ is the group velocity of the phonon with wavevector $\mathbf{k}$, and $f_i(\omega, T)$ is the Bose-Einstein distribution
Fig. 2 Illustration of the physical mechanisms of thermal boundary resistance. TBR is explained in terms of heat fluxes impinging on the interface: part of the flux coming from hot side is effectively transmitted to the cold one; the remaining is back-reflected. Analogously, a similar flux comes from cold side (not shown here), part of which will be transmitted across the interface and the rest back-reflected

function. The integral extends over all the phonon wavevectors $\mathbf{k}'$ in the Brillouin zone actually incident on the separation plane, i.e., such that the corresponding group velocity $\mathbf{v}$ has a positive (negative) component along the z-axis for $\alpha = 1$ (2). Finally, $\sum_p$ indicates the sum over all possible phonon polarizations. Changing the integration variable to the frequency ω and introducing angular coordinates (the azimuth angle φ is defined by the vector $\mathbf{n}$ and a direction normal to z, while the θ angle is defined in the plane normal to the azimuthal direction), the formula above can be recast in the form

$$J_\alpha = \sum_p \int_0^{\omega_{max}} \int_{\varphi=0}^{2\pi} \int_{\theta=-\pi/2}^{\pi/2} \hbar\omega_p \, f_\alpha(\omega_p, T) \, v_p(\omega_p) \cos(\theta) \sin(\theta) D_i(\omega_p) d\theta d\varphi d\omega_p$$

(12)

where the phononic density $D_\alpha(\omega_p)$ of the side α has been introduced.

Any given phonon has a certain probability $t_{\alpha \to \beta}(\mathbf{k})$ of being transmitted from side α to side β. Multiplying the previous expression by this factor, we obtain that the heat flux from one side to the other is given by

$$J_{\alpha \to \beta} = \sum_p \int_{\mathbf{k}'} \frac{1}{4\pi} \hbar\omega_p(\mathbf{k}) \, f_\alpha(\omega_p(\mathbf{k}), T) \, t_{\alpha \to \beta}(\mathbf{k}) \, \mathbf{v}_p(\mathbf{k}) \cdot \mathbf{n} \, d\mathbf{k}$$

(13)

The resulting net heat flux across the surface is then readily computed as

$$J_h = J_{1 \to 2} - J_{2 \to 1}$$

(14)

As we have already pointed out, the transmission probability depends on the microscopic details of the interface, and its calculation is a major theoretical task. In order to proceed, an average transmission probability can be identified as $\bar{t}_{\alpha \to \beta} = J_{\alpha \to \beta}/J_\alpha$. How to compute its value will be discussed in the next section: here we assume that $\bar{t}_{\alpha \to \beta}$ is known. Then, the overall heat flux, when a temperature difference $\Delta T = T_2 - T_1$ is applied, can be equivalently expressed by

$$J_h = [J_1 \cdot \bar{t}_{1 \to 2}]_{T_1} - [J_2 \cdot \bar{t}_{2 \to 1}]_{T_2}$$

(15)

Recalling that at equilibrium ($\Delta T = 0$), the above quantity is zero, i.e.

$$[J_1 \cdot \bar{t}_{1 \to 2}]_{T_1 = T} = [J_2 \cdot \bar{t}_{2 \to 1}]_{T_2 = T}.$$

(16)

one can finally obtain an expression for the thermal boundary resistance $R_{\text{kapitza}} = \frac{\Delta T}{J_h}$ by linearly expanding the J_h formula for a small temperature offset $\Delta T \to 0$, yielding

$$R_{\text{Kapitza}} = \lim_{\Delta T \to 0} \left[\frac{J_h|_{T+\Delta T} - J_h|_T}{\Delta T} \right]^{-1} = \left[\frac{\partial}{\partial T} [J_{1\to 2} \cdot \bar{t}_{1\to 2}] \right]^{-1}$$

$$= \left[\frac{\partial}{\partial T} [J_{2\to 1} \cdot \bar{t}_{2\to 1}] \right]^{-1} \tag{17}$$

This is the formula for the thermal boundary resistance in the phonon picture that we were looking for. Under the adopted assumptions, R_{Kapitza} can in principle be calculated by only making reference to one side of the interface; the other side still enters the game through the transmission probability $\bar{t}$.

According to Eq. 17 and the underlying concepts, a thermal boundary resistance between two materials arises whenever a difference in the phonon dispersion curves is found. This creates, indeed, an imbalance of heat carriers between the two interacting materials and, hence, a non-negligible heat flux when a temperature gradient is applied. In order to get a deeper insight, it is convenient to assume a linear dispersion relation with sound speed v and transmission probabilities not depending on the temperature. Under these assumptions, we obtain

$$R \propto \left[\sum_p \bar{t}_{1\to 2} \, C_{1,p} \, v_{1,p} \right]^{-1} \tag{18}$$

where $C_{1,p}$ is the single-mode contribution to the heat capacity (per unit volume) of material 1. It is now clear how materials whose dispersion relation gives large values for Cv are generally characterized by smaller thermal boundary resistance. Given that the heat capacity depends on the temperature, a variation of its value with T is expected, in addition to the T-dependence imposed in Eq. 11 by the Bose-Einstein distribution. As reported in Swartz and Pohl (1989), one finds $R \propto T^{-3}$ for T smaller than the Debye temperature, while R reaches a plateau for higher temperatures.

Another key factor displayed in Eq. 17 is represented by the transmission probabilities $t(\mathbf{k})$, expressing the capability of each single phonon mode to transmit its energy across the interface. Materials with strong interfacial coupling have generally large values of probabilities and a consequently smaller thermal boundary resistance. The calculation of the transmission probabilities represents a formidable task, and several models have been proposed employing different approximations. The most used and successful modelling attempts are the acoustic mismatch model and diffuse mismatch model that will be presented in the next sections.

4.1   The Acoustic Mismatch Model

The acoustic mismatch model is based on a three-fold assumption, namely, (i) phonons are treated as plane waves, (ii) the medium in which they propagate

is a continuum, and (iii) the interface is as negligibly thick as a plane. Such approximations are expected to be valid only in the regime of low temperatures, where the vibrational spectrum is dominated by phonons with wavelength larger than the interatomic spacing. Equations of continuum acoustics are then applied to phonon waves: a wave incident on the interface generates a reflected and a refracted wave, each of them being the superposition of one longitudinal and two transverse phonon waves. The angles of incidence and refraction θ_{in} and θ_{trans} are governed by Snell's law

$$v_\alpha^{L/T} \sin \theta_{in} = v_\beta^{L/T} \sin \theta_{trans} \tag{19}$$

where $v_\alpha^{L/T}$ is the acoustic longitudinal (transverse) phonon velocity in medium α (see Fig. 3).

Under the continuum ansatz, the transmission probabilities are calculated by the acoustic analog of the Fresnel equations, which translate into a set of boundary conditions. The normal and tangent components of the displacement must be continuous at the interface; moreover, the normal component of the stress tensor must also be continuous. In this way, the transmission probabilities can be computed for each phonon mode and incidence angle. It is noteworthy that, in complete analogy with electromagnetic waves, no guess on the interface energy budget is required (i.e., nor elastic nor inelastic scattering is described by the acoustic mismatch model). Although simple and clear in the underlying physics, the continuum model just described is known to have poor accuracy, generally predicting values of thermal boundary resistance smaller than experimental values at room temperature (Chen 2005).
Fig. 3 Schematic of the many possibilities within the acoustic mismatch model for phonon incident on the interface. When a longitudinal phonon (L) reaches the interface, a superposition of one longitudinal (L) and two transverse waves (T) are transmitted and reflected

4.2 The Diffuse Mismatch Model

The diffuse mismatch model is mainly addressed to describe the effect of scattering of phonons at the interface. The fundamental assumption is that all phonons incident on the interface are diffusively scattered and acoustic correlations between incoming and transmitted phonons are completely destroyed by diffuse scattering. Differently stated, when a phonon impinges on the interface, it is scattered into another phonon which is almost independent from the incoming mode. Hence, any info about the incoming phonon (like its direction and polarization) is lost during the interface scattering event. The only retained information is about the incoming single-mode frequency ω, which is conserved since elastic scattering is assumed.

The probability that the phonon will scatter into a given side of the system is then chosen to be proportional to the vibrational density of states in that side $D_\alpha(\omega)$. The diffuse mismatch model is then more appropriate to describe the transmission probabilities at high temperatures and rough interfaces. At room temperature, indeed, the phonons involved in the heat flux wavelengths which are small compared to the interatomic spacing and surface roughness and can thus hardly see interfaces as flat.

Specifically, the transmission probability for a phonon from side α to side β does not depend on the phonon $\mathbf{k}$, $t_{\alpha\to\beta}(\mathbf{k}, \omega) = t_{\alpha\to\beta}(\omega)$; moreover, the probability for a phonon to be transmitted from side α to side β must be equal to the probability of a phonon in side β to be reflected at the interface, i.e.

$$t_{\alpha\to\beta}(\omega) = 1 - t_{\beta\to\alpha}(\omega) \tag{20}$$

Under these assumptions, the actual values of transmission probabilities can be determined inserting Eq. 20 into Eq. 16. For Debye solids at sufficiently low temperatures, one finds

$$t_{\alpha\to\beta}(\omega) = \frac{\sum_p v_{\beta,p}^{-2}}{\sum_p v_{\alpha,p}^{-2} + \sum_p v_{\beta,p}^{-2}} \tag{21}$$

where $v_{\beta,p}$ is the frequency-dependent group velocity of phonons with polarization p. The diffuse model just presented generally predicts higher thermal boundary resistance than the acoustic model for quite similar materials, smaller resistance for very dissimilar ones (Hopkins 2013).

Variations of the diffuse mismatch model have been proposed to include also interface features: in particular, the effect of interface roughening and the effect of interfacial inelastic scattering.

It is important to recognize that both the acoustic and diffuse models show a rather scarce predictive capability (Stoner and Maris 1993; Swartz and Pohl 1987; Hopkins 2013); notwithstanding, their simplicity and conceptual clarity is efficient enough to highlight the basic physical processes at the core of the thermal boundary resistance at crystalline solid interfaces.

5   The Atomistic Picture for the Thermal Boundary Resistance

The phonon picture developed at different levels in the previous section is based on the treatment of crystalline atomic motions as collective vibrational modes. This picture is no longer valid when translational invariance is lost, as found in many situations of practical interest, including (but not limited to) an interface between noncrystalline (i.e., amorphous or nanocrystalline) materials, diffused or graded interfaces, nonperiodic distributions of defects (like engineered alloying profiles), and nonperiodic multiple interfaces. When the phonon picture is unfeasible (or not accurate enough due to the underlying approximations), we can calculate the thermal boundary resistance by a more direct approach based on molecular dynamics (MD) simulations (Frenkel and Smit 1996).

MD simulations neither assume crystal periodicity nor require the calculation of any phonon property. They make no assumption about the actual scattering mechanisms affecting heat carriers at the interface, while vibrational anharmonicity is fully taken into account as well as the actual atomistic structure of the interface. Rather, MD simulations are based on the non-equilibrium thermodynamics picture described above, and, therefore, the determination of the Kapitza resistance is reduced to separately evaluate the temperature drop ΔT across the interface and the steady-state heat flux J_h passing through. This twofold task requires different simulation strategies, which are addressed below. The overall validity of any MD calculation depends on the reliability, accuracy, and transferability of the adopted force field, an issue which is not address here (Finnis 2003).

5.1   Calculating the Interface Temperature Drop ΔT

In order to attempt a calculation of ΔT, we need at first to unambiguously define the location and the thickness of the interface: to this aim we can follow the *Gibbs construction* (Kjelstrup and Bedeaux 2008).

By selecting a material property showing different values in the two bulk-like regions far away from the interface, we can evaluate its profile $P(z)$ along the same z-direction selected for applying the thermal bias (we understand that such a direction crosses the interface). This is typically accomplished by computing the local value of that property over a set of suitably thin material slabs at sequential z-positions, resulting in a plot like Fig. 4 (top) where $P(z)$ is shown as a thick black line. For instance, in the case an interface between two lattice mismatched semiconductors $P(z)$ could be the interplanar lattice constant along z. Alternatively, $P(z)$ could represent the actual content of a dopant, or a given chemical species, or any other structural defect. Finally, for a crystalline/amorphous interface, $P(z)$ could represent the local average atomic coordination.

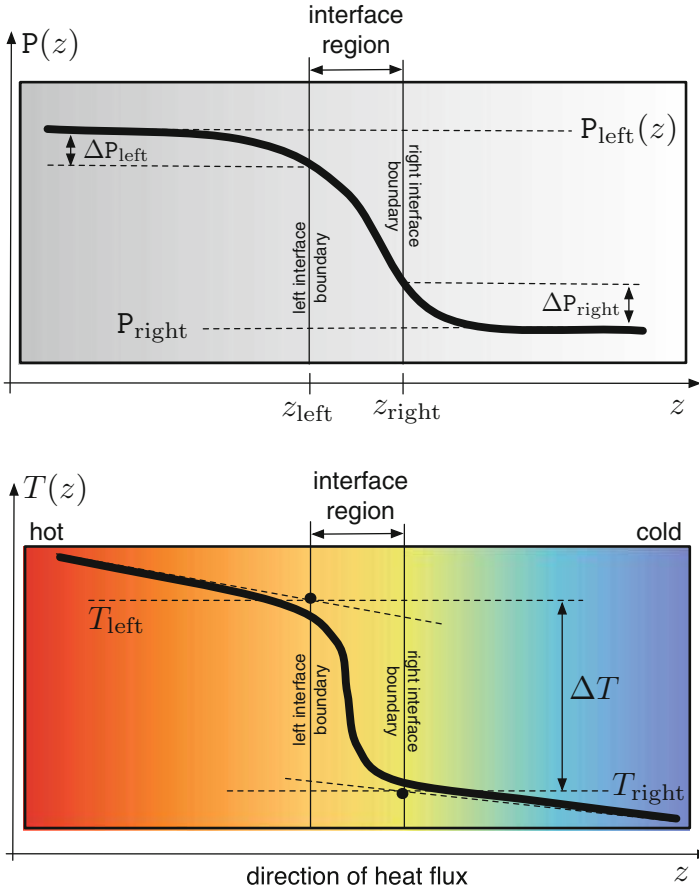
We agree in defining the interface as that region where $P(z)$ differs from the pure material values (hereafter referred to as P_{left} and P_{right}, respectively) by some


Fig. 4 Top: Gibbs construction: a suitable material property $P(z)$ is calculated across the heterojunction, and the interface boundaries are defined according to the criteria described in the text. The gray color shading is a pictorial representation of the local value of the $P(z)$ property. Bottom: determination of the T_{left} and T_{righ} temperatures under a steady-state thermal bias conduction. The temperature field is represented by colors

arbitrary amount. In practice, the position of the left interface boundary is set at z_{left} where the offset $\Delta P_{left} = P_{left} - P(z_{left})$ is typically 2–5% of P_{left}, and similarly for the right boundary. This procedure also defines the actual thickness of the interface region. When applied to real solid-state systems, the Gibbs construction provides evidence that, while $P(z)$ is normally a well-behaved function across the interface region (i.e., it shows a monotonic trend with no abrupt discontinuities), such a material portion is neither symmetrically extended over the two facing leads nor is centered at their nominal boundary: in other words, we have learned that the thermodynamical interface does not coincide with the nominal interface. The

intriguing point is that the Kapitza resistance is determined by a temperature drop across the thermodynamical interface, as detailed below. It has been also shown that the interface region can be treated as an autonomous thermodynamical system (Rurali et al. 2016) with its own temperature T_{int}.

The Gibbs construction provides a robust definition of the interface suitably tailored for the calculations we are interested in. If we apply a temperature bias along z and plot the temperature profile $T(z)$ once the steady-state regime has been reached, we typically obtain what pictured in Fig. 4, bottom: while $T(z)$ displays a linear variation in the two bulk-like regions (with a different slope, the two materials differing in thermal conductivity), it shows a typical sigmoidal behavior over the interface region. This figure directly defines two relevant temperatures in our problem, namely, the left T_{left} and right T_{right} temperatures, just at the boundaries of the interface region: they are straightforwardly calculated at the intercept between the extrapolation of linear trends and the interface boundaries previously defined. We also get a clear indication on how to evaluate the *interface temperature* T_{int}: it is easily evaluated within a MD simulation by simply computing the average kinetic energy among all atoms placed in the interface region.

5.2   Calculating the Heat Flux

5.2.1   Setting up the Thermal Bias Across an Interface

The situation we are interested in is a non-equilibrium one, and, therefore, the first task to accomplish is twofold, namely, (i) applying a thermal bias to the simulation cell and (ii) ageing the system until a steady-state regime of thermal conduction is eventually reached. To these aims, once that the z-direction is selected for heat conduction, a simulation cell as long as L_z is assembled and thermalized through conventional thermostatting (Frenkel and Smit 1996) at a suitable temperature T_0. Next, the opposite terminal ends of the simulation cell are coupled to two thermostats at temperature T_{hot} and T_{cold}, respectively, in such a way that $T_{cold} < T_0 < T_{hot}$. They act, respectively, as a hot and cold reservoir. The system is then aged by keeping both ends at constant temperature while integrating the equations of motions of all atoms in the core region without any thermostatting. This simulation protocol is commonly referred to as the "direct method" (Schelling et al. 2002; He et al. 2012; Sellan et al. 2010; McGaughey and Kaviany 2006).

In order to assess the steady-state condition, the local temperature profile $T(z, t)$ is calculated during the system ageing. This is done by recording the average kinetic temperature over a suitable set of thin material slabs distributed throughout the whole sample: the steady-state condition is proclaimed as soon as the $T(z, t)$ profile does not further evolve in time. At this stage the first needed input to evaluate the Kapitza resistance, namely, the temperature drop ΔT, is straightforwardly obtained by applying the Gibbs construction: T_{left} and T_{right} are easily obtained from the resulting steady-state temperature profile.

5.2.2 Evaluating Heat Flux Through Atomic Trajectories

The evaluation of the heat flux is a very subtle problem. Its microscopic definition is provided by the virial formulation (Fan et al. 2015)

$$\mathbf{J}_h = \frac{d}{dt} \sum_i \mathbf{r}_i E_i = \sum_i \left[\mathbf{v}_i E_i + \mathbf{r}_i \frac{d}{dt} E_i \right] \tag{22}$$

where $\mathbf{r}_i$ and $\mathbf{v}_i$ are the atomic positions and velocities (i labels atoms), while $E_i = 1/2 m_i v_i^2 + U_i$ are the corresponding single-atom energies (m_i are atomic masses and U_i is the on-site potential). The actual calculation of $\mathbf{J}_h$ is made difficult by the fact that, while atomic trajectories and velocities are directly provided on-the-fly during the MD run, single-atom energies are difficult to calculate: as a matter of fact, this task is straightforward only in the case of two-body interaction potentials which, however, are mostly inadequate to describe real materials.

The two contributions appearing on the last right-hand side of Eq. 22 are, respectively, known as the *convective contribution* $\mathbf{J}_h^{\mathrm{conv}} = \sum_i \mathbf{v}_i E_i$ and the *potential contribution*

$$\mathbf{J}_h^{pot} = \sum_i \mathbf{r}_i \frac{d}{dt} E_i = \sum_i \mathbf{r}_i \left[\mathbf{F}_i \cdot \mathbf{v}_i \right] + \sum_i \mathbf{r}_i \frac{dU_i}{dt} \tag{23}$$

where $\mathbf{F}_i(t)$ is the net force on i-th atom at time t. They correspond to similar terms in the Einstein formalism for transport coefficients (Kinaci et al. 2012), and it is similarly found that the convective term is negligibly small in solid-state materials: this remark is consistent with the approximations here adopted to describe pure thermal transport.

The key idea (Fan et al. 2015) to calculate the potential contribution $\mathbf{J}_h^{\mathrm{pot}}$ is that for any particle pair (i, j) we can define a pairwise force $\mathbf{F}_{ij} = -\mathbf{F}_{ji} = \partial U_i/\partial \mathbf{r}_{ij} - \partial U_j/\partial \mathbf{r}_{ji}$ based on the natural choice $U_i = 1/2 \sum_{j \neq i} U_{ij}$, where U_{ij} only depends on the relative distance vectors $\mathbf{r}_{ij}$ originating from particle i. This allows to cast in the most general form the potential contribution to the heat flux as

$$\mathbf{J}_h^{\mathrm{pot}}(t) = \sum_i \sum_{j \neq i} \mathbf{r}_{ij}(t) \left[\frac{\partial U_j(t)}{\partial \mathbf{r}_{ji}(t)} \cdot \mathbf{v}_i(t) \right] \tag{24}$$

where all quantities can be straightforwardly calculated during a MD run, including the instantaneous value of the relative (i, j) distance $\mathbf{r}_{ij}(t) \equiv \mathbf{r}_j(t) - \mathbf{r}_i(t)$. This result is sometimes referred to as the Hardy formula (Hardy 1963).

5.2.3 Evaluating Heat Flux Through Work Rates

An alternative evaluation of the heat flux J_h consists in calculating the rate of thermostatting work separately done by the hot and cold thermostats placed at the terminal ends of the simulated sample. Of course these two quantities must be the same in a steady-state regime, but work is more directly calculated in

MD for any specific kind of adopted force field and implemented thermostat, without the ambiguities reported above for the calculation of the heat flux. In practice, the instantaneous energies injected/extracted by the hot/cold reservoir into/from the system must be computed during the ageing of the system. Their time derivatives have opposite sign and are directly related to the injected J_h^{in} and extracted J_h^{ex} thermal current, respectively. The steady state can be proclaimed when $|J_h^{\text{in}}| = |J_h^{\text{ex}}|$, and it is corresponding set $J_h = |J_h^{\text{in,ex}}|$ to be used in the formula for the Kapitza resistance. The deviation from the asymptotic relative difference $|J_h^{\text{in}} - J_h^{\text{ex}}|/|J_h^{\text{in}}|$ can be usefully adopted for error estimate of the heat current.

Finally, it is possible to design an alternative scheme where it is neither needed to compute microscopically the heat flux nor use thermostats. This second feature is interesting since concerns have been raised about the dependence of the resulting temperature profile upon the kind of heat reservoirs implemented in the MD run (Chen et al. 2012). We can in fact generate the non-equilibrium configuration we are interested in simply by imposing an energy current through the system which generates a nonconstant temperature profile: this simulation protocol is commonly referred to as the "inverse method" (Schelling et al. 2002; Müller-Plathe 1997).

The first way to implement the method consists in starting from a periodic system previously equilibrated at a suitable temperature T^0. Then, by defining two different space regions, hereafter referred to as "hot" and "cold" reservoir, the kinetic energy of any atom there contained is rescaled by the same amount $\pm \Delta e_{\text{kin}}$ during a time interval Δt. The resulting energy (heat) flux imposed to the system is $J_h = \Delta e_{\text{kin}}/2\Sigma \Delta t$, where Σ is the cross section of the simulated system. Eventually, a temperature profile is established, from which the temperature drop at the interface is easily obtained following the methods discussed above. Alternatively, the coldest atom with velocity $\mathbf{v}_{\text{coldest}}$ and hottest atom with velocity $\mathbf{v}_{\text{hottest}}$ are selected, respectively, in the hot and cold reservoir. Their velocities are then swapped. By iterating such a $\mathbf{v}_{\text{coldest}} \leftrightarrow \mathbf{v}_{\text{hottest}}$ swap over a suitable time interval Δt, we effectively impose an energy (heat) flux $J_h = m/2 \sum_{\text{swaps}}(v_{\text{hottest}}^2 - v_{\text{coldest}}^2)/2\Sigma \Delta t$, where m is the atomic mass.

In both cases the steady state can be proclaimed by detecting a stationary temperature profile or by evaluating the work done in the reservoir regions. The Kapitza resistance is eventually calculated by identifying J_h with the energy flux due to rescaling or swapping, while ΔT is evaluated through the Gibbs construction.

6 Conclusion

In this chapter we provided a unified description of the thermal boundary resistance. The most general definition of the problem is realized in the thermodynamics framework, which allows to identify the generalized forces responsible for heat transport and to derive a definition of the thermal boundary resistance as the ratio of temperature gradient and the heat flux passing through the interface. The actual calculation of these quantities can be accomplished adopting two different physical

pictures: the phonon-based picture and the atomistic one. The former, applicable mostly to interfaces between crystalline materials, provides a description of the relevant physical mechanisms in terms of phonons impinging onto the interface and transmission probabilities of their energy. Such a model, although simple and clear, has limited validity (it applies only to crystalline materials and requires quite strong assumptions on the form of the transmission probabilities). As a consequence, it poorly reproduces experimental values. The second approach, based on atomistic simulations, overcomes these limitations by offering a reliable strategy to define the thermal interface in real systems and to properly evaluate heat fluxes and temperature gradients from molecular-dynamics simulations. This strategy has several advantages including the fact that it can be used for all kinds of interfaces, with no constraints imposed on the particular structure of the materials. Although it lacks a clear physical interpretation, it is well suited to study realistic systems and to analyze the effects of imperfections and defects, which are always present in real devices, on the overall thermal transport.

Energy Relaxation and Thermal Transport in Molecules

37

David M. Leitner

Contents

Abstract

The nature of energy relaxation in molecules and its role in mediating thermal conduction through a molecular junction are discussed. In addition to an overview of thermalization in molecules and quantum mechanical effects that influence this process, illustrative examples for alkane chain, perfluoroalkane, and polyethylene glycol (PEG) oligomer junctions are provided over a wide range of temperature. The calculated energy relaxation rates help clarify the scope of applicability of approaches that can be used to predict thermal conduction, e.g., where Fourier's law breaks down and where an approach that neglects energy relaxation and thermalization is suitable, such as one based on a Landauer-like model. Comparison with experimental data, where available, is provided and discussed.

1   Introduction

Energy relaxation and ergodicity in molecules have long fascinated molecular scientists (Uzer 1991; Leitner 2015), in part because of their central role in chemical kinetics (Kuharski et al. 1988; Leitner and Wolynes 2006; Berrios et al. 2013) and molecular spectroscopy (Lehmann et al. 1994; Leitner and Wolynes 1996a; Leitner and Wolynes 1997a; Sibert III and Gruebele 2006) but also due to the many properties dynamics of molecules share with dynamics of other complex systems (Giannoni et al. 1991). In recent years, connections between energy relaxation and thermal transport in molecules have been the focus of much interest. Measurements and molecular simulations reveal that energy relaxation mediates thermal transport across molecular interfaces (Foley et al. 2014; Majumdar et al. 2015). Molecular interfaces have received considerable attention (Cahill et al. 2003, 2014; Segal et al. 2003; Galperin et al. 2007; Kuang and Gezelter 2011; Losego et al. 2012; O'Brien et al. 2012; Lee et al. 2013; Leitner 2013; Luo and Chen 2013; Stocker and Gezelter 2013; Gaskins et al. 2015; Majumdar et al. 2015; Craven and Nitzan 2016; Giri et al. 2016; Segal and Agarwalla 2016; Stocker et al. 2016), due in part to their many potential applications, ranging from nanoscale devices comprising composite materials, to photothermal therapies in the cell (Qin and Bischof 2012), to charge transfer with potential thermoelectric applications (Craven and Nitzan 2016, 2017; Chen et al. 2017).

In this perspective article, we discuss the role of energy relaxation on thermal transport across molecular interfaces, as in Fig. 1, where two substrates bridged by a monolayer junction are depicted. One object, for instance, a gold substrate or nanoparticle, is held at temperature, T_1, and is separated from the thermal bath at T_2, which could be another solid substrate, or a liquid or membrane, by a monolayer at the interface. If local temperature were well defined at the scale of atoms or a few atoms, we could sketch a temperature profile between T_1 and T_2, where for $T_1 > T_2$ we would observe a drop in temperature from the gold to the molecule, across the molecule, and again from the molecule to the outer layer. The boundary resistance between the gold and the outer layer is the sum of these resistances in series. Such a temperature profile is typically produced from the data provided by classical molecular dynamics (MD) simulations, since temperature can always be defined as proportional to the mean square atomic velocity in a classical system. However, local temperature in the molecules between the substrates may be less clear. For local temperature to be well defined, energy relaxation must be rapid, hence the need to clarify the nature and rate of energy relaxation in molecules. Local temperature can be established by inelastic processes, resulting from anharmonic interactions, which redistribute vibrational energy among the vibrational states (Allen and Feldman 1993; Cahill et al. 2003). We focus here on energy relaxation in molecules and its effect on thermal conduction.

In one limit energy relaxation is very rapid, which allows local temperature to be defined on essentially the scale of the atoms in the molecule, a condition for Fourier's heat law to apply. In the other limit, in the absence of thermalization, a
Fig. 1 (**a**) Two thermal baths at different temperature, T_1 and T_2, with perfluorododecane molecules bridging the baths. Red circles indicate bonding between molecules and substrates. quantum mechanical approach based on a Landauer model, which neglects effects of inelastic scattering (Hopkins 2013; Li et al. 2015; Majumdar et al. 2015), may be appropriate for modeling thermal conduction. The Landauer formalism, introduced to quantify electrical conductance in mesoscopic systems (Datta 1995; Li et al. 2017), can be applied to thermal transport through molecules between two leads at different temperature and can accommodate elastic scattering of vibrational quasiparticles, i.e., the vibrational excitations of the molecule akin to phonons in a solid, which carry heat. By examining the extent of thermalization within molecules, we aim to clarify the scope of applicability of Landauer and fully thermalized pictures. The differences in thermal conduction from these two perspectives when one of the objects in Fig. 1 is gold can be quite striking, due to the low Debye temperature of gold relative to the vibrational frequencies of the surrounding layers.

Classical molecular dynamics (MD) simulations can be used to predict thermal conductance across molecular interfaces and the mechanisms that control it. However, in some cases energy relaxation, and its role in thermal conduction, may be exaggerated. This possibility was found in an experimental-computational study of

thermal transport through a molecular interface between two metal leads (Majumdar et al. 2015). The measured interface conduction between two leads, at least one gold, bridged by alkane chain monolayer junctions decreases with increasing mismatch of the vibrational density of states of the metal leads, whereas results of MD simulations indicate an increase over the same range of vibrational density mismatch. The authors suggest (Majumdar et al. 2015) scattering based on anharmonic interactions within the junction is likely exaggerated in the classical simulations, allowing vibrational energy entering from Au (Debye temperature 170 K) to up-convert and transfer to Pd (Debye temperature 275 K), channels apparently not available in the molecular interface probed experimentally (Majumdar et al. 2015).

Energy transport in molecules and effects of energy relaxation on transport are measured by a variety of time-resolved spectroscopies (Botan et al. 2007; Backus et al. 2008a, b, 2009; Rubtsov 2009; Fujii et al. 2014; Hassan et al. 2014; Rubtsova and Rubtsov 2015; Kondoh et al. 2016) and determined by molecular simulations and other computational approaches (Buldum et al. 1999; Leitner 2001a, b, 2002, 2012; Yu and Leitner 2003a, b, 2005; Enright et al. 2006; Enright and Leitner 2005; Ishikura and Yamato 2006; Leitner and Straub 2009; Xu et al. 2013; Agbo et al. 2014; Xu and Leitner 2014; Ishikura et al. 2015; Leitner et al. 2015; Leitner and Pandey 2015a, b; Buchenberg et al. 2016). Thermal conductance across molecular interfaces can be measured by thermo-reflectance (Hopkins 2013) and scanning thermal microscopy (Meier et al. 2014) techniques. For molecules attached to substrates, as in Fig. 1, bonding to the leads has been found to control thermal transport at the interface (Losego et al. 2012; O'Brien et al. 2012). In studies where the molecular length dependence has been examined, resistance within the molecule itself has also been observed to influence the boundary conductance (Gaskins et al. 2015).

Discussion of energy dynamics within a molecular junction is often framed within the limits of ballistic and diffusive, but it is important to clarify processes that give rise to non-ballistic dynamics and thermal resistance. While non-ballistic dynamics and thermal resistance can emerge from elastic and inelastic processes in the molecule, the response of the resistance to change in temperature depends on its origin. Inelastic scattering arises from the anharmonic coupling of the vibrational modes of the molecule, as well as from interactions between the molecule and its environment. Elastic scattering within the molecule arises from its aperiodicity, analogous to transport by diffusion modes of aperiodic materials (Fabian and Allen 1996). Eigenmodes that carry energy diffusively appear to share (Fabian and Allen 1996; Pandey and Leitner 2017a) properties predicted by random matrix theory (Feingold et al. 1989, 1991; Giannoni et al. 1991; Mehta 1991; Wilkinson et al. 1991; Leitner 1993; Leitner et al. 1994). The influence on the resistance of inelastic scattering, which gives rise to thermalization and local temperature and is necessary for Fourier's law, is quite different from effects of elastic scattering, which does not yield thermalization but nevertheless introduces resistance and diffusive vibrational quasiparticle dynamics. We consider the bonding or interaction between the molecule and the leads to which it is coupled to be sufficiently strong that thermal resistance in the junction arises from processes that occur within the

molecule itself, the origin of which may be elastic, inelastic, or both. A major aim of our work is clarifying the origin of thermal resistance.

In this perspective we discuss three classes of molecules: (i) alkane chains, (ii) perfluoroalkane chains, and (iii) polyethylene glycol (PEG) oligomers, which are depicted in Fig. 1. The PEG oligomers we examine here are $HO\text{-}(CH_2CH_2O)_n\text{-}CH_3$, $n = 2$ and 4, which are about 0.8 nm and 1.6 nm in length, respectively. We discuss for these systems thermal conduction and energy relaxation, which gives rise to thermalization in these molecules over a variety of lengths and temperature. At room temperature, and at a modest length of about 2 nm, we find no resistance or thermalization in alkane chains, some resistance but little thermalization in perfluoroalkanes, and significant thermalization and resistance in a PEG oligomer. These molecules thus exhibit significant diversity in thermalization and thermal resistance.

In Sect. 2 we discuss the nature and rate of energy relaxation in molecules, including the possibility of many-body localization (MBL) in the vibrational state space of a molecule, and effects of coupling between the molecule and thermal baths on MBL. In Sect. 3 we summarize two methods for estimating thermal conductance through a molecular junction, applicable in the limits of no energy relaxation and very rapid relaxation. In Sect. 4 we present calculations for alkane chains, perfluoroalkanes, and PEG oligomer junctions to illustrate effects of energy relaxation in molecules on thermal transport across a molecular junction. Section 5 summarizes this perspective.

2 Energy Relaxation in Molecules

Thermalization, the relaxation of vibrational energy in the molecule, occurs by inelastic scattering via anharmonic interactions. One approach to estimate the rate of thermalization quantum mechanically is to adopt first-order time-dependent perturbation theory, or Fermi's golden rule (GR). Because of restrictions on the applicability of the GR approach, however, the GR may break down when applied to the problem of energy relaxation in molecules. In particular, if the product of the local density of vibrational states and the matrix elements that couple them is smaller than order 1, we cannot use the GR to reliably estimate the energy relaxation rate in a molecule. In that case a more general approach is required, and we present such an approach below.

We address first energy relaxation in a molecule that is decoupled from its environment. We write the vibrational Hamiltonian of the molecule as $H = H_0 + V$, where the zero-order Hamiltonian, H_0, is expressed as a sum of the energy in each of the N vibrational modes, i.e., $H_0 = \sum_{\alpha=1}^{N} \varepsilon_\alpha \left(\hat{n}_\alpha\right)$, where α labels a mode, the number operator is defined by $\hat{n}_\alpha = b_\alpha^+ b_\alpha$, b_α^+ and b_α are raising and lowering operators, and ε_α is the energy in mode α. The vibrational modes of the molecule are coupled by anharmonic interactions, V. We take V

to include coupling to third order in the anharmonicity; terms of higher order can be included but typically decrease exponentially in magnitude (Gruebele and Bigwood 1998), and we thus neglect them. The zero-order states are product states labeled by the number of vibrational quanta in each mode. If the molecule, H, is prepared initially in one of the eigenstates of H_0, then energy may be redistributed via the anharmonic interactions, rearranging mode populations until the molecule has thermalized. However, for the isolated molecule, H, regardless of size, energy relaxation may not occur (Logan and Wolynes 1990; Leitner and Wolynes 1996a, b, c; Leitner 2015), even if we were to account for all anharmonic interactions, if the product of the magnitude of the interaction and the density of states coupled by the anharmonic terms is less than order 1. This is an example of a many-body localized (MBL) system (Lev and Reichman 2014; Burin 2015, 2017; Nandkishore and Huse 2015), where an isolated, many-body system cannot thermalize under its own dynamics. MBL has been observed in numerous vibrationally excited polyatomic molecules in the gas phase (Bigwood et al. 1998; Leitner 2015). Effects of MBL in molecules influence rates of chemical reactions (Leitner and Wolynes 1997; Leitner 1999, 2005, 2015; Leitner et al. 2003; Leitner and Gruebele 2008; Keshavamurthy 2013a, b).

As noted, localization occurs if the product of the average anharmonic matrix element and the local density of states coupled by anharmonicity is less than order 1. Detailed analysis leads to the criterion (Leitner 2015):

$$T(E) \equiv \frac{2\pi}{3} \langle |V_{\alpha\beta\gamma}| \rangle^2 \rho^2(E) < 1, \tag{1}$$

where ρ is the local density of states and $\langle |V_{\alpha\beta\gamma}| \rangle$ is the average size of the matrix element coupling the triple of modes α, β, and γ. This criterion emerges from a self-consistent analysis of the distribution of rates at which states on the energy shell relax toward equilibrium. The most probable rate in a large molecule is always 0 when $T < 1$, despite finite coupling between vibrational states due to anharmonic interactions.

It is convenient to separate the interactions between vibrational states into two relaxation processes that can occur while conserving energy. In one process, decay, a quasiparticle in a mode of frequency ω_α, i.e., a vibrational excitation in that mode, decays into two quasiparticles of frequency ω_β and ω_γ. In the other process, collision, a quasiparticle in a mode of frequency ω_α, combines with another of frequency ω_β to create a quasiparticle of frequency ω_γ. The matrix elements are of the form $|V_{\alpha\beta\gamma}| = |\Phi_{\alpha\beta\gamma}| \sqrt{n_\alpha (n_\beta + 1)(n_\gamma + 1)}$ for interactions in a decay process and $|V_{\alpha\beta\gamma}| = |\Phi_{\alpha\beta\gamma}| \sqrt{n_\alpha n_\beta (n_\gamma + 1)}$ for interactions in a collision. $\Phi_{\alpha\beta\gamma}$ are the coefficients of the cubic terms in the expansion of the interatomic potential in normal coordinates. To determine whether an isolated molecule can thermalize under its own dynamics, we need to calculate $T(E)$ by averaging over all states on the energy shell. For a large molecule, most states are occupied very

nearly according to $\langle n_a \rangle = \left(e^{\hbar\omega/k_B T} - 1 \right)^{-1}$, so for n_α we use $\langle n_a \rangle$. Averaging $\left| \Phi_{\alpha\beta\gamma} \right| \sqrt{n_\alpha \left(n_\beta + 1 \right) \left(n_\gamma + 1 \right)}$ and $\left| \Phi_{\alpha\beta\gamma} \right| \sqrt{n_\alpha n_\beta \left(n_\gamma + 1 \right)}$ for resonant coupling, we define $T = T_d + T_c$, where:

$$T_d \left(\omega_\alpha \right) = \frac{2\pi}{3} \langle \left| \Phi_{\alpha\beta\gamma} \right| n_\alpha \left(n_\beta + 1 \right) \left(n_\gamma + 1 \right) \rangle^2 \rho_{res}^2 \left(\omega_\alpha \right) \tag{2a}$$

$$T_c \left(\omega_\alpha \right) = \frac{2\pi}{3} \langle \left| \Phi_{\alpha\beta\gamma} \right| n_\alpha n_\beta \left(n_\gamma + 1 \right) \rangle^2 \rho_{res}^2 \left(\omega_\alpha \right). \tag{2b}$$

Finally, we average over the modes at a given temperature (internal energy):

$$T \left(\mathrm{T} \right) = Q^{-1} \sum_\alpha T \left(\omega_\alpha \right) e^{-\hbar\omega/k_B \mathrm{T}}, \tag{3}$$

where Q is the partition function.

We calculate the rate of thermalization as the thermal average of the most probable energy relaxation rate for each of the modes of the molecule. To determine the most probable rate, we begin with the average relaxation rate for excess energy in a mode, which can be estimated with the GR to third order in anharmonicity. Relaxation then has decay and collision contributions with rates W_d and W_c, respectively. For a vibrational mode α with frequency ω_α and excess vibrational excitation, the average rate can be written as $W_{ave} = W_d + W_c$, where (Maradudin and Fein 1962):

$$W_d \left(\omega_\alpha \right) = \frac{\hbar}{16\omega_\alpha} \sum_{\beta,\gamma} \frac{\left| \Phi_{\alpha\beta\gamma} \right|^2 \left(1 + n_\beta + n_\gamma \right)}{\omega_\beta \omega_\gamma} \frac{\left(\Gamma_\alpha + \Gamma_\beta + \Gamma_\gamma \right)}{\left(\omega_\alpha - \omega_\beta - \omega_\gamma \right)^2 + \left(\Gamma_\alpha + \Gamma_\beta + \Gamma_\gamma \right)^2 / 4}, \tag{4a}$$

$$W_d \left(\omega_\alpha \right) = \frac{\hbar}{8\omega_\alpha} \sum_{\beta,\gamma} \frac{\left| \Phi_{\alpha\beta\gamma} \right|^2 \left(n_\beta - n_\gamma \right)}{\omega_\beta \omega_\gamma} \frac{\left(\Gamma_\alpha + \Gamma_\beta + \Gamma_\gamma \right)}{\left(\omega_\alpha + \omega_\beta - \omega_\gamma \right)^2 + \left(\Gamma_\alpha + \Gamma_\beta + \Gamma_\gamma \right)^2 / 4}. \tag{4b}$$

Γ_β is the rate at which a vibrational excitation in mode β relaxes due to coupling to other modes and to the environment, n_α is the population, and $\Phi_{\alpha\beta\gamma}$ the coefficients of the cubic terms in the expansion of the interatomic potential in normal coordinates. For most vibrational modes of large molecules, Γ_β is of the order 1 ps^{-1} (Leitner 2008). For a large molecule often $(\omega_\alpha - \omega_\beta - \omega_\gamma)^2 < (\Gamma_\alpha + \Gamma_\beta + \Gamma_\gamma)^2/4$, i.e., the spacing between resonances is typically much smaller than the line width, and in practice the GR rate does not depend much on the value of Γ_β. We have used 1 ps^{-1} for each Γ_β in calculations, as in previous calculations for large

molecules (Stuchebrukhov 1986; Stuchebrukhov and Marcus 1993; Leitner 2012), and checked that the GR value remains essentially unchanged upon varying this value. However, for some molecules this condition may not be met, as we now consider.

If T is significantly larger than 1, the average relaxation rate calculated with the GR goes over to the most probable relaxation rate (Leitner 2015). However, near the MBL transition, the most probable rate is smaller than the average rate, meeting it only at large T. Correcting for the effects of a finite local density of states in the molecule, the most probable relaxation rate becomes (Leitner 2015):

$$W_d^{mp}\left(\omega_\alpha\right) = W_d\left(\omega_\alpha\right)\left(1 - T^{-1}\left(\omega_\alpha\right)\right)^{1/2}, T \geq 1 \tag{5a}$$

$$W_c^{mp}\left(\omega_\alpha\right) = W_c\left(\omega_\alpha\right)\left(1 - T^{-1}\left(\omega_\alpha\right)\right)^{1/2}, T \geq 1 \tag{5b}$$

We take a thermal average of the rates:

$$W\left(\mathrm{T}\right) = Q^{-1}\sum_\alpha \left(W_c^{mp}\left(\omega_\alpha\right) + W_d^{mp}\left(\omega_\alpha\right)\right)e^{-\hbar\omega/k_B\mathrm{T}}. \tag{6}$$

We use the transition rates given by Eqs. (5) and (6) to estimate the relaxation rate in molecules that form a thermal bridge between two substrates when $T > 1$.

A molecule at the interface between two substrates, as depicted in Fig. 1, is of course not isolated but is coupled to thermal baths. The molecular eigenstates are thus not localized, but the rate of thermalization is nevertheless reduced if the isolated molecule exhibits MBL. Even when the molecule is not isolated, the most probable rate at which excess vibrational energy in a mode relaxes toward equilibrium remains in practice slow if $T < 1$. We account for energy transfer to and from the thermal baths, assuming vibrational quasiparticles enter and leave the molecule in steady state.

MBL is lost as a result of dephasing (Leitner 2015) due to coupling between the molecule at the junction and its environment. We calculate the dephasing rate, η, using a ballistic transport time as an upper estimate; if there is elastic scattering, the time for a quasiparticle that has entered the molecule to leave it will be longer and η smaller. Using the larger, ballistic estimate has very little practical effect on the rate of thermalization, which is generally small if $T < 1$ (Pandey and Leitner 2016). The ballistic transport time is estimated as the ratio of the speed of sound in the molecule at the junction and the length of the molecule. For the three classes of molecules we consider here, alkanes, perfluoroalkanes, and PEG oligomers, the speed of sound has been calculated to be 1768 ms^{-1}, 641 ms^{-1} and 833 ms^{-1}, respectively (Pandey and Leitner 2016, 2017b).

Calculation of the effects of dephasing on thermalization within molecules is carried out as follows: For convenience we define dimensionless variables, $\overline{W}_{mp}(E)$ and $\overline{\eta}$, as

$$\overline{W}_{mp}(E) = W_{mp}(E)/W_{ave}(E) \tag{7a}$$

$$\overline{\eta}(E) = \eta(E)/W_{ave}(E) \tag{7b}$$

Solving for $\overline{\eta}$ we have (Leitner 2015):

$$\overline{\eta}(E) = \frac{\left(1 \pm \left[1 - 4T^{-1}(E)\overline{W}_{mp}^2(E)\right]^{1/2}\right)}{2\overline{W}_{mp}(E)} - \overline{W}_{mp}(E) \tag{8}$$

Since both $\Delta'_{mp}(E)$ and $\overline{\eta}$ are real and nonnegative, when $0 \le T \le 2$ and if $0 \le \overline{\eta} \le \eta_{max} = [2-T]/2T^{1/2}$, we choose the negative sign, while for $\overline{\eta} \ge \eta_{max}$ we choose the positive sign. For $T \ge 2$ only the positive sign is correct.

3   Thermal Conductance in Limits of Slow and Rapid Energy Relaxation

We illustrate the impact of energy relaxation in molecules on thermal conduction through a molecular interface by comparing two limits, one in which energy relaxation is severely restricted or so slow as to have no effect on thermal conduction and the other where it is so rapid that local temperature is well defined within the molecule. We consider the former case first and then turn to the latter.

3.1   No Thermalization: Landauer Model

Consider the thermal boundary conductance, h_{Bd}, between two materials, the inverse of the thermal boundary resistance or Kapitza resistance. (Swartz and Pohl 1989) is expressed in terms of the heat flow, $\dot{Q}$, driven by the difference in temperature, ΔT, between the two sides of the interface, and the area of the interface, A:

$$h_{Bd} = \frac{\dot{Q}}{A\Delta T} \tag{9}$$

Let the temperature on one side of the molecule be T_1 and the other T_2. The boundary conductance can be expressed (Swartz and Pohl 1989) in terms of the gross rate of heat flow from one side, say the left, L, to the other, R:

$$h_{Bd} = \frac{\dot{Q}_{L \to R}^{gross}(T_2) - \dot{Q}_{L \to R}^{gross}(T_1)}{A(T_2 - T_1)} \tag{10}$$

Thermal transport through the molecules at the interface can be expressed in terms of the quasiparticles, e.g., phonons in a solid, with energy $\hbar\omega$. The vibrational mode density per unit volume on side j is $\overline{\rho}_j(\omega)$; the mode occupation number is $n(\omega, T) = (\exp(\beta\hbar\omega) - 1)^{-1}$, where $\beta = 1/k_B T$; and the phonon speed on side j is $v_j(\omega)$. In the limit $T_2 = T_1 + dT$:

$$h_{Bd} = \frac{1}{A}\frac{d}{dT}\dot{Q}_{L \to R}^{gross} = \frac{1}{4}\frac{d}{dT}\int d\omega \, v_L \overline{\rho}_L(\omega) \; \hbar\omega \, n(\omega) \; \tau(\omega), \tag{11}$$

where τ is the transmission coefficient. In Eq. (11), the factor ¼ accounts for all incident angles of vibrational quasiparticles striking the interface (Swartz and Pohl 1989). Equation (11) is the thermal boundary conductance predicted by the diffuse mismatch model (DMM) (Swartz and Pohl 1989).

One contribution to the transmission coefficient, τ_0, accounts for detailed balance between the left and right sides of the interface:

$$\tau_0(\omega) = \frac{v_R \overline{\rho}_R(\omega)}{v_L \overline{\rho}_L(\omega) + v_R \overline{\rho}_R(\omega)} \tag{12}$$

Another contribution accounts for scattering within the molecules. Let l be the mean free path and L the length of the molecule. If upon scattering the vibrational excitation reverses direction 50% of the time and otherwise continues in the same direction, and if we neglect interference effects, the transmission coefficient, τ, is given by:

$$\tau(\omega) = \frac{\tau_0(\omega)}{1 + (L/l)\,\tau_0(\omega)}. \tag{13}$$

In the absence of inelastic processes, the integral in Eq. (11) is taken from 0 to the lower Debye frequency, ω_D, of the materials at each side of the interface. In general the mean free path, l, depends on temperature, but if we neglect that dependence, then only n in Eq. (11) is temperature-dependent and $\hbar\omega\frac{dn}{dT}$ is the heat capacity, $C(\omega)$. We write the thermal boundary conductance as

$$h_{Bd} = B \int d\omega \, v_L \overline{\rho}_L(\omega) \; C(\omega) \; \tau(\omega). \tag{14}$$

In Eq. (14) an additional factor, B, appears, which includes the factor of $1/4$ in Eq. (11) and allows, e.g., for incomplete surface contact, though for the examples illustrated here, we simply fit B to experimental data. It is convenient to adopt a Debye model for the phonon densities in Eqs. (11), (12), and (14). In that case we use for the mode density $\overline{\rho}(\omega) = \frac{3\omega^2}{2\pi^2 v^3}$, where we take one representative value for the speed of sound, v, for simplicity.

While we started with the DMM, we refer to Eq. (14) as a Landauer model to emphasize the absence of inelastic scattering through the junction and to permit elastic scattering, with scattering length, l, within each molecule, analogous to the treatment of the mean free path of an electron in a conductor (Datta 1995). The more standard form for the Landauer expression for thermal conductance is $\frac{1}{4\pi} \int d\omega \; \hbar\omega \frac{\partial n(\omega,T)}{\partial T} \overline{\tau}(\omega)$ (Dhar 2008; Wang et al. 2008; Duchemin and Donadio 2011), where the transmission coefficient is $\overline{\tau}(\omega)$, and can be related to Eq. (14) by $\overline{\tau}(\omega) = 4\pi B v_L \overline{\rho}_L(\omega) \; C(\omega) \; \tau(\omega)$. Thermal conduction using a Landauer expression may be calculated more directly, without separately estimating the mean free path in harmonic approximation, using methods based on the nonequilibrium Green's function formalism described by Dhar (2008), Wang et al. (2008), Duchemin and Donadio (2011), and Buerkle et al. (2015).

3.2   Rapid Thermalization: Series Model

If the Landauer approach neglects energy relaxation altogether, the other extreme is energy relaxation that is so rapid that temperature is well defined on the scale of an atom or a few atoms. If local temperature is well defined, we can calculate the resistance across the junction using a series model:

$$1/h_{Bd} = 1/h_{Bd}^{L-mol} + 1/h_{Bd}^{R-mol} + 1/h_{mol}, \tag{15}$$

where $1/h_{mol}$ is the thermal resistance within the molecule and $1/h_{Bd}^{L-mol}$ and $1/h_{Bd}^{R-mol}$ are, respectively, thermal resistance between the left substrate and the molecule and right substrate and molecule.

For the purpose of comparing results of a series model with those of a Landauer-like model, we simply estimate the conductance of the molecule in Eq. (15) in the limit where local temperature is well defined as

$$h_{mol} = \frac{1}{VL} D \sum_{\alpha} C_{\alpha}, \tag{16}$$

where α labels a vibrational mode of the molecule; the sum is taken over all modes; D is the coefficient for energy diffusion, taken as independent of mode frequency for simplicity; and V is the volume of the molecule. While the volume is somewhat arbitrary (Wu et al. 2017), we estimate it in a way that matches the Landauer formalism in the limit of low temperature, as it must.

The resistance through the molecule, $1/h_{mol}$, dominates the resistance in the junction when the junction is long. In general, $1/h_{Bd}^{L-mol}$ and $1/h_{Bd}^{R-mol}$ need to be evaluated, which we have done using Eq. (14) for convenience, though of course a more precise approach would account for the discrete modes of the molecule. The contributions of $1/h_{Bd}^{L-mol}$ and $1/h_{Bd}^{R-mol}$ to the thermal conductance are relatively small in the illustrative calculations we present in the following section.

4   Thermalization Rates in Molecules: Alkanes, Perfluoroalkanes, and PEG Oligomers

We consider first whether or not the molecules exhibit MBL when they are separated from the substrates. The vibrational states of a molecular junction cannot be localized because of contact with heat baths. However, if the states of the same molecule in isolation are localized, the rate of thermalization is predicted by Eq. (8), rather than the GR, and is in practice very small. We thus begin by evaluating the transition parameter, T, defined by Eqs. (2) and (3).

Values of T for hexane, dodecane, perfluorohexane, perfluorododecane, PEG_2, and PEG_4 are plotted in Fig. 2a at internal energies corresponding to temperatures from 100 to 400 K. The indicated temperature is the value used in the thermal averaging in Eq. (3). At 100 K all lie below or near $T = 1$, so that most of these molecules exhibit effects of MBL at low temperature. At 200 K the alkanes still exhibit MBL, but the longer perfluoroalkane and PEG_4 do not. By 300 K we find $T < 1$ only for hexane. Overall, the thresholds differ among these systems because of differences in the local density of states of the molecules, which becomes somewhat larger as the molecule becomes larger for these cases or becomes larger with addition of fluorine.

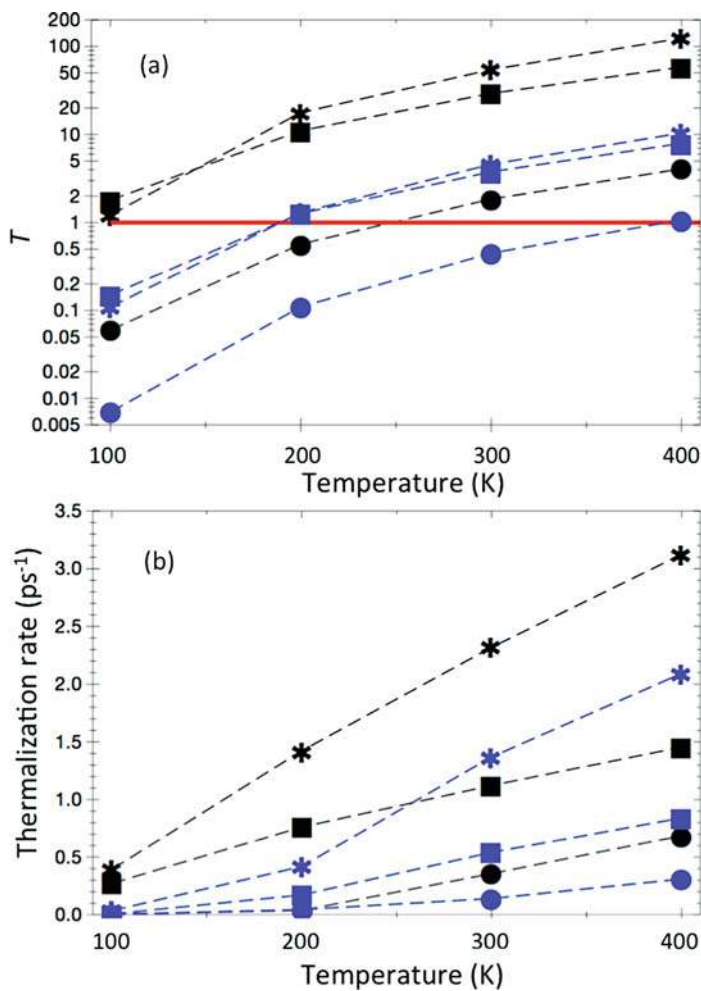
Using the values of T plotted in Fig. 2a, we have calculated the most probable relaxation rates with Eqs. (4), (5), and (6), where $T > 1$, and with Eqs. (7) and (8) where $T < 1$. The thermalization time may of course exceed the relaxation time for excess energy in a mode, but we expect the rates to be similar if T_1 and T_2, the temperatures of the substrates, are close, i.e., the linear response regime. We observe overall that the thermalization rates in the smaller molecules of a particular class appear to be slower than the larger molecules of that class. The variation of the thermalization rate with temperature for the smaller molecules is highly nonlinear, the result of effects of small T for those molecules, particularly at low temperature, yielding very small rates at those temperatures. At 300 K the thermalization rates are slowest for alkane chains, then for PEG oligomers, and fastest for the perfluoroalkanes. For example, at 300 K the thermalization rate for the larger alkane chain, $C_{12}H_{26}$, was calculated to be 0.7 ps^{-1}, slower than the


Fig. 2 (**a**) Transition parameter, T, plotted against temperature for alkanes (circles), perfluoroalkanes (squares), and PEG oligomers (*). Hexane, perfluorohexane, and PEG$_2$ are blue, and dodecane, perfluorododecane, and PEG$_4$ are black. The MBL threshold, $T = 1$, is shown as the red line. (**b**) Thermalization rate is plotted against temperature for the same systems

rate, 1.5 ps^{-1}, found for the larger PEG oligomer, and much slower than the rate of 3.1 ps^{-1} for perfluorododecane.

4.1   Thermalization Length

We refer to the thermalization length as the length in the molecule over which thermalization occurs. This length depends on the speed at which vibrational energy

propagates. We estimate the thermalization length as the ratio of the speed of sound along the molecule and the thermally averaged relaxation rate. For the molecules we consider here, alkanes, perfluoroalkanes, and PEG oligomers, we have noted the speed of sound obtained in earlier computational work (Pandey and Leitner 2017a) as 1768 ms^{-1}, 641 ms^{-1}, and 833 ms^{-1}, respectively. Using these speeds and the values of the thermalization rates plotted in Fig. 2, we have calculated the length over which thermalization occurs for PEG$_4$, perfluorododecane, and dodecane, which we plot in Fig. 3.

We also plot the result for pentadecane, where the effects of MBL on the most probable rate of thermalization are not included, i.e., we simply use the GR estimate for the energy relaxation rate. This is referred to in Fig. 3 as a long alkane, for which we expect effects of MBL on thermalization rates to be negligible. It is instructive to compare this result with the result for dodecane, since in the latter we find a substantial difference between the thermalization rate predicted by the GR and the actual thermalization rate, particularly at lower temperature. This gives rise to a sizable difference between the length over which thermalization occurs in dodecane at, say, 300 K, which is about 10 nm, and a long alkane, which is 5 nm. For PEG oligomers we have found that thermalization in PEG$_4$ is representative of that in a longer oligomer, and we find for this molecule and for longer perfluoroalkanes a thermalization length that is below 1 nm at 300 K.

Perfluoroalkanes and PEG oligomers also exhibit elastic scattering. We calculated the energy diffusion coefficient in harmonic approximation by propagating wave packets in terms of the normal modes for these molecules and found for perfluoroalkanes an energy diffusion coefficient of $D = 17.7$ Å^2 ps^{-1}, whereas
Fig. 3 Scattering length in PEG$_4$ (*), perfluorohexane (squares), a long alkane (gray circles), and dodecane (black circles) is plotted from 100 to 400 K. The mean free path for elastic scattering in PEG oligomers (blue line) and perfluoroalkanes (red line) is also plotted

for the PEG oligomers, we found $D = 30.0$ Å^2 ps^{-1} (Pandey and Leitner 2017b). The mean free path in these quasi-one-dimensional systems is given by $2D/v$. For perfluoroalkanes and PEG oligomers, the speed of sound is $v = 6.41$ Å ps^{-1} and $v = 8.33$ Å ps^{-1}, respectively, yielding, respectively, a mean free path for elastic scattering of 5.5 Å and 7.2 Å. We note that no elastic scattering was found for alkane chains up to at least C$_{15}$H$_{32}$.

4.2   Thermal Conduction

The results of the energy relaxation calculations help us assess which picture is appropriate for describing thermal conduction, one in which a vibrational quasiparticle travels across the molecule without thermalizing or one in which thermalization occurs over the length of a few atoms within the molecule. This picture, in turn, points us to the appropriate method to calculate thermal conductance across a molecular interface. For molecular junctions of about 2 nm, alkanes and fluorinated alkanes are not sufficiently thermalized, at least to about 400 K, to be able to apply a series model such as Eq. (15). In this case, a Landauer-like approach, which neglects thermalization, should provide a good estimate to the thermal conductance. We shall take this approach for those molecules and compare with experimental measurements of thermal conductance through similar molecules between gold and sapphire carried out by Hopkins and coworkers (Gaskins et al. 2015). However, we have seen that energy relaxation in PEG oligomers of comparable length ($n = 4$ or longer) occurs more rapidly. We therefore expect a Landauer approach, which does not capture this, to be of more questionable utility in predicting the thermal conductance. We thus compare the result of a Landauer model prediction and a resistance in series prediction for the thermal conductance between gold and sapphire.

To compare the predictions for alkanes and perfluoroalkanes with the measurements reported by Gaskins et al. (2015), we use Eq. (14) with a $L = 2$ nm perfluorinated alkane, the junction length in the experiments (Gaskins et al. 2015), and we use the mean free path $l = 0.55$ nm found in the elastic scattering calculation discussed above. A value of $B = 0.21$ was used, as this fits the measured data over a wide range of temperature. In Fig. 4 we plot the thermal conductance from Au to sapphire with a molecular layer of alkanes and a molecular layer of perfluoroalkanes between them, at 100 K, 200 K, 300 K, and 400 K. We observe in Fig. 4 good agreement with experiment. The calculated elastic mean free path introduced into the Landauer model appears to describe well the effect of fluorination on thermal transport in the molecular layer.

Turning to the Au-PEG$_4$-sapphire system, we again begin with the Landauer model in Eq. (14). We use for the speed of sound in sapphire 7229 m s^{-1} (Gaskins et al. 2015). The length of PEG$_4$ is about $L = 1.6$ nm and the mean free path plotted above is $l = 0.77$ nm. We plot the results in Fig. 4. We compare the results using the Landauer model with results calculated using the resistors-in-series model,
Fig. 4 Calculations of thermal conductance between Au and sapphire bridged by alkanes and perfluoroalkanes (red) and PEG oligomers (black) for temperatures from 100 to 400 K. A Landauer model is used with calculated elastic scattering length for the alkanes (dashed) and perfluoroalkanes (solid) and for PEG$_4$ (solid). A series model is also used for PEG$_4$ (dot-dashed) for comparison. Experimental results from Gaskins et al. (2015) are plotted (Au-sapphire red circles, closed and open, respectively, for carbon-chain interfaces that are fluorinated and not fluorinated) with reported error bars

where for the latter we introduce a cross-sectional area of 0.13 nm^2 so that the two calculations meet at low temperature.

We observe a striking difference in the temperature dependence of the thermal conductance produced by the Landauer and resistors-in-series pictures. Thermalization increases thermal conduction as additional transport channels are opened up by anharmonic interactions within the molecules at the interface, particularly at higher temperature. Because of those channels, phonons from gold that enter the molecule can up-convert and the resulting vibrational energy transferred to sapphire, a pathway that is unavailable in the absence of thermalization.

Enhancement of thermal conduction from one material to another via a molecular layer has been observed in other molecular simulations of heat transport. Thermal transport from gold to an organic solvent via an organic capping agent was found to be enhanced compared to thermal conduction across the gold-organic solvent interface in the results of MD simulations (Kuang and Gezelter 2011). The capping agent provides a bridge between gold vibrations and the surrounding liquid (Kuang and Gezelter 2011), which can result when vibrational energy is thermalized in the capping agent, facilitating thermal transport.

Some studies have compared results of calculations of thermal conductance in molecular junctions using a Landauer picture with the results of MD simulations as a check on the assumption that, over the length of the junction, thermalization effects on thermal conduction in the molecule are likely small. For example, a recent computational study using both a nonequilibrium Green's function approach (Buerkle et al. 2015) and nonequilibrium MD simulations of thermal transport in a

polyethylene junction (Buerkle and Asai 2017) found good agreement between the two calculations over a wide range of temperature, including room temperature, suggesting thermalization is likely negligible in this case. MD simulations have in other cases been found to exaggerate the role of anharmonicity, as discussed above. We thus prefer to calculate the rate of thermalization quantum mechanically as a check on the validity of a Landauer-like picture, where diffusive transport and thermal resistance may still arise by elastic scattering, but where the response to temperature change is quite different than if anharmonic effects were important.

5   Conclusions

In this perspective we have discussed the role energy relaxation plays in mediating thermal transport through molecular junctions. We have discussed energy relaxation in molecules, which arises from anharmonic interactions among the vibrational modes of the molecule, as well as from interactions between the molecule and its surroundings. Rapid energy relaxation is essential for local temperature to be established in a molecule, a condition that we have seen is often not met on the molecular scale. For that reason, approaches that neglect inelastic scattering within the molecule often predict thermal conductance in molecular junctions quite well. However, for many molecules, particularly of increasing length, complexity, and at room temperature or higher, inelastic scattering via anharmonic interactions is sufficiently rapid that it must be taken into account. We have summarized a general formalism for calculating the rate of energy relaxation via anharmonic interactions in a molecule, which includes the golden rule as a special case. In some molecules, even rather large ones, quantum mechanical effects can reduce the rate of relaxation below that predicted by the golden rule. We considered three classes of molecules, alkane and perfluoroalkane chains and PEG oligomers. Alkane chains, in particular, exhibit quantum mechanical effects that severely limit the rate of energy relaxation.

PEG oligomers exhibit the most rapid thermalization among these groups. While alkane chains thermalize over 10s or 100 s of nm, depending on temperature, perfluoroalkanes thermalize over shorter lengths on the order of 1 nm, and for PEG oligomers temperature is well defined over a few atoms at most temperatures of interest. Because thermalization is relatively rapid in PEG oligomers, molecular modeling methods that use temperature profiles to predict thermal boundary conductance for these systems should work well. That stands in contrast to alkane chains, where artifacts from the lack of thermalization in these systems have been found when using classical MD simulations to predict thermal conductance (Majumdar et al. 2015).

When thermalization in a junction is absent or occurs slowly, a Landauer model can be adopted to predict thermal transport through the junction. If there are vibrational modes of the molecule that are higher in frequency than those of the leads, they are not available as additional channels for vibrational energy transport. In this case, the increasing vibrational mismatch between two leads yields a smaller thermal conduction that cannot be remedied by a molecular interface between them, as has been observed for alkane chain junctions (Majumdar et al. 2015).

If thermalization occurs we expect the mismatch effect to be diminished and the temperature dependence of the conductance to be more pronounced. Indeed, we have illustrated how thermalization within a molecular junction can facilitate thermal transport by opening channels for vibrational energy to transfer to the leads.

A Statistical Approach of Thermal Transport at Nanoscales: From Solid-State to Biological Applications

38

Yann Chalopin

Contents

Abstract

This collection of materials has been articulated to illustrate the idea that observing equilibrium short-scale processes and performing statistical measures through correlations contribute a great deal to revealing macroscopic thermal properties of condensed matter. The questions addressed here arise from a change of paradigm as soon as one comes to describe a system response at a scale shorter than the characteristic lengths of its underlying microscopic phenomena.

e-mail: yann.chalopin@centralesupelec.fr

We restrict our analysis here to nanoscale heat transport by conduction or radiation and to a lesser extent in liquid and soft materials. A description of the mechanisms of phonon transmission at solid-state constrictions (or interfaces) is introduced. Infrared absorption in dielectric nano-objects is next discussed as well as a calculation of the absorption spectra in cellular membranes. Finally, the Brownian relaxation of magnetic nanoparticles is revisited in the light of accounting for long-range dipolar interactions.

1   A Brief Historical Review

As it is frequently the case in physical sciences, early developments come from experimental breakthroughs. Despite it was not a single man's contribution, the mercury thermometer can be considered as the first modern "device" capable to measure a quantity of energy: the temperature. Interestingly, the underlying concept of mean-free-path, which nowadays remains essential to formulate a microscopic description of transport phenomena, was first introduced by Clausius in 1857. In the middle of the nineteenth century, one realized that light would also allow a form of heat transfer, according to Kirchhoff and its formulation of emission and absorption of radiation, and shed the light, *Ex tempore* onto the concept of "black body." In a slightly different field, Einstein and Langevin discovered, respectively, the Brownian motion (1905) and the stochastic equation (1900), which are central in many areas of current research. Finally, Ritov (1959) did an important theoretical step forward by describing the structure of the radiation spectrum as being related to microscopic fluctuations of its current sources. Although this historical introduction remains shallow, it brings up most of the core concepts commonly discussed in this chapter: (1) Conduction occurs in solids and appears in the form of microscopic vibrations (the phonons). (2) Convection/diffusion in a gas or in a fluid corresponds to momentum exchanges in collisions between atoms and molecules. (3) Thermal radiation allows heat exchanges by photons between distant objects. These three modes of energy transfer are triggered by microscopic carriers that exhibit themselves characteristic time and length scales. Based on this very broad set, an important idea of this chapter is simply to demonstrate that observing the time fluctuations of such carriers (e.g., charge density, phonons, molecules) allows to predict the susceptibilities of these systems (and more specifically the dissipation properties). In this respect, we first introduce an atomistic formulation of the phonon conductance and transmission, to deal with heat transfer at molecular interfaces. To complement our approach, we present how infrared absorption in confined dielectrics can be calculated using molecular dynamics simulations. In both of these examples, we discuss the advantage of an atomistic formulation to unveil microscopic effects neglected when considering macroscopic properties. We next illustrate how such technics can be applied to nano-objects of biological relevance. We discuss the thermal properties of lipid bilayers which correspond to a model of a cellular membrane. Also, we address the problem of estimating thermal heat by coupled magnetic nanoparticle in a cellular (liquid) environment.

The practical application behind these topics is cancer hyperthermia, which of course encompasses many other areas of research.

2   Transport at Phonon Interfaces and Conductance in Nano-objects

Thermal properties of nanostructures are strongly influenced by phonon scattering at boundaries and interfaces (Carey et al. 2008; Cahill et al. 2003). Consequently, in recent years, interfacial thermal transport has become a major subject of interest with regard to two important technological applications, namely: thermoelectric materials development (Gao et al. 2010) and microelectronics thermal management. At the present stage of the physical understanding, two other key questions remain concerning heat conduction in materials with interfaces: what is the contribution of interfacial scattering compared to that of internal scattering in thick layer systems, and what are the mechanism of transmission and recombination of the vibrational modes at the contact?

2.1   A General Equilibrium Formulation of the Phonon Conductance at Molecular Interfaces

Thermal conductance at the nanoscale is extensively studied by various numerical approaches such as the Boltzmann transport equation, molecular dynamics (MD) simulations, or the atomistic Green's function (AGF) method (Mingo and Yang 2003; Zhang et al. 2007a, b) also referred as nonequilibrium Green's function (NEGF). As reported in the literature (Zhang et al. 2011; Schelling et al. 2002; Becker et al. 2006; Panzer et al. 2008; Ong et al. 2010), thermal conductance predictions based on MD simulations rely on a nonequilibrium procedure where a constant heat flux is fixed across the junction. From these considerations, we propose a formulation for calculating thermal conductance of any type of interfaces using an equilibrium approach analog to the well-known Green-Kubo (GK) method (Kubo et al. 1985) for thermal conductivity (Allen et al. 1987). We illustrate our technique on perfect Si/Ge superlattices and compared to experimental works.

2.1.1   Equilibrium Approach for Thermal Conductance Across an Interface

Let us assume two systems A and B exchanging energy and initially set at the same equilibrium temperature. The total Hamiltonian at equilibrium can be written as $H = H_A + H_B$, H_A and H_B being defined from a local energy at each atomic site as follows:

$$H_{A/B} = \sum_{i \in A/B} h_i = \sum_{i \in A/B} \frac{p_i^2}{2m_i} + V_i \qquad (1)$$

where p_i and m_i refer to the atom i momentum and mass. In the case of pair potential interactions, $V_i = \sum_{j \neq i} V(r_i - r_j)/2$, and half of the interaction belongs to H_A and to H_B. To obtain the interfacial thermal conductance, we use the linear response formalism (Pottier et al. 1999) where an infinitesimally small temperature difference is applied between the two systems A and B. $\Delta T = T_B - T_A$ is sufficiently small such that temperatures T_A and T_B in systems A and B are uniform. A and B are considered as thermal reservoirs. The static response function χ_o to the applied static temperature difference is defined by $<Q> = \chi_o \Delta T$, and taking the parameter $\lambda = 0$ provides the relationship between the static response and (*equal-time*) correlations in the system:

$$\chi_o = \frac{< Q H_B >}{k_B T^2} \tag{2}$$

Setting $Q = \dot{H}_A$ allows to find the rate of heat added to the subsystem *A* per unit time when a temperature difference ΔT is applied between A and B. The definition of the thermal conductance $\mathcal{G}$ is:

$$\frac{d < H_A >}{dt} = \mathcal{G} \Delta T \tag{3}$$

Using Eq. (2) obtains:

$$\mathcal{G} = \frac{1}{k_B T^2} < \frac{d H_A(t)}{dt} H_B(t) > . \tag{4}$$

2.1.2   Use of Equations of Motion to Compute $\mathcal{G}$

The Hamiltonian equations of motion can be used to obtain the time derivative of H_A:

$$\frac{d H_A(t)}{dt} = \sum_{i \in A \cup B} \left(\frac{\partial H_A}{\partial p_i} \cdot \dot{p}_i + \frac{\partial H_A}{\partial q_i} \cdot \dot{q}_i \right)$$

$$\dot{p}_i \equiv -\frac{\partial H}{\partial q_i} = F_i^A + F_i^B \tag{5}$$

$$\dot{q}_i \equiv \frac{\partial H}{\partial p_i} = \frac{p_i}{m_i} = v_i \tag{6}$$

$$\frac{\partial H_A}{\partial q_i} = -\left(F_i^A + \frac{1}{2} F_i^B \right) \text{ for } i \in A \tag{7}$$

$$\frac{\partial H_A}{\partial q_i} = -\frac{1}{2} F_i^A \text{ for } i \in B \tag{8}$$

F_i^S being the force from the side S on atom i. We include half of the $A - B$ interaction energy in H_A and the other half in H_B. Hence,

$$\frac{dH_A(t)}{dt} = \frac{1}{2}\left[\sum_{i \in A} v_i \cdot F_i^B - \sum_{j \in B} F_j^A \cdot v_j\right] \tag{9}$$

which corresponds to the net power (or heat flux) exchanged by system A. We can also derive a more familiar-looking formula by considering $H_B(t) = \int_{-\infty}^{t} \dot{H}_B(t')\,dt'$. The thermal conductance can be expressed as a time integral over the dissipated power correlator:

$$\mathcal{G} = \frac{1}{k_B T^2} \int_{-\infty}^{t} < \dot{H}_A(t)\dot{H}_B(t') > \, dt' \tag{10}$$

$$= \frac{1}{k_B T^2} \int_{0}^{\infty} < \dot{H}_A(\tau)\dot{H}_A(0) > \, d\tau \tag{11}$$

which looks like the usual GK formula.

Figures 1 and 2 illustrate our methodology by reporting autocorrelation function and the thermal conductance obtained for a $5 \times 5 \times 40$ Si/Ge superlattice at 440 K using the Stillinger-Weber potential (Stillinger and Weber 1985). Based on the assumption that the transport is ballistic within a period, interface scattering is predominant in Si/Ge, and the thermal conductivity of the superlattices is obtained by using the relation:

$$\lambda = GL/2, \tag{12}$$

Fig. 1 Net heat flux autocorrelation function at 440 K. Inset shows a zoom of the 0–2 ps time interval
Fig. 2 First and second
neighbor contributions to the
thermal conductance of a
Si/Ge junction at 440 K
Fig. 3 Green's function
calculation at a single Si/Ge
interface (Zhang et al. 2007c)
(Green). Computed and
measured (Lee et al. 1997;
Borca et al. 2000) interface
thermal resistance as a
function of the period
where G is the thermal conductance calculated by MD, L being the superlattice
period, and λ its corresponding thermal conductivity (Fig. 3).

It can be seen that above a critical thickness, phonon transport in the superlattice
becomes strongly impacted by the defects included during the growing/deposition
process in the fabrication step. This additional effect has not been included in MD
simulations, and the trend of the thickness dependence can no longer be compared

with experiments. EMD provides in this case only a good estimation of the order of magnitude of the thermal boundary resistance. The next part of this note is devoted to extend this formulation with a frequency dependence.

2.2   Spectral Conductance: An Equilibrium Approach

This section presents an approach for estimating the frequency vs. wave-vector-dependent phonon transmission across a solid-solid interface. We show that the spectral properties of the heat flux can be generally deduced from the equilibrium displacement fluctuations of the contact atoms. We have applied and demonstrated our formalism with molecular dynamics simulations to predict the angular and mode-dependent transmission. We first carry the study to the case of semiconductor interfaces (silicon and germanium thin films).

2.2.1   Derivation

To express the frequency and wave-vector-dependent phonon transmission, we start from the expression of the heat flux obtained from the Hamiltonian equation of motion (Chalopin et al. 2012b) of two interacting phonon systems whose Hamiltonians are H_A and H_B with $Q = - <\dot{H}_A> = <[H, \ H_A]>$,

$$Q(t) = 1/2 \sum_{\substack{i \in A, j \in B \\ \alpha, \delta \in \{x,y,z\}}} k_{i,j}^{\alpha,\delta} \left(\left\langle \dot{u}_i^\alpha(t) u_j^\delta(t) \right\rangle - \left\langle u_i^\alpha(t) \dot{u}_j^\delta(t) \right\rangle \right). \tag{13}$$

u_i refers to the atomic displacement of atom i, $\dot{u}_i$ the instantaneous velocity of atom i. The α and δ exponents refer to the x, y, or z component. $k_{i,j}^{\alpha,\delta}$ is the interatomic force constant between atoms i and j. Rewriting the correlation $\left\langle \dot{u}_i^\alpha(t) u_j^\delta(t) \right\rangle$ as

$$\left\langle \dot{u}_i^\alpha(t) u_j^\delta(t) \right\rangle = \lim_{t' \to t} \frac{d}{dt'} \left\langle u_i^\alpha(t') u_j^\delta(t) \right\rangle = \lim_{\tau \to 0} \frac{d}{d\tau} \left\langle u_i^\alpha(\tau) u_j^\delta(0) \right\rangle,$$

introduces a characteristic time $\tau = t - t'$ which is related to the vibrational dynamics. Applying the Fourier transform on the correlations yields

$$Q(\omega) = 1/2 \sum_{\substack{i \in A, j \in B \\ \alpha, \delta \in \{x,y,z\}}} k_{i,j}^{\alpha,\delta} \left[\dot{u}_i^\alpha(\omega) u_j^{*\delta}(\omega) - u_i^{*\alpha}(\omega) \dot{u}_j^\delta(\omega) \right]. \tag{14}$$

Here, u^* is the complex conjugate of u. Equation (14) can be compared to the following Landauer expression (Landauer 1970):

$$Q_{LD}(\omega) = \hbar\omega(n_a^0(\omega) - n_b^0(\omega))T(\omega), \tag{15}$$

where $\hbar\omega$ stands for the energy quantum and T for the phonon transmission. $n_{a,b}$ corresponds to the Bose-Einstein occupation numbers of systems A and B, respectively. Identifying the first term of the difference of Eq. (14) to the one in Eq. (15) and considering the classical limit ($\hbar\omega \ll k_B T$) allow us to extract the following frequency-dependent transmission:

$$T(\omega) = \beta/2 \sum_{\substack{i \in A, j \in B \\ \alpha,\delta \in \{x,y,z\}}} k_{i,j}^{\alpha,\delta} \left[\dot{u}_i^\alpha(\omega) u_j^{*\delta}(\omega) - u_i^{*\alpha}(\omega) \dot{u}_j^\delta(\omega) \right], \qquad (16)$$

which can be simplified into

$$T(\omega) = \beta \mathrm{Re} \left\{ \sum_{\substack{i \in A, j \in B \\ \alpha,\delta \in \{x,y,z\}}} k_{i,j}^{\alpha,\delta} \dot{u}_i^\alpha(\omega) u_j^\delta(\omega) \right\} \qquad (17)$$

where $\beta = 1/k_B T$ and k_B denotes the Boltzmann constant. Equation (17) highlights that the atoms involved are those in interaction across the interface. A further step can be taken by considering the atomic velocities in the wave-vector reciprocal space defined by:

$$\dot{u}_{\mathbf{k}}^\alpha(\omega) = \sum_i \dot{u}_i^\alpha(\omega) e^{i\mathbf{k}\cdot\mathbf{r}_i^0},$$

where $\mathbf{r}_i^0$ refers to the equilibrium position of atom i. Replacing the velocities by their expressions in Eq. (17), the transmission from wave-vector $\mathbf{k}$ to $\mathbf{k}'$ at frequency ω can be written as:

$$T(\omega, \mathbf{k}, \mathbf{k}') = \beta/2i\omega \sum_{\alpha,\delta \in \{x,y,z\}} \dot{u}_{\mathbf{k}}^\alpha(\omega) \dot{u}_{\mathbf{k}'}^{*\delta}(\omega) D^{\alpha,\delta}(\mathbf{k}, \mathbf{k}'), \qquad (18)$$

where $D^{\alpha,\delta}$ stands for the interfacial phonon dynamical matrix as:

$$D^{\alpha,\delta}(\mathbf{k}, \mathbf{k}') = \sum_{i \in A, j \in B} k_{i,j}^{\alpha,\delta} e^{i(\mathbf{k}\cdot\mathbf{r}_i^0 - \mathbf{k}'\cdot\mathbf{r}_j^0)}.$$

2.2.2 Example on a Si/Ge/Si Heterostructure

From Eq. (17), we have calculated the Si/Ge transmission for L ranging between 0.5 and 10 nm as well as that of the perfect Si/Si transmission.

Results are reported on Fig. 4 inset (a), (b), and (c) highlighting two important features. Inset (a) shows that the optical modes coming from the Si substrate above the frequency $\nu > 15$ THz are poorly transmitted while a significant contribution to transmission (noted S on inset (b)) is observed at $\nu \sim 14$ THz. This later peak does
not appear in perfect bulk silicon (inset (c)) because it corresponds to an interface
mode. Additional modes are transmitted above the Ge bulk cutoff frequency ν_{Ge}
(Fig. 4 inset (a) represented by the dotted vertical line). This indicates that inelastic
processes occur at the contact layers with additional transport channels transferring
thermal energy above ν_{Ge}. The degree of accuracy of this microscopic description
is benchmarked by comparing the total thermal resistance of the junction to that
retrieved by more conventional approaches reported in the literature. We have
compared the thermal resistance R obtained from

$$R^{-1} = k_B \int_\omega T(\omega)d\omega, \tag{19}$$

to nonequilibrium molecular dynamics (NEMD) simulations (Landry and
McGaughey 2010) and AGFs (Zhang et al. 2007c) calculations. Both calculations
rely on the same interatomic potential (Stillinger and Weber 1985). As seen on
Fig. 5, thermal resistance increases with the layer thickness. The NEMD data trend
(red crosses) is recovered (blue triangles) within a satisfying range of accuracy.
AGFs overestimate the thermal resistance by less than 30 percent when compared
to other predictions. The harmonic feature of the theory can be considered at the
origin of this mismatch.

Figure 6 reports the wave-vector **k** and frequency-dependent transmission
$T(\omega, \mathbf{k})$ when Ge layers have two different thicknesses. **k** is constructed in the

Fig. 5 Thermal resistance obtained from the transmission of Fig. 4 and compared to the NEMD direct calculation (red circle) and AGFs (dark square) for several layer thicknesses
Fig. 6 Wave-vector-dependent phonon transmission calculated from MD at T = 400 K for Ge layer thicknesses of L = 0.54 nm (**a**) and L = 5.4 nm (**b**)
plane defined by the [100] and [110] directions. The right-hand side graphs represent the total transmissions previously calculated. A significant part of the transmitted energy arises in the low frequency range, i.e., below the Ge optical mode frequencies, where phonon modes exist in both materials. The localized interface mode (S) is found to be weakly dispersive and, as deduced from the spectral distribution, has important contributions to thermal transfer at the interface.

2.3 Concluding Remarks

An equilibrium formulation of thermal interface conductance has been derived according to the linear response theory for molecular dynamics simulations. It can

be applied to a wide range of systems, including the effect of anharmonicity which is central in thermal transport. While conductance is related to the fluctuations of the net heat flux obtained by the contact atoms, interface transmission can be viewed as the cross power spectral density of these later. A wave-vector decomposition and a detailed analysis of the modes that govern the phonon transmission for Si/Ge interfaces were presented. It turns out that the interfacial transport cannot be accurately estimated from bulk properties. The present formulation of the interfacial transport has the advantage of remaining general and rather simple to implement.

3   Anomalous Susceptibilities in Dielectric and Magnetic Nanoparticles

The description of the optical properties of nanomaterials involves two classes of physical systems: metals and dielectrics. At the nanoscale, both exhibit particularly interesting properties due to the resonances activated by the confining boundary conditions – e.g., surface phonon-polariton for dielectrics and surface plasmon for metals. Understanding the mechanism of coupling between light and nanomaterials forms the cornerstone of the fields of nanophotonics and nano-optics, and a large panel of applications have recently emerged such as the enhancements of Raman scattering (Nie and Emory 1997), the fluorescence imaging (Shafiei et al. 2013), or the control of coherent thermal radiation (Greffet et al. 2002). When studying how size confinement impacts optical properties at short scales, it has been reported that nonlocal effects take place in metals (McMahon et al. 2009; David and Garcia de Abajo 2011) such as the spill- out of electrons (Voisin et al. 2001; Gaudry et al. 2000): For systems smaller than 10nm, a strong increase of the intrinsic electron-phonon interaction can be observed. On the other hand, very few work reported peculiar size effects in dielectric material (Chalopin et al. 2012a) although there has been much effort devoted to exploring optical modes of vibration in these systems (Jones and Fuchs 1971; Tong and Maradudin 1969). This section is turned toward the study of the mechanisms of infrared absorption in confined dielectrics with the mean of molecular dynamics (MD) simulations. We found that light absorption in the THz occurs predominantly through anomalous surface modes which are reported to be confined in space, demonstrating that macroscopic description of electrodynamics fails at He nanoscale. This particular feature is illustrated on solid as well as in soft matter.

3.1   Microscopic Models of Nonlocal Dielectric Constant

Our approach is formulated on the basis of the linear response theory where the bulk susceptibility $\chi^{\alpha,\beta}(\omega, \mathbf{k}) = \varepsilon_r^{\alpha,\beta}(\omega, \mathbf{k}) - 1$ subjected to an external electric field $\mathbf{E}$ can be written as:

$$P^{\alpha}(\omega, \mathbf{k}) = \varepsilon_0 \chi^{\alpha, \beta}(\omega, \mathbf{k}) E^{\beta}(\omega, \mathbf{k}).$$

ε is the material dielectric tensor and P the polarization induced by E. α, β stands for the space coordinates. For any anisotropic materials, the fluctuation-dissipation theorem (Kubo 1966) allows to generally express χ as (Chalopin et al. 2011):

$$\chi^{\alpha, \beta}(\omega, \mathbf{k}) = \frac{1}{\varepsilon_0 k_B T V} \left[\left\langle P^{\alpha}(0, \mathbf{k}) P^{\beta}(0, \mathbf{k}) \right\rangle + i\omega \int\limits_0^{\infty} e^{i\omega t} \left\langle P^{\alpha}(0, \mathbf{k}) P^{\beta}(t, \mathbf{k}) \right\rangle dt \right],$$
(20)

where V is the volume of the dielectric system and $P(t)$ the polarization state at time t. In the reciprocal space P is expressed as:

$$P^{\alpha}(t, \mathbf{k}) = \sum_{i \in V} q_i \cdot \mathbf{r}_i^{\alpha}(t) e^{i\mathbf{k} \cdot \mathbf{r}_i^0},$$
(21)

$\mathbf{r}_i^0$ is the equilibrium position of atom i caring the charge q_i. Hence, the optical spectra of any polar material are extracted from the fluctuations of the system at thermal equilibrium, and the nonlocal description of the dielectric properties corresponds to the 2D Fourier transform of the charge fluctuations. Recalling that ε is complex $\varepsilon_r = \varepsilon_r' + i\varepsilon_r''$, one has $\varepsilon_r' = \text{Re}\{\chi\} + 1$ and $\varepsilon_r'' = \text{Im}\{\chi\}$. Using the convolution theorem, one can thus retrieve the absorption spectra through the imaginary part of the polarizability tensor $\alpha = \alpha' + i\alpha''$ as:

$$P^{\alpha}(\omega, \mathbf{k}) = \alpha^{\alpha, \beta}(\omega, \mathbf{k}) E^{\beta}(\omega, \mathbf{k})$$

with

$$\alpha''^{\alpha, \beta}(\omega, \mathbf{k}) = \frac{\omega}{k_B T V} \frac{P^{\alpha}(\omega, \mathbf{k}) P^{*\beta}(\omega, \mathbf{k})}{\tau}$$
(22)

3.2   Surface-Enhanced Infrared Absorption in Dielectric Thin Films with Ultra-strong Confinement Effects

3.2.1   The Bulk Dielectric Constant: An Example with MgO

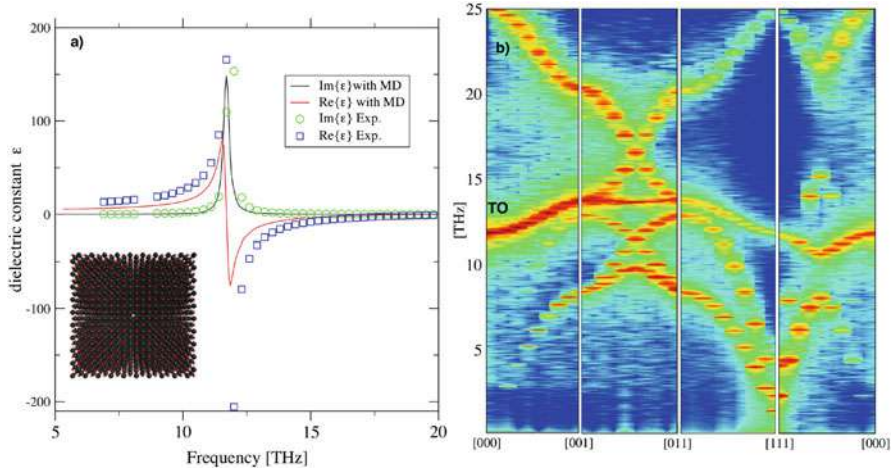
We validate our approach by comparing the dielectric constant at $\mathbf{k} = 0$ with the available experimental data (see upper Fig. 7). The Matsui (1989) potential has been used. We have calculated the nonlocal (i.e., k-dependent) dielectric constant (Eq. 22) with $\mathbf{k}$ ranging along the main directions lying within first Brillouin zone (FBZ). Figure 7 reports the results obtained for $\mathbf{k}$ ranging along the points Γ [000], Σ [001], X [011], and L [111]. This physical process is already known and it has been demonstrated experimentally (Scarel et al. 2008; Fray et al. 1961) 8 cm.


Fig. 7 Top figure: frequency-dependent bulk dielectric constant compared to Palik and Bennett (1991). Bottom figure represents the corresponding nonlocal description of the absorption along the main direction of the MgO first Brillouin zone. A log representation of Eq. 22 has been performed for more contrast

3.2.2   Confinement Effects and Surface Mode

We next consider the case of crystal slabs with finite thicknesses L in the [001] direction and periodic in two lateral ones ([100 and [010]). The translational symmetry preserved along two axes allows a wave-vector description of the in-plane mode $\mathbf{K} = (\mathbf{k_x}, \mathbf{k_y})$ as $\varepsilon^{\alpha,\beta}(\mathbf{K}, \mathbf{q}, \omega)$. $\mathbf{q}$ stands for the modes along the [001] confined direction. As for the bulk case, we first look at the absorption at long wavelength limit for thicknesses (L) ranging from 0.42 to 4.2 nm. An atomic representation of a 0.84 nm thick slab is illustrated in Fig. 8 as well as the calculated absorption spectra (Imα) B. It can be seen that IR absorption occurs through mainly two bands having particular resonances spreading around 12 and 24 THz. These two bands lie at the bulk TO and LO frequencies, respectively, and interestingly their structure strongly depends on the size:

3.2.3   Limit of the Classical Electrodynamics at the Nanoscale: The Dielectric Screening Length

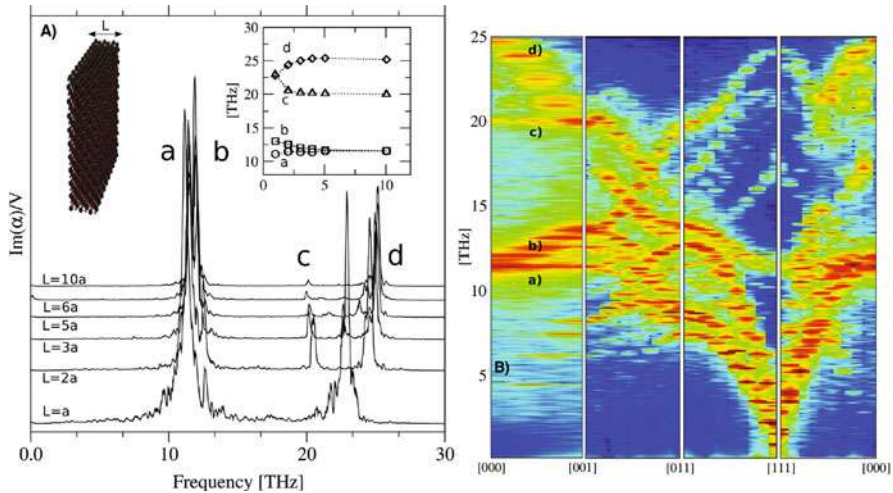
From this study, we see that the 12 THz band corresponds to a competition between the TO polariton mode and a surface mode (also known as Lucas mode Chen et al. 1972; Lucas 1968) strongly localized at the topmost atomic layers: At the smaller thickness, absorption is driven by this surface mode, whereas the TO requires the system to have a sufficient number of layer to get activated: When increasing the layer thickness above 1 nm, the TO polariton starts to dominate over the surface mode. In a similar fashion, the optical absorption at higher frequencies (20–25 THz) corresponds to localized surface modes for the smaller thicknesses: The contribution of these resonances attributed to the surfaces get progressively replaced by that


Fig. 8 Top figure (**a**): Size-dependent dielectric constant with thicknesses ranging from 1 to 10 MgO unit cells. Bottom figure represents the corresponding nonlocal description for the size of 3 unit cells with a log representation of Eq. 22 for more contrast

of the LO polariton for thickness >1 nm which is a volume mode (see bottom of Fig. 8): This effect arises from the fact that the topmost atomic layer undergoes interatomic force constants much weaker than that of the volume layers where the atoms are isotropically bonded and consequently their vibrational dynamics differs.

An important aspect of this analysis allows to conclude that none of the slabs' absorption spectra can be deduced from the calculated bulk dielectric constant; in particular, the well-known Clausius-Mossotti relation predicts a polariton resonance for $\epsilon = -1$ that is at the frequency of 17 THz if we consider the bulk ϵ calculated in Fig. 7. In fact the bulk LO polariton mode is found to occur at the frequency of 25 THz for all thickness which can be attributed to the effect of dielectric screening with a characteristic distance corresponding to the lattice parameter. Consequently, any macroscopic description of IR absorption in thin film clearly breaks down at this scale.

3.3   Infrared Absorption in Cellular Membrane Models Made of Lipid Bilayers

The dielectric properties of lipid bilayers have been studied for the past years for their central role in the protein and ion permeability of the membrane as well as electroporation. It has been reported that in lipid bilayers, the static dielectric permittivity is spatially nonuniform, but no work has addressed so far the infrared properties in the terahertz (THz) regime. The polarizability of two types of bilayers made of DPPC and POPC lipids is presented here. The two lipids have very similar
Fig. 9 Simplified Lewis formula of DPPC and POPC lipids

chemical formulas, and despite these similarities, their organization in bilayers displays dissimilar structure, which in turn dramatically affects the THz spectra. The calculations have been compared to Raman experiments and show a fair agreement.

3.3.1 Atomistic Modeling of the Lipids and Bilayers

The Lipid bilayers investigated here are made of two different lipids, namely, the 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC) and the 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC). Their chemical formulas are depicted in Fig. 9. The DREIDING (full atomistic) potential has been accounted for the lipids with an experimentally validated TIP3P interaction model for the water molecules (Jorgensen et al. 1983). Optical and morphological properties are extracted from the displacement and velocity fluctuations of the atoms in the micro-canonical ensemble (constant energy and volume) to ensure the validity of the fluctuation/dissipation theorem (FDT). Figure 10 depicts an atomic view of the relaxed bilayers at the temperature of 310 K. The resulting morphologies are in agreement with previous calculations reported in the literature.

3.3.2 Dielectric Properties

The static polarizability is first studied and compared to the literature. To confront our calculations with experiments, we have extracted the electrical capacitance C of the membrane according to $C = \frac{\alpha(\omega=0)\epsilon_0 S}{d}$, where d corresponds to the layer thickness. Various measurements have been reported in the literature (Benz et al. 1975; Toyama et al. 1991; Berestovsky et al. 1978; Montal and Mueller 1972; Lee and Bain 2005), where C ranges from 0.01 to 0.03 F.m^2 which is in agreement with our calculations (Fig. 11 (full lines)). Note that the capacitance does not vary in the same way as the polarizability due to change in volume by the temperature. More interestingly Fig. 11 reports that DPPC and the POPC bilayers have a static response which differs by a factor of 3. The imaginary part of the polarizability, $\alpha''(\omega)$ is shown in Fig. 12 (black line) and compared with Raman experimental data (Lee and Bain 2005) for a spectra ranging above 40 THz. Below that frequency, no data have been reported so far. The origin of the absorption can be attributed to specific
Fig. 10 Atomic view of POPC and DPPC lipid bilayers

Fig. 11 Cross-plane static polarizability and electrical capacity of DPPC and POPC bilayers as a function of temperature. Inset: Size effect (the number of lipids in the simulation box) on the static polarizability
dipoles where, for instance, the bonds C-H and N-H are activate, respectively, at 85 and 100 THz. A very satisfactory agreement is found for those modes. The 50 THz band corresponds to the carbon bonds such as C-C, C-O, and C-N. The P-O bonds also lie in this frequency domain.

3.3.3 Interplay Between Absorption and Morphology

The IR properties of the bilayers are investigated here to identify where the absorption occurs in both configurations and what are the associated resonances.

Fig. 12 Imaginary part of the permittivity in DPPC and POPC bilayers and the comparison with Raman experimental data (Lee and Bain 2005) and the vibrational densities of states (DOS)
We have thus computed (Fig. 13) the densities of chemical elements forming each bilayers as well as the radial distribution function (Fig. 14). The density drop at the center of the DPPC bilayer (see Fig. 13 black arrow) indicates less interdigitation between the two lipid layers leading to a 0.5 nm thicker bilayer than the POPC as reported in the literature (Karjiban et al. 2013; Vermeer et al. 2007; Kupiainen 2005). In addition, the radial distribution function of the two membranes, Fig. 14, clearly indicates that the ordering of the POPC lipids is significantly reduced compared to that of the DPPC lipids: The density probability of the former becomes flatter behind the first neighbor peak. Furthermore, the first neighbor distance becomes larger for the case of POPC with a lower average density (i.e., tail of the correlation function). This is explained by the effect of the double bond at the tail of the POPC lipids that prevents perfect stacking. Thus the average distance between lipids in the same layer is larger which results in a lower surface density. This reduced surface density, which concomitantly involves a thinner bilayer, is not sufficient to fully explain the weaker static polarizability of the DPPC layers. The charge density is predominantly distributed at the hydrophilic heads (Fig. 13), and considering the highest mobility of the lipids, we can deduce that the local dipoles exhibit more angular fluctuations for the case of the POPC bilayer. To unveil this effect, we have computed the projection of the dipole moment along the surface ($p_{||}$) versus the perpendicular direction (p_z); hence the dipoles orientate predominantly in the planes as $\frac{p_z}{p_{||}} = 0.0309$ for POPC vs 0.0017 for DPPC: The difference in angular fluctuations leads to a higher projected dipole component (p_z) for the case of POPC. This explains the larger static polarizability.

It is possible to compute the spatially dependent absorption spectra in a direction perpendicular to the lipid planes with a 0.2 nm thick resolution (Fig. 15). The top

and charge density profile in
DPPC and POPC lipid
bilayers
Fig. 14 In-plane radial
distribution function of the
DPPC and POPC lipid
bilayers
of Fig. 15 presents the total absorption integrated over the whole spectrum. It
demonstrates that the DPPC bilayer absorption is mainly localized in the heads
of the lipids (40 and 85 Å), whereas for the case of POPC, the maximum of the
absorption occurs more homogeneously within the bilayer.

Fig. 15 Total absorption and absorption at 53 THz as a function of the position in the bilayer
3.4 Concluding Remarks

To conclude, it has been demonstrated that optical absorption in polar nanomaterial is driven by anomalous absorption processes that cannot be predicted by any macroscopic description of electrodynamics. These optical properties are extremely confined in space and predominant in absorbing IR radiation. This approach provides a possible tool for predicting radiative properties of biological systems as well as in solid-state systems.

4 Brownian Dissipation by Magnetic Nanoparticles

Clusters of magnetic nanoparticles have received considerable interest in various research fields. Their capacity to generate heat under an alternating magnetic field has recently opened the way to applications such as cancer therapy by hyperthermia. The physics underlying the dynamics of interacting dipoles in systems of microscopic dimension is so rich that tremendous efforts have been devoted to address this subject from experimental (MacIsaac et al. 1996; Morup and Tronc 1994) and theoretical (Dejardin 2011) approaches. Predicting the dynamics of the dipolar sets, comprising magnetic and dielectric nanostructures, is an important challenge as the long-range and anisotropic-dipolar interactions (Corato et al. 2014) entail a wealth of nonindependent degrees of freedom, difficult to track analytically. The developments of both numerical and analytical methods assessing the particles' response to an external field (Branquinho et al. 2013; Ruta et al. 2015; Tan et al. 2014), and

powerful enough to handle the complexity of the couplings, are still to be found. Heat generation is driven by two processes: The Neel and the Brownian relaxation. Regarding the former, many works have reported a shortening of the magnetization relaxation time when increasing the dipolar interactions (Dejardin 2011; Berkov and Gorn 2001; Denisov and Trohidou 2001; Brinis et al. 2014). In addition, various studies have further addressed the case of two-dimensional square arrays (Denisov and Trohidou 2001; Brinis et al. 2014; Denisov et al. 2003; Sugano et al. 2007; Stariolo 2008; Bahia 2004; Farrell et al. 2004) which are suited for experimental investigations (Stariolo 2008). In a similar fashion, dielectric relaxation in systems subjected to rotational Brownian motion remains an important question (Jimenez et al. 2006; Zhou and Bagshi 1992) . It is relevant to the study of dynamic light scattering, Raman scattering, and liquid crystals. Some analytical approaches have accounted for approximations in which the many-body system is casted in terms of a two-body problem (Felderhof 2002) or a single dipole in a mean field.

Here, our interest focuses on the problem of evaluating the effect of the interactions between rigid dipoles carried by particles damped by a viscous torque (Coffey and Kalmykov 2012). Our analysis thus aims at identifying to what extent the Brownian relaxation process is affected by the particle interactions without any restriction on their density. For this purpose, we have formulated a statistical approach based on numerical simulations that reproduce the equilibrium orientational fluctuations of dipoles interacting in a heat bath. Hence, by means of the fluctuation-dissipation theorem, we have predicted the frequency-dependent imaginary part of the susceptibility of the system, subjected to an external ac field $\vec{B}_1$.

4.1 Statistical Modeling with the Langevin Equation

We considered a square array of magnetic rigid dipoles $\vec{\mu}_i$ carried by spherical particles with volume V and inertia momentum I, immersed in a liquid with viscosity η at the temperature of 320 K. With the help of the fluctuation-dissipation theorem, it is possible to formulate a general approach to derive the macroscopic nonequilibrium response of the system by tracking numerically the microscopic equilibrium fluctuations of the dipoles $\vec{\mu}_i$. The Hamiltonian of the system can be written as:

$$H = \frac{1}{2} \sum_{i,j=1}^{N} U_{ij} - \sum_{i=1}^{N} \vec{\mu}_i \cdot \vec{B}_1, \tag{23}$$

considering the dipole-dipole coupling energy

$$U_{ij} = \frac{\mu_0}{4\pi r_{ij}^3} \left[\vec{\mu}_i \cdot \vec{\mu}_j - 3 \frac{\left(\vec{\mu}_i \cdot \vec{r}_{ij}\right)\left(\vec{\mu}_j \cdot \vec{r}_{ij}\right)}{r_{ij}^2} \right], \tag{24}$$

where $\vec{r}_{ij} = \vec{r}_i - \vec{r}_j$. The magnetization of the system is defined here as:

$$\vec{M} = \sum_i \vec{\mu}_i. \tag{25}$$

We consider the rotation of the magnetic dipoles with a position fixed in a two-dimensional square lattice along the (x, y) plane. The nearest neighbor distance d corresponds to a dipole surface density $\rho = 1/d^2$. Each dipole $\vec{\mu}_i = \mu \vec{e}_i$ undergoes a viscous torque $\vec{\Gamma}_{\text{vis},i} = -\zeta \vec{\omega}_{p,i}$, with $\vec{\omega}_{p,i}$ the instantaneous rotation vector of dipole $\vec{\mu}_i$ and $\zeta = 6\eta V$ the angular viscous friction coefficient. In addition to this damping, each dipole i is subjected to a magnetic torque $\vec{\mu}_i \times \vec{B}_i$ with

$$\vec{B}_i = \vec{B}_1 - \frac{\mu_0}{4\pi} \sum_{j \neq i} (\vec{\mu}_j \cdot \vec{\nabla}_i) \left(\frac{\vec{r}_{ij}}{r_{ij}^3} \right).$$

To account for the collisions with the liquid molecules, we have considered an angular Langevin equation with a stationary random torque $\vec{\Gamma}_{\text{rnd},i}$ acting on $\vec{\mu}_i$. The correlation time of this torque is consequently the collision time, which remains much smaller than the relaxation time of the angular velocity $\vec{\omega}_{p,i}$. $\Gamma_{\text{rnd}}(t)$ is thus delta-correlated in time: $\langle \Gamma_{\text{rnd}}(t)\Gamma_{\text{rnd}}(t+\tau) \rangle = 2\zeta k_B T \delta(\tau)$. The complete set of differential equations describing the dynamics of the magnetic dipoles damped in a liquid is

$$\begin{cases} I d\vec{\omega}_{p,i}/dt = \vec{\mu}_i \times \vec{B}_i - \zeta \vec{\omega}_{p,i} + \vec{\Gamma}_{\text{rnd},i}(t) \\ d\vec{\mu}_i/dt = \vec{\omega}_{p,i} \times \vec{\mu}_i \end{cases} \tag{26}$$

In principle, it would be possible to study the response of the system illuminated by an external alternating field $\vec{B}_l(\omega)$ along direction l by including explicitly B_l in Eq. 26. The dynamics of a magnetic dipole in an oscillating field has been studied with a similar approach (Engel et al. 2003). Practically, this procedure requires too many calculations to determine the whole spectrum of the magnetic susceptibility tensor $\alpha(\omega)$ defined as:

$$\vec{M}_k(\omega) = \alpha_{kl}(\omega)\vec{B}_l(\omega). \tag{27}$$

Thanks to the fluctuation-dissipation theorem (Callen et al. 1951; Landau and Lifshitz 1980) (FDT), the components of the imaginary part of the magnetic susceptibility tensor $\alpha'' = Im(\alpha(\omega))$ can be obtained from the time correlation function of $\vec{M}$ as:

$$\alpha_{kl}(\omega) = \frac{\langle M_k(0)M_l(0) \rangle}{Nk_B T} + \frac{i\omega}{Nk_B T} \int_0^\infty \langle M_k(t)M_l(0) \rangle e^{-i\omega t} dt, \tag{28}$$

with

$$\langle M_k(t)M_l(0)\rangle = \int\limits_{-\infty}^{+\infty} M_k(t+\tau)M_l(\tau)d\tau, \qquad (29)$$

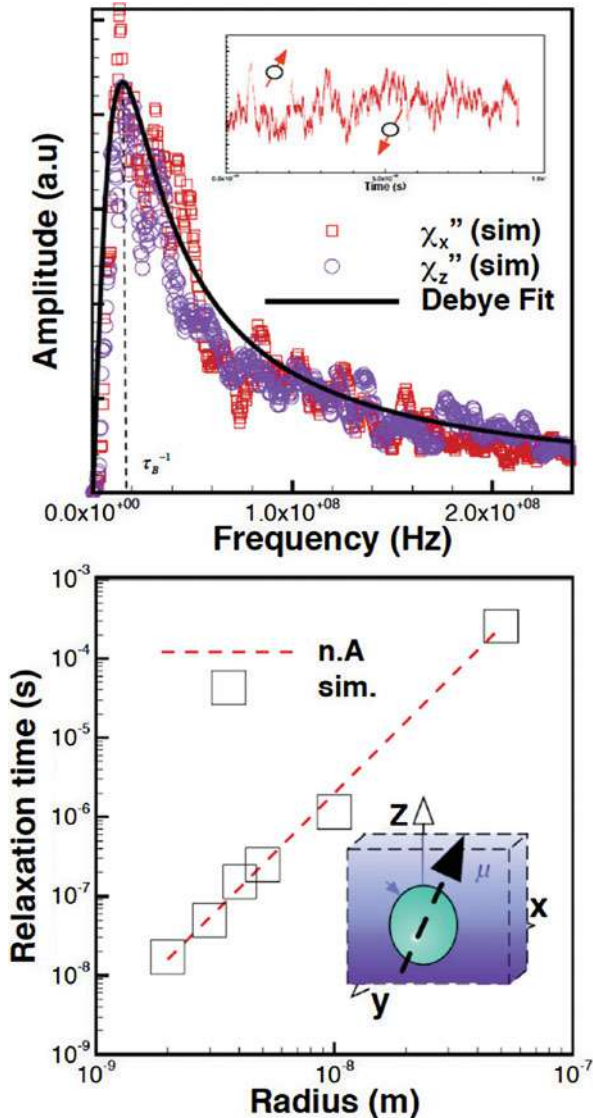
$k, l \in \{x, y, z\}$ and N is the number of particles considered. This approach can be compared with some correlation functions of the magnetization trackable experimentally (Grimm et al. 2011).

4.2   Collective Behaviors in Large Clusters of MN Nanoparticles

Let us consider the case of noninteracting rigid dipoles. It corresponds to the limit where the inter-particle distance $d \rightarrow \infty$, so that there is no effect of the dipolar interactions and $\rho = 0$. The dipoles are carried by spherical particles of various diameters. Figure 16 depicts the time fluctuations of the components of the magnetization $\vec{M}(t)$ and the imaginary part of the susceptibility spectra $\alpha''(\omega)$ extracted from these fluctuations following Eq. (28). As expected, it can be observed that $\alpha''(\omega)$ fits with a Debye law according to the formula:

$$\alpha''(\omega, \rho = 0) = \alpha(\omega = 0, \rho = 0)\frac{\omega\tau}{1 + (\omega\tau)^2}. \qquad (30)$$

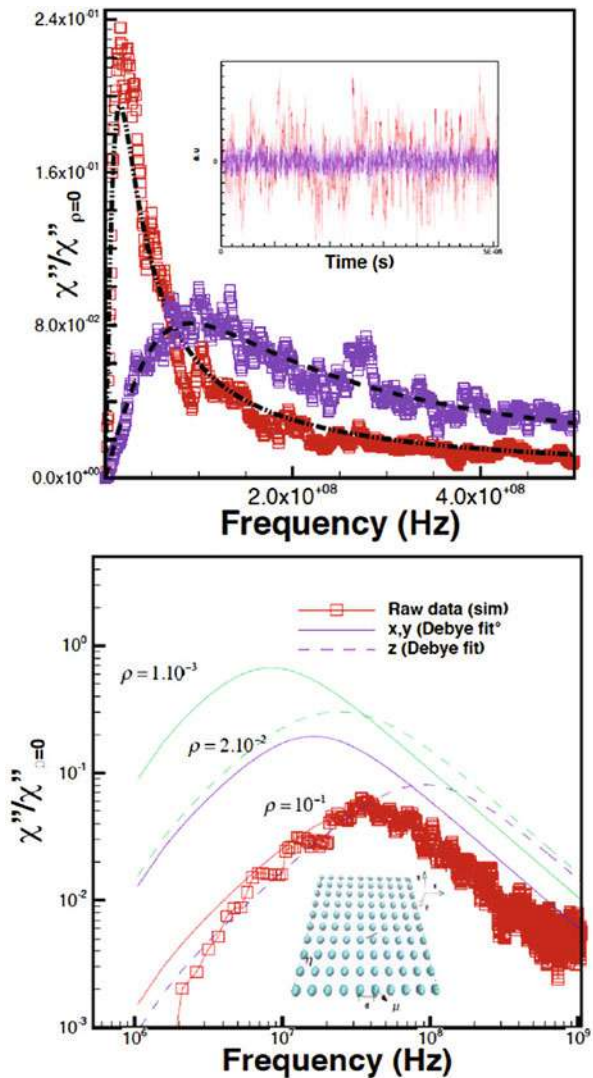
The lowest frequencies are attributed to the slowest characteristic times; thus, the longer one increases the simulation duration, the better one estimates the lowest frequency part of the spectra (in our case, $N_s = 1^8$ steps with $dt = 1\,\text{ms}$). At the optimal excitation angular frequency $\omega = \tau^{-1}$, the dissipation $\alpha''(\rho = 0)$ reaches its maximum value $\alpha''_{\text{max}}(\rho = 0) \equiv \alpha(\omega = \tau^{-1}, \rho = 0) = \alpha(\omega = 0, \rho = 0)/2$, where τ is the relaxation time of the system (Fig. 16b). For MNPs with hydrodynamic diameters ranging from 5 to 50 nm, the simulations give relaxation times that quantitatively agree with the expected Nernst-Einstein relation $\tau = \tau_B = \zeta/2k_BT = 3\eta V/k_BT$ (Fig. 16c). This result validates the statistical calculation in the well-known case of noninteracting rigid dipoles experiencing angular Brownian relaxation. Note that, as expected, the in-plane component of the susceptibility $\alpha''_{n/p}$ ($\vec{e}_n$ and $\vec{e}_p$ being any couple of orthogonal in-plane directions) and the cross-plane components of the susceptibility α''_z are identical in this case. We have next included the dipole-dipole interactions between MNPs. The strength of the interactions is tuned with the particle surface density ρ. Figure 17b displays the anisotropic dissipation spectra for the two components α''_n and α''_p in the plane and the perpendicular component α''_z, at the density of $1.5 \cdot 10^{-2}\,\text{nm}^{-2}$. The corresponding time fluctuations of these magnetization components are illustrated on the inset. We have identified on the same figure a range of concentration (gray) where the Knudsen number $K_n = \Lambda/l$, obtained from the water mean-free path

Fig. 16 Top: Imaginary part of the susceptibility from equilibrium simulations. Inset shows the time evolution of the momentum. A Debye fit is shown with the bold lines. Bottom: Validation with the Nernst-Einstein formula


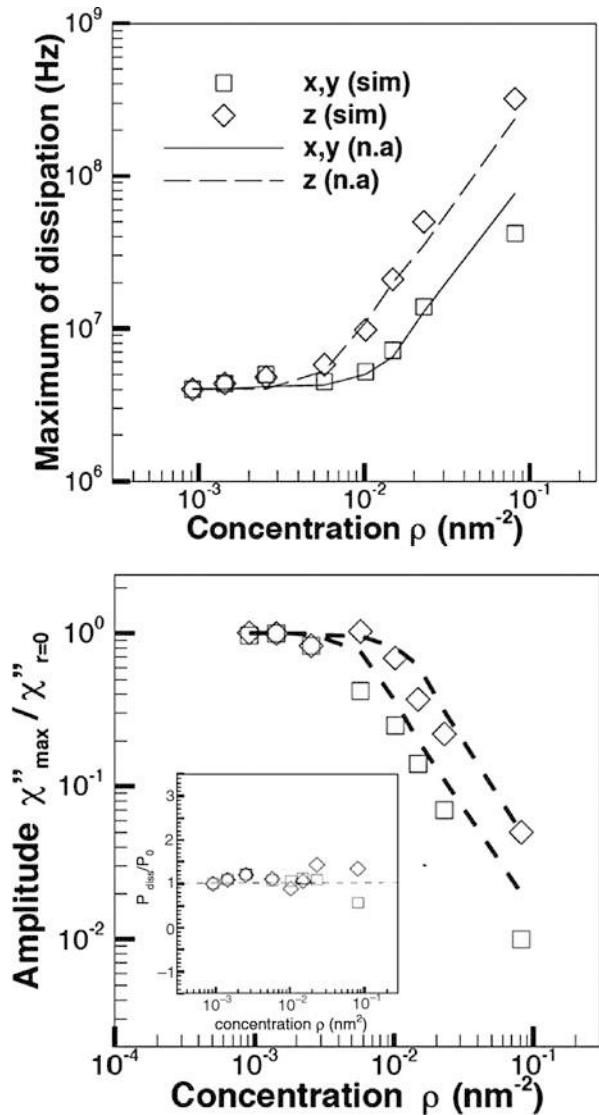
$(\Lambda = 2.5 \cdot 10^{-10} \, \text{m}$ in water) and the edge-to-edge inter-particle distance l, is not small enough to guaranty the absence of hydrodynamic effects. As shown on the same plot, this particular regime occurs in the restricted case where the particles are in contact $(\rho \sim 10^{-2} \, \text{nm}^{-2})$. As we will see later in this work, the damping by the liquid is so weak compared to the dipole-dipole interactions that the effect of the liquid can be completely neglected.

4.3   The Effect of the Dipole-Dipole Interaction

The dipole-dipole interactions (illustrated in Fig. 17) impact the amplitude of $\alpha''(\omega)$, which is dramatically decreased, and the maximum of dissipation is shifted toward higher frequencies. In the time domain, orientational fluctuations of interacting dipoles are both accelerated and limited in amplitude compared to noninteracting dipoles. This is consistent with what has already been reported independently (Landi 2014; Denisov and Trohidou 2001; Zhou and Bagshi 1992). To estimate the mass concentration of nanoparticle in g/l from which the effect of the interactions

Fig. 17 Top: Imaginary part of the susceptibility from equilibrium simulations. The in-plane (red) and cross-plane (blue) dissipation are plotted. Bottom: Evolution of the susceptibility spectra with the concentration. The simulation points have been fitted with continuous curves for the sake of clarity


becomes observable, we consider the mass density of iron oxide ($5 \cdot 10^3$ kg/m^3). Dipolar effects occur as soon as the inter-particle distances become shorter than roughly three times the particle diameter (this correspondence between the dipolar energy cutoff and the particle diameter remains a good approximation even at other sizes, when accounting for a volume-dependent dipole moment). Considering the case of an isotropic particle distribution, the mass concentration is of the order of 250 g/L. Figure 17b presents the amplitude at the maximum of dissipation $\alpha''_{max}(\rho)$ as a function of the density, for each component. These amplitudes are normalized

Fig. 18 Power law with the inter-particle distance. (Bottom) The relaxation frequency as function of the concentration. (TOP): The amplitude of absorption as function of the concentration


by the corresponding values in the noninteracting case. Similarly, Fig. 17c displays the frequency of maximum dissipation $1/\tau$ as a function of the MNP density. Importantly, above a density threshold of $\rho = 4 \cdot 10^{-4} \, \mathrm{nm}^{-2}$, the optimal frequency increases with density as $\rho^{3/2}$, similarly to the coupling energy U which scales as $d^{-3} = \rho^{3/2}$. According to the Debye structure of the dissipation spectra, we deduce that the relaxation rate of rigid interacting dipoles includes an additional term which accounts for the interactions (Fig. 18):

$$\tau^{-1} = \tau_B^{-1} + \tau_U^{-1}(\rho), \tag{31}$$

with $\tau_U(\rho) = \zeta / U(\rho)$.

4.3.1 Concluding Remarks

Considering the equilibrium orientational fluctuations of magnetic dipoles, we have demonstrated that one can quantify the Brownian dissipation without approximations. Our work suggests that the interactions between magnetic dipoles have a dramatic impact on the fundamental mechanisms of dissipation: Increasing the dipole pair energy enhances the Brownian relaxation rate and diminishes the magnitude of absorption. Practically, these mechanisms are essential in the context of hyperthermia research. A perspective of this work would be to carry this analysis in situ, in order to study the heat diffusion in more complex environments, where the intracellular confinement has affected the particle concentration.

Thermal Conductivity of Nanostructured Semiconductor Alloys

39

Meenakshi Upadhyaya and Zlatan Aksamija

Contents

Abstract

This chapter provides a comprehensive description of phonon transport in nanostructures of silicon-based Group-IV alloys. We employ the phonon Boltzmann transport equation (pBTE) formalism with full phonon dispersion and a partially diffuse momentum-dependent specularity model for boundary roughness scattering. The results show thermal conductivity in Si-Ge nanostructures including thin films, superlattices (SLs), nanowires (NWs), and nanocomposites (NCs) to be well below their bulk counterparts, reaching almost to the amorphous limit. Further minimization of lattice thermal conductivity is shown in binary (SiSn and GeSn) and ternary (SiGeSn) alloys and their thin films. Si-Sn alloys have the lowest conductivity (3 W/mK) of all the bulk alloys, which reduces further to around 1 W/mK in 20-nm-thick Si-Sn films. Thermal transport in nanostructures is tunable by extrinsic boundary effects such as sample size in thin films, period

thickness in SLs, length/diameter in NWs, and grain size in NCs. Additionally, boundary/interface properties, such as roughness, orientation, and composition, also play a significant role in thermal transport and offer additional degrees of freedom to control the thermal conductivity in nanostructured semiconductor alloys. Thermal conductivity can be minimized in SLs by growing short-period $Si/Si_{1-x}Ge_x$ SLs with the Si-Ge alloy layer thicker than the Si one. We describe a Monte Carlo method of sampling the phonon mean free paths (MFPs), capable of capturing both partially diffuse boundaries and ballistic effects in the calculation of thermal conductivity of Si-Ge NWs. The computed phonon flights are comprised of a mix of long free flights over several μm interrupted by bursts of short flights, resulting in a heavy-tailed distribution of flight lengths, indicating superdiffusive phonon transport, which results in $L^{1/3}$ scaling across a wide range of NW lengths up to nearly $10\,\mu$m. Lastly, our pBTE model for nanocomposites, based on Voronoi tessellation to capture the grain structure in NCs, is described. The size scaling of thermal conductivity observed in NWs persists in NCs as well and is found to be insensitive to the variance in grain sizes.

1   Introduction

This chapter discusses thermal transport in silicon-based semiconductor alloys, which has drawn considerable interest in recent years. Much of the work employs a combination of alloying (Bera et al. 2010) and nanostructuring (Hicks and Dresselhaus 1993a; Dresselhaus et al. 2007) techniques to reduce the lattice thermal conductivity and improve the thermoelectric (TE) conversion efficiency of semiconductors (Joshi et al. 2008; Minnich et al. 2009; Zhu et al. 2009). TE energy conversion efficiency, given by the ratio between heat absorbed and the energy produced, is primarily dictated by a dimensionless figure of merit $ZT = S^2\sigma T/\kappa$, where S is the Seebeck coefficient, T is the absolute temperature, σ is the electrical conductivity, and κ is the thermal conductivity, composed of both lattice and electronic contributions (DiSalvo 1999). Most moderately doped semiconductors have high electrical conductivity σ and a moderate Seebeck coefficient S, with σ increasing and S decreasing with doping. Even when doping levels are optimized for a maximal power factor ($S^2\sigma$), ZT is still limited by the high thermal conductivity. The lattice contribution to thermal conductivity (κ_l) far outweighs its electronic counterpart (κ_e), and is the only property which can be tuned somewhat independently, without adversely affecting the power factor.

Silicon-based TEs are attractive due to the abundant availability of Si, relatively low cost, and previously established processing technology. In addition, they integrate easily with existing microelectronics microelectronics, opening up the possibility for on-chip cooling and improved thermal management in ultra-scaled CMOS circuits (Chowdhury et al. 2009; Pop 2010; Ryu et al. 2010). However, the high lattice thermal conductivity of bulk silicon at room temperature (146 W/m · K) (Glassbrenner and Slack 1964; Maycock 1967) limits the ZT of silicon to

approximately 0.05 (Liao et al. 1999), almost two orders of magnitude below the value of $ZT = 3$, which is considered desirable for solid-state TE devices to replace the conventional methods of cooling and power generation (Majumdar 2004). However, a more modest ZT of $1.5-2$ may suffice for kW-range applications such as vehicle heat recovery, car cooling/heating, and home cogeneration (Vining 2009).

Group-IV alloys of Si-Ge with varying composition have long been employed in TE energy conversion applications, such as NASA radioisotope TE generators, and have $ZT > 1$ around 900 K (Snyder and Toberer 2008). The improvement in ZT is primarily from the order-of-magnitude reduction in the lattice thermal conductivity κ_{ph} due to the mass-difference phonon scattering induced by alloying. However, the lattice thermal conductivity in $Si_{1-x}Ge_x$ alloys reaches a broad plateau between $0.2 < x < 0.8$ (Maycock 1967), which limits the lowest conductivity achievable through alloying. The mass-difference phonon scattering that dominates lattice transport in the alloy depends on the difference in atomic mass between the constituent materials (in this case Si and Ge) and the average mass in the alloy (given by $M_{Si}(1 - x) + M_{Ge}x$). Initially, increasing the Ge concentration moves the average further from the Si mass, resulting in an increase of the scattering rate (discussed in detail in Sect. 2). However, increasing the Ge concentration past a certain point (around x = 0.2) does move the average further from the Si mass but at the expense of moving it closer to the increasingly large fraction of Ge atoms in the alloy, resulting in a broad plateau in thermal conductivity vs. composition. Hence, additional methods of reducing the lattice thermal conductivity are required. Within this plateau, nanostructuring results in stronger decrease of thermal conductivity (three to five times lower than the bulk) than variation in Ge composition, while outside the plateau, compositional variation dominates.

The low-dimensional approach to reduce thermal conductivity was first proposed in seminal papers by Hicks and Dresselhaus (1993a, b), leading the way for numerous studies on $Si_{1-x}Ge_x$ alloy nanostructures, such as SiGe thin films (Cheaito et al. 2012), $Si/Si_{1-x}Ge_x$ superlattices (Lee et al. 1997; Lee and Venkatasubramanian 2008; Liu et al. 2001; Aksamija and Knezevic 2013; Upadhyaya et al. 2015), nanowires (Khitun et al. 1999; Wang and Mingo 2010; Lee et al. 2012; Hsiao et al. 2013; Upadhyaya and Aksamija 2016), and nanocomposites (Joshi et al. 2008; Wang et al. 2008; Aksamija 2014). Lattice thermal conductivity in nanostructures is dominated by scattering from the rough boundaries or interfaces between layers, even at room temperature. Therefore, in addition to composition, boundary/interface properties, such as roughness and orientation, are expected of freedom to control the thermal conductivity in semiconductor nanostructured alloys.

Our methodology is described in Sect. 2 and is based on solving the phonon Boltzmann transport equation (pBTE) in the relaxation time approximation, combining the full phonon dispersion calculated from Weber's adiabatic bond charge model (Weber 1974). All the relevant intrinsic scattering mechanisms spanning 3-phonon anharmonic umklapp and normal, isotope, impurity, and alloy mass difference are included. In order to accurately treat extrinsic phonon scattering from rough boundaries/interfaces, we employ a momentum-dependent specularity

parameter that depends on phonon wavelength and rms roughness amplitude. Several key results are discussed, beginning with Si-Ge alloy thin films in Sect. 3, and superlattices in Sect. 4, where diffuse interface scattering results in highly anisotropic thermal transport, with conductivity below that of a random alloy. Thermal conductivity can be further minimized by growing short-period $Si/Si_{1-x}Ge_x$ SLs with the SiGe layer thicker than the Si one. Calculation of the lattice thermal conductivity in Si-Ge nanowires (NWs) based on solving the pBTE by Monte Carlo method of sampling the phonon MFPs is discussed in Sect. 5. In alloy NWs, unlike their non-alloy counterparts, phonon transport is essentially superdiffusive, and thermal conductivity scales with the length of the NW as $\kappa \propto L^{1/3}$ over a broad range of wire lengths $10\,\text{nm} < L < 10\,\mu\text{m}$ regardless of diameter and roughness. This is a consequence of Levy-like phonon transport where series of short random flights are interrupted by several-μm-long leaps, leading to a heavy-tailed flight distribution.

Next, Sect. 6 on alloy NCs describes our Voronoi tessellation technique to compute the grain size distribution and interconnections. The size-dependent thermal conductivity in each grain is computed, and the resulting grain distribution is iterated until convergence to find the effective thermal conductivity in micron-sized samples, composed of tens of thousands of nanoscale grains. The size scaling observed in NWs persists even in nanocomposites, where the conductivity scales with the mean diameter of the grains as $\kappa \propto D^{1/3}$ in SiGe and $\kappa \propto D^{2/3}$ in Si NWs. However, the conductivity is found to be insensitive to the variance in grain sizes. Much work remains to be done in co-optimizing the complex morphology of NCs for simultaneous decrease in thermal and gain in electrical conductivity. Lastly, Sect. 7 discusses material advancement beyond SiGe, to Group-IV alloys containing tin, including binary Si-Sn and Ge-Sn and Si-Ge-Sn ternary alloys. Si-Sn was found to possess the lowest thermal conductivity among all the cases, and its nanostructures have conductivity nearing the amorphous limit. We conclude in Sect. 8 that Group-IV alloy nanostructures, in particular SLs, NWs, and NCs containing a mix of Si-Ge and Si-Sn, hold tremendous promise for future high-efficiency TE energy conversion applications.

2   Phonon Transport Model

Most theories that simultaneously capture both electron and phonon transport in crystalline solids employ the Boltzmann transport equation (BTE). The BTE theory can explain a broad range of relevant effects in bulk or homogeneous materials, including the dependence of the electrical conductivity, the thermal conductivity, and the Seebeck coefficient on temperature, impurity content, isotope scattering, and quantum confinement (Cahill et al. 2003). We focus herein on the lattice thermal conductivity via the transport of phonons, where the BTE approach can be complementary to other methods, such as molecular dynamics (MD). By solving the time-independent phonon Boltzmann transport equation (pBTE) in its relaxation-time-approximation (RTA) form, the steady-state distribution function

can be obtained, which is then used to determine lattice heat conductivity. In steady state, the time-independent pBTE is given as (Carruthers 1961)

$$\upsilon_{b,\mathbf{q}} \cdot \nabla N_{b,\mathbf{q}}(x, y, z) = -\frac{N_{b,\mathbf{q}}(x, y, z) - N_{b,\mathbf{q}}^0(T)}{\tau_{b}^{\text{int}}(\mathbf{q})}. \tag{1}$$

As indicated in the pBTE, the steady-state phonon distribution $N_{b,q}(x, y, z)$ is a function of the phonon branch b, wave vector $\mathbf{q}$, and position in 3D space (x, y, z). Here τ_q^{int} is the relaxation time due to all the intrinsic scattering mechanisms occurring in the interior of the material, including both resistive umklapp and non-resistive normal anharmonic phonon-phonon, isotope, impurity, and alloy mass-difference interactions. τ_q^{int} can be obtained using the standard single-mode relaxation time approximation from elasticity theory (Morelli et al. 2002) or from first principles, which typically leads to a quadratic (Ward and Broido 2010) or cubic (Esfarjani et al. 2011) frequency dependence of the anharmonic scattering rates in the long-wavelength limit. The equations hold for each branch, and interbranch scattering is included in $\tau_{b}^{\text{int}}(\mathbf{q})$. In the calculation of relaxation time $\tau_{b}^{\text{int}}(\mathbf{q})$ for a phonon in branch b and with wave vector $\mathbf{q}$, we consider normal (N) and umklapp (U) three-phonon scattering, impurity (I, if present through doping or defects), and mass-disorder scattering (Mass) with branch- and momentum-dependent relaxation times $\tau_{b,N}(\mathbf{q})$, $\tau_{b,U}(\mathbf{q})$, $\tau_{b,I}(\mathbf{q})$, and $\tau_{b,\text{Mass}}(\mathbf{q})$, respectively. The total intrinsic relaxation time is given by

$$\frac{1}{\tau_{b}^{\text{int}}(\mathbf{q})} = \frac{1}{\tau_{b,N}(q)} + \frac{1}{\tau_{b,U}(q)} + \frac{1}{\tau_{b,I}(q)} + \frac{1}{\tau_{b,\text{Mass}}(q)}. \tag{2}$$

When two materials are combined into an alloy, in this case $Si_{1-x}Ge_x$, variation in the local atomic mass leads to perturbations of lattice waves, which results in strong mass-difference scattering of phonons. In alloys, mass-disorder scattering will have three components: alloying, isotopic mass variation, and the small local strain field induced by variations in the atomic species (Si or Ge). The scattering strength will be proportional to the total fraction of mass-disordered constituents: (Carruthers 1961)

$$\Gamma_{\text{Mass}}(x) = \Gamma_{\text{Alloy}}(x) + \Gamma_{\text{Iso}} + \Gamma_{\text{Strain}}(x). \tag{3}$$

The alloy mass-difference constant is defined as (Abeles et al. 1962)

$$\Gamma_{\text{Alloy}} = \sum_i f_i (1 - M_i/\overline{M})^2, \tag{4}$$

where f_i is the proportion of material i with mass M_i while the average mass is $\overline{M} = \sum_i f_i M_i$ (Morelli et al. 2002). The strength of the alloy mass-difference scattering has a quadratic dependence on the ratio between the masses of constituent

atoms (M_i) and the average alloy mass ($\overline{M}$) in Eq. 4. In the present case of $Si_{1-x}Ge_x$ alloys, the mass disorder depends on the germanium fraction:

$$\Gamma_{Alloy}(x) = x(1-x)\frac{(M_{Ge} - M_{Si})^2}{(xM_{Ge} + (1-x)M_{Si})^2}. \tag{5}$$

The primary driver of thermal conductivity reduction from pure Si or Ge to the SiGe alloy is the quadratic dependence on the germanium concentration in alloy mass-difference $\Gamma_{Mass}(x)$. The energy dependence of the alloy scattering rate follows a Rayleigh-like ($\tau^{-1} \propto \omega^4$) trend and is calculated from (Tamura 1983; Maris 1990):

$$\frac{1}{\tau_{Mass}(\omega)} = \frac{\pi}{6}V_0\Gamma_{Mass}\omega^2 D(\omega), \tag{6}$$

where V_0 is the volume per atom and $D(\omega)$ is the vibrational density of states per unit volume (Garg et al. 2011). The total energy-dependent vibrational density of states is given by a sum over all phonon branches b:

$$D(\omega) = \sum_b \int \frac{d\mathbf{q}}{(2\pi)^3}\delta\left[\omega - \omega_b(\mathbf{q})\right]. \tag{7}$$

The volume integral of the energy-conserving delta function over the whole first Brillouin zone (BZ) is calculated from the full phonon dispersion using the extrapolation method of Gilat and Raubenheimer (1966). In this method, the BZ is discretized, and the area of the intersection between the constant-energy surface described by the delta function $\delta\left[\omega - \omega_b(\mathbf{q})\right]$ and each discretization cube is calculated. Then the areas are divided by the gradient of the dispersion and summed (Gilat and Kam 1969; Gilat 1972).

The contribution due to isotopic variation in each of the constituent materials can be obtained by combining the isotope constants for each pure material as

$$\Gamma_{Iso}(x) = \frac{(1-x)\Gamma_{Si}M_{Si}^2 + x\Gamma_{Ge}M_{Ge}^2}{(xM_{Ge} + (1-x)M_{Si})^2}, \tag{8}$$

where the pure silicon and germanium isotope scattering constants Γ_{Si} and Γ_{Ge} were taken from Morelli et al. (2002). An additional component to alloy scattering arising from the strain field due to the difference in lattice constants of pure Si and Ge and their alloys has been proposed. The contribution due to strain is then given by (Abeles et al. 1962)

$$\Gamma_{Strain}(x) = \varepsilon x(1-x)\frac{(a_{Ge} - a_{Si})^2}{a_{SiGe}^2(x)}, \tag{9}$$

where $a_{\mathrm{SiGe}}(x)$ is the composition-dependent alloy lattice constant, taken in the virtual crystal approximation, including bowing (Rieger and Vogl 1993). The empirical strain parameter is taken to be $\varepsilon = 39$ (Abeles 1963). It is estimated on the basis of the impurity model (Klemens 1960) and is in good agreement with experimental results for SiGe alloys. For most values of germanium concentration x, the strain contribution $\Gamma_{\mathrm{Strain}}(x)$ is found to be much smaller than the mass-difference component.

The resistive anharmonic phonon-phonon scattering rate was calculated in the standard approximation for dielectric crystals (Morelli et al. 2002):

$$\tau_{\mathrm{b,U}}^{-1}(\mathbf{q}) = \frac{\hbar \gamma_{\mathrm{b}}^2}{\overline{M} \Theta_{\mathrm{b}} \bar{\upsilon}_{\mathrm{b}}^2} \omega_{\mathrm{b}}^2(\mathbf{q}) T e^{-\Theta_{\mathrm{b}}/3T}, \tag{10}$$

where the speed of sound $\bar{\upsilon}_{\mathrm{b}}$ of each branch b is determined from the average slope of its dispersion curve near the Γ point and $\overline{M}$ is the average atomic mass. The Grüneisen parameter γ_{b} was obtained for each branch from the phonon dispersion and has the value of 1.1 for the longitudinal acoustic branch and -0.6 for the two transverse acoustic branches. The expression in (10) contains the exponential term $e^{-\Theta_{\mathrm{b}}/3T}$ in the temperature dependence, which controls the onset of resistive umklapp scattering for each phonon branch through the branch-specific Debye temperatures Θ_{λ}, which were obtained from (Slack 1979):

$$\Theta_{\mathrm{b}}^2 = \frac{5\hbar^2}{3k_B^2} \frac{\int \omega^2 D_{\mathrm{b}}(\omega) d\omega}{\int D_{\mathrm{b}}(\omega) d\omega}, \tag{11}$$

where the branch-wise vibrational density of states (vDOS) function $D_{\mathrm{b}}(\omega) = \sum_{\mathbf{q}} \delta \left[\omega - \omega_{\mathrm{b}}(\mathbf{q}) \right]$ was calculated for each phonon branch b from the full dispersion, as described previously. This way, the temperature dependence of the contribution from each phonon branch to the total thermal conductivity is accurately represented.

In the bulk case, the crystal is assumed infinite and uniform. The distribution is only a function of temperature, and in the absence of boundaries and interfaces, the solution of the pBTE equation is simply given by

$$n_{\mathbf{q}} = \tau_{\mathrm{int.}}(\mathbf{q}) \upsilon_{\mathbf{q}} \cdot \nabla_{\mathbf{r}} T \frac{\partial N_{\mathbf{q}}^0(T)}{\partial T}. \tag{12}$$

In contrast, boundaries and interfaces play an important role in the solution of pBTE in nanostructures. Hence, in nanostructures, an extrinsic relaxation rate $\tau_{\mathrm{b,B}}^{-1}(\mathbf{q})$ due to boundary-roughness scattering is added. Each time a phonon reaches the boundary, the probability of it not being scattered by the roughness is captured through the momentum-dependent specularity parameter $0 < p(\mathbf{q}) < 1$ given by

$$p(\mathbf{q}) = \exp\left(-4\Delta^2 q^2 \cos^2 \Theta\right), \tag{13}$$

with Δ being the rms boundary roughness (typically $0.1 < \Delta < 1$ nm, depending on sample quality and processing) and Θ being the angle between the direction of propagation of the phonon wave and the boundary normal. The specularity parameter allows us to capture both the magnitude and the angle dependence of the scattering and distinguish between the contribution to the heat flux from phonons traveling into the boundary (small Θ, hence smaller $p(\mathbf{q})$ and more scattering) and phonons traveling parallel to the boundary (large Θ and larger $p(\mathbf{q})$, leading to less scattering). The specularity parameter is used in solving the pBTE as a boundary condition, with $[1 - p(q)]$ giving the fraction of the incoming phonons which are scattered randomly.

As boundary scattering is a momentum-randomizing elastic process, the scattered phonons will carry zero heat flux, so they can be represented by the equilibrium Bose-Einstein distribution, leading to a boundary condition of the form:

$$N_{\mathrm{b}}(\mathbf{q})^{+} = p(\mathbf{q})N_{\mathrm{b}}(\mathbf{q})^{-} + [1 - p(\mathbf{q})] N_{\mathrm{b},T}^{0}(\mathbf{q}). \tag{14}$$

with $+$ and $-$ representing the solution before reaching and after leaving the boundary, respectively, and $N_0(\mathbf{q})$ is the equilibrium Bose-Einstein phonon distribution of phonon mode $\mathbf{q}$ in branch b. The boundary scattering rate for a film of thickness H is then obtained as (Aksamija and Knezevic 2013)

$$\tau_{\mathrm{b,B}}^{-1}(\mathbf{q}) = \frac{\upsilon_{\mathrm{b},\perp}(\mathbf{q})}{H} \frac{F_p(\mathbf{q}, H)}{1 - \frac{\tau_{\mathrm{b}}^{\mathrm{int}}(\mathbf{q})\upsilon_{\mathrm{b},\perp}(\mathbf{q})}{H} F_p(\mathbf{q}, H)}, \tag{15}$$

where a mode-dependent scaling factor $F_p(\mathbf{q}, H)$ is given by

$$F_p(\mathbf{q}, H) = \frac{[1 - p(\mathbf{q})]\left\{1 - \exp\left[-H/\tau_{\mathrm{b}}^{\mathrm{int}}(\mathbf{q})\upsilon_{\mathrm{b},\perp}(\mathbf{q})\right]\right\}}{1 - p(\mathbf{q})\exp\left[-H/\tau_{\mathrm{b}}^{\mathrm{int}}(\mathbf{q})\upsilon_{\mathrm{b},\perp}(\mathbf{q})\right]}. \tag{16}$$

This formulation of interface scattering allows for the rates of internal (intrinsic) and boundary roughness scattering to be added together, despite their interdependence (Turney et al. 2010). The factor given by Eq. (16) encapsulates the competition between boundary and internal scattering: the effective strength of boundary scattering will depend on the relative strength of the competing internal scattering mechanisms.

The full thermal conductivity tensor $\kappa^{\alpha\beta}$ is calculated as a sum over all phonon momenta and branches:

$$\kappa^{\alpha\beta}(T) = \sum_{\mathrm{b}} \sum_{\mathbf{q}} \tau_{\mathrm{b}}(\mathbf{q})C_{\mathrm{b}}(\mathbf{q}, T) \upsilon_{\mathrm{b}}^{\alpha}(\mathbf{q})\upsilon_{\mathrm{b}}^{\beta}(\mathbf{q}), \tag{17}$$

where $\tau_{\mathrm{b}}(\mathbf{q})$ is the total phonon relaxation time [for a bulk sample, $\tau_{\mathrm{b}}(\mathbf{q}) = \tau_{\mathrm{b,Internal}}(\mathbf{q})$ from Eq. (2)] and the phonon heat capacity per mode $C_{\mathrm{b}}(\mathbf{q}, T)$ is given by

$$C_{\mathrm{b}}\,(\mathbf{q},\,T) = \frac{[\hbar\omega_{\mathrm{b}}(\mathbf{q})]^2}{k_B T^2}\,\frac{e^{(\hbar\omega_{\mathrm{b}}(\mathbf{q})/k_B T)}}{\left[e^{(\hbar\omega_{\mathrm{b}}(\mathbf{q})/k_B T)} - 1\right]^2}. \tag{18}$$

All the phonon branches have to be considered in the calculation of heat transport (Klemens 1958), although optical branches represent standing waves with very low group velocities and hence contribute comparatively little to the overall thermal transport, relative to their acoustic counterparts. Despite this, in some nanostructures with strong boundary scattering, the contribution from the acoustic branches decreased to the point that the optical phonons, which do not scatter as often from boundaries due to their low group velocity, can make a non-negligible contribution (Tian 2011).

The $v_{\mathrm{b}}^{\alpha,\beta}(\mathbf{q})$ are the components of phonon velocity vector calculated from the full phonon dispersion based on Weber's adiabatic bond charge (ABC) model (Weber 1974). The ABC model includes interactions between ions, bond charges, bond bending, and long-range electrostatic interactions and has been shown to reproduce measured phonon vibrational frequencies in virtually all Group IV (Weber 1977; Rustagi and Weber 1976), III–V (Strauch and Dorner 1990; Rustagi and Weber 1976), and II–VI (Rajput and Browne 1996) semiconductors with excellent accuracy. It has also recently been re-parametrized from first principles (Colombo and Giannozzi 1995). The ABC phonon dispersions for Si can be found in Aksamija and Knezevic (2010a) and for Ge in Weber (1977) and Rustagi and Weber (1976). Vibrational properties of $Si_{1-x}Ge_x$ alloys, including phonon dispersion and velocity, are calculated in the virtual crystal approximation (VCA) (Abeles 1963), which has been shown to accurately capture the phonon modes of random alloys (Larkin and McGaughey 2013). The full phonon dispersion allows accurate treatment of the inherent anisotropy which arises out of the combination of phonon focusing and the momentum-dependent boundary-roughness scattering.

3   Lattice Thermal Conductivity in Si-Ge Alloy Thin Films

The calculated thermal conductivity of bulk and thin films as a function of varying Ge composition is shown in Fig. 1a. The symbols represent experimental measured data by Cheaito et al. (2012). The thermal conductivity rapidly decreases with increasing germanium composition in the range of $0 < x < 0.2$, and the strongest reduction is achieved as it reaches an almost flat plateau between $0.2 < x < 0.8$, after which the conductivity again increases between $0.8 < x < 1$. Virtual crystal approximation is applied to Si_xGe_{1-x} by replacing the mass-disordered lattice by an ordered virtual crystal with randomly distributed atoms of constituent materials. A similar reduction has been shown in $Al_xGa_{1-x}N$ alloys at high temperature using the VCA by Liu and Balandin (2005). They found that the thermal conductivity reduces from 200 W/mK for Al_1Ga_0N to 50 W/mK for $Al_{0.9}Ga_{0.1}N$ and 20 W/mK for $Al_{0.5}Ga_{0.5}N$, about a factor of 10 decrease in conductivity for the 50% GaN case.

We find that the reduction is much higher in Si-Ge alloys, about a factor of 18, as the conductivity reduces from 146 W/mK for Si_1Ge_0 to 8 W/mK for $Si_{0.8}Ge_{0.2}$.

The effect of nanostructuring in reducing thermal conductivity can also be observed in thin films. As shown in Fig. 1a, the strong quadratic dependence on germanium concentration dominates the variation in thermal conductivity. However, inside the plateau region, changing the thickness has a much greater effect on thermal conductivity than variation of Ge composition, while outside the plateau, compositional variation dominates. As the film thickness decreases, alloying induces smaller changes in the thermal conductivity as size effects begin to dominate. There is significant reduction in the thermal conductivities of thin films as compared to bulk, which is due to boundary scattering of the long wavelength phonons which are the primary thermal carriers. Consequently, achieving minimum thermal conductivity requires composition inside the plateau region in combination with nanostructuring well below the bulk limit.

In Fig. 1b, the calculated thermal conductivity of $Si_{1-x}Ge_x$ thin films is plotted against sample thickness for different boundary roughness, showing reduction in conductivity with decreasing film thickness. The behavior of thermal conductivity as the thickness is reduced to the subnanometer regime depends on the model and assumptions therein. Cahill's minimum thermal conductivity model (Cahill et al. 1992) implies that the scattering rate has an upper bound which is reached when the phonon lifetime equals one period of vibration. Hence the upper bound on the scattering rate is given by $\tau_{\max}^{-1} = \omega/\pi$, and setting this upper bound on the phonon scattering rate reproduces the experimental values for amorphous Si (1 W/mK) and Ge (0.6 W/mK), as shown by solid lines in Fig. 1b. In the completely diffuse limit (p = 0), the boundary scattering rate is proportional to thickness, and the conductivity scales linearly with thickness. If the boundary scattering rates are allowed to scale with decreasing thickness above the $\tau_{\max}^{-1}$, then the thermal conductivity gradually dips below the minimum value predicted by the minimum thermal conductivity model, often referred to as the amorphous limit, as shown by dashed lines in Fig. 1b. In that case, the trends are in agreement with recent measurements below the amorphous limit by Feser et al. (2013).

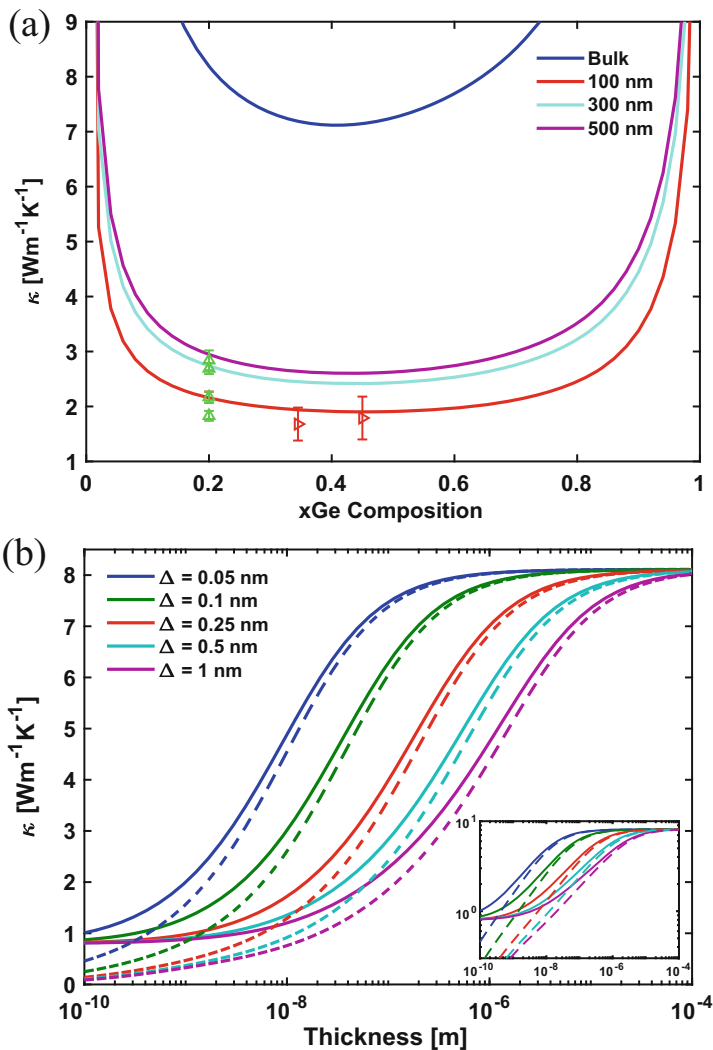
More generally, this model connects the boundary specularity $p(\mathbf{q})$ with roughness and finds that specularity depends exponentially on the rms roughness Δ; when thickness is reduced to the point that boundary roughness becomes comparable to the thickness, the exponential dependence of conductivity on roughness becomes more prominent, and the conductivity would tend to zero at a slower rate than the linear dependence predicted by the completely diffuse model. Hence, the dependence of the thermal conductivity on thickness would also include the consideration of roughness, and the amorphous limit is reached when both roughness and thickness become comparable to the unit cell size (0.543 nm in Si). Increasing the boundary roughness yields a reduction in thermal conductivity due to increased boundary scattering, more emphasized in larger samples as at smaller scales the conductivity is already limited by the size of the sample and increasing the boundary scattering will not reduce it further.


Fig. 1 (**a**) Thermal conductivity as a function of Ge composition is plotted for bulk and thin-film $Si_{1-x}Ge_x$ for three different thickness values of 100, 300, and 500 nm at room temperature. The symbols correspond to experimental data on the thickness series (upward triangles) and composition series (rightward triangles) by Cheaito et al. (2012). The plot demonstrates strong quadratic dependence on the germanium composition with a plateau between $0.2 < x < 0.8$. (**b**) Thermal conductivity of $Si_{1-x}Ge_x$ alloy is plotted versus film thickness for five different roughness values and germanium composition of 0.2. The solid lines represent the conductivity tending to the amorphous limit, and the dashed lines show the conductivity scaling with thickness below the amorphous limit. Increasing the roughness yields a gradual reduction in thermal conductivity, reaching the amorphous limit as the thickness approaches the nanometer scale. (Inset) The same plot on a log-log scale to show the conductivity scaling linearly with thickness below the amorphous limit (dashed lines). (Adapted from Upadhyaya et al. 2015)

4   Lattice Thermal Conductivity in Si-Ge Superlattices

SiGe SLs are bi-/multilayered structures composed of regular alternating layers of Si, Ge, or Si-Ge of varying composition, wherein the individual thickness of each layer is on the order of a few nanometers to several tens of nanometers. SLs have been found both experimentally and theoretically to have thermal conductivity below that of bulk $Si_{1-x}Ge_x$ alloys due to the combined effect of alloying and quantum confinement of particles due to nanostructuring. Bismuth-based SLs have been reported to possess very high figures of merit of around 2.6 (Venkatasubramanian et al. 2001). The impact of SL structure on lattice thermal conductivity has been attributed to a number of effects such as modification of the phonon spectrum, phonon localization, and scattering of phonons at the rough interfaces. Thermal conductivity of Si/Ge SL samples was measured to be lower than that of the corresponding alloy films (Huxtable et al. 2002), while in other materials, such as GaAs/InAs and bismuth-based SLs, the thermal conductivity was measured to be higher than that of the alloy film having equivalent overall composition.

Thermal transport in semiconductor SLs can be separated into two main directions based on symmetry: one being parallel called the in-plane transport (Khitun et al. 2001) and the other, perpendicular to the plane of the layers, called the cross-plane direction. The cross-plane direction is typically of much more interest for TE applications due to its lower lattice thermal conductivity (Cahill et al. 2003, 2014). In SLs with small period thickness, phonons are scattered by atomic-scale roughness present at the boundaries between successive layers. Roughness scattering is especially prominent in the cross-plane lattice thermal conductivity, which is governed by extrinsic rather than intrinsic effects (Chen 1998; Simkin and Mahan 2000; Yang and Chen 2001). This is particularly true for Si-Ge and $Si/Si_{1-x}Ge_x$ SLs, where the large mismatch between lattice constants and other material properties can lead to significant imperfections and appreciable roughness at the interfaces between layers, typically having several monolayers (ML, where $1\,ML \approx 0.13\,nm$) of roughness between the dissimilar layers in the SL (Huxtable et al. 2002). Therefore, interface properties, such as roughness (Martin et al. 2009), transport direction, and crystal orientation (Aksamija and Knezevic 2010a), in addition to alloy composition (Dismukes et al. 1964), are expected to play a significant role in thermal transport. They offer additional degrees of freedom to control the thermal conductivity in semiconductor nanostructures based on SLs, thereby opening up possibilities for further enhancement of the TE figure-of-merit through the reduction in lattice thermal conductivity.

Inside each layer of superlattice, every time the phonon reaches the boundary of that layer, one of two things must happen: the phonon will either continue traveling unscattered to the neighboring layer; this occurs in the case of a specular interaction, with probability given by the momentum-dependent specularity parameter $p(\mathbf{q})$, given earlier in Eq. (13). In the alternate case, called the diffuse case, the phonon will be scattered in a random direction with probability $1 - p(\mathbf{q})$. The addition of boundaries in one of the crystal directions breaks the symmetry and increases the anisotropy of the thermal transport between the direction of transport and

the direction normal to the boundaries. In general, since the boundary scattering rate for each phonon mode depends on the angle between its group velocity and the boundary normal, phonons interacting with the boundaries at low angles of incidence will undergo fewer and more specular collisions, thereby contributing more to transport in the direction parallel to the boundaries and increasing the anisotropy.

Once the thermal conductivity tensor κ for each of the two alternating layers is obtained, it can be decomposed into the two primary in-plane and cross-plane components. Owing to the cubic crystal symmetry of the underlying lattice, the tensor is diagonal. However, the diagonal components are not all equal due to the periodic SL structure breaking the rotational symmetry. From the full thermal conductivity tensor in Eq. (17), we can compute thermal conductivity by projecting it along any direction as $\kappa^{\alpha\beta} = \hat{n}^{\alpha}\kappa\hat{n}^{\beta}$ with $\hat{n}$ being the unit vector along the direction of transport (Aksamija and Knezevic 2010b). Subsequently, the conductivities of the two repeating layers in the SL will be combined in series for cross-plane transport and in parallel for in-plane transport; however, the cross-plane direction also has a small additional component of thermal resistance due to the acoustic mismatch between the layers, which adds a Kapitza resistance in series with the individual layers themselves:

$$\kappa_{\text{in-plane}} = \frac{L_1\kappa_1^{xx} + L_2\kappa_2^{xx}}{L_1 + L_2}$$

$$\kappa_{\text{cross-plane}} = \frac{L_1 + L_2}{\frac{L_1}{\kappa_1^{yy}} + \frac{L_2}{\kappa_2^{yy}} + \frac{1}{\sigma_1^{AIM}} + \frac{1}{\sigma_2^{AIM}}}. \quad (19)$$

The acoustic impedance mismatch (AIM) term has been found to add only a minor correction to the overall thermal conductivity in the extreme case of a Si/Ge SL and even smaller in alloy-based SLs due to smaller mismatch when both layers are composed of SiGe alloys (Aksamija and Knezevic 2013).

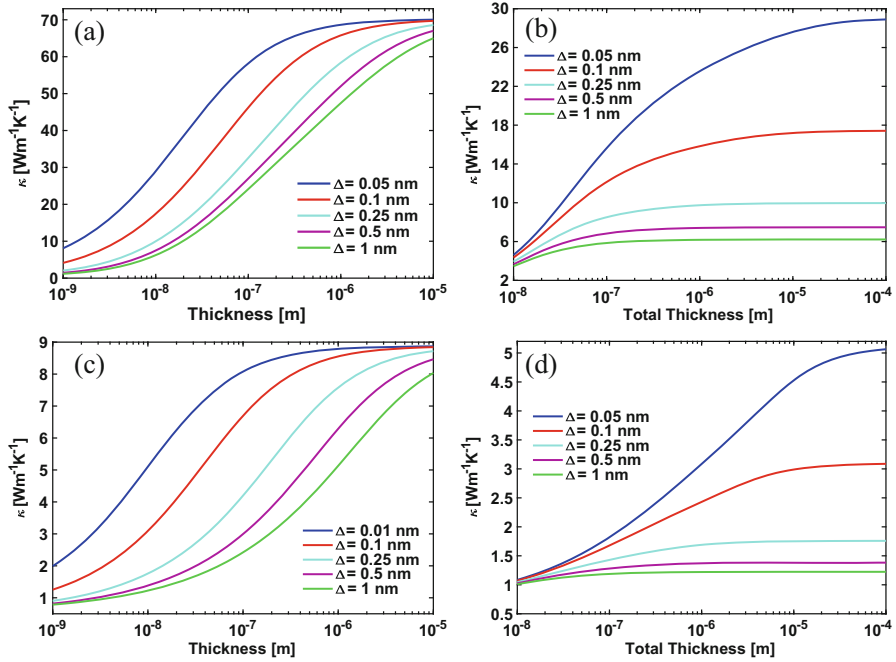
The additional scattering of phonons at the imperfect interfaces separating the SL layers leads to a two-order-of-magnitude reduction in thermal conductivity compared to bulk in Si/Ge SLs (Fig. 2a, b). The resulting thermal conductivity is lower than that of a $Si_{1-x}Ge_x$ alloy with the same proportions of silicon and germanium in agreement with Thumfart et al. (2017). This can be attributed to the additional boundary roughness scattering of phonons, especially the low-energy (long wavelength) acoustic phonons which are not strongly scattered by the Rayleigh-like mass-disorder scattering, given previously in Eq. (6). The lowest thermal conductivity is achieved when each of the layers is an alloy, which requires that the two layers are made up of different alloy compositions. In such a SL, thermal conductivity almost reaches the amorphous limit due to the combined effect of strong mass-difference scattering internal to the alloy layer and roughness scattering at the boundaries between the alloy layers, seen in Fig. 2c where both the layers are $Si_{1-x}Ge_x/Si_{1-y}Ge_y$ alloys with different composition of x = 0.2 and y = 0.8. In SLs, both period thickness and total length play an important role; however,


Fig. 2 Room temperature cross-plane thermal conductivity of a Si/Ge SL versus (**a**) SL bi-layer period thickness with fixed total sample thickness of $200\,\mu$m and (**b**) total sample thickness with fixed period thickness of 10 nm. Cross-plane thermal conductivity of a $Si_{0.8}Ge_{0.2}/Si_{0.2}Ge_{0.8}$ as a function of (**c**) bi-layer period thickness, with total sample thickness of $200\,\mu$m, and (**d**) total sample thickness with period thickness of 10 nm, for five different boundary roughness values of 0.05, 0.1, 0.25, 0.5, and 1 nm. Increasing the boundary roughness yields further reduction in thermal conductivity, more emphasized in larger samples because at smaller scales the conductivity is already limited by the overall size of the sample and increasing the boundary scattering between successive layers will not reduce it further. (Figure adapted from Upadhyaya et al. 2015)

total sample thickness is only significant when the roughness is small and the phonon mean free paths (MFPs) are not interrupted by the roughness scattering at the layer boundaries before they can reach the sample ends, as shown for both pure Si-Ge (Fig. 2b) and alloy SLs (Fig. 2d). The dependence on both sample and period thickness is more pronounced in pure Si/Ge SLs where the absence of alloy mass disorder implies that the thermal conductivity reaches the bulk limit in thick samples.

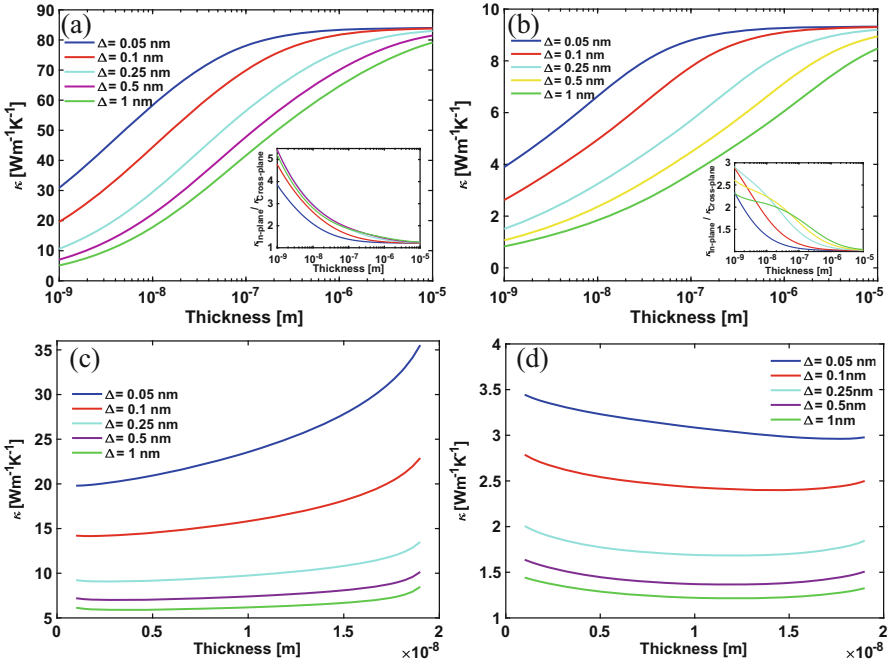
Figure 3a, b shows the in-plane conductivity for the Si-Ge and $Si_{0.2}Ge_{0.8}/Si_{0.8}Ge_{0.2}$ SLs. The in-plane thermal conductivity is higher due to the reduced effect of the boundary roughness scattering, which is more emphasized as the thickness of the individual layers is reduced. The inset figures show the anisotropy ratio (in-plane/cross-plane conductivity), which has the highest value at small layer thickness and saturates to a value of approximately as the layer thickness is increased above $1\,\mu$m.


Fig. 3 Room temperature in-plane thermal conductivity of (**a**) Si/Ge SL and (**b**) $Si_{1-x}Ge_x/Si_{1-y}Ge_y$ consisting of bi-layers with germanium composition of $x = 0.2$ and $y = 0.8$, respectively. Results are plotted as a function of bi-layer period thickness for five different boundary roughness values of 0.05, 0.1, 0.25, 0.5, and 1 nm (the total sample thickness is 200 μm). (Inset) The anisotropy ratio (in-plane/cross-plane conductivity) as a function of total sample thickness showing increasing anisotropy as thickness is reduced. Room temperature lattice thermal conductivity of (**c**) Si-Ge and (**d**) $Si_{1-x}Ge_x/Si_{1-y}Ge_y$ consisting of bi-layers with germanium composition of $x = 0.2$ and $y = 0.8$. The period thickness is held fixed at 20 nm and total sample thickness is 200 μm, while the thickness of the first layer is varied from 0 to 20 nm. (Adapted from Upadhyaya et al. 2015)

Varying the relative thickness of the two layers, while keeping both period and total sample thicknesses fixed at 20 nm and 200 μm, respectively, shows that the lowest thermal conductivity occurs when the Si layer is thinner than the Ge layer in pure Si/Ge SLs (Fig. 3c). This is due to the lower intrinsic thermal conductivity of Ge ($\kappa \cong 56$ W/m/K at room T (Glassbrenner and Slack 1964)). In contrast, alloy SLs have lower thermal conductivity when the Si-heavy layer (with $x = 0.2$ of Ge) is dominant (thicker) and the second Ge-heavy layer (with $y = 0.8$) is thinner, as shown in Fig. 3d. This is again caused by the layer possessing lower thermal conductivity being preferred; in the alloy case, it is predominantly the Si layer which has lower conductivity (as seen from the asymmetry of the curves toward the Si side in Fig. 1a, especially in the bulk case) due to the smaller Si mass being further from the alloy average than the heavier Ge mass, causing more mass-disorder scattering, as defined in Eq. (5). Hence, composition must be precisely taken into account when

designing SiGe SLs for TE applications because the lattice thermal conductivity will in general be minimized by making the layer with lower thermal conductivity thinner; for example, in a SL where only one layer is composed of an alloy (while the other is either pure Si or pure Ge), the non-alloy layer should be made as thin as possible in order to emphasize the contribution from the roughness scattering, while the alloy layer can be made thicker since the mass disorder will keep its conductivity low.

5   Thermal Conductivity in Si-Ge Nanowires

Thermal transport along Si nanowires has been of particular interest owing to their potential applications in TE conversion (Boukai et al. 2008; Hochbaum et al. 2008). Ideally, the reduction of thermal conductivity due to alloy scattering could be combined with the effect of boundary scattering; then Si-Ge nanowires (SiGe NWs) could lead to even more dramatic improvements of ZT (Shi et al. 2009). MD simulations suggested that the reduction in alloy NWs (relative to small-diameter Si NWs) is only a factor of 5 (Chen et al. 2009). Several measurements of thermal conductivity in thin SiGe NWs with rough boundaries were performed (Kim et al. 2010; Yin et al. 2012; Lee et al. 2012) and confirmed the weak diameter dependence of thermal conductivity in Si-Ge NWs.

Semiconductor NWs are typically grown using the VLS procedure (Li et al. 2003), producing a circular geometry which leads to the usual Casimir limit $\tau_B^{-1} \propto v_s/D$ in the case where boundary scattering is independent of angle (Xie et al. 2014). The closed-form solution used in the planar (membrane or thin film) case (Aksamija and Knezevic 2013; Sellan et al. 2010) in the previous sections is not valid here because the distance from each point on the interior of the circular wire to the rough surface depends on both the angle (determined by the phonon group velocity vector) and the point of origin, in contrast to the planar case. In addition, the specularity of the boundary depends not only on the roughness but also on the angle of incidence between the phonon and the local boundary normal (Aksamija and Knezevic 2010a; Soffer 1967). To overcome these challenges, the phonon Monte Carlo (pMC) technique has been widely used to solve the phonon Boltzmann transport equation (pBTE) (Mazumder and Majumdar 2001; Chen et al. 2005; Lacroix et al. 2006; Jeng et al. 2008; Randrianalisoa and Baillis 2008; Péraud and Hadjiconstantinou 2011; Ramayya et al. 2012). The pMC allows us to sample the phonon lifetimes (McGaughey and Jain 2012) and find the combined phonon lifetime in the presence of both intrinsic scattering (from anharmonic phonon-phonon and mass-difference interactions inside the wire) and partially diffuse boundary scattering at the rough surface in circular wires (Martin et al. 2009).

In the phonon Monte Carlo algorithm, an ensemble of phonons is initialized according to the Bose-Einstein distribution (McGaughey and Jain 2012). Then the free-flight time until scattering of each phonon is determined by first selecting a random number $r_{int.}$, uniformly distributed between 0 and 1, and sampling the lifetime according to $t_{int.} = -ln(r_{int.})\tau_{int.}(\mathbf{q})$ (Maurer et al. 2015). The phonon

lifetime ($\tau_{\text{int.}}\mathbf{q}$) combines all the intrinsic scattering mechanisms. Once the phonon free-flight time is determined, each phonon travels along the propagation direction given by its group velocity $\mathbf{v}_g(\mathbf{q})$, until scattering at the end of the "free flight" at $t_{\text{int.}}$ or until it encounters a boundary or contact, whichever occurs first.

The boundary roughness scattering is characterized through a momentum-dependent specularity given in Eq. 13. When a phonon reaches the rough boundary, another random number $r_{\text{spec.}}$ is used to select between a specular and diffuse scattering. If $r_{\text{spec.}} < p(\mathbf{q})$, then the boundary interaction is specular and the phonon is simply reflected at the boundary by flipping its momentum about the boundary normal $\mathbf{q}_{\text{final}} = \mathbf{q}_{\text{init.}} - 2\mathbf{q}_{\text{init.}} \cdot \hat{s}$. Otherwise, the interaction is diffuse: the phonon path is terminated and the boundary scattering time t_B is recorded as the time at which the diffuse scattering occurred and the process is restarted. The quasi-ballistic contribution arising from phonons which reach the contacts (at time t_C) before scattering internally or at the boundaries is also captured. When all the phonon flights are terminated in either internal or boundary scattering or at a contact, thermal conductivity is computed from the average:

$$\kappa = \frac{1}{N_\mathbf{q} N_i} \sum_{\mathbf{q},i} v_g^2(\mathbf{q}) \min\{t_{int.}, t_B, t_C\} C(T, \mathbf{q}), \qquad (20)$$

where $C(T, \mathbf{q})$ is the modal volumetric heat capacity (McGaughey and Jain 2012) and $N_\mathbf{q}$, N_i are the number of phonons and iteration in the simulation, respectively, both being typically 100,000.

Figure 4a depicts the thermal conductivity vs. diameter for NWs of different lengths and surface roughness Δ. The results were computed for NWs with 20% Ge concentration at room temperature. The conductivity shows an almost linear diameter dependence at intermediate diameter values for pure Si (Xie et al. 2014), where boundary scattering is dominant. The deviation from this linear dependence increases with alloying. Alloy scattering rate follows a Rayleigh-like trend (Eq. 6) and suppresses most of the higher-frequency phonons, whereas the low-frequency (long-wavelength) phonons remain nearly unaffected.

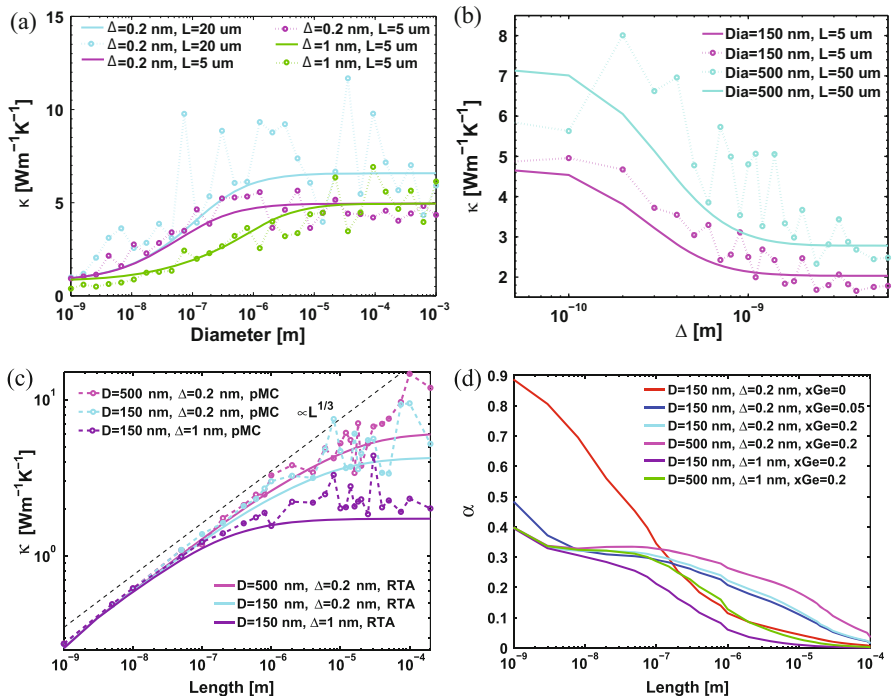
The high-frequency phonons tend to undergo a more diffuse scattering at the boundaries causing a stronger diameter dependence seen in SiNWs, whereas the low-frequency phonons undergo a more specular boundary scattering and have smaller diameter dependencies, indicating that it is the midrange phonons that cause the weak diameter dependence in SiGe NWs. Surface roughness dependence of thermal conductivity is shown in Fig. 4b. There is a steady decrease in conductivity with an increase in surface roughness up to 1 nm due to more diffuse boundary scattering, but increasing the roughness further does not reduce the conductivity, which saturates to a value much lower than in pure SiNWs. However the reduction in conductivity due to increased diffuse boundary scattering in SiGe NWs is not as effective as in pure Si NWs, primarily in thin wires where boundary scattering is dominant, due to the suppression of the high-frequency phonons by alloy scattering. For a pure Si NW of 10 nm diameter and 100 nm length, there is a 75% reduction


Fig. 4 (**a**) Thermal conductivity is plotted as a function of the wire diameter. The diameter dependence is weak due to strong intrinsic scattering. The solid lines represent the relaxation time approximation (RTA), and dashed lines represent the MC results. (**b**) Thermal conductivity is plotted as a function of surface roughness. For Δ values of 1 Å or less, the conductivity is unaffected, and it steadily decreases as the roughness is increased, without any further significant decrease beyond 1 nm. (**c**) Thermal conductivity as a function of length. The conductivity exhibits a $L^{1/3}$ behavior and gradually transitions into the diffusive regime at lengths exceeding 10 μm. (**d**) Exponent of length dependence α as a function of length. In SiGe NWs, $0.3 < \alpha < 0.4$ over a broad range of lengths, indicating non-diffusive transport. (Adapted from Upadhyaya and Aksamija 2016)

in conductivity when surface roughness is increased from 0 to 1 nm, whereas the reduction is about approximately 52% for a SiGe NW of the same dimension.

Figure 4c shows the dependence of thermal conductivity from pMC simulations on NW length. The dashed lines and symbols are the Monte Carlo results, while solid lines are the deterministic solution of the pBTE in the RTA, shown for comparison, and they are in close agreement. There is a gradual change in thermal conductivity with length, as seen in Fig. 4c, with the crossover to purely diffusive transport only occurring at lengths exceeding 10 μm, far in excess of the average phonon MFP and in agreement with measurements (Hsiao et al. 2013). Alloying suppresses most of the high-frequency phonons while the low-frequency phonons possess very long MFPs, allowing them to travel several microns without being scattered internally. However, even at very small NW lengths, the linear trend in the

length dependence is not present that would be characteristic of ballistic transport; instead, as seen in Fig. 4c, the conductivity scales as $L^{1/3}$.

A plot of the running exponent, defined as $\alpha(L) = d \ln \kappa(L)/d \ln L$ (Saito and Dhar 2010), in Fig. 4d shows that all SiGe NWs follow the same trend regardless of diameter, with 0.4, even when $L < 10$ nm. In contrast, short Si NWs reach the fully ballistic regime (characterized by $\alpha = 1$). The $\alpha \approx 0.33$ behavior has been observed in many momentum-conserving systems (Dhar 2008), including one-dimensional chains (Lepri et al. 2003; Mai et al. 2007), alloy thin films (Vermeersch et al. 2016), and, over a much narrower range of lengths, even thin Si NWs (Yang et al. 2010). However, the upper limit of length at which exponent $\alpha \approx 1/3$ depends on boundary scattering: in a rough wire ($\Delta = 1$ nm), the exponent reduces to the diffusive $\alpha = 0$ at a shorter length than in a smooth wire (where $\Delta = 0.2$ nm). Diffuse boundary scattering limits the longest MFP and thus results in a more uniform MFP distribution. Hence boundary scattering affects the range of length over which $\alpha = 1/3$ is observed, but not the length-scaling exponent α. Alloy scattering, on the other hand, results in an intrinsically different mode of transport having a broader range of MFPs with very few purely ballistic phonons.

Non-diffusive behavior of phonons can be readily seen in a plot of the distance along the NW traveled by one simulated phonon through a sequence of free flights interrupted by scattering events. Each flight number in the plot corresponds to a single free flight between successive scattering events for both Si (Fig. 5a) and $Si_{0.8}Ge_{0.2}$ (Fig. 5c). One phonon is chosen from the ensemble at random as a representative and plotted, as all of the simulated phonons exhibit qualitatively similar behavior. The scattering is predominantly elastic, arising in both cases from boundary roughness, while in alloy NWs there is a strong additional component due to mass disorder. It is interspersed by less frequent inelastic (anharmonic phonon-phonon) events which mix the phonon modes. Si NWs have a continuous distribution of distances due to the series of relatively uniform flight characteristic of diffusive transport, leading to a white noise-like appearance seen in Fig. 5a, which is readily associated with Brownian motion and predominantly diffusive transport.

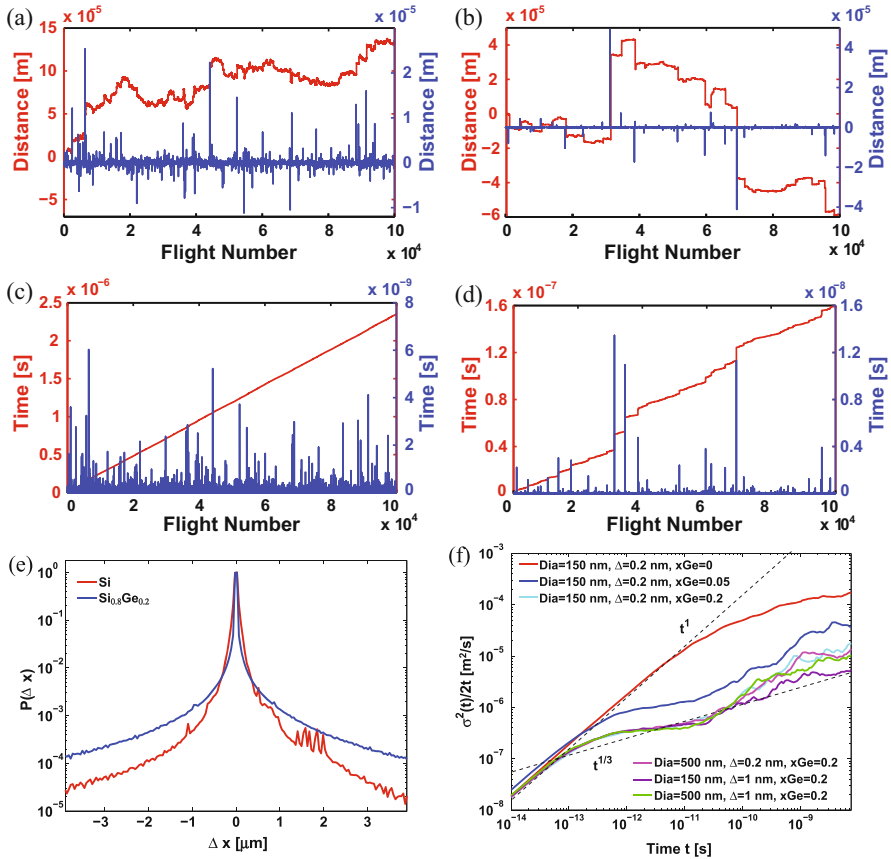
In contrast, phonon flights in SiGe NWs are comprised of sequences of many short flights interrupted by rare long leaps, as evidenced by the micron-sized jumps in the distance traveled by the phonon shown in Fig. 5c. This behavior in the alloy is a consequence of the strong mass-disorder scattering, which affects the upper portion of the phonon spectrum far more than the low-frequency modes. Viewing the whole phonon ensemble collectively, the result is a heavy-tailed distribution of free-flight lengths, shown in Fig. 5e. The difference is especially prominent when alloy NWs are compared to pure Si NWs, in which the tail of the phonon flight distribution decays faster. Phonons making long jumps exceeding $1\,\mu$m are more than twice as frequent in SiGe NWs as they are in Si NWs, as seen in the distribution of flight lengths Δx as measured in the direction of heat flow along the NW. The difference between alloy and non-alloy steadily increases for longer leaps, in spite of alloy scattering causing phonons in SiGe to have MFPs more than an order of magnitude shorter on average than pure Si. The heavy-tailed behavior is characteristic of Lévy walk dynamics (Dhar et al. 2013; Zaburdaev et al. 2015), which has already been


Fig. 5 The distance traveled by one simulated phonon between successive scattering events (blue dotted line) and the cumulative distance (red line) vs. flight number is plotted for (**a**) a pure Si NW and (**b**) a $Si_{0.8}Ge_{0.2}$ NW. Also, the time between scattering events (blue dotted line) and the cumulative time (red line) is plotted vs. the flight number in (**c**) pure Si NW and (**d**) $Si_{0.8}Ge_{0.2}$ NW. (**e**) Histogram of the individual free-flight lengths in Si (red) and $Si_{0.8}Ge_{0.2}$ NWs (blue). SiGe NWs show a larger proportion of long leaps, which leads to a heavy-tailed distribution. (**f**) Diffusion coefficient vs. time. In SiGeNWs there is a broad intermediate regime in which the exponent of the diffusion coefficient is ≈ 0.33 over several orders of magnitude in time, whereas in SiNWs $\alpha = 1$ in the ballistic regime followed by a smooth transition into the diffusive ($\alpha = 0$) regime. (Adapted from Upadhyaya and Aksamija 2016)

linked to superdiffusive phonon transport in low-dimensional (Cipriani et al. 2005) and alloy systems (Vermeersch et al. 2015).

Non-diffusive behavior of phonons in alloy NWs is further examined by the time-dependent phonon transport calculated from pMC simulations. The time dependence of the mean square energy displacement (MSD) (Denisov et al. 2003) is calculated from $\sigma^2(t) = \langle \Delta x^2(t) \rangle$ and related to an exponent $\sigma^2(t) \propto t^{\beta}$. Consequently, the diffusion coefficient $\sigma^2(t)/2t \propto t^{\beta-1}$. The exponent of length

dependence α, shown previously in Fig. 4d, has also been related to the MSD through $\alpha = \beta - 1$ (Liu et al. 2014). In normal diffusion, where Fourier's law remains valid, phonons undergo Brownian motion resulting in $\beta = 1$ (as $\sigma^2(t) \propto t$) (Shlesinger et al. 1993), which also means the exponent of length dependence $\alpha = 0$ and the conductivity is constant, independent of length. In contrast, when the system size is smaller than the MFP, phonon flights are uninterrupted by scattering, and their distance from origin grows in proportion with time; hence, ballistic MSD is quadratic in time ($\beta = 2$), implying that $\alpha = 1$ and the conductivity is linearly proportional to length (Li et al. 2015).

   $\alpha = 1/3$ scaling is attributed to an intermediate regime of superdiffusion: when $1 < \beta < 2$ transport is neither entirely ballistic nor diffusive. Instead, it is collectively characterized by a mix of long quasi-ballistic leaps, interrupted by bursts of short, diffusive steps. Consequently, the diffusion coefficient $\sigma^2(t)/2t \propto t^{\alpha}$ should also imply a length exponent $0 < \alpha < 1$ in the superdiffusive regime. The diffusion coefficient $\sigma^2(t)/2t$ is plotted as a function of simulation time in Fig. 5f, and $\alpha = 1/3$ (and $\beta = 4/3$) is observed over a wide range of timescales in SiGeNWs. In bulk SiGe alloys and SiGe thin films in the cross-plane direction, Vermeersch et al. (2015, 2016) have shown that $\beta = 1.34$, confirming that length scaling is a consequence of superdiffusion.

   The range of lengths over which superdiffusion is observed ($\alpha \approx 1/3$ over $10\,\text{nm} < L < 10\,\mu\text{m}$) far exceeds the average phonon MFP in the system; instead, it maps directly to the wide range of timescales over which superdiffusion is observed here in SiGeNWs (2 ps $< t <$ 2 ns in Fig. 5f) using the simple cutoff $t_s \approx L/v_s$ for superdiffusion in finite systems (Lepri et al. 2003; Liu et al. 2014), with v_s being the speed of sound ($v_s \approx 5000$ m/s in SiGe, depending on alloy composition). The diameter and roughness do not alter the exponent of the diffusion coefficient; instead, they affect only the onset of the transition from superdiffusion ($0 < \alpha < 1$) into purely diffusive regime ($\alpha = 0$), reducing the resulting conductivity in the steady state analogously to its length dependence in Fig. 4c. Thus, lattice conductivity is length tunable even in NWs several microns long, with potential applications to reducing thermal conductivity and thus increasing TE figure of merit in alloy NWs with sub-ten-micron lengths.

6   Thermal Conductivity in Si-Ge Nanocomposites

Despite their desirable properties, the cost of growing SLs is prohibitive, and nanocomposites (NCs) offer a tremendous advantage in their ease of manufacturing. Rather than having to grow SLs layer by layer from the ground up, NCs are made by relatively simple and cheap mechanical processing of materials, such as ball milling the bulk material into a fine powder of nanoscale grains, followed by spark plasma sintering into a nanostructured bulk composite (Liu et al. 2012), thereby making such nano-bulk materials much more amenable to scaling and commercialization (Lan et al. 2010). In addition to Si-Ge NCs, nanocrystalline Si has similar grain

structure and has also been studied as a platform to achieve high ZT in a Si-based system (Neophytou et al. 2013; Shiomi 2016).

However, the resulting NCs have a very heterogeneous structure with grains ranging in size from a few nanometers to hundreds of nanometers, typically following an exponential distribution (Lan et al. 2009). The grain properties, including atomic-scale grain boundary roughness (GBR), orientation, and composition, will also substantially affect thermal transport in NCs, offering numerous ways of adjusting their thermal conductivity by manipulation of grain size, shape, and crystalline angle distributions. Hence NCs can be designed to improve ZT by reducing lattice thermal conductivity by a combination of approaches including additional scattering of phonons from the interfaces between nanoscale grains of dissimilar materials, alloys of different composition, or grains with different crystal orientation (Kazan and Volz 2014).

Our model for NCs is based on solving the phonon Boltzmann transport equation (pBTE) with partially diffuse boundary conditions at the grain boundaries, similar to the model described previously in Sect. 3, but modified to capture fully the complex heterogeneous structure of the NC (Aksamija 2014). Voronoi tessellation (VT) is employed to discretize the material into grains which resemble closely the complex random grain structure of real NCs (Priolo et al. 1992; Bartkowiak and Mahan 1995). A cubic region is discretized, typically several micrometers in each direction, using the VT technique, which starts with a set of seed points and determines the division of the simulation domain into distinct and non-overlapping polyhedra. Each cell grows from its seed point until reaching its nearest neighbors at which point a grain boundary forms. The grain boundary always bisects the line connecting adjacent seed points. The VT follows the rules for constructing Wigner-Seitz cells except on the scale of grains rather than lattice cells (Aksamija and Knezevic 2014). Once the VT is complete, it provides critical information about the morphology of the NC, including the size of each individual grain, the grain size distribution, their interconnectivity (who the neighbors of each grain are), as well as the area of the contact region between neighboring grains. The grain size distribution is typically lognormal when starting from seed points uniformly distributed at random (Ferenc and Nda 2007) but can be modified to follow other prescribed size distributions (Fan et al. 2004).

When grain boundaries are introduced, the pBTE solution becomes position-dependent along the direction of propagation of the phonon mode (b, $\mathbf{q}$) because of scattering at the grain boundaries, which partially randomizes the direction of propagation of the incoming phonons, and scattering inside the grain. At the grain boundary, phonons will interact with the atomic-scale roughness, and a fraction $p_{\mathbf{q}}$ of the incoming phonons will pass through unchanged (coherent or specular part) while the rest $(1 - p_{\mathbf{q}})$ will be absorbed by the boundary and reemitted in a random direction (diffuse part). An effective scattering rate Γ_i^{GBR} due to the interactions of phonons with the GBR in the i-th grain can be defined by averaging the pBTE solution over the volume of each grain (Carruthers 1961; Wang and Mingo 2011) to obtain the final expression for the effective GBR scattering rate:

$$\frac{1}{\tau_{b,i}^{GBR}(\mathbf{q})} = \frac{v_b(\mathbf{q})}{D_i} F_{b,i}(\mathbf{q}) \left/ \left[1 - \frac{\Lambda_b^{int.}(\mathbf{q})}{D_i} F_{b,i}(\mathbf{q}) \right] \right. , \tag{21}$$

with D_i being the average distance a phonon travels inside the i-th grain. D_i can be related to the cubic root of the volume of the grain V_i, calculated for each grain from the VT, as $D_i = f_i S_i^{1/3}$, where f_i is the dimensionless form factor which captures the peculiarities of the specific geometry of each grain. For grains roughly approximated as disks, $f = \frac{8}{3\pi^{3/2}} \approx 0.48$. The parameter $F_{b,i}(\mathbf{q})$ fully captures the competition between GBR scattering at the boundaries of the grain and internal scattering inside the grain and is completely analogous to the one given previously for thin films, with D_i replacing the film thickness L. The GBR scattering rate $1/\tau_{b,i}^{GBR}(\mathbf{q})$ in Eq. (21) can be added to the rates due to intrinsic scattering processes internal to the grain to obtain the total scattering rate of mode $(b, \mathbf{q})$ in grain i as $1/\tau_{b,i}(\mathbf{q}) = 1/\tau_b^{int.}(\mathbf{q}) + 1/\tau_{b,i}^{GBR}(\mathbf{q})$.

In the steady state, the net heat flux through the boundaries of each grain must be zero. Therefore, fluxes in and out of its neighbors and any external heating source Q_i applied to i-th grain must add up to zero. This assertion allows us to calculate the temperature T_i inside the i-th grain from:

$$\sum_{j=\text{n.n.}} G_{ij} (T_i - T_j) + S_i Q_i = 0, \tag{22}$$

with the summation index j running over all the grains that neighbor grain i. The thermal conductance G_{ij} between neighboring grains i and j is given by the usual expression:

$$G_{ij} = \frac{\left[d_i \kappa_i(T_i) + d_j \kappa_j(T_j) \right] A_{ij}}{d_{ij}^2}. \tag{23}$$

with κ_i being the thermal conductivity of the i-th grain including the corresponding GBR scattering rate. Here, $d_{ij} = d_i + d_j$ is the distance between the centers of the two grains, i.e., the length of the straight line connecting the two centers, while d_i and d_j are the lengths of the line's segments inside the i-th and j-th grains, respectively. A_{ij} is the surface area of the grain contact region separating the two grains. This way, thermal resistor network is obtained, which can be solved iteratively (Braginsky et al. 2002), repeatedly updating the temperature of each grain based on the past values of the temperatures of its neighbors until convergence.

A heat sink is applied to the outer grains in the simulation domain so that the boundary condition on temperature outside of radius r_2 is kept constant. A heat source Q is applied to the grains inside a radius $r_1 = 1\,\mu$m around the center and is allowed to diffuse. Q is determined, upon iteration of the temperature, to ensure the peak temperature in the center to be a few Kelvin ($\approx 1\%$) above the temperature of

the heat sink. Convergence is reached when the total flux entering each grain equals the flux leaving it and the temperatures of all grains reach a constant value. After the temperature throughout the simulation domain reaches steady state (measured by the relative change in the temperature from one iteration to the next), the effective thermal conductivity is extracted using the below equation:

$$\kappa_{\text{eff}} = \frac{Q \log\left(\frac{r_2}{r_1}\right)}{2\pi (T_1 - T_2)}. \tag{24}$$

Effective thermal conductivity depends on the direction of heat propagation inside the NC, leading to strong directional anisotropy which arises from the local morphology of the grains, their sizes, and interconnections.

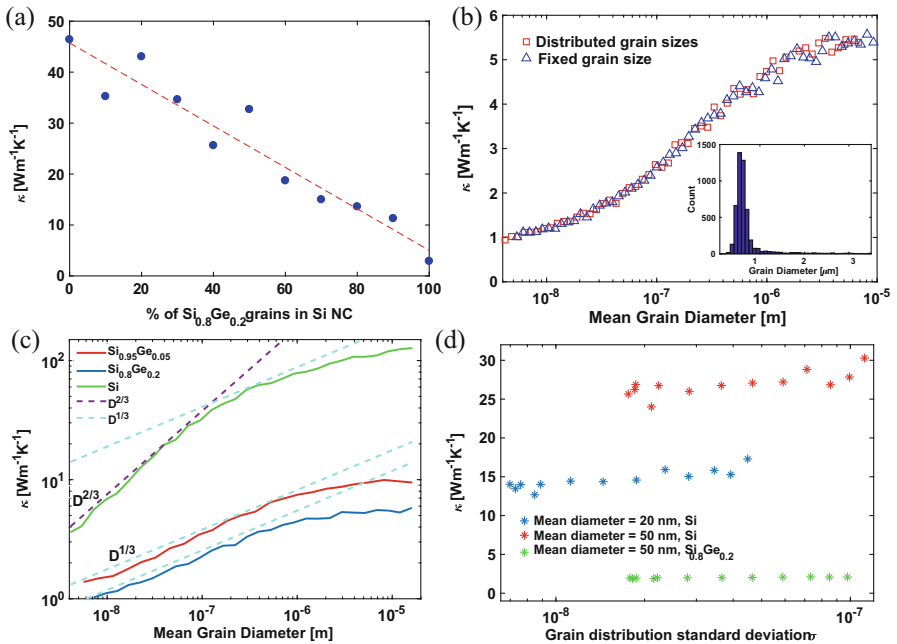
We find that the lattice thermal conductivity decreases with average grain size, as shown in Fig. 6b, analogous to the thickness dependence in thin films and SLs


Fig. 6 (a) Thermal conductivity of a Si/Si$_{0.8}$Ge$_{0.2}$ NC is plotted versus the percentage of Si$_{0.8}$Ge$_{0.2}$ grains. (b) Thermal conductivity of a Si$_{1-x}$Ge$_x$ NC with germanium composition of x = 0.2 is plotted versus average grain size for both uniform and randomly distributed grains. (Inset) The distribution of grain sizes. (c) Thermal conductivity of a Si$_{1-x}$Ge$_x$ NC with germanium composition of x = 0, 0.05 and 0.2 is plotted versus average grain size. Conductivity scales as $D^{2/3}$ in Si NC and $D^{1/3}$ in SiGe NCs indicating superdiffusive transport. (d) Thermal conductivity vs. standard deviation of the grain size distribution showing negligible effect of size distribution on conductivity. (Partially adapted from Upadhyaya et al. 2015)

discussed in previous sections. Further reduction in thermal conductivity can be achieved by making a NC with grains comprising of different material/composition due to increased mass-difference scattering. This trend is observed when a NC is made of intermixed Si and SiGe grains as shown in Fig. 6a. The size dependence is gradual and begins at grain sizes of several micrometers and saturates toward the amorphous limit as grain size approaches the nanometer scale, as seen in Fig. 6c.

It is interesting to note that despite the heterogeneity and disorder in the NC structure, the crossover to purely diffusive transport occurs only when average grain diameter exceeds $10\,\mu m$, similar to what we observed in SiGe NWs. The conductivity scales as $D^{2/3}$ in Si NC and $D^{1/3}$ in SiGe NCs, indicating a breakdown of Fourier's law and superdiffusive transport in both these systems. Even in the absence of alloy scattering, phonon transport in Si NCs is never predominantly ballistic due to the strong GBR scattering at the interface of each grain. However, the wide distribution of grain sizes (Fig. 6b (inset)), coupled with momentum-dependent GBR scattering that is more specular for long wavelengths, suppresses mid- and high-frequency phonons while allowing low-frequency (long-wavelength) phonons with long MFPs to travel several microns before being scattered internally, somewhat analogous to alloy scattering. This leads to superdiffusive transport even in non-alloy NCs.

On the other hand, the shape of the grain size distribution appears to have little effect, at least in alloy NCs, as both uniform and randomly distributed grain sizes lead to the same thermal conductivity for a given average grain size. We study the dependence on the grain size distribution in more detail by starting with a uniform distribution of seed points, which leads to a VT with uniform grains and a tight distribution of grain sizes. Next, we increasingly perturb the initial seed points to reach a broader size distribution and compute the standard deviation of grain sizes from the mean and its corresponding thermal conductivity. Our finding that the shape of the distribution has modest effect is further confirmed by Fig. 6d, which shows that varying the standard deviation of the grain size distribution in Si-Ge NCs has no effect on the thermal conductivity, after averaging over all transport directions. This trend is explained by the gradual dependence of the thermal conductivity of each grain on its size, caused by the competing alloy scattering in their interior. On the other hand, in Si NCs where the size dependence is more pronounced, we observe a gradual increase with as much as 20–30% variation, in agreement with a recent study (Hori et al. 2015).

We conclude that our model, based on the Voronoi tessellation and the pBTE solution in each grain, captures the grain structure of the NC and its impact on the thermal conductivity much more directly than empirical approaches such as the effective medium approximation (EMA) (Aksamija 2014). Reducing grain size into the nanometer regime or adding nanoscale grains into the bulk matrix is the most effective way to reduce thermal conductivity in NCs, with the additional benefit of lower cost and simpler fabrication than SLs. At such scales, energy-filtering effects are expected to lead to a boost, rather than a reduction, in the electronic power factor (Zebarjadi et al. 2011).

7   Beyond SiGe: Lattice Thermal Conductivity in Binary and Ternary Group-IV Alloys

Lately, there has been some interest in Sn-based Group-IV alloys, in particular, because of their widely tunable band gap (Zhu et al. 2015), which has opened the possibility of Si-based direct-band-gap semiconductors (Moontragoon et al. 2012; Gaiduk et al. 2014) with potential application in optoelectronics (Kouvetakis et al. 2006; Soref et al. 2007). Ternary Group-IV alloys such as $Si_{1-x-y}Ge_xSn_y$ and their heterostructures are also potential candidates for IR devices and quantum-well photodiodes (Fischer et al. 2015). However, growth of Si-Sn and, to a lesser extent, Ge-Sn alloys with high Sn concentration remains challenging due to the large lattice mismatch (19.5% between Si and α-Sn) and low solubility of Sn in Si ($\approx 5 \times 10^{19}$ cm^{-3}) (Min and Atwater 1998). Spurred on in part by potential TE applications (Tonkikh et al. 2014; Khatami and Aksamija 2016), recent work has demonstrated growth of thin-film $Si_{1-x}Sn_x$ with large concentration x on Si, Ge, and InP substrates (Kurosawa et al. 2017).

The phonon transport model used for computing thermal conductivity in Si-Ge alloys described in Sect. 2 holds for ternary Group-IV alloys as well. However, the isotope scattering term is modified to include contribution due to isotopic variation in each of the three constituent materials by combining the isotope constants as

$$\Gamma_{\text{Iso}}(x, y) = \frac{(1 - x - y)\Gamma_{\text{Si}}M_{\text{Si}}^2 + x\Gamma_{\text{Ge}}M_{\text{Ge}}^2 + y\Gamma_{\text{Sn}}M_{\text{Sn}}^2}{(xM_{\text{Ge}} + (1 - x - y)M_{\text{Si}} + yM_{\text{Sn}})^2}, \tag{25}$$

where Γ_{Sn} is calculated from known isotope composition of naturally occurring tin to be $\Gamma_{\text{Sn}} = 3.64 \times 10^{-4}$ from Eq. 4, which holds for isotope scattering within each material in the alloy (Liu and Asheghi 2005). An additional component to alloy scattering arising from the strain field due to the difference in lattice constants of pure Si and Ge and their alloys has been proposed. The contribution due to strain is then given by (Abeles et al. 1962)

$$\Gamma_{\text{Strain}} = \varepsilon \sum_i f_i(1 - a_i/\bar{a})^2, \tag{26}$$

where f_i is the proportion of material i with lattice constant a_i in this case Si, Ge, and Sn while the average lattice is given by $\bar{a} = \sum_i f_i a_i$. Here $a_{\text{SiGeSn}}(x)$ is the composition-dependent alloy lattice constant, taken in the virtual crystal approximation (VCA), including bowing (Rieger and Vogl 1993). The empirical strain parameter is taken to be $\varepsilon = 39$ (Abeles 1963).

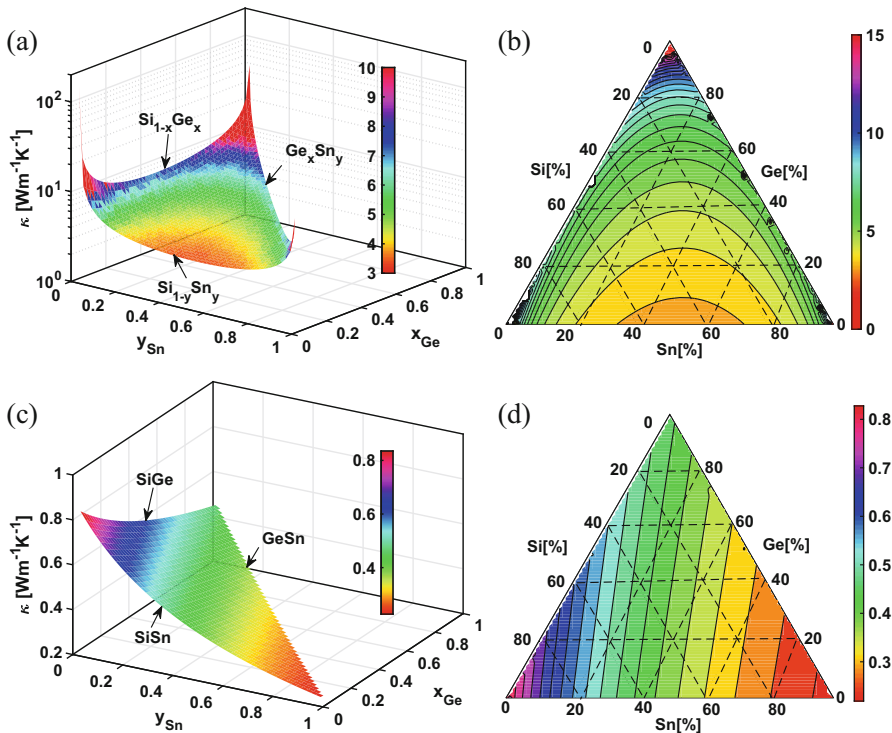
The lattice thermal conductivity of bulk ternary alloy SiGeSn is calculated from the full dispersion pBTE model. Figure 7a depicts thermal conductivity of bulk SiGeSn alloys against the contributed composition of each material. Thermal conductivity of binary alloy SiGe can be seen along the edge where Sn composition is equal to zero, similarly for SiSn and GeSn where Ge and Si composition,


Fig. 7 (**a**) 3D plot of thermal conductivity vs. Sn and Ge composition in bulk SiSn, GeSn, and SiGe. SiSn has the lowest thermal conductivity in bulk form. (**b**) Ternary plot of thermal conductivity vs. alloy composition. (**c**) 3D surface plot of the lowest achievable thermal conductivity vs. alloy composition in SiGeSn. Binary alloys correspond to the data points on the edges of the triangle and show that Sn has the lowest thermal conductivity in the amorphous (disordered) limit. (**d**) Ternary plot of the same. (Figure adapted from Khatami and Aksamija 2016)

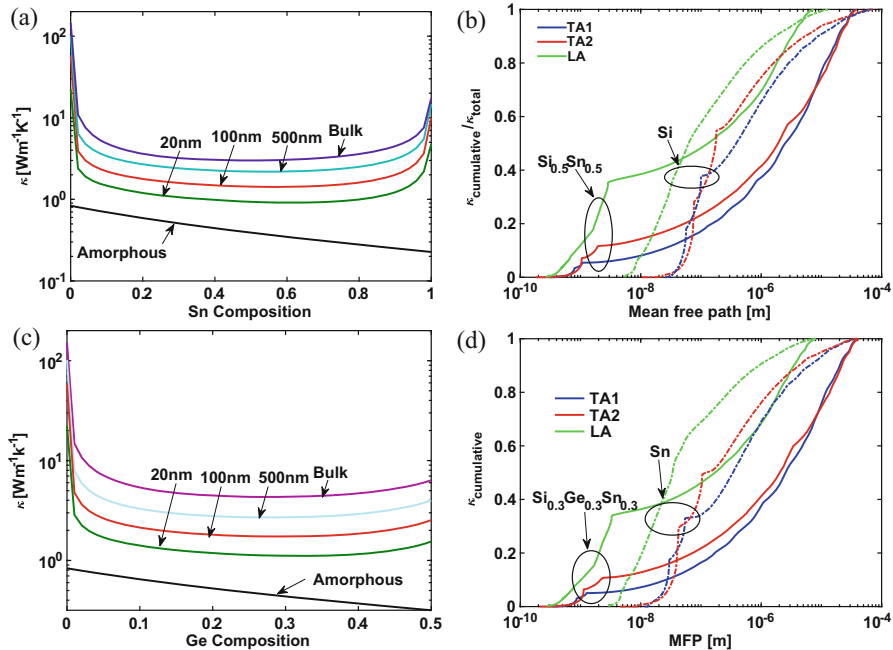
respectively, are equal to zero. Similar to SiGe (discussed in Sect. 3), thermal conductivity reaches a broad plateau in the alloy composition range $0.2 < y < 0.8$ of tin composition in $Si_{1-y}Sn_y$ and $Ge_{1-y}Sn_y$, due to dominance of mass-disorder scattering which depends quadratically on the difference in atomic mass between the constituent materials and the average mass. The lowest thermal conductivity for bulk binary alloy SiSn is 3 W/mK, at Sn composition of 0.5, is in good agreement with RNEMD calculations with mass ratio of 4.2 between Si and Sn (Frachioni and White 2012), and 5.86 W/mK in GeSn at Sn composition of 0.61, in agreement with the range of values (5–9 W/mK) measured in annealed poly-GeSn (Uchida et al. 2015). The large mass difference between Si and Sn results in a higher mass-disorder scattering rate, hence a lower lattice thermal conductivity, below the lowest value of 6.67 W/mK at Ge composition of 0.38 in SiGe. Fig. 7c shows the calculated amorphous (disordered) thermal conductivity, which is below 1 W/mK, and provides some indication of the minimum conductivity achievable through


Fig. 8 Thermal conductivity of (**a**) SiSn vs. Sn composition and (**c**) SiGeSn vs. Ge/Sn composition, for bulk, 500, 100, and 20 nm thick samples, simulated at room temperature with roughness of 0.45 nm and sample thickness of 1 μm. Cumulative thermal conductivity vs. MFP of (**b**) pure Si (dashed lines) and SiSn alloy (solid lines), (**d**) pure Sn (dashed lines) and $Si_{0.3}Ge_{0.3}Sn_{0.3}$ alloy (solid lines). (Figure adapted from Khatami and Aksamija 2016)

disorder (a combination of mass/alloy and boundary roughness) in each of these binary and ternary alloys.

The lowest thermal conductivity of SiSn at 20 nm thickness is 0.91 W/mK (Fig. 8a), achieved at Sn composition of 0.59. This value is below that of a high-performance TE BiSbTe alloy NC (κ_{ph}=1.1 W/mK at room temperature) having comparable (20 nm average) grain size (Poudel et al. 2008). SiSn alloys with high Sn concentration have not been demonstrated previously, due to the low solid solubility of Sn in Si; nonetheless, thermal conductivity in 20 nm thick SiSn film at 18% Sn concentration, the highest Sn fraction demonstrated thus far (Kurosawa et al. 2015), only increases to 1.22 W/mK, which is nearly a 30% reduction from the lowest value achievable in SiGe thin films of equal thickness. A room temperature thermal conductivity of 2.5 W/mK, with a lattice contribution of 1.8 W/mK and corresponding ZT of about 1.3 at 900 °C, was reported in a $Si_{0.8}Ge_{0.2}$ NC with average nanoparticle size of about 20 nm (Wang et al. 2008; Lan et al. 2010). The calculated thermal conductivity of $Si_{0.82}Sn_{0.18}$ is 50% smaller that could potentially lead to a ZT of 1.7, assuming the same electron contribution to thermal conductivity $\kappa_e = 0.7$ W/mK. In p-type SiGe NCs, the peak ZT value is around 30% smaller than

n-type, likely due to lower hole mobility (Fischetti and Laux 1996), reaching 0.95 at 850 °C (Joshi et al. 2008; Zhu et al. 2009).

Figure 8c depicts the ternary alloy thermal conductivity vs. Ge and Sn composition, keeping Ge x and Sn y composition equal ($x = y$). x and y are varied from 0 to 0.5, while the silicon composition ($1 - x - y$) is reduced from 1 to 0. At $x = y = 0.32$ and the film thickness of 20 nm, the thermal conductivity reaches its lowest value of 1.11 W/mK, slightly higher than the lowest value achieved in SiSn at that same thickness. However, this is the closest value to the lowest achievable thermal conductivity given by the corresponding amorphous limit.

Figure 8b, d shows the normalized cumulative thermal conductivity vs. MFP in SiSn and SiGeSn, respectively. The optical modes are omitted due to their low contribution to thermal conductivity, caused by their very flat dispersion and consequently low phonon group velocities. The density of states peaks near van Hove singularities and the sharp bends in the slope of the cumulative thermal conductivity plot correspond to these peaks. In the diffuse case, boundary scattering limits the phonon MFP; hence, only phonons having MFP smaller than or equal to the film thickness will contribute to thermal conductivity, and its value can be estimated using the cumulative plot by taking the MFP equal to thickness and reading off the corresponding thermal conductivity. In SiSn, phonons having MFPs below 20 nm still contribute around 40% of thermal conductivity, significantly more than they contribute in SiGe (Khatami and Aksamija 2016). Alloying leads to a broader range of MFPs and a more gradual dependence of conductivity on MFP in Fig. 8c.

Group-IV alloys containing Sn have tunable band gaps which may expand the range of temperatures at which they are competitive with existing materials. For example, bulk Bi_2Te_3 is commonly used at room temperature because of its small band gap (150 meV at room temperature (Bejenari and Kantser 2008)) and low thermal conductivity (1.4 W/mK measured in a 1 μm film (Goncalves et al. 2010)); both of these are achievable with SiGeSn alloys, with the added advantage of compatibility with current Si-based nanoelectronics. While it is too early to fully evaluate the potential for SiGeSn to replace or improve existing TE materials, these recent findings will spur further research into the growth of bulk and nanostructured Group IV alloys containing Sn and their optimization for TE applications.

8   Conclusions

This chapter describes the lattice thermal conductivity in nanostructured SiGe alloys, including thin films, SLs, NWs, and NCs. The pBTE is solved with the full phonon dispersion and a momentum-dependent specularity model for boundary roughness scattering that effectively captures the interplay between intrinsic and interface scattering mechanisms. There's an order-of-magnitude reduction in thermal conductivity due to alloying, and further decrease is achieved in each of the nanostructures, with conductivity nearing the amorphous limit. Among Group-IV binary (SiSn and GeSn) and ternary (SiGeSn) alloys and their thin films, SiSn

has the lowest conductivity (3 W/mK) of all the bulk alloys, which reduces further to around 1 W/mK in 20-nm-thick SiSn films. Thermal conductivity is optimized in SLs by reducing the overall thickness of the superlattice period, increasing the roughness of the interfaces, and either introducing alloying into both layers of the superlattice or minimizing the thickness of the pure layer in silicon-alloy superlattices.

A Monte Carlo technique is used to compute the thermal conductivity in SiGe NWs. We find that thermal conductivity scales as $L^{1/3}$ over a broad range of lengths and the direct ballistic-to-diffusive crossover picture should be augmented by superdiffusion in the broad intermediate range of NW length from 10 nm to 10 μm. A Voronoi tessellation model was employed to treat the complex heterogeneous grain structure in NCs. The size scaling observed in NWs persists in nanocomposites and is insensitive to the variance in grain sizes. Alloy nanostructures exhibit novel heat dynamics and can be used as a unique fundamental platform to study the breakdown of Fourier's law and superdiffusive heat transport. The results demonstrate tunability of thermal transport through boundary and interface properties including structure size, roughness, and composition that are relevant to guiding the design of nanostructured SiGe alloys for thermoelectric applications.

Resonant Thermal Transport in Nanophononic Metamaterials

40

Mahmoud I. Hussein and Hossein Honarvar

Contents

Abstract

Thermoelectric materials allow heat to be converted directly into electricity or, conversely, to be absorbed or rejected when electrical power is provided. A key requirement for a thermoelectric material is to exhibit a low thermal conductivity while simultaneously possessing a high power factor, which is proportional to the electrical conductivity. The challenge, however, is that these two property targets are coupled and are at odds with each other in common materials. This natural

constraint has limited the performance of thermoelectric materials and impeded their industrial proliferation. In this chapter, we present a recently proposed material concept, termed *nanophononic metamaterial*, which overcomes this historical constraint. One promising configuration of a nanophononic metamaterial consists of a silicon membrane with inherently attached local resonators in the form of nanopillars distributed on the surface. The nanopillar local resonances, or *vibrons*, hybridize with the underlying phonon waves carrying the heat in the membrane, which leads to significant reductions in the phonon group velocities and to mode localizations within the nanopillars. These two wave-based phenomena, supplemented by reductions in phonon lifetimes, together cause a reduction in the lattice thermal conductivity along the base membrane. Since the nanopillars are located external to the main body of the membrane, changes to the electronic band structure and electron scattering are both minimized – thus a negligible effect on the generation and flow of electrons is expected. This novel nanostructure-induced mechanism therefore has all the ingredients to enable thermoelectric energy conversion at record high performance while using a low-cost and practical base material such as silicon. This chapter includes lattice dynamics- and molecular dynamics-based analyses of the underlying physical processes stemming from the presence of the local resonances and discusses how the nature of *resonant thermal transport* is shaped particularly by the wave-based mechanism of phonon-vibron coupling.

1 Introduction

Thermoelectric materials (TE) convert heat into electricity or vice versa through a solid-state process. For the conversion efficiency to be competitive with fluid-based technologies, a TE material must be a good insulator of heat while, simultaneously, exhibiting good electrical properties – a combination that is hard to find in common materials. Here we present the concept of a locally resonant nanophononic metamaterial (NPM) (Davis and Hussein 2014; Hussein and Davis 2016; Honarvar and Hussein 2016, 2018; Honarvar et al. 2016) to overcome this natural properties trade-off. One realization of an NPM is a freestanding silicon (Si) membrane (thin film) with a periodic array of nanoscale pillars erected on one or both free surfaces. Heat is transported along the membrane portion of this nanostructured material as a succession of propagating vibrational waves, *phonons*. The atoms making up the minuscule pillars on their part generate stationary vibrational waves, which we describe as *vibrons*. These two types of waves interact causing a mode coupling for each pair which appears as an avoided crossing in the pillared membrane's phonon band structure. This in turn (1) reduces the base membrane phonon group velocities, as well as (2) enables the generation of new modes localized in the nanopillar portion(s) in physical space; it also (3) drops the phonon lifetimes at and around the phonon-vibron coupling regions in the phonon band structure. These three effects in tandem cause a reduction in the in-plane lattice thermal conductivity of the underlying membrane.

Given that the number of vibrons scales with the number of degrees of freedom of a nanopillar, the three effects intensify as the size of the nanopillar(s) increases and in principle may be tuned to influence the entire phonon spectrum (which for silicon extends up to over 17 THz). This novel *full-spectrum* phenomenon thus provides an opportunity for achieving exceptionally strong reductions in the thermal conductivity. Furthermore, since the mechanisms concerned with the generation and carrying of electrical charge are practically independent of the phonon-vibron couplings, the Seebeck coefficient and the electrical conductivity are at most only mildly affected, if not at all. In this chapter, we introduce the concept of an NPM and resonant thermal transport, provide a lattice dynamics (LD) analysis highlighting the impact of local resonances on the phonon band structure, and present thermal conductivity predictions using molecular dynamics (MD) simulations. Finally, projections of record-breaking values of the TE energy conversion figure of merit ZT are provided.

2   Classical Macroscopic Metamaterials for Electromagnetic and Acoustic/Elastic Waves

Metamaterials are artificially structured materials that possess properties generally viewed to exceed what we expect to find in naturally occurring materials. The concept was first introduced in electromagnetics and optics (Pendry et al. 1999; Smith et al. 2000) and shortly afterward in acoustics (Liu et al. 2000). Examples of such unusual properties include subwavelength band gaps and negative refraction. In both electromagnetic and acoustic/elastic metamaterials, the feature of interest appears in the subwavelength regime and in the context of extreme effective properties. A form of local resonance is usually associated with this behavior. The local resonance is introduced by embedding or attaching resonating substructures into/to the host or base material medium (Hussein et al. 2014). At a resonance frequency, a coupling takes place between the resonating substructure and a traveling wave mode associated with the underlying medium. This coupling creates an avoided crossing in the electromagnetic or acoustic/elastic band structure of the overall system, which may result in the opening of a band gap and the creation of negative (or generally extreme) effective properties at and around the resonance frequency.

An example of a classical macroscopic metamaterial, proposed in a seminal paper by Liu et al. (2000), consisted of a relatively light and compliant matrix material, namely, epoxy, hosting heavy inclusions coated with a highly compliant material, namely, rubber-coated lead spheres. In this acoustic metamaterial, the lead spheres acted as the resonating masses, whereas the rubber coating served the role of supporting springs. An example of an elastic metamaterial was presented by Pennec et al. (2008) and Wu et al. (2008) in the form of a plate with pillars erected on one surface. The thickness of the plate and the size of the pillars were selected to be on the order of a few millimeters, which results in local resonances and hybridization band gaps at frequencies as low as a few hundred Hertz. In both sets of examples, the coated inclusions and the pillared plates, the resonating components

were placed in a spatially periodic fashion. While periodicity is advantageous in terms of compactness and ease of analysis and characterization, it is not necessary in a metamaterial (Achaoui et al. 2013).

3 Nanophononic Metamaterials for Thermal Transport

Similar to electromagnetic and acoustic/elastic metamaterials, an NPM also features resonating substructures, except as implied by the terminology; these substructures are of nanoscale size which makes their atomic structure directly relevant to the emerging resonance characteristics (Honarvar and Hussein 2018). Moreover, in classical metamaterials, typically the interest is in a single low-frequency resonance in the kHz or MHz regime. In an NPM, on the other hand, the entire set of resonances is of interest due to the nature of nanoscale thermal transport which in principle is formed from the collective contributions of all phonon modes. In a semiconducting material, the resonance spectrum spans an extremely broad frequency range, for example, reaching over 17 THz for silicon. The number of local resonances is equal to the number of atoms comprising a nanoresonator multiplied by three, which is the number of degrees of freedom for the motion of an atom. Thus for a resonating substructure on the order of a few tens of nanometers in size, the number of local resonances could be in the hundreds of thousands or millions.

3.1 Nanopillared Membranes for Thermoelectric Energy Conversion

In TE materials, the underlying process of power generation from temperature differences is referred to as the Seebeck effect, while the process of heat pumping or refrigeration driven by an electrical current is known as the Peltier effect (Vineis et al. 2010; Chen et al. 2013). Since no moving mechanical components, fluid systems, or chemical reactions are involved, TE materials provide good reliability and stability. On the other hand, their low efficiency is a significant obstacle that impedes their wide use for large-scale industrial and domestic energy conversion. The performance of a TE material is based on a well-defined figure of merit, $ZT = (S^2\sigma/k)T$, where S is the Seebeck coefficient (representing the amount of voltage generated per unit temperature gradient), σ is the electrical conductivity, k is the total thermal conductivity (consisting of a lattice component k_l and an electronic component k_e), and T is the average temperature between two material junctions (Rowe 2005).

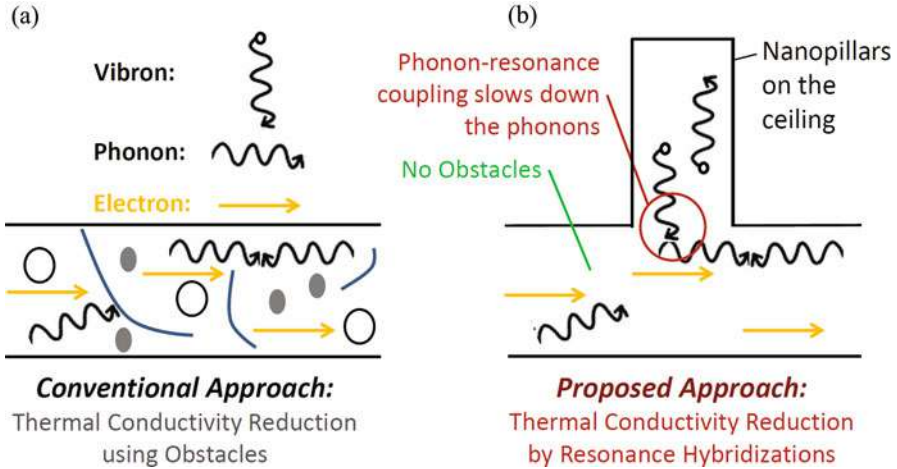
A key requirement for a TE material is to exhibit a low thermal conductivity while simultaneously possessing a high Seebeck coefficient and a high electrical conductivity. The challenge, however, is that these two sets of requirements – the thermal and the electrical – are tightly coupled and cannot be both met, especially in industrial materials like silicon. At present, commercially available TE devices exhibit ZT values near 1; yet a value of 3 or higher is needed to enable industrial-


Fig. 1 Illustration of thermal conductivity reduction in a membrane by (**a**) scattering (using obstacles; conventional approach) versus by (**b**) the resonance hybridizations mechanism (without obstacles; proposed approach)

scale deployment of thermoelectrics for waste heat conversion to electricity and for cooling and refrigeration (Vineis et al. 2010). Over the last two decades, an overriding philosophy for increasing ZT has been to introduce small features (such as holes, particles, and/or interfaces) within the internal domain of the material in order to scatter the heat-carrying phonons and consequently reduce the thermal conductivity (Vineis et al. 2010; Snyder and Toberer 2008) (Fig. 1a). This strategy, however, still suffers from the properties trade-off mentioned above since the scatterers are also likely to affect charge generation and impede the transfer of electrons and thus negate any possibility of substantial increase in ZT.

The historical performance limitations of TE materials are potentially overcome via an NPM configuration that is based on a thin membrane of silicon with a periodic array of closely packed nanopillars standing on its surface (i.e., exterior to the membrane cross section) (Davis and Hussein 2014; Hussein and Davis 2016; Honarvar and Hussein 2016, 2018; Honarvar et al. 2016). A large portion of the heat transported in this nanostructured material is carried by phonons, a collection of propagating vibrational waves. The atoms making up the nanoscale pillars on their part generate stationary vibrational waves. These two types of waves, the traveling and the standing, interact and cause a substantial portion of the energy of the heat-carrying phonons to divert into the nanopillars and remain localized there (Fig. 1b). In addition, the coupling between the resonances and the underlying heat-carrying phonons traveling in-plane in the membrane causes the phonon group velocities to drop significantly. Furthermore, the nanopillars reduce the phonon lifetimes at and around the hybridization zones that feature in the phonon band structure. These three effects cause a reduction in the lattice thermal conductivity along the membrane. This novel mechanism of phonon-vibron coupling via nanostructuring is practically

independent of the mechanisms of generation and transport of electrical charge and therefore does not significantly affect the Seebeck coefficient and electrical conductivity, respectively.

3.2 Vibrons: Standing Phonons

In an NPM, the substructure resonances are denoted as vibrons, which unlike phonons are wavenumber-independent because they are localized standing waves. The frequency spectrum of vibrons made available by a resonating nanosubstructure may be designed to couple with heat-carrying phonon modes belonging to all or most of the dispersion branches across the full spectrum of the host medium. This atomic-scale coupling mechanism gives rise to a *resonance hybridization* between pairs of vibrons and wavenumber-dependent phonons of the host medium.

This phenomenon has been demonstrated theoretically using LD calculations and a Boltzmann transport model on a system based on a 3-nm-thick suspended Si membrane with Si nanopillars, yielding a factor of 2 reduction in the thermal conductivity due to the presence of the nanopillars (Davis and Hussein 2014). This discovery was the topic of a focus article in *Physics* (Monroe 2014) and, more recently, has been described in a German online book on renewable energy and energy efficiency as one of the recent ideas in thermoelectrics that "is radical and potentially overcomes the main problem that has limited the development of the field since its birth in 1821" (Khammas 2007–2018). In Fig. 2, we consider a freestanding Si membrane but use gallium nitride (GaN) for the nanopillars as another example of an NPM (modeling details are provided in the next subsection). As shown in Fig. 2a, avoided crossings between horizontal resonance modes (i.e., the vibrons) and the underlying membrane dispersion branches take place. In Fig. 2b, we clearly observe how an avoided crossing causes mode localization. We note that the nanopillar-membrane coupling in this multi-material structure is sufficiently strong to still generate these avoided crossings which lead to a reduction the in-plane thermal conductivity along the membrane.

3.3 Frequency Limits for "Active" Resonance Hybridization

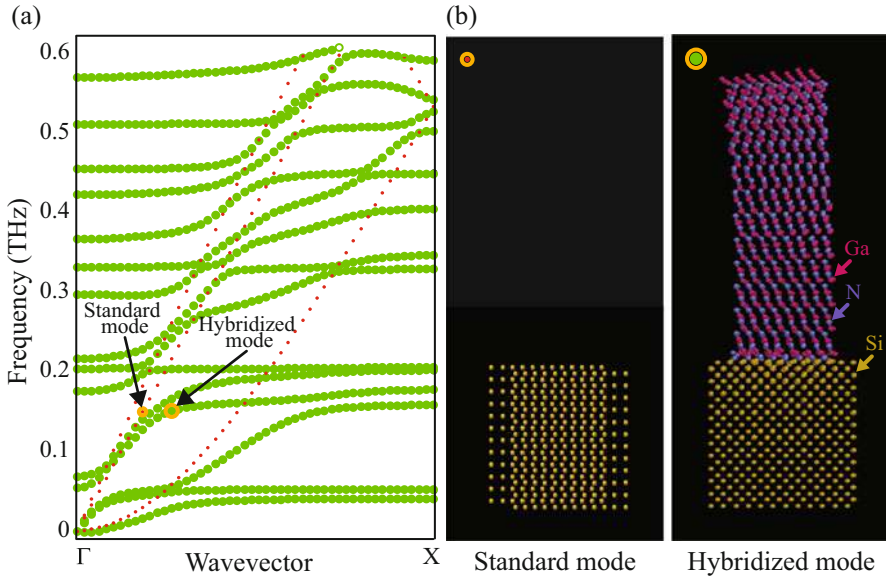
Thermal transport in silicon is carried by very short wavelength waves which puts low-frequency limits on the nanopillar generated vibrons that couple with the phonons. To investigate these limits, we switch back to a simpler nanopillared membrane configuration where both the membrane and nanopillar portions are made out of silicon. We use this model throughout the rest of the chapter. Two NPM configurations are considered, namely, a membrane with nanopillars (1) on a single surface and (2) on each of the two surfaces. We only examine base membrane and nanopillars formed from defect-free single-crystal silicon. Figure 3 displays the unit cells of these two NPM configurations as well as the structure of a conventional cell (CC) and a unit cell of a uniform (unpillared) membrane with the same thickness as


Fig. 2 Illustration of the resonance hybridization phenomenon from a lattice dynamics perspective. (**a**) Phonon band structure of a Si membrane with GaN pillars standing on one surface (green) versus that of a uniform Si membrane with the same thickness (red). (**b**) Atomic displacements for a standard heat-carrying phonon indicating activity within the Si membrane portion. (**c**) Atomic displacements of a hybridized mode revealing localized pillar motion and almost "thermal silence" in the Si membrane portion. A small model (3264 atoms in the unit cell) is displayed for clarity

the thickness of the base membrane in the NPM. The geometry of a membrane with nanopillars on each surface is represented as $aA_x \times aA_y \times d + b \times b \times h_T + b \times b \times h_B$ which may be converted to CC by dividing each dimension by a. This same representation is used for an unpillared surface by simply dropping each of the last two terms. Figure 3 provides a pictorial definition of all geometric parameters. In all our analyses, room temperature at $T = 300\,\text{K}$ is assumed, and the Stillinger-Weber

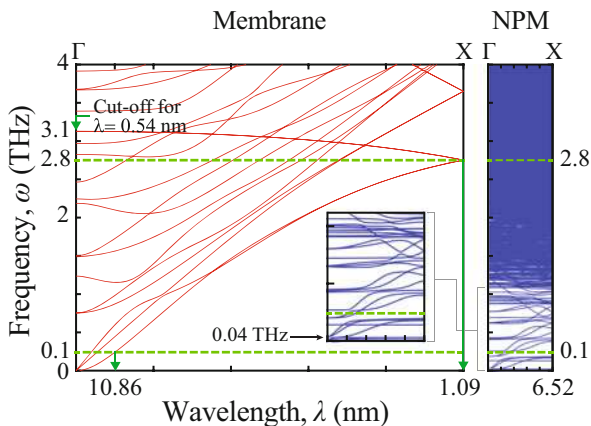
limits for "active" vibrons
considering phonons with
wavelengths ranging from
0.54 to 10.86 nm


empirical potential is used to represent the interactions between neighboring atoms
(Stillinger and Weber 1985).

In bulk silicon, thermal transport is carried by phonons with wavelengths ranging,
roughly, from 0.4 to 10 nm at room temperature with the majority of the distribution
being between 0.4 and 2.2 nm (Esfarjani et al. 2011). In Fig. 4, we show the phonon
band structure for an unpillared membrane unit cell of size $1 \times 1 \times 6$ CC (i.e., 0.543-
nm wide) and a nanopillared membrane unit cell of size $6 \times 6 \times 6 + 4 \times 4 \times 12$
CC (i.e., 3.259-nm wide). In principle, the Brillouin zone of this NPM unit cell
may be unfolded six times and mapped onto the unit cell of the uniform membrane
to enable direct comparison. In the figure, we consider the wavelengths of $\lambda =$
0.54, 1.09, and 10.86 nm and mark the frequency where each of these wavelengths
intersects the lowest dispersion curve of the uniform membrane. The intercepts
correspond to frequencies $\omega = 3.1$, 2.8, and 0.1 THz, respectively. These values
represent the lower frequency limits for vibrons that are capable of coupling with
phonons at each of these wavelengths and lower. For example, any local resonance
that is 2.8 THz or higher is, in principle, available for coupling with phonons with a
wavelength of 1.09 nm or lower. Furthermore, we observe from an extended version
of Fig. 4 that the longitudinal acoustic branch reaches nearly 7 THz upon unfolding
once. Thus the numerous vibrons spanning the 3–7 THz range are available for
coupling and hybridization with a wide selection of phonons with wavelengths
between 0.5 and 1 nm, and many more vibrons are active when also considering
phonons with wavelengths larger than 1 nm. From the inset of Fig. 4, we observe
that the vibrons for this example NPM structure start at 0.04 THz and populate as we
move upward in the frequency domain; therefore there is an abundance of vibrons
available for resonance hybridizations to take place within the full range of relevant
phonon wavelengths.

The other critical size-dependent factor for the NPM concept is the distribution
of the phonon mean free path (MFP). The MFP distribution for bulk silicon
at $T = 300$ K ranges from a few nanometers to a few microns (Esfarjani

et al. 2011). For Si membranes with a thickness on the order of a few tens or hundreds of nanometers, the room-temperature MFP distribution was shown in recent experimental investigations to comfortably cover a range that is at least on the order of the membrane thickness; see, for example, Neogi et al. (2015), Johnson et al. (2013), and Minnich (2012). The active wavelengths (which as discussed above can be as small as a few angstroms) are able to travel relatively long distances within the nanopillared membrane structure as long as these distances fall within the range of the MFP distribution. In order to directly account for the effects of phonon-phonon and boundary scattering, MD simulations are needed. In MD simulations, any limitations on the dynamical processes involving the nanostructure phonon and vibron modes are inherently incorporated in the results. The reader is referred to Honarvar and Hussein (2016) where direct evidence of the existence of the resonance hybridization phenomenon in room-temperature MD simulations was demonstrated using spectral energy density (SED) calculations (Thomas et al. 2010; Larkin et al. 2014).

4   Thermal Conductivity Prediction by Molecular Dynamics Simulations

4.1   Simulation Parameters and Analysis Tools

To incorporate the effects of anharmonic phonon-phonon interactions and to predict the lattice thermal conductivity, we resort to equilibrium MD (EMD) simulations. In these simulations, the computational domain consists of one or more of the unit cells shown in Fig. 3, and standard periodic boundary conditions are applied at the in-plane boundaries. The MD results are post-processed using the Green-Kubo (GK) formulation to predict the thermal conductivities (Zwanzig 1965; Ladd et al. 1986; McGaughey and Kaviany 2004; Landry et al. 2008). Classical MD simulations like the ones we conduct here are valid at room temperature where quantum effects are negligible. The GK approach follows the linear response theorem and is based on the dissipation of equilibrium fluctuations for the heat current vector, $\boldsymbol{J}$. Defining the time average of the heat current autocorrelation function (HCACF) for a generally anisotropic material as $\langle \boldsymbol{J}(0) \otimes \boldsymbol{J}(t) \rangle$, where $\otimes$ denotes the tensor product, the thermal conductivity tensor is expressed as

$$\boldsymbol{k} = \frac{1}{k_B V T^2} \int \langle \boldsymbol{J}(0) \otimes \boldsymbol{J}(t) \rangle \mathrm{d}t, \qquad (1)$$

where k_B is the Boltzmann constant, V is the system volume, and t is time.

In order to examine whether the resonance hybridization mechanism does indeed exist and unfolds within the MD simulations (and as suggested by the quasi-harmonic phonon band diagrams), we compute the spectral energy density (Thomas et al. 2010; Larkin et al. 2014), which is a quantity obtained directly from the simulations. There are two SED formulations reported in the literature for phonon

transport problems. In one SED expression, referred to as Φ, the MD atom velocities are projected onto the phonon normal modes of the constituent unit cell, which are obtained separately from phonon band structure calculations. This approach allows for an accurate prediction of both phonon frequencies and lifetimes (Larkin et al. 2014). In an alternative formulation, the SED expression requires knowledge of only the crystal unit-cell structure and does not require any *a priori* knowledge of the phonon mode eigenvectors. This alternative SED expression, referred to as Φ', accurately predicts only the phonon frequencies and not the lifetimes (Larkin et al. 2014). In seeking to obtain evidence for the existence of local resonances and phonon-vibron couplings within an MD simulation, we intentionally seek an SED technique that enables us to extract the frequency-wave vector spectrum directly from the simulations without any prior knowledge of the phonon band structure. Thus the Φ' formulation is perfectly suited for this aim.

As provided by Thomas et al. (2010), the SED expression, Φ', is a function of wave vector, $\boldsymbol{\kappa}$, and frequency, ω, and for an all-silicon system is given by

$$\Phi'(\boldsymbol{\kappa}, \omega) = \mu_0 \sum_{\alpha}^{3} \sum_{b}^{n} \left| \sum_{l}^{N} \int_{0}^{\tau_0} \dot{u}_\alpha \binom{l}{b}; t \right) e^{i\left[\boldsymbol{\kappa}.\boldsymbol{r}_0 \binom{l}{0} - wt \right]} dt \right|^2, \qquad (2)$$

where $\mu_0 = m/(4\pi\tau_0 N)$, m is the mass of a Si atom, τ_0 is the total simulation time, $\boldsymbol{r}_0$ is the equilibrium position vector of the lth unit cell, and $\dot{u}_\alpha$ is the α-component of the velocity of the bth atom in the lth unit cell at time t. There are a total of $N = N_x \times N_y \times N_z$ unit cells in the simulated computational domain with n atoms per unit cell. The phonon frequencies in Eq. (2) can only be obtained at the set of allowed wave vectors as dictated by the crystal structure. For our model, the ΓX-path wave vectors are $\kappa_x = 2\pi j/(N_x A_x)$, $j = 0$ to $N_x/2$.

4.2   Simulation-Based Evidence of Phonon-Vibron Coupling

In implementing the Φ' form of the SED method, we consider a unit cell similar to the one depicted in Fig. 3 with $A_x = A_y = A_z = 6$, $A_{px} = A_{py} = 2$, and $A_{pz} = 6$ considering only a single nanopillar. For the computational domain, we set $N_x = 50$ and $N_y = N_z = 1$, which gives a ΓX wave vector resolution of $\Delta\kappa_x = 0.04$. MD simulations under NVE (constant mass, volume, and energy) conditions are executed for this system for 2^{22} time steps where the duration of each time step is $\Delta t = 0.5$ fs. Equation (2) is evaluated by computing the Fourier transform of the velocity trajectories extracted every 2^5 time steps.

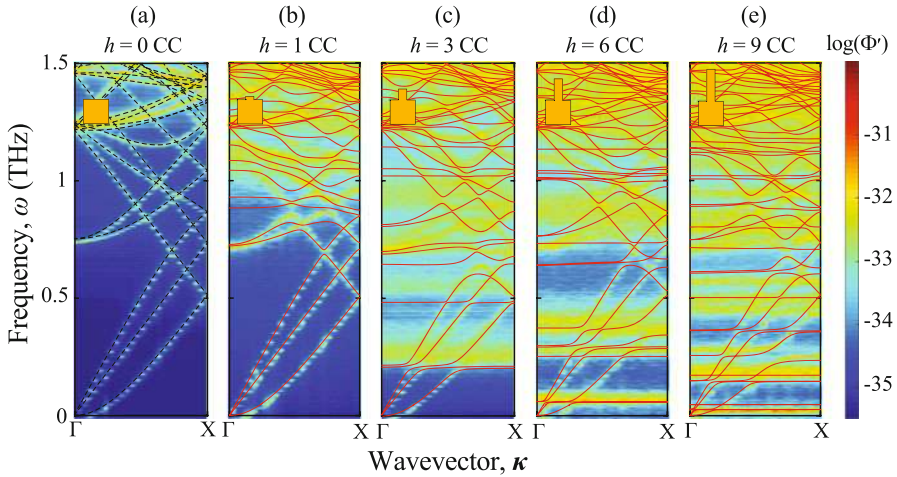
The SED spectrum is shown in Fig. 5a for the uniform membrane and in Fig. 5b–e for the NPM with different nanopillar heights. Only the frequency range $0 \leq \omega \leq 1.5$ THz is shown because higher frequencies are difficult to distinguish in the SED field. This frequency range is responsible for roughly 40% of the total lattice thermal conductivity (Davis and Hussein 2014). The phonon


Fig. 5 Phonon dispersion of several NPMs with various nanopillar heights. The subfigures show the phonon dispersion as revealed by the SED field as a function of wave vector and frequency, and superimposed are the dispersion curves as directly obtained from harmonic LD calculations. The NPM unit-cell dimensions are $6 \times 6 \times 6 + 2 \times 2 \times h$ CC; the uniform membrane unit-cell dimensions are $6 \times 6 \times 6$ CC, i.e., $h = 0$ for the uniform membrane. Each inset presents a schematic of the unit cell analyzed

dispersion emerging from the MD simulations matches very well with that obtained by the independent LD calculations, thus providing confidence in both sets of simulations/calculations (upon close inspection, there is a slight upward deviation in the SED phonon dispersion curves compared to the LD dispersion curves, the extent of which is indicative of the degree of anharmonicities in the MD simulations). Considering the NPM case with $h = 3$ CC (Fig. 5c) as an example, we observe in the NPM SED spectrum the first two nanopillar local resonances appearing as horizontal lines at nearly 0.2 THz. More importantly, the interaction of these resonances with the acoustic branches of the underlying membrane is distinctly observed and follows closely the hybridization profiles featured in the LD dispersion curves. Resonance hybridizations are also seen at higher frequencies where vibrons interact with optical phonon dispersion branches. Upon comparing Fig. 5b–e with each other, the effects of changing the nanopillar height on the locations of the vibrons within the frequency spectrum are shown. The taller the nanopillar, the lower the first resonant frequency.

4.3   Maximization of Phonon-Vibron DOS Conformity

As we have described earlier, the key mechanism in an NPM is the coupling between phonons whose motion is confined to the in-plane directions within the base membrane and vibrons whose motion is limited primarily to the domain of each

nanopillar. The more effective this coupling across the full spectrum, the stronger we expect to achieve a reduction in the thermal conductivity. In Fig. 6, we examine how the overall size of the NPM affects the phonon and vibron density of states (DOS) distributions, separately and with respect to each other. A key factor in this comparison is the degree of DOS conformity, which may be quantified. For this purpose, we introduce a metric to represent the inverse of conformity, namely, the *nonconformity factor* $\hat{R}_{pv}$, which is defined as

$$\hat{R}_{pv} = \|R_{pv} - R_{pp}\|, \tag{3}$$

where R_{pv} is the cross-correlation between the phonon and the vibron DOS, R_{pp} is the autocorrelation of the phonon DOS, and $\|.\|$ denotes the double norm. The reader may refer to Rabiner and Gold (1975) for the definitions of correlation functions. The nonconformity factor varies between 0 (perfect conformity) and ∞ (no conformity). We see in Fig. 6 that as the sizes of the membrane and nanopillar portions are increased at an identical rate (the top path), the value of the nonconformity factor rises. On the other hand, we observe that when the size of the nanopillar portion is increased at a higher rate compared to the membrane portion (the bottom path), this value decreases, i.e., the degree of conformity intensifies. The former scenario corresponds to the set of cases considered by Honarvar et al. (2016). On the other hand, the latter scenario represents a design pathway that creates what we describe as *vibrons compensation* (Honarvar and Hussein 2018). Under this design scheme, nanopillar vibrons are added at a higher rate than membrane phonons as the overall size of the unit cell examined is increased. The outcome is that not only (1) the phonon band structure gets enriched with a higher vibrons-to-phonons ratio, but also (2) the level of conformity between the phonon and vibron DOS distributions gets significantly increased.

4.4 NPM Performance: Ultralow Thermal Conductivity

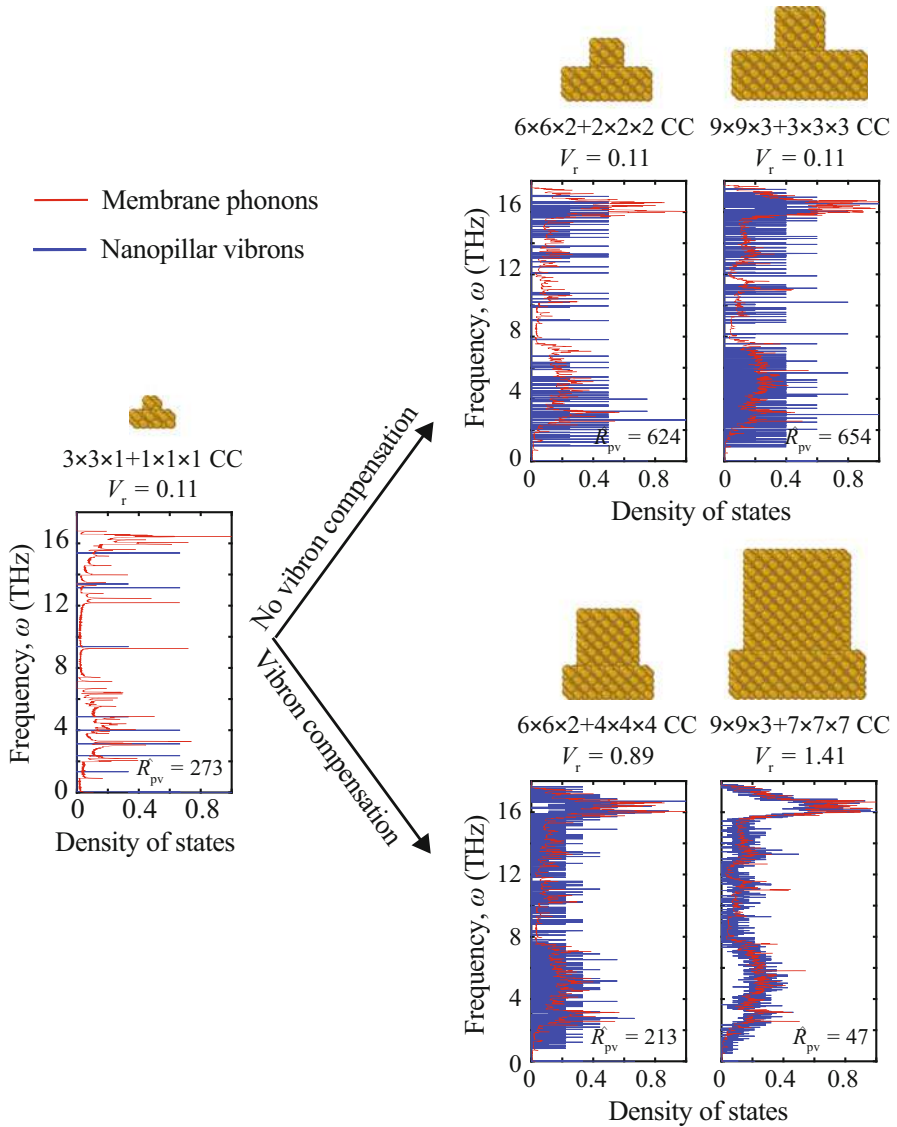
The size and geometry of the nanopillars are key to increasing the intensity of the resonance hybridization effect, as demonstrated in Fig. 6. In this subsection, we provide predictions of the thermal conductivity and seek to further explore the conditions for its extreme reduction. Equilibrium MD simulations and the GK method are used for the thermal conductivity calculations. The simulations are conducted using the LAMMPS software (Plimpton 1995). The systems are equilibrated under NVE ensembles with a time step $\Delta t = 0.5$ fs for a time span of 6 ns, which is sufficiently large compared to the longest phonon lifetime. The HCACFs converge within the first 500 ps. To minimize statistical error, the average of values from six independent simulations with different initial velocities is considered. Furthermore, the thermal conductivity predictions are averaged in the x- and y-directions, effectively resulting in an averaging over 12 predicted values.


Fig. 6 Demonstration of phonon-vibron conformity as a function of unit-cell size and V_r. Relative distributions of the phonons and vibrons DOS are shown for three NPMs whose V_r values are kept constant (top route) and increased as the overall unit-cell size grows (bottom route). The leftmost NPM configuration has a $3 \times 3 \times 1$ CC membrane and a $1 \times 1 \times 1$ CC nanopillar. The vibrons DOS are obtained by considering the nanopillar as an independent nanostructure with free boundary conditions. All quantities are normalized with respect to their maximum values. Increasing the size of the nanopillar at a higher rate than the size of the membrane leads to higher phonon-vibron conformity, which corresponds to lower values of $\hat{R}_{pv}$ and a more intense resonance hybridization effect

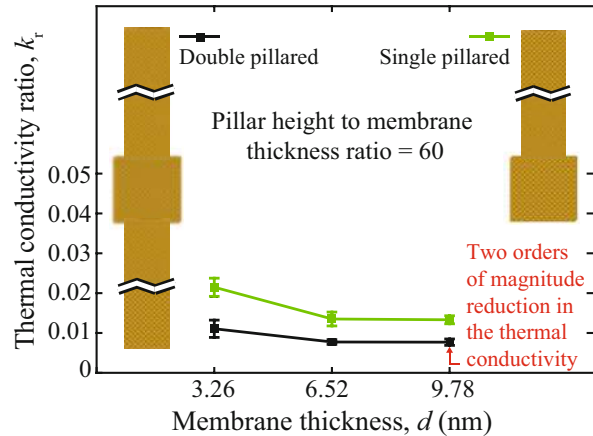
Fig. 7 With nanopillar design optimization, the reduction in the thermal conductivity is shown to reach a factor of 130 (compared to a corresponding unpillared membrane). These predictions are obtained by equilibrium molecular dynamics simulations and the Green-Kubo method for Si-on-Si NPM models


Figure 7 presents the reduction in the in-plane thermal conductivity for various NPM sizes and geometries. The reduction is represented by k_r, the lattice thermal conductivity of a membrane with nanopillar(s) in the unit cell divided by that of a uniform membrane with the same thickness. Key factors in this analysis are (1) the relative volumetric size of the nanopillar(s) with respect to the base membrane within the unit cell (this quantity is denoted V_r and is equal to DOF_{Pillar}/DOF_{Base} where DOF_{Pillar} and DOF_{Base} denote nanopillar(s) and base membrane number of degrees of freedom, respectively) and (2) the rate of change of V_r and the manner by which the geometry of the different NPM components (membrane and nanopillar) change relative to each other, as the size is increased. We consider a Si membrane with a Si nanopillar at each of the top and bottom surfaces. Using α as a size parameter, we specifically consider configuration $6\alpha \times 6\alpha \times 6\alpha + (6\alpha - 2) \times (6\alpha - 2) \times 6\alpha\beta + (6\alpha - 2) \times (6\alpha - 2) \times 6\alpha\beta$ where β is the nanopillar height divided by the membrane thickness. We also consider a single nanopillar unit cell which is described by the same configurational formula minus the last term.

The three data points shown in Fig. 7 represent $\alpha = 1$, 2, and 3, respectively, and for all the results shown, we have selected $\beta = 60$. These parameters give us $V_r = 53.3$, 83.3, and 94.8 for these three α values, respectively, which correspond to a case of profound vibron compensation. The thermal conductivity results, in turn, do yield improvements with upscaling as shown for both the single-pillared and double-pillared cases. We observe a reduction in the thermal conductivity by a factor of 75 ± 14 for the former case and a factor of 130 ± 28 for the latter case, for a membrane 9.78-nm thick with each nanopillar extending up to 586.5 nm in height. These are exceptionally strong reductions given that no scatterers have been introduced in the interior domain of the membrane and the membrane surfaces have not been roughened or oxidized. Yet more reductions are possible with further increases in nanopillar size and augmentation with conventional treatments such as optimized alloying (Xiong et al. 2016). Future research will explore different nanoresonator configurations to reduce the need for occupying a large volume. For

example, the nanopillars may be made from a higher atomic density material in order to generate the same number of vibrons using smaller heights or may be made from a material with heavier atoms in order to shift the vibron DOS to lower frequencies and thus be effective in reducing the thermal conductivity with shorter nanopillars.

4.5   Nanopillars Versus Nanowalls

The resonating substructures in an NPM may take a variety of forms. For example, instead of nanopillars we could instead erect nanowalls with a finite thickness along one direction in the plane of the membrane and extended to infinite in the orthogonal direction. A schematic of this modified NPM configuration is shown in Fig. 8a where a nanowall extends along the full length of the periodic unit cell in the x-direction and has a specified thickness along the y-direction. Compared to a squared nanopillar with the same thickness as the nanowall, the latter has more DOF; thus the NPM exhibits a higher value of V_r and is therefore expected to deliver a stronger level of thermal conductivity reduction. Furthermore, the asymmetry of the nanowall substructure is expected to produce anisotropic phonon dispersion characteristics and anisotropic planar thermal conductivity.

To confirm and quantify these expected results, we investigate a nanowalled membrane with dimensions $6 \times 6 \times 6 + 6 \times 4 \times 6$ CC and, for direct comparison, a corresponding nanopillared membrane with dimensions $6 \times 6 \times 6 + 4 \times 4 \times 6$ CC. The nanowall on top of the membrane has the same length as the unit cell along the x-direction and is therefore a contiguously extended substructure in this direction due to the application of the periodic boundary conditions. Along the y-direction, both the nanowall and nanopillar have the same thickness. In Fig. 8b, the dispersion curves for a uniform, a nanopillared, and a nanowalled membrane are shown; for the nanowalled case, phononic band structures are shown for wave propagation along both the ΓX and ΓY directions. We observe the ΓX dispersion diagram is relatively similar to that of the uniform membrane; indeed there is no periodicity in that direction and the nanowalled membrane is in fact a uniform waveguide. The ΓY dispersion diagram, on the other hand, is comparable to the nanopillared case because the nanowalls form a periodic system with freely vibrating substructures that exhibit a wide range of vibrons.

In Fig. 8, the ΓX thermal conductivity k_x and the ΓY thermal conductivity k_y of the nanowalled membrane are computed using EMD simulations and the GK method and compared to the nanopillared case. A total of six simulations were performed for each case. It is clear that the nanopillared membrane is practically isotropic with respect to the x- and y-directions. The nanowalled membrane, on the other hand, displays a strong reduction in the k_y/k_x ratio. In the y-direction, the thermal conductivity of the nanowalled system is noticeably smaller than the nanopillared system and reduces with increasing nanowall height (following a similar saturating trend as for nanopillared membranes). For a nanoresonator height of $h_T = 15$ CC, we predict an average k_r value of 0.1966 ± 0.0572 for the two

Nanopillar or nanowall height, h_T (CC)

Fig. 8 (**a**) Nanowalled membrane versus nanopillared membrane. (**b**) Phonon dispersions of uniform, nanopillared, and nanowalled membranes. (**c**) Ratio of the thermal conductivity along the y-direction to the thermal conductivity along the x-direction for nanopillared (background bars) and nanowalled (foreground bars) membranes. The anisotropy in the planar thermal conductivity is evident for nanowalled membranes. Specific values of x- and y-direction thermal conductivities for each of the configurations are provided

nanopillared cases and k_r values of 0.3157 ± 0.06368 and 0.1255 ± 0.0255 for the ΓX and ΓY nanowalled cases, respectively. The additional reduction in the thermal conductivity brought about by the nanowalls is a direct outcome of increasing the volume of the nanoresonator. In summary, replacing the nanopillars by nanowalls is shown to (1) reduce the thermal conductivity significantly (by a nearly 30% in the present example) and (2) introduce a sharp planar anisotropy in the thermal conductivity (by nearly a factor of 2 in the present example). Furthermore, adopting nanowalls might be more amenable for nanofabrication over nanopillars.

5   Thermoelectric *ZT* Figure-of-Merit Projections

Accurate prediction of thermoelectric *ZT* values for the NPM configurations investigated in this chapter requires intensive electronic structure calculations followed by implementation of techniques for obtaining the electrical properties

(e.g., see investigation by Mangold et al. (2016) for calculations and models used for thermoelectric analysis of uniform Si membranes). However, one may generate rough estimates of the ZT performance by projections. We recall that the lattice thermal conductivity of the double-nanopillar case reported in Fig. 7 is lower than a corresponding uniform membrane by a factor of 130 ± 28. We may multiply this number by 3.7 ± 0.7, which is the factor by which k_l drops for a 9.78-nm-thick uniform silicon membrane compared to the bulk form. This gives a total reduction factor of 481 ± 55. By conservatively assuming the same k_r value for $\alpha = 6$ for the same geometric configuration, a 19.55-nm-thick NPM would exhibit a lattice thermal conductivity reduction by a factor of 311 ± 85 with respect to bulk silicon. (We predict k_l of a 19.55-nm-thick uniform silicon membrane to be 2.4 ± 0.4 times lower than the bulk form.) If we assume $k_e \approx 0$ (Shanks et al. 1963), we may apply a one-to-one mapping between the lattice thermal conductivity reduction and the increase in ZT. (This assumption is supported by experimental studies of similarly sized freestanding nanomeshed silicon membranes (Yu et al. 2010) and silicon nanowires (Boukai et al. 2008). Considering the electrical conductivity in particular, the MFP of electrons in bulk silicon at room temperature has been determined experimentally to range, roughly, from 10 to 30 nm depending on the level of doping (Weber and Gmelin 1991); thus with moderate doping (which is recommended to optimize between S and σ), it is conceivable that a nanostructure with a 20-nm characteristic size would exhibit a negligible change in σ compared to the bulk form.) Given that ZT of moderately doped bulk silicon at $T = 300$ K is 0.01 at a minimum (Weber and Gmelin 1991; Stranz et al. 2013), we obtain through this mapping a projected room-temperature ZT value of 3.1 ± 0.9. (If we assume that the electrical properties also do not change for the best 9.78-nm-thick double-nanopillar case, we would obtain a room-temperature ZT value of 4.8 ± 0.6.)

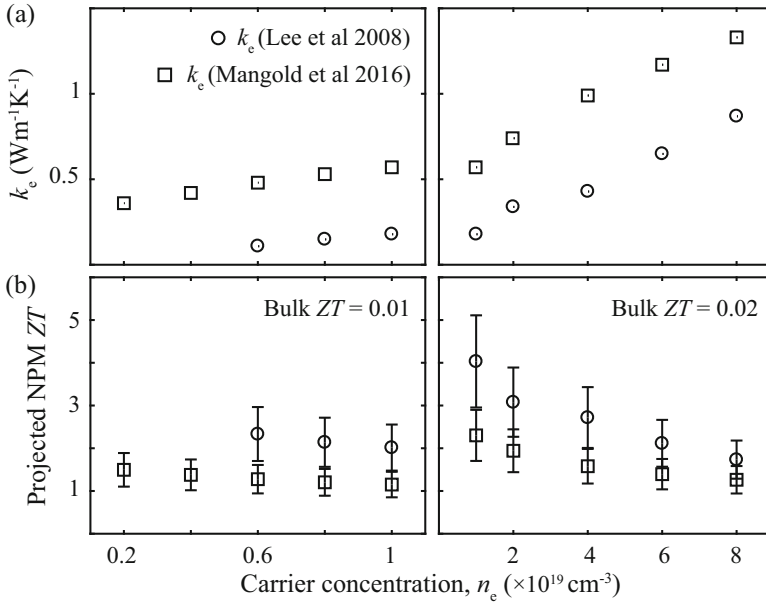
In some references, the contribution of the electronic thermal conductivity in silicon is reported to be relatively significant (Lee et al. 2008; Mangold et al. 2016). This would require a modification to our projections. When accounting for k_e, we will still assume that the NPM electrical properties are bulk-like, i.e., the NPM electronic thermal conductivity is the same as the bulk electronic thermal conductivity. By considering a nonzero k_e, there is now a one-to-one mapping between the total (not lattice) thermal conductivity and ZT improvement. The predicted values of the bulk electronic thermal conductivity are taken from the studies by Lee et al. (2008) and Mangold et al. (2016). These values were obtained by first principles calculations and are shown in Fig. 9a for doping concentrations in the range of 0.2–$8 \times 10^{19} \text{cm}^{-3}$. Across these two references, there are some discrepancies between the two sets of results that would affect the ZT projections as is also shown in Fig. 9 – the k_e values predicted by Mangold et al. are generally higher than the ones reported by Lee et al. In our analysis, the k_e values are first normalized by an experimental value of the lattice thermal conductivity, which we take as $k_l = 160 \, \text{Wm}^{-1} \, \text{K}^{-1}$. This fraction is then multiplied by the EMD-GK lattice thermal conductivity of $k_l = 376 \pm 19 \, \text{Wm}^{-1}\text{K}^{-1}$ to estimate the corresponding k_e values for our models. Following these assumptions, in Fig. 9b, the NPM ZT values are projected based on the bulk ZT values of 0.01 (for carrier concentrations


Fig. 9 (**a**) Electronic thermal conductivity k_e and (**b**) projected NPM ZT versus carrier concentration. The experimental and theoretical values of the bulk lattice thermal conductivity are chosen to be $k_l = 160\,\mathrm{Wm^{-1}K^{-1}}$ and $k_l = 376 \pm 19\,\mathrm{Wm^{-1}K^{-1}}$, respectively (Kremer et al. 2004; Honarvar and Hussein 2018)

in the range 0.2–1 $\times$ $10^{19}\mathrm{cm^{-3}}$) and 0.02 (for carrier concentrations in the range 1–8 $\times$ $10^{19}\mathrm{cm^{-3}}$) (Stranz et al. 2013). Depending on the carrier concentration and k_e values, the projected NPM average ZT varies roughly between 1 to 4. For example, for silicon that is doped with a carrier concentration of $1 \times 10^{19}\,\mathrm{cm^{-3}}$ and has a bulk ZT value of 0.02, we project a ZT value of 4 ± 1.1 for the 19.55-nm-thick double-nanopillared silicon membrane. The upper bound of this range is significantly higher than any previously reported ZT value at any temperature, for silicon and for thermoelectric materials in general.

6 Conclusions

This chapter presents elements of phonon dynamics of a recently developed class of nanostructured metamaterials, nanophononic metamaterials, that have their thermal conductivity dramatically decreased by an array of distributed resonating substructures. The substructures' numerous local resonances hybridize with the phonon modes of the underlying host, or base, material, which leads to reducing

their group velocities significantly and creating energy localization–two factors that reduce the thermal conductivity. In addition, the local resonances, also termed vibrons, reduce the phonon lifetimes at and around the hybridization regions in the phonon band diagram thus causing even more reduction in the thermal conductivity.

A particularly useful type of an NPM is in the form of an all-silicon nanopillared, or nanowalled, freestanding membrane. This configuration is advantageous because the nanoresonators are located outside the domain of the transport medium, which is the membrane, and is therefore not expected to significantly alter the electrical properties. Such outcome is ideal for thermoelectric energy conversion which requires a material with as low thermal conductivity as possible and as high Seebeck coefficient and electrical conductivity as possible.

The notion of conformity between the membrane and nanoresonator density of states is presented and analyzed. It is shown in Fig. 6 that this conformity in a nanopillared membrane increases when the size of the nanopillars increases at a higher rate than the base membrane (when considering progressively larger unit cells). This scenario, termed vibrons compensation, enables a stronger reduction in the thermal conductivity with upscaling – a trait that is highly desirable for potential integration of NPMs into TE devices.

From our calculations, the lattice thermal conductivity of a 9.78-nm-thick uniform silicon membrane is 3.7 ± 0.7 times lower than the bulk form. Multiplying this by the factor of 130 ± 28 for the double-nanopillar case reported in Fig. 7 gives a total factor of 481 ± 55, which corresponds to roughly half the thermal conductivity of bulk amorphous silicon (He et al. 2011; France-Lanord et al. 2014; Larkin and McGaughey 2014). By conservatively assuming the same k_r value for $\alpha = 6$ for the same geometric configuration, the lattice thermal conductivity for a 19.55-nm-thick NPM would be lower than for bulk silicon by a factor of 311 ± 85. Assuming that all the electrical properties retain their bulk values at a length scale on the order of 20 nm and at $T = 300$ K (see Section 5), we may estimate the effect of a decrease in the lattice thermal conductivity on the ZT value. Given that the ZT of moderately doped bulk silicon at $T = 300$ K ranges from 0.01 to 0.02 (Stranz et al. 2013), we obtain a projected room-temperature ZT value in the range of 1–4 depending on the specific level of doping. The upper bound for this projection is significantly higher than any previously reported ZT value at any temperature, not only for silicon but for thermoelectric materials in general.

Modeling of Heat Transport in Polymers and Their Nanocomposites

41

Pawel Keblinski

Contents

Abstract

In this chapter, methodology to model heat flow in polymers and their nanocomposites will be presented. One focus will be on the use of molecular-level modeling techniques for the thermal conductivity determination of bulk polymers. In the case of polymer nanocomposites, the methods for molecular-level modeling of the interfacial thermal resistance will be described, and its role along with other factors, such as filler shape, orientational distributions, and dispersion on the composite thermal conductivity, will be analyzed within the homogenization analysis.

1   Introduction

Polymers, as well as their composites, constitute complex materials with a number of structural characteristics, such as polymer chain backbone chemistry and con-

---
P. Keblinski (✉)
Department of Materials Science and Engineering, Rensselaer Polytechnic Institute, Troy, NY, USA
e-mail: keblip@rpi.edu

formation, side groups, and filler particle size and distribution, all of which are influencing properties, including thermal transport characteristics. The structural complexity of these materials requires an informed approach in order to model their heat transport coefficients. On one hand, one needs to capture the most important structural and bonding features to enable predictions with a reasonable level of fidelity, and, on the other hand, the model has to be tractable either analytically or computationally.

We will limit our consideration to solid polymers and their composites and thus disregard contributions to the heat flow from convection that might play a role in the liquid phase during polymer processing. Within this constraint, from a practical perspective, the most important characteristics for heat conduction are thermal conductivity, κ (W/m-K), and volumetric heat capacity, C (J/K-m^3). The thermal conductivity is defined via Fourier's law:

$$j_q = -\kappa \nabla T \tag{1}$$

where j_q is the heat flux (W/m^2) and ∇T is the temperature gradient (K/m). Accounting for energy conservation and heat sources, one can derive the diffusive heat flow equation:

$$C \frac{\partial T}{\partial t} - \nabla (\kappa \nabla T) = \frac{\partial q_V}{\partial t} \tag{2}$$

where q_V is the volumetric heat source. The above two equations are general and describe heat conduction in all materials at the macroscopic scale. Therefore the modeling of the specific materials focuses on the modeling and determination of the thermal conductivity and heat capacity, and the rest is the analytical or numerical solution of the well-known continuum problem given by Eq. 2, with appropriate boundary and initial conditions.

The determination of thermal conductivity and its relationship to the underlying structure and bonding, in addition to practical value, is motivated by scientific discovery. Such scientific knowledge exposes the underlying the mechanism of thermal transport and provides guidance toward the design of the materials with the desired thermal conductivity. In this context, modeling and simulations are uniquely positioned to contribute to such design as one can control and characterize the structure and relate it to thermal conductivity to a much larger extent than is possible in experiment.

In order to systematically present an approach to modeling of the thermal conduction of polymers and their nanocomposites, this chapter is composed of several sections. The following section provides background on thermal conduction due to vibrations of ion and atoms, i.e., phonons that are the dominant heat carriers in polymers, along with conceptual models of the thermal conductivity of polymers. The third section presents the use of molecular dynamics simulations for thermal conductivity determination, particularly in the context of polymers.

The fourth section describes molecular-level modeling of the interfacial thermal resistance associated with dissimilar constituents forming polymer nanocomposites. The fifth section provides a connection between molecular-level modeling and heat flow at larger scales either by solutions of the continuum heat flow equation or homogenization theory. The last section will provide a summary and conclusion.

2   Conceptual Models of Thermal Conduction in Polymers

To provide a fundamental context of heat conduction modeling in polymers and nanocomposites, we briefly discuss phonon (vibration)-based thermal transport kinetic theory. Within this theory, for crystalline materials, each propagating vibrational mode (phonon) contributes to thermal conductivity, and for a system of volume V, the bulk thermal conductivity is given by (Ziman 1960):

$$\kappa = \frac{1}{3V} \sum V_j(v)\lambda_i(v)c_j(v, T) \tag{3}$$

where $c_i(v, T)$ is the spectral heat capacity, i.e., a temperature dependent of heat capacity of a harmonic oscillator with a frequency v, v_i is the mode-specific group velocity (in the low frequency limit, it is the speed of sound), and λ_i is the phonon mean free path, and the summation is done over all vibrational modes. Such formulation is very successful in modeling of thermal transport in crystalline materials. In this case determining the phonon mean free path or alternatively, the phonon lifetime, poses the biggest challenge. This quantity is affected by multiple phonon scattering processes, such as anharmonicity-related phonon-phonon scattering, or phonon-defect scattering, and can be calculated from theory or evaluated in molecular-level simulations (Turney et al. 2009).

The description of phononic heat conduction provided above has some relevance to polymers in the case of polymers with a degree of crystallinity and, perhaps most prominently, in the case of polymer fibers with highly aligned polymer chains. The vast majority of polymers, however, have an amorphous structure or at most a semicrystalline structure involving a mix of crystalline and amorphous regions. This renders the kinetic theory of propagating phonons largely not applicable.

However, the heat conduction in amorphous polymers is still carried by vibrations. For such materials, as well as other nonmetallic glasses, the basic heat transport model is the so-called minimum thermal conductivity, which was first proposed by Einstein and later developed by Slack (Cahill et al. 1992). The basic heat transport model builds upon the Einstein model and borrows from the Debye model of solids to allow for different frequencies and wavelengths. The model assumes that the lifetime of the vibration is half of the period of vibrations, and summing up the contribution of all vibrations with the Debye dispersion relationships, it yields minimum thermal conductivity, $\kappa_{\min}$, via the following formula:

$$\kappa_{min} = \left(\frac{\pi}{6}\right)^{1/3} k_B n^{2/3} \sum_j V_j \left(\frac{T}{\theta_j}\right)^2 \int_0^{B,/T} \frac{x^3 e^x}{(e^x - 1)^2} dx \qquad (4)$$

where the sum is calculated over one longitudinal and two transverse phonon branches, with their respective speeds of sound, $v_{i=v_l}$ *or* $v_{i=v_t}$, and Debye temperatures, θ_i. In Eq. 1, n is the number density of atoms or ions, and k_B is the Boltzmann constant. Equation 3 correctly predicts a continuous increase of κ from zero as a function of temperature, due to increasing heat capacity, with κ saturating at higher temperatures. Examination of the κ predictions for a variety of glasses and disordered crystals indicates that this theory/estimate provides a good representation of the experimental measurements (Cahill et al. 1992).

In the case of amorphous polymers, at room temperature or above, we can take the high-temperature limit of the expression given by Eq. 3, yielding $\kappa_{\min} = 0.4 k_g n^{2/3} (V_i + 2V_t)$. This expression was tested in experiment and molecular dynamics simulations by monitoring thermal conductivity dependence on high pressure applied to amorphous poly(methyl methacrylate) (PMMA) (Hsieh et al. 2011), yielding reasonable agreement with the experimental data and even better agreement with the result of molecular dynamics simulations. Such good agreement is rather surprising because polymer materials exhibit highly nonhomogenous bonding with stiff bonds within the polymer chain backbone and side groups and much softer nonbonded interactions. Furthermore, nonbonded interactions between the chains are significantly nonlinear, and anharmonic interactions between localized vibrations, of the type invoked in "fracton hopping" models (Alexander et al. 1986), could conceivably contribute to heat transport. Evidence for the importance of anharmonicity in the thermal conductivity of amorphous polymers was recently observed in molecular dynamics (MD) simulations of polystyrene (PS) (Shenogin et al. 2009).

It is also likely that the minimum thermal conductivity model is a poor predictor of thermal conductivity in the case of amorphous polymers when polymer chains are characterized by relatively long straight sections, i.e., by a large persistence length In this case, the nature of the heat flow involves a rapid propagation of heat along the straight sections and slower propagation between sections.

The effect of such straight sections is even more pronounced for oriented polymers and can be characterized by a much larger and highly anisotropic conductivity, with a high conductivity in the alignment direction and a low conductivity in the transverse directions. While drawing *amorphous* polymers increases their conductivity by about a factor of ~3 in the draw direction (Kurabayashi 2001), drawing of semicrystalline polymers can increase their thermal conductivities 100-fold (Choy et al. 1978).

Current theoretical descriptions of heat transport in such complex polymeric materials involve phenomenological and continuum-level models. For example, recognizing that heat flow along the covalently bonded polymer backbone is more efficient than in the transverse directions, a simple model of oriented resistors was proposed to describe the anisotropy of drawn amorphous polymers (Henning 1967).

To obtain upper and lower bounds (Ward 1971) for the effective conductivities, resistor-in-series and resistor-in-parallel models are used. According to the literature, a resistor-in-series model provides a better prediction of experimental behavior. For such a model, orientational averaging gives the following expression for macroscopic conductivities, $k_{||}$ and $k_{\perp}$:

$$\frac{1}{K_{\perp}} = \frac{1}{2}\left[\left(\frac{1}{K_{ji\perp}} + \frac{1}{K_{ji||}}\right) - \left(\frac{1}{K_{ji||}} + \frac{1}{K_{ji\perp}}\right)\left\langle\cos^2\delta\right\rangle\right] \quad and$$

$$\frac{1}{K_{||}} = \frac{1}{2}\left(\frac{1}{K_{ji||}} - \frac{1}{K_{ji\perp}}\right)\left\langle\cos^2\delta\right\rangle + \frac{1}{K_{ji\perp}}$$

(5)

where δ is the angle between the chain direction and direction of heat flow and $\langle\cos^2\delta\rangle$ is the orientational average over the sample. Although the above model provides a reasonable description of the thermal conductivity of deformed amorphous polymers, the parameters of the model are obtained from fits to the data and have no fundamental microscopic justification. The much larger conductivity and anisotropy observed in aligned semicrystalline and liquid crystal polymers is described by rapid heat flow along the well-connected "continuum" network of conducting fibers of highly aligned and crystalline polymers (Ashton et al. 1969).

In these phenomenological approaches, the "microscopic" thermal conductivities are treated simply as adjustable parameters to be fitted to the experimental data. Physically, of course, the true microscopic parameters are determined by the details of the atomic-level bonding and the conformation of the polymer chains. In this instance, one has to resort to more fundamental modeling approaches, most prominently to atomic-level models of polymers and the use of molecular dynamics simulations to predict thermal conductivity that will be described in the following section.

3   Molecular Simulations of Polymers Thermal Conductivity

As already discussed above, the key goal of polymer thermal transport modeling is relating the structure and bonding to thermal transport characteristics to enable an informed design of the polymers with desired thermal conductivity and to gain insights into the fundamental mechanism of thermal transport in these materials. To achieve this goal one can resort to the use of molecular dynamics (MD) simulations.

Molecular dynamics is a well-developed classical simulation method in which Newton's equation of motion, $F = ma$, is integrated in time for a collection of atoms. The force between the atoms is prescribed in a semiempirical or empirical manner, carefully fitted to pertinent experimental data or to electronic structure calculations. The MD approach can capture all of the features of the vibrational motions of the atoms and can reproduce the phonon spectrum of the system in a quantitative or semiquantitative manner.

Molecular dynamics (MD) simulations are classical and are thus strictly only applicable above the Debye temperature. For example, for polyethylene (PE), strong covalent intra-chain bonds lead to Debye temperatures of 1650 K and 700 K for longitudinal and transverse along-the-chain (one-dimensional) modes, respectively. Much weaker nonbonded, van der Waals interactions lead to corresponding temperatures of 223 K and 134 K (Tucker and Reese 1967). Since for practical applications room temperature behavior is the most relevant, at first glance this would appear to produce an insuperable obstacle to classical simulations in which all vibrations are fully excited, regardless of the temperature. However, thermal energy is mostly carried by low-frequency and intermediate-frequency vibrations. By contrast, high-frequency phonons have rather low group velocities and are easy to scatter; thus, although overrepresented in the classical simulation, they do not contribute significantly to thermal transport. As an approximation to real quantum behavior, a temperature renormalization technique has been developed, where the temperature at which the classical simulation is performed actually corresponds physically to a somewhat higher temperature for a quantum system of the same mean kinetic energy (Wang et al. 1990). However, the dynamics of such a system are still classical, and, by definition, it is assumed that all excited phonons contribute equally to the heat transport. Goddard and his coworkers performed semiclassical analysis that took into account quantum effects (Che et al. 2000). Remarkably, they found that quantum corrections, even for diamond (Debye temperature is ~2200 K), do not significantly affect thermal transport at room temperature. Given the similar strong bonding in polymeric materials, a purely classical approach is both completely suitable and computationally the most efficient for the description of polymer's thermal transport properties even at room temperature.

We also note that full electronic-level approaches for MD simulations, i.e., ab initio MD or quantum-mechanics-based tight-binding MD simulations, do not provide significant advantages and have their own limitations. While in these methods, the forces between atoms and ions are calculated more accurately using quantum-mechanics-based calculations, the computational load is very significant and often prohibitive, and the dynamics of atomic/ionic motion is still classical.

One challenge in using MD simulations for polymers lies in the fact that the structural relaxation time even in polymer melts is much longer than that accessible to molecular dynamics. Therefore it is critical to construct outright model structures representative of real polymers. The amorphous structures can be created using a method first proposed by Suter and collaborators (Muller et al. 2001). This method (the software is named PolyPack) consists of a heuristic search algorithm in the space of torsion angles, which automatically delivers the correct conformational statistics of the chains maintaining so-called rotational isomeric states (RIS). Such structures can be later deformed to mimic drawing (see Fig. 1). Hybrid approaches need to be employed to create models or semicrystalline polymers that involve "composites" of crystalline and amorphous regions (Lee and Rutledge 2011).

Once model structures are generated, the forces acting between ions and atoms need to be prescribed. For simulations of thermal transport polymers, there are two levels of molecular modeling. The first is united atom (UA) description,

Fig. 1 Fully atomistic
polycarbonate structure
prepared with PolyPack
software and deformed under
constant load in tension. The
color code represents the
local strain
where hydrogen atoms are not represented explicitly, but are "united" with carbon
or other heavy atoms. This simplification is not expected to significantly affect
thermal energy propagation, since hydrogen atoms introduce very-high-frequency
local vibrations that are very weakly coupled to vibrations responsible for heat
transport. For example, the UA description used in simulations of thermal transport
in crystalline and liquid paraffin (see Fig. 2) predicted thermal conductivity in
excellent agreement with experiment (Babaei et al. 2013). The chief benefit of the
UA approach is the ability to access one order of magnitude longer simulation times
and larger structures at the same computational cost.

Effects associated with the explicit presence of H atoms are expected to play a
role associated with altered nonbonded interactions. For example, it is known that
explicit atom models are needed to correctly reproduce the crystalline PE structure
(Duffour and Malfreyt 2002) or more accurate structures of more complex polymers.
For this purpose one of the most widely used descriptions of atomic interactions is
the polymer consistent force field (PCFF) (Sun 1998), a second-generation force
field, derived from ab initio models and is an extension of CFF91 force field, which
was parameterized against a wide range of experimental observables for organic
compounds.

The most popular descriptions of interaction for both united and all-atom models
are given in the following general form:

$$V = V_2\left(r_{ij}\right) + V_3\left(\theta_{ijk}\right) + V_4\left(\phi_{ijkl}\right) + V_{nb}\left(r_{ij}\right) \qquad (6)$$
Fig. 2 United atom models of crystalline and liquid paraffin. Red "united atoms" are end chain CH_3 groups, and gray atoms represent CH_2. (From Babaei et al. 2013)

where the stretching of the covalent bonds is described by a pair potential V_2, preferably accounting for anharmonicity, and thus capable of capturing bond-stretching-related contributions to the phonon-phonon scattering process. We note, however, that even with a harmonic bond-stretching potential, due to coupling with bending, the system is not harmonic with respect to atomic displacements. Furthermore, except for highly oriented polymers, phonon scattering is dominated by structural scattering. The bond-bending potential, V_3, describes interactions between three consecutive bonded atoms and depends on the equilibrium angle and the spring constant parameterized to the frequencies of bending. The torsional potential, V_4, describes the different energetics of trans and gauche configurations (Duffour and Malfreyt 2002). Finally, the nonbonded interactions (i.e., those between united or explicit atoms on different chains and united atoms on widely separated parts of the same chain) use pair potentials to describe hard-core repulsion (preventing atomic overlap), van der Waals attraction, and Coulomb interactions, if applicable. Once the model structures are prepared, and atomic interactions described, the proper MD simulations can be executed.

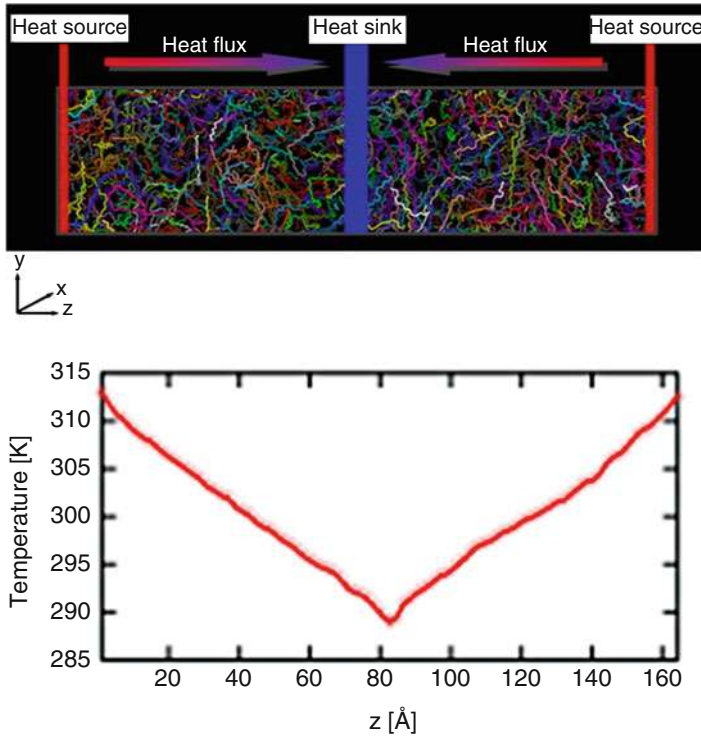
The most straightforward method for thermal conductivity determination via the MD simulations is the nonequilibrium molecular dynamics (NEMD) method. The most popular NEMD approach is analogous to a simple experimental setup with a temperature gradient induced by a planar heat source and heat sink. This method is referred to as the direct method or heat source and sink method (Schelling et al. 2002). In this method the temperature of the sink and the source is kept constant by the application of local thermostats, or heat energy is added to the source and removed for the sink at a constant rate. In both approaches, heat power can be determined, and thus the heat flux can be evaluated. At the same time, after a transient period, when the system reaches a steady state, the temperature profile between the source and the sink is determined, which in the this simple planar


Fig. 3 Top: The simulation cell containing amorphous PE subjected to a steady-state heat flow. Bottom: The corresponding temperature profile. (From Kikugawa et al. 2013)

geometry is simply a straight line (see Fig. 3). Subsequently, with the known heat flux and temperature gradient, the thermal conductivity can be determined from Eq. 1.

In the direct methods simulations, the molecular-level formula for the heat flux allows one to look into more detail into the path and channels of the heat flow. This formula is typically given for the so-called heat current, $J_q = V j_q$., where j_q is the heat flux form (see Eq. 1) and V is the volume considered. In the case of pairwise atomic interactions, the heat current is given by:

$$\mathbf{J}_q = \sum_i \mathbf{v}_j \varepsilon_i + \frac{1}{2} \sum_{ij \; i \neq j} \mathbf{r}_{ij} \left(\mathbf{F}_{ij} \cdot \mathbf{v}_i \right) \tag{7}$$

where the sum is over all atoms, or atomic pairs in the given volume, $\mathbf{F}_{ij}$ is the force on atom i due to atom j, ε_i is the energy of atom i, and $\mathbf{v}$s are atomic velocities. The above formulation can be generalized in the case of many body interactions, such as three-body bond-bending and four-body torsional interactions (Torii et al. 2008). Using the above formula, one can create a spatial map of the heat current density

or evaluate contributions to the heat flow separately from bonded and nonbonded interactions – such analyses were performed for regular and crossed-linked PE (Kikugawa et al. 2013).

The thermal conductivity determination from the direct method assumes that Fourier's law is valid. The validity of Fourier's law relies of the diffusive heat flow mechanism, i.e., on the fact that the mean free path of the majority of the heat-carrying vibrations is much shorter than the distance between the heat source and heat sink. If this is not the case, the heat-carrying vibrations can propagate ballistically, and Fourier's s law is not valid. To assess such possibility, one has to execute several simulations using simulation cells of varying lengths. If the thermal conductivity is length-independent, the results indeed represent bulk thermal conductivity. Otherwise one can try to extrapolate thermal conductivity to an infinite system size by plotting the inverse of the conductivity as function of the inverse of the system size (Schelling et al. 2002). In the case of amorphous polymers, in which the phonon mean free path is short, size effects are negligible, and the above-described method is accurate and practical. On the other hand, in the case of highly aligned chains, the phonons can propagate by large distances, and the convergence of the direct methods can be challenging and in some cases prohibitive.

The convergence challenge that the direct method suffers in some cases can be alleviated by the use of the equilibrium MD (EMD) (Schelling et al. 2002) techniques based on Green-Kubo formalism. In particular, the Green-Kubo approach is an EMD method that uses fluctuations in the heat current components, $J_{x,y,x}$ (t), to compute the whole thermal conductivity tensor via the fluctuation-dissipation theorem:

$$k_{\mu v}\left(\tau_m\right) = \frac{1}{V k_B T^2} \int_0^\tau \left\langle J_\mu\left(\tau\right) J_v(0)\right\rangle d\tau \tag{8}$$

where τ_m is the upper integral limit that has to be large enough to reach the convergence of the integral and the angular brackets denote a time average of the heat current autocorrelation function. The analytic form of the heat current is determined for the interatomic interactions (see Eq. 7). In this method, there are no heat sources and sinks, and with the use of the periodic boundary conditions, vibrations can propagate across the simulation cell multiple times without scattering, thus eliminating the associated size effects present in the direct method. Also the total thermal conductivity can be broken down into contributions from the autocorrelations of each of the various terms in Eq. 7 plus cross terms involving, e.g., correlations between bond stretching and bond bending. The correlation function in Eq. 8 typically decays exponentially with a time constant yielding the relaxation time of the dominant phonon. Furthermore, in the EMD method has a significant conceptual advantage over the NEMD method since there is no temperature gradient imposed, which eliminates the need to use heat sinks and sources. This leads to a practical advantage that smaller system sizes can be used, albeit typically for
Fig. 4 Heat current autocorrelation function for the perfect crystal PE (red curve) and a single straight PE chain (black curve). While the former function converges to zero, the latter shows persistent positive values indicating non-convergent thermal conductivity given by the integral of the function in Eq. 7. (From Shen et al. 2010)

significantly longer simulation times. Also the fact that a single simulation can provide the whole thermal conductivity tensor is useful for anisotropic materials.

In the case of highly oriented/crystalline polymer fibers, the EMD method is perhaps the only practical method. For example, the MD simulations of Henry and collaborators demonstrated the thermal conductivity of a perfect crystal PE chain can be over ∼100 W/m-K (Shen et al. 2010). However, in the case of single, isolated straight PE chains, even EMD faces convergence problems (Henry and Chen (2008) (see Fig. 4).

4   Interfacial Thermal Resistance

The heat conduction of polymer nanocomposites, or for that matter of any material with high density of interfaces, is significantly affected by the interfacial thermal resistance and known as the thermal boundary resistance, R_{Bd}, or Kapitza resistance. This resistance represents an additional resistance to the heat flow, beyond that due to bulk material. The inverse of R_{Bd} is interfacial thermal conductance, G_k. G_k is an interfacial thermal transport parameter and is quantified in via an equation analogous to Fourier's law (Eq.1):

$$j_q = -G_K \Delta T \qquad (9)$$
Fig. 5 Temperature profile across silicon-amorphous PE interface – the temperature drop at the interface is due to thermal boundary resistance. (From Hu et al. 2007)

However, the role of the temperature gradient is replaced with the discontinuous temperature at the interface, ΔT (see Fig. 5).

As an alternative to the steady-state heat flow simulations across the interface, one can determine the interfacial conductance by mimicking a laser pump-probe experimental measurement (Shenogin et al. 2004). In this case, one material forming the interface that is nanoscopic in size, such as nanoparticle or nanoscopic film, is subjected to a pulse heating. The observation of the thermal relaxation/equilibration of the system allows to extract the interfacial conductance. As shown in Fig. 6, the temperature difference between the two materials forming the interface exhibits exponential decay. The exponential decay is the result of the heat flow being limited predominantly by the thermal resistance at the interface. Under such conditions, the time constant of the decay, τ, depends on the heat capacity, C, of the nanoscopic component and the interfacial thermal conductance via:

$$\tau = \frac{C}{G_K A},$$ (10)

where A is the interfacial area.

Fig. 6 The exponential decay of the temperature difference between a graphene layer and polymer matrix as a function of time in thermal relaxation molecular dynamics simulations. (From Hu et al. 2011a)
While the heat source-sink method and thermal relaxation method allow for the determination of the value of the conductance, a more detailed understanding of the thermal coupling across the interface can be obtained from equilibrium MD simulations (Barrat and Chiaruttini 2003). Specifically, an interface-specific Green-Kubo relationship is employed, which relates the fluctuating cross interfacial heat power, $P(t)$, to the interfacial conductance via:

$$G_K = \frac{1}{A k_B T^2} \int_0^\infty \langle P(t) P(0) \rangle \, dt, \tag{11}$$

where $\langle P(t)P(0) \rangle$ is the interfacial heat power autocorrelation function and A is the interfacial area. The interfacial heat power can be easily obtained by monitoring the total energy of the material on the one side of the interface and then taking its time derivative. Also, the upper limit of the integral given by Eq. 11 is in practice finite as the autocorrelation function decays to zero. In addition to the value of G_K, the full functional form of $\langle P(t)P(0) \rangle$ provides dynamical information about coupling between molecular vibrations in the two phases forming the interface. As pointed out by Barrat and Chiaruttini, the Green-Kubo relation in Eq. 11 is rigorously valid for an infinite system where the heat capacity of both materials forming the interface is infinite. When the system size is small, the effects of the finite heat capacity need to be accounted for (Barrat and Chiaruttini).

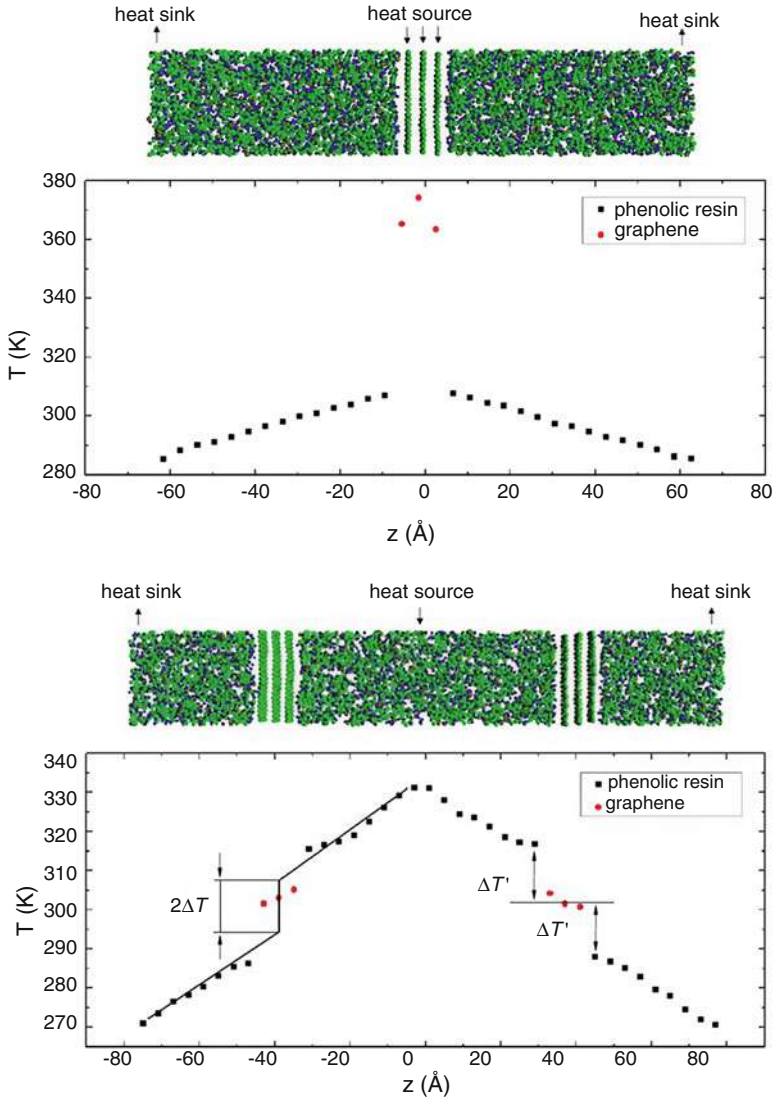
In addition to the finite heat capacity effects, in the limit of extremely small nanoscopic object, such as single-walled carbon nanotube or few atomic layer graphene, more fundamental issue affects the determination of the interfacial thermal resistance. This is illustrated in Fig. 7. When in steady-state direct method simulations, the heat source is placed on graphene, the temperature drop at the interface is very large, and the associated G_K is $\sim$20 MW/m^2-K. Essentially the same value of the G_K is obtained in thermal relaxation simulations (Hu et al. 2011a).


Fig. 7 Left panel: Model structure with a graphene layer in polymeric material along with the steady-state temperature profile obtained from the heat source-sink method, with graphene constituting the heat source. Right panel: Similar to the left panel, but with heat sources and sinks outside graphene. (From Hu et al. 2011a)

By contrast, when the heat sources and sinks are outside graphene, the temperature drop at the interface is much smaller (see Fig. 7), and the associated G_K $\sim$170 MW/m^2-K is much larger.

The above difference is due to the fact that low-frequency vibrations dominate thermal transport across the weakly bonded interface. Consequently, in the simulations where the graphene is the heat source (including thermal relaxation simulations), the interfacial resistance has two main contributors: (i) the internal to graphene resistance between high-frequency modes (that have the majority of thermal energy) and low-frequency modes and (ii) the external resistance between low-frequency modes in graphene (that carry most heat across the interface) and the matrix. When the heat sources and sinks are outside graphene, the internal resistance plays no role in interfacial thermal transport, and in effect, the interfacial conductance is much higher.

The significance of the above finding lies in the fact that the relaxation method that mimics the experimental laser based pump-probe measurements of the interfacial thermal resistance might not provide relevant information about the interfacial thermal transport in terms of predicting and understanding the thermal conductivity of nanocomposites.

Yet another value of the effective interfacial thermal conductance, of about $30\,\mathrm{MW/m^2}$-K, was calculated for the case of heat entering a high aspect ratio carbon nanofiber in order to propagate along the fiber (Hu et al. 2011b) (see Fig. 8). In this case, the heat enters the fiber predominantly via low-frequency modes involving vibrations normal to the interface. However, rapid transport along the carbon fiber is facilitated by acoustic modes with little or none of the normal to the interface displacement. Consequently, the heat flow in this configuration involves energy redistribution over modes within the fiber and is thus affected by associated internal to the fiber phonon-phonon coupling.

All the cases described above show that interfacial thermal transport can involve a complicated process in which the phonons carrying most of the heat across the interface are not necessarily the phonons carrying the heat in the bulk or along the fiber, which in turn makes phonon-phonon coupling within each material forming the interface an important factor. The associated effects are not just artifacts of the simulations, but are present in the pump-probe transient experimental measurements and are relevant to the heat conduction, particularly in the case of high aspect ratio fiber composites.

5   Thermal Conductivity of Polymer Composites

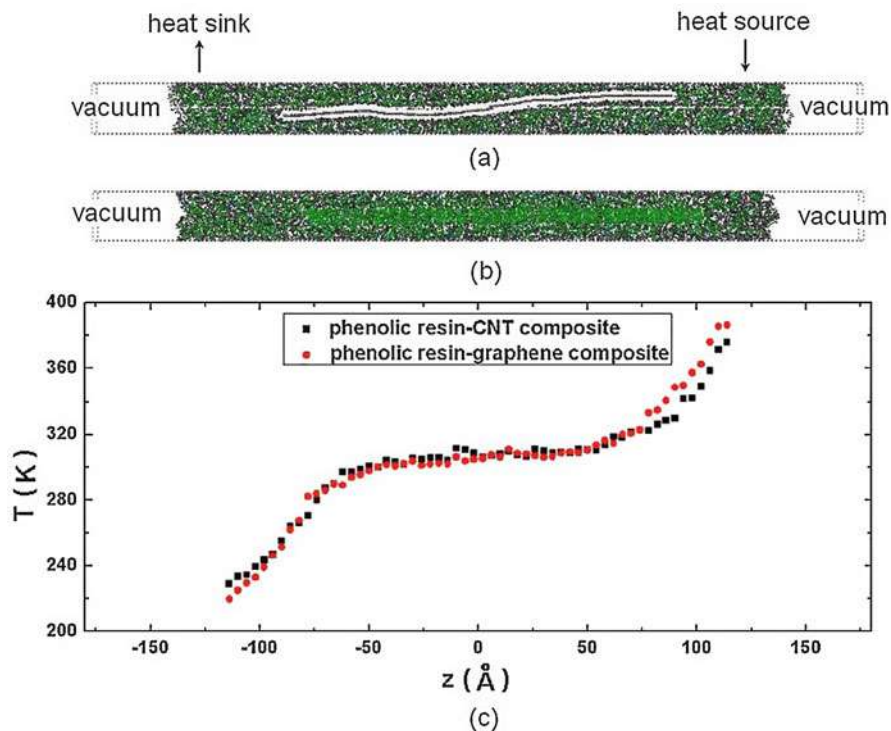
The thermal conductivity of polymer composite is affected by a number of factors, including bulk thermal conductivity of the polymer matrix, interfacial thermal resistance, conductivity of the filler, filler loading, filler shape, and the spatial and orientational distributions of the fillers. Molecular simulation-based methods can provide quality data on bulk and interfacial thermal conductivities, as described above, as well as on the heat flow around individual small nanofillers. However, even such fillers as multiwalled carbon nanotubes (MWCNs) with diameters of tens of nanometers and much larger lengths are much too large to simulate with molecular dynamics.


Fig. 8 (**a**) Model structure of resin/graphene composite. (**b**) Model structure of resin/CNT composite. (**c**) The steady-state temperature profile obtained from the nonequilibrium, heat source-sink method. (From Hu et al. 2011b)

To treat larger-scale fillers and assemblies of multiple fillers, one can resort to the solution of the diffusive heat flow equation (Eq. 2). In amorphous polymer cases, the continuum equation holds all the way to the atomic scale as mean free paths of vibrations are very short. For highly conductive fillers, the mean free path can be longer than the filler size, so in principle, the diffusive equation for the heat flow might not be valid. However, in these cases, it might be enough to use the continuum equations, with the stipulation that filler conductivity be much higher than the matrix, as far as the heat flow is mainly limited by the matrix and interfacial thermal resistances.

An example of finite element method (FEM) analysis of the 90° junction between two MWCNs is shown in Fig. 9. This analysis accounted for the interfacial thermal resistance between the tubes and the matrix using surface elements (Shenogina et al. 2005). Interestingly, the above analysis demonstrated that as far as the distance between tubes is much smaller than their length, the separation between the tubes does not affect the rate of the heat flow between the tubes noticeably. Even if tubes are in physical contact, the rate of heat flow is not increased noticeably when contact

Fig. 9 A picture of the meshed model used in an out FEM analysis of two tubes crossed at 90° in a cylinder-shaped calculation box (Shenogina et al. 2005)
resistance is present. The situation would be different when the contact resistance is negligible, such as the case when the carbon nanotubes are covalently bonded.

The numerical solution of the diffusive heat flow equation can be applied to large filler and its environment and also to multiple filler ensembles. However, a simulation volume that faithfully represents the bulk nanocomposite with a number of associated fillers and their distributions can be prohibitively expensive to treat even with a numerical solution of the continuum heat flow equation. In this case, one can resort to the homogenization treatments, where, e.g., a case of heat flow around a single ellipsoidal inclusion is solved analytically and also analytically averaged over distributions of filler orientations.

To this end, the homogenization treatment due to Nan et al. (1997) is particularly useful in the case of polymer nanocomposites as it accounts for the interfacial thermal resistance. In this treatment, the effective thermal conductivity of the composite along a specific direction, K_{33}^*, is given by:

$$K_{33}^* = K_m \frac{1 + f \left[\beta_{11} \left(1 - L_{11} \right) \left(1 - \langle \cos^2\theta \rangle \right) + \beta_{33} \left(1 - L_{33} \right) \langle \cos^2\theta \rangle \right]}{1 - f \left[\beta_{11} L_{11} \left(1 - \langle \cos^2\theta \rangle \right) + \beta_{33} L_{33} \langle \cos^2\theta \rangle \right]}, \quad (12)$$

with

$$\beta_{ii} = \frac{K_{ii}^c - K_m}{K_m + L_{ii} \left(K_{ii}^c - K_m \right)} \quad (13)$$

$$L_{11} = L_{22}$$

$$= \begin{cases} \frac{p^2}{2(p^2-1)} - \frac{p}{2(p^2-1)^{3/2}} \cosh^{-1} p, & \text{for } p > 1, \\ \frac{p^2}{2(p^2-1)} + \frac{p}{2(1-p^2)^{3/2}} \cos^{-1} p, & \text{for } p < 1, \end{cases} \quad (14)$$

$$K_{ii}^c = K_p / \left(1 + \gamma L_{ii} K_p / K_m\right), \tag{15}$$

with

$$\gamma = \begin{cases} (2 + 1/p)\,\alpha, \text{ for } p \geq 1 \\ (1 + 2p)\,\alpha, \text{ for } p \leq 1 \end{cases}.$$

and

$$\alpha = \begin{cases} a_k/a_1, \text{ for } p \geq 1, \\ a_k/a_3, \text{ for } p \leq 1, \end{cases} \tag{16}$$

where K_m is the thermal conductivity of the matrix, K_p is the thermal conductivity of the ellipsoidal filler particle, and L_{33} are geometrical factors dependent on the particle shape. Other parameters are given as follows: $p = a_3/a_1$ is the aspect ratio of the graphene given by the ratio of longest to shortest radii of the ellipsoid; $\gamma = (2 + 1/p)\alpha$, $a_k = R_{\mathrm{gd}} K_m = K_m/G_k$ is the Kapitza length, i.e., the length over which the temperature drop in the matrix is the same as at the interface; and f is the particle (filler) volume fraction. Finally the triangular brackets in $\langle \cos^2 \theta \rangle$ indicate the orientational average over a specific distribution of fiber orientations, for example, for fully randomly oriented fibers $\langle \cos^2 \theta \rangle = 1/3$ and for fully aligned fibers, along the alignment direction $\langle \cos^2 \theta \rangle = 1$.

Using Eqs. 12, 13, 14, 15, and 16 and the results of molecular dynamics simulations on graphene fiber composites (see Fig. 8), Hu and collaborators (Hu et al. 2011b) extracted the effective interfacial thermal conductance, G_K, for different fiber lengths and obtained consistent value of about 30 MW/m²-K. These results indicate the effective medium theory is indeed capable of an accurate estimate of the composite conductivity for a wide range of aspect ratios, filler volume fractions, and filler orientations.

The effective interfacial thermal conductance of ~30 MW/m²-K is relatively low, and for a typical polymer thermal conductivity, the corresponding Kapitza length is equal to about 10 nm. Even more important for the thermal conductivity of fiber composites is the estimate of the "critical" filler length, L_C, over which the heat flown in to the fiber is dissipated to the matrix, given by (Huxtable et al. 2004):

$$L_c = \sqrt{\frac{rK_p}{G_k}} \tag{17}$$

where K_p and r are the filler conductivity and thickness, respectively. Using $K_p = 1000$ W/K-m, $r = 0.3$ nm, and $G_K = 30$ MW/m²-K, Eq. 17 yields L_C of 100 nm, with the corresponding aspect ratio of about 300. The importance of L_C lies in the fact that for fillers significantly longer than L_C, the interfacial resistance plays a minor role on thermal conductivity, while for fillers shorter than L_C, the conductivity is severely limited by the interfacial resistance. This finding indicates

that for fillers with large enough aspect ratios, the limitation associated with the interfacial resistance can be largely alleviated.

When filler aggregation leads to effectively lower aspect ratio fillers, it is detrimental to thermal transport. To illustrate this point, Fig. 10 shows the effective thermal conductivity for randomly oriented carbon graphene fibers – polymer nanocomposites predicted by Eqs. 12, 13, 14, 15, and 16. In this case, the thermal conductivity is isotropic. Using $K_p = 1000$ W/K-m and $G_K = 30$ MW/m^2-K, the conductivity of the composite at 1% of the graphene volume fraction, as a function of the diameter of the graphene platelets, is shown in Fig. 10 for two cases: (i) single graphene-layer platelets and (ii) five graphene-layer platelets corresponding to ∼2 nm platelet thickness. In both cases, conductivity increases rapidly with an increasing diameter and converges to the common upper limit value given by $1/3K_P f + (1 - f) K_M$ (Nan et al. 1997). However, the upper limit is reached at smaller diameters for single graphene-layer platelets, emphasizing the benefit of good dispersion, resulting in a higher effective aspect ratio.

As discussed above for the very high aspect ratio (∼>500), the interfacial resistance plays no role, and for random filler orientation, the effective thermal conductivity is $1/3K_P f + (1-f) K_M$, while for aligned fillers in the alignment direction, the effective thermal conductivity is $K_P f + (1-f) K_M$. These results are also applicable when the filler forms a well-connected network, i.e., a continuum phase.

By contrast, in the case of spherical and well-dispersed fillers, the homogenization theory in the limit of low volume fractions of nanoparticles, and with $K_p \gg K_m$, predicts:

$$\frac{K_{eff}}{K_p} = 1 + 3f \frac{a_K/r - 1}{a_K/r + 2}, \tag{18}$$
Fig. 11 Schematic of a homogenization approach for fractal particle clusters. The aggregate is decomposed into dead ends with the fluid and the backbone. The effective thermal conductivity of the aggregate with only particles belonging to the dead ends is first calculated using homogenization theory. In the next level of homogenization, linear chains embedded inside a medium with effective conductivity of k_{nc} are considered. (From Prasher et al. 2006)

where a_K is the Kapitza length as before and r is the particle radius. According to Eq. 18, when the particle radius becomes equal to the Kapitza length, there is no thermal conductivity enhancement at all, while for larger interfacial resistance or smaller particle radius, the addition of particles actually decreases the thermal conductivity of the composite.

Homogenization theories can also be applied to more complex situations where small aspect ratio nanoparticles agglomerate, but into sparse fractal patterns. This way they create fillers with an effectively much larger aspect ratio. Such situations can occur in suspensions of solid nanoparticles in fluids (so-called nanofluids) and possibly in polymer resin before curing. Prasher and collaborators (2006) introduced an interesting homogenization treatment for such systems depicted in Fig. 11. According to Fig. 11, a fractal cluster is embedded within a sphere of radius equal to Rg and is composed of a few approximately linear chains, which span the whole cluster (aggregate) and side chains. The linear chains are treated as high aspect ratio fillers, while side chains are treated as well-dispersed particles. Such an approach enables the prediction of thermal conductivity for a variety of particle agglomeration states.

6 Summary and Discussion

In this chapter, an approach to model the heat conduction in polymers and their nanocomposites was presented. Classical molecular dynamics simulations were

presented as the method of choice for the thermal conductivity determination of bulk polymers which combine the computational efficiency and the relative accuracy of the description of atomic structure, chemistry, polymer chain conformation, and bonding. This allows studying the relationship between these structural characteristics and thermal conductivity. The MD-based methods for determining the interfacial thermal conductance were introduced and described in the context of inorganic-polymer interfaces present in the polymer nanocomposites. The incorporation of such determined thermal transport parameters including thermal conductivity of bulk polymers and interfacial thermal resistance into homogenization theories was discussed. These theories allow predicting the role of these parameters, along particle size, shape, volume fraction, distribution of particle orientations, and agglomeration state on thermal conductivity.

While the presented approach constitutes a quality predictive tool for the heat flow analysis in polymers and their composites, a number of challenges and limitations need to be recognized. A standard challenge in MD simulations is the accuracy of describing the interatomic forces. In the case of bulk amorphous polymers, the situation can be quite favorable. The interatomic potentials along with the Monte Carlo-based algorithms allow the preparation and the simulation of the polymer structures which accurately represent real materials. The thermal conductivity predictions for these materials compare favorably with their experimental values. This agreement might be partially due to the fact that some details of the models and atomic interactions might be not that consequential for thermal transport properties. Most likely and good account for the chain conformation (trans-gauche statistics), polymer density and elastic modulus might be sufficient for accurate thermal conductivity predictions.

The situation is more challenging in the cases of highly oriented polymers that exhibit a multifold higher thermal conductivity. The first challenge here is the creation of the quality model structures. Also, in the case of highly aligned and crystalline polymer fibers, the phonon scattering can be very weak and dominated by phonon-phonon scattering, instead of structural scattering. In this case, it is imperative to use both high-accuracy model structures and atomic interaction that would also account for the anharmonic nature of the bonding. However, these bonding parameters are typically not considered when the force fields are designed and parameterized. Nevertheless, the MD simulation studies of the role of chain orientation and their alignments are feasible, particularly to develop correlations, rather than to determine the absolute values of the thermal conductivity.

Contents

Abstract

The growth of computational resources has enabled investigations of large-scale and highly correlated problems by using first principles computational techniques such as density functional theory (DFT). In context of oxide materials, these problems include oxide surface reconstructions (Diebold et al. 2010), diffusion and reaction barriers in heterogeneous systems (Chizallet and Raybaud 2014; Aksyonov et al. 2018), phase diagrams for transition metal oxides (Park et al. 2014; Leonov 2015), and point defects as well as extended defects (Youssef and Yildiz 2012; Sun et al. 2015). These developments have opened up new

opportunities for predicting not only the bulk crystal properties of oxides, but also the effect of complex microstructures such as associated point defects (Hu et al. 2013; Liu et al. 2012; Zhang et al. 2014; T-Thienprasert et al. 2012), grain boundaries (Polfus et al. 2012; McKenna and Shluger 2009; Hojo et al. 2010), dislocations (Sun et al. 2015; Hojo et al. 2011; McKenna 2013), and surfaces (Lee and Morgan 2015; Freysoldt and Neugebauer 2018; Bajdich et al. 2015) under thermodynamic drivers. These developments can ultimately allow for ab initio prediction of realistic device performance. Yet, challenges remain on both the theoretical and algorithmic level to accurately predict oxide materials properties on a complex potential energy surface. Here we summarize several growing fields in addressing these challenges and present our perspectives on future directions that these methods will enable.

1   Methods: Overview and Perspectives

Developing functionals towards chemical accuracy: Developing functionals that accurately describe the exchange and correlation energy has been a continuing interest ever since the development of Kohn-Sham (KS) DFT (Mattsson 2002). For oxides, the use of standard KS-DFT is known to give errors in properties such as electronic structures (Li et al. 2013), formation energies (Kirklin et al. 2015), and surface adsorption energy and reaction barriers (Lousada et al. 2013). These errors hinder the accurate prediction of phase diagrams (Heinemann et al. 2013; Hautier et al. 2012), redox potentials (Chevrier et al. 2010), surface reactivities (Nørskov 2011) for many materials of interest for energy storage and conversion and for information processing. Increasing the accuracy of functionals by moving from local to nonlocal descriptions is called climbing the "Jacob's ladder" (Perdew et al. 2005). To date, five rungs of Jacob's ladder have been extensively investigated and readily applied to oxide solid state systems: local density approximation (LDA), generalized gradient approximation (GGA), meta-GGA, hybrid functionals, and random phase approximation (RPA) (Tran et al. 2016; Perdew and Schmidt 2001; Tao et al. 2003; He and Franchini 2017). Despite the increasing accuracy in treating the exchange-correlation energies and the computational cost paid going up on the ladder, the concurrent DFT methods still fail to accurately treat short-range, intermediate-range, and long-range accurately at the same time (Becke 2014). One of the consequences is that systems with diverse bond types (covalent, metallic as well as ionic, hydrogen, and van der Waals bonding) are hard for DFT prediction. One notorious example is the prediction of molecule adsorption energies on oxide surfaces. Bajdich et al. showed that on alkaline-earth metal oxides surfaces, the best-behaving functional gives errors of up to 0.1 eV compared to the experimentally measured value, and this error is significant for weakly bound molecules (Bajdich et al. 2015). It can be foreseen that improving the accuracy of DFT functionals will still be a major field of interest in the coming years, both by climbing up the Jacob's ladder (Bechstedt 2018) and by developing problem-specific methods, such as DFT + U (Anisimov et al. 1991), SCAN-meta-GGA, and van der Waals schemes (Kulik 2015; Sun et al. 2016; Klimeš and Michaelides 2012).

Treating excited electronic states: Excited state calculations are of interest in many photonic, optoelectronic, and photochemistry processes. In particular, for oxide materials, photoluminescence (Chizallet et al. 2008), carrier transport (Han et al. 2016), and photocatalytic activity (Abe et al. 2013) are important in determining the performance of the material in applications ranging from transparent conducting oxides (Varley et al. 2017) to solar cells (Makhal et al. 2010; Fattori et al. 2010), and photoelectrochemical cells (Zhao et al. 2015). First-principles-based calculation of spectroscopic features which are accessible experimentally, such as in X-ray absorption, photoemission, and electron energy loss spectroscopy, has been helpful in uncovering the photo- and electro-dynamics of chemical bonds and electronic transitions as they take place (di Valentin et al. 2014). Such studies have been demonstrated on various device applications such as photovoltaics (Labat et al. 2012), photocatalysis (Suzuki et al. 2012), and light emitting diodes (Kuttipillai et al. 2016). However, due to challenges in selecting functionals (Leang et al. 2012; Laurent and Jacquemin 2013), convergence on a complex potential energy surface (Plasser et al. 2012), and high computational cost, excited state calculations have been so far limited mainly to simple systems. An archetypal case is the band gap of semiconductor and insulator, a key quantity for virtually all applications, which is not accurately accounted for within standard local and semilocal functionals. Recent advances in quasiparticles approaches in the framework of the GW approximation (Hedin 1965) have proven to be a viable route for a precise prediction of band gaps even in complex oxides (Klimeš et al. 2014; Ergönenc et al. 2018). Another challenging example is that in modeling dye-sensitized solar cells, predicted energy level alignment between TiO_2 and organic dye can vary up to 1 eV with different functionals and thus, cannot lead to a conclusive quantitative result (Pastore et al. 2013). Further method development in this direction is needed, and the most promising approaches for assessing optical and electronic excitations at present include the time-dependent DFT (TD-DFT) (Runge and Gross 1984; Petersilka et al. 1996; Stratmann et al. 1998) and many body Green's function approaches such as solving the Bethe–Salpeter equation (BSE) (Salpeter and Bethe 1951; Onida et al. 2002; Reining et al. 2002). Developments in this direction can allow for applying excited states calculations to obtain optical and electronic properties of surface complexes, hetero-interfaces, and defects, opening up opportunities to tune oxide-based electronic and electrochemical devices by defect and interface engineering (Pentcheva and Pickett 2010; Mannhart and Schlom 2010). An alternative approach to describe the many-body physics of correlated materials is the dynamical mean field approximation (DMFT) (Georges et al. 1996), that in recent years has demonstrated its validity in interpreting optical spectra and optical transitions and is becoming applicable to realistic problems in materials science.

Embedding methods for large-scale problems: In many atomistic modeling problems, a fraction of the system is of special interest and worth being treated with a higher-level theory. The rest of the system serves as its environment and can be treated rather at a lower level. Problems of interest include chemical and electrochemical reactions on oxide catalysts or oxide electrodes that depend on the surface morphology or particle shape, such as corners, facet edges, kink,

surface-terminated dislocations (McKenna 2013; Zheng et al. 2015; Cao et al. 2010; Kleijn et al. 2014; Meyer and Reuter 2014; Stecher et al. 2016) Methods that combine an expansive, more accurate method and a computationally cheap, low-level method are called embedding methods (Sun and Chan 2016). These methods allow for treating large-scale problem while maintaining accuracy for the active region of interest. Depending on the choice of the two levels of methods, embedding methods come with many flavors, such as quantum mechanics/molecular mechanics (QM/MM) (Lin and Truhlar 2006), which combines classical force field with quantum chemistry methods, DFT embedding (Libisch et al. 2014) (different levels of DFT or DFT with many-electron wave function methods), Green's function embedding (Chibani et al. 2016) (DFT with Green's function). Besides the challenges for individual methods as mentioned previously, embedding methods bring about more challenges in terms of developing the embedding potential and coupling the two methods in a reliable and computationally efficient way across their border region.

Including finite temperature effects: Temperature effect is important to be taken into consideration to accurately predict oxide properties in real applications. Accounting for finite-temperature effects is important in many properties of materials, such as heat conduction, phase transitions, and transport properties (Togo and Tanaka 2015; Mankowsky et al. 2014; Serrano et al. 2010; Lee and Rabe 2010). Introduction of temperature effects to couple with first principles calculations involves two lines of effort: (1) explicit free energy terms with all relevant excitation mechanisms such as electronic, quasiharmonic, and anharmonic vibrational terms and (2) explicit account for defect equilibria at finite temperature and their effect on material properties. On the first, calculating anharmonic vibrational contribution generally requires sufficient high-quality DFT force data and is limited mainly to bulk compounds at present (Grabowski et al. 2009; Duff et al. 2015; Zhou et al. 2014; Tadano and Tsuneyuki 2015). Phonon properties and phonon-electron coupling at hetero-interfaces remains a question of interest as well (Sadasivam et al. 2017; Wang et al. 2016). On the second aspect, a successful case is the prediction of point defect equilibria in bulk oxide materials by combining first-principles and statistical mechanics calculations (Youssef and Yildiz 2012; Freysoldt et al. 2014; Youssef et al. 2016). On the other hand, equilibrium structures of extended defects, including surfaces, grain boundaries, and interfaces, and their effects remain largely unexamined for oxide materials. Scaling up of DFT methods, development in advanced sampling techniques (Chua et al. 2010; Harmer 2011), and including the embedding methods discussed above can enable more progress in this context of taking into account temperature effects at extended defects of oxides.

2   Highlights from the Part

Below, we highlight key points of the chapters covered in this section, each demonstrating the state of the art at present in addressing the challenges summarized above. These works include the modeling of charged point defects and hetero-interfaces

from an electronic structure perspective and extending these studies to continuum level equilibria and transport kinetics, ferroelectric, and multiferroic properties, and transport and charge transfer properties in battery and solid oxide fuel cell materials in bulk and at surfaces.

The chapters by Shluger, Reticcioli et al., and Youssef et al. address the modeling of point defects in oxides as relevant to electronic and electrochemical properties. Shluger in ▶ Chap. 43, "Defects in Oxides in Electronic Devices," provides an overview of established models of some of the typical defects in oxides used in microelectronic devices. Defects in oxide dielectric films are often electrically active, capturing and emitting charge carriers from the interfacing materials. Such charge trapping and emitting defects strongly affect the device characteristics, sometimes leading to device failure. This chapter highlights some recent results of theoretical modeling as well as existing problems of computational methods in handling such defects. The properties considered concern mainly nonstoichiometry and disorder of oxides as well as the role of hydrogen. These recent results demonstrate that theoretical modeling and simulation of complex and often defective and disordered thin oxide films is a powerful tool of materials discovery. Importantly, the chapter brings together calculations and results from a range of oxide materials, provides an opportunity to compare models of similar defect species in different materials, and identifies interesting trends that are not obvious from disparate data available in different research fields. The chapter points to the challenges related to lack of transferability of the found defect models from crystalline bulk structures to disordered structures or to surfaces and interfaces. The chapter also points to the lack of direct links from the present static calculations to the dynamics going on in electronic devices, calling for more method development in addressing spatial and time scales that are reachable with first principles methods.

In ▶ Chap. 44, "Small Polarons in Transition Metal Oxides" Reticcioli et al. address the physics of polarons, a quasiparticle defect ubiquitous in polar semiconductors and transition metal oxides which affects the fundamental properties and functionalities of the hosting materials. The chapter begins with a thorough introduction on the concept of polaron, including theoretical accounts (from the seminal model descriptions of Fröhlich and Holstein to a modern view of polarons based on first principles theories) and experimental aspects (how to detect and measure polaron properties). Then, according to the aims of this handbook, the authors describe different types of computational procedures and prescriptions to model the formation, stability, and dynamics of polarons (including charge-trapping techniques, molecular dynamics, statistical analysis and energetics) and provide evidence that this array of schemes is capable to disclose and interpret the role of polarons in the paradigmatic polaronic material TiO_2.

The chapter by Youssef et al. takes the defect studies from single defect properties to establishing equilibria of a multitude of point defects in the bulk and near interfaces of oxides, in ▶ Chap. 45, "Defect Equilibria and Kinetics in Crystalline Insulating Oxides: Bulk and Hetero-interfaces." This is an important step in predicting and controlling the properties of metal oxides under different thermodynamic conditions. This chapter introduces the approach of coupling electronic

structure methods, thermodynamics, electrostatics, and transport theory, to predict defect equilibria and transport kinetics in metal oxides. Equilibria in the bulk is captured by combining first principles calculations of defect formation energies with statistical mechanics, that self-consistently solves for concentration of defects and the established electron chemical potential as a function of temperature and oxygen chemical potential. The framework is extended to interfaces, by calculating defect energies at the interface as well, and connecting the interface to bulk by solving for the Poisson-Boltzmann formalism. The kinetics of defect transport is captured by using concentrations and migration barriers found from first principles in random walk and kinetic Monte Carlo calculations. The demonstrations of this framework are shown on ZrO_2 as a model system for insulating oxides. In the end, the chapter points to challenges in implementing this framework to metallic oxides which are typically strongly correlated systems whose electronic structure and thus defect properties are difficult to capture accurately. In addition, in more complex oxides with multiple elements and a large range of defect types, automated algorithms would be beneficial to systematically analyze the possible defects and pinpoint the most important ones. Finally, the chapter calls for studying the effect of other thermodynamic forces, including electromagnetic fields and nonhydrostatic stresses.

▶ Chapter 46, "Oxide Heterostructures from a Realistic Many-Body Perspective" by Lechermann et al., focuses on materials design from a many-body perspective. The materials at stake are oxide heterostructures and the computational methodology is based on DMFT. The creation of oxide heterostructures represents a relatively new paradigm in condensed matter research which enables a controlled design of new materials and the onset of novel quantum phases arising from (i) the interplay between the diverse electronic characteristics of the bulk constituents and (ii) the presence of interface regions. In this chapter, Lechermann shows that this complex class of materials can be reliably described using DMFT. The authors offer a focused presentation of the concept of strong electronic correlation in solids, conveys a concise and well-documented introduction to DMFT, and discusses the applicability of DMFT to two exemplary interfaces: band-band insulators and Mott-band insulators.

The importance of interface effects is also addressed in ▶ Chap. 47, "First-Principles Modeling of Interface Effects in Oxides" by Demkov et al., in the context of single-particle DFT. The authors review several important aspects related to the first principles modeling of interfaces (supercell approach, band alignment, construction of the structural models, dipole corrections, defect energy-levels) and validate the reliability of these schemes to technologically relevant interfaces based on transition metal oxides materials as well as Si-based structures. Here the focus is to provide a proper account of several measured properties such as electron energy loss spectra, scanning transmission electron microscopy images, core-level x-ray photoemission spectra.

In ▶ Chap. 48, "Design of New Multiferroic Oxides" Lu and Reticcioli discuss a fundamentally and technologically relevant class of materials, multiferroics. After providing a classification of multiferroic systems in terms of the specific

mechanism enabling the coupling among different ferroic orders (spontaneous ferroelectricity, ferromagnetism, and ferroelasticity), the authors focus their presentation on theoretical and computational protocols necessary to design novel materials with enhanced ferroic properties. These design principles are based on chemical considerations (crystal stricture and composition), electronic properties (the system must exhibit an insulating regime), lattice dynamical analysis (polar phonons), and spin properties (magnetic exchange interactions). The authors show that all these aspects can be assessed in the framework of DFT (suitably extended to account for electronic correlation effects), which provides a computationally reliable scheme to interpret the coexisting ferroic responses and phase stability in realistic situations.

The chapter by Wang et al addresses larger scale simulations by phase field method, which can input thermodynamic data deduced from first principles calculations, in a multiscale manner. The chapter takes ferroelectric domains, ▶ Chap. 49, "Strain Control of Domain Structures in Ferroelectric Thin Films: Applications of Phase-Field Method." Phase-field method has been extensively applied to understanding the underlying physics of the experimentally observed domain structures and predicting their responses to external electrical, mechanical, thermal, and chemical stimuli. This chapter reviews the fundamentals of the thin-film phase-field method and its applications in predicting the effects of strains on the phase transitions, domain structures, and the domain switching. The chapter also presents the prospects of using the phase-field method in microstructure design and property optimization for ferroelectric thin films. Of particular interest to note here is that, this approach has only been applied to a limited number of materials due to the lack of the thermodynamic parameters including the Landau coefficients, electrostrictive coefficients, elastic constants, and gradient energy coefficients. Obtaining Landau coefficients, the polarization, and dielectric responses as a function of temperature experimentally is challenging. First-principles or atomistic calculations can fill this gap, providing the needed input to phase field calculations to address a broader range of ferroelectric oxide materials.

The chapters by Chu et al. and by Kozinsky review the advances brought to energy storage materials by first principles modeling techniques. Ong and Meng and coauthors, in ▶ Chap. 50, "Battery Electrodes, Electrolytes, and Their Interfaces" introduce how the well-established ab initio modeling methods were implemented widely in studying and predicting battery materials, electrodes, electrolytes and their interfaces, from both the thermodynamic and kinetics aspects. The thermodynamic approaches include the computations of equilibrium voltage and voltage profiles, electronic structure, and stability analyses. The kinetics approaches cover methods for ionic diffusion studies, including transition state theory and nudged elastic band method, and ab initio molecular dynamics. This chapter presents an illustrative demonstration of the need for close-loop interaction of first-principles calculations with experimental design and data. The authors conclude by defining their perspective on the pressing challenges in modeling noncrystalline systems, e.g., the presence of intrinsic defects and the electrolyte/electrode interfaces, and the design of high-voltage high-capacity

cathode materials. They call for developments in the areas of multiscale approaches to bridge the multiple time and length scales, and automation software and machine learning tools to facilitate and accelerate the studies of battery materials.

In line with the challenge and need described in ▶ Chap. 51, "Transport in Frustrated and Disordered Solid Electrolytes," Kozinsky addresses ion transport studies in highly defective and disordered materials for Li-ion conduction in solid state. The aim is to reveal the descriptors or design principles for enabling high ionic conductivity in inorganic materials at room temperature. This chapter assesses the effects of strong ion-ion interaction, geometric frustration, disorder, and collective motion in ionic motion and illustrates applications of atomistic computational tools in combination with techniques of statistical mechanics, group theory, and computational geometry for analyzing dynamics and transport mechanisms in the context of Li-ion conducting oxides. In particular, the chapter demonstrates that ab initio molecular dynamics in combination with coarse graining is a very useful tool in resolving ionic transport mechanisms in ceramic electrolytes. A key result is that the overall ability of the Li sublattice configuration to rearrange with low transition barriers in the oxide is found as the necessary ingredient of high ionic conductivity. This requires symmetry breaking and maximizing the amount of geometric frustration in the Li sublattice, preventing the system from settling into a low-entropy arrangement. The chapter calls for systematic consideration of the complex regimes of high Li-ion concentration and strong interaction in different classes of Li-ion conductors.

In ▶ Chap. 52, "Solid Oxide Fuel Cell Materials and Interfaces" Hess et al. present computational studies of the bulk and surface chemistry of perovskite oxides that are widely used as catalysts and electrocatalysts in energy conversion devices. Here the specific focus has been the operating conditions of solid oxide fuel cells. For these materials, while the ion and electron transport properties in their bulk are generally well understood, the surfaces remain much less explored and challenging. Depending on the temperature, oxygen pressure, and electrochemical potential, the surface and near-surface region of doped perovskite oxides can significantly deviate from bulk, in terms of chemistry, atomic structure, and even phase composition. It is known in the field that such deviations are detrimental to surface catalytic properties under operating conditions. The chapter first presents a short description of the bulk defect chemistry of perovskite oxides and highlights the challenges for both theory and experiment in treating these materials. The authors then present the work from the field in investigating surface instabilities and their potential reasons, including electronic reconstruction, ionic segregation, and the formation of stable AO surface terminations. Finally, the chapter examines oxygen adsorption and dissociation reactions on different terminations of selected perovskite oxides. The outlook in this field is to advance the computational frameworks to capture both the equilibrium and dynamic structure of surfaces of complex oxides, a yet unresolved field but immensely important for a range of catalytic and energy conversion applications.

Abstract

This chapter provides an overview of established models of some of the typical defects in oxides used in microelectronic devices, highlighting some recent results of theoretical modeling as well as existing problems of computational methods. In numerous electrical measurements, defects in oxide dielectric films have been demonstrated to be electrically active, meaning that they can capture and emit charge carriers from the substrate as well as the gate. These defects, commonly referred to as charge traps, can strongly affect the device characteristics or even impair their functionality causing device failure. Predictive theoretical modeling and simulation of growth and properties of complex and often disordered thin oxide films became a powerful tool of materials discovery where new sophisticated methods of computer experiments

play an important part in designing and screening new materials and studying and predicting their properties.

1   Introduction

Defects play a crucial role in the performance and reliability of microelectronic devices, optical fibers, transparent conductors, catalysts, sensors, and many other systems. Achieving a better understanding of defect structures and processes has been a driving force behind the development of many powerful theoretical concepts and methods. For example, extensive studies of color centers in the 1960s driven by radiation physics and chemistry helped to shape point defect, polaron, and exciton theories and to develop a wide range of scintillators, laser materials, and dosimeters. Doping of semiconductors, which proved to be vital for microelectronics industry, has long been an inspiration for developing computational solid-state methods. Problems related to the mechanisms of silicon oxidation, reliability of microelectronic devices, Bragg grating formation in optical fibers, luminescence of porous silicon, and others promoted extensive studies of amorphous materials. More recent examples concern the development of new high-k dielectrics for microelectronics applications, transparent conductive oxides, materials exhibiting magneto-resistant properties, high-T_c superconductors, and various applications of quantum dots. Again, most of the work is performed in experimental labs where various combinations of materials are tried and their properties tested. At the same time, predictive theoretical modeling and simulation of growth and properties of complex and often disordered thin oxide films became a powerful tool of materials discovery where new sophisticated methods of computer experiments play an important part in designing and screening new materials and studying and predicting their properties.

A significant component of this research, close to the interests of the authors of this chapter, is related to defects in oxides. They are responsible for leakage current, breakdown and degradation of microelectronic devices, Bragg grating formation, conductivity of electro-active insulators, chemical sensing, and many other processes. Defects are likely to play even more important roles as devices continue to scale and reach dimensions where single defects can affect their performance.

In this chapter we provide an overview of established models of some of the typical defects in oxides, highlighting some recent results of theoretical modeling as well as existing problems of computational methods. We will focus mainly on oxides relevant for applications in microelectronics. This choice is mainly determined by our assertion that these materials are likely to remain in focus of active research for the next few years. However, we hope that this review will provide a useful source of models and understanding of theoretical modeling in a wider area of wide-gap oxides.

Successful development of new materials for gate oxides and transparent conducting oxides (TCOs) poses difficult problems for theoretical modeling. Some of the typical problems include predicting stable structures and electronic properties of Si/dielectric systems. This implies calculations of band offsets; possible interface

defects, such as dangling bonds, Si–Si bonds, hydrogen defects, etc.; studies of the structure and properties of grain boundaries (they can, e.g., accumulate vacancies); and electronic states due to disorder if the dielectric is amorphous. Another important issue concerns predicting the structure and energy levels of possible defects induced by growth and post-deposition annealing in different ambient conditions, for example, due to incorporation of boron, chlorine, oxygen, nitrogen, hydrogen, and other species. Determining the most stable charge states of interface and bulk defect species and their possible role in static charging of as-grown and annealed oxides has long been one of the main challenges of theoretical modeling. An even more difficult problem concerns transient electron and hole traps responsible for leakage current and degradation of oxide films and possible ways of eliminating them. This includes predicting defect diffusion and re-charging in applied electric fields. Defect-induced conductivity is the key issue for TCOs, such as indium tin oxide (ITO). Theory should also help in identifying defects by predicting their vibrational, EPR, optical, and other properties.

Figure 1 gives an overview of some of the processes relevant to gate oxide films: creation of defects, incorporation from the environment and creation during growth; charge transfer, defects can change their charge state due to electron and hole trapping; reactions, defects react with each other to form different defects; and defect diffusion. Theoretical models discussed in this chapter may help to
Fig. 1 Diagram showing the different defect processes which can be important to the properties to gate oxide films. These include defect creation during growth and post-deposition anneal, electron transfer processes between defects and from/to silicon, reactions between defects leading to formation of more complex species and annihilation of existing defects, and defect diffusion

understand the mechanisms of these processes as well as the structure and electronic properties of defects as a function of oxide composition.

The initial stage of studying defects in a new material concerns building structural models of defect species. For example, hydrogen, oxygen, and nitrogen species can incorporate into the lattice during growth or annealing of oxide films in atomic and molecular forms in different charge states. Another class of problems is related to energy levels of vacancies and incorporated species. As-grown films are almost always nonstoichiometric. In relatively narrow-gap oxides, such as In_2O_3, SnO_2, and $Sr(Ba)TiO_3$, oxygen vacancies are the source of electron doping, which makes them n-type conductors. On the other hand, electron and hole trapping by interstitial oxygen and oxygen vacancies from Si in gate oxides may lead to oxide charging and affect leakage current. Charged defects can create strong electric fields and affect band offsets. They can contribute to dielectric loss and their diffusion in an electric field is equivalent to electrolysis. Building a complete picture of defect processes also includes defect reactions, requiring the parameters of electron transfer between defects, calculations of defect diffusion, and recombination. More complex modeling concerns the dynamics of defect processes, mechanisms of energy dissipation, and ultimately absolute rates of these processes.

In many cases, reliable and predictive theoretical screening of complex oxide materials takes much longer than the decision regarding their irrelevance for particular applications reached experimentally. Therefore computer experiments to investigate characteristics related to basic electronic properties, processing, and operational performance of these materials are carried out mainly on prototype systems. In the case of high-k dielectrics, these include ZrO_2, HfO_2, and $HfSiO_4$. The best-studied prototype TCOs include SnO_2 and In_2O_3. SiO_2 has long served and will still continue to serve for some time as a gate dielectric and the material of optical fibers and optical components in lithography. Therefore many of our examples will concern basic defects in this material. Finally, there are many relevant studies of electron and hole defects in the bulk and at surfaces of MgO, some ferroelectrics and in other oxide materials. They allow one to outline some general defect models and trends from their properties. For this chapter we will focus mainly on oxygen- and hydrogen-related defects in these materials due to their ubiquitous nature and general relevance.

Below we will give a brief overview of defects and defect processes relevant for electronic devices. Many of these defects and related processes have been previously studied in bulk, crystalline oxides. Therefore we will discuss the transferability of defect models developed in model oxides to other more complex materials and will consider the effect of disorder in amorphous materials on defect properties.

This chapter inevitably provides only a very specific slice of an extensive and vibrant area of research. Recent excellent reviews related to the topics outlined here may help to broaden the picture. In particular, defects in cubic oxides have been considered in Henderson (1980), Hayes and Stoneham (1985), and Kotomin and Popov (1998). Extensive reviews of defects in SiO_2 in relation to Bragg grating formation in optical fibers and in gate dielectrics can be found in Pacchioni et al. (2000), Lenahan and Conley (1998), and Fleetwood et al. (2008). Advances in

the theory of oxide-semiconductor interfaces have been discussed in Edwards and Fowler (1999) and more recently in extensive collections of papers (Massoud et al. 2000; Jupille and Thornton 2015; Netzer and Fortunelli 2016). The role of oxide defects in reliability of microelectronic devices has recently been discussed in Fleetwood et al. (2008) and Grasser (2014). Defects in wide bandgap II-VI crystals and in transition metal oxides have been reviewed in Neumark (1997), Pacchioni (2000), and Hofmann et al. (2007). Models of radiation-induced point defects and oxygen vacancies in MgO and several ferroelectric perovskites have been considered in Kotomin and Popov (1998), Islam (2000), Kotomin et al. (2002), and Popov et al. (2010). Methods and challenges for atomic-scale modeling of electronic materials and high-k dielectrics have been reviewed in Zunger (1998), Kawamoto et al. (2000, 2002), and Freysoldt et al. (2014). A significant part of research related to defects in oxides is carried out in relation to diverse applications of oxide surfaces in catalysis and in solid electrolyte fuel cells as reviewed in Gellings and Bouwmeester (2000) and Jupille and Thornton (2015).

2 Calculation of Defect Properties

2.1 Formation Energies

In thermodynamic equilibrium, the probability of creating an individual defect D in the charge state q is determined by the defect formation energy Freysoldt et al. (2014):

$$E_{for}(D) = E_D^q - E_0 - \sum_{i=1} n_i \mu_i + q E_F + E_{corr}, \tag{1}$$

where $E_{for}(D)$ is calculated as the total energy difference between the system with the defect E_D^q and the system without the defect E_0. The integer $n_i > 0$ indicates the number of atoms of type i, which can be the host atoms missing or impurity atoms added to the system to form the defect, and the μ_i are the corresponding chemical potentials of these species. The Fermi energy E_F is analog of the chemical potential of the electrons. E_{corr} is a correction term that accounts for finite size of the periodic cell used for calculating the system with the defect.

Defining the chemical potentials of the atomic species in a compound crystal is impossible without further information. Usually, the atomic chemical potentials are set to reflect the experimental conditions, which define the properties of the reservoirs of atoms in equilibrium with the system. If, for example, the sample of MgO has been annealed in an oxygen atmosphere, the chemical potential of the oxygen atoms is the same as in gaseous molecular oxygen at the experimental partial pressure and temperature. The chemical potential of the oxygen atoms in well-annealed oxide in thermodynamic equilibrium is thus strongly dependent on temperature and pressure. However, most calculations do not consider the *process* of formation of a vacancy or incorporation of an atom or molecule. For example,

during annealing of an oxide film in oxygen atmosphere, oxygen molecules can dissociate into atoms at the surface or due to irradiation. However, in most cases calculations are concerned only with final possible state of an atom or molecule in the bulk of material in thermodynamic equilibrium. If atoms are available directly from an oxygen atomic source, then an atomic reference for energy E_O is used. If an O_2 molecule can dissociate into atoms in the process of incorporation, then half of the molecular energy is taken as a reference to account for the dissociation costs. Thus the formation energy gives just a reference for the difficulty of forming a defect in the oxide – the higher the energy, the more difficult it is to create.

2.2   Electrical Levels

Yet another issue, specific for device applications, is that the oxide of interest can be in contact with the electrode(s) – semiconducting (e.g., silicon) or metallic – which set a Fermi level E_F in the system and provide a source of extra electrons. Also an oxide film can be placed in the electric field between the two electrodes, which may alter the defect charge states. To define which charge state of an intrinsic defect (e.g., vacancy) or incorporated defect specie is favored, assuming the common case of oxide film grown on silicon, the chemical potential of the electron can be chosen at the bottom of Si conduction band or at the silicon midgap energy (Blöchl 2000). Electrons can tunnel elastically or inelastically from/to these states to/from defect states in the oxide and change their occupation creating charged defects. Since the interface is not explicitly included in most calculations, one needs to use the experimental information (Alay and Hirose 1997; Mihaychuk et al. 1999) (e.g., 4.6 eV for the valence band offset at the Si/SiO$_2$ interface, 1.1 eV for the bandgap of Si) to estimate the energy of an electron at the bottom of the conduction band of Si with respect to the theoretical zero energy level (see Fig. 2). The calculated energies are readily adjusted if doping, temperature, or bias favors another source of electrons.

To study the dependence of the defect charge state on the position of the system Fermi energy, it is useful to define the thermodynamic charge transition level, E_{th}. The $E_{th}(q_1/q_2)$ is defined as the Fermi-level position for which the formation energies of charge states q_1 and q_2 are equal. Both charge states can coexist near the charge transition level energy.

Once the charge transition levels are defined, the dependence of the defect charge state on the electrode Fermi energy can be introduced via a correction term qE_F, where E_F is varied in the energy range from the top of the oxide valence band to the bottom of the conduction band (providing the bandgap is correctly reproduced). The results are presented as plots of $E_{for}(D)$ vs. E_F calculated for different values of E_F. The crossing points of the corresponding lines determine the E_F where one charge state of a defect becomes more favorable than the other, i.e., charge transition levels. Although the exact position of the Fermi energy can be unknown in some experiments, such diagrams allow one to identify some critical cases and help in the analysis of the experimental data. An example of such a plot is shown below in Fig. 5.
Fig. 2 Schematic band offset diagram showing the relative energies of the top of the valence bands and the bottom of the conduction bands of the bulk materials in contact (for the Si/SiO$_2$ interface Alay and Hirose 1997; Mihaychuk et al. 1999). The figure shows two discrete black levels in the silica bandgap, which correspond to the positions of occupied states of neutral and positively charged oxygen vacancy in α-quartz. To the right from these levels are schematically shown distributions of levels of neutral and positively charged vacancies in a-SiO$_2$: discrete levels correspond to the finite number of vacancies in a periodic cell and continuous distributions to a macroscopic sample. Note that the zero energy level in theoretical calculations of bulk materials is poorly defined and can be even below the top of the calculated valence band

3   Oxygen Vacancies

Oxide films in electronic devices are often nonstoichiometric on oxygen, and their structure includes oxygen vacancies. Oxygen vacancies are likely to be the most prevalent defects in many oxides and may have several charge states. They are characterized by formation energies, position of defect levels with respect to the valence and conduction bands, structural models, spectroscopic properties (including optical absorption and luminescence energies, parameters of EPR spectra, and IR and Raman spectra), mechanisms of diffusion, electron transfer and recombination with other defects, and other characteristics. The study of vacancies in bulk oxides has a long history (e.g., see reviews in Pacchioni 2000, Popov et al. 2010, Hofmann et al. 2007), and here we will try to only highlight those aspects which are of specific interest. First, we will introduce some general models and will illustrate them by several examples. Then we will consider in more detail a case study: oxygen vacancies in hafnia.

Dependent on material and particular application, vacancies can be classified as electron donors or hole traps. Their most stable charge state depends on whether the oxide is in contact with Si or other electron source and on applied voltage. Another type of classification is based on structural models. It provides a rough but very

simple cross section through different oxides in terms of two common types: F, centers, and $Me\bullet$, centers. The main difference between the two structural models discussed below is in the character of localization of electrons left by removed oxygen and of the lattice relaxation.

F-like centers are known to form in cubic alkali halides and oxides, such as MgO, CaO, and BaO (Pacchioni 2000). In these ionic materials, the oxygen site is surrounded by six equivalent metal ions. A classical F-center will have one (alkali halides) or two (cubic oxides) electrons in an s-type deep state in the bandgap. Formation of this defect is accompanied by small and fully symmetric (O_h point group) relaxation of the surrounding ions. A significant amount of the electron density is localized in the vacancy with considerable and equal contributions of neighboring metal ions (see Fig. 3a). Ionization of the F-center will lead to characteristic strong and, again, symmetric distortion of surrounding ions, where the nearest metal ions are moving outward from the vacancy and the 12 next nearest-neighbor anions move inward.

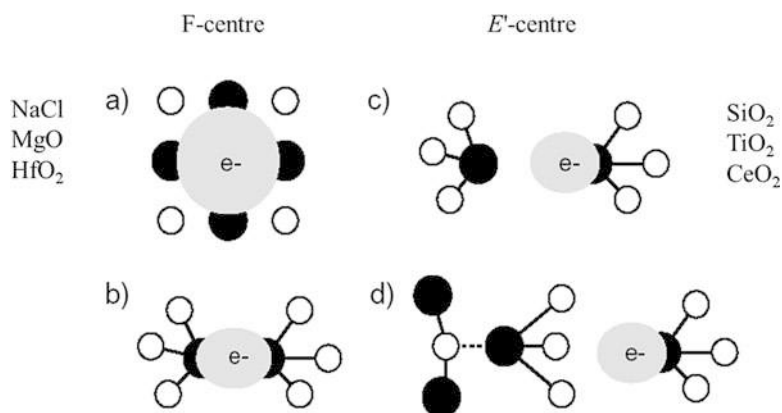
MgO represents perhaps the most studied of oxides, and therefore we will use it as a reference for other oxide materials. In the context of electronic devices, it is used, e.g., in magnetic tunnel junction devices. The properties of neutral and charged oxygen vacancies in MgO have been studied experimentally in great detail (Chen et al. 1969; Hofmann et al. 2007). It is well established that vacancies in MgO can be described by an F-center model (Hayes and Stoneham 1985; Pacchioni 2000) (see also Fig. 3a). As discussed previously, a neutral vacancy possessing two electrons is called an F-center, and a positively charged vacancy, which keeps only one electron, is called an F^+ center, respectively. The paramagnetic F^+ center has been well described using ESR and ENDOR (Henderson and Wertz 1977). The unpaired electron of the F^+ center is shown to be well-localized in the vacancy


Fig. 3 Schematic of different types of oxygen vacancies in insulators. Cations are shown in black and anions in white. (**a**) An F-like center defect characterized by symmetric electron distribution centered in the vacancy (shown in gray); (**b–d**) various types of $Me\bullet$ – center models (see text for discussion). Again electron localization is shown schematically in gray

with only small hyperfine interaction with the surrounding Mg nuclei (Henderson and Wertz 1977). Both centers have close optical absorption energies -4.92 and 5.01 eV for the F and F^+ center, respectively (Chen et al. 1969). Surface analogues of bulk F-centers have long been considered to be part of various surface processes (see, e.g., the recent review Pacchioni 2000).

Another characteristic oxygen vacancy type is represented by what may be called a $Me\bullet$ model. In this case the electrons left in the vacancy reside on the neighboring Me ions rather in the vacancy, in contrast with the F-center model. Oxygen vacancies of this type are formed in different phases of SiO_2, GeO_2, and in silicates, where each oxygen ion is surrounded by only two nearest neighbor positive ions. Formation of a neutral oxygen vacancy in these materials is accompanied by the creation of a $Me--Me$ bond and by strong displacements of these two Me ions toward each other (see Fig. 3b). In TiO_2 and CeO_2 electrons occupy Me ions in the vicinity of the vacant site, but there is no $Me--Me$ bond formation.

The model of a neutral vacancy in SiO_2 is in marked contrast with cubic oxides, such as MgO and the more complex HfO_2 discussed below. In those materials, despite the substantial ionic polarization, the formation of a neutral oxygen vacancy leads to only very small displacements of the surrounding metal atoms. In the case of MgO, ionic displacements are isotropic and at a distance of 8.0 Å from the neutral vacancy are less than 0.002 Å. A double positively charged anion vacancy in MgO produces a much stronger perturbation, but again, the displacements of the lattice ions decrease relatively rapidly and do not exceed 0.02 Å at a distance 8.0 Å from the vacancy. This results from the different structure and chemical bonding in these materials. In particular, in MgO, unlike α-quartz, the oxygen site is the center of inversion. The peculiar structure of α-quartz is also manifested in the strong asymmetry of the relaxation of the two Si atoms neighboring the vacancy (see Sulimov et al. 2002).

The E'-center is perhaps the most famous defect related to oxygen deficiency in silica, which also plays a very important role in many applications of silica in microelectronics and fiber optics. The E'-center is thought to be a positively charged oxygen vacancy. Ionization of the neutral vacancy leaves a relatively weak bond between two silicon atoms. Flexibility of the amorphous structure gives room to formation of several centers. In particular, the E'_γ-center identified by EPR in a-SiO_2 (Griscom et al. 1974; Griscom 2000) has an unpaired spin localized on a dangling bond of a silicon atom (see Fig. 3c, d). This defect has an optical absorption band at 5.85 eV with line-width (FWHM) of 0.8 eV and an oscillator strength f $= 0.14\pm0.1$. This absorption yields no luminescence. The EPR spectrum of E'_1-center in α-quartz is similar to that of the E'_γ center in amorphous SiO_2, as shown in Weeks (1956) and Weeks (1994). However, in spite of some analogies between models of vacancy defects in α- quartz and amorphous SiO_2, it is becoming increasingly clear that there are significant differences too. Some of them stem from the fact that, in contrast with crystalline α-quartz, there are various types of a-SiO_2, which differ by preparation, treatment, water content, and other parameters.

Having discussed the "classical" F-center and $Me\bullet$ case, we will now briefly review models of oxygen vacancies in two other oxides widely used in devices.
Fig. 4 Structural models and spin density distribution in O vacancies in α-Al$_2$O$_3$ and monoclinic HfO$_2$. (**a**) An energy level diagram for the neutral vacancy in α-Al$_2$O$_3$ showing the symmetry forbidden and allowed optical transitions and the molecular orbitals of the A$_1$ and T$_2$ states involved in the symmetry allowed excitations. (**b**) Spin density in a plane containing three Hf ions neighboring the three-coordinated oxygen vacancy (V) with one electron removed from the system. Black arrows show directions of displacements of Hf ions neighboring the vacancy resulting from the electron removal. Charge density is in 0.1 e/Å^3 and all distances are in Å

Sapphire or α-Al$_2$O$_3$ is a representative of a wide class of ceramic materials important for applications in microelectronics and laser optics, as a substrate, and in many other areas. Each Al atom in this material is bonded to six oxygen ions, and each oxygen ion is surrounded by four nearest neighbor Al ions in the form of distorted tetrahedron. Recent ab initio calculations (Hine et al. 2009; Weber et al. 2011) demonstrated that oxygen vacancies in α-Al$_2$O$_3$ form an F-center type defect (see Fig. 4a). However, the relatively low symmetry of the vacancy and mixed ionic-covalent bonding of alumina means that there is significant relaxation (up to 16% of the original bond lengths) of the Al and O ions around the vacancy. The neutral vacancy, F-center, introduces a doubly occupied deep level of about 3.0 eV above the valence band edge, whereas the position of the F^+-center state is predicted to be only 0.25 eV lower. Analysis of the electron density shows that the ground state of the F-center is strongly localized inside the vacancy with large contributions on the surrounding Al and O ions (see Fig. 4a). An energy level diagram for the neutral vacancy in α-Al$_2$O$_3$ in Fig. 4a shows the symmetry forbidden and allowed optical transitions, and the molecular orbitals of the A$_1$ s-type and T$_2$ p-type states involved in the symmetry allowed optical excitations.

Hafnium oxide, HfO$_2$, is widely used in microelectronics as a gate dielectric as well as in memory cells and other applications. Together with ZrO$_2$ they represent the case of mixed ionic-covalent type of chemical bonding and materials with a relatively high ($\approx$20) dielectric constant. Oxygen vacancies in monoclinic hafnia can form at either a four-coordinated tetragonally or three-coordinated trigonally bonded lattice oxygen site. The spin density distribution inside the positively

Fig. 5 Calculated formation energies of the singular O vacancy in monoclinic HfO$_2$ as a function of the electron chemical potential with the origin corresponding to the VB maximum. Charge states are indicated in the inset
charged vacancy in Fig. 4b shows strong electron localization inside the vacancy and on the d–orbitals of Hf ions surrounding the vacancy. Due to the high dielectric constant and d-character of the conduction band they can exist in both positively and negatively charge states (Muñoz Ramo 2007). The formation energy diagram as a function of Fermi-level position in Fig. 5 shows that vacancies prefer to be positively charged at Fermi-level position below 4.3 eV and may become negative at Fermi-level position close to the bottom of the conduction band. The lattice relaxation around neutral vacancies involves small displacements of the nearest neighbor Hf ions. The displacements of these ions for both types of vacancies are in the range of 0.01–0.02 Å, which corresponds to 0.5–1.0% of the HfO bond length. Such small displacements are characteristic for the F-center-type defects. In the negatively charge state, extra one or two electrons are localized on the Hf ions surrounding the vacancy (Muñoz Ramo 2007).

These results provide examples of relatively complex systems where periodic DFT calculations allow one to routinely investigate models and ground state electronic properties of defects in different charge states.

4   Defects at Interfaces

Devices are systems of interfaces between different materials. Electronic properties of thin oxide films grown on Si and other substrates vary widely with their morphology and with the morphology of the interface. The oxide film morphology, in turn, is very sensitive to small variations in chemical composition and to deposition and post-deposition processing. Most as-deposited thin oxide films are amorphous, and annealing at high temperature leads to their partial or full crystallization and formation of polycrystalline films. Structural disorder in amorphous films and grain

boundaries in polycrystalline films help to reduce strain developing at the interface due to misfit of structural parameters of interfacing materials.

Over the years atomistic modeling proved to be instrumental in understanding the structure and defect properties of silicon/oxide and metal/oxide interfaces. The earlier works on metal/oxide interfaces emphasized the role of image interactions, which has been later included in atomistic simulations. More recent work is using DFT and molecular dynamics to predict interface structures. There are broadly three approaches employed for constructing semiconductor/oxide and metal/oxide interfaces. All of them employ a periodic model along the interface plane and therefore are subject to constraints when trying to accommodate two materials in a periodic cell of certain dimension.

One of the most common approaches combines lattice matching with anneal using molecular dynamics. This mimics a growth process and gives additional freedom for the interface atoms to relax. Powered by several types of classical interatomic potentials, it has been used to construct models including more than ten million atoms (Bachlechner et al. 1998). Reactive force fields have been developed and applied to modeling interfaces between crystalline Si and amorphous SiO_2 (van Duin et al. 2003), often accompanied by DFT simulations. Similar approach using DFT and molecular dynamics to melt and quench a-SiO_2 layer sandwiched between two crystalline Si substrates has been used to model a $Si/SiO_2/Si$ systems and more recently $Ge/GeO_2/Ge$ and $Si/SiO_2/HfO_2$ stacks.

The most popular approach to constructing metal/oxide interfaces is using static DFT calculations for systems constructed by lattice matching (Tse et al. 2010) for different values of oxygen pressure (Netzer and Fortunelli 2016). The main criterion of the interface stability is the interface free energy as a function of oxygen pressure (Zeng et al. 2014). In particular, static DFT calculations have been performed to model the formation of the interface between silicon and strontium titanate and its atomic structure (Forst et al. 2004). In this case the order of deposition is important, and this study shows that atomic control of the interfacial structure by altering the chemical environment can dramatically improve the electronic properties of the interface to meet technological requirements.

Another approach is based on simulating the film growth via atomic layer deposition (ALD) or chemical vapor deposition (Dkhissi et al. 2008, 2009). Other studies, focused on the interface growth kinetics, suggested that HfO_2 film growth on Si may be substantially non-epitaxial and would strongly depend on precursor chemistry.

Although atomistic modeling to date had established several important structure-property dependencies, the main challenge remains in identification and characterization of the realistic interface models as opposed to simplified (and possibly even unstable) structures and characterization of interface defects. Electrically active interface defect states may lead to degradation of device characteristics, such as the threshold voltage, the on-current, or the surface carrier mobility. Creation of an interface naturally leads to breaking some of the bonds in the interfacing materials. To further improve the interface quality, the number of dangling bonds can be further reduced by annealing the system in forming gas with hydrogen atoms. The purpose
Fig. 6 Schematic showing P_{b0} and P_{b1} defects located at the interface between an amorphous SiO_2 film and Si substrate with the (100) orientation. The P_{b0} center is back-bonded to three silicon atoms and electrically very similar to the P_b center. The silicon atom of the P_{b1} center is back-bonded to two other silicon atoms and an oxygen atom. Both traps are electrically active as their energy lies in the silicon bandgap making their charge state Fermi-level dependent

of annealing is to reduce the number of structural defects formed during the film growth and to passivate dangling bonds.

Figure 6 shows a schematic of Si/SiO_2 interface. The structure of the interface depends on the Si surface exposed to the oxidation (Massoud et al. 2000; Fleetwood et al. 2008; Grasser 2014). P_b centers are dangling Si bonds remaining at the interface after the oxidation. P_{b0} and P_{b1} centers in Fig. 6 are located at the interface between an amorphous SiO_2 film and the (100) Si substrate. The P_{b0} center is back-bonded to three Si atoms. The silicon atom of the P_{b1} center is back-bonded to two other silicon atoms and an oxygen atom. Both centers are electrically active as their energies lie in the silicon bandgap making their charge state Fermi-level dependent. These dangling silicon bonds are usually passivated by hydrogen after anneal, forming Si-H bonds. With this treatment the amount of electrically active interface states can be reduced to $\approx 10^{10}\,cm^{-2}\,eV^{-1}$. The exact properties of the interface defects, which are trivalent silicon atoms with one unpaired valence electron $Si_3 \equiv Si^{\bullet}$, or $Si_2O \equiv Si^{\bullet}$, depend on the atomic configuration and on the orientation of the substrate. While P_b centers are formed on (111) oriented substrates, P_{b0} and P_{b1} centers exist when Si (100) substrates are used.

It is instructive to consider an example of a more complex $Si/SiO_2/HfO_2$ interface shown in Fig. 7. To construct this periodic cell, a Si/SiO_2 interface was generated in a large supercell of $15 \times 15 \times 40\,\text{Å}$. The bottom silicon (001) layer was passivated by hydrogen and kept constrained during subsequent geometry optimizations using DFT calculations (Gavartin and Shluger 2007). The rest of the system, including the fully hydroxylated SiO_2 surface, was relaxed using simulated temperature annealing followed by static relaxation. Then a block of the monoclinic HfO_2 was added at the top of the structure, such that each hydrogen atom at the SiOH surface was replaced by the Hf at the bottom of HfO_2. The top surface of the HfO_2 block was also hydroxylated to eliminate dangling bonds. Subsequent simulated high temperature annealing leads to a dramatic relaxation of the interface manifested

Fig. 7 The atomistic
structure of a periodic cell
used to calculate the
electronic structure and defect
properties in HfO$_2$/SiO$_2$/Si
stack. In DFT calculations,
the cell is translated in the
direction along the HfO$_2$
surface. Formation energies
of 43 neutral oxygen
vacancies at various positions
between the Si and HfO$_2$
parts of the stack are shown
in the graph below the
structure. The rightmost
defects are directly at the
HfO$_2$/SiO$_2$ interface and the
leftmost directly at the
SiO$_2$/Si interface
by highly correlated oxygen diffusion from the bulk HfO$_2$ toward the interface.
Then the number of Si layers was increased with respect to the original structure to
converge the bandgap of the Si substrate to 1.2 eV. The geometric structure of the
whole stack has been optimized using the hybrid density functional. The thickness
of the SiO$_2$ layer is about 0.65 nm and that of the HfO$_2$ layer is about 1 nm, close to
the technologically relevant structures.

Defects in the SiO$_2$ and HfO$_2$ layers affect reliability of devices and have been
studied extensively. However, the *nm* thickness of oxide layers, confinement, and
strain at interfaces change the defect characteristics with respect to the bulk oxide.
In addition, disorder in the amorphous SiO$_2$ layer leads to a site dependence and
distribution of defect properties. This is illustrated in Fig. 7 where the formation
energies of a sample of O vacancy defects at sites throughout the SiO$_2$ part of the
model interface were calculated. There is a considerable spread in the formation
energies of oxygen vacancies at different sites within the stack. Importantly, O
vacancies tend to segregate at the Si/SiO$_2$ interface.

5   Hydrogen Defects

The lightest element, hydrogen, is probably also the most abundant, as well as
the least detectable impurity in the dielectric oxides. It is also believed to be the
most damaging for the dielectric properties of the gate stack – leading to interface

charging (Afanas'ev and Stesmans 1998), stress-induced leakage currents, and ultimately an electrical breakdown of the dielectric films (Stathis 2002; Fleetwood 2002; Degreave et al. 1999; Fleetwood et al. 2008; Grasser 2014). However, in traditionally used Si/SiO$_2$ systems, hydrogen also plays a positive role in passivating Si dangling bonds, as discussed in the previous section.

Abundance of hydrogen in a dielectric film arises from it being present throughout the manufacturing process. For example, hydrogen is abundantly available during atomic layer deposition of HfO$_2$ and subsequent device processing. It can also be injected into the oxide during device operation and electrical stress from gate stack or from the spacer regions and remains trapped in the film in various stable forms, not all of which are easily detectable. For example, molecular hydrogen does not usually interact strongly with the dielectric lattice and may be identified by Raman spectroscopy. Neutral hydrogen atoms can be detected in the EPR (electron paramagnetic resonance) measurements, but the complications arise from a high mobility of hydrogen atoms. In contrast, various hydroxide ions (OH)$^-$ and water molecules can be probed using the FTIR (Fourier-transform infrared spectroscopy) techniques, although an ambiguity often arises as to where from in the sample (device) an IR signal originates.

Due to difficulties in experimental detection, most of the evidence of the involvement of hydrogen in the electric degradation of CMOS devices is indirect (Fleetwood et al. 2008; Grasser 2014). Though technology primarily aims at passivation of existing defects by hydrogen to improve the device performance, it may also induce new defects or charges detrimental to the reliability. For example, most of the charging phenomena in much better studied insulating a-SiO$_2$ films are associated with hydrogen-related network fragments. Oxygen vacancies in a-SiO$_2$ can effectively trap hydrogen resulting in, e.g., a hydrogen bridge center where hydrogen replaces the bridging oxygen. As discussed earlier, anion vacancies have a large electron affinity, and so does the hydrogen bridge center.

The interaction of hydrogen with transition metal oxides is important for a wide range of applications and has also been studied extensively. DFT investigations of thermodynamic stability and charge transition levels of hydrogen in stoichiometric monoclinic HfO$_2$ and ZrO$_2$ as a function of the Fermi-level position using nonlocal DFT functionals concluded that H is a negative-U system, with the $+1$ or -1 charge states lower in energy for all relevant Fermi-level values (Godet et al. 2007; Li and Robertson 2014; Lyons et al. 2011). In the positive charge state, the hydrogen interstitial is bonded to a threefold-coordinated oxygen atom, with a bond length of 0.98 Å. Negatively charged H$^-$ ion sits interstitially and is coordinated by two (Li and Robertson 2014) or three Hf atoms (Lyons et al. 2011). Such behavior is characteristic to many other crystalline wide-gap oxides (Li and Robertson 2014).

The dynamics of interaction of hydrogen with crystalline oxides is complex, and its understanding has been aided tremendously by the so-called oxide muonics, where muonium is used as a pseudoisotope of hydrogen, as summarized in Cox et al. (2006) and Cox (2003). In a nutshell, hydrogen atom injected into in wide-gap perfect bulk oxide can be (meta)stable and diffuse through the lattice. If the so-called $+/$ pinning level (Li and Robertson 2014) is above the bottom of the conduction

band or the bandgap is smaller than about 5.5 eV, atomic H will eventually donate
an electron into the conduction band and become a proton and bind to the lattice
oxygen ion. If there are defects in bulk material, such as oxygen vacancies, grain
boundaries, and misfit dislocations, atomic hydrogen can donate its electron to these
defects and again form an OH bond at one of the lattice sites. If the Fermi level set
by external electrodes or dopants is high enough, it will eventually trap an extra
electron and become H^-.

The final result depends on the character and concentration of electron trapping
sites in a particular system. For example, atomic hydrogen does not react with
terraces at the MgO (001) surface, but donates electrons to three-coordinated Mg
sites at corners and kinks at that surface, creating new $[Mg^+\!\!-O\text{-}H]$-type centers
(Ricci et al. 2003). The recent study of amorphous silica has concluded that,
unlike in α-quartz, atomic H can break some strained Si-O bonds and form a
new thermodynamically stable defect, termed hydroxyl E' center (El-Sayed et al.
2015). In this case, the electron is localized on a Si atom and a proton forms
an O-H bond nearby. However, the proton is loosely bound, and the volatility
observed in electrical measurements of SiO_2-based CMOS devices can be explained
by the motion of the proton from one O ion to another (Wimmer et al. 2016).
In amorphous HfO_2, hydrogen is also negative-U, with charged states being the
most thermodynamically stable at all Fermi-level positions. However, metastable
atomic hydrogen can share an electron with intrinsic electron trapping precursor
sites forming a $[Hf^{3+}\!\!-OH]$ type center (Kaviani et al. 2017), which is lower
in energy on average by about 0.2 eV. These electron trapping sites can affect both
the dynamics and thermodynamics of the interaction of hydrogen with a-HfO_2 and
the electrical behavior of amorphous hafnia films in CMOS devices. Thus structural
disorder adds important new features to the interaction of hydrogen with materials.

6   Defects in Amorphous Oxides

Amorphous oxides are produced using different methods: metal oxidation, film
growth on semiconductor, and metal substrates using different techniques, such
as atomic layer deposition (ALD), pulse laser deposition (PLD), chemical vapor
deposition (CVD), molecular-beam epitaxy (MBE), rf-sputtering, sol-gel dip coat-
ing, chemical synthesis of powders, and other methods. Densities and atomic
structures of produced samples strongly depend on the method and temperature
of growth, anneal, and other treatments. In this chapter we mainly consider oxide
films grown on metal and semiconductor substrates, which are better studied due
to their wide applications. Still, different communities use different methods of
preparation and propose different ideas regarding the structure of these films. For
example, the thermodynamic approach suggests that an amorphous structure of
oxide overgrowths on metals may be stabilized with respect to the corresponding
crystalline oxide, up to a certain critical oxide-film thickness. This results from
the absence of mismatch strain for the amorphous oxide film (in contrast to an
epitaxial or semi-coherent crystalline oxide film). The value of critical oxide-film

thickness when initial amorphous oxide film transforms into a crystalline oxide film depends on the substrate orientation, temperature, and metal-oxygen system under study (Reichel et al. 2008). However, density, thickness, and morphology of oxide films strongly depend on the substrate and method of deposition, and amorphous films well exceeding a critical thickness are grown on many substrates. They have a varied degree of crystallization depending on the growth conditions, anneal temperature, as well as other factors, such as oxygen pressure. Low oxygen pressure leads to the formation of oxygen vacancies which may induce a decrease of the valence state of the metallic ions or a phase separation reaction in the oxide (Millon 2013). These results highlight the fact that, unlike bulk crystal phase, the morphology and atomistic structure of amorphous films are extremely varied dependent on the sample preparation, which makes simulation of these structures challenging (Medvedeva et al. 2017; Pandey et al. 2016).

By far the most popular method of creating atomistic models of bulk amorphous oxides is based on melting crystalline samples using periodic boundary conditions and then cooling the melt to low temperatures. This method is based on the assumption that all liquids can be frozen into amorphous state by fast cooling. Application of 3D periodic boundary conditions helps to eliminate nucleation of crystal phases unless crystalline nuclei are deliberately introduced into melt. Cooling is usually unrealistically fast due to computer limitations and the cooling rate is rarely slower than 1 K/ps. In many cases, especially when quantum mechanical methods are employed, the cooling rate can be as high as 500 K/ps. Since many oxides are so-called intermediate glass formers, they tend to crystallize at low cooling rates. Further optimization of the volume and geometry of these structures and calculations of defect states are often performed using DFT and periodic models of a system.

The biggest complication for modeling defects in amorphous oxides is related to the variations in their local environment due to disorder. Defects in the bulk crystalline phase formed at equivalent lattice sites have equivalent properties. However, in amorphous structures, all sites are different, and any comparison of model parameters with experiment must involve statistical analysis of different configurations. Using periodic cells is required in order to avoid border effects which may affect defect characteristics. However, this makes the amorphous structures quasiperiodic and induces constraints on the structural relaxation accompanying defect creation. Taken together these factors imply that simulations should be performed in the largest periodic cells feasible for DFT calculations. To credibly predict distributions of properties, calculations at many sites in amorphous structure and of many models are required.

Some of the effects of disorder have been mentioned above when discussing the spread in the formation energies of oxygen vacancies at different sites within the $Si/SiO_2/HfO_2$ stack in Fig. 7. In the previous section, we mentioned that hydrogen can react differently with certain sites in amorphous oxides creating specific defects which do not exist in the crystalline phase. Perhaps the most straightforward manifestation of structural disorder is distribution of defect one-electron states and charge transition levels illustrated in Fig. 2. The figure shows

two discrete black levels in the silica bandgap, which correspond to the positions of occupied states of neutral and positively charged oxygen vacancy in α-quartz. To the right from these levels are schematically shown distributions of levels of neutral and positively charged vacancies in a-SiO$_2$. To calculate such a distribution, one would usually position vacancies at different sites in a periodic cell simulating an amorphous structure. Discrete levels correspond to the finite number of vacancies in a periodic cell and continuous distributions to a macroscopic sample. Different levels correspond to vacancies formed at different sites in an amorphous structure. The distribution of levels leads to inhomogeneous broadening of optical spectra and gives rise to a large variety of possible combinations of relaxation energies and energy barriers when considering defect diffusion and electron capture and emission processes (Wimmer et al. 2016).

7   Outlook

We reviewed some of the main issues pertaining to calculations of point defects and defect processes in oxides for microelectronics. To some extent we followed empirical approaches, which rely on knowledge of other materials in similar states to those to be used in devices. Therefore we have drawn some analogies with other oxides, such as alumina and MgO. The properties we considered concern mainly non-stoichiometry and disorder of oxides as well as related issues, such as the role of hydrogen.

Theoretical modeling is a source of reliable models of defects and defect processes. They are impossible to develop fully from the experimental data alone. A comparison of models of similar species in different materials points to interesting trends, which are not obvious from disparate data available in different research areas. Particularly striking are similarities in models of structure and diffusion of interstitial atomic oxygen species in different oxides. They form peroxy linkage-like species symmetric with respect to the original oxygen site and usually diffuse by the exchange (interstitialcy)-type mechanism (Foster et al. 2002a, b). On the other hand, oxygen vacancies, which are intrinsic structural defects, form a range of models depending on the ionicity of the material and coordination of oxygen sites. In ionic materials with high coordination, such as MgO, Al$_2$O$_3$, and HfO$_2$, they form F-center-like defects and deep states in the bandgap. In more covalent materials, such as SnO$_2$ and CeO$_2$, electrons left in the vacancy tend to be more localized on surrounding metal atoms. In SiO$_2$ where oxygen sites are only two-coordinated, neutral vacancies can be viewed as a Me-Me chemical bond.

The direct relevance of this to technological applications is perhaps not immediately evident. Certainly defect models discussed above have been developed as a result of analysis of large amount of experimental data. In return, they helped to rationalize that data and predict models are transferable between different materials. Still specific problems pertaining to microelectronics are different: defects initiate degradation; they cause charge trapping and provide fixed charge; dielectric performance will vary in time, as the defects or charge state populations evolve;

thin film materials will often be inhomogeneous because of the different epitaxial constraints at the two interfaces; finally, there will be effects on interface properties, including interface dipoles. The mechanisms of these processes remain largely unresolved although the number of works trying to bridge the gap between defect modeling and real processes is growing fast. Establishing a direct link between defect models and properties and their role in processes leading to degradation of microelectronic devices remains one of the main challenges of both theoretical modeling and experiment.

Among other challenges one can note computational studies of the effect of structural disorder on the structure and properties of defect in oxides, which have only started to appear, with the main emphasis on amorphous silica. They demonstrate the limited transferability of defect models developed in crystals within disordered amorphous materials. One can also expect limited transferability of defect models onto thin films and interfaces. Direct modeling of defects in these systems will become extremely important with the ever-decreasing thickness of oxide films and increasing computer resources. Linking the static properties of these defects with real processes in microelectronic devices requires more effort on the front of modeling dynamics of defect reactions. In particular, calculations of the cross sections of defect states with respect to charge transfer processes, studies of effectiveness and rates of defect reactions, and the effect of energy dissipation are bound to become extremely important. This should begin to bridge the size and timescale gap existing in most of the calculations discussed above.

Abstract

The formation of polarons is a pervasive phenomenon in transition metal oxide compounds, with a strong impact on the physical properties and functionalities of the hosting materials. In its original formulation, the polaron problem considers a single charge carrier in a polar crystal interacting with its surrounding lattice.

Depending on the spatial extension of the polaron quasiparticle, originating from the coupling between the excess charge and the phonon field, one speaks of small or large polarons. This chapter discusses the modeling of small polarons in real materials, with a particular focus on the archetypal polaron material TiO_2. After an introductory part, surveying the fundamental theoretical and experimental aspects of the physics of polarons, the chapter examines how to model small polarons using first-principles schemes in order to predict, understand, and interpret a variety of polaron properties in bulk phases and surfaces. Following the spirit of this handbook, different types of computational procedures and prescriptions are presented with specific instructions on the setup required to model polaron effects.

1   Introduction

Electrons in perfect crystals are adequately described in terms of periodic wave functions. However, rather than being constituted by a perfect lattice, real materials are often characterized by the presence of defects, such as point defects (vacancies or interstitials), impurities, grain boundaries, and dislocations (Ashcroft and Mermin 1976; Crawford and Slifkin 1972). Defects in the crystal break the periodicity of the electronic charge density. They can lead to the formation of localized states (Freysoldt et al. 2014; Pacchioni 2015), which affect the materials properties and, thus, their performance in applications. Less intuitively, such localized states could exist also in the absence of any defects in the crystal, i.e., they can form in perfect lattices. This phenomenon is referred to as polarons. A polaron is a quasiparticle originating from the interactions between charge carriers (i.e., electrons or holes) and lattice ion vibrations (Holstein 1959). More precisely, due to Coulomb forces, the excess charge displaces the ions in its neighborhood creating a polarization cloud that follows the charge carrier as it moves through the crystal (see Fig. 1). Such quasiparticles differ from lattice defect states own peculiar properties and are described by well-developed quantum field theories based on effective Hamiltonians (Fröhlich 1954; Holstein 1959).

Formation of polarons is particularly favorable in polar semiconductors and transition metal oxides owing to the strength of the electron-phonon interaction and is further promoted in the vicinity of a surface, where the crystal lattice is more flexible and the necessary lattice relaxations cost less energy (Deskins et al. 2009, 2011; Kowalski et al. 2010; Setvin et al. 2014a, b). Polarons play a decisive role in a wide range of phenomena, including electron transport (Crevecoeur and De Wit 1970; Moser et al. 2013), optical absorption, and chemical reactivity, and have crucial implications in high-T_c superconductivity (Salje et al. 2005), colossal magnetoresistance (Teresa et al. 1997; Rønnow et al. 2006), thermoelectricity (Wang et al. 2014a), photoemission (Cortecchia et al. 2017), and photochemistry (Linsebigler et al. 1995).

This chapter is mostly focused on the first-principles modelling of small polarons (Sect. 2) and its application to TiO_2 (Sect. 3), an archetypal and widely studied

Fig. 1 Pictorial view of a polaron. An excess charge is trapped in a lattice site (bright) and distorts the surrounding lattice
polaron material. This introduction is complemented with a brief summary of the fundamental theoretical aspects defining the physics of polarons and with an overview of the experimental techniques used to detect polaron features in materials.

1.1 Theoretical Background

The emergence of polaron theory can be traced back to 1933 when Landau elaborated on the possibility for lattice distortions to trap electrons by means of an intrinsic modification of the lattice phonon field induced by the electron itself (Landau 1933). The resulting electron-phonon quasiparticle was later called polaron, a coupled electron-phonon system in which the polarization generated by the lattice distortions acts back on the electron renormalizing the electronic properties, for instance, the effective mass. An analogous discussion is valid for holes rather than electrons. A first formal description of the polaron problem was published in 1946 by Pekar (1948), who considered a free electron interacting with lattice deformations in the continuum approximation. Therefore, Pekar's study is limited to the case of polarons with a size larger than the lattice constant, so that the atomic discreteness is negligible (Alexandrov and Devreese 2010). With the ionic lattice described as a polarizable dielectric continuum, Landau and Pekar showed that the polaron mass m^* is enhanced with respect to the "bare" electron mass (Landau and Pekar 1965), an important result that set the basis for all subsequent theories.

During the 1950s, the second quantization formalism was used to refine the description of the polaron problem in terms of quantum effective Hamiltonians including an electronic term (H_e), a phonon term (H_{ph}), and the electron-phonon coupling term (H_{e-ph}). The $e - ph$ term is of fundamental importance for understanding the polaronic states, since it takes into account the type (e.g., short- or long-range) and intensity (weak to strong) of the mutual interactions between charge carriers and lattice vibrations. However, a complete analytic solution of the polaron Hamiltonian cannot be achieved, and approximations are needed. Fröhlich et al. (1950) and Holstein (1959) separately addressed different aspects of the problem and proposed mathematically more tractable formulations. Fröhlich theory relies on the continuum approximation and assumes long-range forces (large polarons), whereas Holstein theory takes into account explicitly the lattice periodicity and treats the electron-phonon coupling as a short-range interaction (small polaron). The distinction between small and large polaron is defined according to the strength of the electron-phonon coupling (weak/strong) and the extension of the lattice distortion around the electron (large/small) (Alexandrov and Devreese 2010; Rashba 2005; Hahn et al. 2018). The distinct features of small and large polarons are discussed at the end of this section.

1.1.1 Fröhlich Hamiltonian

Fröhlich theory treats the situation of long-range coupling between electrons and phonons, which leads to the formation of large polarons (Fröhlich et al. 1950; Fröhlich 1954; Alexandrov and Devreese 2010) and is formalized by the Hamiltonian:

$$H = \sum_{\mathbf{k}} \frac{k^2}{2} c_{\mathbf{k}}^\dagger c_{\mathbf{k}} + \sum_{\mathbf{q}} b_{\mathbf{q}}^\dagger b_{\mathbf{q}} + \sum_{\mathbf{k},\mathbf{q}} \left[V_d(\mathbf{q}) b_{\mathbf{q}}^\dagger c_{\mathbf{k}-\mathbf{q}}^\dagger c_{\mathbf{k}} + V_d^\dagger(\mathbf{q}) b_{\mathbf{q}} c_{\mathbf{k}+\mathbf{q}}^\dagger c_{\mathbf{q}} \right] \quad (1)$$

where $c_{\mathbf{k}}$ and $b_{\mathbf{q}}$ are annihilation operators for a particle with wave vector $\mathbf{k}$ and a phonon with wave vector $\mathbf{q}$, respectively, and $V_d(\mathbf{q})$ is the electron-phonon coupling function for a system in d dimensions, in three dimensions:

$$V_3(\mathbf{q}) = i \left(\frac{2\sqrt{2}\pi\alpha}{V} \right)^{\frac{1}{2}} \frac{1}{q}. \quad (2)$$

Here V is the volume of the system, and α is the dimensionless Fröhlich electron-phonon coupling constant defined in terms of the reduced Planck constant $\hbar$, the charge carrier charge e, the phonon frequency ω of the long-wavelength optical longitudinal phonon, and the material's static and high-frequency dielectric constants ε_0 and ε_∞, respectively (ε_0 includes ionic relaxation effects, whereas the ion-clamped ε_∞ accounts only for electronic contributions):

$$\alpha = \frac{e^2}{\hbar} \sqrt{\frac{m}{2\hbar\omega}} \left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0} \right). \tag{3}$$

In real materials, α ranges between ≈ 0.02 (InSb) and ≈ 3.8 (SrTiO$_3$). In the weak-coupling regime (small α), the Fröhlich Hamiltonian can be solved using perturbation theory, and the Feynman's path integral approach provides accurate results for all coupling strengths (Feynman 1955; Rosenfelder and Schreiber 2001). In the large polaron Fröhlich picture, the spatial extension of the large polaron is bigger than the lattice constant, and the dressed electron is accompanied by a phonon cloud, whose density determines the size of the polaron effective mass m^* and the polaron energy (Devreese 1996; Emin 2013). Recently, the Fröhlich problem has been recast within a first-principle perspective by F. Giustino, which allows for predictive nonempirical calculations of material's specific electron-phonon properties (Giustino 2017).

1.1.2   Holstein Hamiltonian

Holstein considered the polaron determined by a short-range strong-coupling regime, the so-called small polaron, spatially confined within a radius of the order of the lattice constant, described by the general Holstein Hamiltonian (Holstein 1959; Ramakumar and Das 2004):

$$H = -t \sum_{<ij>} c_i^\dagger c_j + \omega \sum_i b_i^\dagger b_i + g \sum_i n_i (b_i^\dagger + b_i) \tag{4}$$

where t is the hopping amplitude between neighboring sites, $c_i(b_i)$ and $c_i^\dagger(b_i^\dagger)$ are fermionic (bosonic) creation and annihilation operators acting on the site i, ω the phonon frequency, g the electron-phonon coupling strength, and $n_i = c_i^\dagger c_i$ is the fermionic particle number operator. As opposed to the Fröhlich model, the Holstein model only considers electron-phonon interactions at a single lattice site, greatly simplifying the model. In the simplified case of a polaron trapped in a linear molecule, hopping between different molecular sites (Holstein 1959, 2000), the Hamiltonian in Eq. 4 reduces to a two-site Hamiltonian describing the electron hopping between two sites, interacting with an ion placed in between via its vibrational mode (Alexandrov and Devreese 2010):

$$H = t \left(c_1^\dagger c_2 + c_2^\dagger c_1 \right) - \frac{1}{2M} \frac{\partial^2}{\partial x^2} + \frac{\gamma x^2}{2} + g x \left(c_1^\dagger c_1 + c_2^\dagger c_2 \right) \tag{5}$$

with M the ion mass, $\gamma = M\omega^2$ the spring constant and x the linear ion displacement from the equilibrium position. The state $|\psi\rangle$ with an extra electron introduced into the unperturbed system $|0\rangle$ and localized at the site 1 or 2 with amplitude probability $u(x)$ and $v(x)$, respectively, is written as

$$|\psi\rangle = \left[u(x) c_1^\dagger + v(x) c_2^\dagger \right] |0\rangle . \tag{6}$$

Despite the simplicity of this model, an analytic solution for the Schrödinger equation $H\psi = E\psi$ can be found only in special cases (e.g., ionic vibration perpendicular to the hopping direction), and one has to rely on numerical approximations or restrict the study to the nonadiabatic ($t \ll \omega$) or adiabatic ($t \gg \omega$) limits. The modelling of small polaron within a first-principles picture is addressed in Sect. 2.

At this point, the distinction between polarons and electrons trapped at lattice defect sites stands out clearly by inspecting the Fröhlich's and Holstein's analysis. First of all, as already mentioned above, polaron formation occurs even in absence of defects, i.e., in the perfect crystal. Moreover, polarons are not stuck to a specific lattice site; rather they can move around in the system. Both these characteristics, i.e., spontaneous localization and mobility, were pointed out by Holstein, who summarized the concepts in few brilliant sentences (Holstein 1959):

> Let us imagine that an electron is momentarily fixed at some point of the crystal. As a result of electron-lattice interaction, the surrounding lattice particles will be displaced to new equilibrium positions [...] such as to provide a potential well for the electron. If the well is sufficiently deep, the electron will occupy a bound state, unable to move unless accompanied by the well, that is to say, by the induced lattice deformation.

At variance, the physics of an electron attached to a defect is rather different, as it is typically not mobile and its characteristics strongly depend on the type of defect (Freytag et al. 2016).

1.1.3   A Few Additional Considerations on Small and Large Polarons

Many other theoretical studies have further developed the ideas of Fröhlich and Holstein, leading to two alternative (and to some extent more advanced) descriptions of large and small polarons (Rashba 2005). Table 1 summarizes the main distinctions between the large and the small polaron (Emin 2013).

As already mentioned, their names reflect the length scale of the spatial localization: while the small polaron electronic charge is usually confined in the primitive cell (a few Å), the large polaron extends over several lattice sites (typically about 20 Å). Also, the two types of polaronic states exhibit distinct energy scales. The large polaron is usually a shallow state, few tens of meV below the conduction band minimum (CBM). Conversely, the small polaron is firmly trapped by local distortions in a stronger potential well, which determines the formation of a deeper in-gap state well localized around 1 eV below the CBM (see Fig. 2).

Table 1 General properties of large and small polarons

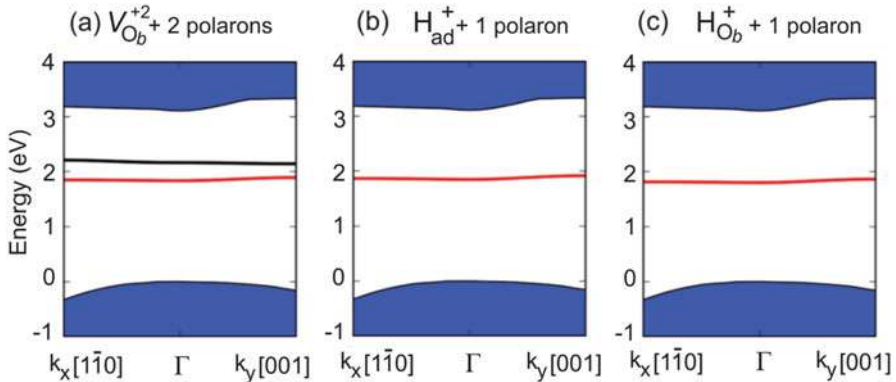
Large polaron	Small polaron
Polaron radius $\gg$ lattice parameter	Polaron radius $\simeq$ lattice parameter
Shallow state ($\sim$10 meV below CBM)	In-gap state ($\sim$1 eV below CBM)
Coherent motion (scattered occasionally by phonons)	Incoherent motion (assisted by phonons)
Mobility $\mu \gg 1\,\mathrm{cm^2/Vs}$	Mobility $\mu \ll 1\,\mathrm{cm^2/Vs}$
Decreasing mobility with increasing temperature	Increasing mobility with increasing temperature


Fig. 2   Polaron in-gap level. Small polaron band-gap states in the surface of rutile TiO$_2$ formed by excess electrons donated by so-called bridge-bonded oxygen vacancies (V_{O_b}), hydrogen adsorbates (H$_{ad}$), or hydrogen hydroxyls (H$_{O_b}$). Results based on first-principles calculations within the hybrid-DFT approach. (This figure is taken from Moses et al. 2016)

The localization process is also different: a charge carrier introduced into a system can quickly equilibrate with the lattice and form a large polaron, whereas the formation of a small polaron occurs only after overcoming an energy barrier (Mott and Stoneham 1977; Lany 2015). Finally, the two types of polarons are characterized by very different transport properties. The large polaron, a heavy quasiparticle, is weakly scattered by phonons. This weak scattering can compensate the large mass, resulting in a large mobility for the large polaron. A small polaron instead hops between trapping sites with a lower mobility. Since its motion is assisted by phonons, the mobility of small polarons increases with increasing temperature. Both large and small polarons have been observed in several experiments, as reported in the next section, and studied by simulations and computational techniques. Historically, large polarons have been investigated mostly via effective Hamiltonians, in particular by means of variational treatments solved by Feynman's path integral techniques and by diagrammatic Monte Carlo (Feynman 1955; Prokof'ev and Svistunov 1998; Mishchenko et al. 2000; Rosenfelder and Schreiber 2001; Gerlach et al. 2003; Gerlach and Smondyrev 2008; Hahn et al. 2018) approaches. First-principles techniques are more suitable for the description of the small polaron, but successful attempts to address the large polaron case have been presented in the last few years (Setvin et al. 2014a; Verdi et al. 2017; Miyata et al. 2017).

1.1.4   How First-Principles Modeling Can be Used

The Fröhlich and Holstein model Hamiltonians are simplifications of the more general electron-phonon Hamiltonian that is discussed in great detail in a recent review of Giustino (2017). Giustino also explains how the individual terms can be derived by first-principles density functional theory, as briefly recapitulated below: (i) The first term describes the one-electron band structure, and that can obviously be calculated and parameterized using density functional theory, hybrid functionals

or the GW approximation. The original Fröhlich and Holstein Hamiltonian involve only a single band, with a parabolic dispersion in the Fröhlich case, and a tight binding form in the Holstein case. In the case of electron (hole) polarons, one thus needs to parameterize the conduction (valence) band. (ii) The second term describes the vibrational frequencies of the optically active mode. The frequencies as well as the eigenmodes can be calculated by density functional perturbation theory. The Fröhlich Hamiltonian involves only a single dispersion free phonon mode, which couples with a wave vector dependent coupling term q. The functional form used by Fröhlich is exact in the long-wavelength limit. The Holstein model involves a single local mode, where the local displacement couples (somehow) to the electronic bands. (iii) The coupling between the electronic and phononic subsystem are described by the last term. The matrix elements in Fröhlich model can be exactly calculated using density functional perturbation theory (Verdi et al. 2017). The Holstein model is somewhat too simplistic and cannot obviously be mapped onto first-principles calculations.

The main issue with both approaches is twofold: (i) In many cases, the restriction to a single band and phonon mode is a too severe simplification, (ii) and even for a single band and a single phonon mode, the solution of the full many body problem can be formidable. This is the main reason why realistic modeling of polarons in real materials has hereto hardly been attempted. Nevertheless, the single band and single phonon model might be very accurate for many simple polar semiconductors and insulators. In this case, all one needs to determine are the effective masses, the phonon frequencies, and the dielectric constants. Then the solution of the Fröhlich model is fairly straightforward and expected to be accurate. Furthermore, there is little reason to invoke first-principles calculations for large polarons, if all materials parameters are experimentally established.

The situation is more complicated for small polarons. As already mentioned, the Holstein model is a too simplistic approach: for small polarons, the lattice distortions are usually large around an atom, and it is not obvious how to map the distortions to a single effective mode; furthermore the implicitly assumed harmonic approximation might not be accurate if the distortions are large. However, small polarons often involve fairly large energy scales around 1 eV. In this case, one might consider to treat the ionic degrees of freedom as classical particles. In many transition metal oxides, this should be a valid approximation, since the typical vibrational frequencies are small compared to the considered energy scales. In other words, quantum fluctuations of the ions can be disregarded. The second crucial approximation is to treat the electronic degrees of freedom using a mean field theory, such as DFT. There is no need to discuss the accuracy of DFT; it often works exceedingly well. Polarons though pose a particular challenge, since they involve localization of the electrons, which many density functionals fail to describe accurately because of self-interaction errors (see Sect. 2). Compared to the model approach, the full first-principles approach is much simpler. One simply choses a large unit cell, adds an electron, and lets the system evolve into the ground state. The disadvantage compared to the model approach is about giving up on the quantum nature of the ions and restricting the treatment of the electrons to a mean field

approximation. The advantages are, however, numerous. The model Hamiltonians are obtained by expanding the full electron-phonon Hamiltonian around a reference ground state to second order in the ionic displacements (recall, one can use density functional perturbation theory to calculate the vibrational frequencies, as well as the electron-phonon coupling). Anharmonicities are therefore implicitly neglected in the model approach. In this respect the simplistic, brute force approach certainly excels the model approach.

1.2   Experimental Observations of Polarons

Several years after the first theoretical predictions, experimental observations based on different techniques started to detect the presence of polarons in real materials and to study their properties. Nowadays, it is a common practice to complement experimental data with theoretical interpretations based on electronic structure simulations. Table 2 lists significant experimental studies revealing polaron formation in oxide materials. This list also represents the variety of experimental techniques used to observe both small and large polarons, formed by both negative (electron) and positive (hole) excess charges in oxide materials.

1.2.1   Conductivity Measurements

The first observation of polarons is attributed (Stoneham et al. 2007) to an experimental study published in 1963 (Nagels et al. 1963). Experiments on oxidized uranium dioxide reported an increasing hole conductivity with raising temperature, following a behavior well described by the formula:

$$\mu \sim \frac{1}{T} \exp\left(-\frac{\Delta E}{k_B T}\right), \tag{7}$$

indicating small polaron hopping from U^{5+} to U^{4+} sites upon thermal activation, an interpretation further substantiated by the observation that the activation energy ΔE decreases with increasing oxygen concentration.

Experimental confirmations of Eq. 7 were obtained for a wide range of materials, with charge carriers injected by different types of defects. Examples are given by the hole small polarons observed in Li-doped MnO (Crevecoeur and De Wit 1970) and by the electron small polarons in oxygen-deficient cerium dioxide (Tuller and Nowick 1977). In the latter example, two excess electrons originate from every oxygen vacancy present in the system. Each excess electron localizes at one Ce^{4+} site forming a Ce^{3+} ion. Hopping is activated by temperature, and the conductivity measurements confirmed the expected trend for polarons (Eq. 7). Moreover, by measuring the Seebeck coefficient for thermo-electricity, the number of carriers was found to be temperature independent. This is in contrast with the band model for the conductivity, which predicts an increasing number of charge carriers with raising temperature. On the contrary, according to the polaron hopping model, the charge

Table 2 List of experimental observations of polarons in oxide materials using different techniques

Type	Material	Source	Exp. technique	Publication
Hole, small polaron	UO_2	Oxidation	Conductivity measurement	(Nagels et al. 1963)
Hole, small polaron	MnO	Li doping	Conductivity measurement	(Crevecoeur and De Wit 1970)
Electron, small polaron	CeO_2	O vacancies	Conductivity and Seebeck	(Tuller and Nowick 1977)
Electron, small polaron	$BaTiO_3$	Nb doping	EPR	(Possenriede et al. 1994)
Electron, small and large polaron	$a\text{-}TiO_2$ and $r\text{-}TiO_2$	Nb doping	Conductivity and optical measurements	(Zhang et al. 2007)
Electron, small polaron	$r\text{-}TiO_2$	O vacancies	Resonant photoelectron diffraction	(Krüger et al. 2008)
Electron, small polaron	$r\text{-}TiO_2$	O vacancies	EPR	(Yang et al. 2013)
Electron, large polaron	$a\text{-}TiO_2$	O vacancies	ARPES	(Moser et al. 2013)
Electron, small polaron	$r\text{-}TiO_2$	O vacancies	STM and STS	(Setvin et al. 2014a)
Electron, small polaron	$r\text{-}TiO_2$	UV irradiation or H adatom	IR spectroscopy	(Sezen et al. 2015)
Hole, small polaron	$LiNbO_3$	Visible light	IR spectroscopy	(Freytag et al. 2016)
Electron, small polaron	$r\text{-}TiO_2$	O vacancies	IR spectroscopy on adsorbates	(Cao et al. 2017)
Electron and hole, large polaron	Lead halide perovskites	Laser pulse	TR-OKE	(Miyata et al. 2017)

carriers are introduced in CeO_2 only by defects, and the mobility increases with raising temperature due to the increased phonon populations.

1.2.2 Electron Paramagnetic Resonance

Electron paramagnetic resonance (EPR) is another experimental technique able to identify lattice ions with unpaired electrons, a distinct feature of the polaron state. In EPR experiments, an external magnetic field splits the energy level of the unpaired electrons (Zeeman effect), thus determining energy levels available by emitting or absorbing a photon at a specific frequency: the sample is illuminated by light, typically at constant frequency, while the magnetic field varies, and the resonance peaks are measured as function of the magnetic field when the conditions for the level transitions are satisfied. The shape, intensity, and energy values of the

resonance peaks determine the electronic states of the atoms in the sample where charge trapping can be detected. Small polarons were identified by EPR in Nb-doped $BaTiO_3$ samples (Possenriede et al. 1994; Lenjer et al. 2002) and other materials including oxygen-deficient rutile TiO_2 samples (Yang et al. 2013).

1.2.3 Optical Measurements

The difference between small and large polarons manifests itself prominently in the optical properties of materials. An example is the response of two different polymorphs of TiO_2, rutile and anatase, to (electron) doping with Nb, reported by Zhang et al. (2007). Epitaxial thin films of the two different polymorphs were grown on appropriate substrates, $SrTiO_3(001)$ or $LaAlO_3(001)$ for anatase and $Al_2O_3(r$ and c-cut) for rutile. By substituting 4-valent Ti with 5% of 5-valent Nb, electrons were added to the system. The two types of films showed contrasting behavior in conductivity measurements: anatase films were metallic while rutile films semiconducting. Together with the similar carrier density observed in both films, this is consistent with the formation of large and small electron polarons, respectively. The optical transmittance of 80% in the visible range for epitaxial anatase films shows that these films can be characterized as transparent conductive oxides (Klein 2012).

1.2.4 Resonant Photoelectron Diffraction

The charge distribution in reduced TiO_2 rutile (110) single crystals was first determined by Krüger et al. (2008, 2012). Their experiment is based on angle-resolved x-ray photoemission (XPS). Intensity variations in a specific photoelectron peak (here Ti-$2p$) are recorded while changing the polar and azimuthal emission angle. Since forward focusing dominates the scattering of electrons with kinetic energies of a few hundred eV, the configuration of near-range atomic neighbors can be accessed in a rather direct manner and modeled in a simple cluster geometry (Chambers 1992). In their work, the authors took advantage of the fact that the Ti-$2p$ XPS peak shows a clear shoulder that is attributed to Ti^{3+}; the intensity of this feature was additionally increased by tuning the photon energy to a resonance condition (Bertel et al. 1983). The photoelectron diffraction pattern of the Ti^{4+} peak (from Ti^{4+} at regular lattice sites) and the reduced Ti^{3+} signature turned out to be drastically different, and the best fit was obtained by attributing the excess electrons to the subsurface Ti atoms. This is true independently of the way the excess electrons are introduced into the lattice, either by creating O vacancies (Krüger et al. 2008) or by adding electrons via Na deposition (Krüger et al. 2012). This points to the fact that the location of polarons in subsurface position is an intrinsic feature of rutile TiO_2.

1.2.5 Angle-Resolved Photoemission Spectroscopy

TiO_2 has been investigated by numerous different experimental techniques in addition to the methods mentioned above. Angle-resolved photoemission spectroscopy (ARPES) (Moser et al. 2013) was used to identify the presence of large polarons in the anatase polymorph of titanium dioxide. The energy dispersion close to the Fermi level measured by ARPES experiment shows satellite (shallow) states below

the conduction band, corresponding to large electron polarons, brought about by the oxygen vacancies present in the sample. By tuning the amount of oxygen vacancies (via UV irradiation Locatelli et al. 2007), the density of charge carriers can be controlled. At high vacancy concentrations, the satellite states disappear, due to the overlap of the polaronic wavefunctions, giving rise to a metallic behavior indicated by the crossing of the conduction band with the Fermi energy.

1.2.6   Scanning Tunneling Microscopy and Spectroscopy

A direct view at the polaronic states in TiO_2 can be achieved by using scanning tunneling microscopy (STM) and spectroscopy (STS) (Setvin et al. 2014a). In-gap states stand clearly from the STM and STS studies on both anatase and rutile TiO_2 polymorph, due to charge carriers (electrons) induced by oxygen vacancies or Nb doping. However, the two polymorphs present quite different polaronic states: while rutile TiO_2 is a prototypical small polaron material, anatase was found to host predominantly large polarons. STM is capable to provide information on the spatial distribution of the polaronic charge at the surface, which is helpful for the identification of small and large polarons.

1.2.7   Infrared Spectroscopy

Small polaron states have been detected in TiO_2 also by absorption infrared (IR) spectroscopy experiments (Sezen et al. 2015). The vibrational energies of the lattice bonds are typically in the infrared regime. Therefore, by exposure of the sample to IR light, resonance peaks appear in the measured transmitted and reflected beams. In the presence of small polarons, the localized charge together with the local lattice distortions contributes to form resonant peaks at characteristic vibrational frequencies. Interestingly, the polaron peaks in TiO_2 were found to be independent on the source of charge carriers, H adsorption and UV irradiation, a strong evidence of the polaron nature of the peaks. The characteristic vibrational spectra of a defect state, at a donor would, in fact, be susceptible to the type of the donor.

Infrared spectroscopy can also be used to detect polarons indirectly, by inspecting the vibrational properties of bonds in the vicinity of the trapping site. Electron small polarons were found to redshift the stretching frequency of NO molecules adsorbed on reduced TiO_2 surfaces with respect to the pristine samples (Cao et al. 2017). Analogously, hole small polarons modify the vibrational frequency of the OH impurities at Li vacancies in $LiNbO_3$ samples (Freytag et al. 2016). In the latter study, irradiation in the visible region was used to generate hole small polarons at O sites and electron polarons at Nb sites. The hole polarons localize in the vicinity of the Li vacancies, due to the a more favorable electrostatic potential, and therefore strongly contribute to the frequency shift of the OH impurities. Once the source is turned off, hole and electron polarons recombine, since their mobile character, and the original vibrational frequency is restored.

1.2.8   Time-Resolved Optical Kerr Effect

Recently, the time-resolved optical Kerr effect (TR-OKE) was used to investigate polaron formations in $CH_3NH_3PbBr_3$ and $CsPbBr_3$ perovskites (Miyata et al. 2017).

In a TR-OKE experiment, a laser pulse is sent to the material, and the polarization rotation is detected. With laser pulses of energy larger than the energy gap value, the experiment probes the TR-OKE response upon charge injection. In these lead halide perovskites, the detected signals are compatible with a description of the altered phonon dynamics in terms of the formation of hole and electron, large polarons in the $PbBr_3$ sublattice. This TR-OKE study reported also interesting insights on the polaron formation dynamics. In fact, the two materials show different rates for the polaron formation. This is attributed to the reorientations of the cations in $CH_3NH_3PbBr_3$, which determine a faster polaron formation than in $CsPbBr_3$.

2   Modeling Small Polarons by First Principles

The electronic structure community has been quite active in the study of polarons in real materials. Simulations can be helpful to understand and interpret the experimental findings or to predict the formation of polaronic states. This section provides a short overview of the first-principles methods generally used to model polarons in materials and discusses different computational procedures to acquire information on the formation and dynamics of polarons and on their mutual interaction.

2.1   Theories and Methods

Density functional theory (DFT) has been largely applied as a starting point to study polarons in materials. However, common schemes used to describe the exchange-correlation functional in DFT simulations, such as the local density and generalized gradient approximations (LDA and GGA, respectively), fail to describe properly the charge localization at atomic sites. By using LDA or GGA, the excess charges are delocalized overall in the lattice, and partial occupations of the available electronic levels are favored against integer occupations. Therefore, the modeling of polarons requires a correction in order to overcome the drawback of standard local and semilocal exchange-correlation approximations.

According to the Janak's theorem (Janak 1978), variations of the total energy E due to the electronic occupation (n_i) of the state i are given in terms of the DFT Hamiltonian eigenstates ε_i, as $dE/dn_i = \varepsilon_i$, independently of the exchange-correlation approximation. The expected behavior of the exact total energy is a piecewise linear function of the electronic occupation, with discontinuities in the first derivative for integer values ($n_i = N$) (Perdew et al. 1982; Perdew and Levy 1983), that is $d^2E/dn_i^2 = 0$ except at integer occupancies. Therefore, the energy of the state i remains constant during electron addition or removal.

At variance with the expected behavior, LDA and GGA generally result in a convex function for the total energy, i.e., $d^2E/dn_i^2 > 0$. This is schematically shown in Fig. 3. The energy change of the state i upon its own occupation reflects a spurious self-interaction effect, introduced by the type of exchange-correlation

Fig. 3 Total energy vs. occupation in DFT and HF. Total energy as a function of the electronic occupation in DFT (convex function) and HF schemes (concave function)
approximation. As a consequence of the convexity of the calculated energy, partial occupations are preferred over integer occupations. This leads to well-known failures of DFT simulations including the underestimation of the energy band gaps, the description of strongly correlated insulators as metals, and the difficulty to account for charge localization.

The tendency of DFT to delocalize charge can be corrected via modifications of the exchange-correlation approximations (To et al. 2005). An efficient remedy is to construct hybrid functionals by mixing LDA or GGA with the Hartree Fock (HF) exchange (Becke 1993), following the general formula

$$E_{XC}^{\mathrm{Hybrid}} = \alpha_1 E_X^{HF} + \alpha_2 E_X^{LDA/GGA} + \alpha_3 E_C^{LDA/GGA}. \tag{8}$$

The mixing ratios α's (and in some screened hybrids the screening length) can be tuned to match physical quantities determined empirically, such as the energy band gap (He and Franchini 2012). Alternatively, the hybrid functional parameters can be determined ab initio by requiring the linearity of the total energy (Kronik et al. 2012; Elmaslmane et al. 2018) or following a self-consistent procedure (He and Franchini 2017) or fitting the parameters to the dielectric function of the material (Chen et al. 2018; Cui et al. 2018). This is possible since HF theory predicts an opposite result as compared to DFT: The energy change upon electronic occupation is described by a concave function of the electronic occupation, $\mathrm{d}^2E/\mathrm{d}n_i^2 < 0$; thus, the charge localization is overestimated by HF. This overestimation is due to neglecting screening effects, which are usually not negligible in solids.

As an alternative to hybrid functionals, which are usually computationally quite demanding, corrections can be applied to the standard formulation of the density functional theory in order to restore the expected behavior for the charge localization (Maxisch et al. 2006; Nolan and Watson 2006). To this class of methods belongs the DFT+U method, where an additional term is added to the expression for the total energy. The DFT+U total energy $E_{\mathrm{DFT}+\mathrm{U}}$ is given by

$$E_{\text{DFT}+\text{U}} = E_{\text{DFT}} + E_{\text{U}}(U, J) \, , \qquad (9)$$

where E_{DFT} is the energy obtained by standard DFT, while E_{U} is an on-site correction arising from a local Hubbard-like Coulomb repulsion (U) and a Hund's parameter (J), including double-counting corrections. Various expressions for E_{U} have been proposed (Anisimov et al. 1991, 1993; Liechtenstein et al. 1995; Dudarev et al. 1998a, b), such that the integer occupation of electronic states is energetically favored. Clearly, the results depend on the choice of U and J, which is not trivial, and, as a matter of fact, these quantities are typically treated as fitting parameters, by adjusting their values such that a specific quantity (e.g., the band gap) is predicted accurately. In order to maintain the ab initio character of DFT, procedures have been defined to calculate the DFT+U parameters from first principles such as the constrained local density approximation (Gunnarsson 1990; Cococcioni and de Gironcoli 2005), where the interaction parameters are obtained by considering the total energy variation with respect to the occupation number of localized orbitals, and the constrained random-phase approximation (cRPA), which allows for an explicit calculation of the matrix element of the screened interactions U and J (Aryasetiawan et al. 2004). Alternatively, in the specific case of excess charge introduced by impurities, the $E_{\text{U}}(U, J)$ term can be substituted by an on-site angular-dependent potential that does not affect the states of the defect-free system. The potential depends on parameters which are tuned to restore the linearity of the total energy (Lany and Zunger 2009; Lany 2011).

2.2   Polaron Formation: Energetics and Structural Distortions

In the framework of DFT, regardless of the specific choice for the correction to the local/semilocal exchange-correlation approximation (DFT+U or hybrids), the stability of polarons is analyzed in terms of a set of different energies. Unfortunately, the notion of the polaronic energies is not well standardized, and it varies according to the authors' preferences. The important ingredients to consider in order to characterize a polaron system are:

1. Type of electronic state: (a) excess charge localized in a lattice site (polaron solution with integer particle occupation on an energy level localized at one lattice site) or (b) delocalized in the entire sample (no polaron, fractional occupation on several lattice sites).
2. Type of structural solution: (a) local distortions at the trapping site (polaron solution) or (b) absence of local distortions (uniform lattice, no polaron). The lattice distortions are obtained fully self-consistently through the minimization of the forces acting on the ions (To avoid any confusion, we specify that also in the non-polaron state, the forces are minimized, but since the excess charge is delocalized in the lattice, the structural changes are uniform and generally very small and become zero for very large supercells.).
Fig. 4 Polaron energies. Sketch of the polaron formation energy (E_{POL}), the structural energy cost (E_{ST}), and the electronic energy gain (E_{EL}) obtained as combinations of the calculated total energies in the localized and delocalized solutions ($E_{\mathrm{dist}}^{\mathrm{loc}}$, $E_{\mathrm{unif}}^{\mathrm{deloc}}$, and $E_{\mathrm{dist}}^{\mathrm{deloc}}$). The delocalized and localized electronic charge densities are also shown for rutile TiO_2, together with the polaronic lattice distortions Δ_i

Considering that the polaron represents an unpaired electron, DFT-based calculations have to be performed taking spin-polarization into account. In order to force the system to relax into a delocalized solution, it is necessary and often sufficient to use a non-spin-polarized setup (this prescription is valid for both DFT+U and hybrid runs). By selectively switching on or off charge localization and/or lattice distortions, it is possible to compute the total energy of the system in different regimes (see Fig. 4):

$E_{\mathrm{dist}}^{\mathrm{loc}}$: Total energy of the polaron state: charge localization plus lattice distortions;

$E_{\mathrm{unif}}^{\mathrm{deloc}}$: Total energy of the system with delocalized charge carriers and uniform lattice;

$E_{\mathrm{dist}}^{\mathrm{deloc}}$: Total energy of the system with delocalized charge constrained into the lattice structure of the polaron state. Since that solution is only metastable, it might be difficult to realize it in practice (for instance, by enforcing a non-spin-polarized ground state).

In order to compare these energies with each other, the computational setup must be kept fix (except for the spin degree of freedom) in all type of calculations, in particular the total number of electrons (including excess electrons), the unit cell size, and the value of U and J (or the value of the mixing parameter in hybrid-DFT).

Figure 4 sketches the variations of the energy of the system in the delocalized and localized solutions as a function of lattice distortions, considering a quadratic (harmonic) energy versus structure curve. Important insights on the formation of polarons can be obtained by combining the values of $E_{\mathrm{dist}}^{\mathrm{loc}}$, $E_{\mathrm{unif}}^{\mathrm{deloc}}$, and $E_{\mathrm{dist}}^{\mathrm{deloc}}$, which

define the set of polaronic energies E_{POL} (polaron formation energy), E_{ST} (strain energy), and E_{EL} (electronic energy gain):

$$E_{\mathrm{POL}} = E_{\mathrm{dist}}^{\mathrm{loc}} - E_{\mathrm{unif}}^{\mathrm{deloc}}, \tag{10}$$

$$E_{\mathrm{ST}} = E_{\mathrm{dist}}^{\mathrm{deloc}} - E_{\mathrm{unif}}^{\mathrm{deloc}}, \tag{11}$$

$$E_{\mathrm{EL}} = E_{\mathrm{dist}}^{\mathrm{loc}} - E_{\mathrm{dist}}^{\mathrm{deloc}}. \tag{12}$$

The stability of a polaron solution can be analyzed in terms of the polaron formation energy. A negative E_{POL} stands for stable polarons, i.e., the polaronic solution is energetically more convenient than a system with delocalized charge carriers. E_{ST} quantifies the structural cost needed to distort the lattice in order to accommodate the excess charge to form a polaron, whereas E_{EL} is the electronic energy gained by localizing the charge in the distorted lattice via the electron-phonon interaction. The values of E_{ST} and E_{EL} depend on the degree of charge localization and the size of the lattice distortion (see the horizontal shift of the parabolas in Fig. 4) and on the curvature of the parabola in Fig. 4. The three polaronic energies are strongly connected. For instance, E_{POL} can be interpreted as the result of the competition between the structural cost E_{ST} and the electronic energy E_{EL} (Setvin et al. 2014a):

$$E_{\mathrm{POL}} = E_{\mathrm{EL}} + E_{\mathrm{ST}} . \tag{13}$$

In addition to the polaronic energies, purely structural properties can also provide important information on the nature and extension of the polaron state. To this aim, one can define the average bond-length distortion D around the polaron site to quantitatively measure the degree of local structural distortions (Reticcioli et al. 2018a):

$$D = \frac{1}{n} \sum_{i=1,n} |\Delta_i| \tag{14}$$

where $\Delta_i = \delta_i^{\mathrm{dist}} - \delta_i^{\mathrm{unif}}$ is the change of the bond length δ for the ion site i between the polaronic (distorted lattice) and uniform solutions and n indicates the total number of ions considered in the sum (for small polarons typically first and second nearest neighbors).

2.3   Site-Controlled Localization

Typically, charge trapping occurs at different sites of a given material. The various polaronic configurations are characterized by different energies. In general, there is no guarantee that a DFT+U or hybrid functional DFT calculation leads to the global minimum of the polaronic system. In fact, the formation of polarons could spontaneously occur at less favorable lattice sites or occur not at all. Therefore, it

is important to control the site localization of polarons, by inspecting the formation of polarons at different sites, and compare the relative formation energies. For this purpose it is essential to establish a protocol capable to selectively control charge trapping at specific sites.

Since charge localization strongly depends on the initial conditions (input) of the calculation, a selective charge trapping can be achieved by forcing initial perturbations in form of structural distortions or strong on-site Coulomb energy (Deskins et al. 2011; Shibuya et al. 2017; Hao et al. 2015). Starting from a biased setup, it is easier for the system to relax into one desired configuration at the end of the electronic *and* structural self-consistent calculation (output). Structural perturbations can be introduced manually by distorting the local structure around a given atomic site, resembling the expected polaron-induced lattice distortions. Alternatively, the initial perturbation can be achieved by chemical substitution, as explained below for the small electron-polaron case:

Step 1: Chemical substitution at the selected site where charge trapping should occur with an atom containing one more electron than the original native atom (e.g., Ti $\rightarrow$ V). Structural relaxation performed at spin-polarized DFT+U level will yield local lattice distortions around the chosen site.

Step 2: The initial element is reinserted at its original position (e.g., V $\rightarrow$ Ti). It is often necessary to use a larger value of U at the selected site, while the other atoms keep the original value of U. The manual initialization of the local magnetic moment has to take into account the presence of the localized electron at the selected site. A new relaxation is performed starting from the optimized structure obtained in Step 1. The self-consistent run should be able to maintain the polaron solution obtained in Step 1.

Step 3: A final step is necessary, performed by using the original value U for all atoms. In this case it is recommended to initialize the orbitals with the one obtained in Step 2. In fact, by using a random initialization, it can happen that the self-consistent loop will end up in a different polaron solution (different polaron site) or in a delocalized solution (Papageorgiou et al. 2010; Deskins et al. 2009; Meredig et al. 2010; Morgan and Watson 2009).

The effective final localization of the electron at the end of each step can be verified by analyzing the local magnetic moment at the selected site. Step 2 (i.e., using a larger U) usually helps to localize the electron at the selected site. However, it is possible, in simple problems, to skip this step and obtain charge localization at the selected site by simply performing Steps 1 and 3. This strategy can be extended to the hybrid-DFT level, by using the orbitals and the optimized structure obtained in Step 3 as an input for the hybrid functional calculations. In case more than one electron needs to be localized at selected sites, the Steps 1 to 3 can be performed for every selected site separately, one after the other or, alternatively, at the same time.

A systematic use of this strategy allows the identification of the polaronic ground state (global minimum) of the system (Reticcioli et al. 2018a).

2.4   Polaron Dynamics

As mentioned in the introduction, polarons are mobile quasiparticles, whose mobility can be activated or increased by temperature. Polaron hopping can be modeled in DFT, by merging first-principles total energies to the Marcus (Marcus and Sutin 1985) and Emin-Holstein-Austin-Mott (EHAM) formalisms (Deskins and Dupuis 2007; Brunschwig et al. 1980; Spreafico and VandeVondele 2014) or, more effectively, by performing first-principles molecular dynamics (FPMD) (Kresse and Hafner 1993; Kowalski et al. 2010; Setvin et al. 2014a) or nudged elastic band (NEB) calculations (Henkelman et al. 2000; Bondarenko et al. 2015; Janotti et al. 2013).

FPMD data can reveal important insights into polaron dynamics, including site population analysis (sites visited by the polarons during their hopping motion), temperature- and/or concentration-dependent polaron-related transitions, and polaron diffusion trajectories. By means of a detailed statistical analysis, one can acquire information on the interaction with specific lattice sites, with lattice or chemical defects, or on the mutual polaron-polaron interactions (Kowalski et al. 2010; Setvin et al. 2014a; Hao et al. 2015; Reticcioli et al. 2018a). An example of polaron dynamics in oxygen-deficient $SrTiO_3$ is given in Fig. 5, showing the temperature-dependent interaction between two polarons and the (immobile) oxygen vacancy (V_O): at T = 700 K one polaron remains anchored to V_O and the second one has a reduced hopping activity; at higher T (T = 1000 K), both polarons become very mobile and start to explore sites far away from V_O, but the strong Coulomb attraction between the negatively charged polaron and the positively charged V_O regularly brings polarons back into the vicinity of V_O, forming polaron-V_O complexes (Hao et al. 2015).

The statistical analysis is usually performed by investigating the occurrences of charge trapping at each lattice site in the simulation cell (site-decomposed population analysis) and by computing different types of correlation functions aiming to describe the interaction of a polaron with other polarons or lattice defects:

(i) Polaron-polaron site correlation function. The polaron-polaron site correlation function $S_{pol-pol}$ can be defined as the distribution of the site distance i along a particular direction in the crystal, between two polarons at a given time-step t, averaged over all the FPMD time steps τ:

$$S_{pol-pol}(i) = \frac{1}{N}\frac{1}{\tau}\sum_{t=0}^{\tau}\sum_{j}\rho_j(t)\rho_{j+i}(t) \,, \qquad (15)$$

where N is the number of atomic sites and $\rho_j(t)$ indicates the polaronic site density at time t, and it is equal to 1 for the j-th site hosting a polaron and 0 otherwise.
Fig. 5 Polaron dynamics. Example of small polaron dynamics in reduced bulk SrTiO₃. Two excess electrons donated by one oxygen vacancy form two polarons whose mobility is temperature dependent: almost immobile at 700 K and polaron-hopping at 1000 K. The position of the polarons is given in terms of their distance to the oxygen vacancy, which remains at rest at any temperature. (Figure taken from Hao et al. 2015)

(ii) Radial correlation function. Analogously, the polaron-polaron $R_{pol-pol}$ and defect-polaron $R_{def-pol}$ radial correlation functions can be defined as a function of the distance r:

$$R_{pol-pol}(r) = \frac{1}{\tau} \sum_{t=0}^{\tau} \sum_{(q,p)} \delta(|\mathbf{r}_q - \mathbf{r}_p|, r, t) ,$$

$$R_{def-pol}(r) = \frac{1}{\tau} \sum_{t=0}^{\tau} \sum_{(def,p)} \delta(|\mathbf{r}_{def} - \mathbf{r}_p|, r, t) ,$$

(16)

where the variables $\delta(|\mathbf{r}_{def} - \mathbf{r}_q|, r, t)$ and $\delta(|\mathbf{r}_q - \mathbf{r}_p|, r, t)$ assume the value 1 if, at time t, the polaron p is at distance r from the defect at position $\mathbf{r}_{def}$ or from the polaron q at position $\mathbf{r}_q$, respectively, and are 0 otherwise.

These statistical quantities ($S_{pol-pol}$ and $R_{pol-pol}$) furnish information on the spatial distribution of polarons in the lattice, by indicating the statistically more favorable polaron configurations.

The FPMD calculation is also useful to investigate the stability of the polarons under different conditions, as an alternative to the site-controlled localization

strategy discussed above. In fact, a FPMD run leads to a set of high-temperature structures, hosting polarons in various configurations, which might be difficult to access by simple structural relaxations. A useful strategy is to use the high-T structures obtained by FPMD as starting structures for relaxations and check their stability by inspecting the corresponding polaron formation energies E_{POL} and ultimately determine the global minimum (polaronic ground state) (Setvin et al. 2014a; Reticcioli et al. 2017). This strategy is obviously similar to simulated annealing.

As mentioned above, in addition to the FPMD approach, polaron dynamics can be investigated by a sequence of static calculations along pre-defined trajectories, using a linear interpolation scheme (LIS) (Deskins and Dupuis 2007; Janotti et al. 2013) or the NEB approach. In the LIS scheme, the energy barrier for the transition of a polaron between different polaronic configurations can be estimated by static DFT calculations on intermediate distorted structures (Deskins and Dupuis 2007). Such intermediate structures $q(x)$ are obtained by a linear interpolation of the ionic positions assumed at the initial (A) and final (B) polaronic states, i.e., $q(x) = (1 - x)q_A + xq_B$, which define the polaron pathway from A to B (Deskins and Dupuis 2007), see Fig. 6. At each considered configuration, an electronic self-consistent calculation is performed in order to compute the total energy at each step and to construct an energy diagram of the polaron transition as a function of the reaction coordinate x, as those shown in Fig. 6 (Sun et al. 2017). The form of the energy profile determines whether the polaron transfer is an adiabatic or diabatic (i.e., nonadiabatic) process (Fig. 6a) (Deskins and Dupuis 2007). If the coupling between the initial and final state V_{AB} is strong (large V_{AB}, see Fig. 6a), the activation barrier for polaron transfer decreases, and the energy curve exhibits a smooth transition: this corresponds to an adiabatic mechanism which occurs via thermal hopping. The alternative case is when the interaction between the initial and final states is low and the transfer follows a nonadiabatic process. In this case, the energy curve exhibits a cusp at the intermediate state, and the electron transfer occurs via quantum tunneling.

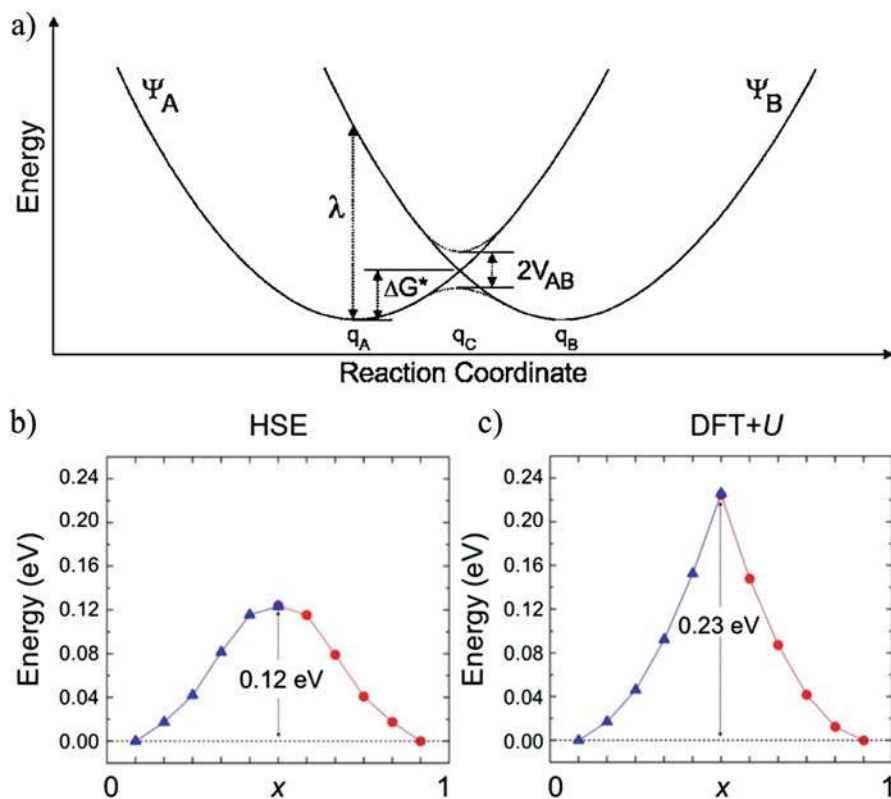
It is important to note that, unfortunately, different functionals can lead to a different description of the polaron transfer process. For instance, DFT+U and hybrid functional approaches can lead to qualitative different results, as shown in Fig. 6 (Sun et al. 2017). In DFT+U, the partial localization is unfavored, the charge carrier is strongly localized in one site only, the interaction between the initial and final configuration is weak, and the hopping occurs typically diabatically. In this case the energy as a function of the lattice distortions resembles the intersection of two parabola, as shown in Fig. 6c. The cusp is most likely an artifact of the one-center terms in the DFT+U approach, which does not allow for localization of the electron between two lattice sites. Conversely, hybrid functionals predict usually an adiabatic hopping, with a more realistic gradual transfer of the electronic charge from one trapping site to the other one, as shown in Fig. 6b. As a consequence, activation barriers for polaronic hopping are usually smaller in hybrid-DFT compared to DFT+U.


Fig. 6 Polaron transfer. (**a**) General scheme of the Marcus-Emin-Holstein-Austin-Mott theory showing the adiabatic and the nonadiabatic mechanism. (Taken from Deskins and Dupuis 2007). First-principles results of polaron transfer in CeO_2 based on (**b**) hybrid-DFT (HSE parametrization) and (**c**) DFT+U. Depending on the computational scheme, the polaron transfer is described as an adiabatic (HSE) or nonadiabatic (DFT+U) process, resulting in different activation barriers. (This Figure is adapted from Sun et al. 2017)

3   Small Polarons in TiO_2

Charge trapping and the formation of polarons is a pervasive phenomenon in transition metal oxide compounds, in particular, at the surface. As already outlined, polaron formation influences the fundamental physical and chemical properties of materials, manifested by a local alteration of the bond lengths, a change of the formal valence at the specific polaronic site, and the emergence of a characteristic peak localized in the gap region (Nagels et al. 1963; Verdi et al. 2017; Sezen et al. 2015; Freytag et al. 2016). These changes affect virtually all functionalities of the material in practical applications. This section is devoted to the presentation of selected results on polaron effects in TiO_2, one of the most studied transition metal oxides and a prototypical polaronic material. The results are obtained using the array

of first-principles schemes described in the previous section. Considering that small polarons show similar properties among transition metal oxides, the methodologies adopted for TiO_2 should be representative for this class of compounds.

TiO_2 has been studied by several experimental techniques, making the basic properties of this material well characterized (Diebold et al. 2010). TiO_2 is used in many applications, primarily as white pigment in paints and cosmetic products and as a physical blocker for ultraviolet UVA in almost every sunscreen, it is added to cement and tiles (to give the material sterilizing, deodorizing, and antifouling properties), it is utilized in self-cleaning glasses as optical and corrosion-protector (this type of glass is coated in a thin layer of transparent anatase), it is a component of Grätzel cells (in nanostructured form), and it can be used as varistor in electric devices.

The first-principles modeling of polarons is performed by introducing excess charge carriers in a variety of ways:

1. Introducing defects, such as oxygen vacancies, interstitial Ti atoms, or Nb impurities.
2. By suitably changing (by hand) the number of electrons of the system. In this way, one mimics excess charges injected by UV irradiation in perfect (i.e., defect-free) samples (Sezen et al. 2015) or cases where the donor and excess charge are spatially separated.
3. In surface environments, by means of adsorbates (e.g. hydrogen).

As already mentioned, the stability of the polaron state depends on many factors, in particular, the location of the trapping site (a particularly delicate issue at surfaces where the broken symmetry results in various inequivalent Ti sites), the interaction with defects, and the concentration of charge carriers (polaron-polaron interaction). The system is generally characterized by an energy profile with several local polaronic minima (even the delocalized solution might trap in a local minimum), and there is no guarantee that single-shot runs will lead to the identification of the most favorable configuration; this issue is discussed in Sect. 2.3.

3.1 Rutile and Anatase

TiO_2 exists in various crystal structures (polymorphs). Rutile and anatase, the most common and stable TiO_2 polymorphs, bear the formation of polarons (Yin et al. 2018), with some important distinctions. The two polymorphs show different properties upon injection of an excess charge into the system, e.g., anatase becomes metallic, while rutile remains semiconducting upon Nb doping (Zhang et al. 2007) (as mentioned in Sect. 1), consistent with the formation of large and small polarons, respectively. Large polarons have been reported in anatase also by ARPES (Moser et al. 2013) and STM (Setvin et al. 2014a) measurements and interpreted by first-principles calculations (Setvin et al. 2014a; Verdi et al. 2017). Conversely, small polarons have been found to localize easily in pristine or defective rutile, while their

formation in anatase is more seldom. Small polarons in anatase have been observed only in samples containing chemical or structural defects (e.g., oxygen vacancies and step edges) (Setvin et al. 2014a, b).

The theoretical analysis based on first-principles calculations has shed some light on this distinct behavior of rutile and anatase (Setvin et al. 2014a; Spreafico and VandeVondele 2014). In particular it was found that the trapping energy in rutile is significantly larger than in anatase, where a larger U (probably unrealistically large) is required to form a small polaron (see Fig. 7b). By considering a realistic U of ≈ 4 eV, obtained fully ab initio by cRPA, small polarons are formed in rutile but not in anatase (Setvin et al. 2014a). This behavior is explained by inspecting the density of states, shown Fig. 7a. The formation of a polaron involves the perturbation of the conduction band minimum (CBM), which has a different character in the two TiO_2 polymorphs: the CB minimum in anatase lies at a lower energy than in rutile, and it exhibits a wider bandwidth, suggesting that a larger U is required to change this favorable configuration (Setvin et al. 2014a).

On the other hand, at reducing conditions, i.e., under conditions where O vacancies (V_O) are present, small polarons can be formed on the surface of both polymorphs, but their degree of mobility is rather different, as demonstrated by the FPMD analysis shown in Fig. 7c. In rutile, polarons (orange lines) are very mobile and hop preferentially among subsurface and surface sites, while in anatase the polaron is immobile, and it stays attached to the V_O, forming a polaron-V_O defect-like complex (Setvin et al. 2014a) (the following sections are devoted to a more detailed discussion of the small polaron properties of rutile TiO_2).

The representative examples discussed in this chapter are mostly focused on the rutile phase, in particular on the $TiO_2(110)$ surface.

3.2   Small Polarons on the Surface of Rutile TiO$_2$

Rutile TiO_2 crystallizes in a tetragonal symmetry with each Ti atom surrounded by six O atoms in a distorted octahedral configuration (Grant 1959). Neighboring octahedra share one corner and are rotated by 90°. The titanium atoms are in a nominal 4+ oxidation state (Ti^{4+}), while the oxygens are in a 2− state (O^{2-}). Rutile can be easily reduced by intrinsic defects, such as interstitial Ti atoms and double-charged oxygen vacancies, and by doping and molecular adsorption. Regardless of the source used to obtain charge carriers in TiO_2, excess electrons show similar behaviors (Janotti et al. 2013; Deák et al. 2015; Moses et al. 2016): they are trapped at a titanium site, which becomes a Ti^{3+} site, a hallmark revealed and confirmed by EPR experiments (Yang et al. 2009, 2013).

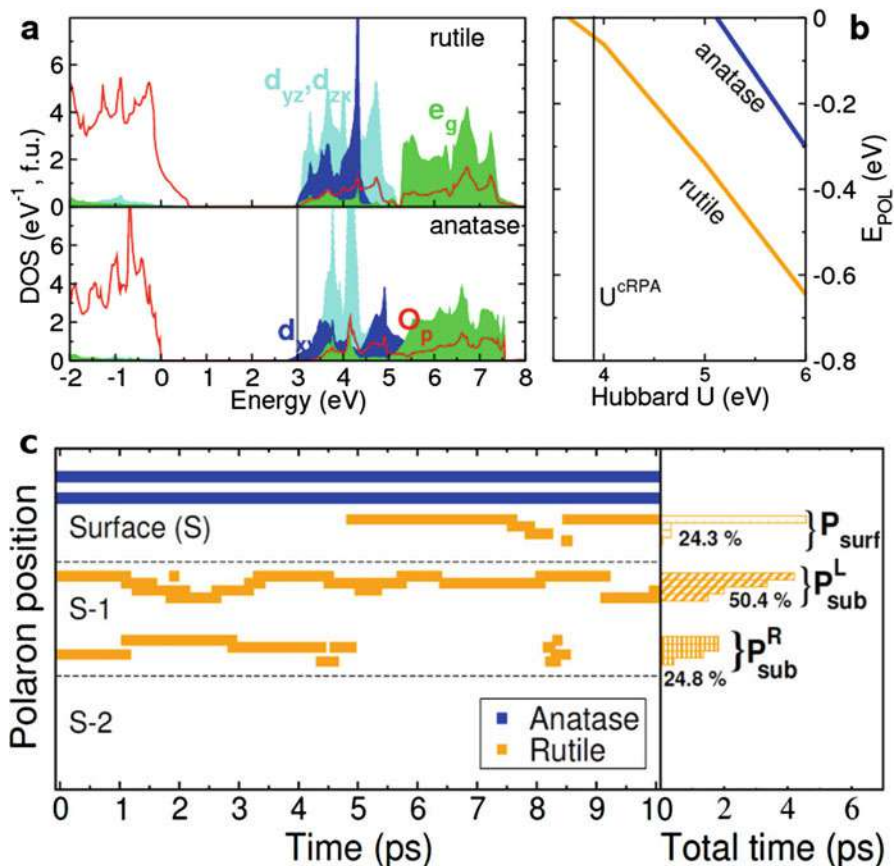
DFT-based simulations are capable to describe the formation of small polarons in rutile, but the stability of the polaronic states, defined in terms of the polaron formation energy, E_{POL}, does depend on the computational approach and on the input parameters (Yin et al. 2018), such as the on-site Coulomb interaction in DFT+U (Calzado et al. 2008; Setvin et al. 2014a) and the amount of mixing in hybrid functional DFT (Spreafico and VandeVondele 2014). The calculated E_{POL}


Fig. 7 Small polaron formation in TiO$_2$. Basic polaron properties of rutile and anatase TiO$_2$: (**a**) Density of states and (**b**) polaron formation energies in the bulk phases and (**c**) FPMD trajectories for oxygen-deficient surfaces. (Adapted from Setvin et al. 2014a)

values are spread in a broad range between 0.1 and 0.8 eV (Yin et al. 2018). Despite these quantitative differences, the predicted properties are qualitatively in good agreement among the various methods and also with the experiments. It has been argued that beyond DFT methods, such as RPA, could result in a more reliable quantitative determination of E_{POL} (Spreafico and VandeVondele 2014), but the high computational cost of the RPA method and the difficulty to implement forces at the RPA level (Ramberger et al. 2017) (in existing RPA calculations the lattice has been always relaxed at DFT+U or hybrid-DFT level) have limited its applicability. In fact, the large size of the cell, needed to accommodate the polaron together with the induced lattice distortions, prohibits simulations with more advanced quantum chemistry methods, and DFT+U and to a lesser extent hybrid-DFT remain the most popular choice.

Fig. 8 The rutile TiO₂(110). Side view of the (1 × 1) phase of rutile TiO₂(110). The atoms marked by *A* are the Ti$_{5c}$ atoms on the *S*0 layer and the atoms below; analogously, the atoms marked by *B* are the Ti$_{56}$ atoms on the *S*0 layer and the atoms below. (This Figure is adapted from Reticcioli et al. 2017)
The rutile surface deserves particular attention in the study of polarons, since charge trapping is more favored in the proximity of the surface than in the bulk. The most stable surface of rutile, the TiO₂(110) surface, consists of a bulk-terminated (1 × 1) surface (see Fig. 8), with large relaxations of the atoms at the surface layers, predominantly along the [110] direction. The surface slab is formed by a sequence of tri-layer building blocks, constituted by a central layer comprising an equal number of Ti^{4+} and O^{2-} atoms sandwiched between two layers of oxygen atoms. The topmost (110) layer (the surface layer) is very corrugated since it terminates with undercoordinated (twofold) oxygen atoms (O$_{2c}$) arranged in rows along [001]. The layer below the O$_{2c}$ rows is constituted by trifold coordinated oxygen [001] rows alternated to sixfold coordinated (Ti$_{6c}$) and fivefold coordinated (Ti$_{5c}$) titanium [001] rows (see Fig. 8). Obviously, the surface breaks the symmetry of the Ti and O atoms and exhibits a higher degree of flexibility and different type of structural distortions compared to the bulk-like layers.

The O$_{2c}$ atoms are relatively easy to remove by thermal annealing, irradiation, electron bombardment, or sputtering, because of their coordinative undersaturation, and this is the main source of excess charge for rutile surfaces. In fact, the propensity to O$_{2c}$ removal reduces the system, and each V_O results in the injection of two excess electrons, which are eligible to form small polarons. The ability to control the amount of defects and the concentration of polarons is extremely important, as this can be used to tune the chemical and physical properties of the surface. For instance, under extreme reducing conditions, TiO₂(110) undergoes a structural reconstruction, from the (1 × 1) to a (1 × 2) phase, doubling the periodicity along [1̄10] (Onishi and Iwasawa 1994, 1996; Onishi et al. 1995; Reticcioli et al. 2017). Different models have been proposed to describe the atomic structure of this reconstruction. The debate is still open, but the Ti₂O₃ model proposed by Onishi appears to be the most probable one (Wang et al. 2014b; Reticcioli et al. 2017).

3.2.1   Polaron Configurations and Properties

Preferable trapping site. The first question to address while modeling the polaron formation is the determination of the optimal polaron sites. According to FPMD

calculations, Ti sites in the subsurface layer ($S1$) are the most favorable trapping centers for excess electrons. Specifically, the site-dependent analysis of E_{POL} shows that the most favorable sites are the Ti atoms (Ti_{S1}^A) at the $S1$ layer below the Ti_{5c} atoms, as indicated by the histogram analysis shown in Fig. 7c. Formation of polarons at the $S1$ (Ti_{S1}^B) sites below the Ti_{6c} atoms is less probable, due to an unfavorable local structural relaxation. Polaron formation at deeper layers is hindered by the stiffness of the lattice, which rises the energy cost to locally distort the lattice. The FPMD analysis in Fig. 7c also shows that polaron formation at the surface layer ($S0$) is not particularly favorable, mostly due to the reduced electron screening at the surface and large local distortions.

Polaron orbital symmetry. A second important aspect is the orbital symmetry of the polaron state. Depending on the hosting site, the excess electron occupies different d orbitals. Which d orbital becomes populated is predominantly determined by the local chemical environment, the crystal field splitting, and the flexibility of the neighboring atoms. Polarons in the Ti_{5c} sites on the surface layer (Ti_{S0}^A) are characterized by a $d_{xz} - d_{yz}$ orbital symmetry as evidenced by the polaron charge density plot displayed in Fig. 9a, b. On the other hand, below the surface, in the subsurface layer ($S1$) and in deeper layers, small polarons assume $d_{z^2} - d_{x^2-y^2}$ and $d_{x^2-y^2}$ orbital symmetries, alternately along [110] and [1$\bar{1}$0] (see Fig. 9c–f). This stacking is the result of the orientation of the local environment (i.e., the orientation of the coordination octahedron around the trapping Ti site). The lattice distortions are larger for the Ti_{5c} polarons (the Ti site hosting the polaron relaxes outward along [110], and the surrounding O atoms and the nearest-neighbor Ti atoms are pushed away by the excess electron), while the relaxations in deeper layers are smaller (the Ti-O distance in the TiO_6 octahedron increases, and the nearest Ti^{4+} sites relax toward the polaronic site).

Statistical analysis: polaron-polaron and polaron-vacancy interaction. Another relevant aspect to understand the physics of polarons is the Coulomb-like polaron-polaron and polaron-defect (in this case V_O) interaction. Being positively charged, a V_O acts as an attractive center for the small polarons and, from the structural point of view, renders the local structure more flexible and reduces the structural cost E_{ST} to distort the lattice. Conversely, the polaron-polaron interaction is repulsive and particularly effective at small distances. The relative distance among polarons and between polarons and V_O considerably affects the energy and the degree of localization of the characteristic in-gap polaronic states. For instance, at short distance the interaction between polarons can be strong enough to split the polaron levels and lead to the onset of double in-gap peaks well separated in energy (Reticcioli et al. 2018a). As mentioned in the methodology section, a useful tool to decipher these intricate interactions is the statistical analysis of the polaron energies in the explored configuration space. The results for polarons in rutile TiO_2 are summarized in Fig. 10.

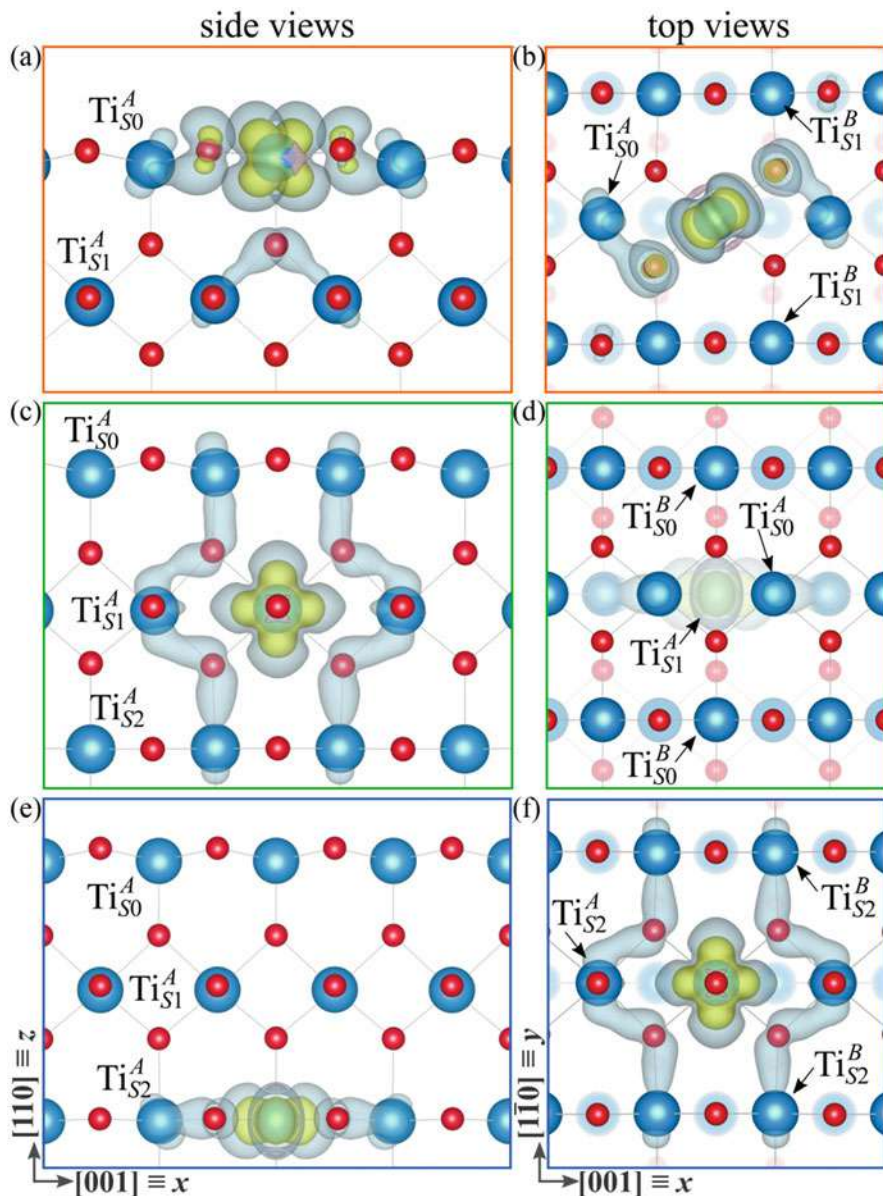
Figure 10a, b clearly show that the polaron energy decreases with increasing polaron-polaron distance and with decreasing polaron-V_O distance. Polaron pairs at nearest-neighbor Ti sites along [001] (i.e., a polaron-polaron distance of about 3 Å) is very unstable, due to the strong polaron-polaron repulsion. This Coulomb


Fig. 9 Small polarons for the rutile TiO$_2$(110) surface. Side (**a, c, e**) and top (**b, d, f**) views of the electronic charge density of polarons on the surface $S0$ (**a, b**), sub-surface $S1$ (**c, d**) and sub-sub-surface $S2$ (**e, f**) layers. The atoms marked by A are the Ti$_{5c}$ atoms on the $S0$ layer and the Ti atoms below; analogously, the atoms marked by B are the Ti$_{6c}$ atoms on the $S0$ layer and the Ti atoms below. (This Figure is adapted from Reticcioli et al. 2018a)
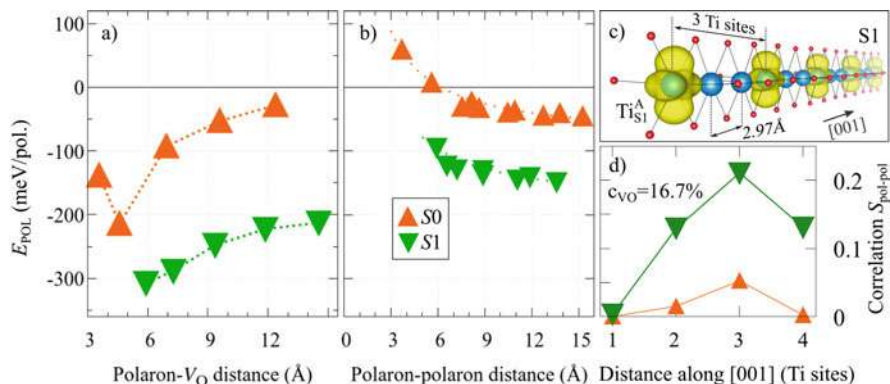

Fig. 10 **Statistics of polarons on rutile TiO$_2$(110):** (**a**) polaron-V_O and (**b**) polaron-polaron interactions, (**c**) sketch of the optimal 1×3 polaron pattern in the sub-surface of rutile TiO$_2$ at the critical V_O concentration (16.7%), and (**d**) the spatial correlation function. (Adapted from Reticcioli et al. 2017)

repulsion is enhanced by the overlap of the polaron charges. In fact, only 70% of the excess charge is confined at the trapping site, while the remaining charge is spread around the surrounding atoms and hinders nearest-neighbor polaronic configurations. For the sake of clarity, it should be noted that the polaron-polaron curve shown in Fig. 10b is obtained for a perfect crystal without any V_O, in order to decouple the polaron-polaron interaction from the polaron-V_O interaction. In defective samples, the optimal polaronic configuration is the result of the balance between these two opposite effects: within a simplified picture, one can conclude that polarons try to maximize their mutual distance and to minimize the polaron-V_O distance.

Clearly the most favorable polaron arrangement and its energetics is concentration dependent. In rutile TiO$_2$, the highest V_O concentration experimentally achievable is $\approx$16.7% (Reticcioli et al. 2017). At low concentrations, polarons occupy $S1$ sites. By progressively increasing the reduction level, the excess electrons form increasingly more polarons at the most convenient sites in $S1$, finally forming a characteristic 1×3 pattern at the optimal concentration of 16.7% (Reticcioli et al. 2017; Shibuya et al. 2017). This is well reproduced by theory, as exemplified by the peak at a three-site distance in the correlation function shown in Fig. 10d. A pictorial view of the 1×3 pattern is shown in Fig. 10c. Larger V_O concentrations are energetically problematic, since additional polarons in $S1$ would result in strong polaron-polaron repulsion. To solve this instability, the system undergoes a structural reconstruction, as discussed in the following.

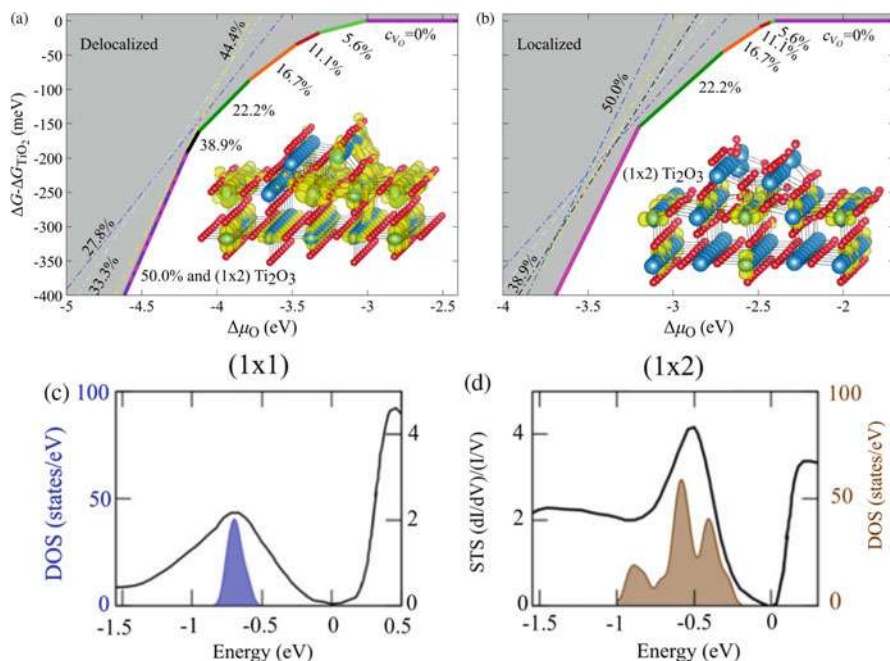
Surface phase diagram (polaron-induced surface reconstruction). The existence of a critical concentration of polarons determines a limit for the oxygen vacancy formation via O$_{2c}$ removal. In fact, rutile TiO$_2$ is able to host up to 16.7% V_O on the surface, which corresponds to a concentration of 33% polarons in the $S1$ Ti


Fig. 11 Rutile TiO$_2$(110) phase diagram. The surface energy of the (1×1) phase with various concentrations of oxygen vacancies (c_{V_O}) and of the (1×2) phase is reported as a function of the oxygen chemical potential μ_O, as obtained by delocalized (**a**) and localized (**b**) calculations. Panels (**c**) and (**d**) display a comparison between the experimental (STS) and simulated (DFT+U) polaronic peak in the (1×1) and reconstructed (1×2) surfaces. (This Figure is adapted from Reticcioli et al. 2017)

[001] rows (each V_O introduces two excess electrons). However, the system can host larger quantities of excess electrons via a structural reconstruction. The (1×1) surface undergoes a (1×2) reconstruction, specifically the Ti$_2$O$_3$ model (Onishi and Iwasawa 1994; Reticcioli et al. 2017), which is able to conveniently handle a larger reduction of the system (50%), as discussed in Reticcioli et al. (2017). This surface reconstruction problem can be described by DFT+U by construction of an appropriate phase stability diagram (see Fig. 11b), by calculating the surface free energy using standard ab initio atomistic thermodynamics (Reuter and Scheffler 2001). The resulting phase diagram is shown in Fig. 11. Close to the critical concentration, the free energy of the reconstructed surface is lower than the corresponding unreconstructed one, thereby marking the structural phase transition. Remarkably, by neglecting polaron effects (panel (a), delocalized setup), DFT+U calculations find the (1×2) phase unstable, in disagreement with observations (Reticcioli et al. 2017).

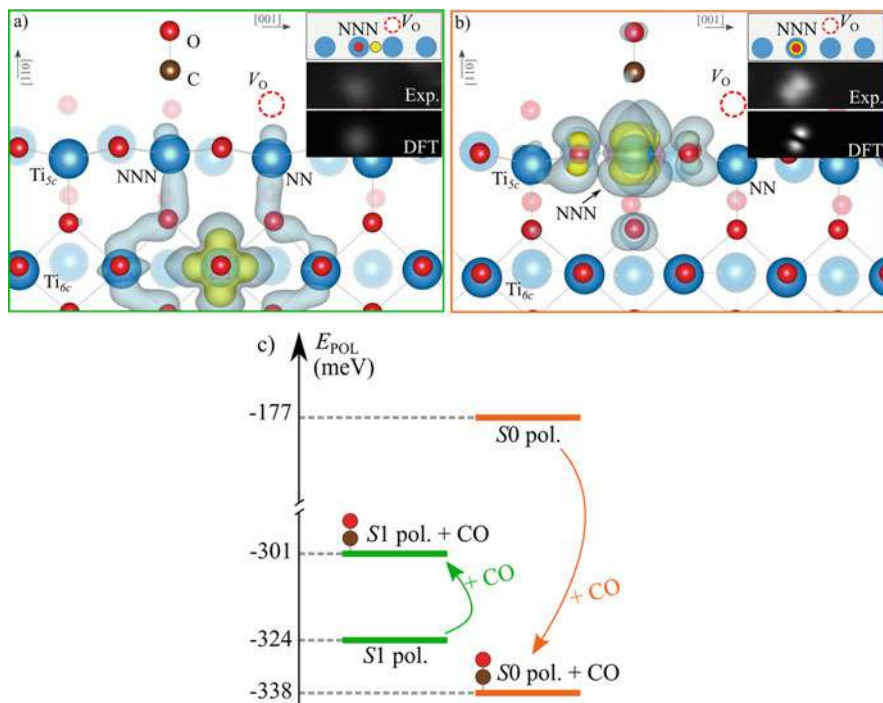
It is important to remark that the structural reconstruction is associated with changes of the in-gap states, as shown in Fig. 11c, d: The localized polaron peak,


Fig. 12 CO adsorption on rutile TiO$_2$(110). The CO adsorption at Ti$_{5c}$ sites in presence of subsurface (**a**) and surface (**b**) polarons. The insets sketch the geometric configuration and report the simulated and experimental STM signatures. The polaron formation energy perturbed by the CO is compared to the unperturbed case (**c**). (This figure is adapted from Reticcioli et al. 2019)

typical of the (1×1) surface (see the corresponding band dispersion in Fig. 2), becomes broader in the reconstructed (1×2) phase as a consequence of the higher amount of excess charge localized on the surface.

Interaction between polarons and adsorbates. A final paradigmatic case of the importance on polarons on surfaces is the interaction of polarons with adsorbates. This interaction is essential to decode the initial stage of catalytic reactions at defective surfaces. It has been shown that even when adsorbates do not transfer any charge carrier to the substrate, polarons can affect the energetics and configuration of the adsorption process. This is the case for CO adsorption on TiO$_2$(110) (Reticcioli et al. 2019), where the polaron stability is altered by the presence of this adsorbate, as shown in Fig. 12.

Adsorbed CO shows attractive coupling with polarons on the surface layer and repulsive interaction with polarons in the subsurface. As a result, upon CO adsorption, the most convenient polaron site is not in $S1$ anymore: polarons are attracted onto the surface layer ($S0$) and bind with the CO (Fig. 12c). The effect of polarons on $S0$ stands out clearly from the STM analysis of the TiO$_2$ sample. A polaron at $S0$, coupled with the CO, is characterized by a bright filled-state STM

signal with two lobes tilted with respect [001] (Fig. 12b), while the $S1$ polaron, right beneath the CO, generates a feeble single spot, due to a lack of polaronic charge transfer toward the adsorbate (Fig. 12a).

4   Summary

Small polarons can easily form in oxide materials, in particular near the surface where the increased structural flexibility, molecular adsorption, and the easy formation of surface defects facilitate the transfer of charge and its coupling with the lattice. Small polarons can be effectively studied using first-principles techniques in the framework of DFT. The main issue to be aware of is that small polarons involve the localization of charge on a particular lattice site. Usually this goes in hand with a change of the transition metal oxidation state, for instance, in TiO_2, from Ti^{4+} to Ti^{3+}. Such a localization is often not well described by standard semilocal LDA and GGA functionals because of self-interaction errors. Therefore it is compulsory to use functionals beyond the semilocal approximation, for instance, GGA+U or hybrid functionals. It goes without saying that such functionals always involve some empiricism, since increasing U or the amount of exact exchange will favor charge localization and, thus, the formation of polarons. Currently no entirely satisfactory approach exists giving an unambiguous answer whether polaron formation is favorable or not. But there are many principles – such as determination of U using some first-principles approaches or inspection that the energy versus electron number shows a straight line behavior – that can guide our choices. Ultimately, comparison with the experiment, however, remains necessary and mandatory.

While modeling small polarons, the most important aspects to address are the trapping process, polaron mobility, and polaron electronic properties. Using the computational prescriptions presented in this chapter, it is possible to explore the configuration space by either guiding the excess charge to localize in selected lattice sites or by performing FPMD calculations. The analysis of the polaron energies (polaron formation energy, structural energy cost, and electronic energy gain) allows to identify the global polaronic minimum and its fundamental energy profile. In order to fully characterize the polaronic state, it is useful to inspect the degree and extent of the local structural distortions, the mutual interaction among polarons, as well as their coupling with defects. This can be done by performing a statistical analysis in terms of the polaron-polaron site correlation function and radial correlation function. A statistical scrutiny of the FPMD data furnishes also important insight on the mobility pattern. An alternative way to study polaron mobility is Markus theory and the Emin-Holstein-Austin-Mott formalism, which model polaron hopping between two sites and permit to discern between adiabatic or nonadiabatic processes. The electronic characteristics of small polarons are defined by the typical band-gap state formed below the conduction band. For an isolated polaron, this state is well localized and typically resides 1 eV below the conduction band. Its specific orbital character (symmetry of the d level where the excess charge is trapped) depends on the local structural and chemical environment. For interacting

polarons, the situation is more complicated as spin-exchange effects; Coulomb repulsion and hybridization can significantly modify the energy location and the width of the polaron state.

Apart from their intrinsic significance, polarons can induce dramatic changes in the hosting materials and can be used as a mean to drive and control different types of transitions, including metal-to-insulator transitions (not discussed here, an example is given in Franchini et al. 2009), structural transitions, or adsorption processes. Two examples were discussed in this chapter: (i) polaron-induced surface reconstruction (by increasing the polaron concentration the rutile $TiO_2(110)$ undergoes a transition from a (1×1) to a (1×2) surface termination) and (ii) substantial changes of the adsorption energy (the interaction between CO and polarons changes the polaron configuration and affects the CO adsorption scheme).

Finally, it is important to underline that the quality of the theoretical modeling can be assessed by a direct comparison with experimental data, including EPR (by recognizing the change in the formal valence state of the trapping site; for instance in TiO_2 polaron formation changes the Ti valence state from Ti^{4+} to Ti^{3+}), spectroscopy (energy level and band dispersion), or STM (by a direct comparison between measured and simulated STM images).

behavior of metal oxides under different thermodynamic conditions. Since defects are responsible for the major part of the properties of metal oxides, it is highly desirable to have powerful predictive models for defect equilibria and kinetics in oxides and their interfaces. In this chapter we show that a fruitful coupling between electronic structure methods, thermodynamics, electrostatics, and transport theory provides a coherent framework for the study of defect equilibria and kinetics of metal oxides, in their bulk as well as near their interfaces. We present demonstrations of this framework on the ZrO_2 model system and discuss the remaining fronts that need further research and method development efforts.

1 Introduction

Our continuous search for a deeper understanding of metal oxides is motivated by their prevailing presence in modern technologies and the fact that we live in a planet furnished by metal oxides. Energy conversion and storage devices, modern computer memories, modern electronics and spintronics, and many other technologies rely on metal oxides. The earth crust and mantle, the reservoir of our materials, and the origin of earthquakes consist predominantly of metal oxides. Oxides protect our metallic structures from continuous environmental degradation. Even water, the liquid of life, is an oxide.

Upon attaining equilibrium, metal oxides crystallize in ordered crystalline structures that are dictated by the chemical composition of the oxide and the surrounding thermodynamic boundary conditions. Most metal oxides around us and in technological applications are crystalline oxides. But it is also possible to trap metal oxides in nonequilibrium disordered states, amorphous, but these fall beyond the scope of this chapter. Crystalline oxides, however, are not truly perfect. They do contain imperfections which are termed "defects." Defects can be three-dimensional such as cracks and voids, two-dimensional such as grain boundaries and hetero-interfaces, one-dimensional such as dislocations, or zero-dimensional such as point and electronic defects. The presence of zero-dimensional defects minimizes the overall free energy of the crystal mainly because of their configurational entropy. This chapter explains the equilibria and kinetics of zero-dimensional defects in the bulk of metal oxides and also in the presence of an interface between two metal oxides. Whenever we refer to "defects" in the rest of this chapter, it implicitly implies zero-dimensional defects.

One might wonder about the necessity of studying defects in oxides given that we anticipate them to occupy a tiny fraction of the host lattice sites. This anticipation is justified since we are studying crystalline oxides, and if the concentration of defects becomes excessive, then we would rather classify this oxide as amorphous or disordered. The truth is even the smallest fraction of defects can significantly alter the electric, optical, magnetic, mechanical, and thermal properties of the oxide (Kalinin et al. 2012; Kalinin and Spaldin 2013; Baiutti et al. 2015; Cao et al. 2015). In fact there are many useful properties of oxides that are solely

attributed to the presence of defects. A canonical example is ZrO_2. This oxide is a poor electric conductor intrinsically. However, doping and introducing oxygen vacancies in the host crystal can significantly increase its electrical conductivity to the extent of becoming a useful component in solid oxide fuel cells (Minh 1993; Fergus 2006; Wachsman and Lee 2011). A more dramatic effect is phase transitions induced by defects. The whole crystal structure of a metal oxide can change upon the introduction of defects in the lattice. An example for these is the phase transition among the two phases $SrCoO_{2.5}$ and $SrCoO_3$ which is induced by controlling the oxygen defects (Lu and Yildiz 2016). These two phases have completely different electronic, magnetic, and mechanical properties. Thus, defects provide a large engineering landscape to tune the properties of metal oxides to fit into applications, and as such it is of great importance to quantitatively understand the equilibria and kinetics of defects in oxides. "Defect equilibria" is the study of the defect concentrations and their variations under the action of thermodynamic forces in the bulk of the crystal and at higher dimensional defects, whereas "defect kinetics" in this chapter implies the analysis of the mobility of these defects. The thermodynamic forces include temperature, chemical potential, stress, and electromagnetic fields. First, we discuss the equilibria in the bulk of an oxide far away from any interfaces; next, we extend the analysis to hetero-interfaces between two different oxides since this setup appears frequently in applications related to property control at nanoscale; then we discuss defect kinetics; and finally we present a summary and outlook.

2 Defect Equilibria in the Bulk of Oxides

2.1 Theory

We limit our presentation for the bulk equilibria to non-interacting defects in binary insulating metal oxides. The notion of non-interacting defects implies that each defect type is sufficiently isolated from other defects in the lattice such that its abundance can be described by a formation free-energy function that has no dependence on neighboring defects. Interacting defects in oxides is a nontrivial problem which is an active research field (Žguns et al. 2017). The restriction to binary oxides is to avoid unnecessary complexity of representing the defect equilibria at this introductory level and also to avoid a persistent ambiguity in comparing theoretical calculations to experiments (Smyth 2000). If the oxide is not binary, then number of independent chemical potentials of the elements of the oxide is greater than one. Experimentally it is common to control only the chemical potential of oxygen, and the chemical potentials of the rest of the elements equilibrate in an uncontrolled manner. Thus, even if we have a detailed theoretical calculation for the equilibria as a function of all independent chemical potentials, it is still unclear how to compare with experiments. Because of this we limit the presentation to binary oxides for which specifying the chemical potential of oxygen is sufficient to determine the chemical potential of the metal. Finally, we chose to

restrict the presentation to insulating oxides by which we mean oxides that have a nonzero electronic band gap, and as such we are excluding metallic oxides. Metallic oxides are dynamically strongly correlated systems from an electronic point of view (Goodenough 1971; Lankhorst et al. 1997), and understanding their defect physics is still an ongoing research. For example, it is unclear if notions such as charged defects, holes, and electrons which are legitimate descriptions of insulating oxides would apply to metallic ones.

To setup a defect equilibria model of a binary oxide whose chemical formula is M_xO_y, we need first to determine all zero-dimensional defects that we have to take into account. There are two main categories of zero-dimensional defects, electronic and ionic (or point). Ionic defect includes oxygen vacancies V_O, metal vacancies V_M, oxygen interstitials O_i, metal interstitials M_i, oxygen antisites (oxygen ions setting on metal lattice sites) O_M, and metal antisites M_O. These are the so-called native or intrinsic defects. It is worth noting that there might be more than one interstitial site in the unit cell of the oxide (Youssef and Yildiz 2012), and in this case, one has to enlist in the model all possible interstitial defects. In addition to these six types of native ionic defects, it is also possible to have defect complexes due to the association of two or more of these defects. For example, an oxygen vacancy and a metal vacancy can associate together to form a Schottky defect. Another example is the concurrent presence of a metal vacancy and a metal interstitial leading to the formation of the so-called Frenkel defect or the concurrent presence of an oxygen vacancy and an oxygen interstitial leading to the formation of an anti-Frenkel defect. In fact, the antisite defect is a defect complex formed by the association of an interstitial of the metal (oxygen) and an oxygen (a metal) vacancy. The number of possible complex defects is large and grows significantly as the oxide admits extrinsic defects (explained below). Typically one relies on prior literature or experiments to have hints about the possible defect complexes that need to be considered in the equilibria model; otherwise a systematic search can be very time-consuming. Each one of the ionic defects can have multiple charge states. The charge meant here is a relative charge with respect to the original lattice site. So if a lattice site was occupied by an oxide ion $(2-)$ and then this ion is not present anymore, then the resulting defect is $2+$ oxygen vacancy where the $2+$ is the charge of null with respect to $(2-)$. Such a vacancy is denoted by $V_O^{\bullet\bullet}$ using Kröger-Vink notation. If an electron localizes on the vacant site of the $2+$ vacancy, its charge state becomes $1+$, $V_O^{\bullet}$, and if a second electron localizes on that site, then the vacancy becomes neutral, $V_O^{\times}$. It is recommended to study the literature of the particular oxide of interest and perform some tests using the available computational techniques to determine the possible charge states for each defect. For example, one is advised to study references (Kohan et al. 2000; Zhang et al. 2001) for ZnO defects and references (Foster et al. 2002a; Gavartin et al. 2006) for HfO_2 defects. In addition to intrinsic defects, the oxide also can admit extrinsic defects of some element X. These defects can be substitutional on the oxygen sublattice X_O, substitutional on the metal sublattice X_M, or interstitial X_i. Electronic defects, on the other hand, include holes and electrons. If an electron (a hole) lives in the extended conduction (valence) band

states and its charge density is spread over many ions, then it is considered free or a large polaron. Computing the concentration of such a defect requires an integration of the extended band states they occupy as discussed below. On the other hand, if the electron (hole) is localized on a single ion and occupies an in-gap state, then it is considered a small polaron. In computing the concentration of a small polaron, it is treated as an ionic defect since it is localized on a single ionic site.

Once we decided which defects to include in the equilibria model, we have to choose a thermodynamic ensemble that is a best representation for the real life or experimental situation we are trying to model and simulate. To clarify this, we examine the first differential of the internal energy dU of an oxide:

$$dU = TS - PdV + \mu_O dN_O + \mu_M dN_M + \mu_e dN_e + \varphi dq + \overrightarrow{\mathbf{E}} \cdot d\overrightarrow{\mathbf{p}} + \overrightarrow{\mathbf{B}} \cdot d\overrightarrow{\mathbf{I}},\tag{1}$$

where T, S, P, and V are the temperature, entropy, pressure, and volume, respectively. The chemical potentials μ_O, μ_M, and μ_e are those of oxygen, cation M, and electrons, respectively; and N_O, N_M, and n_e are the number of particles of oxygen, cation M, and electrons, respectively. φ is the electrostatic potential and q is the charge transferred. $\overrightarrow{\mathbf{E}}$ is an external homogenous electric field, and $\overrightarrow{\mathbf{p}}$ is the macroscopic electric dipole moment. $\overrightarrow{\mathbf{B}}$ is an external homogenous magnetic field and $\overrightarrow{\mathbf{I}}$ is the macroscopic magnetic dipole moment. Other conjugate pairs (force-displacement) can appear in the above equation if there is a need to include them (e.g., a surface-tension-like term). From each conjugate pair, we have to choose the one that is controlled in the experiment or real-life application we are trying to model. So out of the temperature and entropy pair, certainly we would choose the temperature. Out of the pressure and volume pair, we can choose either, and if we decide to choose the volume, we end up with a Helmholtz-like thermodynamic potential, whereas if we choose the pressure, we end up with a Gibbs-like thermodynamic potential. Typically in experiments we control the chemical potential of oxygen by controlling the oxygen partial pressure, and this in fact determines also the chemical potential of the metal μ_M since both of them are constrained by:

$$\mu_{M_x O_y} = x\mu_M + y\mu_O,\tag{2}$$

where $\mu_{M_x O_y}$ is the chemical potential of the oxide. Out of the chemical potential of electrons and number of electrons, we choose the former as a natural variable not because it can be controlled in experiments, but for theoretical convenience (Freysoldt et al. 2014). Once the list of all natural variables has been selected, a partial Legendre transformation of U can be performed to obtain a convenient thermodynamic potential that describes the oxide crystal (Callen 1985). Minimization of this potential decides the equilibrium state of the crystal and determines an expression for the concentration of the ionic defects in terms of what is known

as the free energy of formation of the defect. Equation 3 gives the most common thermodynamic potential used in modeling defects in the absence of electromagnetic fields which is commonly termed Gibbs free energy (G) in the defects community although it might be more appropriate to call it a grand potential:

$$G = U - TS + PV - \mu_O N_O - \mu_e n_e, \tag{3}$$

where T, P, μ_O, and μ_e were chosen as natural variables. For a given defect d whose charge is q, it is possible to define the Gibbs free energy of formation of this defect to be:

$$G_{d,q}^{form} = \left(U^{def} - U^{perf} \right) + P \left(V^{def} - V^{perf} \right) - T \left(S^{*def} - S^{*perf} \right)$$
$$- \mu_O \left(N_O^{def} - N_O^{perf} \right) + q\mu_e. \tag{4}$$

The definition is a straightforward difference in the terms of the thermodynamic potential between the defective crystal and the perfect crystal at fixed natural variables. There are some important observations to note. *First*, the entropy in the above expression includes all non-configurational entropies (mainly vibrational and band electronic). The contribution of configurational entropies to the abundance of the defects appears in the final expression of the defect concentration. *Second*, it looks unclear how this formation expression represents cation defects when it does not contain any information about the cation chemical potential or number of particles. Here, one appeals to the natural variables we choose for our thermodynamic potential and to the experimental setup we are simulating. Since we only control μ_O, then cation defects need to be created by exchanging oxygen between the crystal and the surroundings of the crystal. Thus, a cation vacancy in M_xO_y is formed by transferring y/x oxygen atoms from the surroundings into the crystal. Similarly creating cation interstitial is formed by destroying an $MO_{y/x}$ unit, such that y/x oxygen atoms are transferred into the surroundings and a metal atom remains in the crystal as interstitial. To summarize, when it comes to cation defects, the formation expression given above is still usable by careful consideration of the number of oxygen particles in the defective and perfect crystals. *Third*, if one is interested in analyzing dopants and their solubility in the oxide, then we need to add an extra term to the thermodynamic potential (Eq. (3) above). If the dopant is X and we select its chemical potential μ_X as a natural variable, then we add the term $(-\mu_X N_X)$ to G. Of course in the perfect crystal of the oxide, the number of particles of the dopant N_X is null. Consequently, Eq. 4 for the formation free energy needs to be updated by a term $(-\mu_X N_X^{def})$. Finally, all the terms of $G_{d,q}^{form}$ are usually computed from first-principles electronic structure methods. Density functional theory (DFT) (Kohn 1965) and its advanced derivatives (Perdew 2013) are becoming the electronic structure method of choice to study the defects of oxides. DFT is a reformulation of the quantum mechanical description of matter from a 3N-dimensional wave function to a three-dimensional electron density, where N is the number of electrons. The

literature of computing $G_{d,q}^{form}$ is mature (Freysoldt et al. 2014) and is evolving rapidly to account for new thermodynamic forces that has not been considered previously for metal oxides such as electric fields (Youssef et al. 2017a) and the simultaneous action of temperature and pressure (Youssef et al. 2017b).

Creating an ionic or electronic defect requires paying a free-energy penalty, but that increases the free energy of the defective crystal with the respect to that of the perfect one. Simultaneously the creation of the defect (ionic or electronic) results in an increase in the configurational entropy which lowers the free energy of the defective crystal with respect to the free energy of the perfect crystal. At a given set of thermodynamic conditions (natural variables discussed above), there is a unique minimal free energy of the defective crystal (less than that of the prefect crystal) obtained by a unique set of concentrations of the defects. The minimization has been carried out analytically (Schmalzried 1995; Kasamatsu et al. 2011) in the limit of non-interacting defects, and the resulting expression for the concentration of an ionic defect d with charge q is:

$$[d^q] = n_d \frac{\exp\left(\frac{-G_{d,q}^{form}}{k_B T}\right)}{1 + \sum\limits_{q^*} \sum\limits_{d^*} \exp\left(\frac{-G_{d^*,q^*}^{form}}{k_B T}\right)} \tag{5}$$

Here n_d represents the number of possible and degenerate ways of including the defect d in the lattice space occupied by the chemical formula M_xO_y. k_B is Boltzmann constant as expected, and the summation in the denominator is taken over all defects d^* with charge q^* that can occupy the same lattice site of the defect d. For example, the defect site of a 2+ oxygen vacancy can also be occupied by a neutral oxygen vacancy, a fluorine substitutional of charge 1+, and any other defect that resides on the oxygen sublattice. If $G_{d,q}^{form} \gg k_B T$ for all defects, then the summation in the denominator can be ignored, and we recover the familiar Boltzmann-like expression. The minimization of the free energy of the defective crystal also produces expressions for the concentration of free electrons $[e]$ and free holes $[h]$ which are:

$$[e] = \int\limits_{E_{CBM}}^{\infty} g_c(E) \frac{dE}{1 + \exp\left(\frac{E - \mu_e}{k_B T}\right)}, \quad [h] = \int\limits_{-\infty}^{E_{VBM}} g_v(E) \frac{dE}{1 + \exp\left(\frac{\mu_e - E}{k_B T}\right)}, \tag{6}$$

where E is the electron energy; E_{CBM} and E_{VBM} are the edges of the conduction and valence bands, respectively; and $g_c(E)$ and $gv(E)$ are the electronic density of states in the conduction and valence bands, respectively. The density of states can be computed using electronic structure methods under the assumption that they do not change with temperature or defect concentration.

Once we specify the control variables T, P, μ_O, and μ_X, then all defect concentrations (ionic and electronic) turn into a single-variable function of the

chemical potential of electrons μ_e. The latter cannot be specified; instead it is determined by the condition of charge neutrality inside the bulk of the oxide, which can be formulated as:

$$\sum_{d,q} q \left[d^q \right] + [h] - [e] = 0. \tag{7}$$

Solving the charge neutrality equation which can be done by a root-finding numerical method such as the bisection method, we can obtain a unique value μ_e that achieves charge neutrality. The latter can be used to determine the concentrations of all defects at the specified thermodynamic conditions. It is important to check that the formation free energies of all defects at the resulting μ_e are greater than zero. A negative formation free energy for a defect indicates crystal instability (Todorova and Neugebauer 2014) and an inaccessible thermodynamic regime for the oxide phase under consideration (e.g., under these thermodynamic conditions that oxide decomposes into a metal and oxygen gas).

After computing the defect concentrations as a function of the natural variables (T, P, μ_O), it remains to choose a graphical representation for these concentrations. For that purpose, it is common to fix T and P and plot the concentrations as a function of the chemical potential of oxygen (or oxygen partial pressure). The resulting plot is usually termed Kröger-Vink diagram. Notice that number of particles (defect concentrations) and chemical potential are conjugate thermodynamic variables, and as such the Kröger-Vink diagram comes in the spirit of T-S and P-V diagrams that are very common in thermodynamics. The slopes of the curves on T-S and P-V diagrams are related to very fundamental thermodynamic properties, such as the specific heat and the compressibility, respectively. Similarly, the slopes of the defect concentrations on Kröger-Vink diagrams (although they do not have names) are of great importance since they can be measured experimentally via electric conductivity measurements. By measuring these slopes, it is possible to guess the underlying dominant charged defects utilizing the charge neutrality condition and the law of mass action. This experimental approach is analogous and synergistic to the modeling and simulation approach which we explained in this section.

2.2 Defect Equilibria in Intrinsic and Doped ZrO$_2$

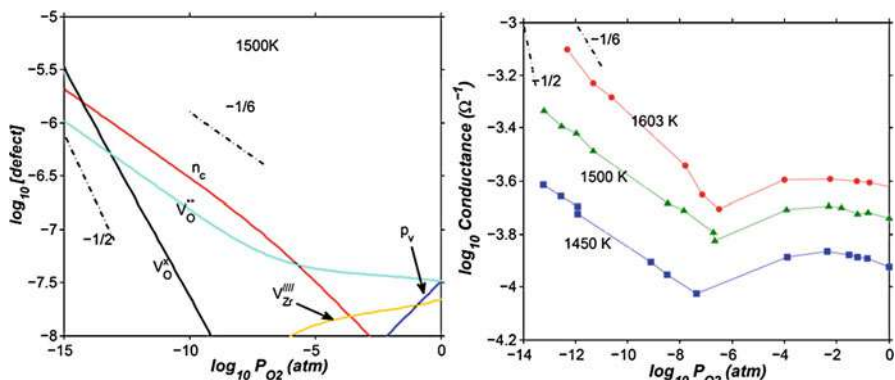
An example for computed defect equilibria (Kröger-Vink diagram) is shown in the left panel of Fig. 1 for tetragonal ZrO$_2$ (Youssef and Yildiz 2012). It is clear that oxygen chemical potential variation has a dramatic effect on the dominant defects in the oxide. At very high oxygen partial pressure, 2+ oxygen vacancies $V_O^{\bullet\bullet}$ and 1+ holes p_v are charge compensated with 4- zirconium vacancies V_{Zr}''''. Then at around oxygen partial pressure of 10^{-3} atm, the charge compensation mechanism changes to be among $V_O^{\bullet\bullet}$ and -1 electrons. Another key observation is the characteristic slopes of the concentrations of the dominant charged defects, 0 slope at high partial pressure and $-1/6$ slope at low partial pressure, which are obtained from the


Fig. 1 (left) Calculated Kröger-Vink diagram for tetragonal ZrO_2 at 1500 K. (right) Electric conductivity measurements on tetragonal ZrO_2 by Kofstad and Ruzicka (Kofstad and Ruzicka 1963). (The figure is adapted from Youssef and Yildiz (2012)). In the left panel, n_c and p_v denote conduction band electrons and valence band holes, respectively.

defect equilibria model and also consistent with electric conductivity measurements (Kofstad and Ruzicka 1963) shown on the right panel of the figure. This consistency gives mutual credibility to both theoretical and experimental approaches. Note, however, that at very low oxygen partial pressure, theory predicts the predomination of the neutral oxygen vacancies $V_O^\times$. Being neutral, this defect is not amenable to discovery via electric conductivity experiments. The electronic structure approach that provided the raw formation free energies of the defects presented in Fig. 1 is standard DFT equipped with some corrections (Youssef and Yildiz 2012). It is possible to resort to more accurate electronic structure methods (Perdew 2013) to confirm and possibly correct the predictions of standard DFT especially in situations where experimental validation becomes difficult as in the case of neutral defects.

It is also possible to use defect equilibria models to predict the solubility of an element inside the oxide. This is essentially the sum of the concentrations of all the defects of this element in this oxide at the highest possible chemical potential of the element. A further utility of the defect equilibria models is computing the solubility of an undesirable element X when the oxide is doped intentionally by an element Y. An example for this calculation is shown in Fig. 2 which shows the solubility of hydrogen in monoclinic ZrO_2 as a function of 3D transition metals dissolved in the same oxide (Youssef et al. 2016). Hydrogen is the undesirable dopant here because hydrogen pickup and embrittlement is a main design-limiting factor for zirconium alloys in water-induced corrosion environments (Cox 2005). Three-dimensional transition metals are added intentionally to ZrO_2 to engineer its hydrogen resistance. The plot shows that Co when dissolved in ZrO_2 can increase the solubility of hydrogen by about 5 orders of magnitude compared to undoped ZrO_2.

It is possible to recast the results presented in Fig. 2 into a design paradigm as shown in Fig. 3 which presents the solubility of hydrogen as a function of

temperature and electron chemical potential μ_e (Youssef et al. 2016). The figure
shows that hydrogen solubility has a "valley" shape due to the presence of a
minimum solubility at any given temperature. The task now is to search for
dopants which either minimize the solubility (triangle markers) or do something
else desirable such as maximizing μ_e (circle markers). Note that at maximum μ_e,
the dominant hydrogen defect is substitutional on Zr site which is a less mobile
form of hydrogen compared to interstitial protons that dominate the minimum μ_e
part of the valley. In reference (Youssef et al. 2016), a search was performed to
found dopants that maximize μ_e which would be beneficial for protecting Zr alloys
against the ingress of hydrogen, and a list of not previously explored elements were
identified (Ta, P, Mo, W).

3   Defect Redistribution at Oxide Hetero-Interfaces

3.1   Theory

Modeling point defect equilibria from first-principle calculations have proven itself
a powerful tool for understanding defect chemistry of oxide materials in their bulk
as discussed in the previous section. In this section, we introduce how to extend
this predictive scheme to interface systems. Suppose we have obtained bulk band
structure and defect equilibria of two oxide materials; there are three factors that
drive charged defect redistribution if the two materials form a hetero-interface: first,
the discontinuities of valence band ΔE_v and conduction band ΔE_c immediately at
the interface without considering any defect. Theoretically, this band discontinuity
Fig. 3 Hydrogen solubility in monoclinic ZrO_2 as a function of temperature and electron chemical potential at oxygen- and water-rich conditions. The triangles indicate the minimum solubility "valley" of hydrogen, whereas the circles represent the solubility at the maximum electron chemical potential. To the right of the "valley," the dominant hydrogen defect is substitutional on Zr site with a charge of 3-, and to the left of the "valley," the dominant hydrogen defect is interstitial proton. (The figure is adapted from reference Youssef et al. (2016))

corresponds to the large electrostatic potential gradient at ideally abrupt defect-free interfaces. This discontinuity is localized in the few atomic layers in the immediate vicinity of the interface and is independent of external perturbations such as dilute doping and applied electric bias (Van de Walle and Martin 1987). Second, charged species have different electrochemical potentials in equilibrium bulk materials. When two materials are put into contact, electronic and ionic defects start to diffuse to reequilibrate, driven by this chemical potential difference. This leads to buildup of local electric field and in turn drives drift flux in the opposite direction. When the system equilibrates, drift and diffusion fluxes cancel out, leading to a reduced form of drift-diffusion equation with zero flux (Markowich 1990), which is equivalent to the Poisson-Boltzmann formalism used by the solid state ionics field (Maier 2004). Third, atoms near an interface are in a distinct bonding environment compared to atoms in bulk. Defect formation energy will change due to the interfacial lattice relaxation and chemical composition variation. This adds the segregation energy, $E_{D^q}^{seg}$, to defect formation energy of ionic defects in the vicinity of the interface. This region where the segregation energy is non-negligible is termed as the core zone. Noting that now we have an electrostatic distribution profile across the interface, electrochemical potential should be used to describe the energetics and kinetics of charged defects:

$$\tilde{\mu}_{D^q} = \mu_0 + \mu_{cfg} + q\phi. \tag{8}$$

Here μ_0 is the concentration-independent contribution. In the context of our model and because of the complexity of studying interfaces with electronic structure methods, we ignore the formation entropies, $\mu_0 = E_{D^q}^{f,\text{bulk}} + \Delta E_{D^q}^f$. $\Delta E_{D^q}^f$ represents the energetic preference of defects segregating to or depleting from the interfacial core region due to the bonding environment variation. μ_{cfg} represents the configurational entropy generated by defects. ϕ is the electrostatic potential in the space-charge layer. The drift-diffusion flux is defined by:

$$J_{D^q} = -M_{D^q} \nabla \tilde{\mu}_{D^q} \tag{9}$$

where M_{D^q} is the mobility. Assuming that there is no generation or annihilation of defect during the transport process, the transport equation is:

$$\frac{\partial [D^q]}{\partial t} = -\nabla \cdot J_{D^q} \tag{10}$$

Under equilibrium, the fluxes of all species should be zero, which means the electrochemical potential is constant. Equation (10) reduces to:

$$J_{D^q} = 0 \tag{11}$$

The defect electrochemical potential in bulk is given by:

$$\overset{\sim\text{bulk}}{\mu}_{D^q} = E_{D^q}^{f,\text{bulk}} + k_B T \ln\left([D^q]_{\text{bulk}}\right), \tag{12}$$

assuming dilute limit is satisfied. Since equilibrium is reached across the interface, $\tilde{\mu}_{D^q}(z)$ is equal to $\overset{\sim\text{bulk}}{\mu}_{D^q}$ throughout the oxide material, we arrive at the equation for defect concentration:

$$[D^q](z) = [D^q]_{\text{bulk}} \exp\left(-\frac{q\Delta\phi(z) + \Delta E_{D^q}^f}{k_B T}\right) \tag{13}$$

With this expression we can now self-consistently solve Poisson's equation:

$$\frac{d^2\phi_{\text{scl}}(z)}{dz^2} = -\frac{\rho(z)}{\varepsilon\varepsilon_0}, \tag{14}$$

where ε is the relative permittivity of the oxide and ε_0 is the permittivity of vacuum.

Under the constraint of global charge neutrality:

$$\int_0^L \rho(z)dz = 0 \tag{15}$$

where $\rho(z)$ is the total charge concentration including electrons, holes, and all types of charged point defects:

$$\rho(z) = \sum_{D,q} q \left[D^q \right](z) + p_v(z) - n_c(z) \tag{16}$$

Under equilibrium, bulk defect chemistry is retrieved far away from the interface. The corresponding boundary conditions are:

$$\frac{d\phi_{scl}}{dz}\bigg|_{z=0} = 0, \ \ \frac{d\phi_{scl}}{dz}\bigg|_{z=L} = 0 \tag{17}$$

z equals 0 and L represents the starting and end points of the modeled hetero-junction. This framework for describing defect equilibria at hetero-interface is summarized in Fig. 4. The three factors listed above can be obtained from different simulation and experimental methods; here we will focus on first-principles electronic structure approach. Density functional theory (DFT) calculations can provide bulk defect formation energies, segregation energies, and band offsets. These DFT results can be fed into the model described above to generate the defect equilibria profiles across the hetero-interface. Though the discussion here is focused on oxide hetero-interface, similar scheme is also applicable on grain boundaries (Souza 2009), surface segregation (Polfus et al. 2016), and metal/oxide interface (Kasamatsu et al. 2011).

3.2   Defect Equilibria Near ZrO₂(001)/Cr₂O₃ Interface

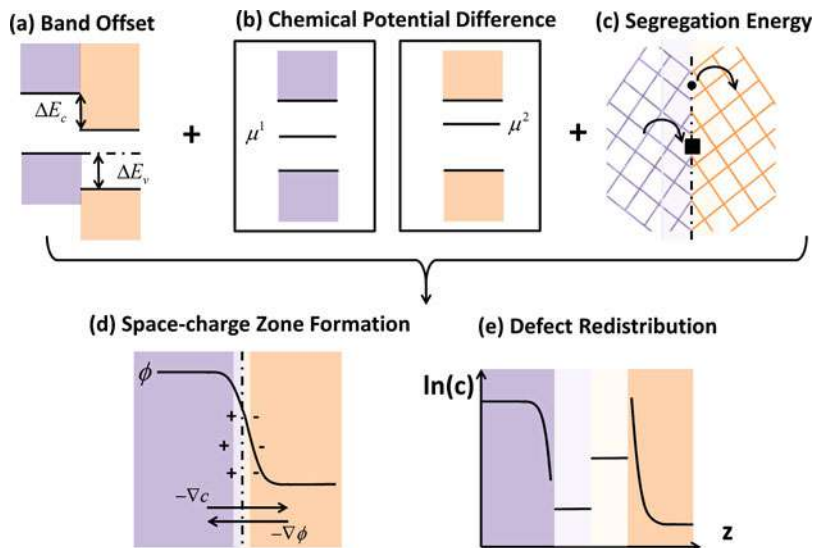
As an example, we demonstrate the capability of the above described framework on the model system monoclinic-ZrO_2(001)/Cr_2O_3(01-$\bar{1}$2) interface (Yang et al. 2017). This interface system is of interest in the context of high-temperature water-induced corrosion of Zr alloys (Pêcheur et al. 1992; Hatano and Sugisaki 1997). Due to the low solubility of alloying elements (such as Cr) in zirconium oxide, alloying elements precipitate and further get oxidized in the passive film. As a result, Cr alloying of Zr forms Cr_2O_3 precipitates within the ZrO_2 matrix. The space-charge effect of such hetero-interfaces can greatly alter oxygen and hydrogen incorporation kinetics and therefore is important to examine quantitatively. First, we take a close look at the electrostatic profiles close to the interface as plotted in Fig. 5. Here we see a positive built-in potential and downward band bending on ZrO_2 side and upward band bending on Cr_2O_3 side. The positively charged defect species are depleted, and negatively charged defects accumulate in both the space-charge and core zones of ZrO_2, and the reverse happens for Cr_2O_3. It is immediately observable that the electrostatic potential profile is not differentiable at the interface, which corresponds to an abrupt change in electric field. This is because the electric displacement field $D = \varepsilon\varepsilon_0 E$ is continuous throughout, as required by Poisson's equation, but ε takes different values on the two sides. D is not smooth both at the interface and at the


Fig. 4 Schematics for a comprehensive framework for predicting point defect equilibria across hetero-interfaces. Three important factors can be assessed at the atomistic level by DFT calculation: (**a**) band offset of the ideal interface, (**b**) bulk defect equilibria on each side of the interface, and (**c**) defect segregation or depletion due to interfacial structural and compositional change. At a hetero-interface, these three factors determine the difference in chemical potential of charged defects and thus drive their redistribution (Maier 2004; Markowich et al. 1990; Franciosi and Van de Walle 1996). When equilibrium is reached, the electrochemical potential should be constant throughout for electronic defects and constant for ionic defects in the oxide side in which they exist. The steady-state drift-diffusion model can be solved in a self-consistent way which produces (**d**) the electrostatic profiles in the space-charge and core zones, and (**e**) the defect redistribution profiles across the interface with explicit consideration for the interfacial core zone. Upon equilibrium, diffusion flux driven by concentration gradient ∇c should cancel out with drift flux driven by electrostatic potential $\nabla \phi$. In (**d**) and (**e**), light-colored regions in the immediate vicinity of the interface represent core regions, which extend for only several atomic layers. (Figure reproduced from Yang et al. (2017))

boundaries of core layer due to the abrupt change in charge concentration caused by segregated species.

To examine the effect of defect redistribution on transport properties of ZrO_2 with embedded Cr_2O_3 particles, in Fig. 6 we show the spatial distribution of free electrons, electrons and holes, and doubly charged oxygen vacancy across such interface with varying oxygen partial pressure. By looking at the concentration distribution of oxygen-related defects and electronic defects, we can analyze how electron transport and oxygen diffusion are changed in the space-charge layer of ZrO_2 compared to its bulk due to the change in the concentration of these defects in the space-charge layer. In Fig. 6a because the bands bend down on the ZrO_2 side, the concentration of electrons is increased in the space-charge layer compared to bulk, and subsequently holes are decreased as well in this layer. In addition, the
Fig. 5 Electrostatic profiles calculated for m-$ZrO_2(001)$/$Cr_2O_3(01\bar{1}2)$ interface. (**a**) Electrostatic potential ϕ, (**b**) The magnitude of the electric field E and electric displacement field D and (**c**) charge concentration ρ close to the interface at 1200 K and $P_{O_2} = 10^{-5}$ atm. Regions with green and blue background color represent core layer on ZrO_2 and Cr_2O_3 side, respectively. (Figure reproduced from Yang et al. (2017))

sum of electron and hole concentrations is plotted in Fig. 6b. If we assume that the mobilities of electrons and holes are on the same order of magnitude, this quantity should give us an estimation of the change in total electronic conductivity in the space-charge layer. Figure 6b shows that when $P_{O_2} < 10^{-12}$ atm, the space-charge layer of ZrO_2 is in its n-type regime. In this case, the total electronic conductivity in the space-charge zone is increased. On the other hand, when ZrO_2 becomes p-type at higher P_{O_2}, the total electronic conductivity is decreased in the space-charge layer in comparison to bulk due to the downward band bending.

A major advantage of this first-principles-based method is that it decouples 0 K effect from finite temperature effect, allowing for a quantitative comparison of the two effects on the electrostatic properties. In Fig. 7 we plot electrostatic potential V, electric field E, and charge density ρ from both DFT-calculated profile for defect-free interface and space-charge model considering charged defect redistribution. These two effects coexist in every interface between two semiconductors (or
Fig. 6 Spatially resolved concentrations of (**a**) electrons, (**b**) sum of electrons and holes, and (**c**) $V_O^{\bullet\bullet}$ as a function of oxygen partial pressure at T = 1200 K. Circles and squares in panel (**c**) represent the concentrations in the core layer on the ZrO_2 and Cr_2O_3 sides, respectively. (Figure reproduced from Yang et al. (2017))

insulators) and can both influence the interface properties. However, because of the difference in spatial scales of these two effects, either could be dominating at different spatial positions around the interface. The highly localized nature of the field and the dipole arising from the defect-free interface gives rise to the catalytic activity of exposed or barely hidden interfaces (Lee and Selloni 2014). It can also influence the transport processes right at the interface (parallel or across). On the other hand, the field and dipole generated by defects at finite temperatures influence the transport processes over an extended region around the interface.

4   Defect Kinetics

Upon establishing the defect equilibria for a binary metal oxide at a given thermodynamic condition, it is possible to determine the self-diffusivity of the oxide anion or the metal cation under these conditions. For example, the total self-diffusion coefficient D_{tot} of the oxide anion can be written as:
Fig. 7 Macroscopic average of (**a**) electrostatic potential V, (**c**) electric field E, and (**e**) charge density ρ from the perfect interface calculated by DFT at 0 K, compared with the same quantities (**b**), (**d**), and (**f**) contributed by the redistribution of defects at T = 1200 K and $P_{O_2} = 10^{-5}$ atm. (Figure reproduced from (Yang et al. 2017))

$$D_{tot} = \sum_{d,q} \left[d^q \right] D_d^q \tag{18}$$

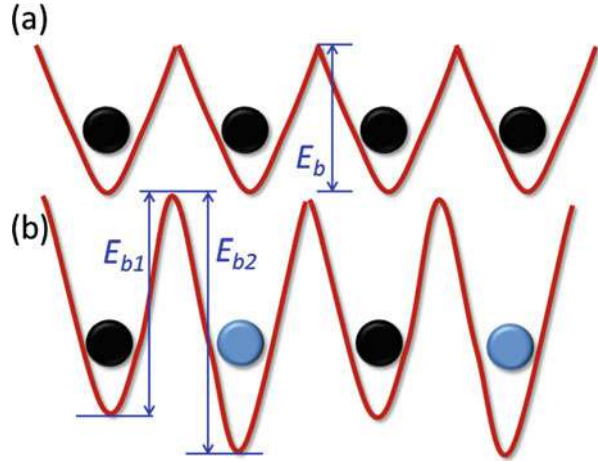
where the summation is taken over all oxide anion defects d and the possible charge states q for these defects and each term is simply the concentration of the defect $[d^q]$ multiplied by its diffusivity D_d^q. A similar expression can be written for the cation self-diffusivity and also for an extrinsic dopant. We described computing the concentrations of the defects, and it remains to clarify evaluating the defect diffusivities. The most direct way to calculate the diffusivities is through molecular dynamics simulation whose input structure contains defect concentrations corresponding to the defect concentrations evaluated by the equilibria model. Although this approach requires no a priori knowledge of the defect diffusion mechanisms, it has a major drawback. The temperature of the simulation needs to be very high (on the order of 1000 K) so that the defect diffusion events are observable during the course of the simulation. The reason for this is that solid state diffusion is a temperature-activated process and as such at low temperatures the diffusion events become very rare. To overcome this challenge, one can rely on rare-event simulation methods to compute the activation barrier E_b of each diffusion mechanism. The most relevant method for the defect diffusion in the dilute limit is the so-called nudged elastic band (NEB) method and its descendants (Henkelman et al. 2000). For this method, all what is needed is the initial state of the defect, the final state, and of course a total energy calculation method such as DFT. Then, the NEB algorithm is capable of finding the minimum energy pathway and the corresponding activation barrier. Clearly this

approach requires a prior knowledge of the defect diffusion mechanism to prepare the initial and final states accordingly. However, for binary oxides the most relevant diffusion pathways are four which we define here for the case of the oxide anion diffusion, although the same rationale applies to cation diffusion as well. *First*, we have the vacancy mechanism in which an oxide ion hops from a lattice site to fill in a neighboring oxygen vacancy. Equivalently, we can say that the vacancy hops from one lattice site to a neighboring one. *Second* is the antisite mechanism in which an oxygen ion sitting on the cation sublattice hops to a neighboring cation vacancy. *Third* is the direct interstitial mechanism in which an interstitial oxide ion hops from an interstitial site to a neighboring interstitial site. *Fourth* is the interstitialcy mechanism in which an interstitial ion knocks on a neighboring lattice oxygen ion and eventually the original lattice oxygen ion becomes interstitial and the original interstitial becomes a lattice oxygen ion. The net effect is a net displacement for an interstitial oxide ion. The above discussion focused on the diffusion of point defects. Localized electronic defects (small polarons) hop in a similar fashion to point defects, although their hopping involves some complications related to the adiabaticity of the hopping process (Emin and Holstein 1969; Holstein 2000; Austin and Mott 2001; Wang and Bevan 2016). The very same complication arises as well in the theory of electron transfer in chemical reactions (Marcus and Sutin 1985; Marcus 1993). On the other hand, the transport of delocalized electronic defects (large polarons) requires a different approach such as solving Boltzmann transport equation (Madsen and Singh 2006). In this chapter, we focus on ionic defect diffusion.

The complexity of the crystal structure of the metal oxide dictates the next step after sampling the activation barriers of the relevant diffusion mechanisms. Recall that the main goal at this step is calculating D_d^q so that we can obtain the overall self-diffusivity as in Eq. (18). We discuss two approaches to calculate D_d^q. For simple structures which do not contain nonequivalent sites for the ions (e.g., cubic fluorite oxides such as ZrO_2, CeO_2, ThO_2, and UO_2), there is a unique activation barrier E_b along each crystallographic direction as shown schematically in Fig. 8a. In this case, it is straightforward to compute the defect diffusivity from random walk diffusion theory (Tilley 2008).

The premise of random walk diffusion theory is that a defect migrates (jumps) between neighboring equivalent sites corresponding to local energy minima. The migration takes place between the two equivalent sites and across an energy activation barrier E_b which is readily computed using the NEB method. Each migration step is thermally activated and is independent of the previous ones, that is, there is no memory. Under these assumptions, the diffusivity of a defect d whose charge is q a long a crystallographic direction k is given by:

$$D_{d,k}^q = \frac{1}{2}\zeta_k \lambda_k^2 v_{d,k} \exp\left(\frac{-E_b}{k_B T}\right), \qquad (19)$$

Fig. 8 Two possible energy landscapes for the diffusion of a defect along a crystallographic direction in a metal oxide crystal. (**a**) All energy minima are equivalent, and there is a unique activation barrier E_b characterizing diffusion along this direction. (**b**) There are two (or more) nonequivalent energy minima along this path and hence two different activation barriers E_{b1} and E_{b2}


where ζ_k is the multiplicity of the crystallographic direction k. For example, in the cubic fluorite structure, the multiplicity of the [001] direction is 3 because [001], [010], and [100] are crystallographically equivalent. λ_k is the jump length along the k direction. $v_{d,k}$ is the attempt frequency for the defect d to migrate along the crystallographic direction k. For solids this frequency is between 1 and 10 THz. Once $D_{d,k}^q$ is computed for the most relevant crystallographic directions (the ones that lead to short diffusive jumps on the order of the lattice parameter), it is possible to calculate the "isotropic" diffusivity D_d^q of each defect by some averaging procedure. The diffusion of oxygen in tetragonal ZrO_2 (Youssef and Yildiz 2014), and oxygen in ZnO (Erhart and Albe 2006) were analyzed using this approach.

On the other hand, if the crystal structure is complicated due to the presence of many nonequivalent sites for the same ions as in Fig. 8b, then simple random diffusion theory with its analytical form (Eq. 19) cannot account for this complexity. A viable alternative is on-lattice kinetic Monte Carlo (kMC) simulation (Voter 2007). A kMC simulation models in a stochastic way the time evolution of a system under the assumption that all relevant processes and their relative probabilities are known a priori. In the context of modeling the diffusion process, kMC generates a series of atomistic diffusion events according to the probability distribution of these as dictated by the activation barrier of these diffusion jumps. In each kMC step, a diffusion event for the defect is chosen using a random number from a list of pre-calculated diffusion jumps (using NEB). Then, the clock is advanced according the activation barrier of the selected event. A high-activation barrier event corresponds to a long time span and vice versa. After a converged number of kMC steps, the defect diffusivity can be calculated from the mean square displacement $\langle \vec{r}(t)^2 \rangle$ of the defect using Einstein's expression:

$$\langle \vec{r}(t)^2 \rangle = 6D_d^q t \tag{20}$$

Fig. 9 Total oxygen
self-diffusivity in monoclinic

partial pressure. On an
isotherm, the diffusivity is
dominated by 2− interstitial
for oxygen-rich conditions
and 2+ vacancies for oxygen
poor conditions. (The figure
is adapted from Yang et al.
(2018))
where t is the time. The kMC simulation has to be repeated at each temperature of interest and of course for each defect type. An excellent introduction for the kMC method can be found in reference (Voter 2007). Whether the defect diffusivity was computed using random walk or kMC, the final self-diffusivity of the ion is obtained by summing over all the defects of this ion using Eq. (18). An example of computing oxygen self-diffusivity is shown in Fig. 9 for the case of monoclinic ZrO_2 (Yang et al. 2018) as a function of temperature and oxygen partial pressure. Monoclinic phase is of interest because it is the stable phase for ZrO_2 below 1440 K (Abriata et al. 1986), and so it forms during oxidation of Zr and because of other functional oxides bearing the same structure (Foster et al. 2002b). Generating this plot required computing the overall defect equilibria (Youssef et al. 2016), sampling the activation barriers for all oxygen defects, and performing kMC simulations for those defects that have multi nonequivalent lattice sites. This effort leads to a complete picture for oxygen defect kinetics in monoclinic ZrO_2; in particular we see that each diffusivity isotherm has a minimum. Toward oxygen-rich conditions, the diffusivity increases thanks to interstitial defects, and toward oxygen poor conditions, the diffusivity increases too, but this time due to oxygen vacancies. Such comprehensive picture facilitates defect engineering and design where we can adjust the thermodynamic conditions to obtain a desired diffusivity.

5   Summary and Outlook

The basic question we tried to answer in this chapter is the following: Given certain thermodynamic conditions, and given a certain arrangement for a metal oxide such as uniform bulk or with extended defects such as a hetero-interface, what is the equilibrium concentration and diffusivities of the zero-dimensional defects? The answer to this question requires a coupling between thermodynamics, electrostatics, transport theory, and electronic structure methods. Such coupling provides a fruitful field to study defect equilibria in metal oxides. We gave examples based on ZrO_2 and its interface with Cr_2O_3. However, the approaches and ideas have broad applicability. From a practical point of view, having a model and simulator for defect equilibria with accurate prediction capability opens the door for material design and defect engineering. We can dub this field as defect genomics. For a given application or technology, we can select optimal dopants, optimal interfaces, or optimal thermodynamic conditions that can maximize or minimize certain defects.

In spite of being perceived as a mature field, the physical chemistry of defects still needs major research efforts. A cross-validation between theory and experiments for the defect equilibria models for some of the most technologically important oxides (e.g., iron oxides) is still missing. Metallic oxides which are typically dynamically strongly correlated systems pose severe challenges to electronic structure theory and hence to predicting their defect equilibria. These oxides are becoming increasingly important for various applications, and engineering their defects on physical grounds calls for advances in understanding their electronic structure. This, in turn, requires more advanced methods beyond standard density functional theory. Ternary, quaternary, and higher multielement oxides are rising in many applications, but the number of possible defects that can arise in them is intractable. Automated defect study algorithms might be needed to systematically analyze the possible defects of these systems and to pinpoint the most important ones. Again cross-validation with experiments is crucial here as well. Moreover, studying defect redistribution at interfaces, surfaces, and dislocations of metallic oxides and multielement oxides requires more elaborate effort on top of what we presented for binary insulting oxides. Finally, although we focused here on studying the effect of temperature and chemical potential on the equilibria of defects, studying the effect of other thermodynamic forces such as electromagnetic fields and non-hydrostatic stresses (Youssef et al. 2017a, b; Chi et al. 2018) is equally important and deserves more attention from the defect physical chemistry community.

Oxide Heterostructures from a Realistic Many-Body Perspective

46

Frank Lechermann

Contents

Abstract

Oxide heterostructures are a new class of materials by design that open the possibility for engineering challenging electronic properties, in particular, correlation effects beyond an effective single-particle description. This short review tries to highlight some of the demanding aspects and questions, motivated by the goal to describe the encountered physics from first principles. The state-of-the-art methodology to approach realistic many-body effects in strongly correlated oxides, the combination of density functional theory with dynamical mean-field theory, will be briefly introduced. Discussed examples deal with

e-mail: Frank.Lechermann@physnet.uni-hamburg.de

prominent Mott-band and band-band type of oxide heterostructures, where different electronic characteristics may be stabilized within a single architectured oxide material.

1   Introduction

Since the early days of quantum solid-state research, transition-metal oxides are known to pose very challenging problems in condensed matter physics and materials chemistry (Mott and Peierls 1937). The delicate balance between localization and itinerancy of electrons stemming from partially filled d-shells in these systems is at the origin of many intriguing phenomena. Spanned by the basic electronic phases, namely, band insulator, Mott insulator, and conventional metal, the rich transition-metal-oxide phase space encloses, e.g., delicate forms of transport and magnetism (Imada et al. 1998). The identification of high-temperature superconductivity (coined high-T_c) in CuO_2-based systems (Bednorz and Müller 1986), eventually well above the liquid-nitrogen temperature, still marks the hallmark finding in this group of compounds.

A new chapter in the research of such materials systems opened in the early 2000s, when systematic studies of oxide heterostructures appeared (e.g., Ohtomo et al. 2002). Ever since, that topical field belongs to a key focus in condensed matter and materials science (see, e.g., Zubko et al. (2011), Hwang et al. (2012), and Chakhalian et al. (2014) for reviews). Important advancements in experimental preparation techniques allow researchers to design oxide materials beyond known appearance in nature. Materials developments from this area may hence be relevant for future technological applications. However, due to the unique combination of the well-known demanding physics of bulk transition-metal oxides with the modern architecturing possibilities, oxide heterostructures furthermore challenge known paradigms in condensed matter physics. The coexistence and mutual affection of intriguing bulk-like electronic phases, each up to now associated with a given oxide compound, within a single oxide heterostructure may be imagined. Moreover, due to the seminal role of the interface in these novel systems, new exotic phases, unknown in present bulk compounds, may emerge.

As of today, already a faithful theoretical investigation of bulk transition-metal oxides with a weakly screened local Coulomb interaction remains a difficult task. Restriction to (effective) single-particle schemes often misses key oxide phenomenologies, such as, e.g., the many-body concept of Hubbard bands or local-moment formation. Therefore, the standard first-principles tool of materials science, density functional theory (DFT) in the Kohn-Sham representation, is in many cases not sufficient. Realistic methods beyond conventional DFT that highlight the importance of strong local Coulomb interactions in connection with true many-body electron states are on their way of becoming rather routinely applicable to the correlated electronic structure of bulk oxides. But the sophisticated structural aspects of oxide heterostructures still promote the task to another level of complexity.

The goal of this review is to highlight the many-body character of some oxide heterostructure problems and to discuss recent first-principles approaches to deal with the physics. We focus on works based on the combination of DFT with the dynamical mean-field theory (DMFT). This is motivated by the fact that the DFT+DMFT framework has evolved to the state-of-the-art realistic many-body approach to cope with the strong-coupling problem of challenging oxide electron systems. In order to set the stage, the starting Sect. 2 provides a brief reminder on the phenomenology of strongly correlated electrons and some thoughts on the relevance of heterostructure physics. Section 3 delivers an account of the DFT+DMFT technique, while Sect. 4 presents a selected overview of existing applications to oxide heterostructure problems.

2   Preliminary Considerations

In the given context, it is relevant to appreciate the many-body phenomenology of correlated electrons and its difference to sole effective single-particle picturings. Therefore, a quick summary of the key characteristics of strongly correlated electron systems renders the text more self-contained. Second, some general thoughts on the research motivation in the field of oxide heterostructures seem in order.

2.1   Brief Reminder on Strong Electronic Correlations in a Solid

In various transition-metal oxides, the key many-body aspects reside within the electronic subsystem. The Pauli principle and the mutual Coulomb interaction among the electrons give rise to an intricate many-particle wave function. While the former exchange physics, in its pure appearance, may be cast into a Slater determinant, the explicit interaction leads to more intriguing modifications of the wave function. Electronic correlations, as defined from quantum chemistry, are routed in the latter. Though the Coulomb interactions is long-ranged, screening processes in the solid restrict in most cases its actual relevant range to rather short distances. To a good approximation for many systems, a sole *local* interaction appears sufficient to describe the dominant physics. Given that viewpoint, the Hubbard model stands out as the seminal picturing of the competition between localization and itinerancy among interacting condensed matter electrons, i.e.:

$$H_{\text{Hubbard}} = -t \sum_{\langle i,j \rangle \sigma} \left(\hat{c}_{i\sigma}^{\dagger} \hat{c}_{j\sigma} + \text{h.c.} \right) + U \sum_{i} \hat{n}_{i\uparrow} \hat{n}_{i\downarrow}, \tag{1}$$

whereby i, j are site indices, $\sigma = \uparrow, \downarrow$ is the spin projection, and $\hat{n}_{\sigma} = \hat{c}_{\sigma}^{\dagger} \hat{c}_{\sigma}$. The nearest-neighbor hopping t describes the electron tendency to delocalize on the lattice, giving rise to the noninteracting band structure, whereas the Hubbard U marks the local Coulomb interaction. The given basic Hamiltonian is appropriate for a (effective) one-band problem. Description of multiband systems asks in addition
Fig. 1 Local spectral function $\rho(\omega)$ of the Hubbard model on a three-dimensional lattice for different U/t ratios. The quantity D marks the half bandwidth. The nomenclature $A(\omega) = \rho(\omega)$ is often understood, if the explicit k-dependence in the complete spectral function is not discussed

for an implementation of the local Hund's physics, as enforced by the Hund's exchange J_{H}.

Depending on the ratio U/t, Fig. 1 displays the principle behavior of the k-integrated spectral function $\rho(\omega) = \sum_{\mathbf{k}} A(\mathbf{k}, \omega)$ on a three-dimensional lattice for the so-called half-filled case $n = 1$, i.e., nominally one electron per lattice site. For small U/t, the system is a very good metal, close to a Fermi gas, with maximum spectral weight at the Fermi level ε_{F}. Note that in that regime, the spectral function reduces to the common density of states (DOS). On the contrary for large U/t, the lattice is in an insulating state, since the electrons localize in real space because of the strong Coulomb repulsion. In spectral terms, removing/adding an electron is associated with states in the lower/upper Hubbard band. Importantly, this *Mott-insulating* state is strikingly different from a conventional band insulator which arises due to complete band filling in reciprocal space.

For U/t in between the named limits, the system is in the most interesting regime of a correlated metal. Subtle spectral-weight balancing between the emerging Hubbard bands and the coherent quasiparticle (QP) peak close to ε_{F} takes place. The QP peak is the reminder of the original band states, i.e., encloses states with a well-defined wave vector k, but strongly renormalized and with a weight $Z \leq 1$. The apparent *band-narrowing* included in Z deviating from unity is readily understood: the effective hopping t is reduced due to the electron's hesitation to delocalize when having to pay the Coulomb penalty U while meeting another electron on the nearby lattice site. An existing QP weight Z defines a *Fermi liquid*, since more formally, the quantity Z is derived from the electronic self-energy $\Sigma(\mathbf{k}, \omega)$ via $Z = (1 - \partial \Sigma / \partial \omega|_{\omega \to 0})^{-1}$ (see, e.g., Imada et al. (1998) for more details). Notably, the electronic self-energy integrates all many-body effects and is the key quantity of the interacting system. Most common metals are Fermi liquids, but it is obvious that there may exist other forms of correlated metals, where a linear self-energy term at low energy is missing. Robust QPs are then absent and the metal is, somewhat vaguely, termed *non-Fermi liquid* (NFL). Various unusual electronic phases of transition-metal oxides are associated or in proximity to NFL characteristics, such as, e.g., in the phase diagram of the high-T_{c} cuprates.

2.2 Why Oxide Heterostructures?

Deviations from the standard band picture of lattice electrons are often encountered in bulk oxides. Therefore by heterostructuring these materials, a unique playground

for investigating, tailoring, and designing correlation effects is opened. The challenges are twofold in this respect. First, *known* bulk correlation phenomena are transferred into the heterostructure environment and may be tuned by various means. Second, by interfacing different electronic bulk phases, *new* interface phases are generated, eventually even without a distinct bulk analogon. A very strict separation between these both research directions is albeit delicate.

In the first challenge, common correlation features, e.g., strong spectral-weight transfer, formation of Hubbard satellites, enhanced susceptibilities, local-moment formation, Kondo physics, magnetic ordering, metal-insulator transition, and charge-density-wave or superconducting instabilities, are studied within heterostructure architectures. Proximity to an interface, different structural/geometrical relaxations/constraints, symmetry breakings due to layering (cf. Fig. 2), or polarization effects because of a heterostructure-adapted electric field are only a few impacts that are able to influence and modify the original bulk electron system. Already a lot of work has been performed in this context, and much is cited in the review articles given in the introduction.

For a concrete example, the physics of doped Mott insulators is a key research field in strongly correlated condensed matter. Bulk doping however poses many difficulties in view of a well-defined theoretical description. Most importantly, the intertwining with disorder mechanisms in the electronic and structural sector often hinders a straightforward modeling. Those problems may be overcome in Mott-oxide heterostructures, since electron, hole, or structural (i.e., effects only due to the different ion size of the valence-identical dopant) doping can nowadays be realized by respective doping layers, e.g., via molecular beam epitaxy (cf. Eckstein and Bozovic (1995) and Stemmer and Millis (2013) for reviews). Therewith, the correlated doping physics becomes accessible in a well-defined manner by model-Hamiltonian and/or first-principles techniques. In general, accompanied by this progress, the examination of the influence of defects in strongly correlated materials has gained renewed interest, being explored by considering the detailed defect chemistry together with a state-of-the-art treatment of electronic correlations.

The second challenge is even more demanding and might be associated with the physics of conducting quasi-two-dimensional electron interface systems emerging in oxide heterostructures consisting of bulk band insulators. In principle, selected surface systems may also be counted in this regard. Yet the clarification of the

Fig. 2 Principle issue of symmetry breaking induced by an interface in an oxide heterostructure, leading to layer-dependent electronic self-energies Σ_{ij}
uniqueness of such engineered electron phases beyond respective bulk counterparts is still ongoing research. Topological nontrivial electronic states are surely to be considered, but there the explicit interplay between the topological aspect and electronic correlations is still largely uncharted territory. In the following, these latter material possibilities will not be covered, but the interested reader finds some ideas on this in a recent review (Keimer and Moore 2017).

3 Theoretical Approach: Realistic Many-Body Theory

3.1 Electronic Density Functional Theory (DFT)

Electronic density functional theory marks an everlasting milestone in condensed matter research, it is and will remain a key step in the first-principles investigation of matter. There are excellent reviews and books on DFT, so there is no need here to iterate thereon. In essence, the framework maps the problem of interacting electrons onto the problem of noninteracting particles within a complicated effective potential. In the present context, it is vital to note that although DFT represents *in principle* a complete many-body account of interacting electrons, the most common Kohn-Sham representation based on the conventional local-density or generalized-gradient approximations (i.e., LDA or GGA) marks this method as an effective single-particle approach. In condensed matter, it therefore describes band electrons, whereby the original many-body effects are cast into the named effective potential.

3.2 Dynamical Mean-Field Theory (DMFT)

When it comes to strongly correlated lattice electrons, the dynamical mean-field theory (Metzner and Vollhardt 1989; Georges and Kotliar 1992) has the reputation of being the many-body scheme with the best compromise between generality, accuracy, and performance. Also DMFT describes a mapping, and it is here from the problem of interacting lattice electrons onto the problem of a quantum impurity within a self-consistent energy-dependent bath, as sketched for the Hubbard model in Fig. 3.

The one-particle Green's function provides seminal access to the spectral properties and the total energy of an interacting electron system on a lattice. For chemical potential μ, and Hamiltonian $H(\mathbf{k})$ at wave vector $\mathbf{k}$, it reads:

$$G(\mathbf{k}, i\omega_n) = [i\omega_n + \mu - H(\mathbf{k}) - \Sigma(\mathbf{k}, i\omega_n)]^{-1} \quad . \tag{2}$$

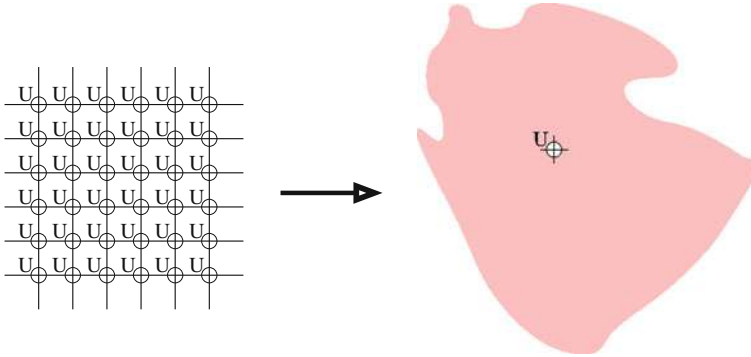
Note that here and in the following part of the text, fermionic Matsubara frequencies $\omega_n := (2n + 1)\pi T$ are employed to emphasize the treatment at *finite* temperature. The analytical continuation to real frequencies ω in actual calculations may, e.g., be performed via the maximum entropy method (see, e.g., Imada et al. (1998) and Georges et al. (1996) for more general details).


Fig. 3 Sketch of the DMFT mapping of an interacting lattice problem (left) onto a problem of an impurity within an energy-dependent bath (right), assuming a sole on-site Coulomb interaction U

In DMFT, the local Green's function is approximated with the help of a k-independent impurity self-energy $\Sigma_{\mathrm{imp}}(i\omega_{\mathrm{n}})$, i.e.:

$$G_{\mathrm{loc}}^{\mathrm{DMFT}}(i\omega_{\mathrm{n}}) = \sum_{\mathbf{k}}[i\omega_{\mathrm{n}} + \mu - H(\mathbf{k}) - \Sigma_{\mathrm{imp}}(i\omega_{\mathrm{n}})]^{-1}, \tag{3}$$

whereby the corresponding impurity problem reads:

$$\Sigma_{\mathrm{imp}}(i\omega_{\mathrm{n}}) = \mathscr{G}_0(i\omega_{\mathrm{n}})^{-1} - G_{\mathrm{imp}}(i\omega_{\mathrm{n}})^{-1} \quad . \tag{4}$$

The Weiss field $\mathscr{G}_0(i\omega_{\mathrm{n}})$ is a unique function of the local Hamiltonian (expressed within a localized basis), and, importantly, the DMFT self-consistency condition implies $G_{\mathrm{imp}} = G_{\mathrm{loc}}^{\mathrm{DMFT}}$. The calculational loop is depicted in the DMFT-loop box of Fig. 4, and quantum impurity solvers based, e.g., on quantum Monte Carlo, exact diagonalization, etc. yield the solution. For more details, we refer to Georges et al. (1996) for a review. Note that local-interaction diagrams are included to all orders in this non-perturbative theory. The vital energy dependence of the Weiss field ensures the qualitatively correct description of low-energy QP features as well as high-energy incoherent (Hubbard) excitations. Extensions to overcome the restriction to a k-independent self-energy, e.g., via cluster schemes, are available. But those will not be further pursued in the present text.

3.3   Combining DFT and DMFT

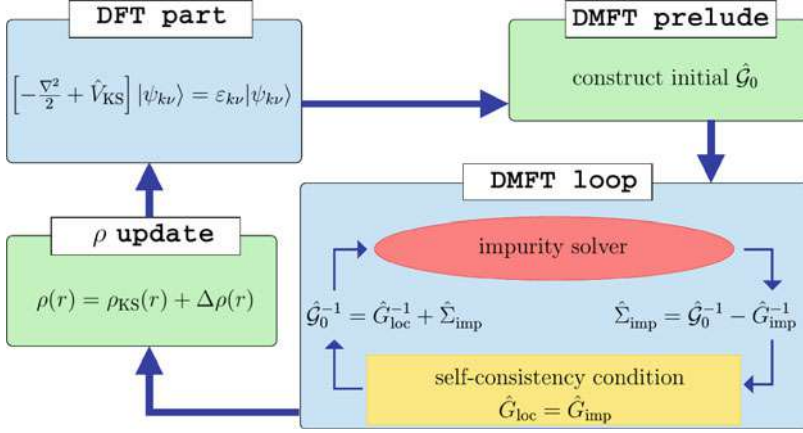
The first explicit promotions of DMFT to the realistic level through a merging with Kohn-Sham DFT has been realized end of the 1990s (Anisimov et al. 1997; Lichtenstein and Katsnelson 1998). Importantly, since the many-body part incorporates a Hubbard-model(-like) picturing of a suitably chosen *correlated*


Fig. 4 State-of-the-art charge self-consistent DFT+DMFT loop. (After Lechermann et al. 2006). The calculation usually starts from a self-consistent Kohn-Sham solution. The correlated subspace is defined and the initial Weiss field $\mathscr{G}_0$ constructed. Afterward, a single (or more) DMFT step is performed. The obtained self-energies are upfolded and an updated charge density $\rho(\mathbf{r})$ is computed. A new charge density implies a new Kohn-Sham potential, and a single new Kohn-Sham step is performed; therefrom a new Weiss field is generated, etc

subspace, a (partly) local-orbital representation is an essential building block of the DFT+DMFT framework. Linear-muffin-tin orbitals (Andersen 1975); Wannier(like) functions, e.g., of maximally localized kind (Marzari et al. 2012); or projected-local orbitals (Amadon et al. 2008; Anisimov et al. 2005) are usually in charge of that representation. The correlated subspace is understood as a quantum-numbered real-space region where correlated electrons hide. The key interfacing blocks of the complete DFT+DMFT self-consistency cycle (Savrasov et al. 2001; Minár et al. 2005; Pourovskii et al. 2007; Grieger et al. 2012) (cf. Fig. 4) are marked by the downfolding of the full-problem Bloch space to the correlated subspace and the upfolding of the DMFT self-energy back to the original space. The main respective formulas for sites $\mathbf{R}$, local orbitals mm' and band indices $\nu\nu'$, read:

$$G_{mm'}^{\mathbf{R},\mathrm{imp}}(i\omega_n) = \sum_{\mathbf{k},(\nu\nu')\in\mathscr{W}} \bar{P}_{m\nu}^{\mathbf{R}}(\mathbf{k})\, G_{\nu\nu'}^{\mathrm{bloch}}(\mathbf{k}, i\omega_n)\, \bar{P}_{\nu'm'}^{\mathbf{R}*}(\mathbf{k}), \qquad (5)$$

$$\Delta\Sigma_{\nu\nu'}^{\mathbf{R},\mathrm{bloch}}(\mathbf{k}, i\omega_n) = \sum_{\mathbf{R},mm'} \bar{P}_{\nu m}^{\mathbf{R}*}(\mathbf{k})\, \Delta\Sigma_{mm'}^{\mathrm{imp}}(i\omega_n)\, \bar{P}_{m'\nu'}^{\mathbf{R}}(\mathbf{k}), \qquad (6)$$

with $\bar{P}$ denoting the normalized projection between Bloch space and correlated subspace (Amadon et al. 2008). The object $\Delta\Sigma_{\nu\nu'}^{\mathrm{bloch}}$ describes the k-dependent self-energy in Bloch space after double-counting correction. As for the correlated subspace, there is a choice for the range $\mathscr{W}$ of included Kohn-Sham bands in the downfolding. The double-counting correction takes care of the fact that some

correlations are already handled on the DFT level. In the upfolding operation, the charge density will also be updated with correlation effects, i.e.:

$$\rho(\mathbf{r}) = \sum_{\mathbf{k}, \nu\nu'} \langle \mathbf{r}|\Psi_{\mathbf{k}\nu}\rangle \Big(f(\tilde{\epsilon}_{\mathbf{k}\nu})\delta_{\nu\nu'} + \Delta N_{\nu\nu'}(\mathbf{k}) \Big) \langle \Psi_{\mathbf{k}\nu'}|\mathbf{r}\rangle, \tag{7}$$

where Ψ denotes Kohn-Sham states, f is the associated Fermi function, and ΔN is the DMFT self-energy correction term (Lechermann et al. 2006; Amadon et al. 2008). Thus, since a pure band picture is not vital in a many-body system and *real-space* excitations also matter, additional off-diagonal terms in the band index contribute in the correlated regime. This novel charge density accordingly then defines a new Kohn-Sham effective potential. Note finally that this first-principles many-body scheme works, at heart, at finite temperature T. Electron states are therefore subject to the full thermal impact, beyond sole occupational Fermi-function modification. For more formal and detailed accounts on the DFT+DMFT scheme, we refer to Georges (2004) and Kotliar et al. (2006).

In oxide heterostructures, as in various other multiatom unit cells, the correlated subspace invokes not only a single lattice site. For symmetry-equivalent sites, the self-energy is determined for a representative site and transferred to the remaining sites via the proper symmetry relations. A different impurity problem is defined for each symmetry-inequivalent site j through (Potthoff and Nolting 1999):

$$\mathscr{G}_0^{(j)}(i\omega_\mathrm{n})^{-1} = G^{(j)}(i\omega_\mathrm{n})^{-1} + \Sigma_\mathrm{imp}^{(j)}(i\omega_\mathrm{n}), \tag{8}$$

and the coupling is realized via the DFT+DMFT self-consistency condition invoking the computation of the complete lattice Green's function.

4 Selected Studies of the Correlated Electronic Structure of Oxide Heterostructures

There are already various applications of the DFT+DMFT approach to the problem of oxide heterostructures, and the number is expected to further grow substantially. Therefore in a short review, the choice of examples has to be highly selective and is here mainly driven by the author's interest in this field of research. We apologize for not covering many details of other interesting studies. Furthermore, albeit DFT and/or DFT+U studies of oxide heterostructures also provide relevant insight, including a discussion of such works would go beyond the limited scope of the present text.

If not otherwise stated, the materials investigations discussed in Sects. 4.1 and 4.2 involving the author were performed using charge-self-consistent DFT+DMFT based on a mixed-basis pseudopotential code (Meyer et al. 1998) and hybridization-expansion continuous-time quantum Monte Carlo (Werner et al. 2006) in the TRIQS

package (Seth et al. 2016) as an impurity solver. For more technical details on the implementation, the reader is referred to Grieger et al. (2012).

4.1   Mott-Band Insulator Architectures

Joining different bulk electronic phases across the interface of a heterostructure is appealing as a plausible route to emerging physics. Thermodynamics may select novel electronic states different from the original bulk states that cope with the intriguing phase competition.

In this respect, oxide heterostructures composed of a Mott insulator and a band insulator belong to early studied systems, initially via experimental work on the LaTiO$_3$/SrTiO$_3$ (LTO/STO) interface (Ohtomo et al. 2002). While STO is an ideal cubic perovskite at ambient temperature, LTO marks a distorted perovskite with orthorhombic crystal symmetry. First model-Hamiltonian Hartree-Fock studies of a Hubbard-model application to such an interface yielded an intricate phase diagram in the number of La layers and Hubbard U (Okamoto and Millis 2004). Simplified realistic DMFT for LTO/STO by Ishida and Liebsch (2008) emphasized the structural orthorhombic-versus-tetragonal aspect of the LTO part. Transport within a Mott-band insulator heterostructure has been studied again within a model-Hamiltonian approach by Rüegg et al. (2007).

A superlattice DFT+DMFT investigation of LTO/STO (Lechermann et al. 2013) revealed the realistic competition of both insulating systems stacked along the c-axis, giving rise to a metallic interface state. The correlated subspace can be chosen to be spanned by Ti-3$d(t_{2g})$ states, i.e., consists locally of three correlated orbitals. A Hubbard $U = 5$ eV and Hund's exchange $J_\mathrm{H} = 0.7$ eV are applied in that subspace. Orbital-dependent charge transfers lead to a strong Ti-3$d(xy)$, i.e., inplane electronic, polarization in the interface TiO$_2$ layer. Surely, on the STO side, the Ti^{4+} oxidation state with nominal 3d^0 occupation is quickly reached, while on the LTO side, the Ti^{3+}-3d^1 establishes and a sizable lower Hubbard band at ~-1.1 eV is identified in the spectral function (see also Fig. 5). In those calculations, the lattice constant was fixed to the cubic STO value, but local structural relaxations on the DFT level were allowed. It is to be noted that the lattice degrees of freedom are an important aspect in oxide heterostructures. Simplified DFT+DMFT bulk-like studies revealed, e.g., the impact of strain on the Mott-insulating state of LaTiO$_3$ (Dymkowski and Ederer 2014) and LaVO$_3$ (Sclauzero and Ederer 2015).

Even more intriguing physics may be found when starting from a doped-Mott state within the heterostructure setting. Motivated by experimental work (Moetakef et al. 2012; Jackson et al. 2014; Mikheev et al. 2015), a first-principles many-body investigation of δ-doping the rare-earth titanates LaTiO$_3$, GdTiO$_3$, and SmTiO$_3$ with a single SrO layer was undertaken (Lechermann and Obermeyer 2015; Lechermann 2017b). Especially the δ-doped SmTiO$_3$ case displays puzzling physics in experiment, namely, NFL transport that switches to FL-like characteristics upon adding further SrO layers. In the rare-earth titanate 3$d(t_{2g}^1)$ series of distorted-perovskite Mott insulators, the magnetic low-temperature state changes from antiferromagnetic (AFM) to ferromagnetic (FM) with the size of the rare-earth ion. The samarium
Fig. 5 Spectral information for a LaTiO$_3$/SrTiO$_3$ superlattice with 4 SrO and 4 LaO layers. (After Lechermann et al. 2013). Left, total spectrum; right, closer to Fermi level. Note that the DMFT correlated subspace includes only Ti(t_{2g}) functions; therefore, the DFT+DMFT spectra are here chosen to cover also only these contributions. However of course in the charge self-consistent cycle, all states are included

titanate is still AFM, but just on the border toward ferromagnetism. Structurally well-defined hole doping introduced by the SrO monolayer renders SmTiO$_3$ metallic. The DFT+DMFT results (see Fig. 6) reveal significant spectral-weight transfer to higher energies compared to DFT and in addition a complex layer-resolved electronic structure. While far from the doping layer, the system resides in an orbital-polarized Mott-insulating state; it is conducting in an orbital-balanced manner just at the interface TiO$_2$ layer (cf. Fig. 6c). Both regimes are joined by an orbital-polarized doped-Mott layer with a largely renormalized QP peak at the Fermi level. Detailed analysis of the layer- and orbital-dependent self-energies shown in Fig. 6d, e indeed reveals signatures of a NFL exponent for the dominant effective t_{2g} orbital in the second, i.e., orbital-polarized doped-Mott, TiO$_2$ layer. Further investigations hint toward competing AFM-FM fluctuations in the Mott-critical zone as a possible cause for NFL behavior (Lechermann 2017b). A pseudogap(-like) structure in the theoretical spectral function subject to such fluctuations has indeed been identified in experimental studies (Marshall et al. 2016). In an extension of this study, it was shown that the addition of further SrO layers establishes an extra band-insulating regime in the formed SrTiO$_3$-like region, with a stronger inplane xy-polarized metallic layer at the boundary (Lechermann 2017a).

4.2   Band-Band Insulator Architectures

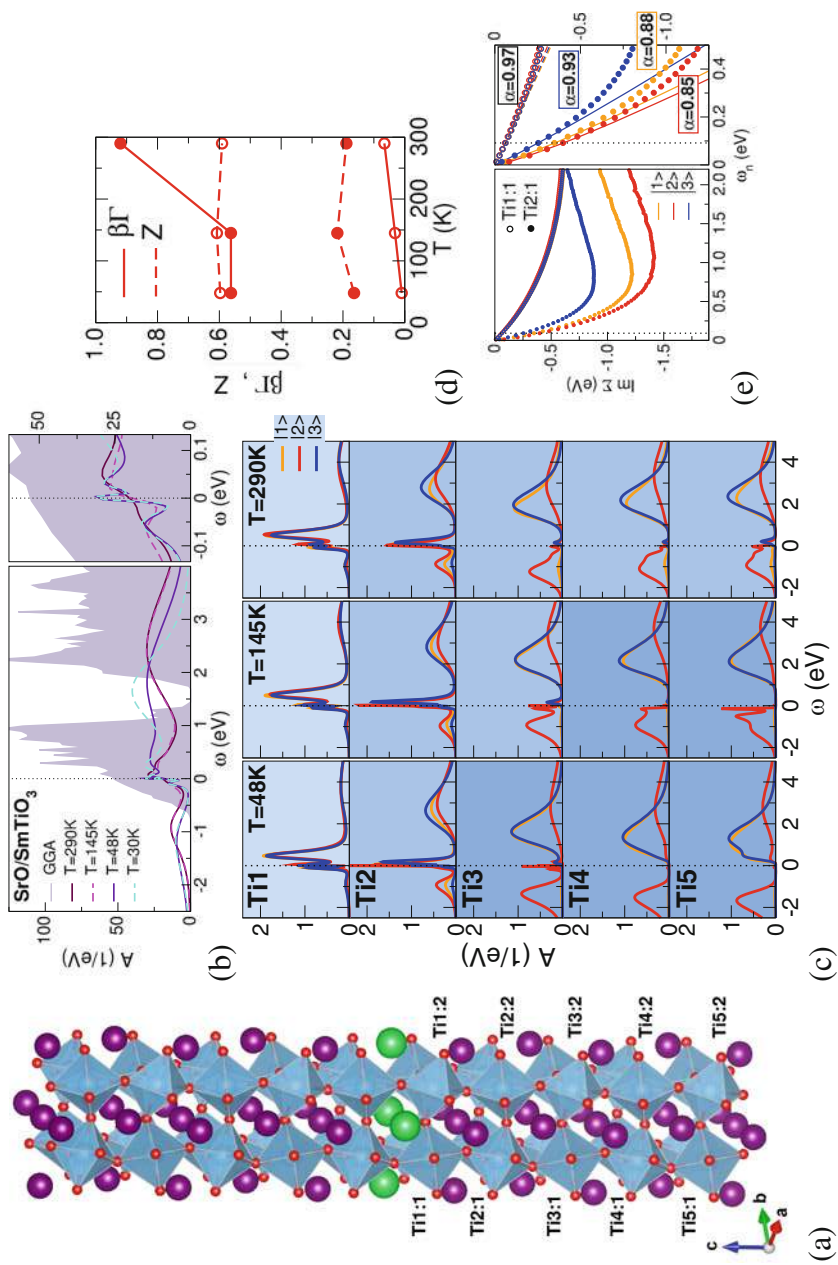
The formation of a metallic two-dimensional electron system (2DES) at the n-type interface between the band insulators LaAlO$_3$ (LAO) and SrTiO$_3$ (Ohtomo and Hwang 2004) has so far been the most appreciated finding in the oxide-heterostructure context. Follow-up experimental studies furthermore revealed the 2DES delicacy, e.g., the possibility for superconductivity (Reyren et al. 2007) as well as magnetic order (Brinkman et al. 2007) in the LAO/STO interface.


Fig. 6 (continued)

A polar-catastrophe mechanism (Nakagawa et al. 2006) is believed to be dominantly at the root of the 2DES buildup.

In view of electronic correlations, this and related interface systems (Chen et al. 2013) appear more subtle since the band-insulating constituents do not already host electrons in partially filled d- or f-states. Nonetheless, the confirmed stabilization of magnetic and superconducting order proves the existence of collective electronic behavior. Then, nonlocal effects might be more crucial than in the former Mott-band heterostructures. However, still relevant local correlations are evident from the coappearance of oxygen vacancies and ferromagnetism in LAO/STO (Salluzzo et al. 2013). Point defects are an important ingredient of the present interface physics, and oxygen vacancies (OVs) so far appear to have major impact (Pavlenko et al. 2012). In a DFT+DMFT study of the LAO/STO interface (Lechermann et al. 2014), it is shown that stable ferromagnetic order needs both, OVs *and* electronic correlations. While Ti-3$d(t_{2g})$ orbitals dominate the states directly above the STO gap, an oxygen vacancy leads to an in-gap state of Ti-3$d(e_g)$ kind, here termed $\tilde{e}_g$. In a minimal model, the correlated electronic structure at the interface may be described by the interplay between $\tilde{e}_g$ and an inplane xy orbital from the t_{2g} threefold (see Fig. 7). Therefore, a reduced Hubbard $U = 2.5\,\mathrm{eV}$ and Hund's exchange $J_H = 0.5\,\mathrm{eV}$ are appropriate in the smaller correlated subspace. Note that a dense-defect scenario is assumed in that superlattice assessment, i.e., there is an OV at every other O site in the interface TiO$_2$ plane. Still an in-gap $\tilde{e}_g$-like state at $\varepsilon_{IG} \sim -1.2\,\mathrm{eV}$ is well reproduced in agreement with experiment (Berner et al. 2013). Close to an oxygen vacancy, the formal oxidation state of titanium is close to Ti^{3+}, i.e., again locally a $3d^1$ occupation is realized with defects. But the emergent spin polarization in the given defect limit is not of purely local kind; it develops substantial dispersive behavior (cf. Fig. 7d, e). In general, such studies show that strong electron correlations, describable within DMFT, may be introduced also in band-band insulator architectures of oxide heterostructures.

Approaching significantly lower OV concentrations in a first-principles manner asks for the handling of much larger supercells. Due to the numerical heavyness of DFT+DMFT, this is yet not easily possible. Instead, a model-Hamiltonian approach, equipped with the relevant ingredients from the dense-defect limit, appears more adequate. Figure 8 displays the setting and some main results of such

---

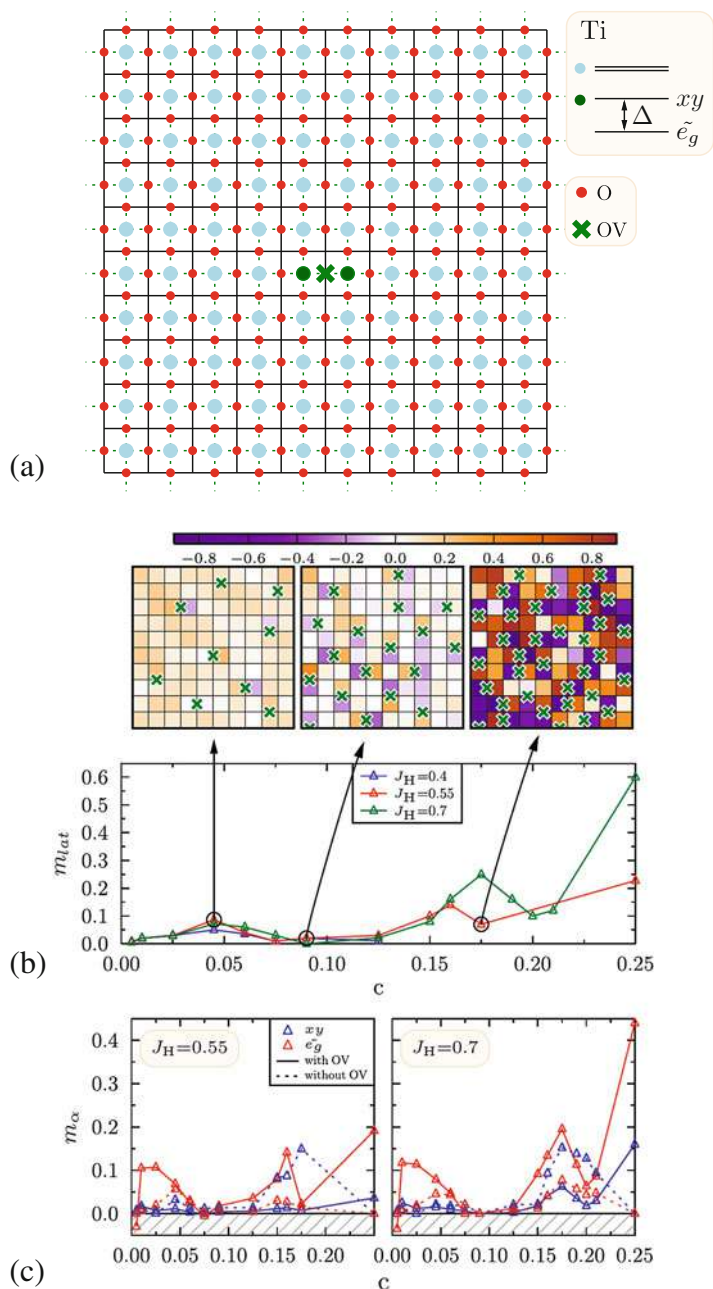
an ansatz (Behrmann and Lechermann 2015). A two-orbital $\tilde{e}_g$-xy Hubbard model is solved on a 10×10 square lattice resembling the TiO_2 interface plane. The efficient rotational-invariant slave boson (RISB) scheme (Lechermann et al. 2007; Li et al. 1989), employing a self-energy which has a linear-in-frequency term and a static term, is put into practice for a simplified treatment. Focusing on the magnetic order, it is shown that there are three regimes with growing number of OVs. At very small concentration, a Ruderman-Kittel-Kasuya-Yoshida (RKKY) coupling leads to FM order, whereas at larger concentration a double-exchange mechanism dominates a different FM phase. In-between local AFM pairs (or, in an advanced self-energy modeling, possibly singlets) result in a nearly absent net magnetic moment. This intricate OV-dependent magnetic exchange is in line with experimental findings of strongly probe-dependent magnetic response.


Fig. 8 Influence of oxygen vacancies in the LAO/STO interface. (After Behrmann and Lechermann (2015)). (**a**) Model setting: 10×10 square lattice, two orbitals per site, oxygen degrees of freedom that are integrated out, nearest-neighbor hopping $t = 0.2$ eV. A crystal-field splitting $\Delta = 0.3$ eV between $\tilde{e}_g$ and xy is applied, if an OV is located nearby. (**b**) Top: color-coded ordered local magnetic moments on the lattice for selected OV concentration. Bottom: lattice net moment per site for different Hund's exchange J_H. (**c**) Orbital-resolved magnetic moment, averaged per site

In parallel to the STO-based heterostructure investigations, studying the $SrTiO_3$ surface attracted significant attention. Interface and surface properties of a chosen oxide are often related and the comparison between both plane defects enables a better understanding of emergent phenomena. A 2DES was initially also found on the oxygen-deficient (001) surface (Santander-Syro et al. 2011; Meevasana et al. 2011) and soon after also confirmed for other cleavage planes, e.g., in (111) direction (McKeown Walker et al. 2014). As a difference to the LAO/STO interface, the defect-free STO surface is believed to be insulating. Due to a missing interface-driven polar-catastrophe mechanism, defects such as OVs are essential to metallize the surface. Similar to the interface spectrum, an in-gap state at a very similar position, i.e., $\sim -1.3\,eV$, has been detected on the STO surface early on Tanaka et al. (1993). Recent DFT+DMFT considerations of the STO(001) surface with OVs indeed verified this in-gap state (Lechermann et al. 2016), which is again dominantly formed by Ti-$3d(e_g)$ weight (cf. Fig. 9). Furthermore, the low-energy structure dominated by Ti-$3d(t_{2g})$ states is also in accordance with experiment. A double-vacancy defect provided the best matching with experiment; however only two distinct vacancy configurations were examined because of the large numerical effort. Nonetheless, the spectral separation of e_g at high energy and t_{2g} is a clear generic feature of the study. Conventional DFT is not sufficient to provide this orbital separation (cf. Fig. 9c, d).

4.3 Further Investigations

So far, the present review mainly focused on early-transition-metal titanate heterostructures, but theoretical work also dealt with other oxide designs. For instance, the late-transition-metal rare-earth (R) nickelate series $RNiO_3$ provides important material building blocks, too (Hwang et al. 2013). Originally, there was the idea to realize cuprate-like physics within nickelates by proper heterostructuring (Hansmann et al. 2009; Han et al. 2011); however experimental success remains absent. Bulk perovskite-like vanadates split into correlated metals, e.g., $SrVO_3$ and $CaVO_3$, and Mott insulators, e.g., $LaVO_3$ and YVO_3. Heterostructures based on $SrVO_3$ were studied in view of a possible loss of metallicity in a small-layer limit (Okamoto 2011; Zhong et al. 2015). Moreover, transition-metal oxides from the $4d$ and $5d$ series serve as further building blocks. For instance, the $4d^4$ physics of strontium and/or calcium ruthenates poses a long-standing problem, which can be tuned by heterostructuring (Si et al. 2017).

5 Outlook

The research field of oxide heterostructures will remain promising, on a basic research level, as well as in view of possible technical applications. Until now, only a few materials classes have been utilized, and there are vast ways of combinations, both in different materials as in different geometries. In addition, the opening

(**a**) 180-atom supercell with a TiO$_2$-terminated surface layer of STO: Sr (green), Ti (blue), O (red), OV (violet). (**b**) Bond charge density $n_{\text{total}}(\mathbf{r}) - n_{\text{atomic}}(\mathbf{r})$: top view (left), side view (right). (**c**) Spectral-weight comparison of the summed Ti(t_{2g}, e_g) (top) and of the dominant Ti-based effective orbital between DFT(GGA) (left) and DFT+DMFT (right). The $\varphi_{\text{DV}}^{(1)}$ Wannier-like orbital is an effective inplane e_g orbital located on the Ti site between the OVs. (**d**) Low-energy spectral-weight comparison of the Ti($3d$) states

toward more general hybrid heterostructures, e.g., with Dirac materials, has just started and will lead to novel phenomena. Detailed studies of challenging spin, charge, or pairing instabilities of oxide heterostructures are still at its infancy, and expectations are high for new surprising findings. Furthermore, the recent focus on the nonequilibrium regime in strongly correlated matter will find an ideal playground in this class of designed materials.

The DFT+DMFT method, and future extensions to it, has the chance to pave the roads toward a new era in materials science, highlighting the many-body character in key functionalities. A better understanding and general appreciation of the intriguing interplay between electron correlation and materials chemistry is believed to be at the heart of this endeavor.

Abstract

This work is an attempt to provide a self-contained introduction to the field of atomic modeling of oxide interfaces, focusing primarily on the first-principles modeling techniques based on density functional theory. By way of introduction,

a brief description of common oxides and their technological applications are included. We then discuss the first principles methods that have proven effective in dealing with oxide-based interface problems, including common techniques of building structural models. Examples of validating the atomistic model of an interface experimentally are given along with predictions of interface properties. We conclude with a brief summary of the field and the remaining challenges it faces.

1   Introduction

Metal oxides play an important role in human society. Their applications range from the mundane, such as kitchen glassware, to the very advanced, such as microelectronics and nanophotonics. Somewhat surprisingly, because the main mineral component of human bone is an oxide mineral (hydroxyapatite), oxides also have a connection to healthcare and medicine. In terms of physical properties, metal oxides exhibit a wide variety of physical phenomena: they can range from being electrically insulating to being very good conductors and can also show interesting properties such as magnetism, ferroelectricity, superconductivity, and nonlinear optical effects, to name a few. Some oxides also show catalytic activity or can be used as mechanical supports for catalytically active particles. As a result, metal oxide nanostructures find applications in a very wide range of devices including field effect transistors, light-emitting devices, photodetectors, catalysts, electromechanical devices, sensor elements, solar cells, and many more.

In most applications, oxides do not exist in isolation but are probed (contacted), manipulated, or supported by other materials. Therefore, oxide interfaces are of great practical as well as fundamental interest. Recent advances in oxide deposition techniques started a true revolution in the field of oxide thin films and heterostructures. Physical deposition methods such as molecular beam epitaxy (MBE) and pulsed laser deposition (PLD) or chemical methods such as atomic layer deposition (ALD) have been re-designed specifically to grow metal oxide films and now allow deposition control at the level of almost a single atomic layer. This has in turn enabled the use of oxide films in nanofabrication as well as creation of artificial oxide-based materials that have never been accessible in bulk form previously. The interface with vacuum is just the oxide surface, and we refer the reader to the abundant literature on the topic of oxide surfaces. An excellent starting point is, of course, the classic by Henrich and Cox (1994).

To make our discussion of oxide interfaces more specific, let us consider a device known as a FerroFET, a field effect transistor (FET) with a thin ferroelectric layer, e.g., $BaTiO_3$ (BTO), as a gate dielectric (see Fig. 1). As the ferroelectric "remembers" its polarization state and can be switched between two stable polarization states by a voltage applied to a gate electrode, the device can be used as a nonvolatile memory. Assuming a Si-based FET, putting a BTO layer on Si with MBE requires the use of a thin $SrTiO_3$ (STO) buffer layer, which grows epitaxially directly on
Fig. 1 The ferroelectric field-effect transistor is a MOSFET with a ferroelectric gate, achieved by replacing the dielectric material of the transistor with a ferroelectric material. This nonvolatile, low power memory device would experience reduced fatigue, due to its nondestructive readout, and more aggressive device scaling could be achieved in comparison to FeRAM where there is a separate transistor and capacitor

Si (a BTO film then grows epitaxially on such a buffer). To describe the electrical properties of this gate capacitor (Si-oxide-gate electrode), one needs to understand at least three interfaces involving an oxide material: (i) the semiconductor-oxide interface (Si-STO), (ii) the oxide-oxide interface (STO-BTO), and (iii) the oxide-metal (BTO-electrode) interface. If in the process, the top Si layer is oxidized and the SiO_2 interlayer is formed, another two interfaces need to be considered, one between Si and SiO_2 and another between SiO_2 and STO.

Note that despite all being oxide-related, these interfaces are quite different from each other, both structurally and chemically, which has implications in how one would model them. For an interface between two crystalline materials, such as Si and STO, one may hope to find a common periodicity unit that would allow the use of the periodic boundary conditions (at least laterally). For the interface involving amorphous SiO_2, this, strictly speaking, cannot be modeled precisely and one has to either use some crystalline form of SiO_2 (such as β-cristobalite) as a proxy or attempt to generate a quasi-disordered SiO_2 structure that can then be used as repeated unit in a periodic calculation. The electrostatic screening in metals and insulators also has a different nature, which places very different requirements on the simulation cell size.

Different interfaces may also require different types and levels of theory. While Si, Sr, or Ba prefer fixed oxidation states (4^+, 2^+, and 2^+, respectively) at oxide-based interfaces, transition metals such as Ti can support several different oxidation states. The existence of multiple oxidation states can be traced to electron correlation in the d-shell of the transition metal ion. A proper treatment of electron correlation requires electronic structure methods going beyond the usual mean-field approximation that is commonly used in approximate density-functional-theory-based methods.

Different applications depend on different properties of the interface. One of the most important properties of an oxide heterostructure is the band offset (the band discontinuity across the interface between two different materials). The band offset plays a key role in determining the degree of carrier confinement and electronic transport along and across the interface. This is a key property for electronic devices as well as for photocatalytic cells. Magnetic properties of the interface are important for spintronics, magnetic storage, and sensing applications. In addition, the interface controls both the electrostatic and mechanical boundary conditions in thin ferroelectrics. Charge transfer at the interface may cause structural distortions and induce metal-to-insulator transitions. Calculating such properties is the main task of the atomic modeling.

The atomistic modeling of an interface can often be performed reliably, provided the atomic structure of an interface is well known. Deciphering the interface structure at the atomic level experimentally, on the other hand, is rather difficult. The atomic structure, of course, can be generated through theoretical modeling; however, due to many uncertainties, the structural model of the interface inferred from theory needs to be properly validated before one makes conclusions about the calculated physical properties using the said model. In some cases, the atomic arrangement in certain directions can be reconstructed directly from electron microscopy. Often photoemission or optical spectroscopic methods such as infrared (IR) absorption or Raman spectroscopy are used to understand the interfacial bonding. (Note that these are difficult experiments as we are extracting information from just a few atomic planes buried under a film and in the presence of a substrate). If the results of such experiments could be predicted theoretically using the interface model, than comparison between theory and experiment can be used to validate the atomic model of the interface.

Therefore, the problem of modeling an oxide interface has two parts: first, an atomistic model of the interface needs to be generated. We emphasize that this is a complicated task as often the atomic geometry and bonding across the interface are not known a priori. Once a structural model is generated, one can compute some of its properties observable in experiment, such as the valence band density of states that can be checked with X-ray or UV photoemission spectroscopy (XPS and UPS, respectively), core-level shifts that can be probed by XPS, or interface-specific vibrational modes to be compared with IR or Raman data. These theoretical values should then be compared with the available experimental data for validation. If the model passes the validation, the second part can be accomplished by computing the device-specific properties of interest.

In this chapter, we will briefly introduce oxide materials in Sect. 2 and describe different types of technologically important oxide interfaces in Sect. 3. In Sect. 4, we will briefly introduce density functional theory and discuss specific methods of building structural models of the interface. Several recent examples of model validation will be given in Sect. 5, and in Sect. 6 we will discuss computational modeling of physical properties of several interfaces. In conclusion, we will describe various remaining challenges in modeling oxide interfaces.

2   Oxides

Oxides are compounds of oxygen with other elements. For the purpose of the following discussion, we shall divide oxides into categories based on the chemistry of the constituent metals and the degree of long-range order. Thus, we will distinguish simple oxides (e.g., SiO_2 or Al_2O_3, see Fig. 2) from transition metal oxides (e.g., VO_2 or $SrTiO_3$) and crystalline oxides (e.g., MgO or α-quartz SiO_2) from disordered or amorphous oxides (amorphous HfO_2 or amorphous SiO_2).

Traditionally, oxides are thought of in terms of the ionic model, where a positively charged metal cation is surrounded or coordinated by negative oxygen anions. This view has some limitations but captures the main feature of oxide structure: the need to minimize the electrostatic energy of a system of positively charged metal ions and negatively charged O^{2-}. The negative oxide ion O^{2-} cannot exist in free space and is only stabilized by the ionic lattice (its Madelung potential) and therefore is extremely sensitive to crystal structure. The key attributes of a crystal structure are stoichiometry and coordination. Stoichiometry describes the relative number of different atomic species and coordination describes the number of ions surrounding a given ion. For example, in the case of α-quartz SiO_2, the stoichiometry says that for each Si ion we have two oxygen ions. The coordination of Si by oxygen is 4 (each Si has 4 oxygen nearest neighbors) and that of oxygen by Si is 2 (see Fig. 2).

The structure is a (4;2) network of almost rigid, corner sharing SiO_4 tetrahedra. On the other hand, the description of the crystal structure in terms of bonding can be insightful. Figure 2 shows the ball-and-stick atomistic model for α-quartz as well as for corundum Al_2O_3 that shows how each atom is bonded to its neighbors.
Fig. 2   Simple oxides: SiO_2 a-quartz (left) and corundum Al_2O_3 (right)
Fig. 3 The simple perovskite structure of cubic SrTiO$_3$ on the left is in sharp contrast with the distorted perovskite-related structure of LaCoO$_3$. The important physics is captured in the tilts of oxygen octahedra shown in blue

The simple perovskite structure ABO$_3$ (SrTiO$_3$, BaTiO$_3$) is shown in Fig. 3. The Ti ions are in the center of a cube and are six-fold coordinated by oxygen ions that assume the centers of cube faces, while Sr is at the cube corners. The structure has a transition metal ion on the B site (in this case Ti) octahedrally coordinated by oxygen. The A site is 12-coordinated in the ideal perovskite, but the coordination can be reduced to as low as 8 by tilting the BO$_6$ octahedra. The ideal perovskite structure is cubic, with orthorhombic and tetragonal phases being the most common noncubic distortions of the structure. A simple structure like that is well explained by a ball-and-stick model shown on the left side of Fig. 3. At the same time, LaCoO$_3$ crystallizes in a structure that is related to a perovskite but is slightly more complicated (rhombohedral distortion). On the right side of Fig. 3, we show the structure with corner-sharing octahedral units explicitly present. The octahedra are rotated and tilted with respect to the orthogonal axes but maintain connectivity. These distortions have a profound effect on the properties of LaCoO$_3$, but the transition metal coordination has not changed. Structurally related to perovskite oxides are bronzes (e.g., WO$_3$) that can be viewed as a perovskite with all A cation sites vacant.

Many common binary oxides crystallize in the cubic ***rock salt*** structure (MgO. CaO, NiO, MnO, and EuO); this structure is shown in the left panel of Fig. 4. Each atomic species is on a separate face-centered cubic Bravais sublattice. The coordination number of each atom is 6. Each metal ion is coordinated by 6 oxygen ions and each oxygen is coordinated by 6 metal ions. In terms of coordination polyhedra, the rock salt structure is composed of edge-shared octahedra. The space group is Fm$\bar{3}$m. The interatomic distance is half of the cubic unit cell length.

Another common structure of binary oxides is tetragonal ***rutile*** (TiO$_2$, SnO$_2$, and RuO$_2$). A unit cell of TiO$_2$ rutile is shown on the right side of Fig. 4. The metal
Fig. 4 The rock salt structure of MgO is shown on the left and a primitive unit cell of rutile TiO$_2$ is shown on the right

cations are six-fold coordinated by oxygen atoms, which form an octahedron around them. These octahedra are arranged in a combination of edge- and corner-sharing. The oxygen anions have a trigonal planar coordination with a coordination number of 3. The space group is $P4_2$/mnm.

Simple oxides such as MgO, SiO$_2$, or Al$_2$O$_3$ differ from the complex transition metal oxides, such as SrTiO$_3$, in their nature of bonding. Simple sp^3 metals such as Si or Al are typically found in a single dominant oxidation state of 4$^+$ or 3$^+$, respectively, and the properties of corresponding oxides are described well within the band structure picture. On the other hand, the ions of transition metals can support multiple oxidation states due to complex electronic reconstruction in the often-correlated d shell. The five-fold degeneracy of the transition metal d state is lifted by the cubic field of the oxygen octahedron. As a result, a triplet known as a t_{2g} state and a doublet known as an e_g state are separated in energy by an energy gap known as the crystal field energy 10Dq. Including into consideration the interaction between the metal d orbitals and p orbitals of the oxygen, adds another energy separation, now between the bonding and antibonding combinations of these states, which is known as a charge transfer gap Δ_{CT}. If the metallic d states are strongly localized, one can think of the problem in the atomic limit and use Hund's rules to predict the electronic configuration. If localization is weak, the itinerant or band structure picture is appropriate. In the intermediate regime, one encounters Mott-Hubbard physics and the eponymous metal-to-insulator transition. If the interaction with the lattice is strong, then Jahn-Teller physics becomes important. The surprising closeness of all the aforementioned energies is responsible for the astounding richness of phenomena observed in transition metal oxides and the reason why they are called complex oxides.

3   Types of Interfaces

As we have discussed in the introduction, depending on the technological application, an oxide film can have interfaces with different types of materials. A simple oxide can interface with a semiconductor, as in the case of the SiO_2-Si interface of the metal-oxide-semiconductor (MOS) stack. One can also have an interface between a complex and a simple oxide, like in the case of SiO_2-HfO_2 that occurs in high-k gate stacks of FETs (Sharia et al. 2007). In the same devices, HfO_2 also has an interface with metals such as Mo (Demkov 2006). The very same metal-complex oxide interface is also responsible for the operation of resistive random access memory (RRAM) devices (O'Hara et al. 2014). Complex oxides can have interfaces with each other as in $LaAlO_3$/$SrTiO_3$ (LAO/STO) interface and so can simple oxides, for example, SiO_2/Al_2O_3 in core-shell structures.

In the field of medical implants, biominerals such as hydroxyapatite (HA) have interfaces crucial to their use, for example, with Ti, water, and the TiO_2 substrate. Wetting properties at the hydroxyapatite/H_2O interface govern its stability characteristics and bioactivity as the hydroxyapatite crystallites get exposed to aqueous solutions in vivo, whereas wetting of hydroxyapatite on the TiO_2 surface dictates its adhesion characteristics to the implant backbone. In addition to the active experimental research conducted in this area (Leon and Janson 2009), a fundamental theoretical understanding of the physics and chemistry at the two relevant interfaces (TiO_2/HA and HA/H_2O) is clearly needed (Slepko and Demkov 2011, 2013). While strong adhesion of HA to the TiO_2 substrate is necessary to prevent premature deterioration of the implant's surface, water is the main medium affecting its ability to connect to biological tissue once immersed into the human body.

Complex oxides can exhibit a wide variety of novel functional properties such as ferromagnetism, ferroelectricity, and metal-insulator transitions, which have been extensively studied during the past decades (Imada et al. 1998). Furthermore, it has even become possible to create and control hybrid oxide heterostructures with abrupt epitaxial interfaces owing to recent advances in the field of oxide heteroepitaxy (Chambers 2010). Epitaxial deposition techniques with the capability of controlling interface composition, length scales, etc., have opened totally new and exciting scientific avenues and have also offered novel device applications to explore (Hwang et al. 2012). One of the most important findings in this research direction is the creation of the two-dimensional electron gas (2DEG) between two insulating complex oxides, which are LAO and STO (Ohtomo and Hwang 2004). The origin of the 2DEG has been largely discussed in the literature, ranging from the original polar-catastrophe argument to the presence of interfacial O vacancy and intermixing at the interface (Mannhart et al. 2008). Furthermore, the LAO/STO interface shows a rich variety of interesting physical properties including magnetism, superconductivity, etc. Now, the field is expanding, exploring epitaxial interfaces of diverse complex oxides, and finding new physics and new emergent phenomena (Chakhalian et al. 2014).

In addition to the interface effects for the emergent properties of oxide heterostructures, bulk properties of an oxide material can be drastically changed (and controlled) when it is integrated as a part of heterostructure (Ismail-Beigi et al. 2017). A key example is strain engineering that one can achieve by epitaxially growing one oxide material on another oxide substrate having a different lattice constant. The perovskite oxides are known to accommodate a relatively high degree of structural distortion such as rhombohedral and tetragonal distortions. In particular, the lattice has additional degrees of freedom in the oxygen octahedra, which can cooperate to tilt and rotate under external perturbations (Rondinelli et al. 2012). Therefore, for the oxide overlayer commensurate with the substrate, epitaxial strain can directly affect the lattice degrees of freedom. Several studies have shown that strain engineering of oxide heterostructures could stabilize novel electronic phases that are not present in their bulk constituents, owing to the close interplay between the lattice, orbital, and spin degrees of freedom present in the complex transition metal oxides (Ismail-Beigi et al. 2017). One exciting example is the recent demonstration of biaxial tensile strain stabilizing an insulating ferromagnetic ground state in $LaCoO_3$, which is normally nonmagnetic at low temperature (Fuchs et al. 2007a, 2008). A number of possible mechanisms have been discussed including low-spin/high-spin mixed state (Seo et al. 2012a) and formation of ordered O vacancy structures (Gazquez et al. 2013).

In the field of renewable energy, oxide-based interfaces play a crucial role, in particular, for the photocatalytic water splitting to generate hydrogen fuel. The interfaces of interest are oxide/nano-metal-clusters (Schneider et al. 2018) and oxide/liquid interfaces (Björneholm et al. 2016). Many complex oxides were identified as promising candidates for photo-catalysts for water splitting. $SrTiO_3$ is an excellent example (Carr and Somorjai 1981). The band gap of STO is 3.2 eV, and its conduction-band minimum, which is positioned about 4.0 eV below the vacuum level, matches up well with the redox potential of water. The overall quantum efficiency is, however, low and a number of limiting factors have been discussed (Chen et al. 2010). A major challenge is to decrease the electron-hole recombination rates after they are created by photon irradiation. A possible solution to this problem is to develop a suitable heterogeneous catalyst that could efficiently separate electrons and holes at the interface. Notably, noble metals, such as Pt, are frequently loaded on titania as a co-catalyst to boost the catalytic activity (Paracchino et al. 2011). The enhanced catalytic activity has been attributed in part to the fact that the rectifying behavior of the Schottky barrier formed between STO and Pt may allow Pt nanoclusters on the oxide surface to trap electrons, effectively reducing the oxidants in a photocatalytic process (Chen et al. 2010). In addition to the oxide/nano-metal-cluster interface, the oxide/water interface is also very important to understand as in a typical photo-electrochemical environment, mixed oxide catalysts are interfaced with water. Thus, the oxide/water interface is actually a crucial component of the entire device to split water. In this regard, there is an excellent review recently published to discuss atomistic modeling of oxide/water interfaces (Pham et al. 2017).

In most cases, we do not know how two materials match at the atomic level, so we need to model the interface theoretically. Usually one tries several plausible atomistic models and chooses the one with the lowest total energy, though nature uses the lowest free energy. One could, in principle, include the entropic terms due to, e.g., cation intermixing and phonons, but it is difficult and not usually done. Also, depending on the type of the interface, one can get away with a small segment replicated via the periodic boundary conditions. But if materials are not epitaxial, a larger lateral length scale is required, which puts an additional constraint on what calculation methods can be used.

4   Atomistic Modeling of Oxide Interfaces

4.1   Density Functional Theory

In this section, we describe modeling techniques to generate atomic level structural models of various oxide interfaces. Systems of interest include metal-oxide, oxide-oxide, and semiconductor-oxide interfaces. There are two basic ways to model the interface structure at the atomic level. One can either model the process of the interface creation, e.g., oxidation of Si or growth of a thin film. Then the interface structure comes out as a result of a direct simulation. Alternatively, one can make a guess of an interface by matching two materials and optimizing bonding across the resulting interface in a simulation. The process modeling or the optimization can be done using molecular dynamics (MD) or Monte Carlo (MC) methods. In turn, the forces used in MD simulations or the energy expression in MC simulation can be classical or quantum mechanical. Classical potential fields offer the advantage of scale (larger systems can be modeled because the simulation is fast), while quantum mechanical treatment offers higher reliability, but at much higher cost. Validation is usually done quantum mechanically, though some properties and, in particular, the mechanical properties can be modeled classically. And of course, magnetic, electric, or optical properties all require a quantum mechanical treatment. Thus, we start with a brief introduction to ab initio techniques.

Density functional theory (DFT) has gained wide-spread acceptance as one of the predominant ab initio or "first-principles" tools for materials modeling owing to its ability to provide relatively accurate atomic and electronic structures under the appropriate approximations. Fundamentally, the task is to solve the many body Hamiltonian for the system in question which is comprised of the kinetic energy of all electronics and nuclei as well as their interactions with each other and is simplified via application of the Born-Oppenheimer approximation (Born and Oppenheimer 1927). Although several methods exist to tackle the problem of determining the electronic structure including Hartree-Fock, configuration interaction, coupled cluster, and perturbative approaches, density functional theory remains one of the most efficient and accurate methodologies. Density functional theory would be an exact theory if the appropriate exchange-correlation (XC) and kinetic energy functionals could be found. While no such universal functional is known,

we rely on a series of approximations and improvements such as the local density approximation (LDA), generalized gradient approximation (GGA), meta-GGAs, and hybrid functionals. As an example, in LDA, the XC potential depends only on the values for the homogeneous electron gas density for a given position in space with the exchange portion calculated exactly and the correlation portion parameterized from quantum Monte Carlo simulations (Ceperly and Adler 1980). Two of the most common flavors of LDA are due to Vosko-Wilk-Nusair (VWN) (Vosko et al. 1980) and Perdew-Zunger (PZ81) (Perdew and Zunger 1981) that use different interpolations of the Ceperly and Adler data. GGA functionals introduce some nonlocality to the XC functional by introducing spatial gradients of the electron density to the functional as in the popular functionals of Perdew-Wang (PW91) (Perdew et al. 1992), Perdew-Burke-Ernzerhof (PBE) (Perdew et al. 1996), and others. Generally each successive step for the functional introduces additional computational complexity and the researcher must choose the best functional to describe the system with a reasonable computational cost. For further details on these developments of DFT, we direct the reader to Chap. 11, "Recent Developments in Density Functional Approximations," by Li and Burke in Handbook of Materials Modeling, Vol. 1, Methods: Theory and Modeling.

Beyond the choice of the functional, other considerations must be made. From a practical standpoint, the wave-functions must be determined within a basis set including real-space finite-difference approaches (such as in the PARSEC code (Chelikowsky et al. 1994a, b)), localized orbitals such as Gaussians (Boys 1950) or linear combinations of atomic orbitals (like in the SIESTA code (Soler et al. 2002)), slater-type orbitals (Slater 1930), plane-wave methods, and hybrid methods which combine localized regions and plane waves (such as (linearized) augmented plane waves (Singh and Nordstrom 2006) and localized muffin-tin orbitals (Skriver 1984)). Owing to their ease of use in systems with periodic boundary conditions, plane-waves are a common choice and implemented in the popular Vienna *ab-initio* Simulation Package (VASP) (Kresse and Furthmüller 1996) and QUANTUM ESPRESSO codes (Giannozzi et al. 2009). Regardless of the basis set used, care must be taken to ensure proper convergence (whether this is the finite-difference grid spacing, number of higher order local orbitals, or the plane-wave cutoff energy). In the case of plane-wave-based codes, portions of the calculation are performed in reciprocal space (or momentum space) and the Brillouin zone must be sampled on a well-converged grid of points (often a Monkhorst-Pack grid (Monkhorst and Pack 1976)). As the volume of the real space cell and reciprocal space Brillouin zone are inversely proportional, fewer k-points are needed for calculations of supercells and heterostructures than their primitive cell counter parts.

Finally, including all electrons in a calculation can lead to severe limits on system size. For example, in the (100) $BaTiO_3$/(100) Pt simulation cell discussed later and shown in Fig. 6 (Fredrickson et al. 2013), there are 10 Ba atoms, 11 Ti atoms, 32 O atoms, and 20 Pt atoms which would imply a total of 2618 electrons. Fortuitously, only the valence electrons participate in the formation of bonds. Hence, we can replace the total electron interaction with an effective interaction through the use of pseudopotentials which treats the core electrons as effectively screening the

nuclear interaction. In certain cases, electrons that are a few shells removed from the valence may also be included explicitly (the so-called semi-core states) to improve the description of the valence electrons. Through the use of pseudopotentials, the total number of considered electrons in the (100) BaTiO$_3$/ (100) Pt is actually only 582, cutting the number of electrons considered by roughly 80%. Common choices include norm conserving pseudopotentials (Rappe et al. 1990; Troullier and Martins 1991) with various pseudoization schemes, ultrasoft pseudopotentials (Vanderbilt 1990), and the projector-augmented wave (PAW) method (Blöchl 1994; Kresse and Joubert 1999).

For the reader wishing to explore further the theoretical and numerical underpinnings of DFT, we direct them to Li and Burke's chapter as well as several other highly detailed treatments such as in (Dreizler and Gross 1990; Engel and Dreizler 2011; Fiolhais et al. 2003; Martin 2004) as well as the manual of their chosen DFT code.

4.2   Construction of Interface Models

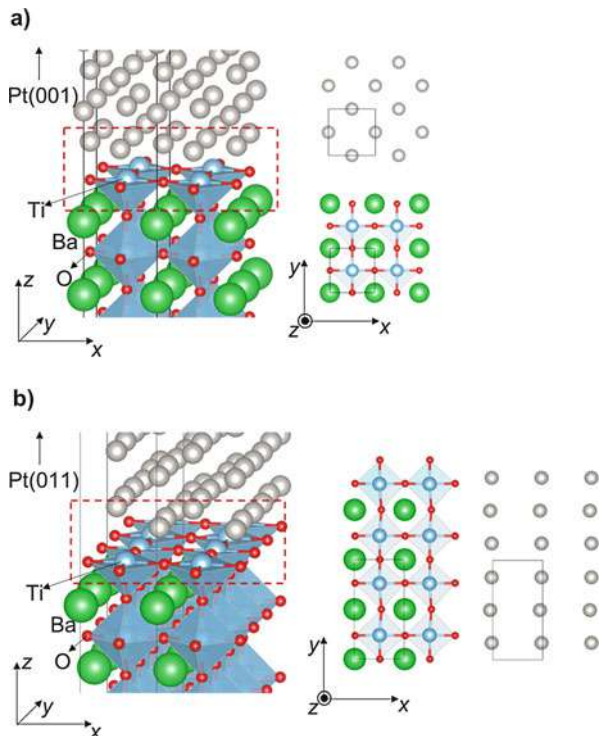
In the following discussion, we will assume that the interface is always perpendicular to the c axis of the considered substrate for convenience. Once the Miller indices of the substrate and the film have been decided, the next step is to consider the alignment of materials A and B. In order to do this, one must consider the most likely source of bonding at the interface. For example, one may want to line up the interface such that the O atoms at the oxide surface are able to bond with appropriate atoms at the interface (there is a strong probability of Ge-O bonds at the Ge/Oxide interface (Fredrickson et al. 2014); however, bonding with O at a noble metal/oxide interface, such as Pt, is probably not very energetically favorable (Fredrickson et al. 2013)).This requires using physical and chemical intuition and there are at best only rough guidelines to follow, and most likely several alignments of the two materials must be tried to find the lowest energy interface. To find the optimum separation distance, an efficient method is to vary the interfacial spacing between the two materials, perform several DFT calculations, and fit the energy/distance curve quadratically to find the expected minimum.

Once an appropriate interface alignment has been chosen, one needs to consider the possible "defects" or missing or extra atoms present at the interface. For example, there may be vacancies at the interface (missing atoms) from either material, or possibly both. These defects are stabilized by chemical conditions at the interface that would not otherwise be energetically favorable in the bulk or at the material's surface (defects also reduce free energy of the system via the entropy term, but this effect is rarely included in the first principles analysis). In addition, extra atoms may be present at the interface that depend heavily on the chemical conditions of the interface under consideration (e.g., extra O atoms may be present at the interface when grown under oxidizing conditions (Fredrickson et al. 2014), whereas you may not expect these same atoms for materials grown under high vacuum (Fredrickson et al. 2013)). Treatment of the substrate chemically may
Fig. 5 An example of an interface (Ge/BaTiO$_3$) that includes considerations for interfacial alignment, interfacial atoms, and defects. Green atoms are Ba, red atoms are O, blue atoms are Ti, pink atoms are Sr, and purple atoms are Ge

introduce other atoms to the interface (e.g., for BaTiO$_3$ grown on Ge, Sr, or Ba atoms are sometimes introduced as a passivation layer, and these atoms are critical for predicting correct band gaps and electronic properties (Fredrickson et al. 2014; Ponath et al. 2015). Examples of the above extra conditions are listed below in Fig. 5.

The implicit assumption we have made so far is that there are just as many unit cells of the substrate A as there is film B, but this will not always be true. This will only work if the specific cut of both the film and the substrate have similar lattice constants, which minimizes the strain of the film. If this is not the case, and the one-to-one unit cell matching between the substrate and film induces a tensile or compressive strain greater than about 5%, the energetics of film growth will be unfavorable, and the results from the calculation will be unphysical. Thus, it is important to find whatever n-to-m (coincidence lattice matching) ratio minimizes the strain and does not result in too large of a unit cell to be unpractical to calculate (e.g., a 10-to-13 matching of substrate may give a very low strain on the film but may be hard to calculate because the system is so large!). One also must consider if the interface matches in both directions of the plane (e.g., the interface may match 1-to-1 in the x direction but (2-to-1) in the y direction). This mismatch can also depend on the specific cut of the film and substrate (Fig. 6).

Another common pitfall on interface modeling is specifically due to the electronic structure, not to the atomic structure as discussed above. Due to the underestimation in band gaps for the LDA and GGA approximations, there can be issues with band alignment due to the incorrect position of the valence band and conduction band of the substrate with respect to either the Fermi level of the metallic film, or the valence or conduction bands of the semiconducting film (e.g., the conduction band of the substrate can be lower in energy than that of the Fermi level of the metal, even though the experimental work functions and electron affinities of the substrate and metal are predicted to be ordered oppositely). In such cases there is a flow of charge from the substrate to the film (or vise-versa) which is unphysical

Fig. 6 An interface between BaTiO$_3$(001) and Pt, with the supercell model of BaTiO$_3$/Pt in a solid-line box. (**a**) The Pt is grown in the (001) direction, with 1-to-1 alignment of Pt on BaTiO$_3$; the alignment is 1-to-1 in the both x- and y-direction. The figures on the right side show the first layer of Pt (top) and the surface layer of BaTiO$_3$ (bottom) at the interface region indicated with a red dashed box in the supercell model. (**b**) The Pt is grown in the (011) direction. The interface matching condition (red dashed box) is shown on the right side in detail, in which a (2x1) BaTiO$_3$ surface cell is used to match the (3x1) Pt(011)


and is solely due to the incorrect energy level ordering in the simulation. To prevent this unphysical flow of charge, a higher level of theory is required that can give more accurate band gaps, such as hybrid functionals (Krukau et al. 2006) or the *GW* method (Fuchs et al. 2007b; Shishkin and Kresse 2006, 2007; Shishkin et al. 2007). A computationally less expensive solution is to use the LDA + U method (Dudarev et al. 1998), which includes a Hubbard-type U that can also increase the band gaps of materials, and which is also effective in preventing the unwanted charge transfer.

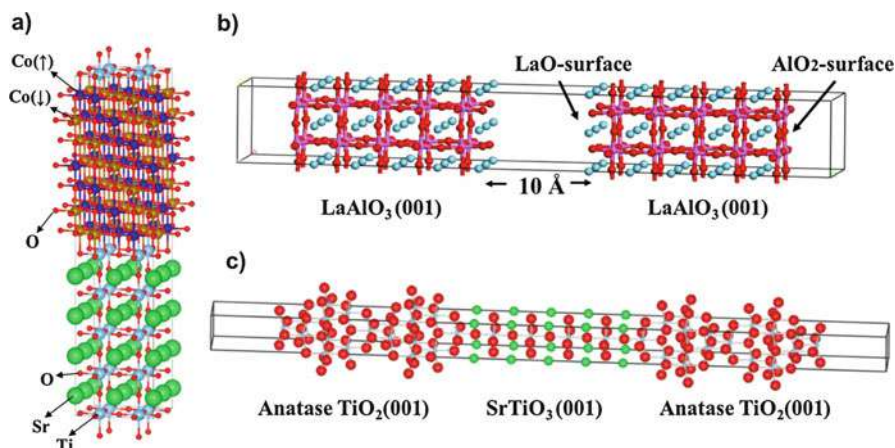
Due to the periodic boundary conditions used in many DFT codes, any calculation must enforce an equal potential at both sides of the cell, i.e., the potential at $z = 0$ and $z = l$ must be equal, where l is the total length of the simulation cell. This provides an extra complication for modeling interfaces, where, by definition, the simulated cell is not symmetric. An important note is that the code will enforce boundary conditions, meaning that if the cell is set up incorrectly, there will be an unphysical electric field across the cell that one might not expect! There are two commonly used methods to avoid this problem. The first way is to consider a symmetric cell, so that the condition of periodic potentials is automatically satisfied (Fig. 7a). For surface problems, one could include a mirror-symmetric structure of a slab model in a supercell to meet the periodic boundary condition as shown in Fig. 7b. A similar method can be used for an interface problem, for which a symmetric supercell such as one shown in Fig. 7a is not possible to construct. As


Fig. 7 A choice for the interface model between material A and B that does not satisfy periodic boundary conditions. (**a**) A superlattice structure could be constructed to study the interface between antiferromagnetic CoO(001) and SrTiO3 (001) within the periodic boundary condition. (**b**) For a surface problem where the surface dipole or an internal dipole moment play an important role, a symmetric slab model could be constructed by containing a slab model's mirror-symmetric structure in the same supercell. An example of polar $LaAlO_3$(001) is shown. (**c**) The mirror-symmetry method described in (**b**) could be used to study an interface problem, for which the superlattice approach (**a**) is not possible. An example of the anatase TiO_2/$SrTiO_3$(001) interface is shown, in which the periodic boundary condition along the c-axis is satisfied by including the TiO_2 layer and vacuum on both sides of the $SrTiO_3$(001) slab. (With permission from Seo and Demkov (2011, 2014), and Seo et al. (2012b))

shown in Fig. 7c, one could include vacuum on either side of the slab to satisfy the periodic boundary condition (Fig. 7c). However, sometimes, this first way of dealing with an artificial electric field could be computationally demanding as it would require doubling the supercell size. To be more computationally efficient, one could use an asymmetric slab model with a dipole field correction that is equal in magnitude but opposite in direction to cancel the artificial electric field induced by the use of an asymmetric slab model (Bengtsson 1999; Makov and Payne 1995). A self-consistent dipole is added to the system with a magnitude chosen to counteract the dipole created by having unequal surface termination on either side of the slab; this dipole creates a large jump in the electronic potential, which ensures that the vacuum levels remain flat. Since the dipole is placed in vacuum, it is far enough away from the surfaces of the slab to not affect the interface or bulk properties of the system. This counteracts the unphysical electric field caused by the nonequal surfaces of the system. In Fig. 8, we show the electrostatic potential calculated for a layer of water, which is highly polar, with and without the dipole correction. We see that without the dipole correction, there is an unphysical field in the vacuum which forms due to the periodic boundary conditions of the cell. With the dipole correction, this field is localized in the vacuum region of the cell, and the electrostatic potential of the water layer is unaffected.

Fig. 8 Laterally averaged electrostatic potential for the electrons in the supercell, with (solid-curve) and without (dashed-curve) dipole correction. (With permission from Bengtsson (1999))
Despite their success, it is worth remembering that *ab initio* methods have some limitations. In particular, the length and time scales of such simulations are rather limited, and in many cases, classical MD and MC techniques become very useful. For example, a problem of cationic exchange at the $LaAlO_3$ and $SrTiO_3$ and its effect on the formation of the two-dimensional electron gas (2DEG) at this interface (Ohtomo and Hwang 2004) has recently received a lot of attention. Stoichiometric epitaxial $LaAlO_3$ grown on TiO_2-terminated $SrTiO_3$ (001) by off-axis pulsed laser deposition is shown to exhibit strong cation intermixing. Qiao and co-workers performed a detailed study of this system using a combination of classical and quantum mechanical calculations of the relative stabilities of abrupt and intermixed interface configurations (Qiao et al. 2010). They were able to show very convincingly that the experimentally measured valence band offset of 0.16 ± 0.10 eV cannot be accounted for theoretically without including intermixing in the physical description of the interface.

5   Validation of Interface Models

There are many experimental methods used to study interfaces, such as scanning transmission electron microscopy (STEM), electron energy loss spectroscopy (EELS), XPS, angle-resolved photoemission spectroscopy (ARPES), and they all can be used to validate the structural model. One needs to use the theoretical structure of the interface and compute a measured quantity. If several properties of the interface are well reproduced, the model is most likely reliable.

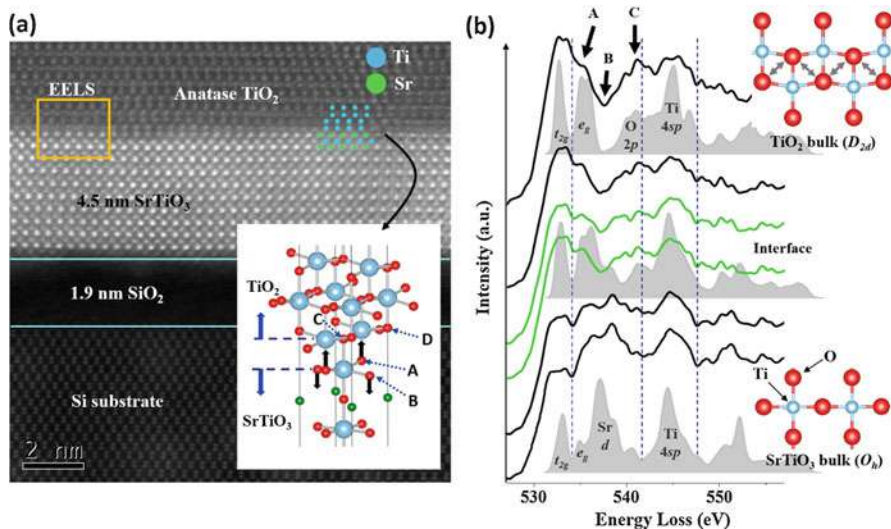
The combination of STEM and EELS is one of the most powerful methods to validate an interface model of an oxide-based heterostructure (Varela et al. 2012). The basic principle of STEM is described in detail elsewhere (Pennycook and Nellist 2011). In a STEM image, an atom with a greater atomic number produces a brighter spot than others with a lower atomic number. Using this "Z-contrast"


Fig. 9 (**a**) Z-contrast STEM image of the $TiO_2/SrTiO_3$ (001) structure and its atomic interface model (inset). Ti, O, and Sr are represented by large blue ball, middle-sized red ball, and small green ball, respectively. In the inset, black arrows show the relaxation pattern of the O ions at the interface. Spatially resolved EELS measurement was performed at the region indicated by the orange box. (**b**) EELS O K edge spectra taken at the interface from the STO side (two bottom spectra) to the anatase TiO_2 side (two upper spectra) through the interface (two middle green spectra). The corresponding 2p-projected DOSs calculated within the $Z + 1$ approximation are overlaid in grey. Two insets show schematic pictures of a TiO_2 plane in bulk anatase TiO_2 (top) and bulk STO (bottom). (With permission from Seo et al. (2012b))

property, one can directly image an oxide heterointerface at the atomic scale. Figure 9a shows the STEM image of the anatase TiO_2/STO (001) heterostructure grown on Si(001) (Seo et al. 2012b). The image was taken along the Si [110] zone axis. A well-ordered epitaxial relationship is shown in the image between the Si substrate, $SrTiO_3$ layer, and anatase TiO_2 film. To infer the most likely structure of the STO/TiO_2 interface, the blue and green balls were superimposed in the image, and the inset of Fig. 9a shows the deduced structural model of the interface. This atomic model can be used as input to subsequent density functional theory calculations for predicting various interface properties, which we will describe later in this chapter.

In addition to atomic-scale imaging, one can analyze the energy of beam electrons in STEM inelastically scattered from the sample (known as electron energy loss spectroscopy or EELS (Pennycook and Nellist 2011)). The inelastically scattered electrons carry information about the local electronic structure of the atom or the local region that they scattered off. Therefore, one can further verify an interface model deduced from a STEM image by comparing the EELS spectrum that is simultaneously obtained from the region of the STEM image to the electronic structure theoretically calculated with the interface model.

For the $TiO_2/SrTiO_3$ heterointerface shown in Fig. 9a, an EELS spectrum was taken across the interface and is shown in Fig. 9b. In particular, an O K-edge spectrum was taken, in which beam electrons in the STEM measurement lose their energy by exciting the 1 s core electrons of oxygen atoms. We note that the optical electronic transition observed in EELS should satisfy the dipole selection rule: the angular-momentum quantum number of a final state should differ by $+1$ or -1. Therefore, in the O K-edge spectrum in Fig. 9b, the 1 s electrons of oxygen atoms are excited into the empty O 2p states of the TiO_2/STO heterostructure. This means that the scattered beam electrons provide the conduction band structure of the TiO_2/STO heterostructure that is derived from the antibonding states of O 2p orbitals.

To track the evolution of the antibonding states of O 2p orbitals across the TiO_2/STO interface, Seo et al. performed DFT calculations (Seo et al. 2012b) at LDA level of theory, using the Ceperley-Alder data parametrized by Perdew and Zunger (1981), as implemented in the VASP code (Kresse and Furthmüller 1996). Projector-augmented wave pseudopotentials (Blöchl 1994) were employed to describe Sr, Ti, and O, along with a plane-wave cutoff energy of 600 eV. Several supercell models were constructed by varying the anatase film thickness from four to eight monolayers in order to model the evolution of the valence band as a function of the film thickness. The slab in each supercell was separated from its nearest neighboring images in the c-direction by 14 Å-thick vacuum space to avoid any artificial interactions.

At the bottom of Fig. 9b, the O K-edge spectrum taken from the STO bulk region is compared to the 2p pDOS calculated at the O site in the STO bulk region of the TiO_2/STO interface model. In experiment, three main features are found between 530 and 550 eV, which are all well reproduced in theory. The first, second, and third main peaks were identified as peaks derived from the interaction with Ti t_{2g}, Sr d, and Ti 4sp states, respectively. On the other hand, in the spectrum taken from the anatase bulk region, quite different spectral features are observed. In addition to the absence of the Sr d peak, there is an appearance of a large spectral weight between 538 and 543 eV (position C), which is not found on the STO side. This peak turns out to be derived from the interaction with the nearest-neighbor O along the c axis as shown in the inset of Fig. 9a. Furthermore, this spectral peak originally emerges at the interface, as shown in the middle of Fig. 9b. When two oxide slabs are brought into contact, chemical bonds are created that result in charge redistribution in conjunction with a structural distortion at the interface. Note that half of O at the "STO surface" is bonded to Ti of anatase, leading to three-fold coordinated O ($O_{3\text{-fold}}$, site A), while the other half of O remains two-fold coordinated ($O_{2\text{-fold}}$, site B). Ti at the STO surface is also bonded to O of anatase at site C. By comparing with the 2p pDOS at the $O_{3\text{-fold}}$ site of the interfacial layer (site A in Fig. 9a), this peak at the interface is identified as the result of the chemical bond formation between anatase TiO_2 and STO. The excellent agreement between the EELS spectrum and the theoretical electronic structure of the interface provides a strong verification of the interface model.

Core-level x-ray photoemission spectroscopy (CXPS) combined with first-principles calculations is another great tool for validation of an atomic model of

a heterostructure (Hufner 2003). When x-ray photons with sufficiently large energy are injected into a sample, they can excite several core-level electrons above the vacuum level. The excess energy of the photo-ejected electrons is transformed into kinetic energy, thus carrying information of the binding energy of the core electrons. The core levels are highly sensitive to the local electronic environment mainly through electrostatic effects and in turn, to the local atomic environment. Therefore, a combination of electronic structure calculation and core level shift measurement can provide a tool to probe the structural information of an interface at atomic scale.

Figure 10 compares the Si 2p core level shifts (CLS) of the bare (2x1) Si(001) surface with those of the Si(001) 2x1 surface in the presence of ½-ML Sr layer on top (Choi et al. 2013a). The notable difference between the two structures is the flattening of the Si dimers on the surface in the presence of the interface with the ½-ML Sr layer. When adsorbed on the Si(001) surface, Sr transfers two electrons to a Si dimer, thus removing the need of Si dimer buckling. In the Si 2p CLS of the Si(001) surface, one can observe two dimer-atom-related peaks labeled as Su and Sd, which are positioned at -0.43 eV and 0.12 eV, respectively, with respect to the Si 2p peak derived from the bulk Si. At the interface of the ½-ML Sr/Si(001) structure, only one dimer-atom-related peak is observed at -0.33 eV with respect to the bulk peak.

In Choi et al. (2013a), the CLS spectrum is also calculated theoretically using the first-principles final state theory based on density functional theory. They performed CLS calculations using the VASP code (Kresse and Furthmüller 1996) at LDA level of theory with the Ceperley-Alder data parametrized by Perdew and Zunger (1981). The PAW pseudopotentials (Blöchl 1994) were used to model Si and Sr along a plane-wave cutoff energy of 500 eV. The Si surface was modeled using a 16-layer thick slab, which was separated from its periodic images in the c-direction by 15 Å of vacuum. They considered the Si(001) p(2×2) surface and the (2×1) surface of 1/2 monolayer (ML) Sr on Si(001). They treated both surfaces of the slab as active surfaces and no hydrogen passivation was used.

When a core electron is excited by a photon with an energy of $h\nu$ and emitted from a sample with a kinetic energy, E_{kin}, the binding energy, E_B of the electron is defined by

$$E_B = h\nu - E_{kin} - \varphi = E\left(n_c - 1\right) - E\left(n_c\right),$$

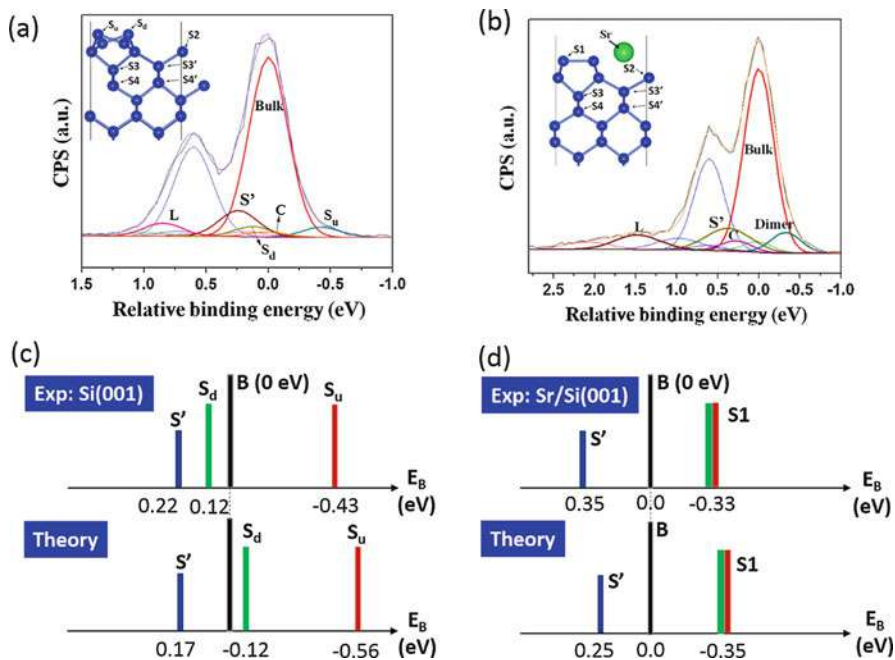
where φ is the work function, $E(n_c)$ and $E'(n_c-1)$ are the system's ground and excited state energies, respectively, with n_c being the number of core electrons. The quantities on the left-hand side can be determined experimentally, and the total energies on the right-hand side are the subject of theoretical calculations. A simple theory to calculate the CLS is based on the Koopmans' theorem in the Hartree-Fock theory, stating that the binding energy is the same as the orbital energy under the frozen orbital approximation (Hufner 2003). Thus, in this theory, the CLS is the same as the shifts of the orbital energy in the ground state due to the change of the local electrostatic potential. This contribution to the CLS is known as the initial state effect. In addition, when a core hole is created, the system tends to screen it


Fig. 10 (**a**, **b**) Si 2p core-level spectrum of clean 2x1 Si(001) (**a**) and ½-ML Sr/Si(001) (**b**) by in situ XPS at room temperature. The energy positions of all components are expressed in terms of the binding energy relative to the binding energy of the well-resolved bulk component. The insets in (**a**) and (**b**) are theoretical structures of Si(001) and ½-ML Sr/Si(001), respectively, obtained from the DFT calculations. Si atoms in the top four layers relax significantly and symmetrically different atoms are labeled accordingly. (**c**, **d**) Experimental (top) and theoretical (bottom) peak positions in the CLS spectrum of Si(001) (**c**) and ½-ML Sr/Si(001) (**d**). (With permission from Choi et al. (2013a))

(the final state effect) as much as possible, providing a relaxation energy gain for the emitted electron and shifting the core level binding energy toward lower binding energy from the initial state result.

Figure 10c and d compare the experimental and theoretical CLS of the bare Si(001) surface and the ½-ML Sr/Si(001) heterostructure, respectively. We observe that the final state theory calculations well reproduce the dimer-related peak positions found in experiment for both cases. For the bare Si(001) surface, the up-atoms of Si surface dimers create a peak at -0.43 eV in experiment, which is well compared to the theoretical value of -0.56 eV. For the ½-ML Sr/Si(001) structure, the position of the dimer peak was theoretically calculated to be at -0.35 eV with respect to the bulk 2p peak, which is in excellent agreement with the experimental value of -0.33 eV. The agreement between theory and experiment strongly supports the atomic model of the Si(001)'s structural reconstruction at the interface of the ½-ML Sr/Si(001) heterostructure.

X-ray CLS is also a powerful tool to probe a buried interface (Himpsel et al. 1988). One of the most studied oxide-based interface systems for applications of CXPS was the Si/SiO_2 interface due to its paramount importance in silicon technology. For the Si/SiO_2 interface, Si 2p core level shifts were mainly used to probe the chemical and structural properties of the interface (Himspel et al. 1988). Himpsel et al. used CXPS to suggest that there is a transition region, in which three distinct intermediate oxidation states of Si are present at the Si/SiO_2 interface. The oxidation state of the atom is heavily dependent on the local O structural environment. Using this property, Himpsel et al. suggested interface models based on the density and distribution of intermediate-oxidation states. However, the underlying structural information obtained solely from the CXPS is indirect and its verification requires a reliable theoretical calculation. Later, Pasquarello et al. used density functional theory to reproduce the important features observed in the previous XPS experiments (Pasquarello et al. 1996). In addition, they combined the DFT-based CLS calculations and the experimental results to suggest and validate structural models of the Si/SiO_2 interface.

One can also use optical spectroscopy to validate interfacial models. Unlike electron microscopy, it is nondestructive and not nearly as expensive. Both IR and Raman spectroscopies are useful in probing interface or defect-related bonds. For example, understanding the atomistic details of how platinum surfaces are oxidized under electrochemical conditions is of importance for many electrochemical devices such as fuel cells and electrolysers. Recently, Huang and co-authors examined the intermediate stages of electrochemical oxidation of single-crystalline platinum using a combination of theoretical modeling and in situ Raman spectroscopy (Huang et al. 2016). The authors used in situ shell-isolated nanoparticle-enhanced Raman spectroscopy to identify the intermediate stages of the electrochemical oxidation of Pt(111) and Pt(100) single crystals in perchloric acid. DFT calculations were used to determine the vibrational frequencies of possible intermediates and products. These in turn were used to assign the experimental Raman bands. The perchlorate anion was suggested to interact with a hydroxyl phase formed on the surface. Peroxo-like and superoxo-like two-dimensional (2D) surface oxides and amorphous 3D a-PtO_2 are sequentially formed during the anodic polarization. The work provided evidence for the structure-sensitive formation of a 2D platinum-(su)peroxide phase and provided a fundamental understanding of the mechanism of degradation of platinum electro-catalysts.

Even more recently, the effect of strain and oxygen deficiency on the Raman spectrum of monoclinic HfO_2 films that serve as gate dielectrics in modern FETs was investigated using first principles calculations (Gao et al. 2017). The results provided a more detailed understanding of vibrational modes in HfO_2, which besides technological applications in transistors is important in resistive random-access memory (RRAM) whose operation relies on oxygen-deficient HfO_x. The simulations of strained oxygen deficient films were compared with experimental results of Raman frequencies for 50 nm HfO_2 thin films. It was possible to identify a localized vibrational mode at $96.4 \ cm^{-1}$ as being introduced by threefold-coordinated oxygen vacancies.

6   Band-Alignment at Oxide Interfaces from First Principles

One of the most important interface properties of an oxide heterostructure is the band offset at the interface. The band offset plays a key role in determining the carrier confinement and electronic transport along and across the interface. The discovery of novel electronic phases emerging at oxide interfaces increased interest in the band offsets of oxide heterostructures (Ohtomo and Hwang 2004; Mannhart et al. 2008). Furthermore, the understanding of band offsets is crucial for many renewable energy applications such as heterogeneous photo-catalyst for water splitting (Chen et al. 2010). However, the band offsets at oxide heterostructures are not as well understood as those between semiconductors and metals. The first step to understand the band offset of an oxide heterostructure is to understand the interfacial chemistry and atomic structure at the interface. Once a representative interfacial atomic model is obtained, one could calculate its band alignment using first-principles methods as we describe below.

In Sect. 5, we discussed an atomic model of the TiO_2/$SrTiO_3$ heterointerface, which was validated by using a combination of the STEM/EELS measurements and the DFT-based theoretical spectroscopic calculations. With this atomic model, one could proceed to calculate the band alignment of the heterostructure in two different ways using density functional theory. The first method is to use layer-by-layer projected densities of states (pDOS). Figure 11a shows the layer-by-layer pDOS of the TiO_2/STO(001) heterostructure, for which the total valence band DOS is projected to each [001] atomic plane: SrO or TiO_2 layer for $SrTiO_3$ and TiO_2 layer for anatase TiO_2. The description of the calculation setups is given in Sect. 5. To extract the valence band offset, one can compare the valence band edge on the STO side (green line in Fig. 11) to that on the TiO_2 bulk region, which was determined to be 0.7 eV.

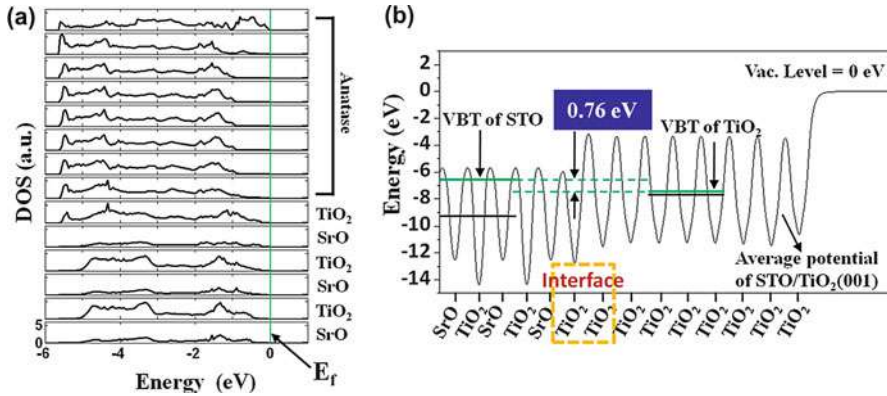
The second method of calculating the band offset at an oxide interface is to use an averaged electrostatic potential across the interface and those of the constituent bulk materials. Figure 11b shows the local electrostatic potential profile across the TiO_2/STO(001) interface, which was obtained by calculating the planar average of the local electrostatic potential and plotting it as a function of distance in the direction normal to the TiO_2/STO(001) interface. Here, "local" in the local electrostatic potential means that we only use the sum of Hartree and ionic potentials. After calculating the oscillating potential profile, one can macroscopically average the potential in the direction normal to the [001] interface plane in order to obtain the reference potential levels at the STO and TiO_2 bulk regions (black lines in Fig. 11b). Then, the next step is to position the valence band edge with respect to this reference potential level on both the STO and TiO_2 side. For this step, one can perform two separate calculations with the STO and TiO_2 bulk unit cells, in which one can directly access the position of the bulk valence band edge with respect to the average of the local electrostatic potential. Using this information, one can determine the valence band edge position on the STO and TiO_2 bulk regions of the supercell (green lines in Fig. 11b). The offset between the green lines is the band offset of the heterostructure, which is 0.76 eV. Note that this result is consistent with the result obtained using the layer-by-layer pDOS in Fig. 11a.


Fig. 11 (**a**) Layer-by-layer projected density of states (pDOS) of the $TiO_2/SrTiO_3(001)$ heterostructure. The green line is the Fermi level, which is determined by the valence band edge of the $SrTiO_3$ bulk (**b**) planar-averaged electrostatic potential of the heterostructure along the (001) direction. The straight black lines indicate the reference electrostatic energy positions with respect to the vacuum level (0 eV) in the bulk region of STO and TiO_2, respectively. The green lines indicate the relative positions of valence band edges of STO and TiO_2 with respect to their corresponding reference energy positions. (With permission from Seo et al. (2012b))

The formation of an interface and its effect on its band offset can be better understood by considering the Schottky-limit band-offset, which is an offset in a situation that no interaction is present between the constituent materials: TiO_2 and STO slabs in the case of TiO_2/STO(001) interface. Then, the valence band offset of the heterostructure can be written as $\Delta E_H = \Delta E_S + \Delta V$, where ΔE_H is the band offset of the actual heterostructure, ΔE_S is the band offset in the Schottky limit, and ΔV is the electrostatic potential drop at the interface due to the heterojunction formation. Therefore, ΔV includes all the important chemical and structural effects due to the formation of the interface. Using the same technique described above, Seo, et al. calculated the Schottky-limit valence band offset of the TiO_2/STO(001) interface to be 0.95 eV, thus ΔV is -0.2 eV (Seo et al. 2012b). The origin of ΔV is often described as the creation of an interface dipole or double layer involving charge transfer and subsequent dielectric screening at the interface.

Another important property that can be obtained from interface calculations is the presence and concentration of conducting states at the interface. These states can either be present due to interfacial states (Fredrickson and Demkov 2016), defects (Kalabukhov et al. 2007), electronic reconstruction like the polar catastrophe as in $LaAlO_3/SrTiO_3$ (Ohtomo and Hwang 2004; Lee and Demkov 2008), or due to charge transfer from ferroelectric films and interfaces (Fredrickson and Demkov 2015; Yin et al. 2015). By examining the pDOS of atoms at the interface, one can see if there are states near the Fermi level that do not exist in the bulk of either the film or the substrate. The atomic and orbital character of these states can offer more clues to the source of the interfacial states.

In certain cases, construction of a realistic interface may prove difficult due to factors such as lateral size, undesired artificial strain, or functional choice. An

alternative to the above described methods can be used to obtain band offsets (and also the relative defect alignments for point defects) between the two materials in question by alignment of the charge neutrality levels of the materials (Flores and Tejedor 1979; Robertson 2000; Tejedor et al. 1977; Tejedor and Flores 1978). There are a variety of ways to do this including calculation of the zero of the Green's function of the density of states (Robertson 2000; Tersoff 1984a, b):

$$G\left(E_0\right) = \int \frac{N\left(E'\right)dE'}{E - E'} = 0$$

However, a more straightforward method for estimating the charge neutrality level can be performed by calculating the $\varepsilon_H(+/-)$ for interstitial hydrogen (Van de Walle and Neugebauer 2003) using the Zhang-Northrup formalism for calculating defect energy levels in bulk materials (Zhang and Northrup 1991):

$$E_{form}\left(H_i^q\right) = E_{tot}\left(H_i^q\right) - E_{tot}(bulk) + \mu_H + q\left(E_F + \epsilon_V + \Delta V\right)$$

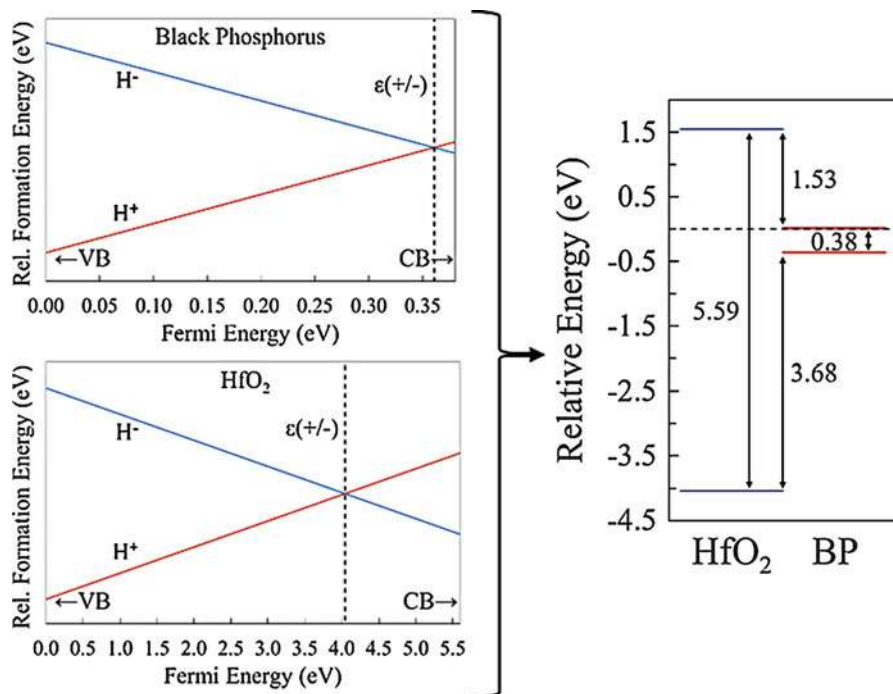
Essentially, a reasonably sized (i.e., well converged, but computationally tractable) supercell is constructed with an interstitial hydrogen atom. The atomic position of the hydrogen is then optimized in the H^+ state and the H^- charged states and the formation energy plotted as a function of the Fermi energy between the valence and conduction bands. Since we only care about the crossing point and not absolute energies, the potential correction (ΔV) can in the present case be neglected as the correction is usually similar for oppositely charged defects of the same type (this is not true generally in defect calculations). The point at which the formation energy for interstitial H^+ and H^- cross is the $\varepsilon_H(+/-)$ level and provides a surface independent estimate for the charge neutrality level. As the charge neutrality level in each material is given relative to the valence and conduction bands of the materials, the relative valence and conduction band offsets can then be determined. Furthermore, since this methodology is essentially an extension of the calculation of point defect transition energy levels, it can provide an easy extension from simply calculating formation energy of vacancies, interstitials, or dopants in oxides to explain their roles as electron or hole "traps" when in contact with semiconductors. In Fig. 12, this process is illustrated for the alignment of dielectric oxide HfO_2 and semiconductor black phosphorus (BP) using hybrid functional calculations as performed in (Liang et al. 2018). The calculations therein were performed using the VASP code (Kresse and Furthmüller 1996) with the HSE06 hybrid functional (Heyd et al. 2003, 2006), PAW pseudopotentials (Blöchl 1994), and a plane-wave cutoff of 400 eV. The hydrogen impurity was placed in a 2x2x2 supercell of HfO_2 and 3x2x1 supercell of BP with experimental lattice constants and optimized in both the H^+ and H^- state by modifying the supercell electron count. We point out that the value obtained for the CNL in BP is similar to that obtained slab models (Cai et al. 2014). Additionally, this method has been


Fig. 12 Calculation of the $\varepsilon_H(+/-)$ level for black phosphorus (top left) and HfO$_2$ (bottom left) and their relative band alignments generated by aligning this level (right). (Adapted from Liang et al. (2018))

used to predict and validate band alignment and relative defect levels of HfO$_2$ and ZrO$_2$ to Si (Lyons et al. 2011), LaAlO$_3$ to Si and III-V semiconductors (Choi et al. 2013b), and chalcogenide semiconductors with ZnO (Varley and Lordi 2013), among others.

While relatively simple and potentially less computationally costly than the local potential method, there are also drawbacks to this method. Principally, the method can only provide band alignments and relative defect alignments for defects that would not be immediately at the interface. By neglecting the specific interface construction, band bending is also neglected. Such methods are thus more suitable to amorphous or polycrystalline interfaces than to high quality epitaxial interfaces or computationally challenging interfaces due to lattice mismatch. Additionally, it neglects the ability to theoretically study the formation of the 2DEG formed in cases like the SrTiO$_3$/LaAlO$_3$ interface (Lee and Demkov 2008) or atomic migration across interfaces like in the case of interfacial hydrogen shuttling (Marinopoulous et al. 2007) or oxygen gettering in resistive RAM applications (O'Hara et al. 2014). Therefore, the decision as to which method is most useful should be made based on the nature of the questions being investigated.

7   Conclusions

From this brief overview, we hope the reader has gained a better understanding of how one can model interfaces involving oxide materials and what kind of information can be obtained from such models. In view of their wide ranging technological applications, a detailed understanding of the physical properties of these interfaces is very important. At the same time, the complexity of the materials involved makes the study of oxide interfaces a highly challenging scientific endeavor. First principles methods have been used with great success in describing and predicting the properties of oxide interfaces, assuming the interface structure is known, but much is left to do. The time and length scales accessible with these first principles methods are rather limited and multiscale computational schemes are often needed for the prediction of many properties. In addition, the approximations made to make the *ab initio* calculations tractable often are inadequate in the context of oxides and specifically the oxide interfaces. Electron correlation dominates the properties of many oxides, particularly those containing transition metals of the iron group (3d metals). As the more accurate quantum mechanical techniques are much more expensive computationally, much of the work relies on semi-empirical methods such as LDA + U. As a result, the predictive power of this approach is somewhat limited. The local approximation causes severe underestimation of the band gap and may cause problems with unphysical charge transfer at the interface if the empty states of the oxide become available for the electrons of the metal because they are positioned too low in energy. But this field of study is extremely active and there is no doubt that in the not so distant future, better computers will allow the use of more accurate theoretical methods for systems large enough to be technologically relevant. The continuous improvement in computing technology as well as techniques to more precisely characterize interface structure and properties will ensure that atomistic modeling of oxide interfaces will in the near future be capable of much more accurate predictions, enabling one to fabricate designer heterostructures with properties tailored for specific applications.

Design of New Multiferroic Oxides

48

Xue-Zeng Lu and James M. Rondinelli

Contents

Abstract

Multiferroics materials, displaying magnetic, polar, and elastic order parameters simultaneously, have garnered intense interests because they may host electric-field controllable magnetism, which can be utilized in devices for information storage and processing. In this chapter, based on recent progress in understanding microscopic mechanisms supporting multiferroism and advances in materials synthesis, we describe the basic routes by which to design new multiferroic oxides using electronic structure based calculations to guide materials selection and discovery.

1   Introduction

Multiferroic materials, as defined in the early days of the field, simultaneously exhibit two or more of the three primary ferroic orders, including spontaneous ferroelectricity, ferromagnetism, and ferroelasticity in a single phase (Schmid 1994). Nowadays, the term is usually used to refer to any material with coexisting (anti)ferroelectricity and (anti)ferromagnetism. Uniting an electric polarization and magnetization in a single material makes these compounds ideally suited to explore magnetoelectric (ME) coupling, i.e., the coupling between the two ferroic orders (Khomskii 2006, 2009; Erenstein et al. 2006; Cheong and Mostovoy 2007; Ramesh and Spaldin 2007; Van den Brink and Khomskii 2008; Picozzi et al. 2008; Wang et al. 2009, 2016; Spaldin et al. 2010; Picozzi and Stroppa 2012; Johnson and Radaelli 2014; Lu et al. 2015a; Fiebig et al. 2016).

The multiferroic field and ME interactions can be traced back to the 1950s, when Landau and Lifshitz proposed the concept of magnetoelectric coupling whereby a material would exhibit a magnetization and electric polarization under the application of an external electric field and magnetic field, respectively, i.e., arising from a nonconjugate field (Landau and Lifshitz 1959). Soon after, Dzyaloshinskii (1960) predicted and Astrov (1960) observed ME coupling in the compound Cr_2O_3. In the early days, this field grew slowly (Ascher et al. 1966; Fox et al. 1980; DiDomenico et al. 1969; Kato et al. 1983; Ismailza and Kizhaev 1965; Teague et al. 1970), on the one hand, because the techniques producing high-quality multiferroics were not accessible and, on the other hand, the weak observed ME coupling did not attract much attention. The situation changed quickly after the development of multiple advanced thin film synthesis techniques, including pulsed laser deposition (PLD) and molecular beam epitaxy (MBE), and improved first-principles computational techniques. For example, $BiFeO_3$, which adopts the $R3c$ symmetry, was the first discovered room-temperature multiferroic. It exhibits ferroelectric (FE) and antiferromagnetic (AFM) transitions at 1103 K and 643 K, respectively (Teague et al. 1970; Sosnowska et al. 1982; Johnson et al. 2013). The polarization is along the [111] pseudo-cubic direction, and the AFM magnetic structure takes the form of a long-wavelength (62 nm) spiral. Early experiments showed that $BiFeO_3$ possesses a small polarization ($\sim$6.1μC/cm^2) in bulk (Kiselev et al. 1963); however, this value was significantly enhanced by almost an order of magnitude ($\sim$100μC/cm^2) in thin film by using a state-of-the-art technique, i.e., PLD, in 2003 (Wang et al. 2003), and the larger polarization value was demonstrated by electronic structure calculations on the $R3c$ structure utilizing the modern theory of polarization (Neaton et al. 2005).

Although transition metal perovskite compounds are among the most promising materials to search for new multiferroics, few were reported to be multiferroic prior to 2003. This is to be contrasted with the abundance of perovskite oxides exhibiting exclusively ferroelectricity or magnetism (Goodenough and Longo 1970; Mitsui et al. 1982). To explain the mutual exclusion between ferroelectricity and long-range magnetic order in transition metal perovskites, Hill proposed a "d^0 rule" in

a seminal paper reported in Hill (2000). It is paraphrased as follows: In most FE materials, the transition metal ion (e.g., represented by B in ABO_3) will be formally a d^0 ion because this electronic configuration can favor hybridization between the B cation antibonding d states that form the conduction band and the oxygen 2p states that form the valence band. Polar B cation displacements are stabilized by the second-order Jahn-Teller effect (Pearson 1975) and result in a spontaneous electric polarization as in $BaTiO_3$. In contrast, when the d shell is occupied (i.e., d^n, n > 0), the energetic gain provided by the SOJT is suppressed and eliminates the driving force for inversion symmetry lifting displacements. In addition, other factors may suppress the FE distortion, such as a first-order Jahn-Teller distortion in $LaMnO_3$ (Mn: $3d^4$ configuration) and $YTiO_3$ (Ti: $3d^1$ configuration) and the strong Hund's exchange energy between occupied t_{2g} and empty e_g orbitals, e.g., in $CaMnO_3$ and $RCrO_3$ (R is rare-earth ion) (Khomskii 2006). In addition, increased electronic Coulomb repulsion can also compete with the hybridization in bond formation leading to a centrosymmetric structure with d^n (n > 0) configuration. However, this d^0 principle can be circumvented when allowing for ferroelectricity and magnetism to arise from different origins; for instance, the magnetism can arise from the magnetic B cations that form one sublattice of the structure, while ferroelectricity can be induced by the A-site cation. This combination of properties arising from coexisting cation sublattices is the basic principle active in $BiFeO_3$ and $BiMnO_3$. In this case, polar Bi displaces arise from Bi-O hybridization due to stereochemically active $6s^2$ lone-pair electrons of the Bi cations (Seshadri and Hill 2001).

The multiferroic boom arrived in 2003 owing to both the discovery of a large electric polarization in $BiFeO_3$ and the discovery of another class of multiferroics in the manganite family. $TbMnO_3$ is an exciting material that violates the d^0 rule owing to spin-induced ferroelectricity (Kimura et al. 2003a). The spiral spin structure with modulation wave vector (0,0.28,0) (Kenzelmann et al. 2005) present in the orthorhombic *Pbnm* crystal structure permits an electric polarization along the c axis. In addition, a moderate magnetic field applied along the b direction can switch the polarization from the c axis to the a axis of the crystal. Since then, numerous multiferroics based on the transition metal perovskites were reported, and they may all generally be clustered into two groups as proposed by Khomskii (2009):

- *Type I Multiferroics*: The ferroelectricity and magnetism arise from the different sources, and thus magnetoelectricity is weak. The critical temperature of the spontaneous polarization is higher than that of the spontaneous magnetization, and the magnitude of the polarization is usually very large ($>1\mu C/cm^2$). The representative Type I multiferroic is $BiFeO_3$.
- *Type II Multiferroics*: The ferroelectricity is caused by complex (non)collinear spin order due to competing exchange interactions and therefore the magnetoelectric coupling is stronger; however, the magnitude of the polarization is usually very small ($<1\mu C/cm^2$). The representative material of this class is $TbMnO_3$.

In both multiferroic types, the critical temperature of the spontaneous magnetic order is usually lower than room temperature, and the magnetic order often leads to no macroscopic magnetization or a weak ferromagnetism.

Both types of the multiferroics have their own drawbacks, which preclude their direct application in new technologies, for example, those based on four-state memory devices and in the writing and reading of magnetic information with low power by exploiting electric field control of magnetism through the magnetoelectric response (Lu et al. 2015a; Fiebig et al. 2016). Beyond these single-phase multiferroic materials, researchers have devoted significant efforts to find alternatives solutions, for examples, artificial materials engineered with epitaxial strain, superlattices comprised of multiferroic constituents or non-multiferroic constituents, ferromagnetic-multiferroic heterostructures, ferromagnetic-ferroelectric interfaces, and domain walls. Recent reviews given in Khomskii (2006, 2009), Erenstein et al. (2006), Cheong and Mostovoy (2007), Ramesh and Spaldin (2007), Van den Brink and Khomskii (2008), Picozzi et al. (2008), Wang et al. (2009, 2016), Spaldin et al. (2010), Picozzi and Stroppa (2012), Johnson and Radaelli (2014), Lu et al. (2015a), and Fiebig et al. (2016) provide a complete description of advances made within these areas. More recently the search for single-phase multiferroics has been buoyed by the formation of new design strategies based on hybrid improper ferroelectrics (or broadly, geometric ferroelectricity) and asymmetric multiferroics.

In this chapter, we describe the design of multiferroic compounds according to the mechanisms permitting the combination of a spontaneous electric polarization and magnetism. The main mechanisms are lone-pair-induced ferroelectricity, charge-order-induced ferroelectricity, spin-driven ferroelectricity, geometric ferroelectricity, asymmetric multiferroics, polymorphic materials, superlattices, ferromagnetic-multiferroic heterostructures, ferromagnetic-ferroelectric interfaces, and domain walls. We conclude the chapter by briefly discussing frontiers and functionalities in multiferroics.

2 Strategy and Considerations for Multiferroics by Computational Design

When beginning to design a new multiferroic, the crystal structure and chemistry require assessment. It was proposed that any functional material is defined by three features, referred to as ACS (Rondinelli et al. 2015), and that property realization through materials-by-design relies on exploiting atomic identities involved (elemental species), composition (integer stoichiometry in compounds or continuous variable, "subscript engineering," in alloys and ceramics), and structure (i.e., where the atoms reside with regard to crystallographic structure). ACS features in this chapter are based on the transition metal oxides exhibiting or derived from the ABO_3 perovskite composition. Owing to the multiferroic behavior, the atomic species of the A and/or B cations must have partially filled d and/or f orbitals. Usually, B magnetic ions are selected to have open d shells, which is achieved by selecting among Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Nb, Mo, Tc, Ru, W, Os, etc.

No matter what is the mechanism inducing the simultaneous electric and magnetic polarization, the material must be insulating. For many transition metal oxides consisting of the aforementioned cations, the electrons in the d orbitals may be considered weakly or strongly correlated, which means that there will be strong repulsion when two electrons with opposite spins occupy the same orbital. This repulsion arises from the Coulomb interaction between the two electrons, which based on a single-site Hubbard model is referred to as the "Hubbard U" (Hubbard 1963). The strength of the U interaction is related to the insulating state and in the solid is screened by the dielectric constant of the material. In practice, this on-site repulsion U can be treated within the density functional theory (DFT) framework by including an on-site interaction for the correlated orbitals when investigating correlated compounds to correctly describe the insulating state (Anisimov et al. 1997, 1991; Solovyev et al. 1994). Note that the U correction depends on the type of the exchange-correlation functional and is not identical to the U that may be extracted from spectroscopic measurements.

To assess if a designed material is insulating, the band structure and density of states can be computed by carrying out DFT calculations. Although the size of the band gap may vary with U, an appropriate U value in the calculations can be identified by examining the robustness of critical physical properties (e.g., computed band gap, magnetic transition temperature, structural and magnetic structure parameters) with respect to U and comparing these results to available experiments on analogous phases. Inaccuracies in the magnitude of the band gap are well-known consequences of the absence of the derivative discontinuity in the exchange-correlation functionals, which are usually the local-density approximations (LDA) (Ceperley and Alder 1980; Vosko et al. 1980), generalized gradient approximations (GGA), and hybrid functionals. At the GGA level, the forms of Perdew-Burke-Ernzerhof (PBE) (Perdew et al. 1996) and Perdew-Burke-Ernzerhof revised for solids (PBEsol) (Perdew et al. 2008) are usually chosen for most studies. In hybrid calculations, the HSE06 functional is most frequently adopted (Paiera et al. 2006) owing to its reduced computational overhead without loss of accuracy. It also performs well for many magnetic oxides and multiferroic materials (Stroppa and Picozzi 2010). The LDA and GGA functionals usually underestimate the band gap, and HSE06 functional overestimates the band gap. Alternative approaches to obtain accurate band gap energies include the GW (or G_0W_0) method, which works well for semiconductor (Hybertsen and Louie 1986; Rohlfing and Louie 2000; Deslippe et al. 2012), and many transition metal oxides (Ergönenc et al. 2018). MetaGGA functionals include the local density (as in LDA) and the gradient of the density (as in GGA) but also the kinetic energy density (Sun et al. 2012, 2013, 2015, 2016). These functionals produce results often much more consistent with experiment and at times perform similarly to a hybrid functional but require less computational resources than hybrid functionals or the GW method. The exchange-correlation functional can also affect equilibrium crystal structures and hence lattice dynamics, electric polarizations, magnetic structure, etc. (Stroppa and Picozzi 2010; Krukau et al. 2006; Seixas et al. 2016; Diéguez and Iñiguez 2015). Thus the selection of a suitable exchange-correlation functional for the study of a known or predicted multiferroic material should be properly justified.

For a potential multiferroic compound, one can determine the equilibrium magnetic structure by using a spin Hamiltonian to model its ordered state, which can be expressed as:

$$\widehat{H}_{spin} = \sum\nolimits_{i<j} J_{ij} \vec{S}_i \cdot \vec{S}_i + \sum\nolimits_{i<j} \vec{D}_{ij} \cdot \left(\vec{S}_i \times \vec{S}_i \right) + \sum\nolimits_{i,\alpha\beta} A_{i,\alpha\beta} \vec{S}_{i\alpha} \vec{S}_{i\beta}$$

$$(1)$$

where J_{ij}, $\vec{D}_{ij}$, and $A_{i,\alpha\beta}$ are the symmetric spin exchange interaction parameters, antisymmetric Dzyaloshinskii-Moriya (DM) interaction vectors, and single-ion anisotropic parameters, respectively, and $\vec{S}_i$ is the spin vector. The DM interaction vector and single-ion anisotropic parameter are a consequence of spin-orbital interactions and in practice require DFT calculations that include relativistic spin-orbital coupling. All of the coefficients can be computed using the four-states mapping analysis and DFT energies (Xiang et al. 2011a, 2013a).

In a material with a simple cubic arrangement of magnetic cations with spin S, for example, one can obtain J_{12}, using four states: (I) $S_1 = S$ and $S_2 = S$; (II) $S_1 = S$ and $S_2 = -S$; (III) $S_1 = -S$ and $S_2 = S$; and (IV) $S_1 = -S$ and $S_2 = -S$. In the calculation, the other spins are kept fixed for each of the four states, and all spins are aligned along the z direction. Then, $J_{12} = \frac{E_I + E_{IV} - E_{II} - E_{III}}{4S^2}$, where E_i ($i = $ I–IV) is the energy for each state. For the collinear spin orders, there are four simple cases, which are FM, A-type, C-type, and G-type orders, respectively (see Fig. 1). After obtaining the coefficients in the spin Hamiltonian, one can also simulate the magnetic transition by performing Monte Carlo simulations based on the Hamiltonian.

To assess the ferroelectric properties, a DFT lattice dynamical analysis can be performed for proper FE materials within a high-symmetry structure (e.g., which may but not necessarily correspond to an observed high temperature paraelectric structure), in which the zone-center FE phonon mode is unstable and exhibits a double-well energy surface versus phonon mode amplitude (see Fig. 2). In addition, phonon calculations can also identify other unstable antiferrodistortive (AFD) lattice modes such as BO_6 oxygen octahedral-rotational modes in corner-shared ABO_3-based perovskites. Such instabilities typically occur at the Brillouin zone boundaries of the high-symmetry phase.

After condensing various combinations of the polar and the AFD phonon modes followed by structural relaxations using DFT, a final stable structure can be regarded as the ground state for the composition. The electric polarization in the ground state structure can be computed by either using the Berry phase method (Resta 1992, 1994; King-Smith and Vanderbilt 1993; Vanderbilt and King-Smith 1993) or by combing the Born effective charges with the ionic displacements found in the ground state structure with respect to a reference structure (i.e., paraelectric state) (Meyer and Vanderbilt 2002). In the Berry phase method, the total polarization (P) consists of electronic (P_e) and ionic (P_i) contributions (i.e., $P = P_e + P_i$), in which P is well-defined modulo $\frac{eR}{\Omega}$, where e, R, and Ω are the charge of the electron, a real-space lattice vector, and the unit cell volume, because of a
Fig. 1 (**a**, **b**) show the FM spin alignment in the *xy* plane; (**c**, **d**) show the checkboard AFM spin alignment in the *xy* plane, where solid circles indicate spin-up and open circles indicate spin-down. In the FM spin structure, there is an $\cdots$A-A-A-A$\cdots$ sequence along the *z* axis; in the A-type AFM spin structure, there is a $\cdots$B-A-B-A$\cdots$ sequence along the *z* axis; in the G-type AFM spin structure, there is a $\cdots$C-D-C-D$\cdots$ sequence along the *z* axis; and in the C-type AFM spin structure, there is a $\cdots$D-D-D-D$\cdots$ sequence along the *z* axis
Fig. 2 The energy versus Q mode amplitude for a proper ferroelectric material. According to a Landau phenomenological model, the energy curve can be described by $E = \alpha Q^2 + \beta Q^4 + higher$ *even-order terms in Q*. When the polar (P) mode is unstable, then the coefficient α becomes negative and results in a decrease of the energy as shown by the double well with negative curvature about the origin (P $=$ 0)

gauge-phase factor in the Bloch function. Then the final polarization is obtained by subtracting any polarization obtained from the paraelectric phase using the same procedures. By using the Born effective charges, $P_\alpha = \frac{1}{\Omega} \sum_{i\beta} Z^*_{i\alpha\beta} \Delta u_{i\beta}$, where Z^*_i and Δu are the Born effective charge tensor and ionic displacement vector of ion i, respectively, such that i and α/β run over all the ions in the cell and the three Cartesian components, respectively. The transition temperature related to the FE orders can also be simulated by Monte Carlo simulations with an effective Hamiltonian including a local-mode self-energy, a long-range dipole-dipole interaction, a short-range interaction between soft modes, an elastic energy, and an interaction between local modes and local strain (Zhong et al. 1994, 1995).

In addition to examining intrinsic FE instabilities, the effect of epitaxial strain on ferroic properties should be assessed because strain engineering is a powerful tool to induce FE instabilities in perovskite oxides (Schlom et al. 2014). The sensitivity of the ferroelectric state in these materials on the strain state of a film coherently grown on a substrate is due to a strain-phonon coupling mechanism. Typically, compressive strain favors an out-of-plane electric polarization, whereas tensile strain supports an in-plane polarization.

In this section, we introduced the basic strategy to investigate the magnetic and FE properties of candidate multiferroic compounds by using different computational tools. Applying this scheme to design new multiferroics relies on harnessing known mechanisms for ferroelectricity and magnetic order. In the next section, we describe how different atomic specifies, compositions, and structures enable or activate the necessary mechanism for multiferroism through specific compounds.

3 Mechanisms to Achieve Coexisting Ferroelectricity and Magnetism

3.1 Lone-Pair-Induced Ferroelectricity

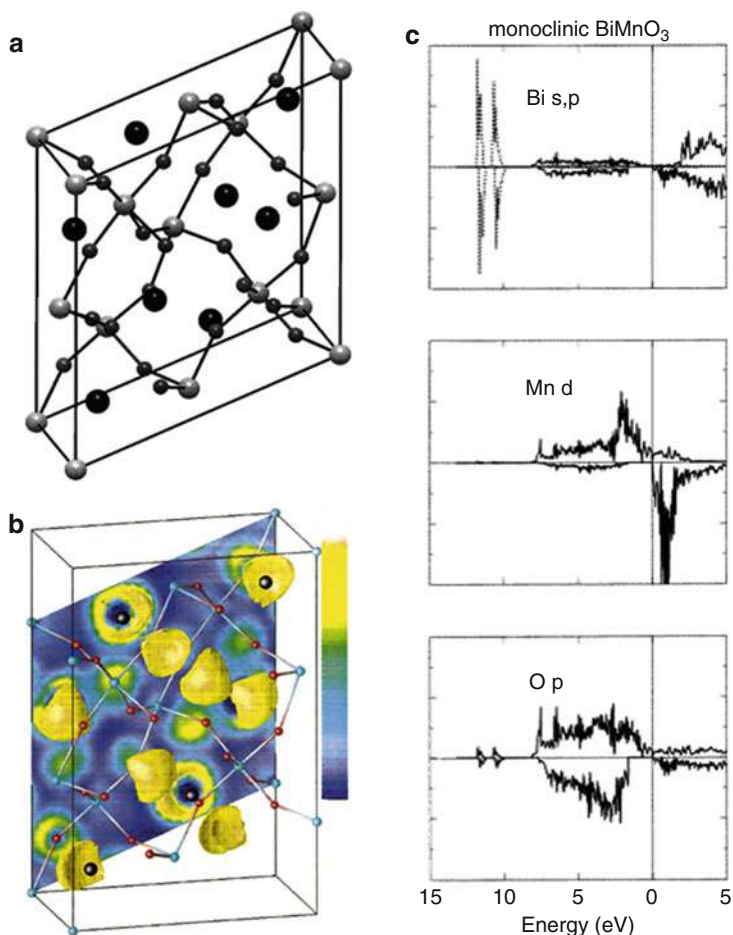
The representative compounds are $BiFeO_3$ and $BiMnO_3$ (Hill and Rabe 1999). By performing DFT calculations, Seshadri and Hill (2001) demonstrated that the Bi-s orbitals can mix with O-p orbitals (see Fig. 3c) in the monoclinic $C2$ structure (see Fig. 3a), which results in a lobe-like shape of the unbonded $6s^2$ lone-pair electrons about the Bi^{3+} ion (see Fig. 3b). The arrangement of this anisotropic distribution of $6s^2$ electrons in the unit cell is the origin for ferroelectricity in the $C2$ structure of $BiMnO_3$. It may also be used to explain the ferroelectricity that arises in the rhombohedral $R3c$ structure of $BiFeO_3$. In $BiFeO_3$, the long-wavelength (62 nm) spiral magnetic structure can be suppressed in thin film where the spin alignment is G-type with weak ferromagnetism within the (111) plane of the $R3c$ structure. In $BiMnO_3$ (Faqir et al. 1999; Moreira dos Santos et al. 2002a, b; Kimura et al. 2003b; Montanari et al. 2005, 2007; Belik and Takayama-Muromachi 2006; Belik et al. 2007), the spin alignment is ferromagnetic (FM), which leads to a magnetization of $\sim 3.6\mu_B$ per formula unit that is close to the nominal magnetic moment of Mn^{3+} ($4\mu_B$). The FM transition temperature occurs at ~ 105 K. Compared with the easy synthesis of the $BiFeO_3$ in bulk and thin film at ambient condition, high pressure is


Fig. 3 (**a**) Monoclinic $C2$ structure of $BiMnO_3$ projected nearly down the b axis. The large black sphere is Bi, and the smaller white sphere is Mn centered in an oxygen octahedron. (**b**) Isosurface with a value of 0.75 of the valence electron localization function of the structure shown in (**a**). Blue color corresponds to nearly no electron localization, and white color corresponds to complete localization. (**c**) Orbital resolved density of states (DOS) in FM $C2$ structure of $BiMnO_3$. The DOS have been rescaled to a single spin direction and to one $BiMnO_3$ formula unit. (Figure reproduced from Seshadri and Hill (2001), Copyright American Chemical Society, 2001)

needed to synthesize isoelectronic bulk $BiMnO_3$ single crystals. In thin film form, relatively strict growth conditions are required even without high pressure (Lu et al. 2015a).

It is noted that the ferroelectricity in $BiMnO_3$ is still under debate (Belik et al. 2007; Montanari et al. 2007; Goian et al. 2012), because a first-principles study showed that the ground state adopts $C2/c$ symmetry in ideal, stoichiometric $BiMnO_3$ where the anisotropic distribution of $6s^2$ electrons around different Bi^{3+} ions cancel perfectly leading to no net polarization (Baettig et al. 2007).

3.2 Charge-Ordering-Induced Ferroelectricity

In 2004, Efremov et al. (2004) proposed ferroelectricity could appear by inducing a charge ordering (CO) state in $Pr_{1-x}Ca_xMnO_3$. The CO can exist for $0.3 < x < 0.8$. When $x = 0.5$, the CO is site-centered, in which the Mn^{3+} and Mn^{4+} alignments take the form of checkboard ordering as shown in Fig. 4a. Upon decreasing x to 0.4, the CO becomes bond-centered as demonstrated by experiments (see Fig. 4b), in which the extra electron is shared by the two nearest-neighboring Mn ions. In both types of charge-ordered state, ferroelectricity is absent owing to the presence of inversion symmetry compatible with the CO state. Theoretically when x is between 0.4 and 0.5, and including $x = 0.4$, the site-centered and bond-centered COs should coexist (see Fig. 4c), which will lead to the loss of inversion and a small electric polarization ($\sim 1mC/m^2$) in the monoclinic $P11m$ structure. (As a point of reference, $BaTiO_3$ exhibits an electric polarization of 300 mC/m^2.) Furthermore, the actual valence difference between the nearest-neighboring Mn ions is less than 0.1e even with $x = 0.5$.

Although the CO-induced ferroelectricity was demonstrated by a degenerate double exchange model, the direct observation of the ferroelectricity has been hindered by the finite conductivity displayed by the compound. Support for the appearance of the ferroelectricity in $Pr_{1-x}Ca_xMnO_3$ is given by the anomaly in the dielectric constant observed in vicinity of the CO transition (Jardon et al. 1999; Mercone et al. 2004).

Another compound proposed to exhibit CO-induced ferroelectricity is $LuFe_2O_4$ (Ikeda et al. 2000, 2005) in which the average valence of iron is $Fe^{2.5+}$. Fe^{2+} and Fe^{3+} undergo a three-dimensional CO under 330 K, where the ratio of Fe^{2+} and Fe^{3+} in one triangular layer comprised of corner-sharing FeO_5 trigonal bipyramids is 1:2, while it is 2:1 in the other triangular layer (see Fig. 5b). With this CO, the structure exhibits a $\sqrt{3}$x$\sqrt{3}$ supercell of the unordered $R\bar{3}m$ variant (see Fig. 5a), and ferroelectricity appears below 330 K. By performing DFT total-energy

calculations with the GGA exchange-correlation functional in PBE form, Xiang and Whangbo (2007) identified that the CO in $LuFe_2O_4$ leads to a ferrielectric arrangement of the dipole moments among the FeO_5 bilayers by comparing the values of the polarizations calculated in the ferroelectric ($\sim$52.7μC/cm^2) (see Fig. 5c) and ferrielectric ($\sim$26.3μC/cm^2) (see Fig. 5d) states with that from experiment (Ikeda et al. 2005) ($\sim$25μC/cm^2 measured at 77 K). Also in the vicinity of a two-dimensional ferrimagnetic order below 240 K, an increase in the magnitude of the polarization was observed, which indicated a coupling between the ferroelectric and magnetic orders in this compound (Ikeda et al. 2005). It should be noted that in a later experiment (de Groot et al. 2012), $LuFe_2O_4$ was shown not to exhibit ferroelectricity because its equilibrium structure is monoclinic $C2/m$

symmetry (centrosymmetric and the inversion center is located in-between the Fe bilayers) with a new CO configuration in the iron bilayer. Therefore, the CO-induced ferroelectricity in $LuFe_2O_4$ is still controversial although the material has more recently been used in oxide superlattices to achieve an artificial multiferroic (Mundy et al. 2016).

3.3 Spin-Driven Ferroelectricity

3.3.1 Microscopic Models for Spin-Driven Ferroelectricity

KNB Model

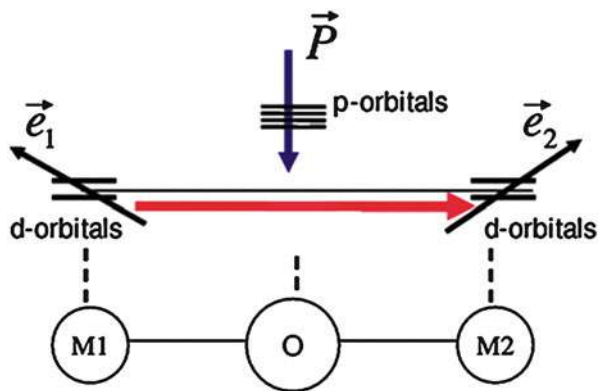
In 2005, Katsura et al. (2005) developed a microscopic electronic model for magnetic materials exhibiting a noncollinear spin structure at low temperatures. This so-called KNB model is based on a three-atom system, in which it is assumed that inversion symmetry exists between the two magnetic ions M1 and M2 as shown in Fig. 6. Owing to inversion, there is no Dzyaloshinskii-Moriya (DM) interaction, and the noncollinear spin alignment is due to the competing symmetric spin-exchange interactions among the magnetic ions. By only considering the t_{2g} orbitals with the spin-orbital coupling (SOC) and on-site Coulomb repulsion on the magnetic ions (i.e., M1 and M2) and relying on a process of electron transfer along the M1-O-M2 bond due to orbital hybridization, the KNB model predicts a polarization $\boldsymbol{P} \propto -\boldsymbol{e_{12}} \times (\boldsymbol{e_1} \times \boldsymbol{e_2})$, where $\boldsymbol{e_{12}}$ is the unit vector pointing from M1 to M2 ions and $\boldsymbol{e_1}$ and $\boldsymbol{e_2}$ are the directions of the two noncollinear spins on M1 and M2, respectively (see Fig. 6). It should be noted that the KNB model is a


Fig. 6 The model with the two transition metal ions M1 and M2 with the oxygen atom O between sites. The noncollinear spin directions on M1 and M2 are represented by $\mathbf{e_1}$ and $\mathbf{e_2}$. $\boldsymbol{P}$ indicates the direction of the polarization, which is proportional to $-\boldsymbol{e_{12}} \times (\boldsymbol{e_1} \times \boldsymbol{e_2})$ where $\boldsymbol{e_{12}}$ is the unit vector pointing from M1 to M2 ions. (Figure reproduced from Katsura et al. (2005), Copyright American Physical Society, 2005)

Bottom: The Mn_2O "molecule" in the cubic perovskite structure, in which $\mathbf{r_n}$ indicates the displacement of the O ion. (Figure reproduced from Sergienko and Dagotto (2006), Copyright American Physical Society, 2006)

purely electronic mechanism for ferroelectricity and there are no ions displacements required or considered in the contribution to the macroscopic polarization.

Inverse Dzyaloshinskii-Moriya Interaction Model

The so-called inverse DM interaction model (Sergienko and Dagotto 2006) arises from the DM interaction in the M1-O-M2 subsystem (M1 and M2 are magnetic ions) *without* inversion symmetry as shown in Fig. 7. By assuming that only the position of the oxygen is allowed to move and those of M1 and M2 are fixed and the DM interaction induced energy is expressed as $\mathbf{D}(r_n) \cdot (\mathbf{S}_n \times \mathbf{S}_{n+1})$, there will be an additional displacement of the oxygen along the *z* direction with the spiral spin structure. The modulation wave vector (0,0.28,0) for the spiral spins was obtained from experiment and $\mathbf{D}^x(r_n) = \gamma(0, -z_n, y_n)$ and $\mathbf{D}^y(r_n) = \gamma(z_n, 0, -x_n)$ in the orthorhombic *Pbnm* symmetry where γ is the DM interaction constant. The result is a polarization along the *z* direction. Although this model was derived based on the spiral spin structure in $TbMnO_3$ compound, the basic physics can be extended to other compounds that permit DM interactions (e.g., those that possess the spiral spin structure) with induced ionic displacements that may significantly contribute to the spin-driven ferroelectricity.

Unified Model for the Spin-Driven Ferroelectricity

Xiang (Wang et al. 2016; Xiang et al. 2011b, 2013b; Lu et al. 2015b) developed a unified model with the pure electronic contribution, ionic displacement contribution, and lattice-deformation contribution together. It is captured by a single formula by expressing the polarization driven by the magnetic structure in the general form: $\boldsymbol{P}_t = \boldsymbol{P}_t(\boldsymbol{S}_1, \boldsymbol{S}_2, \ldots, \boldsymbol{S}_m; \boldsymbol{\mu}_1, \boldsymbol{\mu}_2, \ldots, \boldsymbol{\mu}_n; \eta_1, \eta_2, \ldots, \eta_6)$ where $\boldsymbol{S}_i$ ($i = 1, 2, \ldots, m$), $\boldsymbol{\mu}_j$ ($j = 1, 2, \ldots, n$), and η_k ($k = 1$–6) are the spin vectors, ion displacement vectors, and homogenous strains, respectively. Here, the pure electronic contribution, ion displacement contributions, and lattice deformation contributions arise from the electron density redistribution, ion displacements relative to a paramagnetic (PM)

structure, and changes of the lattice vectors relative to a paramagnetic structure, respectively, due to the appearance of a spin order that occurs upon cooling below the magnetic ordering temperature.

Usually, the spin-order-induced μ_j ($j = 1, 2, \ldots, n$) and η_k ($k = 1$–6) effects are rather small, which allows one to rewrite $P_t \approx P_e(S_1, S_2, \ldots, S_m) + P_{lattice + ion}$ ($\mu_1, \mu_2, \ldots, \mu_n; \eta_1, \eta_2, \ldots, \eta_6$), where the pure electronic contribution (P_e) is separated from the ionic displacement and lattice deformation contributions ($P_{lattice + ion}$). The pure electronic contribution to the polarization (Xiang et al. 2011b) is obtained by considering in the same way a spin dimer (see Figs. 6 and 7), such that $P_e = P_1(S_1) + P_2(S_2) + P_{12}(S_1, S_2)$ where $P_i(S_i) = \sum_{\alpha\beta} P_i^{\alpha\beta} S_{i\alpha} S_{i\beta}$ ($i = 1, 2$) and $P_{12}(S_1, S_2) = \sum_{\alpha\beta} P_{12}^{\alpha\beta} S_{1\alpha} S_{2\beta}$ are the intra-site and inter-site polarization terms, respectively. The inter-site term can be expressed in matrix form as:

$$
P_{12}(S_1, S_2) = \begin{bmatrix} S_{1x} & S_{1y} & S_{1z} \end{bmatrix} \begin{bmatrix} P_{12}^{xx} & P_{12}^{xy} & P_{12}^{xz} \\ P_{12}^{yx} & P_{12}^{yy} & P_{12}^{yz} \\ P_{12}^{zx} & P_{12}^{zy} & P_{12}^{zz} \end{bmatrix} \begin{bmatrix} S_{2x} \\ S_{2y} \\ S_{2z} \end{bmatrix}. \tag{2}
$$

Specifically, if SOC effects are neglected in the P_e contribution, then $P_{12}(S_1, S_2)$ is reduced to be $P_{es}(S_1 \cdot S_2)$ where P_{es} indicates the polarization is induced by exchange striction and $P_{es} = P_{12}^{xx} = P_{12}^{yy} = P_{12}^{zz}$, because any global rotations of all the spins will not change the total electric polarization. If there is inversion symmetry at the center of a spin dimer, then $P_{12}(S_1, S_2)$ can be reduced to be

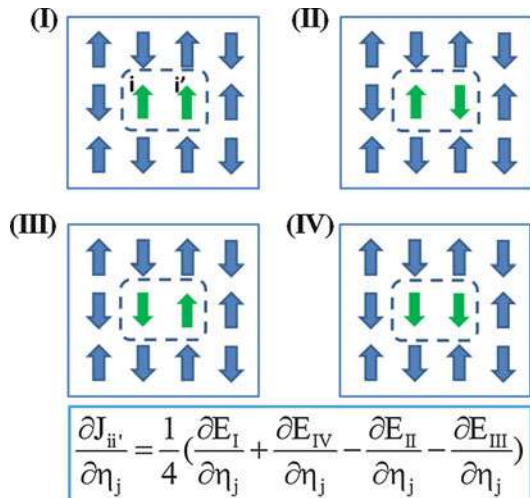
$$
M(S_1 \times S_2) \quad \text{where} \quad M = \begin{bmatrix} (P_{12}^{yz})_x & (P_{12}^{zx})_x & (P_{12}^{xy})_x \\ (P_{12}^{yz})_y & (P_{12}^{zx})_y & (P_{12}^{xy})_y \\ (P_{12}^{yz})_z & (P_{12}^{zx})_z & (P_{12}^{xy})_z \end{bmatrix} \tag{3}
$$

because $P_{12}^{\alpha\beta} = -P_{12}^{\beta\alpha}$ with the inversion symmetry in the dimer. To extract the coefficients in P_e by using DFT calculations, a so-called four-states mapping method analogous to that used to extract the coefficients in the Hamiltonian model as discussed in Session II is applied. Here, taking the coefficient for the exchange striction as an example, we can write $P_{es} = \frac{P_I - P_{II} - P_{III} + P_{IV}}{4}$ in which P_I, P_{II}, P_{III}, and P_{IV} are the polarizations with the spin arrangements of S_1 and S_2 being (+,+), (+,-), (−,+), and (−,-), respectively, and the other spins are kept the same in the calculations of P_I, P_{II}, P_{III}, and P_{IV}.

For the ionic displacement (Xiang et al. 2013b) and lattice deformation contributions (Lu et al. 2015b), one first considers the total energy based on a paramagnetic reference structure expanded as $E_{PM} = E_0 + \sum_m A_m u_m + \sum_j A_j \eta_j + \frac{1}{2} \sum_{mn} B_{mn} u_m u_n + \frac{1}{2} \sum_{jk} B_{jk} \eta_j \eta_k + \sum_{jk} B_{mj} u_m \eta_j + \ldots$ where A_m, A_j, B_{mn}, B_{jk}, and B_{mj} are the forces, stresses, force constants, frozen-ion elastic constants, and internal displacement tensor, respectively. The elements u_m and η_j correspond to the ionic displacement and the homogenous strain in Voigt notation, respectively, for the paramagnetic reference structure. Second, by considering a magnetic transition

that occurs upon cooling to stabilize a magnetically order state, an additional energy $E_{spin} = E_H + E_{DM} + E_{SIA}$ is required, where E_H, E_{DM}, and E_{SIA} are the Heisenberg symmetric exchange interaction energy, the DM interaction energy, and single-ion anisotropic energy, respectively. Then by considering only u_m and η_j to be induced from the E_H contribution, a simplified form of the symmetric exchange energy can be obtained: $E_H = E_H^0 + \sum_{i,i'} \frac{\partial J_{i,i'}}{\partial u_m} \boldsymbol{S}_i \cdot \boldsymbol{S}_{i'} u_m + \sum_{i,i'} \frac{\partial J_{i,i'}}{\partial \eta_j} \boldsymbol{S}_i \cdot \boldsymbol{S}_{i'} \eta_j + \ldots$ in which $\frac{\partial J_{i,i'}}{\partial u_m}$ and $\frac{\partial J_{i,i'}}{\partial \eta_j}$ are the first order derivatives of the Heisenberg symmetric exchange interaction ($J_{i,i'}$) between spins $\boldsymbol{S}_i$ and $\boldsymbol{S}_{i'}$ with respect to u_m and η_j, respectively. (Here an implied sum notation is used for m and j in E_H hereafter.) Then, by minimizing $E_{PM} + E_H$ with respect to u_m and η_j, one obtains that $\begin{cases} B_{mn}u_n + B_{mj}\eta_j = -\sum_{i,i'} \frac{\partial J_{i,i'}}{\partial u_m} \boldsymbol{S}_i \cdot \boldsymbol{S}_{i'} \\ B_{jk}\eta_k + B_{mj}u_m = -\sum_{i,i'} \frac{\partial J_{i,i'}}{\partial \eta_j} \boldsymbol{S}_i \cdot \boldsymbol{S}_{i'} \end{cases}$. The ionic displacements u_m and strains η_j induced by the spin order are readily obtained by solving the two coupled linear equations. Density functional perturbation theory can be used to compute the force constant (B_{mn}) and the internal-displacement tensor (B_{mj}). The frozen-ion elastic constant (B_{jk}) can be straightforwardly obtained by calculating the strain-stress relation within DFT. To compute the first-order derivatives of the symmetric spin exchange parameter $J_{ii'}$ with respect to η_j, we propose a four-states mapping approach: $\frac{\partial J_{ii'}}{\partial \eta_j} = \frac{1}{4} \left(\frac{\partial E_I}{\partial \eta_j} - \frac{\partial E_{II}}{\partial \eta_j} - \frac{\partial E_{III}}{\partial \eta_j} + \frac{\partial E_{IV}}{\partial \eta_j} \right) = \frac{1}{4} \left(\sigma_j^I - \sigma_j^{II} - \sigma_j^{III} + \sigma_j^{IV} \right)$ (see Fig. 8). Here, I–IV refer to the four spin states with different spin orientations for sites i and i' (see Fig. 8 for an example), E and σ denote the total energy and stress, respectively. We note that the stress can be computed without doing additional DFT calculations due to the celebrated Hellmann-Feynman theorem. The first-order derivatives of the symmetric spin

Fig. 8 Schematic illustration of the four spin states in the four-states mapping method to compute the derivative of the exchange parameter with respect to strain $\frac{\partial J_{ii'}}{\partial \eta_j}$. In the four spin states, only the spins at sites i and i' change the orientation. (Figure reproduced from Lu et al. (2015b), Copyright American Physical Society, 2015)

$$\frac{\partial J_{ii'}}{\partial \eta_j} = \frac{1}{4} \left(\frac{\partial E_I}{\partial \eta_j} + \frac{\partial E_{IV}}{\partial \eta_j} - \frac{\partial E_{II}}{\partial \eta_j} - \frac{\partial E_{III}}{\partial \eta_j} \right)$$


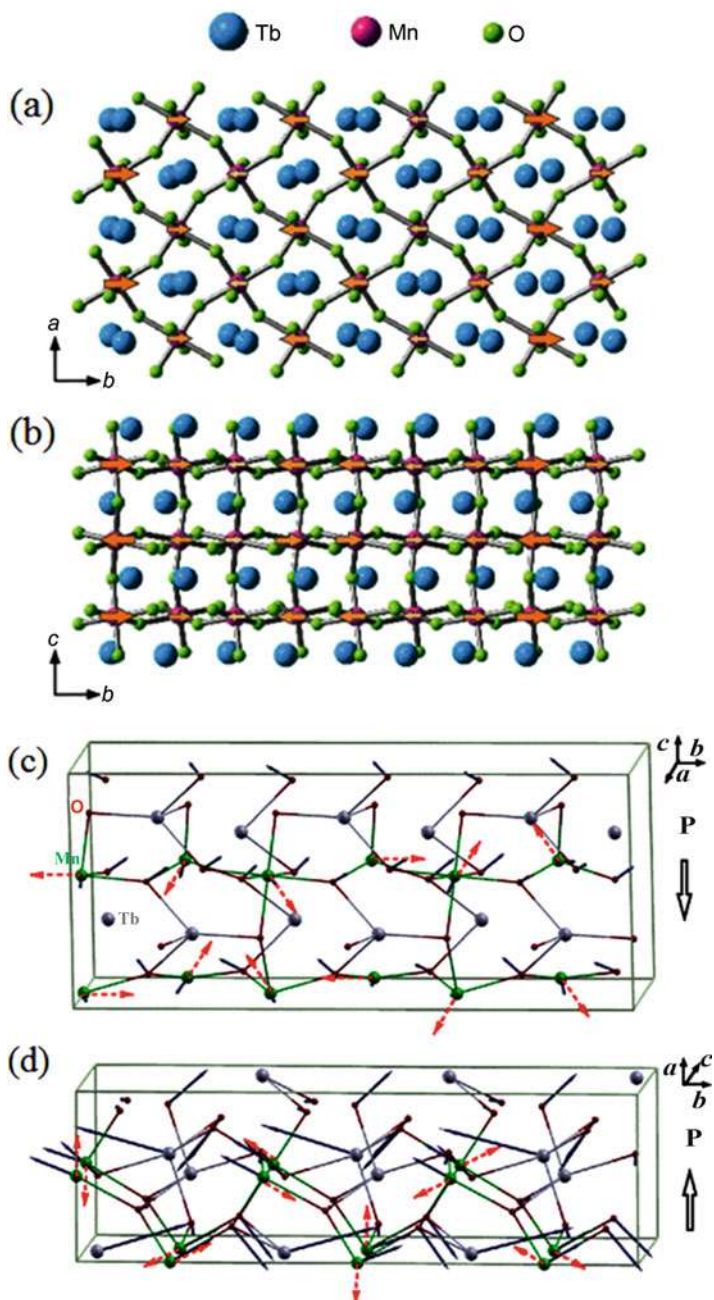


Fig. 9 (continued)

exchange parameter $J_{ii'}$ with respect to u_m can be also efficiently evaluated by using a four-states mapping approach (Xiang et al. 2011a, 2013a). Finally, the electric polarization from the ionic displacements and lattice deformation is given as $P_\alpha = Z_{\alpha m}u_m + e_{\alpha j}\eta_j$ ($\alpha = x,y,z$) in which $Z_{\alpha m}$ and $e_{\alpha j}$ are the Born effective charges and frozen-ion piezoelectric tensors, respectively. These later quantities are directly accessible from a DFT calculation of the non-magnetic or magnetically ordered phase. If one wants to separate P_α into the ionic displacement and lattice deformation contributions, then $\sum_{i,i'} \frac{\partial J_{i,i'}}{\partial u_m} S_i \cdot S_{i'}$ should be set to zero, and the lattice deformation contribution is $P_{lattice} = d_{\alpha j}\sigma_j$ where $\sigma_j = -\sum_{i,i'} \frac{\partial J_{i,i'}}{\partial \eta_j} S_i \cdot S_{i'}$ is the total stress due to the spin structure and $d_{\alpha j} = S_{jk}e_{\alpha k}$ in which S_{jk} and $e_{\alpha k}$ are the relaxed-ion elastic compliance tensor and the relaxed-ion piezoelectric tensor, respectively, and $P_{ion} = P_\alpha - P_{lattice}$.

3.3.2 Multiferroic Materials with Spin-Driven Ferroelectricity

Spin-Orbital Coupling Effects

Cycloidal Spin Structure

TbMnO$_3$ (Kimura et al. 2003a) is the first reported multiferroic material with spin-driven ferroelectricity. Below 41 K, the first magnetic transition occurs, with spins aligned along the b direction of the *Pbnm* structure. The spin structure exhibits a sinusoidal spin-density wave with an incommensurate wave vector (0,0.295,0) as shown in Fig. 9a and b. The experiment showed that there was no ferroelectricity with this magnetic structure. Upon decreasing temperature below 27 K, a second magnetic transition occurs, and the spins rotate in the *bc* plane and form a transverse spiral structure with the wave vector (0,0.28,0) (Kenzelmann et al. 2005) as shown in Fig. 9c. Interestingly, a polarization appears in the vicinity of this magnetic structure. By applying the KNB model (Katsura et al. 2005) and inverse DM interaction model (Sergienko and Dagotto 2006), both approaches can correctly predict the direction of the polarization parallel to the c axis, which was also demonstrated by a phenomenological Ginzburg-Landau model (Mostovoy 2006) and first principles DFT calculations (Xiang et al. 2008; Malashevich and Vanderbilt 2008) with both LDA and GGA (in PBE form) exchange-correlation functionals. Furthermore, the theoretical results (Xiang et al. 2008; Malashevich and Vanderbilt

---

Fig. 9 Schematic illustration of the crystal structure with *Pbnm* symmetry at room temperature (**a**) and spatial variation of Mn magnetic moments along the b axis and atomic displacements ($\Delta z//c$) below 41 K (**b**). Orange arrows indicate Mn magnetic moments below 41 K. The atomic displacements (indicated by solid arrows) of the spin-spiral states after geometry optimization for the *bc* plane spiral (**c**) and the *ab* plane spiral (**d**). The dashed arrows indicate the directions of the Mn spins in the spiral states. The directions of the electric polarizations are also shown. (Figures (**a**) and (**b**) reproduced from Kimura et al. (2003a), Copyright Springer Nature, 2003. Figures (**c**) and (**d**) reproduced from Xiang et al. (2008), Copyright American Physical Society, 2008)

2008) also showed that the polarization in the experiments arises from both the pure electronic contribution from the KNB model and the ionic displacement contribution from the inverse DM interaction model. Moreover, the experiment observed that a moderate magnetic field ($\sim$5 T) along b direction can induce a spin flop (spin-rotational plane is changed from bc to ab planes), which leads to the polarization change from the direction to a direction (see Fig. 9d). This is because the spin-rotational plane is either the ab or bc plane and results from the Mn spin anisotropy (Xiang et al. 2008). The polarization direction with the spin rotating in the ab plane was also correctly predicted by the theoretical works with both models (Xiang et al. 2008). In DyMnO$_3$ (Kimura et al. 2005) and Eu$_{0.75}$Y$_{0.25}$MnO$_3$ (Cheong and Mostovoy 2007; Noda et al. 2006; Hemberger et al. 2007), similar phenomena were observed, and the mechanism is the same as that in TbMnO$_3$. One may find other multiferroics as TbMnO$_3$ with the spiral spin structure in a *Pbnm* crystal structure, such as AMnO$_3$ with A being a rare-earth element.

Helical Spin Structure

MnI$_2$ crystallizes in a centrosymmetric $P\bar{3}m1$ structure (Kurumaji et al. 2011) in which each species forms a triangular lattice stacking along the [001] direction in the sequence of –(I-Mn-I)-(I-Mn-I)- (see Fig. 10a). Upon cooling below 3.45 K, a helical spin structure occurs with spins rotating in the plane perpendicular to the modulation wave vector $\boldsymbol{k}$ = (0.181, 0, 0.439). When a magnetic field of 2.3 T is applied along the [1$\bar{1}$0] direction, the helical spin structure changes to have a propagation wave vector ($\boldsymbol{q}$) along [1$\bar{1}$0] simultaneously with the appearance of an electric polarization along the [110] direction. If the magnetic field is increased to 5 T along the [110] direction, then the helical spin structure will have $\boldsymbol{q}$ along [110] and an electric polarization along (Picozzi et al. 2007). It should be noted that the KNB model, inverse DM interaction model, and the phenomenological Ginzburg-Landau model proposed by Mostovoy cannot describe the aforementioned ferroelectricity induced by the helical spin structure, because $\boldsymbol{q}$ is aligned along the same direction as $\boldsymbol{S}_i \times \boldsymbol{S}_j$, meaning there is no DM interaction between the two nearest-neighboring Mn^{2+} ions.

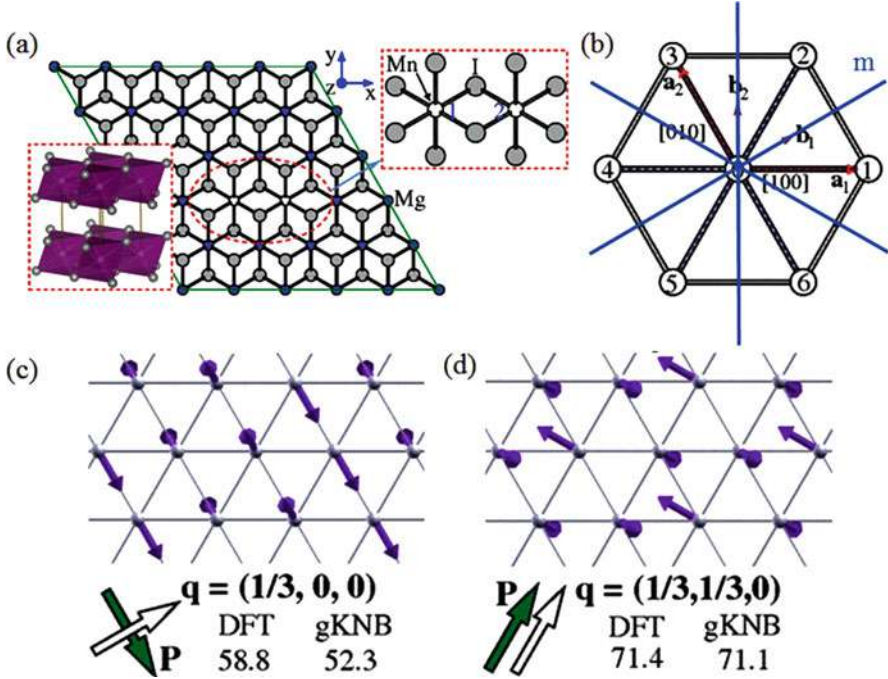
Later, Xiang et al. (2011b) developed a general KNB (gKNB) model to explain the polarization arising from the helical spin structure. Because of the presence of the inversion symmetry between the two nearest-neighboring Mn^{2+} ions (see the right inset in Fig. 10a), the inter-site terms in $\boldsymbol{P}_e$ can be simplified into the form given by Eq. (3). The DFT-LDA calculations showed that $\mathbf{M}$ has the form of $\begin{bmatrix} M_{11} & 0 & 0 \\ 0 & M_{22} & M_{23} \\ 0 & M_{32} & M_{33} \end{bmatrix}$. Therefore, by considering all the Mn^{2+} sites have the same polarization and the contributions from the intra-site terms to the total polarization are zero, $\boldsymbol{P}_{tot} = \boldsymbol{P}_0 = \sum_{k=1}^{6} \boldsymbol{M}_{0k} (\boldsymbol{S}_0 \times \boldsymbol{S}_k)$ where $\boldsymbol{M}_{0k}$ ($k = 1 - 6$) can be obtained from $\boldsymbol{M}$ by using the mirror symmetry of the structure (see Fig. 10b). In the case of the propagation wave vector ($\boldsymbol{q}$) along [Q00] direction, which is redefined in the coordinate system in Ref. (Xiang et al. 2011b) (see Fig. 10b)


Fig. 10 (**a**) The $5 \times 5 \times 1$ supercell of MnI_2 in which all Mn ions except for an isolated nearest-neighboring Mn-Mn pair are replaced by nonmagnetic Mg ions for computing the coefficients in **M** (see section "Unified Model for the Spin-Driven Ferroelectricity"). The left inset displays the layered structure of MnI_2. The right inset shows the top view of the Mn_2I_{10} cluster. (**b**) The triangular lattice of Mn ions, in which the in-plane lattice vectors a_1 and a_2 and the corresponding reciprocal lattice vectors b_1 and b_2 are shown. The blue lines indicate the mirror (m) planes. (**c**) and (**d**) display the spin orientations of two proper-screw spirals with modulation vectors $q = (1/3,0,0)$ and $q = (1/3,1/3,0)$, respectively. The modulation vector q and the polarization vector P are represented by the white and green arrows, respectively. The numbers in $\mu C/cm^2$ indicate the magnitudes of the polarizations obtained from the direct DFT calculations and the gKNB model. (Figure reproduced from Xiang et al. (2011b), Copyright American Physical Society, 2011)

and corresponds to the $[1\bar{1}0]$ direction at the low magnetic field in the experiment (Kurumaji et al. 2011) (see Fig. 10c), $\boldsymbol{P}_{tot} = \left(\frac{\sqrt{3}}{2}A, -\frac{3}{2}A, 0\right)$ in the coordinate system as depicted in Fig. 10a, with $A = (-M_{11} + M_{22}) \sin(2\pi Q)$. And for $\boldsymbol{q}$ along [QQ0] direction (corresponding to [110] direction at the high magnetic field in the experiment (Kurumaji et al. 2011)) (see Fig. 10d), $\boldsymbol{P}_{tot} = \left(\frac{1}{2}B, \frac{\sqrt{3}}{2}B, 0\right)$ with $B = (-M_{11} - 3M_{22} + 4M_{11} \cos 2\pi Q) \sin 2\pi Q$. It is noted that $\boldsymbol{P}_{tot}$ with [Q00] is perpendicular to the propagation vector and $\boldsymbol{P}_{tot}$ with [QQ0] is parallel to the propagation vector. Thus, the gKNB model obtained the correct polarization directions in the helical spin structures at the low and high magnetic fields, respectively. Furthermore, the polarization values from the gKNB model are also in good agreement with those from the direct DFT calculations (see

Fig. 10c and d). Thus, the gKNB model both predicts correctly the direction of the polarization with a certain spin arrangement and gives an accurate value of the polarization. The gKNB model is then useful for predicting the polarization with arbitrary spin arrangements and for investigating the microscopic mechanism on the spin-ordering-induced polarization, such as elucidating the important path and the important coefficients.

In $CuFeO_2$ (Kimura et al. 2006) and $ACrO_2$ (A = Cu,Ag) with the delafossite structure (Seki et al. 2008), similar helical spin structures with propagation wave vectors $(q,q,0)$ where q is incommensurate were also observed. In $CuFeO_2$, the helical spin structure only appears by applying the magnetic field along the out-of-plane axis with a magnitude between 7 and 13 T below 11 K. For small Al substitution values on the B site in $CuFeO_2$ [i.e., $CuFe_{1-x}Al_xO_2$ ($x = 0.01, 0.02$)] (Seki et al. 2007; Nakajima et al. 2008), the helical spin structure can be stabilized without any magnetic field at low temperature (6–9 K for $x = 0.01$ and below 7 K for $x = 0.02$). In $ACrO_2$ (A = Cu,Ag), below 24 K, the helical spin structure appears.

Exchange Striction Effects

Helical Spin Structure

$CaMn_7O_{12}$ (Zhang et al. 2011; Johnson et al. 2012) was reported to exhibit improper ferroelectricity ($0.287\mu C/cm^2$) with a helical spin structure having propagation wave vector $(0,1,0.963)$, where both the microscopic mechanisms for the polarization and magnetic structure can be elucidated by using computational methods. Experiments showed that when the temperature is below 440 K, the structure transforms into a $R\bar{3}$ phase, where there are one Mn^{4+} and six Mn^{3+} ions per formula unit as can be seen in Fig. 11. Figure 11a and b shows the spiral channel comprised of every three chains in which Mn^{3+} ions (Mn1 and Mn2) align along the crystallographic c axis. Moreover, the spiral chains share one Mn^{3+} chains to form hexagonal channels, in which the Mn^{4+} (Mn3) and Ca^{2+} are at the center of the cavities aligned along the c direction (see Fig. 11c and d)]. Experiments showed that a helical spin order appears with the temperature between 48 K and 90 K, in which the spins on the Mn^{3+} ions in one Mn^{3+} chain are ferromagnetic (FM) and the spins between the Mn^{3+} chain in the spiral chain are frustrated and form a $120°$ arrangement (see Fig. 11e and f). The Mn^{4+} spins make an angle of $90°$ with the Mn^{3+} spins in one set of the three FM chains (dotted triangle in Fig. 11f) and $30°$ with the Mn^{3+} spins in another set of the three FM chains (dashed triangle in Fig. 11f). In addition, all the spins lie in the plane nearly perpendicular to the c direction.

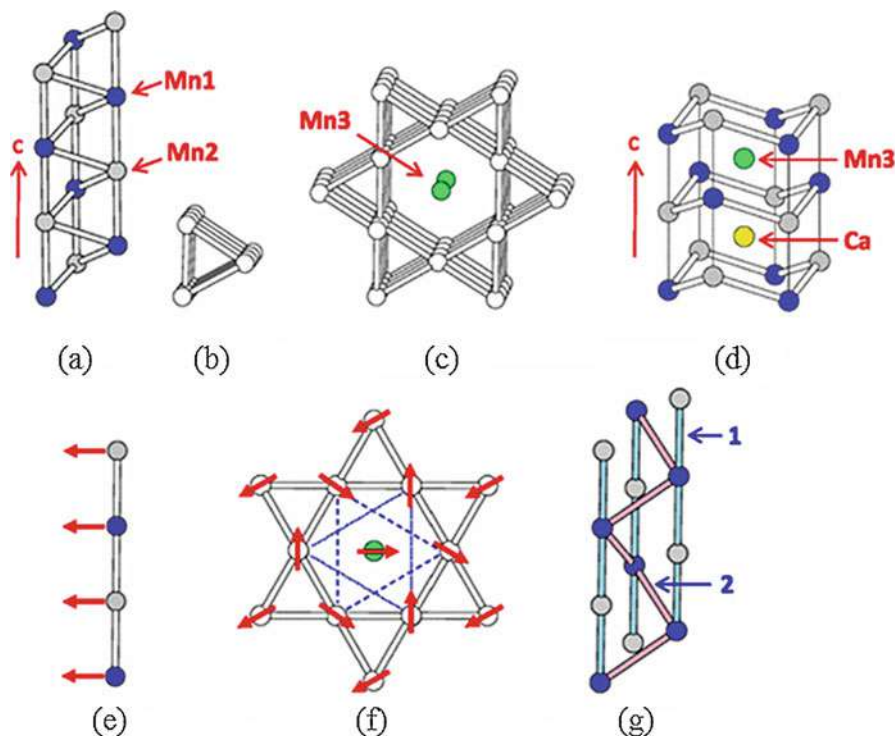
Here, the DFT-PBE + U calculations with the on-site repulsion $U = 3$ eV and the exchange parameter $J = 1$ eV were carried out (Lu et al. 2012), in which the U and J assess the Hubbard U and Hund's energy for the correlated orbitals, respectively, and U was chosen to make the experimental magnetic structure more stable and the system insulating. It was found that the FM order in one Mn^{3+} chain is due to the strong FM spin exchange interaction (J_1) between Mn1 and Mn2. The $120°$ frustrated spin alignment in the spiral chain arises from the strong AFM spin exchange interaction (J_2) between Mn1 ions in the adjacent Mn^{3+} chains (see


Fig. 11 (**a**) Three adjacent chains of Mn^{3+} ions along the c direction, in which the blue and gray circles represent the Mn1 and Mn2 atoms, respectively. (**b**) A spiral chain comprised of three adjacent chains of Mn^{3+} ions viewed approximately along the c direction. (**c**) Three-dimensional arrangement of the Mn^{3+} and Mn^{4+} (Mn3) ions in $CaMn_7O_{12}$ viewed approximately along the c direction. For simplicity, the Ca^{2+} ions are not shown. (**d**) Arrangements of the Mn^{3+} ions surrounding two adjacent Mn^{4+} and Ca^{2+} ions, where green and yellow circles represent the Mn^{4+} and Ca^{2+} ions, respectively. (**e**) Arrangement of the Mn^{3+} spins in a single chain along the c direction. (**f**) Projection view of the Mn^{3+} and Mn^{4+} spin arrangements along the c direction, where each triangle represents three Mn^{3+} chains forming a spiral chain. The spins of each FM chain along the c direction (see (**e**)) are represented by a single spin. (**g**) Two important spin exchange paths in a spiral chain comprised of three adjacent chains along the c direction, where the numbers 1 and 2 indicate J_1 (FM) and J_2 (AFM), respectively. Fig. 11g). The DFT $+ U$ plus SOC effects (DFT $+ U + SOC$) calculations (Lu et al. 2012) also showed that there exists an easy axis for the Mn1 spin and an easy plane for the Mn2 spins, which are both much closer to the ab plane than to the c axis, thus leading to the nearly in-plane alignment of all the spins.

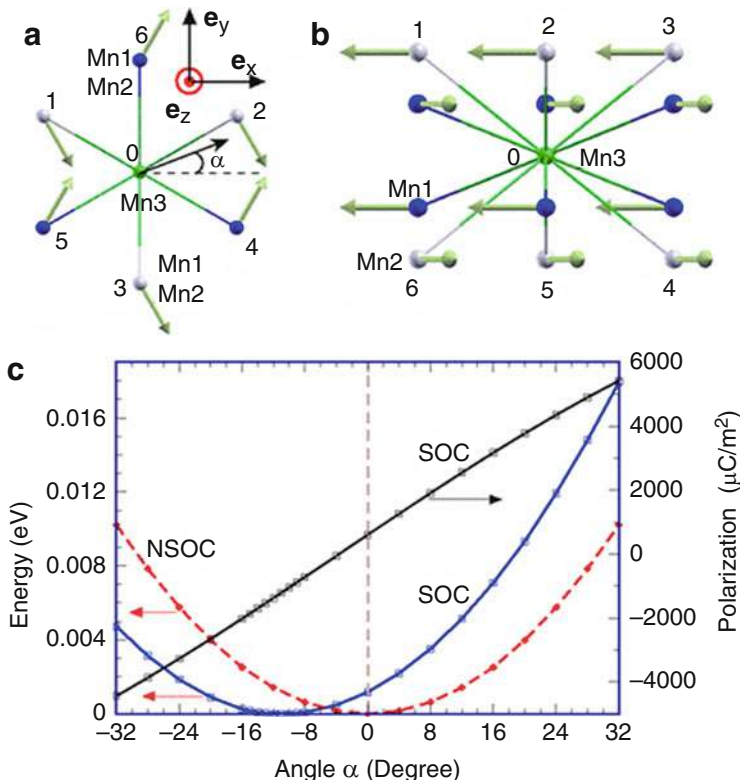
It was also found that if only symmetric spin exchange interactions are considered, then the Mn^{4+} spin will align along the direction of $\mathbf{S}_1 + \mathbf{S}_4$, because the energy of the hexagonal channel (see Fig. 12a and b) $E_{hex} \propto (J_3 + J_4)\cos\alpha$, where J_3 and J_4 are the spin exchange interactions between Mn^{4+} and Mn1 and Mn^{4+} and Mn2, respectively, and they are both negative. Therefore, α will be zero


Fig. 12 (**a**) and (**b**) display the top and side views of six Mn1 and six Mn2 ions around a Mn3 ion, respectively. The directions of the Mn1 and Mn2 spins observed experimentally are also shown. (**c**) The total energy and electric polarization as a function of the Mn3 spin direction α (see the text for the definition). NSOC indicates no SOC involved in the calculations. (Figure reproduced from Lu et al. (2012), Copyright American Physical Society, 2012)

in order to lead to a maximized energy lowering, but this is inconsistent with the experiment showing $\alpha \approx -30°$. To reconcile this discrepancy, the DM interactions between Mn^{4+} and Mn1 and Mn^{4+} and Mn2 were examined, and it was found that the DM interaction ($\mathbf{D}_4$) between Mn^{4+} and Mn2 is very large ($|\mathbf{D}_4|/|J_4| \sim 0.54$, compared with the usual ratio of ~ 0.1). Thus, by adding a DM interaction energy arising from $\mathbf{D}_4$ into E_{hex}, $E_{hex}^{new} \propto (J_3 + J_4)\cos\alpha + D_4^z\sin\alpha$ was obtained. By minimizing E_{hex}^{new}, $\alpha = \arctan\frac{D_4^z}{J_3+J_4} \approx -11.2°$, which is in good agreement with the direct DFT + U + SOC calculations. The quantitative difference in the magnitude of the angle compared with experiment can be improved by decreasing U value. Therefore, a particular spin exchange path between Mn^{4+} and Mn^{3+} ions, in which the DM antisymmetric interaction (Moriya 1960a, b) between them is unusually strong for magnetic insulators (i.e., $|D/J| \approx 0.54$), was uncovered to play a key role in determining the helical spin structure.

Although SOC effects are important to obtain the experimental spin structure, the DFT $+ U +$ SOC calculations with the helical spin structure with the propagation wave vector $(0,1,1)$ in the experimental structure indicated that the SOC contribution to the total polarization is minor. Thus, it becomes important to investigate the role of exchange striction using the $\boldsymbol{P}_{es}(\boldsymbol{S}_1 \cdot \boldsymbol{S}_2)$ term. The model results demonstrated that the polarization induced by the exchange striction arises mainly from the path that includes Mn^{4+} and Mn2 (i.e., P_{es}^4), where the polarization on one Mn^{4+} ion can be written as $\boldsymbol{P} \propto P_{es,4}^z \sin\alpha \operatorname{sign}[\boldsymbol{e}_z \cdot (\boldsymbol{S}_4 \times \boldsymbol{S}_1)]$ because of the threefold rotational symmetry and inversion symmetry between the upper set and bottom set of the Mn^{4+} and Mn2 path. From the form of $\boldsymbol{P}$, it should also be noted that the direction of $\boldsymbol{P}$ is determined by the sign of the scalar chirality $\sigma \sim \boldsymbol{e}_z \cdot (\boldsymbol{S}_4 \times \boldsymbol{S}_1) \sim \boldsymbol{r}_{41} \cdot (\boldsymbol{S}_4 \times \boldsymbol{S}_1)$, and the magnitude is also related to the finite angle α that is due to the large DM interaction ($\mathbf{D}_4$) between Mn^{4+} and Mn2. Moreover, the results from the exchange model are also in good agreement with the direct DFT $+ U$ calculations where the magnitude of the polarization is dependent of α and a large electric polarization of $-0.4 \mu C/cm^2$ is found at $\alpha = -30°$. Therefore, it was confirmed that the large improper polarization in $CaMn_7O_{12}$ with the helical spin structure arises from the combined effects of the exchange striction and strong DM interaction in a particular spin exchange path. To design new multiferroics based on these principles, *A*-site cation (i.e., Ca) substitution (Belik et al. 2016) or doping (Zhang et al. 2015) may be a promising way to optimize the structural and magnetic properties.

Collinear Spin Structure

$HoMnO_3$ with *Pbnm* symmetry was predicted theoretically (Sergienko et al. 2006; Picozzi et al. 2007) to adopt an E-type collinear spin structure in its ground state. This spin structure consists of spins that are aligned ferromagnetically in a zigzag chain, and the spins in different chains are coupled antiferromagnetically as shown in the left panel of Fig. 13. With the E-type spin configuration, the atomic structure adopts a noncentrosymmetric state owing to a net displacement of Mn and O ions along the *c* axis, leading to a relatively large polarization along the *c* direction ($\sim 6 \mu C/cm^2$) (right panel, Fig. 13). The DFT-PBE results also showed that the ferroelectricity is related to the difference ($\Delta\alpha = \alpha_p - \alpha_{ap}$) between the Mn-O-Mn angle (α_p) with parallel spins on Mn ions and the angle (α_{ap}) with antiparallel spins as can be seen in Fig. 14. Here both P and $\Delta\alpha$ decrease with increasing U. Furthermore, the total polarization can be divided into the pure electronic contributions and ionic contribution with almost equal values from each ($3.47 \mu C/cm^2$ and $3.28 \mu C/cm^2$, respectively) (Xiang et al. 2013b; Picozzi et al. 2007).

Experimentally, upon cooling to 26 K in polycrystalline $HoMnO_3$, the E-type spin structure sets in and a spontaneous polarization arises ($\sim 0.001 \mu C/cm^2$) (Lorenz et al. 2007), but it is smaller than the predicted from DFT calculations. Although the polarization increases upon further cooling below 15 K due to a complex magnetic structure arising from the spins ordering of Ho, it does not change significantly ($\sim 0.009 \mu C/cm^2$). Subsequent experimental studies have found that the magnitude of the polarization can be increased significantly when samples are

Mn-O-Mn angle (in degrees) for parallel and antiparallel Mn spins are represented by α_p and α_{ap}, respectively. Right panel: Arrows show the directions of the ionic displacements of Mn (left) and O (right) with the AFM-E spin alignment. The thick arrows at the bottom show the direction of the net displacements of Mn and O ions and the resulting $\boldsymbol{P}$. (Figure reproduced from Picozzi et al. (2007), Copyright American Physical Society, 2007)
Fig. 14 P$_{PCM}$ and α_p-α_{ap} versus U with the AFM-E spin alignment. P is computed by using the point charge model (PCM) with nominal charges (i.e., $-2e$ for O and $+3e$ for Ho and Mn). (Figure reproduced from Picozzi et al. (2007), Copyright American Physical Society, 2007)

grown in thin film geometries, including YMnO$_3$ with $\sim$0.8μC/cm^2 (Nakamura et al. 2011) and TmMnO$_3$ with $\sim$0.45μC/cm^2 (Han and Chao 2010). Both of these materials exhibit the same E-type spins order as reported in HoMnO$_3$. One may use small A-site cation substitution and/or strain engineering to obtain a large polarization in such type of the multiferroics. Before experiment, the DFT

Fig. 15 A schematic description of the spin alignment in TbMn$_2$O$_5$ in the *ab* plane. The angle of spin direction is given in parenthesis, where q$_x$ is the propagation wave vector of the spin order in *x* direction. The dashed, solid, and double lines represent J_3, J_4, and J_5 exchange interaction paths, respectively. (Figure reproduced from Cao et al. (2009), Copyright American Physical Society, 2009)
calculations can be used to model the crystal and spin structures and formulate a design strategy based on the spin Hamiltonian model.

TbMn$_2$O$_5$ (Hur et al. 2004a; Chapon et al. 2004) containing Mn^{4+}O$_6$ octahedra and Mn^{3+}O$_5$ square pyramids exhibits a complex sequence of magnetic phase transitions. An incommensurate spin order with propagation wave vector (0.48,0,0.245) appears below 44 K followed by an incommensurate-to-commensurate spin structure transition, with the propagation wave vector (0.5,0,0.25), at 38 K. The lower temperature transition is accompanied by the appearance of ferroelectricity. Another magnetic transition occurs from the commensurate phase to a different incommensurate spin structure with propagation wave vector (0.48,0,0.28) at 18 K and both dielectric anomaly and significant decrease in the electric polarization arising from the commensurate magnetic order that lifts inversion symmetry.

Most computational investigations (Wang et al. 2008, 2007; Cao et al. 2009) of the ferroelectricity in TbMn$_2$O$_5$ focus on the commensurate spin order depicted in Fig. 15. The spins aligned in the *ab* plane in the zigzag chain along the *a* direction are coupled antiferromagnetically with a small spin canting as are the spins in different zigzag chains along the *b* direction. The spins are arranged along the *c* direction with an order described by a modulation of $\frac{\pi}{2}$ in phase factor. With this magnetic spin structure, the symmetry is reduced from *Pbam* to polar *Pb2$_1$m*, enabling a polarization along the *b* direction.

First-principles calculations (Cao et al. 2009) of TbMn$_2$O$_5$ with this spin configuration (GGA exchange-correlation functional in PBE form was used) indicate that the polarization consists of a pure electronic contribution (minor contribution) from the exchange striction term in $\boldsymbol{P}_e$ and an ionic contribution (main effect) owing to exchange striction. Calculations of the electric polarization also indicated that the ion displacements are mainly from the Mn^{3+}-Mn^{4+}-Mn^{3+} segments along the *b* direction that are connected through the Mn^{3+}-Mn^{3+} spin exchange interaction between the segments. In the Mn^{3+}-Mn^{4+}-Mn^{3+} segment, the spins on the Mn^{3+} ions above and below the Mn^{4+} align in an opposite direction, either parallel or

antiparallel to the spin on Mn^{4+}. Because of this spin order, the Mn^{3+}-Mn^{4+} path in the Mn^{3+}-Mn^{4+}-Mn^{3+} segment exhibits parallel spin alignment that allows the Mn^{3+} and Mn^{4+} cations to move closer to each other in order to lower the exchange energy in the *Pbam* structure. Finally, this exchange striction effect, expressed as $-\sum_{i,i',m} \frac{\partial J_{i,i'}}{\partial u_m} u_m S_i \cdot S_{i'}$ where $J_{i,i'}$ runs over all the spin exchange interactions between nearest-neighboring Mn^{3+} and Mn^{4+} and u_m is the ion displacement (where m includes all the ions in the unit cell), leads to the symmetry reduction to $Pb2_1m$.

Furthermore, owing to the existence of the exchange striction effects in the Mn^{3+}-Mn^{4+} path, the incommensurate magnetic phase competes with commensurate magnetic phase, resulting in the appearance of the incommensurate magnetic phase at 18 K with the anomalous magnetodielectric response. The exchange striction-induced ferroelectricity in $TbMn_2O_5$ was also demonstrated in experiment (Chapon et al. 2004; Kagomiya et al. 2003; Hur et al. 2004b; Higashiyama et al. 2005; Radaelli et al. 2009; Stroppa et al. 2010) by investigating the incommensurate spin order, in which the spins in the different zigzag chains along the *b* direction were found to be almost orthogonal to each other, leading to the loss of the exchange striction effects and the strong reduction of the polarization in the incommensurate phase.

The exchange striction-induced ferroelectricity were also found in $DyFeO_3$ (Stroppa et al. 2010), CdV_2O_4 (Giovannetti et al. 2011), and $Ca_3(Co,Mn)_2O_6$ (Choi et al. 2008) compounds. Because the exchange striction effects are related to $S_i \cdot S_j$, the corresponding ferroelectricity is usually larger than that obtained from the SOC effects ($S_i \times S_j$), because of the fact that the symmetric spin exchange interaction $\sim S_i \cdot S_j$ is larger than the antisymmetric DM interaction $\sim S_i \times S_j$. This trend can be readily observed from pressure-induced magnetic phase transitions in $TbMnO_3$, i.e., upon transitioning from the cycloidal spin structure to the E-type spin structure whereby an enhancement of the polarization to $\sim 1 \mu C/cm^2$ occurs (approximately one that is an order-of-magnitude increase) (Aoyama et al. 2014).

Magnetoelasticity-Induced Ferroelectricity

If a material exhibits a paramagnetic structure that is also piezoelectric, then a magnetic phase transition may induce a polarization that arises from magnetoelastic coupling induced strain on the lattice constants (hereafter denoted by lattice deformation) and the piezoelectricity. And the polarization, as discussed in section "Unified Model for the Spin-Driven Ferroelectricity," can be expressed as $P_{lattice} = d_{\alpha j}\sigma_j$ where $\sigma_j = -\sum_{i,i'} \frac{\partial J_{i,i'}}{\partial \eta_j} S_i \cdot S_{i'}$ is the total stress due to the spin-ordered structure and piezoelectric coefficient $d_{\alpha j} = S_{jk}e_{\alpha k}$ in which S_{jk} and $e_{\alpha k}$ are the relaxed-ion elastic compliance tensor and the relaxed-ion piezoelectric tensor, respectively. Here, we take $BiFeO_3$ compound as an example to understand this mechanism and indeed describe how a large polarization arises from the lattice deformation (spontaneous strain) (Lu et al. 2015b). A G-type spin order was imposed in the DFT-PBE study, and only nearest-neighboring Fe-Fe spin exchange interactions were used in computing the stress σ. This later assumption

Table 1 The different contributions to the electric polarization (in unit of $\mu C/cm^2$) induced by the G-AFM order in $BiFeO_3$ from model and DFT calculations. $P_{lattice}$, P_e, and P_{ion} refer to the lattice deformation, pure electronic, and ion displacement contributions, respectively. Table reproduced from Lu et al. (2015b), Copyright American Physical Society, 2015

Polarization	$P_{lattice}$	P_e	P_{ion}
Model	1.32	0.53	0.56
DFT	1.22	0.40	0.54

proved to be accurate enough to reproduce σ from direct DFT calculations. The $P_{lattice}$ contribution was obtained to be as large as $\sim 1.32 \mu C/cm^2$. It is even larger than the sum of the pure electronic and ion displacement contributions (Table 1). This is an unprecedented result in which a previously unknown spin-order-induced contribution ($P_{lattice}$) to the electric polarization is found to be even larger than the typical contributions (the pure electronic and ion displacement contributions). The result suggests that when one is trying to design new multiferroics, materials large piezoelectricity and spin ordering is a promising candidate with large spin-ordering-induced polarization for strong magnetoelectricity. Table 1 also shows that the result obtained from the model used in this study is in agreement with the direct DFT calculations. Summing up all the three spin-order-induced contributions, the total polarization calculated for the G-type AFM order in $BiFeO_3$ is $\sim 2 \mu C/cm^2$, which is approximately 2% of the total polarization ($\sim 100 \mu C/cm^2$) that is induced by the ionic contribution from the Bi off-centering. The spin-induced polarization in $BiFeO_3$ is also comparable with that of $HoMnO_3$ (Sergienko et al. 2006; Picozzi et al. 2007).

3.4   Geometric Ferroelectricity

3.4.1   Single Primary Mode Coupled to a Polar Mode (Improper Ferroelectricity)

HexagonalYMnO$_3$ (h-YMnO$_3$) (Van Aken et al. 2004) is a ferroelectric (space group: $P6_3cm$) with a T_c as high as ~ 1270 K and an electric polarization of $\sim 5.6 \mu C/cm^2$. Below approximately 70 K, an AFM transition occurs and $YMnO_3$ becomes multiferroic (Lottermoser et al. 2004; Fiebig et al. 2000). Density functional theory calculations within the LDA approximation demonstrated that the polar nature of h-YMnO$_3$ arises from condensation of a zone-boundary phonon in the first Brillouin zone, labeled as K_3, which results in the buckling (trimerization) of MnO_5 bipyramids (Van Aken et al. 2004). The K_3 mode couples to a stable polar lattice mode, which shorten and elongate the Y-O_{eq} distances along the c direction (see Fig. 16) to produce a net ferroelectricity. As a consequence, the polarization P is proportional to either $Q_{K_3}^3$ or Q_{K_3}, depending on the magnitude of mode Q_{K_3} (Fennie and Rabe 2005). The A-site substitution with the elements in the lanthanides can also lead to this type of the improper ferroelectricity (Young et al. 2015).
Fig. 16 The DFT calculated atomic positions in the centrosymmetric and ferroelectric structures. The numbers display the bond lengths in Å. The arrows indicate atomic displacements in the ferroelectric structure with respect to the centrosymmetric structure. (Figure reproduced from Van Aken et al. (2004), Copyright Springer Nature, 2004)

Recently, first-principles DFT-PBE calculations also demonstrated that the K_3 mode may also lead to magnetoelectric coupling in hexagonal LuBO_3 (B = Mn,Fe) (Das et al. 2014), which is isostructural to h-YMnO$_3$. Based on a phenomenological model in which there exists a trilinear term $F_{tri} \sim (\mathbf{Q}_I \cdot \mathbf{L}_I + \mathbf{Q}_{II} \cdot \mathbf{L}_{II}) M_z$ where $\mathbf{Q}_i$ and $\mathbf{L}_i$ (i = I,II) are the K_3 mode vector and AFM vector, respectively, as depicted in Fig. 17b, and M_z is the total magnetization in the two magnetic layers I and II, it was found that if $\mathbf{Q}_i$ changes its tilting direction, then either $\mathbf{L}_i$ or M_z change accordingly in order to lower the energy of the trilinear term F_{tri}. For example, when $\mathbf{Q}_i$ changes from configuration α^+ to β^- (Fig. 17a), the direction of the polarization will reverse, and according to F_{tri}, either $\mathbf{L}_i$ or M_z will be reversed accompanying the reversal of the polarization. The interesting phenomenon here is the switching of the magnetization upon electric polarization switching, while it may not be always true, because if $\mathbf{L}_i$ is reversed, M_z will be unchanged. It should be noted even if $\mathbf{L}_i$ is changed, ME coupling also occurs via the linear ME coefficient $\alpha_{zz} \approx \frac{\partial M_z}{\partial Q_{K_3}} * \frac{\partial P_z}{\partial Q_{K_3}}$ where P_z is the electric polarization along the c axis in hexagonal $P6_3cm$. More details about such ME effects are discussed in the Sect. 3.10.

3.4.2 Two Primary Modes Coupled to the Polar Mode (Hybrid Improper Ferroelectricity)

Hybrid improper ferroelectrics were first proposed to occur in ultrashort period $PbTiO_3/SrTiO_3$ superlattices (Bousquet et al. 2008; Aguado-Puente et al. 2011). Bousquet et al. reported a new mechanism for ferroelectricity, whereby a stable polar mode (P) can be coupled to *two* primary antiferrodistortive (AFD) modes (most unstable modes at the phase transition), i.e., an in-phase oxygen octahedral-rotational mode ($Q_{M_2^+}$) and an out-of-phase oxygen octahedral-rotational mode ($Q_{M_4^-}$). In this particular compound, both rotational modes occur about the out-of-plane axis (c axis) as shown in Fig. 18. This coupling among multiple lattice phonons is referred to as a "trilinear coupling interaction" ($\sim PQ_{M_2^+}Q_{M_4^-}$), because of the total energy of the material can be further lowered by its presence. Consequently, a stable polar mode will condense in the ground state even if it is disfavored in the absence of the rotational modes. This fact makes the ferroelectricity "improper" (Benedek et al. 2015). Later, a similar phenomenon was discovered in $Ca_3Mn_2O_7$ by Benedek and Fennie (2011), in which the trilinear coupling interaction also induces the condensation of an essentially (weakly) stable mode (see Fig. 19a). In contrast to the $PbTiO_3/SrTiO_3$ superlattices, the two primary modes in the manganite are one in-phase oxygen octahedral-rational mode (Q_R) around the out-of-plane axis (e.g., $[001]_{pt}$ pseudo-tetragonal axis) and one out-of-phase oxygen octahedral-tilt mode (Q_T) around an in-plane axis (e.g., $[\bar{1}10]_{pt}$ pseudo-tetragonal axis) so that $F_{tri} \sim PQ_RQ_T$. Such materials containing these trilinear coupling interactions are referred to as *hybrid* improper ferroelectrics, and strategies toward realizing them by computational design have been described in several review articles (Benedek et al. 2012, 2015; Harris 2011; Mulder et al. 2013; Oh et al. 2015; Senn et al. 2015; Liu et al. 2015).

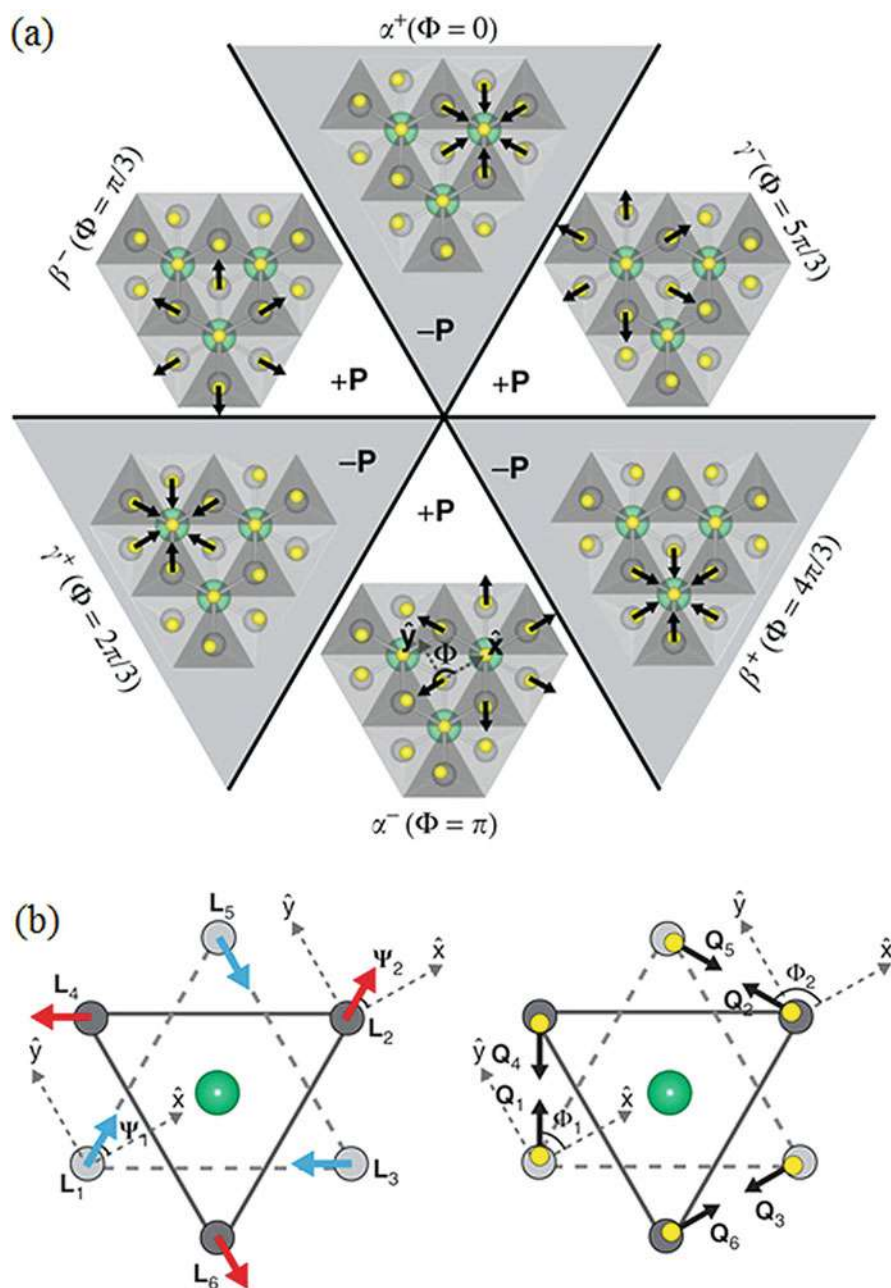
Another intriguing phenomenon reported for $Ca_3Mn_2O_7$ was a novel magneto-electric (ME) coupling mechanism. $Ca_3Mn_2O_7$ crystallizes in the $Cmc2_1$ phase at low temperature and adopts a G-type spins order with the spins along $[001]_{pt}$ and a weak ferromagnetic spin canting along $[110]_{pt}$ (see Fig. 19b). The spins pointing along the $[001]_{pt}$ direction arises from the spin anisotropy, whereas the weak ferromagnetism (wFM) results from the DM interaction in which DM interaction-related energy can be expressed as $E_{DM} = \mathbf{D} \cdot (\mathbf{L} \times \mathbf{M})$ where $\mathbf{D}$, $\mathbf{L}$, and $\mathbf{M}$ are the DM interaction vector, AFM vector $\mathbf{L} = \mathbf{S}_1\text{-}\mathbf{S}_2$, and wFM vector $\mathbf{M} = \mathbf{S}_1 + \mathbf{S}_2$, respectively. The $\mathbf{D}$ vector is also proportional to approximately $\boldsymbol{r_1} \times \boldsymbol{r_2}$, where $\boldsymbol{r_1}$ and $\boldsymbol{r_2}$ are the distance vectors defining the Mn-O bonds in the Mn-O-Mn subsystem as shown in Fig. 19b. It is then readily found by the right-hand rule that the DM vector induced by Q_T can produce wFM according to E_{DM}, which is along the direction perpendicular to both $\mathbf{D}$ and $\mathbf{L}$ vectors (see Fig. 19b). In contrast, the DM vector induced by Q_R is in the same direction as $\mathbf{L}$, which leads to a zero E_{DM} and no weak ferromagnetism. This rotation-control mechanism leads to on/off-control of wFM. Therefore, if an external electric field switches the direction of the polarization, then either Q_R or Q_T will be reversed due to the trilinear coupling interaction. Whether the rotation or tilt mode switches is mainly determined according to which switching path has the lower energy barrier (Benedek and Fennie


Fig. 17 (continued)

2011; Nowadnick and Fennie 2016). If the polarization switching favors switching of Q_T, the direction of the wFM will switch simultaneously because of the reversal of $\mathbf{D} \sim \mathbf{r_1} \times \mathbf{r_2}$, which corresponds to the octahedral tilt control route as shown in the bottom left panel of Fig. 19b.

Rondinelli and Fennie (2012) also reported hybrid improper ferroelectricity in 1:1 $ABO_3/A'BO_3$ superlattices based on the common *Pnma* structures found in ABO_3 and $A'BO_3$ components (Benedek and Fennie 2013). The basic idea here to produce hybrid improper ferroelectricity is to combine two components together and obtain the preferred criteria – coupling of two nonpolar lattice modes to a polar mode – for hybrid improper ferroelectricity. So, why are layered $(AA')B_2O_6$ perovskites and *Pnma* symmetry in each single perovskite component key features of a design strategy for hybrid improper ferroelectricity? To answer the question, the authors proposed a chemical criterion solely based on the symmetry consideration. As can be seen in the left panel of Fig. 20, in the ideal ABO_3 structure, there are inversion centers on both A and B sites. When there is A and A'-layered ordering, the inversion symmetry on the B sites is lifted, while the inversion symmetry on the A sites is kept. When there is B and B′-site-layered ordering, then the inversion symmetry on the A sites is lifted, while the inversion symmetry on B sites is kept. Furthermore, the oxygen octahedral-rotational modes can lift the inversion symmetry on the A site and preserve the inversion symmetry on B sites; therefore, one should anticipate that the A-site-layered cation ordering combined with an additional displacive mode could lift inversion symmetry without requiring a proper ferroelectric mechanism. Ultimately, this combination would lead to hybrid improper ferroelectricity driven by octahedral rotations, which led to a proposed energetic criterion based on lattice dynamical stability. For example, if both the $00a^+$ and a^-a^-0 (in Glazer notation) rotational patterns condense or are at least energetically competitive in each bulk component, then the prototype trilinear coupling interaction inducing the hybrid improper ferroelectricity should arise. The tilt pattern design strategy relies on these two rotational patterns, which combine to produce the common *Pnma* symmetry found in bulk ABO_3 perovskites. Using these guidelines, several new hybrid improper ferroelectrics and multiferroics were predicted.

Building on the work of Rondinelli and Fennie, a similar ME coupling mechanism was predicted in ultrashort period 1:1 $BiFeO_3/LaFeO_3$ superlattices (Zanolli

---

Fig. 17 (**a**) Schematic illustration of the six possible structural domains. Each domain is labelled by its phase Φ, defined to be the (counter)clockwise angle of the displacement directions of the apical oxygen of the trimer distortions relative to those in the α^+ domain. **P** indicates the polarization. (**b**) Left panel: The spin vectors $\mathbf{L_i}$ (i = 1–6) on the magnetic ions for the I (light grey ions) and II (dark grey ions) layers. Right panel: The local trimer distortion vectors $\mathbf{Q_i}$ ($i = 1$–6) on the magnetic ions. Ψ_i represents the angle of the reference $\mathbf{L_i}$ vector in the ith layer ($i = 1,2$), and the relationship among the spin vectors is determined because of the $120°$ spin arrangement; Φ_i represents the angle of the reference $\mathbf{Q_i}$ vector in the ith layer ($i = 1,2$), and the relationship among the $\mathbf{Q}$ vectors is determined according to the symmetry of the K_3 trimerization mode. et al. 2013). Bulk $BiFeO_3$ crystallizes in the *R3c* structure, which competes with the *Pnma* phase (Dieguez et al. 2011). Bulk $LaFeO_3$ adopts the prescribed *Pnma* symmetry for its ground-state structure (Geller and Wood 1956). So, both compounds satisfy the proposed energetic criterion. Indeed, the 1:1 $BiFeO_3/LaFeO_3$ superlattice exhibits a polar *Pmc2₁* symmetry as predicted in Zanolli et al. (2013). Because both compounds have G-type magnetic structure in bulk, the superlattice was assumed to also exhibit G-type magnetic order. The hybrid improper ferroelectricity was confirmed by computing the energy as a function of the mode amplitudes upon freezing each mode separately in the high symmetry structure (i.e., *P4/mmm*) with density functional theory within the LDA. The spin alignment was predicted to be in plane and perpendicular to the polarization direction, which by symmetry allows for wFM controlled by Q_T along the out-of-plane direction as indicated by the form of E_{DM} and confirmed in the first-principles calculations. It is should be noted that there is also wFM controlled by Q_R lying in plane and along the polarization direction, but this kind of wFM cancels between layers and results in a null net weak ferromagnetism. Because the wFM in the 1:1 $BiFeO_3/LaFeO_3$ superlattice is controlled by the tilt mode, it is expected that if the switching path for the polarization reversal can be along a trajectory that changes Q_T, then the direction of the wFM can be simultaneously reversed. Furthermore, because both bulk compounds have high Néel temperatures (i.e., 643 K for $BiFeO_3$ and 750 K for $LaFeO_3$), the 1:1 $BiFeO_3/LaFeO_3$ superlattice was predicted to be room-temperature multiferroic.

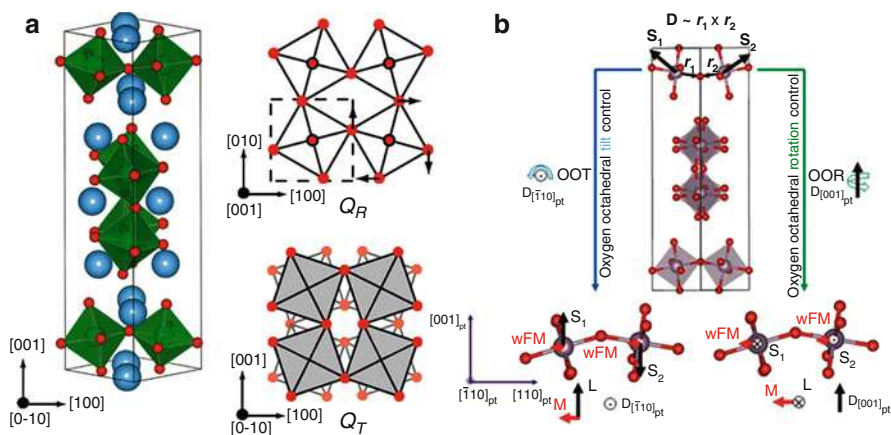
A linear ME response was also predicted in 1:1 $LaFeO_3/LnFeO_3$ superlattices (Ln: lanthanide cation) (Ghosh et al. 2015) and they have the same multiferroic


Fig. 19 (**a**) The $Cmc2_1$ ferroelectric ground-state structure of $Ca_3Mn_2O_7$. The large (blue) spheres are Ca ions. The schematic illustration of the atomic displacements corresponding to the X_2^+ (Q_R) rotation (top) in which the dashed square displays the unit cell of the $I4/mmm$ high-symmetry structure and the X_3^- (Q_T) tilt mode (bottom). The coordinate system is that of the $I4/mmm$ high-symmetry structure. Panel (**b**) shows the mechanisms for oxygen octahedral tilt (left, blue) and rotation (right, green) control of the direction of weak ferromagnetism. $\mathbf{S_i}$ (i = 1,2), $\mathbf{D_i}$ (i = 1,2), $\mathbf{r_i}$ (i = 1,2), $\mathbf{M}$, and $\mathbf{L}$ represent the local spin vectors, DM interaction vectors, unit vectors along the S_i-O bond direction, and the wFM and AFM vectors, respectively. The polar $Cmc2_1$ structure (center) is shown as reference without the A cations for clarity. (Figure (**a**) reproduced from Benedek and Fennie (2011), Copyright American Physical Society, 2011. properties as those in the 1:1 $BiFeO_3/LaFeO_3$ superlattice, i.e., G-type magnetic order and hybrid improper ferroelectricity in $Pmc2_1$ structure. Because of the $m'2'm$ magnetic point group, there are α_{yz} and α_{zy} nonzero components in the magnetoelectric tensor. In addition, α_{zy} was proven to be one order-of-magnitude larger than α_{yz} with α_{zy} proportional to the magnitude of the electric polarization (see Fig. 21) but decreases with increasing m and n in $(LaFeO_3)_m/(LnFeO_3)_n$ period superlattices. Furthermore, the microscopic origin of the linear ME response on α_{zy} is due to changes of the DM interaction along the polarization direction induced by the applied electric field.

As clarified in Young et al. (2015), except the regular rotations such as the oxygen octahedral rotations coupled to the polar mode, there are also pseudo-rotations, which leads to the existence of many other types of improper ferroelectrics providing a new platform to study the multiferroics.

3.5   Asymmetric Multiferroics

To access the strong ME coupling in multiferroic materials, the concept of *asymmetric* multiferroics were proposed (Lu and Xiang 2014). Symmetric multiferroics are
Fig. 20 (**a**) Bulk ABO_3 perovskites where inversion (I) centers are found on both A and B sites, and the highest site-symmetry operator is a threefold rotoinversion ($\bar{3}$). (**b**) A site cation ordering in layered perovskites, in which the inversion centers on the B site are broken leading to a fourfold rotation and remain on the A site through the $\frac{4}{m}$ operation. (**c**) B-site cation ordering in layered perovskites, in which the inversion centers on the A site are broken leading to a remaining fourfold rotation and $\frac{4}{m}$ operation on the B site. those in which the two opposite electric polarization states are symmetry related, usually by an inversion center, and the magnetic states are also symmetrically equivalent (see Fig. 22). Multiferroics such as $BiFeO_3$ and $TbMnO_3$ fall within this classification. In contrast, asymmetric multiferroics exhibit two configurations with electric polarizations in opposite directions for each state but the polarization state of the phase configuration cannot be obtained from the other through the action
Fig. 22 Schematic illustration of symmetric multiferroic and asymmetric multiferroic. The transition state (TS) corresponds to a phase that has the highest energy in the switching path, and **P** and **S** represent the electric polarization and magnetic state, respectively. $\widehat{R}$ is the symmetry operation of point group. In a symmetric multiferroic, the two FE states and the associated magnetic properties are related by the symmetry operation of point group ($\widehat{R}$). (Figure reproduced from Lu and Xiang (2014), Copyright American Physical Society, 2014)

of any symmetry operation of the point group. In addition, the magnetic states can also differ (see Fig. 22). Furthermore, because the two polar state are inequivalent, the transition state between them is noncentrosymmetric, compared to the nonpolar transition state (TS) in symmetric multiferroics.

To explore the feasibility of such materials, computational studies based on DFT at the PBE level of theory with the $LiNbO_3$-type structure were performed. In this example, the high-temperature paraelectric structure adopts the $R\bar{3}c$ symmetry, and the low-temperature FE structure exhibits $R3c$ symmetry (see Fig. 23a). To obtain the two asymmetric polar states, the nominal paraelectric state ($R\bar{3}c$) was designed to be polar by substituting A with A′ or B with B′ to form an ordered $AA'BB'O_6$ compound. The **P** (P_{up}) state is inequivalent with **–P** (P_{dn}) state as shown in Fig. 23a. This strategy was further verified by performing DFT calculations on $AlA'FeCrO_6$ and $AlA'FeMoO_6$ series (A′ = Al,Ga,Sc,In,Y).

Here Fe^{3+}, Cr^{3+}, and Mo^{3+} have high-spin configurations and magnetic moments $5\mu_B$, $3\mu_B$, and $3\mu_B$, respectively. Thus because of the AFM spin-exchange interaction between nearest-neighboring Fe and Cr/Mo ions, the aforementioned compounds are ferrimagnets. As can be seen in Fig. 23b, when changing the states from **P** to **–P**, the J_1 spin-exchange interaction varies dramatically (see inset), leading to variable magnetic transition temperatures with a maximum difference as large as 300 K in $AlYFeMoO_6$. The large changes in the J_1 spin exchange interactions between the two states occur due to the large changes in the real-space exchange paths; for example, it is found that the Fe-O and Cr-O bond lengths are different for the **P** and **–P** states. This bond length difference influences the $\pi - \sigma$ couplings between the occupied Cr t_{2g} orbitals and unoccupied Fe e_g orbitals (see Fig. 23b). Finally, the large differences in the bond environment for the exchange paths leads to a much larger J_1 spin exchange interaction in the **–P** state. Therefore, if the **P** and **–P** states can be switched at a temperature that is lower than that of **–P**

Fig. 23 (continued)

state but higher than that of **P** state, then the reversal of the electric polarization will accompany the ferromagnetic-to-paramagnetic transition.

Although in this strategy the polarization and magnetism arise from different origins, where the electric polarization results from the A ions forming ionic or covalent bonds with the neighboring out-of-plane O ions and magnetism is derived from partially filled d-orbitals of the B-site cations, one may still obtain strong ME coupling. This behavior is different from other Type-I multiferroics with the polarization and magnetism also arising from different origins, such as $BiFeO_3$ and $BiMnO_3$. Lastly, the magnetic transition temperature in these asymmetric multiferroics can also be tuned by adjusting the B-site cations, which is well suited for a comprehensive electronic structure study.

3.6   Polymorphic Materials

Strain engineering is a useful tool to induce emergent phenomena, for example, strain-induced ferroelectricity (Schlom et al. 2014), which provides a route to design new multiferroics. Bulk $EuTiO_3$ is paraelectric antiferromagnetic. The magnetic transition temperature of the G-type AFM order arising from the Eu^{2+} ions occurs at 5.5 K (Katsufuji and Takagi 2001; Chien et al. 1974; McGuire et al. 1966). This material satisfies the design rules proposed by Fennie and Rabe (2006), which rely on an equilibrium material with an AFM and PE ground-state structure that hosts a low-frequency optical phonon mode (TO1 mode) that is exceeding sensitive to the magnetic order and applied epitaxial strain. Therefore, by applying compressive in-plane biaxial strain, it was found from DFT-PBE calculations that the frequency of the A_{2u} mode (split from the TO1 mode because of the in-plane strain) decreases for both AFM and FM orders. Specifically, when the strain reaches -0.92%, the frequency of the A_{2u} mode becomes zero for the FM state, while it remains finite for the AFM order. For strains at -1.2%, the frequency of the A_{2u} mode also becomes zero for the AFM spin configuration. This findings suggested that a large magnetocapacitive response could be found at -0.92% by applying an external magnetic field (see Fig. 24). Furthermore, a FM-to-FE phase should be realized at a strain value of -1.25% when the structure adopts a $P4mm$ symmetry with an

electric polarization of ∼10μC/cm^2. Thus, a strong ME coupling could be expected at −1.25% strain (see Fig. 24), when the AFM-to-PE to FM-to-FE transitions occur by applying an external electric field along the polarization direction in FE phase (out-of-plane axis). Later, the FM-to-FE phase was confirmed by experiment with EuTiO$_3$ films grown under 1.1% tensile strain at 4.2 K (Lee et al. 2010).

SrMnO$_3$ is another interesting compound showing strong spin-phonon coupling. It is a PE and has a G-type magnetic order with the transition temperature of ∼233–260 K (Chmaissem et al. 2001; Takeda and Ohara 1974). There also exists a large frequency difference for the lowest-lying optical phonon mode between AFM and FM orders as shown in Table 2. Therefore, the FM-FE phase was predicted to appear at either compressive (−2.9%) (*I4cm* with a polarization along [001]$_{pt}$) or tensile strains (3.4%) (*Ima*2 with a polarization along [110]$_{pt}$) by using a GGA-PBE + U form in the DFT calculations (see Fig. 25) (Lee and Rabe 2010). The polarizations can be ∼54μC/cm^2 for both strain states, and the magnetic temperatures are both near 92 K. Moreover, a recent experiment indeed found a FE SrMnO$_3$ phase under tensile strain (1.7%) with the polarization along [110]$_{pt}$ but with G-type AFM order (Becher et al. 2015). It should be noted that such spin-phonon coupling as obtained from DFT calculations can be quite sensitive to the choice of the exchange-correlation functional (Hong et al. 2012); therefore, when making material predictions on new compounds relying on this interaction, it is important to test the robustness of the spin coupling for various functionals.

In our recent work (Lu and Rondinelli 2017), we showed an alternative promising route to realize electric field controllable magnetism at room temperature in multiferroics based on the family of A$_3$B$_2$O$_7$-layered perovskites. In this A$_3$B$_2$O$_7$ compound, as mentioned in Sect. 3.4.2, the polar mode (P), oxygen octahedral *rotation* (OOR) (Q_R), and oxygen octahedral *tilt* (OOT) (Q_T) modes couple together by a trilinear interaction, PQ_RQ_T, to stabilize the polar ground-state structure (i.e., *Cmc*2$_1$ symmetry) and lead to the functional electric polarization $P \propto Q_RQ_T$. Our previous work demonstrated that the polarization can be completely suppressed

by application of moderate compressive or tensile strains, i.e., a phase transition from a polar state to a nonpolar state (i.e., *Pbcn* symmetry) for $Ca_3Ti_2O_7$ (Lu and Rondinelli 2016). The strain-induced polar-to-nonpolar (P-NP) transition is a general phenomenon in the $A_3B_2O_7$ family (see Table 3). Remarkably, it arises because of the sensitivity of the trilinear coupling interaction that largely stabilizes the *polar* phase. We further showed that by interleaving two $n = 2\ A_3B_2O_7$ materials together, such that at least one exhibits a strain-induced P-NP transition, even more oxides can be made to exhibit the P-NP transition, specified as B-site cation-ordered $A_3BB'O_7$ films (see Fig. 26).

More interestingly, in the magnetic $A_3BB'O_7$ films, we demonstrated that the removal of the in-plane polarization across the tensile P-NP transition can be utilized to achieve electric field tunable weak ferromagnetism. This novel mechanism arises from a change in sense of the oxygen octahedral *rotation* across the tensile P-NP transition where the *in-phase* rotation in the polar phase changes to the *out-of-phase* rotation in the nonpolar phase (see Fig. 27). An addition requirement for
Fig. 26 Left: Illustration of the layered (001) B-cation order in the Ruddlesden-Popper $A_3BB'O_7$ compound. The high-symmetry structure, which adopts *I4/mmm* symmetry before substitution, undergoes a symmetry reduction to *I4mm* symmetry after substitution. The epitaxial plane is the (001) plane. Right-top and right-bottom show the calculated total energies as a function of biaxial strain for Ca_3TcTiO_7 and Ca_3MnTiO_7, respectively, where the energy is given relative to that of the *Cc* phase at 0% strain. this effect is imposed by the rotation-tunable weak ferromagnetism direction, as shown in Fig. 19b. Either the direction arises as an intrinsic property of the compound or the direction is achieved by an external magnetic field through a spin-flop mechanism. We thus predicted with DFT-PBEsol calculations that the multiferroic cation-ordered Ca_3TcTiO_7 may be a viable candidate for switching-path-independent room-temperature electric field controllable magnetism.

3.7 Superlattices

An artificial superlattice consists of nanostructured materials, whereby each component in the nanostructure may exhibit physical properties different from its
Fig. 27 Illustration of two-step transformation process by OOR at the (P-NP)$'$ phase transition boundary in Ca_3MnTiO_7. I and F indicate the Initial step and Final step in the switching process from the polar Cc (left, with both in- and out-of-plane polarization) phase to the polar $Pna2_1$ (right, with only out-of-plane polarization) phase through the polar Pc intermediate structure with different amplitude rotation angles. The blue and purple arrowed arcs indicate the BO_6 rotation sense in Ti and Mn perovskite layers, respectively. Red open circles and arrows indicate no wFM in Ti perovskite layers and the direction and magnitude of wFM in Mn perovskite layers, respectively. Dashed arrows with a time coordinate shown on the bottom track of the layers in which the sense of OOR changes during the process. bulk analog. The superlattice may be considered as a new material with physical properties that are affected by interface effects (number density and proximity) such that emergent phenomena may appear (Lu et al. 2014). For example, as described in the Sect. 3.4.2, the nonpolar perovskite compounds with $Pnma$ structures can be used as "building blocks" to construct superlattices exhibiting hybrid improper ferroelectricity. However, the building blocks individually do not necessarily need to exhibit ferroelectricity. In this section, we discuss how one can use superlattices to design and discover new multiferroics as a general strategy, not only focusing on the hybrid improper ferroelectricity.

$LiOsO_3$ is a polar metal ($R3c$ symmetry) and nonmagnetic (Shi et al. 2013). $LiNbO_3$ is a ferroelectric insulator ($R3c$ symmetry) and nonmagnetic (Sim and Kim 2014; Giovannetti and Capone 2014). Recently, by carrying out DFT + U calculations (PBE exchange-correlation functional), Puggioni et al. (2015) predicted that a 1:1 $LiOsO_3/LiNbO_3$ superlattice transforms from a nonmagnetic metal into a Mott multiferroic (Pc symmetry) with a finite band gap through correlation effects. Both transition temperatures for the polar and G-type magnetic orders were predicted to be higher than room temperature (927 K and 379 K, respectively),

and the multiferroic phase was calculated to have an electric polarization of approximately $41.2\mu C/cm^2$ by the Berry phase method.

Hexagonal $LuFeO_3$ thin films are multiferroic with coexisting electric polarization (transition temperature, 1050 K) and G-type magnetic order (transition temperature, 440 K) at room temperature (Wang et al. 2013). The origin of the ferroelectricity is the same as that in $YMnO_3$ as discussed in Sect. 3.4. A related ferrate is $LuFe_2O_4$, which undergoes a three-dimensional charge ordering below 330 K, where the ratio of Fe^{2+} and Fe^{3+} in one triangular layer comprised of corner-sharing FeO_5 trigonal bipyramids is 1:2 (A layer), while it is 2:1 in the other triangular layer (B layer) (see Fig. 5b). Ferrimagnetic order sets in below 240 K.

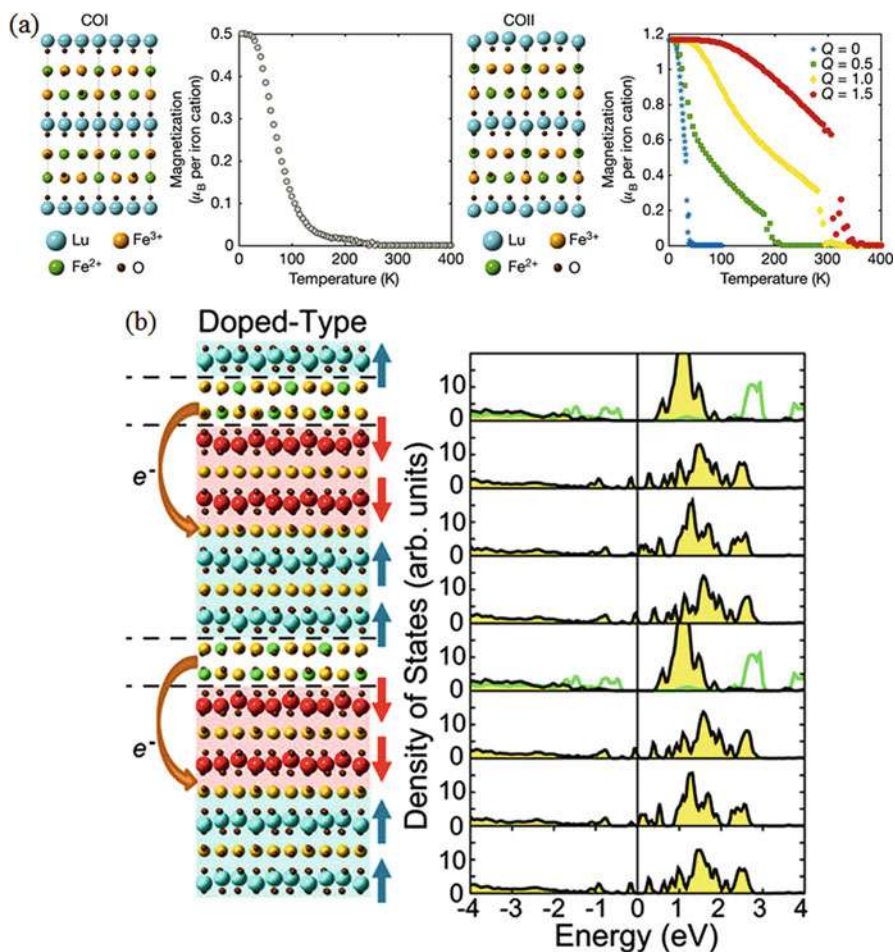
A superlattice comprised of $LuFeO_3$ and $LuFe_2O_4$ has been synthesized recently by oxide molecular beam epitaxy with m periods as $(LuFeO_3)_m/(LuFe_2O_4)_1$ (Mundy et al. 2016). Experimental assessment of the structure and properties shows that the $m = 9$ $(LuFeO_3)_9/(LuFe_2O_4)_1$ superlattice exhibits room-temperature ferrimagnetism and an electric polarization ($\sim 6\mu C/cm^2$). Note that upon decreasing m from 9 to 2, the Curie temperature, magnetization, and polarization of the superlattice also decrease. The authors also found that both the magnetic moment per iron and the magnetic transition temperature in $LuFe_2O_4$ were enhanced relative to the bulk values. The increased transition temperature can be ascribed to the influence of the ferroelectric trimer distortion (Q) on a $LuFe_2O_4$ layer, which was demonstrated by considering a "model $LuFe_2O_4$" structure in which the Q is artificially added into the original $LuFe_2O_4$ structure and mimics the magnetic transition temperature by using a "Ising-like" model with different Q magnitudes in Monte Carlo simulations. In the electronic structure calculations within the GGA-PBE, two charge-ordered structures were considered to understand the effect of Q: first, COI which has the A and B layers along the c direction with the stacking sequence of ABBA (net magnetization, $0.5\mu_B/Fe$), and second, COII with ABAB ($1.2\mu_B/Fe$). It should be noted that the charge ordering also affects crystal symmetry: COI results in the structure having nonpolar $C2/c$ symmetry (ground state), and COII is compatible with Cm symmetry (see Fig. 28a). Only the COII structure is compatible with the Q trimer distortion. As Fig. 28a shows, this distortion is strongly coupled to the magnetic state, i.e., with increasing Q, the magnetic transition temperature in COII increases. Thus, it can be understood why the superlattice exhibits an enhanced magnetic ordering temperature. It results from the Q mode that arises when the superlattice transforms into the COII phase. Although the enhancement of the local magnetic moment remains unclear, two situations were presented: charge transfer from the $LuFe_2O_4$ layers to $LuFeO_3$ layers (see Fig. 28b) and/or charge ordering changes upon going from COI to COII. In any case, both situations are connected with the Q mode-induced structural transition.


Fig. 28 (**a**) Monoclinic nonpolar $C2/m$ structures of bulk $LuFe_2O_4$ with an antiferroelectric charge-ordered (COI) state and the polar Cm structure with the ferroelectric charge-ordered (COII) state. The saturated magnetization per iron cation calculated as a function of temperature for each CO configuration is shown on the right. For the COII configuration, the temperature-dependent saturated magnetization per iron cation is also calculated as a function of Q, the amplitude of the trimer distortions with respect to the high-symmetry $R\overline{3}m$ structure. (**b**) Structure of the interface-doped $(LuFeO_3)_3/(LuFe_2O_4)_1$ superlattice. Electron transfer occurs from the $LuFe_2O_4$ layers to the $LuFeO_3$ layers in the structure (orange arrows). Lu^{3+} are shown in turquoise or red depending on the direction of the ferroelectric polarization, and Fe^{3+}, Fe^{2+}, and O^{2-} are represented by yellow, green, and brown colors, respectively. The DFT-projected density-of-states for Fe^{3+} and Fe^{2+} are plotted in yellow and green, respectively. (Figure reproduced from Mundy et al. (2016), Copyright Springer Nature, 2016)

3.8   Ferromagnetic-Multiferroic Heterostructure

$BiFeO_3$ as discussed has attracted enormous attention, because of its above-room-temperature ferroelectric and magnetic transition temperatures and large electric polarization ($\sim$100μC/cm^2 in thin film). By further investigating the FE and AFM domains in $BiFeO_3$ films (Zhao et al. 2006; Chu et al. 2008; Heron et al. 2014, 2011; Ederer and Spaldin 2005), several researchers have found that the polarization along the rhombohedral [111] direction can be switched by 180°, 109°, or 71°, upon which the direction of the AFM vector may also change by 90° (see Fig. 29a). For example, if the AFM vector is along [110], a 71° polarization switching from [1$\bar{1}$1] to [111] may lead to a 90° rotation of the AFM vector defining the easy plane to be along the [1$\bar{1}$0] direction as depicted in Fig. 29b. Then the wFM direction formerly along [$\bar{1}\bar{1}$2] when the AFM vector is along [110] will also rotate through the 71° FE domain switching. As in the multidomain structure, two domains linked by 71° FE domain wall have a net in-plane polarization, which can be reversed by applying an in-plane electric field. This geometry will result in the simultaneous 180° reversal of the net wFM because of the coupled FE and AFM domain structures (see Fig. 29b) (Heron et al. 2011).

Very recently, it was reported that an out-of-plane electric field also induces a 180° reversal of the wFM that includes a so-called two-step switching path in the FE domain transition process (Heron et al. 2014). Initially, the polarization, AFM vector, and wFM vector are along [1$\bar{1}$1] [110] and [1$\bar{1}\bar{2}$] directions, respectively. Switching occurs first through a 71° FE domain with the polarization, AFM vector, and wFM vector transformed along the [$\bar{1}\bar{1}$1], [1$\bar{1}$0], and [$\bar{1}\bar{1}$2] directions. Next, a 109° FE domain switching occurs, and the polarization, AFM vector, and wFM vector are aligned along [$\bar{1}\bar{1}\bar{1}$], [110], and [$\bar{1}$12] directions, respectively. After the 71° and 109° domain switching paths, the electric polarization and wFM vector will be reversed 180° (see Fig. 30a).

In the two cases mentioned above, the strong ferromagnet CoFe film is deposited on the $BiFeO_3$ film to amplify the microscopic switching process, i.e., to discern changes induced by applying in-plane (Heron et al. 2011) and out-of-plane electric fields (Heron et al. 2014), respectively. The enhancement arises from the exchange coupling between the local CoFe moments and wFM in $BiFeO_3$ (see Fig. 30b for the out-of-plane electric field configuration, where the net $Co_{0.9}Fe_{0.1}$ magnetization reverses after the voltage is applied).

3.9   Ferromagnetic-Ferroelectric Heterointerfaces

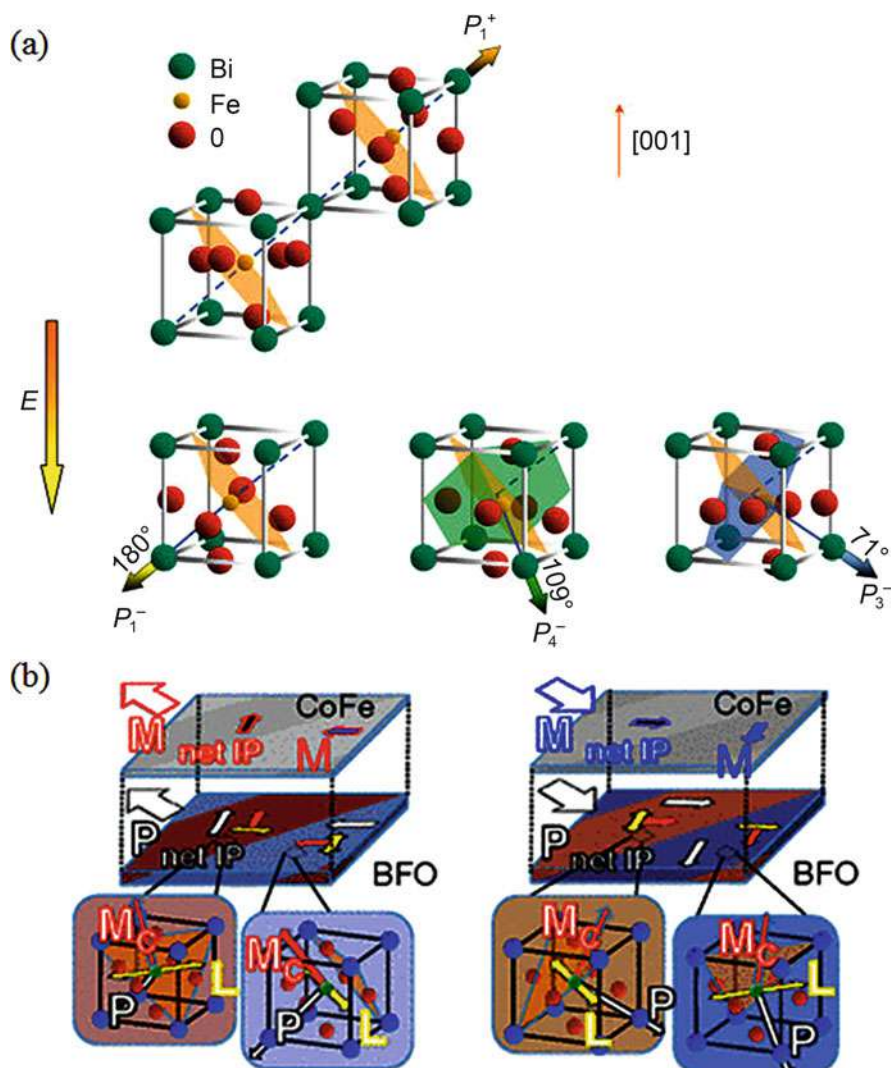
Interface engineering may be combined to design new multiferroics with ME coupling by combining two bulk components which separately exhibit the targeted ferroic properties – strong ferromagnetism and strong ferroelectricity. (100) Fe/$BaTiO_3$ heterostructures like those shown in Fig. 31a were proposed to fulfill this concept and exhibit ME coupling (Duan et al. 2006). Charge transfer at the interface leads to a net magnetism on the interfacial Ti ions, and when the thickness of $BaTiO_3$ is increased to 4 unit cells, the $BaTiO_3$ layers exhibit ferroelectricity,


Fig. 29 (**a**) Possible 180°, 109°, and 71° polarization switching directions by applying an electric field. The antiferromagnetic plane changes from the orange plane to the green and blue planes upon 109° and 71° polarization switching, respectively. (**b**) Schematic description of the one-to-one magnetic interface coupling in the CoFe/BiFeO$_3$ heterostructure in the (left) as-grown state and (**b**) after the first electric pulse. which results in an asymmetric distribution of the magnetic moments on both interfacial Fe and Ti ions. One thing to note is that the degree of charge transfer is dependent on the band alignment at the Schottky barrier formed between Fe (the metal) and BaTiO$_3$ (the ferroelectric). Owing to the underestimation of the
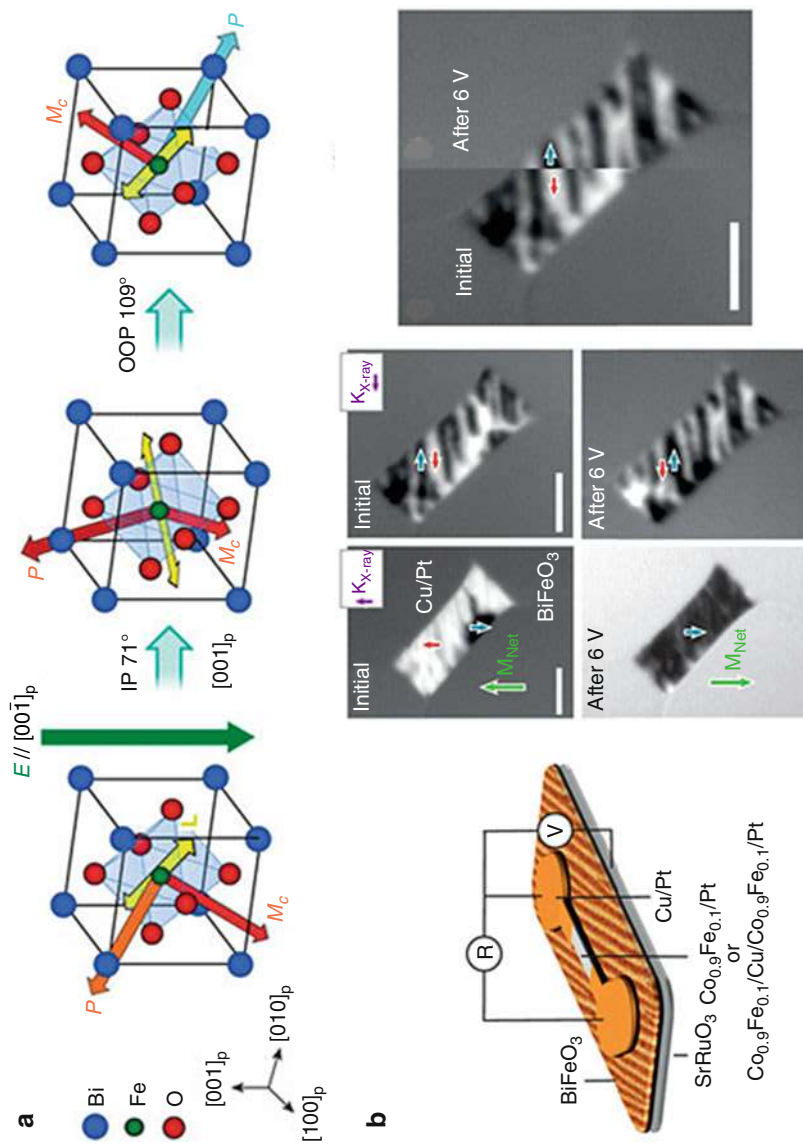

Fig. 30 (continued)

band gap from frequently used LDA and GGA density functionals in the study of multiferroic materials, spurious charge transfer can occur at multiferroic interfaces (Stengel 2011); therefore, when designing new heterostructures from DFT, one should carefully assess the functional-dependent band alignment.

The differences of the magnetic moments between the top and bottom interfaces per Fe and Ti ions are $0.06\mu_B$ and $0.22\mu_B$, respectively. The physical reason for this asymmetric charge distribution is due to the influence of the polar displacements in the $BaTiO_3$ layers on the minority-spin orbital hybridization between Fe 3d and Ti 3d. The polarization leads to shorter bond distances between Fe-O and Ti-O on the top interface than that on bottom interface, thus resulting in a strong orbital hybridization at the upper interface (see Fig. 31b). Therefore, it was proposed that an electric field could change the interfacial magnetic moments by coupling to the electric polarization, leading to a novel ME coupling mechanism.

In an experiment, it has now been found that there is an oxidized Fe layer at the (100) Fe/$BaTiO_3$ heterointerface (Radaelli et al. 2014), and the magnetization can be switched on/off upon reversing the electric field (see Fig. 31c). By carrying out first-principles calculations with the PBE exchange-correlation functional, the origin of this behavior has been attributed to change in the magnetization of the FeO layer in the model system (see Fig. 31d). It can transform from FM to AFM depending upon the direction of the polarization in the $BaTiO_3$ layer when the electronic correlations are sufficiently strong (see Fig. 31d). This is because in the polarization-down state, the Fe-O bond length shortens and the Fe-O-Fe bond angle tends to 180°, which favors the AFM spin alignment. Therefore, the on/off magnetization switching with the reversal of the electric field found at the room temperature in experiment is due to an electric polarization-mediated spin-exchange interaction within the oxidized Fe layers.

3.10   Domains and Domain Walls

As discussed for $BiFeO_3$, the FE and AFM domains can couple to each other and enable strong ME coupling. In this section, we focus on the properties of the domains and domain walls in $YMnO_3$ (Fiebig et al. 2002; Choi et al. 2010), which

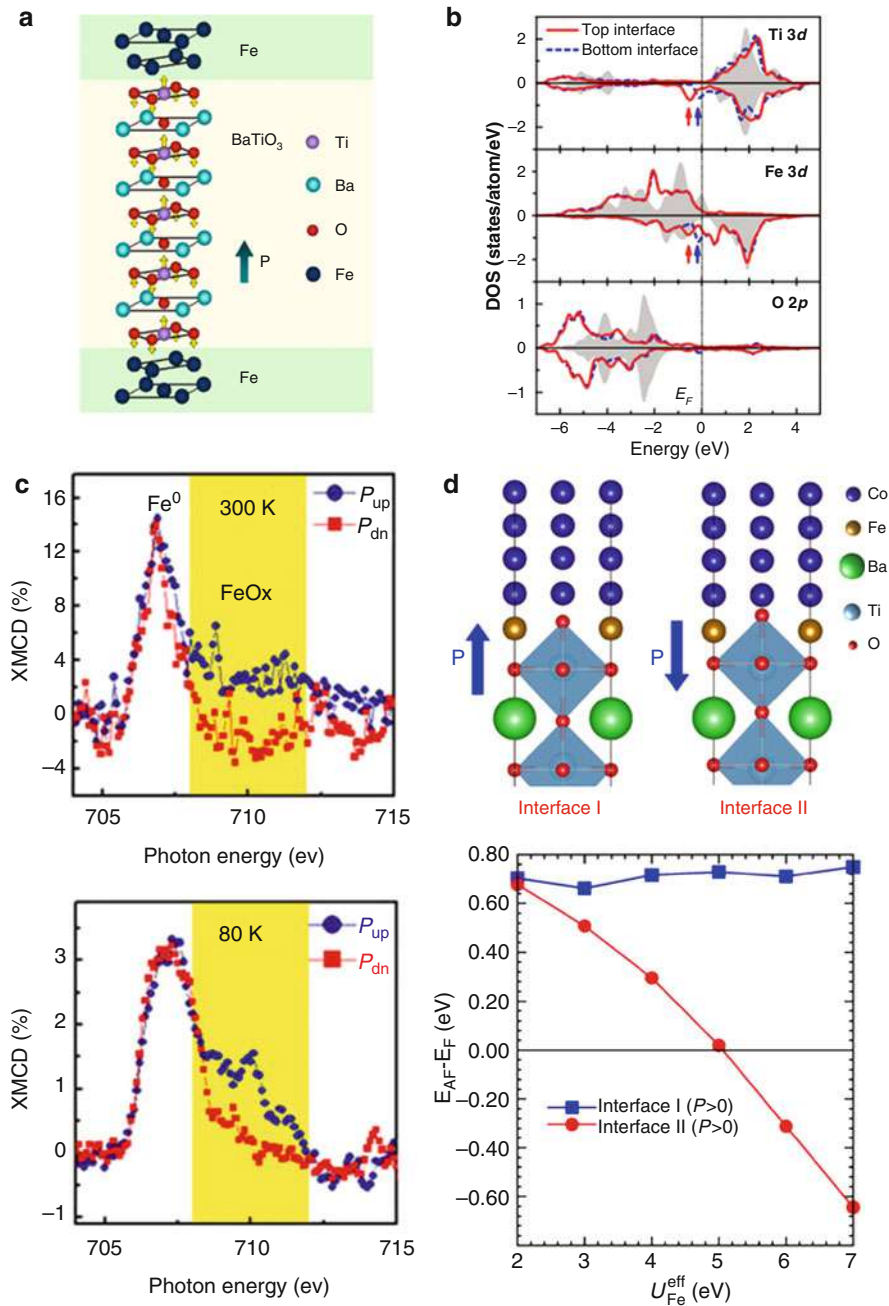

Fig. 31 (continued)

is another well-studied multiferroic material. The types of computational studies performed for this material can be applied to other multiferroics with coexisting FE and magnetic domain structures.

YMnO$_3$ is the improper ferroelectric that the ferroelectricity is caused by the dimerization K$_3$ mode through a coupling interaction $P_z Q_{K_3}^3 \cos(3\varphi)$, where φ is the azimuthal angle describing the direction of the tilt of the K$_3$ mode and describes the tilt distortion (i.e., K$_3$ mode) in each domain. Experimentally, the six domains are observed to be separated by $\sim 60^\circ$ in φ (Choi et al. 2010), resulting in the formation of antiphase (AP) DWs (see Fig. 32a). It was also demonstrated that these domains separated by $\sim 60^\circ$ in φ are also FE DWs, which indicate that the polarization in the two domains exhibit opposite polarization directions. Therefore, the experiments observed those DWs that are both ferroelectric and antiphase, which were also confirmed to be the lowest-energy DWs by first-principles calculations combined with a phenomenological Landau model analysis (Artyukhin et al. 2014).

Additional computational studies showed that there are three basic types of DWs in hexagonal perovskites (Kumagai and Spaldin 2013), which are the {210}, {120}, and {110} DWs as specified in the $P6_3cm$ unit cell (see Fig. 32a). The computed energies of the three types of DWs indicated that the energy of the {210} < {120} < {110} (see Fig. 32b) and the {110} DW can be regarded as the combination of the {210} and {120} DWs (see Fig. 32c). Furthermore, all the DWs are atomically sharp with effectively zero width, which contrasts that found in PbTiO$_3$, where the widths of the 180° DWs are larger than one unit cell (Meyer and Vanderbilt 2002; Lubk et al. 2009; Jia et al. 2008). The authors also showed that any DW with an arbitrary direction can be obtained by using a combination of the {210}, {120}, and {110} DWs through the relationship shown in Fig. 32d. The reason that only the AP + FE DWs were observed in experiment can be explained by noting that the FE-only and AP-only DWs are much higher in energy than the combined AP + FE DWs – they are almost equal to three and two times the average energy of the AP + FE DWs, respectively. This is because the FE-only and AP-only

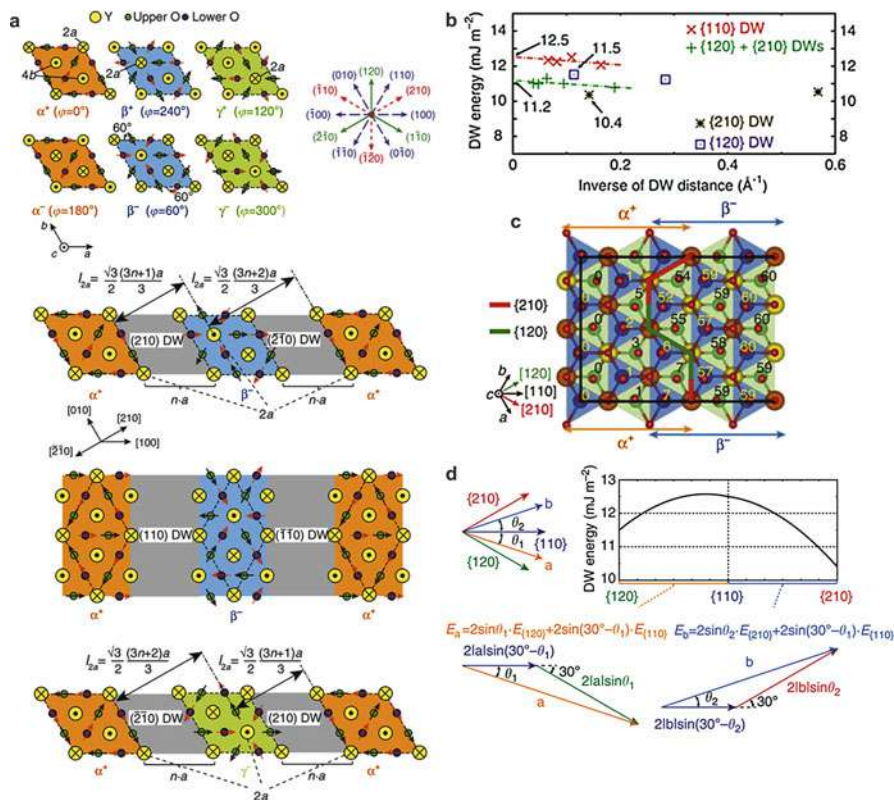
Fig. 31 (**a**) The structure of Fe/(BaTiO$_3$)$_m$ multilayer for $m = 4$ (m is the number of the BaTiO$_3$ layers). Arrows indicate the displacements of Ti and O atoms in BaTiO$_3$ with the net polarization pointing up. (**b**) Orbital-projected DOS for the interfacial atoms of the structure shown in (**a**). The solid and dashed curves correspond to the DOS of atoms at the top and bottom interfaces, respectively. (**c**) XMCD signal in the Fe–L$_3$ energy region for BaTiO$_3$ polarization P$_{up}$ (blue circles) or P$_{dn}$ (red squares) taken on capacitors at 300 K and 80 K, respectively. The yellow shading indicates the region of the spectra corresponding to the oxidized Fe layer in contact with BaTiO$_3$. (**d**) Top: Schematic illustration of the interface regions in the calculations. From top to bottom: Co layer (blue spheres), FeO layer (light brown and red spheres for Fe and O, respectively), and BaTiO$_3$ layer (green, light blue, and red spheres indicate Ba, Ti, and O, respectively). The left (right) panel shows interface I (II), in which the polarization P$_{up}$ (P$_{dn}$) is pointing away from (towards) the BaTiO$_3$ layer. Bottom: Energy difference between FM and AFM spin configurations of the interfacial Fe atoms as a function of the Hubbard U parameter within the DFT + U method. (2014), Copyright Springer Nature, 2014)


Fig. 32 (**a**) Schematic description of the six possible structural domains in h-YMnO$_3$ viewed down the c axis, parallel to the direction of ferroelectric polarization. The large yellow circles show the Y cation positions with crosses or dots indicating displacement into or out of the plane. The small circles are the adjacent oxygen ions at the apical vertices of the trigonal bipyramids with arrows indicating the direction of their displacements from the high-symmetry $P6_3/mmc$ phase. Each domain is labelled by its phase φ, defined to be the (counter)clockwise angle of the displacement directions of upper (lower) oxygen atoms relative to those in the α^+ domain. The (210) and $(\overline{2}10)$ domain walls (DWs) between α^+ and β^- domains are inequivalent as seen by comparing the spacing between the $2a$ Wyckoff positions, ℓ_{2a}. In contrast, the (110) and $(\overline{1}10)$ DWs are equivalent by symmetry. DWs between α^+ and γ^- domains are reversed relative to those between α^+ and β^- domains. (**b**) Energies for {110}, {120}, and {210} DWs calculated with different supercell sizes at the DFT + U with $U = 8$ eV and $J = 0.88$ eV. The dash-dotted lines are linear extrapolations to infinite spacing (zero inverse distance). The plus signs (+) indicate the averages of the {120} and {210} DW energies calculated with the supercells containing both DWs. (**c**) Calculated {110} DW structure for the sharp model. It can be seen that the {110} DW can be regarded as a combination of {120} and {210} DWs. (**d**) DW energy as a function of the DW direction, which is geometrically interpolated from the calculated {120}, {210}, and {110} DW energies, $E_{\{120\}}$, $E_{\{210\}}$, and $E_{\{110\}}$. (Figure reproduced from Kumagai and Spaldin (2013), Copyright Springer Nature, 2013)
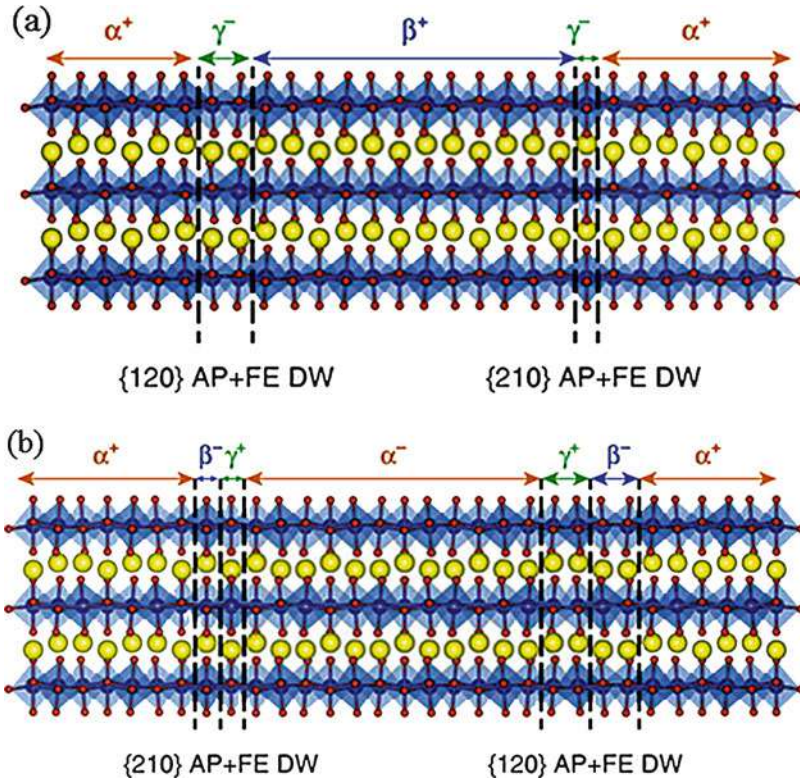

Fig. 33 Calculated (**a**) anti-phase (AP) and (**b**) ferroelectric (FE) DWs perpendicular to the [210] axis with 270- and 300-atom supercells, respectively. The relaxed structures locally preserve the up-up-down or down-down-up displacements of the Y ions across the DWs, resulting in the intermediate domains. (Figure reproduced from Kumagai and Spaldin (2013), Copyright Springer Nature, 2013)

DWs are the composite of the three and two AP + FE DWs, respectively, as can be seen in Fig. 33a and b.

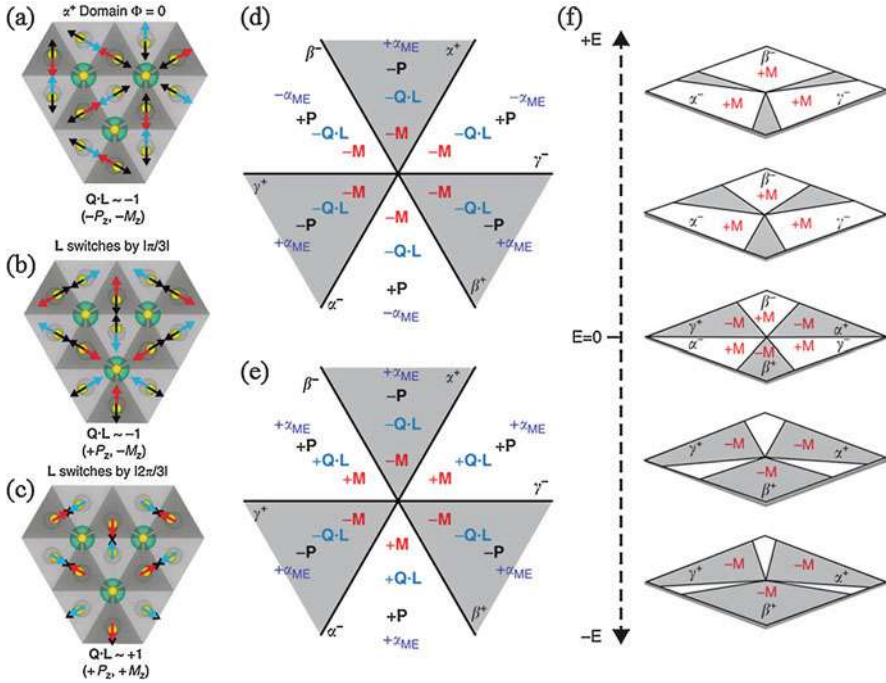
By carrying out a model analysis based on an effective spin Hamiltonian shown in Equation (1), Das et al. (2014) obtained a trilinear coupling term $F_{tri} \propto (\boldsymbol{Q}_I \cdot \boldsymbol{L}_I + \boldsymbol{Q}_{II} \cdot \boldsymbol{L}_{II})M_z$, where $\boldsymbol{Q}_i$ and $\boldsymbol{L}_i$ ($i = I,II$) are order parameters for the K_3 mode having the direction of Φ and AFM vector in the ith layer (see Fig. 34a). According to F_{tri}, $\boldsymbol{L}_i$ will change as $\boldsymbol{Q}_i$ evolves across the DWs so that $\boldsymbol{Q}_i \cdot \boldsymbol{L}_i = 1$ or -1. For example, if $\boldsymbol{Q}_i$ is changed by $\sim 60°$ from α^+ to that in β^-, this produces $\boldsymbol{Q}_i \cdot \boldsymbol{L}_i = -1$ when $\boldsymbol{L}_i$ changes by $\left|\frac{\pi}{3}\right|$ (see Fig. 34b) and $\boldsymbol{Q}_i \cdot \boldsymbol{L}_i = 1$ when $\boldsymbol{L}_i$ changes by $\left|\frac{2\pi}{3}\right|$ (see Fig. 34c). In the first scenario, the weak ferromagnetism along the z direction, M_z, will not change because $\boldsymbol{Q}_i \cdot \boldsymbol{L}_i$ does not change, while in the second scenario, M_z reverses, thus leading to a simultaneous reversal of the electric polarization and wFM.


Fig. 34 (**a**) Initial equilibrium α^+ and **L** domains. (**b**) β^- domain; **L** rotates by $60°$, therefore $-M_z$ maps onto $-M_z$. (**c**) β^- domain; **L** rotates by $120°$, therefore $-M_z$ maps onto $+M_z$. (**d**) The change of the domain by $\frac{\pi}{3}$ and with a rotation of the AFM spin vectors, $\mathbf{L_I}$ and $\mathbf{L_{II}}$, by either $\frac{\pi}{3}$ or $-\frac{\pi}{3}$. (**e**) The change of the domain by $\frac{\pi}{3}$ and with a rotation of the AFM spin vectors, $\mathbf{L_I}$ and $\mathbf{L_{II}}$, by either $-\frac{2\pi}{3}$ or $\frac{2\pi}{3}$. (**f**) The schematic description of the electric field switching of the weak ferromagnetic domains. (Figure reproduced from Das et al. (2014), Copyright Springer Nature, 2014)

Upon considering the changes of $\mathbf{L}_i$ for all six domains arranged in the sequence of $\alpha^+ ->\beta^- ->\gamma^+ ->\alpha^- ->\beta^+ ->\gamma^-$, two scenarios were discussed: (1) $\mathbf{L}_i$ changes but $\mathbf{Q}_i \cdot \mathbf{L}_i$ remains unchanged (see Fig. 34d) and (2) $\mathbf{L}_i$ changes and $\mathbf{Q}_i \cdot \mathbf{L}_i$ reverses (see Fig. 34e). In the first case, there exists a net magnetization owing to the microstructure, which may be not favored. The second case is more likely to occur, because it avoids the formation of the free AFM DWs due to the existence of a net magnetization across the vortex shown in Fig. 34f. An electric field may induce a positive wFM or negative wFM according to the direction of the applied field because the polarization is coupled to the electric field (see Fig. 34f).

4 Perspectives on Multiferroic Materials Design

In this chapter, we summarized the most studied mechanisms active in multiferroic materials and tried to highlight how given a particular mechanism the ferroic properties can be enhanced. In many cases, electronic structure calculations based

on density functional calculations were pivotal in understanding the mechanism and in providing the basis for model formulation. In other cases, such computational methods enabled the discovery of new routes to multiferroism. In addition, there are still many other routes to provide multiferroicity, such as by considering organic substitution in the ABX_3 compounds in which A and X are organic ligands and B is a transition metal (Stroppa et al. 2011, 2013), and different concepts of multiferroicity (Van Aken et al. 2007; Zimmermann et al. 2014; Tolédano et al. 2015; Boström et al. 2018): ferrotoroidicity that has the form of $\mathbf{T} = \sum_i \mathbf{r}_i \times \mathbf{S}_i$ in which $\mathbf{T}$ and $\mathbf{r}_i$ are the toroidal moment and the position of the spin $\mathbf{S}_i$, respectively.

In metal-organic framework (MOF) compounds (Stroppa et al. 2013), ferro-electricity can also arise from a hybrid improper ferroelectric mechanism with the two primary modes being a Jahn-Teller distortion ($Q_{X_4^+}$) and the other one a rotational mode ($Q_{X_1^-}$) such that the polarization $P \propto Q_{X_4^+} Q_{X_1^-}$. In addition for magnetic MOF compounds, both $Q_{X_4^+}$ and $Q_{X_1^-}$ determine the amplitude of the wFM, whereas the direction of the wFM only depends on $Q_{X_4^+}$. In this way, strong ME coupling can be achieved because the polarization and wFM are coupled through the trilinear term $P Q_{X_4^+} Q_{X_1^-}$. It should be emphasized that in all the hybrid improper ferroelectrics, the ME coupling is dependent of the transition path, that is, how the polarization transforms from the $+P$ to $-P$ states. Only when the path includes unambiguously the reversal of the primary mode controlling the direction of the wFM is ME coupling be realized. Generally, this prerequisite is not easily determined by theory and required detailed experimentation. Recently a path-independent ME coupling mechanism was proposed in hybrid improper ferroelectric $A_3B_2O_7$ and $A_3BB'O_7$ compounds through an unusual polar-to-nonpolar phase transition arising from a change in the sense of the out-of-plane oxygen-rotational modes between the two phases. The latter modes are what control the direction of the wFM in each magnetic layer (Lu and Rondinelli 2017); this promising route, however, remains to be validated in experiment.

In ferrotoroidic materials, it is hard to detect the existence of the ferrotoroidicity, because its conjugate field, which is given by the cross product of the electric ($\mathbf{E}$) and magnetic ($\mathbf{H}$) field ($\sim \mathbf{E} \times \mathbf{H}$), can also contribute a linear ME coupling by each field separately. Therefore, such reports on this type of multiferroicity are rare (Van Aken et al. 2007; Zimmermann et al. 2014; Tolédano et al. 2015).

Although there has been much progress, finding or designing multiferroics with high-ordering temperatures, high polarizations, and strong magnetism with robust ME coupling at room temperature is still challenging. Often the magnetic ordering temperature is lower than room temperature, because of the small symmetric spin-exchange interaction and/or the spin frustration. Therefore, many studies have focused on $BiFeO_3$, because it is a room-temperature multiferroic, although other compounds hosting different mechanisms have been predicted (Zanolli et al. 2013; Lu and Xiang 2014; Lu and Rondinelli 2017; Zhao et al. 2014; Wang et al. 2015). Chemical A-O bonding (e.g., ionic and covalent bonding types) usually favor large polarization, but because A-site ferroelectricity relies on a different cation sublattice than the magnetic order (often B-site cation sublattice), these materials always tend to display weak ME coupling (Khomskii 2009). Although

some computational studies propose strong ME coupling in materials based on the $LiNbO_3$-type structure (Wang et al. 2015; Fennie 2008; Ederer and Fennie 2008; Varga et al. 2009; Giovannetti et al. 2016), the magnetoelectric response is based on changing the sign of the DM interaction vector; this sign change is difficult to access in experiment. In addition, a first-principles study proposed that the $LiNbO_3$-type compound Zn_2FeOsO_6 can be a multiferroic with large polarization and ferrimagnetism (Wang et al. 2015), but the strong ME coupling in the system is based on the same coupling behavior found between the AFM domain and FE domains in $BiFeO_3$. This prediction remains to be confirmed.

Despite the aforementioned challenges, the prospects for utilizing multiferroic compounds in several fields remains very much attractive, especially for photo-voltaic devices and in four-states memory devices (Lu et al. 2015a; Fiebig et al. 2016). In $BiFeO_3$, photo-induced voltages are relevant to the $71°$ DWs and were shown to increase by increasing the thickness of the samples, which effectively increase the total DWs (Yang et al. 2010). The enhanced response was attributed to the built-in electric field across the DWs that intrinsically separate the photo-generated electron-hole pairs. For four-state memory applications, $La_{0.1}Bi_{0.9}MnO_3$ films on the $SrTiO_3$ (001) substrates serves as an excellent example (Gajek et al. 2007). It is a FM-FE thin film, and experiment has demonstrated that magnetic and FE tunnel junctions can coexist even when the sample size is miniaturized down to 2 nm, which supports the coexistence of FM and FE orders. Based on the spin-filter effects between $La_{0.1}Bi_{0.9}MnO_3$ and $La_{2/3}Sr_{1/3}MnO_3$ electrodes separated by a $SrTiO_3$ spacer, a four-state cycle can be obtained by applying the magnetic and electric field in the magnetic junction owing to the charge screening at the electrode-barrier interfaces and its different spatial extension in the two electrodes comprising the FE junction.

In summary, we reviewed several mechanisms that may be utilized to design new multiferroic materials and described how density functional calculations can be used to assess the coexisting ferroic responses and phase stability. By considering both the scientific contributions that materials in this field have made to our understanding of how to harmonize (and couple) multiple ordered states and the continued technological importance of multiferroics, we are excited to see which materials will be designed next.

Strain Control of Domain Structures in Ferroelectric Thin Films: Applications of Phase-Field Method

49

Jian-Jun Wang and Long-Qing Chen

Contents

Abstract

Ferroelectric thin films have potential applications in many devices such as memories, microwaves, transduction sensors, actuators, photovoltaics, etc. The mesoscale domain structures and thus properties of ferroelectric thin films depend crucially on the amount of strain imposed upon by the underlying substrates. Phase-field method has been extensively applied to understanding the underlying physics of the experimentally observed domain structures and predicting their responses to external electrical, mechanical, thermal, and chemical stimuli. In this chapter, the fundamentals of the thin-film phase-field method and its applications in predicting the effects of strains on the phase transitions,

e-mail: wjj8384@gmail.com; lqc3@psu.edu

domain structures, and the domain switching are reviewed. The prospect of using phase-field method in microstructure design and property optimization for ferroelectric thin films is discussed.

1   Introduction

The advances in film-growth methods including the pulsed laser deposition (PLD) (Ramesh et al. 1990; Hubler 1992; Frey et al. 1994; Koster et al. 1999) and molecular beam epitaxy (MBE) (Chao and Arthur 1975; Spah et al. 1988; Schlom et al. 1988; Kwo et al. 1988; Eckstein and Bozovic 1995; Theis et al. 1998) have allowed the growth of high-quality epitaxial ferroelectric thin films. An in-plane biaxial strain is typically generated and imposed on the film via the epitaxial lattice mismatch. Compared with the ferroelectric bulk counterparts which would normally fracture under moderate strains such as $\sim\pm0.1\%$, epitaxial thin films can withstand much larger in-plane biaxial strains up to $\sim\pm3\%$ (Schlom et al. 2007, 2008, 2014; Martin and Rappe 2017). Owing to the strong coupling between the polarization and the lattice degrees of freedom in ferroelectrics, novel phases, physics, and properties may emerge in heavily strained thin films. For example, a stress-free $SrTiO_3$ crystal is paraelectric down to 0 K. However, when a (001)-oriented $SrTiO_3$ was epitaxially grown on a (110)-oriented $DyScO_3$ substrate which can impose a tensile biaxial strain of $\sim0.8\%$ on $SrTiO_3$ film, a room-temperature ferroelectricity was observed in the $SrTiO_3$ thin film (Haeni et al. 2004). The similar effect was observed in strained $BaTiO_3$ thin films which show enhanced room-temperature remnant polarization and ferroelectricity at temperatures much higher than the bulk Curie point (Choi et al. 2004). While a stress-free $BiFeO_3$ bulk crystal has a stable rhombohedral symmetry below the Curie temperature of 830 °C (Catalan and Scott 2009), a $BiFeO_3$ thin film on a $LaAlO_3$ substrate is subjected to a huge compressive strain ($\sim-4.5\%$) and was shown to exhibit a highly distorted tetragonal symmetry. As thickness of a $BiFeO_3$ film increases, it gradually loses the coherency strains, leading to the formation of a rhombohedral-tetragonal alternating "stripe-like" mixed-phase structure (Zeches et al. 2009; Li et al. 2015).

The thermodynamic analysis was normally performed to understand the strain effect on the phase transition of ferroelectric thin films (Pertsev et al. 1998; Roytburd 1998; Sheng et al. 2008; Shirokov et al. 2009; Qiu et al. 2010). It starts from the Landau phenomenological theory of a ferroelectric bulk crystal, wherein the Gibbs energy density is used to describe the total free energy of the bulk system with temperature, electric field, and the stress as independent variables. For studying the effect of strain on transition temperatures, it is actually more convenient to use strain rather than stress as the independent variable. Therefore, a Legendre transformation can be performed to obtain the Helmholtz free energy density, in which strain is the independent variable in the mechanical energy term. The stress components can be solved from the combination of thermodynamic property equations (first-order derivatives of the Gibbs free energy) and the mechanical boundary conditions of the epitaxial thin film. More specifically, the first-order derivative of the Gibbs free

energy with respect to a stress component is equal to the corresponding negative strain component. The in-plane strain components of the thin film are fixed by the film/substrate lattice mismatch due to interfacial coherency, and the out-of-plane stress components of the thin film are zero due to the traction-free film surface. Eventually, the equilibrium state and the thermodynamic properties of the thin film can be established by minimizing the total thermodynamic potential of the thin film with respect to the thermodynamic variables.

The thermodynamic analysis has been extensively employed to predict the strain-temperature phase diagrams of various ferroelectric thin films including $PbTiO_3$ (Pertsev et al. 1998; Zembilgotov et al. 2005), $PbZr_{1-x}Ti_xO_3$ (Pertsev et al. 2003; Li et al. 2003a; Qiu et al. 2010), $BaTiO_3$ (Emelyanov et al. 2002; Shirokov et al. 2007; Sheng et al. 2008), $BiFeO_3$ (Zhang et al. 2007; Ma et al. 2008; Karpinsky et al. 2017), etc. One advantage of the thermodynamic analysis is the easy implementation of the thermodynamic potential into MATHEMATICA or MATLAB programs. Using the "minimization function" built in the software, the thermodynamic potential can be conveniently minimized to obtain the equilibrium state and the polarization-related properties such as the polarization, spontaneous strain, dielectric permittivity, and piezoelectric coefficients. However, when considering polydomain structures, the thermodynamic analysis becomes much more complicated (Kouhar et al. 2001; Bratkovsky and Levanyuk 2002; Xu et al. 2015). Moreover, there is no direct access or even impossible to get the kinetic behavior of the polarization and properties on the domain walls through the thermodynamic analysis. In order to achieve this, the interfacial energy or domain wall energy and the time-evolving behavior of the polarization need to be considered.

2   Phase–Field Method

Phase-field method combines the material thermodynamics and kinetics. It has become an important tool for studying microstructure evolution (Chen 2002; Boettinger et al. 2002; Gránásy et al. 2006; Chen 2008; Steinbach 2009). The phase-field method for ferroelectric epitaxial thin films was firstly developed by Li et al., and it has been employed to study the strain-temperature phase diagrams, domain structures, domain switching, and other domain-related properties for various ferroelectric thin films (Li et al. 2001, 2002a, 2002b, and 2003b, 2006; Li and Chen 2006; Zhang et al. 2008; Kontsos and Landis 2010; Winchester et al. 2011; Britson et al. 2014; Hong et al. 2014; Chen et al. 2014; Wang et al. 2016). In the phase-field method of ferroelectric thin films, the polarization vector is selected as the order parameter. The spatial distribution of the polarization represents the domain structures of a thin film. The evolution of polarization can be described by the time-dependent Landau-Ginzburg (TDGL) equations, i.e.:

$$\frac{\partial \mathbf{P}(\mathbf{x}, t)}{\partial t} = -L \frac{\delta F}{\delta \mathbf{P}(\mathbf{x}, t)}, \tag{1}$$

where $\mathbf{P}$, $\mathbf{x}$, t, F, and L represent the polarization vector, spatial coordinate, time, the total free energy of the thin-film system, and the kinetic coefficient that is related to the domain wall mobility, respectively.

In the phase-field method of ferroelectric thin films (Li et al. 2001; Chen 2008), only polarization-related energy contributions are considered in the total free energy, which normally includes the Landau energy (bulk chemical energy), elastic energy, electric energy, and gradient energy, i.e.:

$$F = \iiint_V \left[f_{\text{bulk}}\left(\mathbf{P}, T\right) + f_{\text{grad}}\left(\nabla \mathbf{P}\right) + f_{\text{electric}}\left(\mathbf{P}, \mathbf{E}\right) + f_{\text{elastic}}\left(\mathbf{P}, \boldsymbol{\varepsilon}\right) \right] dV,$$

(2)

where f_{bulk}, f_{grad}, f_{electric}, f_{elastic}, $\boldsymbol{\varepsilon}$, $\mathbf{E}$, and $\nabla \mathbf{P}$ represent the bulk, gradient, electric, elastic energy densities, strain tensor, electric field vector, and polarization gradient, respectively. The bulk energy density can be expressed by a Landau polynomial as function of polarization, i.e.:

$$\begin{aligned} f_{\text{bulk}} = {} & \alpha_1 \left(P_1^2 + P_2^2 + P_3^2\right) + \alpha_{11} \left(P_1^4 + P_2^4 + P_3^4\right) \\ & + \alpha_{12} \left(P_1^2 P_2^2 + P_1^2 P_3^2 + P_2^2 P_3^2\right) + \alpha_{111} \left(P_1^6 + P_2^6 + P_3^6\right) \\ & + \alpha_{112} \left[P_1^4 \left(P_2^2 + P_3^2\right) + P_2^4 \left(P_1^2 + P_3^2\right) + P_3^4 \left(P_1^2 + P_2^2\right)\right] \\ & + \alpha_{123} P_1^2 P_2^2 P_3^2 + \alpha_{1111} \left(P_1^8 + P_2^8 + P_3^8\right) \\ & + \alpha_{1122} \left(P_1^4 P_2^4 + P_1^4 P_3^4 + P_2^4 P_3^4\right) \\ & + \alpha_{1112} \left[P_1^6 \left(P_2^2 + P_3^2\right) + P_2^6 \left(P_1^2 + P_3^2\right) + P_3^6 \left(P_1^2 + P_2^2\right)\right] \\ & + \alpha_{1123} \left(P_1^4 P_2^2 P_3^2 + P_1^2 P_2^4 P_3^2 + P_1^2 P_2^2 P_3^4\right), \end{aligned}$$

(3)

where α_i, α_{ij}, α_{ijk}, and α_{ijkl} are called Landau coefficients relating to the different-order dielectric stiffness. They can be fitted to the bulk properties at zero stress (Haun et al. 1989a; 1989b; 1989c; Li et al. 2005; Wang et al. 2007; Liang et al. 2009; Pohlmann et al. 2017).

The gradient energy density is defined as

$$f_{\text{grad}} = \frac{1}{2} \gamma_{ijkl} P_{i,j} P_{k,l},$$

(4)

where γ_{ijkl} are the components of the gradient energy coefficient tensor and $P_{i,j} = \partial P_i / \partial x_j$.

The electric energy density is given by:

$$f_{\text{electric}} = -P_i\left(\mathbf{x}\right) E_i\left(\mathbf{x}\right) - \frac{1}{2} \varepsilon_0 \kappa_{ij}^{\text{b}} E_i\left(\mathbf{x}\right) E_j\left(\mathbf{x}\right),$$

(5)

where κ_{ij}^{b} are components of the background dielectric constant tensor (Rupprecht and Bell 1964; Tagantsev 2008). The electric field distribution can be solved from

the electrostatic equilibrium equation, which can be dramatically affected by the electric boundary condition. For example, under open-circuit boundary conditions, if the bound charges at the film surfaces are not compensated, a depolarization field will be generated and may significantly suppress the polarization. This effect will be dominant when the thickness of the thin film is down to several unit cells, leading to the disappearance of the ferroelectricity, which is also called the size effect of the ferroelectric thin films (Scott 1988, 1991; Junquera and Ghosez 2003).

The elastic energy density can be calculated according to the Hooke's law:

$$f_{\text{elastic}} = \frac{1}{2} c_{ijkl} e_{ij}(\mathbf{x}) e_{kl}(\mathbf{x}) = \frac{1}{2} c_{ijkl} \left[\varepsilon_{ij}(\mathbf{x}) - \varepsilon_{ij}^0(\mathbf{x}) \right] \left[\varepsilon_{kl}(\mathbf{x}) - \varepsilon_{kl}^0(\mathbf{x}) \right], \tag{6}$$

where c_{ijkl} are components of the elastic stiffness tensor and $e_{ij}(\mathbf{x})$, $\varepsilon_{ij}(\mathbf{x})$, and $\varepsilon_{ij}^0(\mathbf{x})$ are components of the elastic strain tensor, total strain tensor, and eigenstrain tensor, respectively. The eigenstrain tensor $\varepsilon_{ij}^0(\mathbf{x})$, or the stress-free strain tensor, arises from the coupling between the polarization and the lattice degrees of freedom in ferroelectrics. This coupling is also named the electrostrictive effect (Cross et al. 1980; Cross 1996; Sundar and Newnham 1992). It is a universal effect in insulators, and in ferroelectrics the quadratic coupling can be especially strong. The strength of the quadratic coupling between polarization and the lattice degrees of freedom is described by the electrostrictive coefficient Q_{ijkl}, which is a fourth-order tensor. Its values can be obtained by experimental measurements (Yamada 1972) or first-principle calculations (Wang et al. 2010). The eigenstrain $\varepsilon_{ij}^0(\mathbf{x})$ can be calculated from $\varepsilon_{ij}^0(\mathbf{x}) = Q_{ijkl} P_k(\mathbf{x}) P_l(\mathbf{x})$. The total strain $\varepsilon_{ij}(\mathbf{x})$ can be solved from the mechanical equilibrium equation using Khachaturyan's microelasticity theory (Khachaturyan 1983), in combination with the thin-film mechanical boundary conditions (Li et al. 2002).

In the phase-field model of ferroelectric thin film, materials parameters needed include the Landau coefficients, gradient energy coefficients, background dielectric constant tensor, elastic compliance tensor, and electrostrictive coefficient tensor. With these materials parameters available, the domain structures under different temperatures and in-plane biaxial strain conditions can be obtained starting from a random distribution of polarization or from an existing domain structure.

3   Phase Transitions and Domain Structures

In the phase-field simulation of ferroelectric thin films, the equilibrium domain structures can be predicted by quenching an annealed paraelectric state with a fixed substrate constraint to lower temperatures. The main advantage of the phase-field method is the fact that one does not have to make a priori assumptions on the possible ferroelectric phases and domain structures that might appear under a given temperature and an epitaxial strain.

3.1   Misfit Strain–Temperature Phase Diagrams

The phase-field method has been employed to calculate the strain-temperature phase diagrams for several ferroelectric thin-film oxides such as $PbTiO_3$ (Li et al. 2001), $BaTiO_3$ (Choi et al. 2004), $SrTiO_3$ (Haeni et al. 2004), and $PbZr_{1-x}Ti_xO_3$ (Choudhury et al. 2005) (Fig. 1a–d). A common feature of these phase diagrams is the enhanced Curie temperature by the epitaxial strain. This effect can be dramatic as the Curie temperature can be increased by several hundred degrees by only 1% compressive or tensile strain. This effect originates from the strong coupling between the polarization and the lattice degrees of freedom. Another common feature among these phase diagrams is the existence of transition regions along the ferroelectric/paraelectric phase boundaries. For the stress-free bulk ferroelectrics including $PbTiO_3$, $BaTiO_3$, $SrTiO_3$, and $PbZr_{1-x}Ti_xO_3$, the phase transition is normally first-order at which the polarization changes sharply at the transition temperature. However, under thin-film mechanical boundary conditions with con-

(Copyright 2001, American Institute of Physics, Copyright 2004 American Association for the Advancement of Science, Copyright 2004, Springer Nature, Copyright 2001, American Institute of Physics)

straint strains in-plane and stress-free out-of-plane, the paraelectric to ferroelectric phase transition may become second-order (Pertsev et al. 1999). This is caused by the renormalization of the fourth-order Landau coefficients due to the coupling between the polarization and the strain. On the strain-temperature phase diagram of PbTiO$_3$ thin film (Fig. 1a), there is a large region wherein the in-plane a domain and out-of-plane c domain can coexist, which has been verified by numerous experimental observations (Seifert et al. 1995; Kiguchi et al. 2011; Tang et al. 2014). For PbZr$_{0.53}$Ti$_{0.47}$O$_3$ thin film shown in Fig. 1d, there are also some mixed-phase regions. For example, under moderate strains and low temperatures, the tetragonal phase, orthorhombic phase, and distorted rhombohedral phase may coexist. These mixed-phase regions are normally not predicted from thermodynamic analysis without considering the multi-domain structures.

3.2   Domain Structures in Single–Layered Thin Films

A common feature of ferroelectric materials is the formation of domain structures when the material is cooled down from a paraelectric phase to a ferroelectric phase. A ferroelectric domain is defined by a region with uniform electrical polarization. The domain size may range from several nanometers to hundreds of nanometers depending on many factors such as the film thickness, the epitaxial strain, and the electric boundary conditions. The type of domain structures is determined by the total free energy, which can be altered by external stimuli including the mechanical, electric, thermal, and chemical stimuli. One advantage of phase-field modeling of the domain structures in ferroelectric thin films is the theoretically feasible incorporation of arbitrary boundary conditions, although only some of the possible boundary conditions can be realized in experimental configurations.

By incorporating materials parameters and incorporating boundary conditions of the experimental thin films into the phase-field model, the equilibrium domain structures can be obtained and compared with available experimental observations. For example, Fig. 2a shows the a/c domain structures predicted in a (001)-oriented PbTiO$_3$ thin film under a moderate compressive strain, while Fig. 2b gives the domain structures observed in a PbTiO$_3$ thin film epitaxially grown on a (001)-oriented SrTiO$_3$ substrate which can impose a compressive strain on the PbTiO$_3$ thin film. The a domain represents the domains with the polarization along either the x_1 or x_2 axis of the pseudocubic lattice, and the c domain represents the domains with the polarization along the x_3 axis of the pseudocubic lattice. The predicted domain structures (Li et al. 2002) show amazing similarity to the domain structures observed (Seifert et al. 1995) using the transmission electron microscopy (TEM). The formation of the a/c domain structures can be understood from the competition between the elastic energy, the electrostatic energy, and the gradient energy. For the moderately compressed thin films under short-circuit electric boundary conditions, a single c domain can minimize the electrostatic energy and the gradient energy. In this case however the macroscopic deformation along the out-of-plane direction will be maximized, leading to a high elastic energy. Therefore, some a domains
Fig. 2 (**a**) Predicted *a*/*c* domain structures in a (001)-oriented PbTiO$_3$ thin film under moderate compressive strains (adapted from Li et al. 2002), compared with (**b**) the experimental observation in a PbTiO$_3$ thin film epitaxially grown on a (001)-oriented SrTiO$_3$ substrate (adapted from Seifert et al. 1995). (**c**) Predicted a_1/a_2 twinning domain structures in a PbZr$_{0.2}$Ti$_{0.8}$O$_3$ thin film under equally biaxial tensile strains (adapted from Wang et al. 2016), compared with (**d**) the experimental observation in a PbTiO$_3$ thin film epitaxially grown on a (001)-oriented KTaO$_3$ substrate. are generated to decrease the macroscopic deformation and the elastic energy but comprise to slightly increase the electrostatic energy and the gradient energy.

3.3 Domain Structures in Bilayer Thin Films

The phase-field method was also employed by Artemev et al. to study the domain structures in ferroelectric bilayer thin films (Artemev et al. 2008). They found that a poled state can be achieved by a low electric field in the bilayer film with one layer

in a single-domain state and the other layer in a polydomain state. In contrast to the bilayer film with both layers in single-domain states, the presence of a polydomain layer in the bilayer film is responsible for a higher dielectric constant and lower coercive field. The increase in the applied electric field can lead to a transition to single-domain states in both layers of the bilayer film, and the critical field depends on the thermodynamic potentials of the two layers (Artemev et al. 2008). Using the thin-film phase-field method, Xue et al. investigated the effect of interfacial coherency between the two layers in a $Pb(Zr_{0.3}Ti_{0.7})O_3/Pb(Zr_{0.7}Ti_{0.3})O_3$ bilayer thin films on the domain structures (Xue et al. 2013). If the lattice parameters of the two layers end up with the same average lattice parameter, the two layers can be regarded as coherent. For example, the cubic lattice parameters for $Pb(Zr_{0.3}Ti_{0.7})O_3$ and $Pb(Zr_{0.7}Ti_{0.3})O_3$ are 4.0185 Å and 4.1032 Å, respectively, giving rise to an average lattice parameter of 4.0609 Å when the two layers have the same thickness. With a coherent interface, the strained bilayer film has a lattice parameter of 4.0609 Å. Consequently, the $Pb(Zr_{0.3}Ti_{0.7})O_3$ layer tolerates a tensile strain of $(4.0609-4.0185)/4.0185 = 1.05\%$, and the $Pb(Zr_{0.7}Ti_{0.3})O_3$ layer tolerates a compressive strain of $(4.0609-4.1032)/4.1032 = -1.03\%$. For a totally incoherent bilayer film, each layer can be regarded to have similar lattice parameters to their bulk counterparts, unless the clamping effect from the substrate is considered.

The interfacial coherency has significant effects on the domain structures in each layer (Fig. 3a and b). For $Pb(Zr_{0.3}Ti_{0.7})O_3/Pb(Zr_{0.7}Ti_{0.3})O_3$ bilayer thin films with coherent interface, tetragonal a_1/a_2 twinning domain structures (all in-plane polarizations) are predicted in the $Pb(Zr_{0.3}Ti_{0.7})O_3$ layer (Fig. 3a), while in its single-layer thin film, the domain structures are tetragonal a/c types (Fig. 3c, mixed in-plane and out-of-plane polarizations). The $Pb(Zr_{0.7}Ti_{0.3})O_3$ layer in the bilayer film shows tetragonal c domains (all out-of-plane polarizations), compared with rhombohedral domains in its single-layer thin-film counterpart (Fig. 3d). For the bilayer film with incoherent interface, the domain structures in each layer are similar to their single-layer thin-film counterparts, i.e., a/c domains in $Pb(Zr_{0.3}Ti_{0.7})O_3$ layer and rhombohedral domains in $Pb(Zr_{0.7}Ti_{0.3})O_3$ layer (Fig. 3b). The interfacial coherency effects on the domain morphologies can be understood from the strain configuration in the bilayer film. In $Pb(Zr_{0.3}Ti_{0.7})O_3$ layer, the tensile strain 1.05% tends to align all polarizations in-plane, leading to the formation of a_1/a_2 twinning domain structures under the synergistic effect from the bulk chemical energy and elastic energy. In $Pb(Zr_{0.7}Ti_{0.3})O_3$ layer, the compressive strain -1.03% tends to switch all polarizations out-of-plane, leading to the formation of c domains (Xue et al. 2013; Liu et al. 2016).

3.4 Strain Phase Separation

The thin-film phase-field model was also used to understand the formation of mixed phases and domains in strained thin films from the perspective of strain phase separation. In a constrained system, domains or phases can form and coexist with each other to minimize the overall elastic energy, given that each domain or phase
Fig. 3 Effects of interfacial coherency on the domain structures in a $Pb(Zr_{0.3}Ti_{0.7})O_3/Pb(Zr_{0.7}Ti_{0.3})O_3$ bilayer thin film (Xue et al. 2013). Domain structures of the bilayer film when the interface between the two layers is (**a**) coherent and (**b**) incoherent, compared with the domain structures in single-layer (**c**) $Pb(Zr_{0.3}Ti_{0.7})O_3$ thin film and (**d**) $Pb(Zr_{0.7}Ti_{0.3})O_3$ thin film under a moderate strain of 0.2% due to thermal expansion. (Copyright 2013, Elsevier)

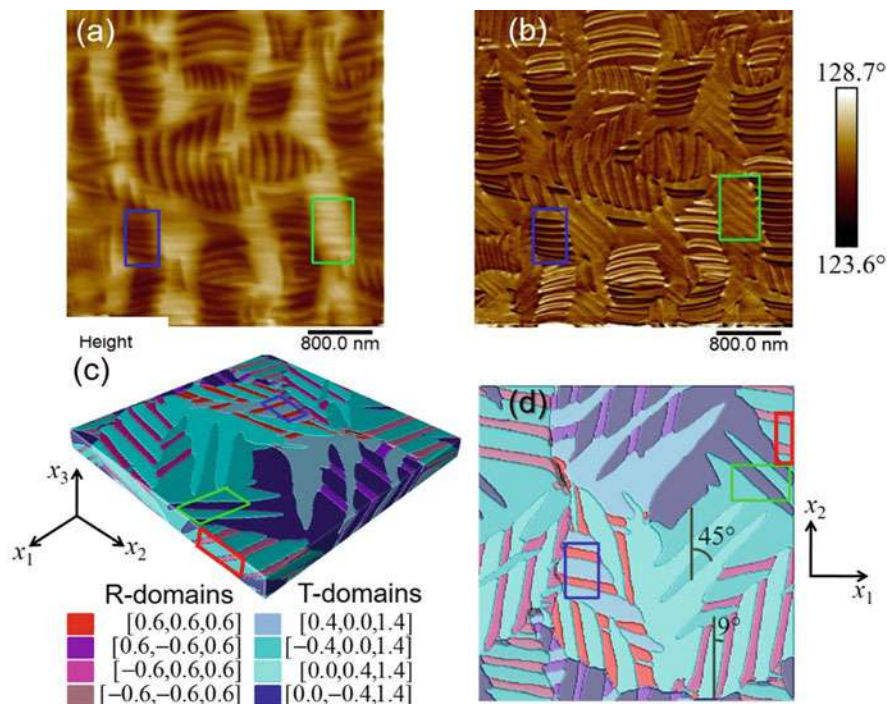
has different local strains. This phenomenon is similar to the phase decomposition process from a chemically homogeneous phase to a two-phase mixture wherein each phase has a different chemical composition. The volume fraction of each phase with a specific composition can be obtained from the lever rule. This idea was used to understand the observed rhombohedral-tetragonal mixed phases in severely compressed $BiFeO_3$ thin films (Xue et al. 2016, 2017). $BiFeO_3$ has a pseudocubic lattice parameter of $\sim$4.0 Å. When it is epitaxially grown on a $LaAlO_3$ substrate with a lattice parameter of $\sim$3.79 Å, a large compressive strain up to $\sim$−5.25% will be imposed on the thin film, leading to a transition from the rhombohedral phase to a tetragonal-like monoclinic phase in $BiFeO_3$ thin film (Zeches et al. 2009; Li et al. 2015; Zhang et al. 2012). With the film thickness increasing to be larger than 100 nm, the large epitaxial strain is partially relaxed, and the rhombohedral phase emerges, forming a tetragonal-like/rhombohedral mixed domain structure (Fig. 4a


Fig. 4 Experimentally observed (**a**) topography and (**b**) the corresponding in-plane piezoresponse force microscopy result of a mixed-phase $BiFeO_3$ thin film grown on $LaAlO_3$ substrate, compared with the simulated (**a**) three-dimensional domain structures and (**b**) in-plane domain morphology from thin-film phase-field method. (Adapted from Xue et al. 2016. Copyright 2016, American Physics Society)

and b). The phase-field model was employed to predict domain structures (Fig. 4c and d) which agree well with the experimental observations and give insights to the underlying physics. With the relaxation of the mismatch strain, the overall strain will be smaller than the critical strain, under which the transition from rhombohedral phase to tetragonal-like phase occurs. Therefore, the phase separation happens to decrease the total elastic energy, analogous to the chemical decomposition process (Xue et al. 2016, 2017).

3.5   Understanding the Polarization Switching in Ferroelectric Thin Films

One advantage of the phase-field method over the thermodynamic analysis is the capability of studying the polarization switching behavior in ferroelectric thin films. The polarization switching driven by externally applied electric fields was simulated

by Li et al. for epitaxial BaTiO$_3$ thin films (Li et al. 2008). They found that the coercive field and saturated polarization in the hysteresis loop strongly depend on the type and density of the interfacial dislocation. For example, the coercive field can be decreased by increasing the density of interfacial misfit dislocations on a (100) slip plane with a Burger vector along [$-$100] direction. With an optimal combination of different misfit dislocations, the remnant polarization can be greatly enhanced and the coercive field can be greatly reduced. The polarization versus electric field hysteresis loops can be distorted to be asymmetric by threading dislocations. Wu et al. investigated the effects of background dielectric constant and interfacial coherency on the hysteresis loops in BaTiO$_3$/SrTiO$_3$ bilayer films (Wu et al. 2012, 2015). It was found that the hysteresis loops can be constricted when the background dielectric constant is decreased. The decrease in the background dielectric constant has a similar effect to the decrease in the space charge density. The phase-field simulation predicted the domain structure evolution during the switching process in the ferroelectric/paraelectric bilayer film, revealing a dipole-dipole inter-action similar to the exchange-spring interaction in magnetic multilayer systems (Wu et al. 2012). The interfacial coherency also has a remarkable impact on the polarization switching behavior. In the bilayer film with fully coherent interfaces, the hysteresis loops are square-like, exhibiting a large coercive field and a large remnant polarization. For the bilayer films with partially relaxed heterointerfaces, the remnant polarization is relatively high but the coercive field is dramatically reduced. For the bilayer film with fully relaxed heterointerfaces, the hysteresis loops are very slim, showing both small remnant polarization and coercive field.

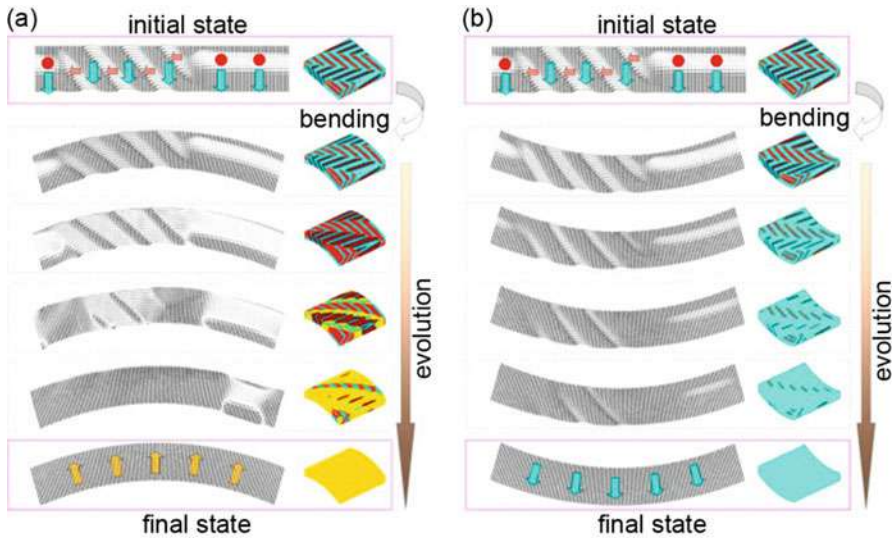
The polarization switching is normally achieved by the externally applied electric field. However, it can also be achieved by a mechanical loading via the flexoelectric effects in epitaxial thin films. The flexoelectric effect is defined as the coupling between the polarization and the strain gradient. This effect is much stronger in ferroelectric thin films than in their bulk counterparts. It has been implemented into the thin-film phase-field model by several research groups (Chen et al. 2014; Ahluwalia et al. 2014; Gu et al. 2014; Chen et al. 2015). In these works, the flexoelectric effects on the domain structures and switching were studied. For example, Chen et al. studied the stability and switching patterns of domain structures in ferroelectric thin films subjected to mechanical loads and related flexoelectric fields (Chen et al. 2015). As shown in Fig. 5a and b, a mixed a/c domain structure can be switched to a single-domain structure by cylindrical bending with a large surface flexoelectric field. For the upward bending case shown in Fig. 5a, the out-of-plane c^- domains are gradually switched to in-plane at first and then are switched to the out-of-plane c^+, while for the downward bending case shown in Fig. 5b, all in-plane domains are switched to the out-of-plane c^- domain. These two switching patterns can be understood from the different flexoelectric fields due to the different bending directions. For the film with an upward bending, the induced flexoelectric field is upward, leading to the switching of polarization to c^+. For the film with a downward bending, the induced flexoelectric field is downward, leading to the switching of polarization to c^-.


Fig. 5 Switching behavior of the domain structure from a/c mixed structures to (**a**) single out-of-plane c^+ domain under upward bending and to (**b**) single out-of-plane c^- domain under downward bending. (Adapted from Chen et al. 2015. Copyright 2015, Elsevier)

4 Toward a Multiscale Simulation

Although the thin-film phase-field method has gained great success in understanding the experimental domain structures and phase transitions, and in predicting the domain structures and switching in thin films under conditions beyond the experiment, it has only been applied to limited material systems due to the lack of the thermodynamic parameters including the Landau coefficients, electrostrictive coefficients, elastic constants, and gradient energy coefficients. For example, up to now, there are very limited materials that have available Landau potentials such as $BaTiO_3$, $PbTiO_3$, $PbZr_{1-x}Ti_xO_3$, $BiFeO_3$, $CaTiO_3$, $SrTiO_3$, $KNa_{1-x}Nb_xO_3$, $LiNbO_3$, $LiTaO_3$, $SrBi_2Nb_2O_9$, and $Sr_{0.8}Bi_{2.2}Ta_2O_9$. However, the ferroelectrics that have been discovered are far more beyond these. In order to obtain the Landau coefficients, the polarization and dielectric responses including both the first-order and higher-order dielectric stiffness as function of temperature have to be measured, which is experimentally challenging especially when the required temperature range is broad. An alternative approach to obtaining the Landau coefficients is the first-principle calculation, which has been employed to obtain the Landau coefficients for $BaTiO_3$ (Íñiguez et al. 2001; Geneste 2009), $CaTiO_3$ (Eklund 2010; Gu et al. 2012), and $BiFeO_3$ (Marton et al. 2017). In addition to the Landau coefficients, the first-principle method has also been employed to calculate the phase transitions (Zhong et al. 1994), elastic constants (Wu et al. 2005), electrostrictive coefficients (Wang

et al. 2010), and polarization domain wall energies (Wang et al. 2013; Diéguez et al. 2013; Li et al. 2014). For the domain wall motion speed which is related to the kinetic coefficient L in the TDGL equation, it can be studied using the atomistic molecular dynamics and coarse-grained Monte Carlo simulations (Shin et al. 2007). All these efforts point toward the multiscale simulation-assisted phase-field modeling for ferroelectric thin films (Völker et al. 2011a, 2011b), which can provide principal inputs for future high-throughput calculation (Shen et al. 2017) and optimization of properties and microstructure design for ferroelectric thin films using machine learning (Li et al. 2017).

Abstract

In recent years, first-principles modeling techniques have made tremendous advances. This allows researchers to estimate the various properties of materials and provide invaluable insights into the physical processes from a microscopic perspective, which cannot directly be assessable by experiments. With the continuing increasing computation powers, first-principles methods are expected to play a more important role in materials design. This chapter aims to serve as a battery-related computation handbook for general readers who may be

new to first-principles calculations. Specifically, this chapter will introduce the well-established ab initio modeling methods widely used in battery-related studies from both the thermodynamic and kinetics aspects. The thermodynamic approaches that will be discussed include the computations of equilibrium voltage and voltage profiles, electronic structure, and stability analyses. The kinetics approaches will cover common methods for ionic diffusion studies: transition state theory and nudged elastic band method and ab initio molecular dynamics. This is followed by the conclusion and outlook.

1   Introduction

Global warming coupled with energy demand has made the development of renewable energy technologies (solar, geothermal, tidal, wind, etc.) a global interest and major concern. However, most renewable energy technologies suffer from high variability and mismatch between demand and supply. Reliable and cost-effective electrical energy storage is therefore a crucial enabler to renewables, as well as nonpolluting means of transportation (Lewis 2007). Among the multitude of energy storage technologies (e.g., zinc-manganese battery, nickel-cadmium battery, nickel-hydrogen battery, lead-acid battery, alkali-ion battery, fuel cell, redox flow battery, etc.), the rechargeable alkali-ion battery has emerged as one of the most attractive candidates for grid and vehicular applications and the dominant one for mobile consumer applications, due to its high specific energy, high operation voltage, wide working temperature, and long cycle life (Tarascon and Armand 2001).

A rechargeable battery comprises two electrodes – the cathode and the anode – separated by an electrolyte (Fig. 1). Alkali ions shuttle between the two electrodes, with the electrolyte acting as an alkali-ion conductor and electrical insulator. During discharge, alkali ions (A^+ in Fig. 1) are extracted from anode and inserted to the cathode, passing through the electrolyte in the process. Meanwhile, electrons pass through the external circuit to perform work. The reverse process occurs during charge.

The energy contained in any battery is the integral of the voltage multiplied by the charge capacity. To achieve high-energy and high-power density for long cycling life in alkali-ion battery, the electrode should have high specific capacity (charge stored per unit mass or volume), high operating voltage, reasonable electron and ionic conductivity, and good phase and electrochemical stability. Suitable electrolyte selection for a pair of electrodes in alkali-ion battery is another important aspect. To prevent the reduction and oxidation of the electrolyte, it is necessary that Fermi
Fig. 1 Schematic of a rechargeable alkali-ion battery with transition metal oxide as cathode (green, alkali-ion; purple, TM; red, oxygen ion), carbon-based material as anode

level of anode should be lower in energy than the lowest unoccupied molecular orbital (LUMO) of the electrolyte, while Fermi level of the cathode should be higher in energy than the highest occupied molecular orbital (HOMO) of the electrolyte (Roy and Srivastava 2015). In the context of solid-state electrolytes, LUMO (HOMO) is referred to as the conduction band minimum (valence band maximum). Additionally, the electrolyte, especially for the solid-state electrolyte, is expected to have good interfacial stability, facile ion conductions which are more stringent than electrodes, and excellent electronic insulations.

Due to the significant advances in computation power in recent years, computer simulations have become an important complementary tool kit to experiments for the understanding and design of materials. First-principles density functional theory (DFT), (Hohenberg and Kohn 1964) especially the framework developed by Kohn and Sham (1965) that evaluates various properties of materials by solving single-particle Kohn-Sham equation with minimal approximation, has been particularly successful in this context. First-principles calculations allow researchers to evaluate the key properties of materials from an atomistic level, and hence provide invaluable insights into the fundamental physical processes that may not be directly assessable by experiments. Moreover, computation-guided discovery of novel materials has made tremendous progress for energy applications, including new alkali-ion battery materials (Deng et al. 2016; Urban et al. 2016). This is facilitated not only by the increasing computer power but also the development of the automated high-throughput first-principles screening that allows rapid identification of the most promising candidates from a pool of hundreds of thousands of initial candidates.

In the following sections, we will give a general introduction of well-established first-principles modeling techniques used to elucidate the thermodynamics and kinetics of battery materials.

2   Thermodynamic Approaches

2.1   Equilibrium Voltage

The operating voltage is a key metric of a battery to evaluate the stored energy density. By definition, the voltage difference between electrodes of a battery is equal to the difference in electron electrochemical potentials of the electrodes:

$$V = -\frac{\eta_{e^-}^{cathode} - \eta_{e^-}^{anode}}{e} \tag{1}$$

where $\eta_{e^-}^{cathode}$ and $\eta_{e^-}^{anode}$ are the electrochemical potentials of electrons (Fermi levels) in the cathode and anode. Inserting alkali chemical potential in any material, $\mu_A^X = \eta_{e^-}^X + \eta_{A^+}^X$, into Eq. 1 yields:

$$V = -\frac{\left(\mu_A^{cathode} - \mu_A^{anode}\right) - \left(\eta_{A^+}^{cathode} - \eta_{A^+}^{anode}\right)}{e} \tag{2}$$

where $\eta_{A^+}^{cathode}$ and $\eta_{A^+}^{anode}$ are the electrochemical potentials of alkali-ion in the cathode and anode. When a battery is at thermodynamic equilibrium ($\eta_{A^+}^{cathode} = \eta_{A^+}^{anode}$), the voltage difference between electrodes can be expressed in terms of the difference in alkali chemical potential:

$$V = -\frac{\mu_A^{cathode} - \mu_A^{anode}}{zF} \tag{3}$$

where z is the amount of charge transferred, and F is the Faraday constant. By definition, $\mu_A = dG/dN_A$ is the change of the Gibbs free energy of the electrode material with alkali-ion concentration (Aydinol et al. 1997). The voltage is thus a function of free energy change of the overall cathode/anode reactions (Nernst equation):

$$\overline{V} = -\frac{\Delta G_r}{zF} \tag{4}$$

where $\overline{V}$ is the average voltage by considering over a finite amount of reactions between cathode and anode.

Assuming that the entropic and volumetric effects are small at low temperature, the Gibbs free energy change for alkali insertion is often approximated by the DFT total energy difference for two alkali-ion concentrations $\Delta G_r = \Delta E_r + p\Delta V_r - T\Delta S_r \approx \Delta E_r$. Taking the lithium-layered oxide cathode Li_xMO_2 with a Li metal anode as an example, the overall reaction is given as follows:

$$Li_{x2}MO_2 + (x_1 - x_2)\,Li \rightarrow Li_{x1}MO_2 \tag{5}$$
with $x_1 > x_2$. Then the reaction voltage can be calculated as:

$$V_{(x_1,x_2)} \approx -\frac{E\left(\mathrm{Li}_{x_1}\mathrm{MO}_2\right) - E\left(\mathrm{Li}_{x_2}\mathrm{MO}_2\right) - (x_1 - x_2)\, E\left(\mathrm{Li}\right)}{(x_1 - x_2)\, F} \tag{6}$$

The energies of $\mathrm{Li}_x\mathrm{MO}_2$, MO_2, and Li can be obtained via DFT total energy calculations. This approximation is not limited to insertion or intercalation electrodes but can also be applied to conversion or alloy reactions.

Most early DFT calculations of average voltage for battery materials were based either on the local density approximation (LDA) or the generalized gradient approximation (GGA) for the exchange-correlation potential (Kohn and Sham 1965; Langreth and Mehl 1983). However, for the modeling of reactions involving changes in electronic states, neither LDA nor GGA are good approximations due to improper cancelation of self-interaction error. Many TM oxides have strongly localized d electrons at the metal center, which leads to the large error of voltage predicting based on LDA or GGA functional. In this regard, an inclusion of a Hubbard U in DFT calculations (aka DFT $+ U$) was developed in the 1990s that significantly improves the DFT results for the system with strong correlated electronic structure (Anisimov et al. 1991, 1993). The method is controlled by Hubbard U parameter, which can be derived for each species either self-consistently (Cococcioni and de Gironcoli 2005) or more often, via fitting to experimental properties such as the oxide formation energy. The idea is borrowed from the Hubbard model in solid-state physics, to describe the transition between conducting and insulating systems. The larger the U value, the greater the penalty for shared electrons, driving the system toward integer electronic occupations (Cococcioni and de Gironcoli 2005). With proper choice of the U parameter, DFT $+ U$ calculations significantly improve the accuracy of predicted voltages over pure LDA or GGA for TM oxides (Zhou et al. 2004). More recently, DFT calculations using screened hybrid functionals, such as the Heyd-Scuseria-Ernzerhof (HSE) functional, (Heyd and Scuseria 2004; Heyd et al. 2003, 2006) have been shown to yield a similar accuracy as GGA $+ U$ without the need for an adjustable U parameter, though at significantly higher computational cost. A detailed comparison of calculated voltages for lithium TM oxides with GGA, GGA $+ U$, and HSE06 can be found in an earlier work by Chevrier et al. (2010)

2.2   Voltage Profile

Calculating the voltage profile requires the knowledge of stable intermediate phases during alkalination/de-alkalination process. The formation energy calculations allow one to determine the ground state energy of the stable phase at all intermediate concentrations. Taking the layered transition metal oxide $\mathrm{Li}_x\mathrm{CoO}_2$ as an example, the formation energy with respect to the stable end members (LiCoO_2 and CoO_2) is expressed as:

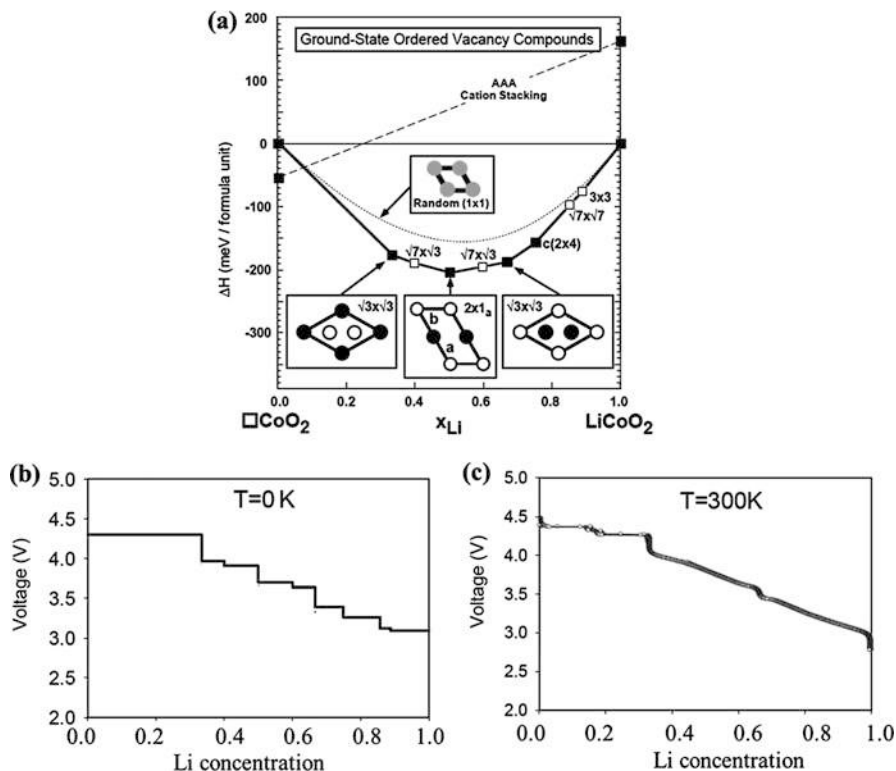
$$E_f\left(\mathrm{Li}_x\mathrm{CoO}_2\right) = E\left(\mathrm{Li}_x\mathrm{CoO}_2\right) - x\, E\left(\mathrm{LiCoO}_2\right) - (1 - x)\, E\left(\mathrm{CoO}_2\right) \tag{7}$$


Fig. 2 (**a**) Stability convex hull (black line) of Li_xCoO_2. Filled square, DFT results; open square, cluster expansion results; filled circles, Li atoms; empty circles, Li-vacancy. (**b**) Predicted Li intercalation voltage of the Li_xCoO_2/Li cell as a function of Li concentration at T = 0 K. (**c**) Equilibrium voltage profile at T = 300 K calculated from Monte Carlo simulations. (Reproduced from Ref. (Wolverton and Zunger 1998) with permission. Copyright (1998) American Physical Society)

The resulting DFT-computed formation energy vs. composition curve (convex hull) is generated as shown in Fig. 2a. In this pseudo-binary stability diagram, the intermediate phases that are thermodynamically stable with respect to the end members ($LiCoO_2$ and CoO_2) form the convex hull. When the energy of an intermediate phase is above the convex hull (e.g., the dotted line in the figure), it implies that such intermediate phase is energetically unstable against its adjacent stable intermediate phases (filled and open squares in the figure) on the convex hull. At each concentration, different configurations of Li-vacancies and oxygen stacking sequence are considered. Examples of some of the predicted Li-vacancy ordering in Li_xCoO_2 are also illustrated in the figure. After the stable intermediate phases are identified, stepwise average voltage can be computed based on Eq. 6, which leads to the voltage profile in Fig. 2b.

It should be noted that the DFT-computed voltage is an approximation without considering entropic effects, and the accessible alkali orderings are also limited by

the supercell size utilized. These approximations work reasonably well for average voltages, especially for two-phase reactions involving ordered phases (e.g., olivine $LiFePO_4$). To obtain a full voltage profile and account for the configurational entropy (important for solid solution regions), one approach is to fit the DFT energies of a large number of alkali concentrations and orderings for a host material to a cluster expansion Hamiltonian. As shown in Fig. 2a, additional stable intermediate phases of Li_xCoO_2 (indicated by open squares on the black line) are discovered by using such approach. The key assumption here is that the contribution to free energy from the other degrees of freedom (e.g., vibrational, electronic) is insignificant and can be coarse-grained out. Monte Carlo simulations, e.g., using the Metropolis algorithm, can then be carried out using the Hamiltonian to sample the configurational space and evaluate finite temperature voltage profile. Details of the cluster expansion method and Monte Carlo simulation can be found in some excellent reviews (Urban et al. 2016; Meng and Arroyo-de Dompablo 2009). As an example, Wolverton and Zunger applied first-principles-based cluster expansion and Monte Carlo methods to model the Li-vacancy orderings in Li_xCoO_2, resulting in the temperature-dependent voltage profiles (see Fig. 2b and c for $T = 0$ and 300 K). Temperature effect mainly results in a continuous voltage slope, which smooths out the voltage steps that are present in the 0 K limit.

2.3   Electronic Structure

The relative energies of electronic levels for different components in alkali-ion battery determine the limitation of the stored energy. Figure 3a schematizes the relation between the equilibrium voltage and electronic structures of the electrode, electrolyte. At open circuit condition, the energy difference of Fermi levels between the anode and cathode builds electron electrochemical potentials. Assuming there
Fig. 3 (**a**) Relative energies of the electrolyte window and the electrode chemical potentials $\mu_A^{cathode}$ and μ_A^{anode} with no electrode/electrolyte reaction. (**b**) Relative positions of energy levels and typical electron configurations in layered Ni-Mn-Co oxide cathode

is no electrode/electrolyte reaction, this electron potential difference equals the difference in alkali chemical potential between the anode and cathode, which is measured as open circuit voltage (V_{OC}). Once charging current is applied, electrons are further pumped out from the valence band of cathode through the circuit to the conduction band of the anode, resulting in the downshift and upshift for the Fermi level of cathode and anode, respectively. Alkali ions are extracted from cathode to the anode with the oxidation change of other ions, e.g., TM ions to balance the charge. The whole process is fully reversible during the discharging process in an ideal case. The redox potential (V_{redox}) measured during charging/discharging process is limited by the "window" of the electrolyte. If the potential of the anode and cathode shift beyond the LUMO and HOMO of the electrolyte, the electrolyte is reduced on the anode and oxidized on the cathode to form the solid electrolyte interphase (SEI). The ideal SEI is an ionic conductor and an electron insulator, which prevents further decomposition of the electrolyte and thus increases stable voltage window.

The electronic levels of the electrode involved in the redox reaction arise from the d-states of the TM cations in most cases. The Fermi level energy as well as the density of states (DOS) near the Fermi level for redox center can be obtained from DFT calculations. Figure 3b qualitatively summarizes the positions of the redox active energy levels for Co^{4+}/Co^{3+}, Ni^{4+}/Ni^{3+}, and Mn^{4+}/Mn^{3+}, as well as the oxygen $2p$ band in TM oxides. In most of the structures including layered, spinel, and disordered rock salt, TM ions occupy octahedral sites that are coordinated by six oxygen atoms. Based on crystal field theory, TM five d orbitals split into two sets of levels labeled t_{2g} and e_g as shown in Fig. 3b. Each of the level can hold two electrons with opposite spin. The commonly observed electronic configurations of d orbitals for Co^{4+}/Co^{3+}, Ni^{4+}/Ni^{3+}, and Mn^{4+}/Mn^{3+} are also illustrated in Fig. 3b. The lone electron in e_g level triggers Jahn-Teller distortion, breaking the degeneracy between the two e_g orbitals to lower the overall energy for the case of Mn^{3+} and Ni^{3+}. When the battery is charged, TM cations are oxidized to 4+ from 3+, and they are reduced back to +3 oxidation state as they receive electrons from the anode during discharging. More importantly, the Co^{3+}/Co^{4+} level is the lowest in energy because Co redox involves the more stable t_{2g} orbitals, while Ni and Mn redox involves the less stable e_g orbitals. This relative alignment of energy levels directly indicates redox reaction sequence of the electrode containing different TM ions since lower energy levels correspond to higher redox voltages.

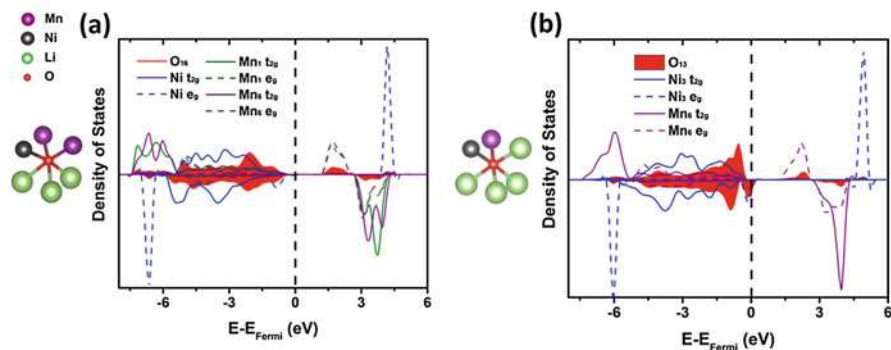
Although the electronic structure is in general complex, it provides another key insight into the available number of electrons near Fermi level. If an alkali-ion is extracted from the cathode host structure, an electron is pumped out from the valence band at the same time. Therefore, the more the available number of electrons are, the higher the alkali-ion storage capacity is. In classical layered cathode, e.g., $LiCoO_2$ and $LiNi_{0.5}Mn_{0.5}O_2$, oxygen ions are coordinated by three Li and three TM ions as shown in Fig. 4a. In this configuration, a much larger projected DOS originating from the TM states than from the O states between 0 and $-1.5\,eV$ below Fermi level (commercial organic liquid electrolyte window) is found, indicating that the redox reactions are dominated and restricted by the TM $3d$ electrons. On the


Fig. 4 An example of an oxygen site in the fully lithiated structure (**a**) without a Li-O-Li linear bond and (**b**) with a Li-O-Li linear bond, required for labile oxygen states

other hand, Li-excess is created by the substitution of some TM by Li, leading to Li-O-Li configurations in many of the new exciting cathode materials. It shows an increased oxygen projected DOS below the Fermi level for oxygen with a linear Li-O-Li bond based on GGA $+ U$ calculations (see Fig. 4b). This labile oxygen observed computationally with increased projected DOS below the Fermi level paves the completely new research on anionic redox and breaks the bottleneck for reaching higher energy density in alkali-ion battery (Grimaud et al. 2016; Okubo and Yamada 2017).

The electronic band gap deduced from the calculated DOS is also useful to investigate the electronic properties of a potential electrode or solid electrolyte material. While high electronic conductivity for the electrode material is a necessary condition for high rate performance of alkali-ion battery, low electronic conductivity is required for the potential electrolyte materials. Similar to the voltage calculation, the introduction of a U correction term in the GGA method could substantially improve the accuracy of calculated band gaps (Zhou et al. 2004). Other helpful information that can be extracted from electronic structure analysis includes chemical bonding, orbital hybridization, magnetic properties, etc.

2.4 Stability Analyses

2.4.1 0 K Phase Stability

The pseudo-binary stability diagram mentioned in the previous subsection essentially works for electrode materials. In a general situation, the thermodynamic stability of any given compound (e.g., solid electrolyte) can be analyzed by evaluating its decomposition energy referenced to the linear combinations of stable compounds in this compositional space. This can be achieved by constructing the convex hull using the DFT energy of all known compounds in this compositional space. In the case of olivine LiFePO$_4$, for example, the related stability analysis

requires the DFT energies of all existing $Li_xFe_yP_zO_u$ compounds (x, y, z, and u are nonnegative integers) including itself in Li-Fe-P-O quaternary compositional space. The stability metric under this circumstance is called the energy above the hull (E_{hull}), (Sun et al. 2016; Ong et al. 2008) which measures how stable a compound is by measuring how high its energy is above the convex hull. It is always nonnegative, and it equals zero for stable compounds. The higher the E_{hull}, the more unstable the compound tends to be. With the advent of large open-source materials databases such as the Materials Project (Jain et al. 2013), a common approach is to leverage on pre-computed DFT energies in these databases for compounds other than that of primary interest, which significantly reduce the computational effort involved, especially for high-dimension compositional space. E_{hull} is frequently adopted as an efficient descriptor for phase stability and synthesizability in high-throughput first-principles screening studies to rapidly rule out structures that are unlikely stable at ambient temperatures (high E_{hull}).

2.4.2   Surface Stability

The real surface configuration rarely coincides with the ideal lattice plane which is a geometrical abstraction of the crystal structure. In reality, the stable surface can contain charged species adsorbed from the environment, charge density rearrangement, and stepped or kinked surface profile. This makes determination of surface thermodynamics very challenging. For this reason, first-principles calculations can be a useful tool to determine facet-specific surface energies. The standard model to calculate surface energies is a two-dimensional surface slab with bulk stoichiometry oriented to expose the facet of interest, with a sufficiently large vacuum layer added on top of the slab to ensure that there is minimal interaction between the slab and its periodic images along the surface normal. The k-point grid for surface slab is thus generated as $k_1 \times k_2 \times 1$, which assures no energy dispersion in the direction out of the surface.

Standard procedures of generating surface slabs include basis transformation, atomic coordinates rescaling, termination choice, and polarity check. Surfaces are typically defined using the Miller index notation by the conventional unit cell. However, first-principles calculation requires the basal plane to be coincident with the constructed slab surface. The basis of the conventional unit cell has to be transformed so that (001) plane of the new basis is parallel to the Miller plane of interest. The third vector should be as orthogonal to the basal plane as possible with a relatively short length. The atomic coordinates are then redefined based on the new basis. For a given surface orientation, a number of termination layers usually exist due to different atomic configurations and can be chosen by placing the basis at different positions along the third vector. Note that a charged surface with a perpendicular dipole moment in a repeated unit (type III according to surfaces classification by Tasker) produces a polarizing electric field in the bulk, leading to infinite periodic cell energies (Tasker 1979). For example, the (111) face of NiO ionic crystal has alternating layers of Ni^{2+} and O^{2-} ions, which forms a permanent dipole moment perpendicular to the surface. Atomic reconstruction by moving half

the charged species on one surface to the other side to cancel out the 2D-dipole is a common approach (the so-called Tasker III to Tasker II reconstruction) to stabilize type III surface (Bruno 2013).

From DFT calculations, the surface energy can be computed using the following expression:

$$\gamma = \frac{1}{2A}\left[E\left(slab\right) - N \cdot E\left(bulk\right)\right] \qquad (8)$$

where A is the surface area of the slab, E(slab) is the surface slab energy, E(bulk) is the bulk energy per atom, and N is the number of atoms in the surface slab. The prefactor 1/2 comes from the fact that each surface slab contains two equivalent surfaces. The Wulff shape, which is the equilibrium shape of the crystal, can be constructed using the lowest surface energies of different facets. The larger the surface area of a facet contributes to the Wulff shape, the more stable that facet tends to be. As an example, surface properties of olivine $LiFePO_4$ cathode were studied by Wang and co-workers (Wang et al. 2007). The two low-energy surfaces (010) and (201) are found to make up almost 85% of the surface area of Wulff crystal shape. More importantly, redox potential for the (010) surface was calculated to be much lower than the bulk value, which shows the anisotropic property of surface redox potentials. This study pinpoints the effect of surface energies and crystal shape on the electrochemistry for electrode materials composed of particles at nanoscale. Surface electronic structure, surface reconstruction, and adsorbate interactions can also be studied based on surface stability calculations.

2.4.3   Electrolyte/Electrode Interface Stability

Understanding of electrolyte/electrode interfaces has become a recent focus of the greatest importance for the performance improvement of electrochemical energy storage systems. For alkali-ion batteries with liquid organic electrolyte, SEI formation due to electrolyte decomposition is critical to cycling performance and safety. For all solid-state alkali-ion batteries with sulfide-type electrolytes, the rate-determining process is usually observed around the cathode/electrolyte interfaces. To predict the electrode/electrolyte interface stability under large variations in environmental conditions is one of the grand challenges for battery study. First-principles calculation using DFT-based methods has been developed to investigate most stable interfacial matching of two crystal solids (Haruyama et al. 2014). In a traditional manner, the procedure to investigate the interface formed by two compounds comprises three major steps: (i) identify the lowest-energy surface facet of each material as detailed in surface stability calculations; (ii) patch the two surface slabs using a reasonably large supercell (with a vacuum layer of ~10 Å) to ensure as small lattice parameter misfit as possible; and (iii) enumerate all possible configurations for the interface supercell including slide of one surface slab with respect to the other, and perform DFT relaxations. The alkali-ion sites and alkali-ion transfer properties in the most stable interface can then be further investigated under different thermodynamic equilibrium conditions.

The explicit interface calculations often require very high computational cost because of the supercell used. For studies of electrolyte/electrode interfacial stability, a critical step is to identify the possible reaction products formed at the interface. In the case of solid electrolyte/electrode interfaces, there are two efficient analysis methods based on two different thermodynamic approximations for such purposes (Zhu et al. 2015a; Richards et al. 2016; Tang et al. 2018).

- *Fast ionic diffusion limit*: In this approximation, the diffusing ions in the solid electrolyte are assumed to be the main mobile species. Under such conditions, the interface can be modeled as an open system with respect to the mobile species. The relevant thermodynamic potential is the grand potential. Taking the Li-ion solid electrolyte as a concrete example, the Li grand potential is expressed as $\varphi = E - \mu_{Li}N_{Li}$, where E, N_{Li}, and μ_{Li} are, respectively, the internal energy, the number of Li atoms in the open system, and the Li chemical potential. When the metallic Li is taken as the anode, the Li solid electrolyte/anode interface is modeled as the solid electrolyte at high $\mu_{Li} \approx \mu_{Li0}$, and the Li solid electrolyte/cathode interface is modeled as the solid electrolyte at low $\mu_{Li} \approx \mu_{Li0} - V$, where V is the cell voltage and μ_{Li0} as the chemical potential in metallic Li.

- *Multi-species equilibrium*: The second method assumes full thermodynamic equilibrium between the solid electrolyte and electrode in varying electrolyte/electrode compositional ratios x (between 0 and 1). Specifically, the equilibrium composition at a given ratio x corresponds to $c_{electrolyte}x + c_{electrode}(1 - x)$ with c_y being the composition of compound y. To estimate the likely reaction products at different x values, a pseudo-binary stability diagram that is like the aforementioned stability diagram for electrode materials is constructed. In this pseudo-binary stability diagram, however, the x values correspond to the compositional ratio x, whereas y values are the associated reaction energy which reaction products have the same composition as $c_{electrolyte}x + c_{electrode}(1 - x)$. This approach tends to be more reflective of the conditions during actual synthesis and assembly conditions.

Note that the approaches presented here are within thermodynamic approximations. To capture the kinetic effects on the formation of electrolyte/electrode interfaces, computationally more demanding approaches, e.g., ab initio molecular dynamics can be adopted (see Sect. 3.2.6).

2.4.4   Defects and Dopability

Extrinsic doping is a common strategy to further optimize battery material properties, such as phase stability, ionic and electronic conductivity, and cost. It is crucial to predict the feasibility of introducing a dopant into a crystal structure based on first-principles calculation. The size of the supercell model is inversely proportional to the dopant concentration. Note that different types of doping, including substitutional, interstitial, and anti-site, need to be considered for the supercell construction. Generally speaking, the dopability of a species depends on

its ionic radius and oxidation state relative to existing species in the crystal. In the case of charge balance doping, the neutral dopant formation energy can be defined as follows:

$$E_f\,(\text{doped}) = E\,(\text{doped}) - E\,(\text{pristine}) - \sum_{i=1}^{N} n_i \mu_i \qquad (9)$$

where $E(\text{doped})$ and $E(\text{pristine})$ are the energies of the structure with and without the neutral dopant, respectively, μ_i is the atomic chemical potential of species i, n_i is the number of atoms of species i being added or removed, and N is the total number of species in the doped structure. Synthesis condition can be selected based on the energy calculation to tune species chemical potential so that the formation energy can be low enough to prevent any species precipitation. Additionally, the doped structure should remain stable without any decomposition during synthesis.

3   Kinetics Approaches

There are two widely used first-principles approaches that can assess the kinetics of alkali-ion diffusion in battery materials: transition state theory-based methods such as the nudged elastic band approach and ab initio molecular dynamics simulations. In the following, we will present the key concept of each approach for ionic diffusion studies as well as their limitations.

3.1   Transition State Theory and the Nudged Elastic Band Method

In materials where the equilibrium lattice sites are well defined, the ionic diffusion can be investigated using transition state theory. From an atomistic viewpoint, diffusion can be viewed as a series of hopping events of ions between neighboring sites. In each hop, an ion migrates from one site to its neighboring vacant site via an activated state (aka the transition state), which has the highest Gibbs free energy along the minimum energy path between the two sites. Based on the transition state theory (Deng et al. 2016; Urban et al. 2016), the rate k at which the hopping event occurs can be expressed as:

$$k(T) = \upsilon^*(T) e^{-\frac{\Delta G_a(T)}{k_B T}} \qquad (10)$$

$$\Delta G_a(T) = G_a(T) - G_i(T) \qquad (11)$$

Here, $\Delta G_a(T)$ is known as the activation barrier, and it is the difference of the Gibbs free energies at the activated state ($G_a(T)$) and initial state ($G_i(T)$). $\upsilon^*(T)$ is the effective attempt frequency at temperature T. In the dilute limit of carrier

Fig. 5 An example of NEB computed migration barriers. The two example structures are LiCoO$_2$ (LCO) and NaCoO$_2$ (NCO). (Reproduced from Ref. (Ong et al. 2011) with permission. Copyright (2011) Royal Society of Chemistry)
concentration, the diffusivity can be approximated as $D(T) \sim d^2 k(T)$ where d is the hopping distance (assumed to be known). Moreover, the attempt frequency $\upsilon^*(T)$ is often assumed to be temperature-independent, and the typical values fall between 10^{11} and 10^{13} s^{-1} (Urban et al. 2016). When the diffusivity follows the Arrhenius relation (see Eq. 18 below), the activation barrier in Eqs. 10 and 11, $\Delta G_a(T)$, can be assumed to be temperature independent. When the entropic effects become negligible, $\Delta G_a(T)$ can be further approximated as DFT energy difference between the activated state and the initial state ($\Delta G_a(T) \approx \Delta E_a$).

For ionic diffusion studies, the nudged elastic band (NEB) method (Jonsson et al. 1998) is a widely used approach to determine the 0 K activation barriers of the ion migration paths for a given atomic configuration. This approach requires the initial and final states of the migration path (aka end points) as input, from which a given set of intermediate states (aka images) are generated to serve as the initial guess of the migration path. The minimum energy path is determined by minimizing the atomic forces in all the images subject to the constraint of a harmonic coupling (in terms of harmonic springs) between adjacent images. In the end, the activation barrier (ΔE_a) is computed as $\Delta E_a = E_{max} - E_i$ where E_{max} is the highest energy along the optimized migration path and E_i is the energy of the initial state. An example of NEB results is shown in Fig. 5 for layered oxides ACoO$_2$ (A = Li and Na) (Ong et al. 2011).

In a typical NEB calculation, it essentially comprises the following four steps:

1. Initial structural optimization calculations of the pristine crystal structure.
2. Structural optimizations of the two initial and final state structures.
3. An interpolation between the initial and final states to generate a set of images along the migration path. The linear interpolation is the most commonly used scheme for such purpose.
4. An NEB calculation to find the lowest-energy migration path, from which the highest energy is determined, and hence the activation barrier.

In the studies of ionic diffusion, the NEB method can be applied to evaluate the barrier of any given migration path. This makes it particularly useful to probe the effects of local environment (e.g., local arrangement of the framework) on the ionic diffusion. Indeed, the NEB calculations have been employed to understand the diffusion mechanisms in several important battery materials, e.g., layered $LiCoO_2$ and olivine $LiFePO_4$ cathodes (Deng et al. 2016; Urban et al. 2016). Moreover, the migration barriers from NEB calculations can also serve as inputs for other techniques, including the kinetic Monte Carlo (KMC) simulations. This is a Monte Carlo simulation method that studies the time evolution of natural processes using lattice models, e.g., the diffusion of alkali ions in the battery materials. Using the local environment-dependent barriers from NEB calculations, a first-principles cluster expansion can be carried out to parameterize these barriers for Monte Carlo simulations. More details about the KMC method, including the basic steps in the simulations, can be found in literature (Deng et al. 2016; Urban et al. 2016).

3.1.1   Limitations of the NEB Method

In studies of alkali-ion batteries, the NEB method has been mainly applied to the bulk systems (pristine electrodes and solid electrolytes). In the case of noncrystalline systems, e.g., electrolyte/electrode interfaces, much higher computational efforts are inevitably required due to the large number of distinct ionic migration paths that need to be considered due to the lower symmetry. There are two further limitations of the NEB method compared to the ab initio molecular dynamics simulations (see Sect. 3.2).

First, the start and end points of the migration path must be specified as inputs for NEB calculations. For alkali battery materials with complex diffusion properties, e.g., when ionic motions are highly concerted (common in superionic conductor electrolytes), the identification of the relevant migration events and local environment become very challenging. In this scenario, ab initio molecular dynamics (see Sect. 3.2) becomes the more appropriate technique to use. For this reason, NEB calculations are primarily performed in dilute carrier limits, e.g., single alkali-ion vacancy migration in an otherwise fully alkaliated structure or single alkali migration in an otherwise alkali-ion-free framework structure.

Second, NEB calculations essentially output the migration barrier at 0 K, i.e., the temperature effects are not considered in the calculations. Besides, to estimate an accurate hopping rate associated with the migration path, and hence the diffusivity, the prefactor in Eq. 10 must be computed explicitly. However, it is often assumed to be some value between 10^{11} and 10^{13} s^{-1}.

3.2   Ab Initio Molecular Dynamics Simulations

Molecular dynamics (MD) simulates the atomic motions at finite temperatures by integrating the Newtonian equations of motions. A key input of this approach is the description of the interatomic interactions, whereas the main output is the trajectories of the atomic motions. Depending on how the interatomic interactions are

obtained, MD simulations can be categorized into two general classes: classical MD and ab initio MD (AIMD) simulations. In classical MD simulations, the interatomic interactions are expressed in terms of analytical functions with parameters fitted using either experimental or first-principles data, whereas in AIMD simulations, the interatomic interactions are obtained by directly solving the Schrödinger equation with approximations.

Although classical MD simulations are computationally less expensive than the ab initio counterpart, it does suffer from serious drawbacks stemming from the use of empirical potentials, e.g., poor transferability across different chemistries, and the difficulty in dealing with complex interatomic interactions with simple function forms. On the other hand, AIMD simulations can generally be applied across broad chemical spaces, and the accuracy of the interatomic interactions is essentially limited by the underlying approximations of the ab initio approach.

There are two main variants of AIMD models today: Born-Oppenheimer (BO) variant and Car-Parrinello (CP) variant (Car and Parrinello 1985; Hutter 2012). For battery-related studies, the former variant is more commonly adopted. The theory behind these AIMD techniques is beyond the scope of this chapter and is extensively covered by many excellent textbooks and reviews (Hutter 2012; Marx and Parrinello 1996). The main disadvantage of AIMD methods is the significantly higher computational cost compared to the classical MD, and also the NEB method (Sect. 3.1). This places constraints on the accessible cell size as well as time scale in AIMD simulations. However, these can be mitigated by the advances in computer power and the nature of the problem under investigation.

The key output from AIMD simulations is the trajectories of ionic motions, from which the diffusion properties of materials, e.g., ionic diffusivity and conductivity, can be evaluated. The AIMD technique has gained tremendous successes in the studies of alkali-ion battery materials, particularly for the understanding and discovering novel alkali-ion superionic conductors. In the following, we will first sketch the well-established analysis methods and how they are applied to understand the ionic diffusions in battery materials. We will also discuss practical considerations on the parameter selection, the applications of AIMD in electrolyte/electrode interfaces, and the limitation of this technique. We should stress that these analysis approaches are agnostic of the types of MD simulations (i.e., classical and ab initio), and they are also applicable to other classes of materials, e.g., oxygen conductors in solid oxide fuel cells.

3.2.1 Ionic Diffusion and Conduction Coefficients

For a given 3D crystal structure with N mobile ions, the self-diffusion coefficient can be computed from AIMD simulations by evaluating the velocity-velocity autocorrelation function (Green-Kubo relation):

$$D^* = \frac{1}{3N} \int_0^\infty dt \sum_{i=1}^N \left\langle \overrightarrow{v_i}\,(t_0) \cdot \overrightarrow{v_i}\,(t + t_0) \right\rangle_{t0} \tag{12}$$

where $\vec{v}(t)$ is the velocity of ion i at time t and angular bracket in the integrand stands for an ensemble average over the initial time argument t_0.

This quantity is more frequently estimated from the ionic displacements via the Einstein equation:

$$D^* = \frac{1}{2dt} \lim_{t \to \infty} \frac{\partial \Delta \vec{r}(t)^2}{\partial t} \tag{13}$$

$$\Delta \vec{r}(t)^2 = \frac{1}{N} \left\langle \sum_{i=1}^{N} \left[\vec{r}_i(t + t_0) - \vec{r}_i(t_0) \right]^2 \right\rangle_{t0} \tag{14}$$

Here, $\vec{r_0}(t)$ is the position of mobile ion i, and $\Delta \vec{r}(t)^2$ is known as the mean square displacement (MSD) of the mobile ions over time t as an ensemble average over the initial time argument t_0.

We should stress that the two expressions (Eqs. 12 and 13) for the self-diffusion coefficient D^* are equivalent. However, due to the short accessible time scales in AIMD simulations that are limited up to a few hundred picoseconds in most cases, the convergence speed becomes an important factor to consider when computing the diffusion coefficient. In this context, Eq. 13 is more commonly adopted for computing D^* because it tends to converge more rapidly than that of Eq. 12 due to the averaging of the square displacements. Moreover, the long-time tail of the integral in Eq. 12 may also cause numerical inaccuracy when evaluating the diffusion coefficient in a short simulation time scale.

With the diffusion coefficient at temperature T in hand, the ionic conductivity can be estimated using the Nernst-Einstein equation expressed below,

$$\sigma(T) = \frac{\rho z^2 F^2}{RT} D^*(T) \tag{15}$$

Here, ρ and z are, respectively, the molar density and charge of the mobile ions in the simulation cell. For example, z $= +1$ for alkali ions such as Li^+ and Na^+. F and R are the Faraday constant and the gas constant, respectively. We should point out that since the computed D^* corresponds to the tracer diffusivity in experiments, the conductivity derived from Eq. 15 assumes no correlations in ionic motions. Here, the correlation essentially describes how the displacement of one ion depends on those of other ions during the diffusion.

In many situations, such ionic correlation can be measured in terms of Haven ratio H_R, (Murch 1982)

$$H_R = \frac{D^*}{D_\sigma} \tag{16}$$

where D_σ is known as charge diffusivity defined below:

$$D_\sigma = \frac{1}{6N} \lim_{t \to \infty} \frac{\partial}{\partial t} \left\langle \left\{ \sum_{i=1}^{N} \left[\vec{r}_i\,(t+t_0) - \vec{r}_i\,(t_0) \right] \right\}^2 \right\rangle_{t0} \qquad (17)$$

The Haven ratio equals one when the ionic motions are uncorrelated, while it is less than 1 for correlated ionic motions. For fast ionic conductors, H_R typically falls between 0.3 and 0.6 (Morgan and Madden 2014; Bron et al. 2013). Given the fact that the convergence of D_σ in any molecular dynamics simulations is usually much slower than that of D^*, there have only been few AIMD studies that attempt to explicitly estimate the H_R value.

3.2.2 Activation Energy

Apart from the ionic diffusivity and conductivity, another key quantity of interest is the activation energy E_a. Under the assumption that there are no phase transitions, one can perform AIMD simulations at multiple temperatures and fit the temperature-dependent diffusivity D to the Arrhenius relationship:

$$D = D_0 e^{-E_a/kT} \qquad (18)$$

Here, D_0 stands for the diffusivity at temperature $T \to \infty$, and k denotes the Boltzmann constant. One can obtain E_a via a linear fitting of the log of D vs. 1/T (see Fig. 6a as an example). We should note that AIMD simulations are usually performed at elevated temperatures, e.g., above 600 K, to increase the number of diffusion events. The diffusivity at ambient temperatures can also be obtained from Eq. 18 via linear extrapolation. Nevertheless, we should stress that the scheme implies that the fundamental diffusion mechanisms remain unchanged between the entire temperature range of interest.

Copyright (2015) American Chemical Society)

3.2.3 Analysis of the Diffusion Process

Besides the ionic diffusivity and conductivity, the ionic trajectory data also provide rich details about diffusion process of ions, including the energy landscape in the battery material and the related diffusion pathways for the mobile ions. The latter information can be obtained by calculating the probability density function $P\left(\overrightarrow{r}, T\right)$, which is a function of both the temperature and a spatial 3D grid (typically a uniform grid). Specifically, for an input trajectory data with a given time scale and temperature T, P is computed by first counting the total number of mobile ions occupying each grid point using a distance-based algorithm. This is followed by a normalization such that $\int_0^{\Omega} P d \overrightarrow{r} = 1$ with Ω being the volume of the unit cell. Two useful pieces of information can be extracted from the probability density function: (1) low-energy sites (corresponding to higher $P\left(\overrightarrow{r}, T\right)$ values) at where the mobile ions prefer to reside and (2) pathways for the ionic diffusion. As an example, Fig. 6b demonstrates the Na^+ probability density function in cation-doped sodium superionic conductor Na_3PS_4. We should point out that the occupancies of the symmetrically distinct sites can also be estimated using this function, which provides useful message for further understanding the ionic diffusion process.

The Van Hove correlation function is a well-known technique to assess the ionic correlations during the diffusion process. Van Hove correlation function is often split into two parts, self-part G_S and distinct-part G_d, and they are expressed as follows:

$$G_s\left(r, t\right) = \frac{1}{4\pi r^2 N_d}\left\langle\sum_{i=1}^{N_d}\delta\left(r - |\overrightarrow{r}_i\left(t + t_0\right) - \overrightarrow{r}_i\left(t_0\right)|\right)\right\rangle_{t0} \tag{19}$$

$$G_d\left(r, t\right) = \frac{1}{4\pi r^2 \rho N_d}\left\langle\sum_{i\neq j}^{N_d}\delta\left(r - |\overrightarrow{r}_i\left(t_0\right) - \overrightarrow{r}_j\left(t + t_0\right)|\right)\right\rangle_{t0} \tag{20}$$

Here, $\delta(\cdot)$ refers to the 1D Dirac delta function. N_d and r are, respectively, the number of mobile ions in the unit cell and the radial distance. ρ is the number density for the mobile ions that is used as the normalization factor such that $G_d \to 1$ when $r \gg 1$. In terms of physical interpretation, the self-part $G_s(r, t)$ can be considered as the probability density of a mobile ion that diffuses away from its initial position by a distance r after time t. The distinct-part $G_d(r, t)$ describes the radial distribution of $N_d - 1$ ions after time t with respect to the initial reference mobile ion. Note that when $t = 0$, $G_d(r, t)$ is reduced to the static pair distribution function.

3.2.4 Practical Considerations in AIMD Simulations

Since the AIMD techniques are computationally expensive, special care is required when selecting the relevant simulation parameters so that it achieves a good balance between the computational cost and the realistic results. In general, the selection of these parameters depends strongly on (i) the specific system under investigation, e.g., fast or slow conductors, and (ii) the type of problem of interest,

e.g., comparative evaluation for systems with similar chemistries/topologies, or accurate diffusivity calculations. For any AIMD simulations of interest, key parameters include the simulation cell size, total simulation time, time step, simulation temperature, the ensemble, and so on. An inclusive summary about the parameter selection can be found in literature for interested readers (Shin and Saal 2018).

3.2.5   Modeling Electrolyte/Electrode Interfaces

AIMD simulations can also be used to explicitly model the electrolyte/electrode interfaces, which play a crucial role in the battery performance during charge-discharge process. To obtain more realistic results, the simulation supercell size for such systems is required to be much larger than the supercell for bulk materials, especially along the lattice direction normal to the interface. In principle, the diffusion properties at the interfaces may be estimated via AIMD simulations. However, that requires significant computational efforts due to the required large supercell and long simulation time scales. More often, AIMD simulations are applied to simulate the structural evolutions during alkaliation/de-alkaliation process (Leung and Budzien 2010) and the chemical reactions between the electrolyte (solid or liquid) and electrode materials from which the likely interfacial reaction products can be identified (Tang et al. 2018). In those simulations, a smaller supercell size with a shorter time scale may be utilized to speed up the AIMD simulations and obtain realistic results in a qualitative manner. Analysis tools have been developed in recent years that aim to efficiently determine the interfacial products from AIMD simulations. Among them include the radial distribution function (RDF) analysis. In that method, the RDFs of all possible products in their crystalline phases are compared to that of the interface to identify the likely reaction products. We should note that all these existing techniques are based on various approximations, and they are required for further improvements.

3.2.6   Limitation of AIMD Simulations

Similar to the NEB method, AIMD simulations are mainly applied to the *bulk* systems for their diffusion properties, especially the alkali-ion superionic conductors. For alkali-ion superionic conductors, key quantities such as ionic diffusivity and conductivity can often be estimated within the accessible AIMD time scale that is typically up to a few hundred picoseconds. For bulk electrode material such as alkali transition-metal oxide cathodes, the presence of transition metals often requires spin polarization calculations. Also, the ionic conduction in the electrode materials is usually much slower than in the superionic conductors, implying that longer simulation time scale may be needed for properly converged ionic conductivity. Therefore, diffusion studies using AIMD simulations for these materials often require substantially higher computational cost, and key diffusion properties such as alkali-ion migration barriers and ionic conductivity are often estimated from NEB calculations (see Sect. 3.1) instead. Nevertheless, AIMD simulations can still be performed for the electrode materials for other purposes, e.g., to estimate the diffusion pathways of the alkali ions, site occupancy, etc.

As a final note for AIMD simulations, the ionic diffusivity (and activation energy) of a material at ambient temperatures is essentially obtained via linear extrapolation from those obtained at elevated temperatures. This implies that the diffusion mechanisms between the ambient temperatures and elevated temperatures must stay unchanged. For materials where such condition does not hold, the NEB method should be utilized instead.

4   Conclusion and Outlook

This chapter provides a general overview of the well-established first-principles methods used in battery-related studies (electrodes, electrolytes, and their interfaces) from both the thermodynamic and kinetics aspects. These include many key properties of alkali-ion battery: equilibrium voltage, phase stability, electronic structures, and ionic diffusion properties. First-principles calculations need to have closed-loop interaction with experimental design and data. Simulations provide insight into development of new materials and aid in the interpretation of experimental observations. Experimental results in turn prove the validity of the theoretical model and proposed mechanism. Despite the remarkable advances of the first-principles methods in recent years, there remain some pressing challenges in modeling technique when it comes to (1) noncrystalline systems, e.g., the presence of intrinsic defects and the electrolyte/electrode interfaces, and (2) the design of high-voltage high-capacity cathode materials.

First, it should be noted that most of the first-principles methods presented here, e.g., voltage calculations and NEB methods, have mainly been applied to perfect crystalline solids. From the experimental perspective, however, intrinsic defects such as dislocations, stacking fault, and micro-strain are always present in the synthesized material. These intrinsic defects can have significant impact on the electrochemical performance of the battery material. In principle, imperfections (e.g., dopants) can be modeled via the construction of supercell, and the size of the supercell depends mainly on the defect concentration. Given that there are often more than one possible configuration upon the introduction of defects, an efficient structural enumeration is needed to be performed, which is followed by DFT calculations for each possible distinct configuration. Hence, it eventually leads to the lowest-energy doped structure. This procedure is often computationally very expensive, especially in the dilute defect concentration.

Solid electrolyte/electrode interface is another important example of noncrystalline first-principles modeling, which is highly challenging at the current stage. To obtain realistic results, the required supercell needs to be sufficiently large, especially the length along the normal of the interface that aims to minimize the artificial interactions between periodic images. In principle, the AIMD method is suitable for interfacial diffusion studies at finite temperatures. Nevertheless, the required long simulation time scales as well as the length scales indicates that such simulations are almost computationally infeasible.

For cathode materials, it should be noted that this chapter is mainly devoted to intercalation electrode materials, wherein energy storage is possible through a reversible intercalation in a stable host framework. Although anionic redox has been recently discovered and confirmed, the capacity of this intercalation type electrode material is mainly limited to one electron per transition metal. Conversion and alloy reactions in electrode material are thus proposed to achieve higher capacities. More oxidation states of TM are feasible in conversion and alloy-type electrodes, which allows more electrons to reversibly change during electrochemical cycling. Similar to intercalation reactions, the thermodynamics of conversion/alloy reactions can be investigated from first-principles calculations by computing the total energy of all the involved compounds. Additional complexity does exist since conversion/alloy reactions produce multiple phases or domains with different chemical composition, where interface and nanosize effects (i.e., requiring noncrystalline modeling) often dominate the thermodynamic properties of materials.

The solutions to the aforementioned limitations and challenges are multifold. First, computational power will continue to grow rapidly, which can allow for longer simulations and larger system sizes and chemical complexity. Second, multi-scale approaches that aim at bridging the multiple time and length scales are expected to further improve in the future. That enables us to probe even more realistic models with higher computational accuracy. Third, the continued development of automation software tools will also facilitate the studies of battery materials and significantly minimize the researchers' time to monitor the simulations. Fourth, building open-access materials science databases from standardized first-principles high-throughput calculations can also facilitate the first-principles modeling. More importantly, with the rapid increase of the computation data, machine learning models can be trained with a higher prediction power, enabling researchers to discover hidden design rules for battery materials.

Contents

Abstract

Materials design for next-generation solid-state Li-ion batteries require atomistic-level understanding of ionic transport mechanisms. It is not well understood what the required ingredients and design principles are for enabling high ionic conductivity of inorganic materials at room temperature. Strong ion-ion interaction, geometric frustration, disorder, and collective motion seem to be emerging as common themes in recent investigations of super-ionic materials. This chapter presents an overview of the essential features of these effects, their relationships, and implications on ionic transport. We illustrate applications of atomistic computational tools in combination with techniques of statistical

mechanics, group theory, and computational geometry for analyzing dynamics and transport mechanisms in the context of understanding and optimization of leading oxide Li-ion conductors.

1 Introduction

Ability of complex oxide materials to conduct ions lies at the heart of key modern technologies with high technological impact. Solid-state batteries, chemical sensors, solid oxide fuel cells, gas separation membranes, and memristors rely on ionic transport for their function. In particular, safe high-energy batteries for automotive and stationary energy storage can unlock a market of several hundred billion dollars, making it arguably the largest technology impact enabled by new functional materials. Today's battery electrolytes are based on liquid organic solvents that are combustible and prone to decompose and passivate the interfaces with electrodes, causing performance degradation. It would be a major technological step forward to replace the liquid electrolyte in a battery with a solid ion conductor that is chemically and mechanically stable against the Li metal anode, whose high gravimetric capacity can double the energy density of conventional cells with graphite anodes. Over the past two decades, significant progress has been achieved in optimizing solid-state Li-ion conductors. However, only a few classes of fast Li-ion conductors are known, and they have been discovered and optimized primarily by haphazard trial and error. Highest ionic conductivities are found in sulfides, particularly crystalline $Li_{10}GeP_2S_{12}$ (12 mS/cm at room temperature) and glassy $xLi_2S\text{-}yP_2S_5$ (3 mS/cm). Oxides are more chemically and electrochemically stable but have lower conductivity, for instance garnets $Li_{6.55}L_3Zr_2Ga_{0.15}O_{12}$ with conductivity of 1.6 mS/cm and NASICON $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ with 1 mS/cm (Meesala et al. 2017). The great technological importance but limited number of fast ion conductors has inspired recent efforts to identify new families of materials more suitable for application in solid-state batteries, but this is inherently challenging given the nonlinear dependence of conductivity on atomic structure and composition. Accelerated materials development requires identification of general design rules and mechanistic principles enabling fast ion transport. Various qualitative descriptions have been proposed over the last decade, such as sufficient volume of conduction pathways and high anion polarizability, but these have limited predictive power. In order to make rational progress in the search and optimization of fast ion conductors, it is important to develop general physics-based models and validate their prediction using statistically significant data sets. Formulating a general microscopic theory of super-ionic transport in solids is difficult because ion-ion interactions and correlations are especially strong when carrier concentration is high. Even qualitative mechanistic principles and design rules that govern "superionic" behavior are not yet established, and generalization from only a few known cases is difficult. This is in stark contrast with the success of band theory and Fermi liquid model in perturbatively describing electron interactions and transport in weakly correlated semiconductors and metals. There is evidence that solid-state

ionic transport in the best conductors exhibits collective features reminiscent of correlated fluids, where ionic transport is typically much faster than in regular solids. Despite the long history of the field, complex effects of many-body interactions on transport in atomic fluids are generally not well captured by analytical models, making explicit atomistic simulations particularly important. In this chapter, we illustrate how combinations of techniques of statistical mechanics, group theory, and molecular dynamics can help develop systematic understanding of ionic transport in strongly interacting and dynamic systems. We give an overview of practical computational approaches useful for analyzing transport mechanisms, studying geometric frustration, and estimating correlation in crystalline and disordered materials and provide examples of their application to understand solid oxide Li-ion electrolytes.

2 Simulation Methods

Fast ion conduction arises due to a delicate balance between the interatomic forces acting on the mobile ions. On one hand, the mobile carrier sublattice needs to be sufficiently coupled to the host lattice in order to ensure overall thermodynamic and mechanical stability of the material. On the other hand, the interaction of the mobile ions with their host cannot be too strong so as to allow for low enough activation barriers in order for ionic current to flow at device operating temperatures. The strong ionic interactions of Li ions with the host lattice determine the topology of sites that can be occupied, typically triangles, tetrahedra, or octahedra formed by the anions (e.g., O, S, N, or F). In the classical picture of solid-state diffusion, an ion spends the vast majority of the time rattling in its site, occasionally escaping and hopping to a neighboring vacant site through a polyhedral face, as illustrated on Fig. 1a. The probability of this hopping event is described by transition state theory as activated by thermal fluctuations of the host lattice, giving the Arrhenius equation for temperature-dependent diffusivity:

$$D(T) = D_0 \exp\left(-\Delta E_a \big/ kT\right) \tag{1}$$

Activation energy ΔE_a corresponds to the height of the barrier in the energy landscape separating the two local minima sites. In the case of a single ion moving in a static periodic potential of an empty lattice, where the transport mechanism is known, this barrier can be computed readily using the nudged elastic band (NEB) method that uses a total energy model, such as density functional theory (DFT) to find the minimum energy path passing through the unstable saddle point (Jónsson et al. 1998). This approach, however, is only simple when Li ions are dilute interstitial defects in an ideal crystal lattice and do not interact while hopping independently of each other. In the best ionic conductors, Li-ion concentrations are high, which means that Li ions are in close contact and Li-Li interactions are not negligible. In such strongly interacting scenarios, forces confining Li ions in
Fig. 1 (**a**) Ionic transport mechanism in Li garnets, showing Li migration from an oxygen-coordinated octahedral site to a neighboring tetrahedral site through a face. Geometric hull analysis determines that the occupancy changed and flags this as a hopping event (Courtesy of Sneha Akhade). (**b**) Voronoi decomposition of a crystal automatically identifies polyhedral sites that are used by the geometric transport analysis algorithm. The thickness of the graph edges connecting the Voronoi sites corresponds to the number of hops detected in the MD simulation analysis. (Courtesy of Leonid Kahle)

their sites are counteracted by electrostatic repulsion from nearby Li ions, and Li ions can displace each other. This leads to a self-blocking interaction where at most one Li ion can occupy a polyhedral site. As a result, there is a significant amount of correlation between mobile ions, meaning that the energy landscape of the Li sublattice (occupancy energies and transition barriers) is complex and depends on local configuration. Configuration dependence of the energy barrier can be introduced using the method of cluster expansions (Van der Ven et al. 2001), but also in this case, the transport mechanisms must be known a priori in order to compute barriers in all configurations relevant for macroscopic transport. If it is possible to obtain the energy barriers, the next step is to construct a kinetic Monte Carlo (KMC) model based on the complete catalog of all possible transitions and their probabilities.

An alternative practical approach to study complex ion conductors is molecular dynamics (MD), where interatomic forces are used to simulate the actual lattice time evolution according to Newton's equations of motion, without taking as input any information about transport mechanisms (Alder and Wainwright 1962). MD has emerged as a powerful tool for examining and optimizing solid ionic conductors, providing insights into transport mechanisms that are not possible to obtain experimentally. MD also relaxes the assumption of KMC models of time-independent transition probabilities, which allows realistic treatment of ion transport in dynamic environment such as liquids and polymers. At the same time, MD is significantly more computationally expensive and statistically inefficient than stochastic methods, since transport is dominated by rare hopping events, and thermal vibrations consume the vast majority of computation time. Typical simulations using ab initio molecular dynamics, where forces are obtained from DFT, are limited to about 200 atoms and 100 picoseconds taking roughly 2 weeks of wall time, using

the typical time step of 1–2 femtoseconds. The standard approach is to perform simulations at significantly elevated temperatures usually above 700 K, in order to rapidly sample ionic motion, and then extrapolate diffusivity to room temperature, assuming that the Arrhenius dependence in Eq. (1) holds. This approach requires caution when transport mechanisms are temperature dependent and if phase transitions occur at lower temperatures. In classical MD, forces are determined from analytical force fields, such as Buckingham and Morse pair potentials, sometimes with core-shell polarization and angle-dependent terms included. Classical MD has the advantage of being several orders of magnitude faster than ab initio dynamics. The limitation is that every material requires careful selection and validation of the functional form and parameters of the force field. Special care is needed especially for ionic transport simulations, since diffusivity is determined by energies of low-symmetry configurations corresponding to transition states, while available force fields are typically parameterized to represent equilibrium properties.

3   Transport Mechanism Analysis and Coarse-Graining

A key advantage of using molecular dynamics to study ionic transport in ceramic electrolytes is the ability to directly characterize atomistic transport mechanisms, which consist of very fast and rare hopping events determining the long-range macroscopic transport character of the material. In order to extract information about the transport mechanisms, it is necessary to separate vibrational motion from hopping events. The goal is therefore to map the dynamics of Li onto a discrete lattice of sites in order to analyze the hopping sequences and statistics. One option for extracting hop events from the MD simulation is to keep a record for every Li of its nearest-neighbor atoms, based on a carefully chosen distance threshold, and to detect significant changes in the neighbor lists. This method is easy to implement but has the disadvantage that trajectory discretization can depend on the distance threshold and neighbor list, since different types of sites have different anion coordination numbers. A more robust approach is to first determine the topology of the host lattice and partition it into nonoverlapping polyhedra formed by immobile anions. This can be obtained from crystallographic information and/or from Voronoi decomposition using anions as the vertices. Every Li ion is then assigned to an available polyhedral site in each MD snapshot. A simple way is to use a 3D convex hull construction (e.g., using the Qhull code) taking as input the positions of the Li ion of interest and all anion vertices of the candidate site. If the Li ion is inside a particular site, then the convex will contain only the anions, and if Li is outside, then its position will be part of the convex hull. This method is reliable, since there are no free parameters, with the assumption that the host lattice does not rearrange. For example, in garnet ionic conductors, this analysis clarified that transport occurs only by tetrahedral to octahedral to tetrahedral site face-crossing hops, contrary to earlier conjectures of direct octahedral-octahedral edge-crossing hops (Fig. 1a). Using MD as a starting point for mechanistic investigations and coarse-graining dynamics simulations is especially useful when transport mechanisms in a complex

new material are not known a priori. In this way, the transport analysis can be automated and used for high-throughput investigation of many diverse structural variations. In practice, this automatic procedure starts from high-temperature ab initio or classical MD to quickly sample important hopping scenarios. Once the MD trajectory is discretized, the site-to-site transition sequences and timings can be extracted to obtain the complete transport mechanism sampled during the MD simulation. Frequency statistics directly from MD are often insufficient to accurately estimate hopping probabilities, especially for the more rare events. In such cases, hopping rates for each event can be estimated using transition state theory, which relies on barrier height estimation using the NEB method. Finally, the catalog of transition probabilities can then be used to define a coarse-grained dynamics models using KMC, mentioned above, which simulates hopping as a stochastic Markov process while keeping track of real system time. However, this last step may not be straightforward in some cases we consider below.

The resulting energy landscape determined by this analysis workflow contains important information about the nature of ionic transport. For example, Fig. 2 shows an example of an MD trajectory of a garnet Li-ion conductor that was first discretized using the geometric method described above and combined with NEB calculation of barriers of the pathways connecting the extracted hop endpoints. It
Fig. 2 Result of geometric discretization of an ab initio molecular dynamics simulation of a Li-garnet structure performed at elevated temperature (800 K) in order to sample a significant number of hops. Endpoint configurations of detected transition paths are used as inputs into NEB computations of migration barriers

is noteworthy that the resulting energy landscape is qualitatively different from the classical picture of a single-ion hopping in a periodic potential landscape of the host lattice. Instead, Li configurations explore a complex energy landscape in a collective way, and some events do not even exhibit barriers. Transport proceeds through a sequence of moves involving multiple Li ions moving downhill or uphill in energy, and constructing a kinetic coarse-grained model may require an alternative approach to the conventional individual ion hop picture.

4   Correlation and Collective Motion

The outputs of both KMC and MD simulations are trajectories, or sequences of atomic positions and corresponding energies and forces on each atom. Information on positions (or velocities) can be used to calculate transport properties, hopping mechanisms, and correlation functions. Ionic conductivity can be obtained using the Green-Kubo formalism, starting from

$$\sigma = \frac{N^2 q^2}{6kTV} \lim_{t \to \infty} \frac{d}{dt} \langle |\mathbf{R}(t) - \mathbf{R}(0)| \rangle = \frac{q^2}{kT} \frac{N}{V} D_\sigma \qquad (2)$$

where N is the number of diffusion Li ions, $q = 1$ is the charge, V is unit cell volume, and $\mathbf{R}(t)$ is the vector connecting the center of mass of all Li ions with that of the host material at time t. The reference to the host material center of mass is especially important in simulations of multicomponent systems where the host exhibits diffusive or fluctuating dynamics (Wheeler and Newman 2004). The second equality in (2) is the Nernst-Einstein equation defining for convenience a "conductivity" diffusion coefficient D_σ which, unlike conductivity itself, is not directly measured. A useful directly measurable quantity is the tracer diffusion coefficient which is given by

$$D^* = \lim_{t \to \infty} \frac{1}{6} \frac{d}{dt} \frac{1}{N} \sum_{i=1}^{N} \left\langle |\mathbf{r}_i(t) - \mathbf{r}_i(0)|^2 \right\rangle \qquad (3)$$

where $\mathbf{r}_i$ are the positions of the Li ions and the quantity under the derivative is called the mean square displacement (MSD). It can be shown that $D_\sigma = D^*$ when all cross-correlations between displacements of different Li ions vanish. This is a good commonly used approximation to obtain ionic conductivity from MD simulations of dilute liquid electrolytes. However, in solid electrolytes, this is not the case due to significant correlations, as mentioned earlier. The importance of correlations can be estimated from the Haven ratio which is defined as $H = D^*/D_\sigma$. Typical Haven ratios for fast Li-ion conductors range between 0.25 and 0.7. The inverse of the Haven ratio has been interpreted as the average number of ions that interacts to move collectively (Doliwa and Heuer 2000). Despite the non-negligible effect of correlations, in practice MSD is the most frequently used

quantity for estimating ionic conductivity from MD since it converges much faster with simulation time than the fully correlated conductivity obtained from the center of mass displacement. The reason is that in the first case, the estimate of the MSD is based on N-independent Li displacements, while in the second case, only the single displacement value of the center of mass is used to estimate the conductivity. Therefore, the statistical variance of the estimate of D^* is smaller than that of the conductivity by a factor of order N^2.

Haven ratio can be directly measured (e.g., from dc conductivity and NMR tracer diffusivity) but only provides a time-averaged indication of ionic correlations. To understand the microscopic nature of correlations, a detailed examination of atomic trajectories is necessary, as discussed in the previous section. In some garnet crystals, Li ions exhibit pronounced collective, or concerted, motion (see Fig. 3a), where multiple ions are displaced at the same time (Meier et al. 2014) rather than individual independent hops. In Li_3PO_4 this type of concerted motion was found to be responsible for low activation energies of 0.2 eV, while direct hopping has a migration barrier of 0.6 eV (Du and Holzwarth 2007). Concerted motion and hopping time correlations were also observed in $Li_xLa_{2/3-x/3}TiO_3$ (Catti 2011) as well as sulfides and NASICON ion conductors using ab initio molecular dynamics (He et al. 2017). In each case, it was noted that collective migrations had lower-energy barriers compared to mechanisms involving single-ion hops.

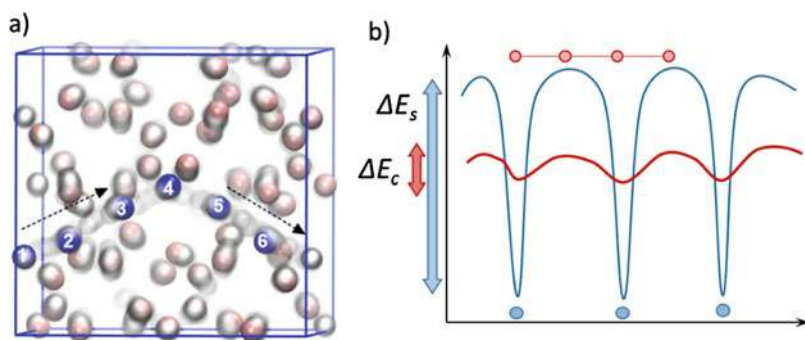
To understand the appearance of collective modes, consider a string of ions moving in a single-particle potential energy surface with amplitude ΔE_s, illustrated in Fig. 3b. If the ion-ion interaction is strong enough and constrains the ions to be spaced apart in a way that is not commensurate with the energy landscape maxima and minima, then the group as a whole experiences a smoother energy landscape, due to a "window-averaging" effect of the original energy landscape. Such collective modes, if they can form and move, will statistically dominate transport relative to


Fig. 3 (**a**) String-like collective motion involving multiple Li ions in tetragonal Li-garnet oxides (Meier et al. 2014). (**b**) Effective flattened energy landscape (red) experienced by a string of ions moving in an external lattice potential (blue). Dilute ions or configurations commensurate with the external potential minima will experience much higher activation energies in their motion, making collective motions more likely

the individual ion hops that are much less frequent due to their higher barriers. This situation can only happen when nearest-neighbor Li interactions are significant, i.e., when the fraction of occupied Li sites is high. This simple picture is an example of the phenomenon of frustration, as discussed in detail below, where strong short-range interactions prevent ions from settling into local minima, ensuring collective mobility. It is interesting that collective "string-like" highly correlated motion has also been noted in other classes of materials, particularly in regimes close to melting and glass transitions (Gebremichael et al. 2004). It is not clear whether collective motion is a necessary ingredient for high ionic mobility or whether it is simply the lowest-energy excitation in highly correlated situations. Their existence points to the possibility that super-ionic conductors are close to a sublattice phase transition where the Li sublattice exhibits liquid-like behavior, motivating the discussion of phase transitions in the next section.

A practical way to quantify position and time correlations of ionic jumps and to detect such collective modes is the distinct part of the van Hove correlation function, defined as

$$G_d\left(r, t\right) = \frac{1}{N} \sum_{i \neq j} \left\langle \delta\left(r - \left|\mathbf{r}_i(0) - \mathbf{r}_j(t)\right|\right) \right\rangle \tag{4}$$

It describes the conditional probability of finding a pair of distinct atoms such that they are separated by distance of r after a time delay of t. $G_d(r, t = 0)$ is just the usual pair distribution function. $G_d(r = 0, t)$ indicates probability of one ion being replaced by another ion in time t, which can be interpreted as a collective simultaneous event when t is comparable to the inter-site transition time scale. In addition to being useful for gaining intuition about ionic transport correlation, the Van Hove correlation function is measurable experimentally. Its Fourier transform is the intermediate scattering function that can be measured by neutron spin echo spectroscopy. This quantity provides a valuable opportunity for direct validation of MD simulations against experimental data.

5   Geometric Sublattice Frustration

The overall ability of the Li sublattice configuration to rearrange with low transition barriers is the necessary ingredient of high ionic conductivity. Since ionic transport is a statistical thermally activated phenomenon, the probability of such rearrangements is proportional to the number of available configurations. It is clear, therefore, that in order to maximize conductivity, we need to maximize the sublattice entropy. As with any system in thermal equilibrium at temperature T, the ionic conductor will minimize the free energy and therefore tend to find low-energy configurations of the Li sublattice. If the ground state is well ordered, the only available mechanism for transport is through creation of mobile defects. In regular periodic crystals, the activation energy required for ionic hopping $E_a = E_{\text{def}} + E_{\text{hop}}$ is a sum of the energy

required to first create a mobile defect and the migration barrier height. However, thermal energy scale at room temperature is rather low, with kT only on the order of 25 meV, making it difficult to overcome strong ionic interactions and disturb a stable ground state configuration in a crystal. This is the reason that in crystalline ionic solids, diffusion is much slower than in liquids. The goal in designing a fast ionic conductor, therefore, is to ensure that the ground state is intrinsically degenerate or nearly degenerate, so that it is able to rearrange with minimal energy cost. In materials science terms, this qualitatively corresponds to engineering a high intrinsic concentration of mobile carriers by varying the composition and structure. In mathematical terms, this can be described as symmetry breaking and maximizing the amount of geometric frustration in the Li sublattice, preventing the system from settling into a low-entropy arrangement.

We generally define *frustration* as competition between local interactions (Li-Li and Li-anion), resulting in near degeneracy and disorder in the ground state configuration of the Li sublattice. Locally, this situation comes about when Li occupancy of a lattice site cannot be decided based on minimizing total interaction energy with its neighbor sites. Globally, frustration manifests itself when there is not a single way to minimize energy by ordering mobile ions on their sublattice.

Intuitively, the role of frustration is to flatten the energy landscape of Li ions, preventing locking of mobile carriers in deep energy minima corresponding to stable ordered arrangements (Fig. 3b). Li ions in the frustrated sublattice are then forced to explore the large number of degenerate states in a narrow energy window. Effective frustration, which maximizes the sublattice entropy, results in a high concentration of charge carriers and high interstate transition rates, the two necessary ingredients for fast ion conduction.

Geometrically frustrated systems have a long history in solid-state physics, traditionally studied in the context of antiferromagnetic spin models on various lattices with short-range interactions. Due to the rich physics and emergence of unexpected phenomena, frustration in magnetism is an increasingly active research field in condensed matter theory (Balents 2010). Complexities arising from the presence of extensive ground state degeneracy lead to unusual thermodynamic and transport effects. These include suppression of finite temperature order-disorder freezing transitions, giving rise to disordered spin liquid ground states. Recently attention to frustrated lattice systems has increased due to the emergence of Majorana fermions, topological quantum excitations resembling relativistic particles (Kitaev 2006).

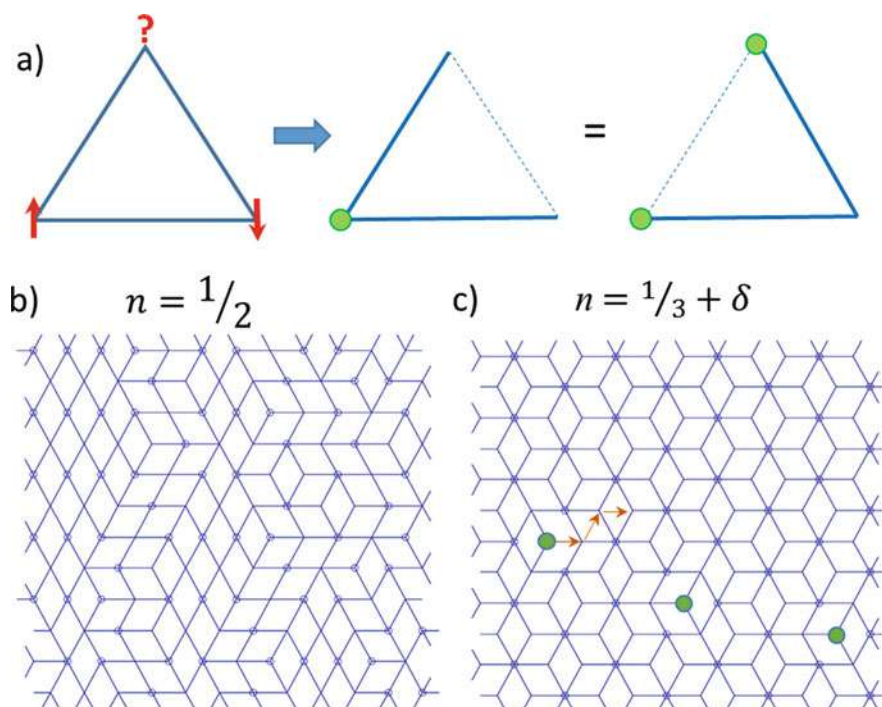
In order to illustrate the concept of frustration and its implication on charge transport, let us consider a simple model: a two-dimensional antiferromagnetic Ising model with nearest-neighbor interactions on a triangular lattice. As illustrated on Fig. 4a, once opposite spins occupy two of the three corners of a triangle, there is no unique choice for the third spin direction that minimizes the energy. To connect this peculiar behavior to charge transport, we can map the lattice spin variables to charge occupancy, so that spin up corresponds to occupied site and spin down to unoccupied, as shown on Fig. 4a. The antiferromagnetic spin interaction physically corresponds to electrostatic repulsion of charges on neighboring sites.


Fig. 4 (**a**) Frustrated configuration of spins on a triangle is mapped onto site occupancy in a lattice gas model. The two configurations have the same energy if only nearest-neighbor interactions are considered. (**b**) One of many possible ground state configurations at ½ occupancy of the triangular antiferromagnetic Ising model. (**c**) A well-ordered low-entropy ground state configuration exists for occupancy fractions 1/3. At slightly higher occupancy, entropy increases, since additional charges can freely move through the ordered background, forming a dilute gas

This construction is representative of a class of lattice gas models with on-site exclusive constraints. Frustrated lattice models are commonly discussed in the context of spin or electron charge degrees of freedom, but it is natural to extend this understanding to crystalline ionic conductors. In fact, the triangular lattice gas model describes Li-ion configurations in transition metal layered oxides $Li_x(Ni,Co,Mn)O_2$ $(0 < x < 1)$, which are by far the most commonly used cathode materials in Li-ion batteries today. In these materials, the crystal structure is made up of layers of oxygen-coordinated edge-sharing octahedral sites filled with transition metals, separated by layers of octahedral Li sites that form a triangular lattice, such that Li ions move in and out of the layers during battery cycling.

Relevant temperature scales in this lattice gas model are approximately given in terms of the nearest-neighbor interaction strength V. The simplest to understand is the high-temperature behavior $kT \gg V$, corresponding to a disordered gas phase in which charges can move via independent hops, only subject to the exclusive site occupancy constraint. At low temperature $kT \ll V$, the system settles into the

ground state configuration (solid phase). At intermediate temperatures, the system leaves the ground state manifold, and a population of mobile defects exist, e.g., all three triangle corners occupied or empty.

Due to local frustration, the ground state at half-filling ($n = 1/2$, i.e., zero average magnetization) is highly degenerate, allowing many configurations with the same lowest energy (illustrated in Fig. 4b). This model with only nearest-neighbor interactions can be solved exactly to show that there is actually no ordering phase transition at any finite temperature (Wannier 1950). In other words, the spin lattice never truly freezes and remains in a glassy state. We should note that this is true because the nearest-neighbor antiferromagnetic interaction is incompatible with the triangular lattice symmetry in the case of $n = 1/2$, but there exists a well-ordered ground state at $n = 1/3$, where a pronounced freezing transition occurs at finite temperature and consequently entropy and transport are strongly suppressed. This emphasizes that "local frustration" does not necessarily guarantee ground state degeneracy. Instead, *ground state degeneracy is a function of both carrier concentration and global lattice symmetry*, as elaborated further in the next section.

Remarkably, the frustrated ground state without any "defect" excitations has substantial ability to rearrange, due to local charge motions. Monte Carlo simulations of thermodynamics and transport indicate that this system appears to possess a sufficient amount of residual entropy in the $n = 1/2$ ground state to allow for finite conductivity, even in the presence of long-range interactions (Levitov and Kozinsky 1999). When long-range screened Coulomb interactions are included for $n = 1/2$, the degeneracy is broken, and an ordering phase transition appears but at much lower temperature than in the case of $n = 1/3$, indicating that frustration effectively suppresses freezing. In this regime, charge transport has collective character of a correlated fluid due to strong short-range correlations between charges which constrain individual charge migrations, preserving the degenerate ground state manifold of configurations. The change in conductivity behavior while cooling down from the disordered into the correlated fluid and solid phases can also be seen in Fig. 5. The low-temperature curves indicate that the conductivity vanishes more quickly near the densities of a simple fraction form ($n = 1/4, 1/3, 1/2$). This corresponds to freezing of the system into states commensurate with the lattice at these values of n. The qualitative features of the phase diagram and its influence on charge transport do not seem to be affected by including disorder (Novikov et al. 2005). So far the model only considers energy of configurations and does not include kinetic details of inter-site transition. Even when more detailed hopping mechanisms are included specifically to describe transport of Li in Li_xCoO_2-layered oxides using cluster expansions and kinetic Monte Carlo, the main effects of concentration dependence of conductivity are preserved (Van der Ven et al. 2001). This simple 2D model demonstrates the key principle that charge transport without defect excitations is possible in an ideal symmetric lattice, as long as frustration exists that establishes degeneracy and disorder at non-commensurate carrier concentrations. In a later section, we will see that this principle allows us to understand and design more complex ionic conductors.
Fig. 5 The scaled conductivity in the triangular lattice gas model with long-range screened Coulomb interaction, as a function of charge occupancy fraction *n* for several temperatures. The temperature values are given in the units of V(a), the nearest-neighbor interaction. Arrows mark the features corresponding to the freezing phase transitions at n = 1/4, 1/3, 1/2. Dashed line corresponds to the high-temperature limit. The symmetric high-occupancy half of the concentration range is not shown. (Levitov and Kozinsky 1999)

5.1 Algebraic View of Sublattice Frustration

We now turn to the discussion of ways to identify and design materials with frustrated mobile sublattices. In mathematical terms, the appearance of a strong degeneracy of the ground state requires that there is no low-entropy highly symmetric configuration commensurate with the host lattice. At the same time, frustration arises due to strong short-range interaction, which requires high Li-ion concentration in the material. From this point of view, when optimizing ionic conductivity of a particular crystal, *Li concentration* is the key tuning parameter. In the light of the discussion in the previous section, our goal is to identify high-symmetry ground states of the sublattice configuration, into which Li ions can freeze. Ability to do this has wide applicability in general, especially for Li-containing crystals, since Li has a very weak X-ray scattering cross-section and Li site occupancies are very difficult to assign without resorting to neutron diffraction of single-crystal samples. The nature of ionic conduction is also very difficult to observe, only indirectly using solid-state NMR techniques. In the

context of fast ion conductors, knowledge of where ordered configurations appear in the composition space is critical to guide optimization away from these Li concentrations, thus maximizing frustrated disorder.

In order to systematically and rigorously identify ordered ground state configurations as a function of Li occupancy, group theoretic tools are particularly effective. We illustrate this approach in the case of Li-garnet family of ionic conducting crystals with room temperature ionic conductivity of up to 1.6 mS/cm. Combined with its electrochemical stability in contact with Li metal and high mechanical toughness, this makes it an attractive and widely investigated candidate for a solid electrolyte in a Li metal battery. The prototypical garnet structure is body-centered cubic (group Ia-3d No. 230) with the chemical formula $Li_xB_3C_2O_{12}$. This structure is remarkably robust in regard to changes in the B and C cation composition (B = La, Ca, Ba, Sr, Y, Pr, Nd, Sm-Lu, and C = Zr, Ta, Nb, Nd, Te, W) and is able to accommodate Li concentrations x ranging from 3 to 7 per formula unit. In the vast majority of crystalline oxides, Li ions occupy octahedral and/or tetrahedral sites. Garnets are no exception; there are two distinct sets of sites: octahedral (O, Wyckoff position 48 g) and tetrahedral (T, at position 24d). The numbers indicate multiplicities, i.e., 48 O sites are equivalent and can thus be either all filled or all empty in the prototype group of the host lattice. Each T site shares a face with four O sites, while each O site shares a face with two T sites, thus forming a percolating Li site network of pathways for ionic conduction.

The arrangement of Li ions among available crystallographic sites is the main degree of freedom that controls ionic transport. However, complete brute-force analysis of Li orderings is impossible: for instance, in the simple cubic cell representation of the $x = 7$ garnet, there are 72 Li sites, of which 56 are occupied, resulting in 10^{15} possible arrangements. In order to deal with the combinatorial space of configurations, it is useful to apply crystal group analysis to classify simply ordered Li arrangements for each composition x. The procedure starts with exhaustive crystallographic projections of the prototype high-symmetry group of the host lattice (Ia-3d No. 230 in case of garnets) onto lower-symmetry subgroups. This allows to split the high-symmetry Wyckoff positions (48 g and 24 d), corresponding to all filled or empty T and O sites, into sets of smaller multiplicities, so that they can be separately occupied. The resulting structures are the highest symmetry configurations, commensurate with the host lattice space group, where Li occupies a fraction of the sites. For instance, group No. 198 $P2_13$ is a cubic subgroup of the parent group, where the T site with the original prototype Wyckoff position 24d is split into two Wyckoff positions 12b corresponding to two subsets of 12 sites related by symmetry operations. Each subset can then be occupied independently. There are many ways of breaking the parent prototype symmetry, and going down to the triclinic group P1 corresponds to removing all symmetry and enumerating all possible configurations, which is not feasible. Therefore, it is practical to constrain the search to structures that have high enough symmetry to be likely ground states and can be represented using small unit cells in an ab initio simulation. Mathematically this corresponds to calculating the tree of maximal subgroups of the parent prototype group of the host lattice, limiting them to certain Bravais lattices

(e.g., only cubic or tetragonal) and a low k-index. The k-index of a subgroup is the multiplication factor relating the volume of the primitive cell of the subgroup with respect to the primitive cell of the original prototype structure. We can then analyze the splittings of Wyckoff positions in each subgroup and conjugacy class in order to identify symmetrically related sets of Li sites and their multiplicities. A simple 2D example of crystal symmetry breaking is illustrated on Fig. 6a. This procedure has the advantage of rigorously evaluating all possibilities starting with the highest symmetry and usually results in only a few hundred high-symmetry configurations with various Li concentrations, a significant reduction compared to the original space of possibilities.

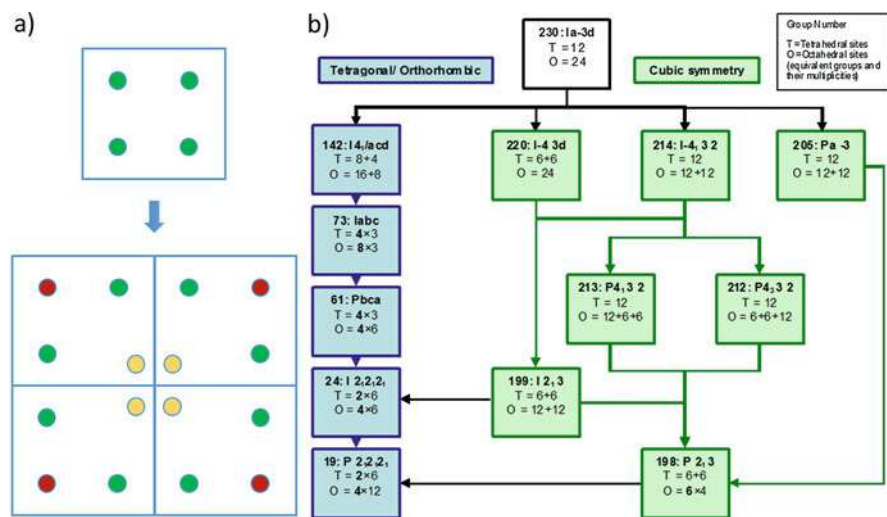
To implement the subgroup projection in practice, it is convenient to use symmetry tools provided by the Bilbao Crystallographic Server (Aroyo 2006). For the case of garnets, a partial tree of maximal subgroup projections down to orthorhombic symmetry and k-index 2 is illustrated on Fig. 6b, which lists symmetry equivalent sets of sites with their Wyckoff multiplicities. Crystal structures are constructed of the simple cubic cell where each independent set of Wyckoff positions is either included or excluded in the structure. The total energy of each configuration is computed using density functional theory. For the garnet family, the result is that there are unique low-energy configurations at certain integer values of Li composition (x = 3, 4, 6, 7). High-symmetry configurations also exist at other integer compositions but are very close in energy (less than 3 meV per atom), resulting in


Fig. 6 (**a**) Illustration of symmetry breaking preserving square symmetry in a larger supercell (k-index 4). Different colors represent sets of equivalent positions that can be removed or displaced according to the subgroup Wyckoff positions. (**b**) Partial group-subgroup relationship tree that exemplifies a typical set of paths from the parent group No 230 to lower-symmetry subgroups. T and O represent tetrahedral and octahedral sets of sites, respectively, together with their multiplicities
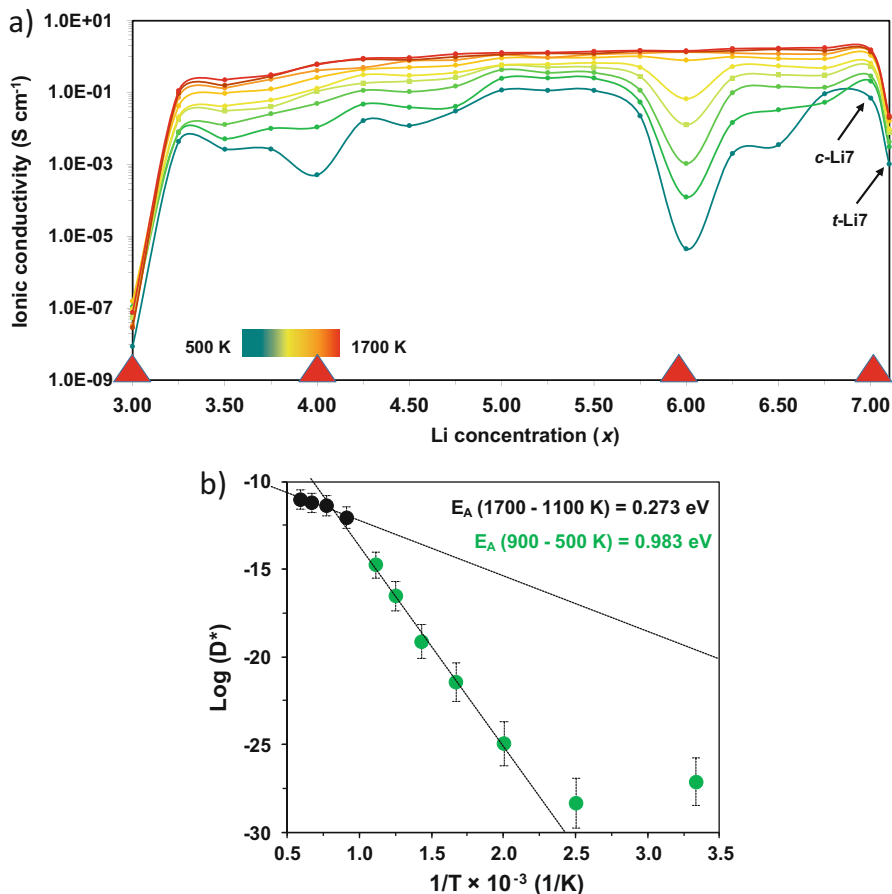

Fig. 7 (**a**) Ionic conductivity as a function of Li content x in the garnet crystal, from MD simulations. Red triangles indicate compositions at which ordered ground states were identified by the subgroup projection method. (**b**) Logarithm of the tracer diffusion coefficient versus inverse temperature for the $x = 6$ structure, illustrating the order-disorder phase transition at about 900 K. Black circles represent high-temperature values, and green triangles represent low-temperature values

disordered structures at room temperature. At non-integer compositions, no low-entropy ground states are found at all by the symmetry analysis, at least within the constraint of a cubic structure with fewer than 200 atoms in the unit cell. Since Li-Li interactions are weak beyond the length scale of the already large unit cell (13 Å), this constraint is physically justified. Compositions where ground states have high degeneracy and frustration due to symmetry incompatibility are expected to have the highest ionic conductivity. Indeed, as illustrated in Fig. 7a, conductivity is noticeably suppressed near precisely the compositions where well-ordered ground state Li configurations exist, with non-negligible excitation energies. On the other

hand, much shallower energy landscapes and degeneracy result in better ionic mobility in disordered configurations that arise in situations of frustration, where order-disorder phase transitions are suppressed (Kozinsky et al. 2016), and much lower conductivity when order-disorder transitions appear at high temperature, e.g., at $x = 6$ (Fig. 7b).

6   Extrinsic Disorder: Amorphous Materials and Random Alloys

An alternative way to avoid ordered Li sublattice configurations is to break the translational symmetry of the host lattice. Extrinsic disorder can be implemented in several ways. By melting and rapidly cooling, some crystalline materials can be turned into glasses that remain in the state of quenched disorder indefinitely at room temperature. This process typically preserves the local coordination and bonding features of the crystal but destroys the long-range order. Examples of materials where ionic conductivity in crystalline form is significantly lower than in amorphous structure are Li_3PO_4 and $LiAlSiO_4$. Geometric frustration between the building blocks of the host lattice (not Li sublattice as discussed earlier) can result in a glassy disordered morphology of the material (e.g., water ice). Disorder can also be introduced by random site occupancy in regular crystals, preserving the long-range lattice structure. For instance, experiments and MD simulations show that random alloying in $Ba_{1-x}Ca_xF_2$ enhances F-ion conductivity by a factor of 10^5 (Duvel et al. 2017). Similarly, classical molecular dynamics indicated that Li_4SiO_4-Li_3PO_4 crystalline alloy mixtures exhibit 2–4 orders of magnitude higher ionic conductivity than either endpoint (Deng 2015).

The effect of extrinsic host disorder on ionic transport is not well understood, despite significant interest (Dyre et al. 2009), and numerical modeling plays a central role in this direction. Open questions remain about the nature of order-disorder phase transitions in lattices with quenched extrinsic disorder. A useful model to represent extrinsic quenched disorder is the "random-field Ising model," where each site experiences a random local chemical potential (Berretti 1985). For strong enough disorder, suppression and eventual elimination of order-disorder transitions are observed, but the cause is very different from geometric frustration. Monte Carlo simulations are used to examine different regimes that are not covered by analytical renormalization group techniques, far away from critical points. There is also incomplete understanding of how quenched disorder relates to ionic transport. Qualitative features of transport in disordered systems are illuminated using the random barrier model (Dyre 1988). In this model, a single particle is hopping on a lattice, where barrier heights between sites are drawn from a smooth probability distribution. In 2D and 3D, long-range transport happens along percolation paths composed of hops with low migration barriers. Thus diffusion at low temperatures is controlled by a single critical percolation energy barrier, explaining why Arrhenius behavior is observed in systems with a wide range of activation energies. In large-scale MD simulations of disordered systems, care must

be taken to ensure that tracer diffusivity is sampled for long enough time for the system to equilibrate and reach a truly long-range diffusive transport regime, as opposed to Li exploring a confined percolation cluster in a sub-diffusive mode. This can be done by checking whether the mean square displacement increases linearly with time, as expected from Fick's law and Einstein relation. At higher temperatures, a wider range of pathways and a larger fraction of activated mobile ions may start contributing to the transport. In experiment deviations from Arrhenius behavior are observed in glass ionic conductivity at high temperatures, but the reason is still not well understood (Kincs and Martin 1996).

6.1 Host Dynamics

In addition to static extrinsic disorder, in some of the best ion conductors, the host itself has mobile degrees of freedom that couple in nontrivial ways with the mobile ions. Host dynamics on the time scale of Li migration can effectively introduce fluctuations of the Li configuration energy landscape, preventing long-term locking in local minima. This effect is well known in liquid electrolytes, where solvation shells of mobile species are dynamic, resulting in very high diffusivity values. The most widely studied solid electrolytes relying on host dynamics are polymer salt solutions, particularly the family of polyethylene oxide (PEO)-based polymers. In these electrolytes, Li ions are coordinated by the polymer, and conduction mainly happens due to segmental motion of the flexible chains, with Li occasionally hopping from one chain to another. As a result, PEO polymer electrolytes only have substantial ionic conductivity above their glass transition temperature, when the host polymer has significant local mobility, similar to a viscous liquid. Due to the dynamic nature of the host, molecular dynamics is the only option for simulation, and due to the size of these amorphous systems (>5000 atoms) and long equilibration times (>10 ns), classical molecular dynamics is the method of choice, typically using force fields developed for organic molecules. In some inorganic materials, dynamic host behavior is also important in assisting ionic transport by preventing mobile ions from ordering and by increasing the rate of exploration of the configuration landscape. In oxides host dynamics are rare due to strong ionic interactions, but some examples are found in covalently bonded oxide polyanion materials. These types of dynamic mechanisms are material-specific, and due to the mixed ionic-covalent nature of bonding, ab initio molecular dynamics is mostly used to study the interplay between structure dynamics and ionic transport. For instance, high proton conductivity is demonstrated by ab initio MD to be mediated by fast SO_4 anion in-place rotations in $CsHSO_4$ proton electrolyte (Wood and Marzari 2007). In the recently discovered class of closo-borate fast ion conductors such as $Li_2B_{12}H_{12}$, the $(BH)_x^{2-}$ anion centers are ordered on a regular lattice due to long-range electrostatic interaction, but their icosahedral geometry is incompatible with the lattice symmetry (Kweon et al. 2017). This geometric frustration causes the anions to exhibit orientation disorder and in-place rotation. Li ions jump in the extremely dynamic energy landscape, driven by its fluctuations, and explore a large

number of available dynamic sites. This type of "dynamic frustration" is a promising mechanism to enhance ionic mobility explore and requires further understanding.

7 Outlook

There is converging understanding from recent molecular dynamics and experimental work that ionic transport in fast Li-ion conductors at room temperature is different from the classical picture of independent migrating defects and that concepts based on single particles are not entirely relevant. Evidence of importance of many-particle collective effects comes from molecular dynamics simulations and from measurements of the Haven ratio. Correlated transport phenomena are prominent, but their origins need deeper microscopic and statistical understanding. In a surprising number of cases, mobile sublattice disorder seems to dramatically improve ionic conductivity, whether it is due to frustration, extrinsic distortion and alloying, or dynamic coupling to the host fluctuations. In particular, Li sublattice frustration with maximal residual entropy may be a promising recipe for high ionic conductivity at low temperature, due to both high carrier concentration and their collectively mobile behavior. The reasons and mechanisms are not yet well known and may not be the same in different materials, but the complex regimes of high Li-ion concentration and strong interaction deserve a general systematic consideration. This further elevates the importance of explicit molecular dynamics approaches and development of fast transferable ways to accurately simulate complex ion dynamics, especially dealing with rare hopping events. Toward the goal of establishing a common framework of understanding room temperature fast ion transport, we underscore the relevance of rigorous methods developed in other fields for describing sublattice order-disorder phase transitions and transport in correlated liquids and disordered media.

Abstract

Perovskite materials are widely used as catalysts and electrocatalysts in energy conversion devices. Their bulk transport properties can be tuned flexibly for many applications. While the ion and electron transport properties in their bulk are generally well-understood, the surfaces remain much less explored and challenging. Surface instabilities give rise to compositional deviations in the near-surface region or even the precipitation of secondary phases. These deteriorate the surface catalytic properties under operating conditions, thus reducing efficiency and lifetime of devices.

In this contribution, the bulk and surface chemistry of perovskite oxides for solid oxide fuel cell applications are explored for selected compounds relevant for application. Starting with a short description of the bulk defect chemistry of perovskite oxides, the challenges for both theory and experiment in treating these materials are highlighted. Surface instabilities and a selection of mechanisms for surface stabilization are explored, such as electronic reconstruction, ionic segregation, and the formation of stable AO surface terminations. Finally, the O$_2$ dissociation is examined at two different stable AO terminations, where it is revealed that the nature of the active sites differs for the SrO and LaO terminations on SrTiO$_3$ and La$_2$NiO$_{4+\delta}$, respectively, so that the O$_2$ dissociation follows fundamentally different mechanisms on these surfaces.

1   Introduction

Perovskite oxides are an important class of materials that are widely applied in solid oxide fuel cells (SOFCs) and solid oxide electrolysis cells (SOECs) as electrode or electrolyte materials (Mahato et al. 2015; da Silva and de Souza 2017). They are also used as catalysts for electrochemical and thermochemical splitting of H$_2$O and CO$_2$ (Scheffe and Steinfeld 2014; Rao and Dey 2016) and as catalysts for production of fuels, such as H$_2$ and syngas (Agrafiotis et al. 2015). These oxides achieve high oxygen ion conductivity at high temperatures as well as high electronic conductivity, both of which are important properties for SOFC electrode materials. The exchange of oxygen at the surface limits the overall rate of the oxygen reduction reaction (ORR) in fuel cells and the oxygen evolution reaction (OER) in electrolysis and thermochemical splitting of H$_2$O and CO$_2$. In general, these reactions will be referred to as oxygen exchange.

Perovskite oxides can be represented by the general formula ABO$_3$, where A is a large cation (typically from the alkaline earth or rare earth groups) and B is a small cation (typically a transition metal). Due to the flexibility of the perovskite structure, the cations in the A- and B-sublattices can be easily substituted by other

ions, thus making it possible to tailor the bulk properties (such as electronic or ionic conductivity or the band gap) as required. The perovskite lattice was originally identified for the mineral $CaTiO_3$. The structure of the perovskite lattice depends on the proper ratio between the radii of the A-site and B-site cations (Abbes and Noura 2015; Goldschmidt 1926). Owing to the large ionic radii, alkaline and alkaline earth elements from the first and second group of the periodic table are often the choice for the A-site cation. They are characterized with low ionic charge: $+1$ or $+2$. B-site elements with small ionic radii are often the transition metals, which are characterized with large ionic charge. The B-site element, i.e., the transition metal, is situated in the center of an octahedral coordination sphere of oxide ions, where one oxide ion bridges two B-site centers. The B-site – O – B-site angle is characteristic for the perovskite lattice varying between 180° and 140° depending on the ratio of radii of A-site and B-site cations and the degree of doping. The tilted octahedral structure forms the BO_2 sublattice of the perovskites. It is worth noting that despite the perovskites showing mostly an ionic character, some degree of covalency is observed due to overlap between the d-orbitals at the B-sites and the 2p-orbitals at the oxide ions (Yagi et al. 2015). That leads to a deviation from the formal charges at the B-sites and the oxide ions and is the foundation for the high electronic conductivity found in some perovskites, e.g., $LaCoO_3$. The perovskite lattice is not limited to oxides but is a more general crystallographic structure that allows the incorporation of organic fragments, e.g., the hybrid perovskites recently applied in the solar cells (Wu et al. 2017).

One of the most important and best-studied perovskite materials for energy conversion applications is $La_{1-x}Sr_xMnO_3$ (LSM). It is a promising material for SOFC/SOEC electrodes that exhibits superior electronic conductivity, oxygen reduction kinetics, thermal stability, and compatibility (e.g., thermal expansion coefficient) with the commonly used solid electrolyte materials, such as yttrium-stabilized zirconia (YSZ) or gadolinium-doped ceria (GDC). As the oxygen exchange at the surface is typically rate-limiting, tuning of the electrode surface is a key aspect in the development and optimization of materials for energy conversion applications. With Sr-doped perovskite materials, a fundamental problem arises because these materials have a tendency to form passivating Sr-rich layers on the surface due to segregation of the dopant strontium ions (Li et al. 2017). This surface layer inhibits the oxygen exchange at the surface, thus increasing polarization resistance and reducing the energy efficiency of the SOFC cell.

A major application of complex perovskite materials is as air electrodes in high-temperature electrochemical solid oxide devices. This is because of their catalytic activity for molecular oxygen activation and molecular oxygen dissociation reactions on cathodes for solid oxide fuel cells, as well as molecular oxygen evolution reaction from anodes in solid oxide electrolyzers (Ishihara 2009). This catalytic activity is characterized by a high value of the surface exchange coefficient for oxygen (k), measured by techniques such as isotopic oxygen exchange, which gives a measure of the flux of oxygen crossing the surface at chemical equilibrium. A proper understanding of the underlying principles of these processes is crucial for the further optimization of the materials used in these solid oxide electrochemical devices.

While studying and understanding the ionic transport through the solid oxide electrolyte require expertise, mainly in the field of materials science, the reactions on the electrode surfaces add many additional levels of complexity. These reactions occur at the solid-gas interface, and their understanding requires expertise in the wider fields of materials science, surface science, and chemical catalysis (Burriel et al. 2014; Li et al. 2015). In order to be able to elucidate the surface processes on perovskite electrodes, one should be able to correctly understand the precise surface composition, surface reconstruction, the difference in properties between the surface and the bulk, as well as the evolution of the molecular chemistry of the catalytic reactions. This requires an active collaboration between material scientists, in materials and device preparation; spectroscopists, applying ion beam-based techniques such as low-energy ion scattering (LEIS) and secondary ion mass spectroscopy (SIMS) (Druce EES 2014; Chen et al. 2015; Téllez et al. 2015); and the efforts of theoreticians applying first-principles quantum mechanical methods to elucidate the molecular catalysis at atomistic scales (Mastrikov et al. 2018; Akbay et al. 2016; Staykov et al. 2015). Thus, to further our understanding of the oxygen reduction reaction on perovskite surfaces, it requires knowledge of the molecular chemistry of oxygen, understanding of the high-temperature surface reconstruction, the bulk material properties, and the catalytic chemistry on the perovskite surface.

2   Regimes in the Bulk Defect Chemistry of LSM

Many properties of perovskite materials, such as oxygen exchange and diffusion coefficients, band gap, and electronic conductivity, are strongly related to the bulk and surface defect chemistries of these materials. The dominant defects in oxides change with $p(O_2)$, and for perovskite oxides, five defect regimes can be identified as shown in Fig. 1a.

Nonstoichiometry, which introduces a high concentration of cation or anion vacancies, can be efficiently probed using thermogravimetric analysis (TGA) after equilibrating the sample in Ar–O_2, CO–CO_2, and H_2/H_2O gas mixtures (resulting in well-defined oxygen chemical potentials $\mu(O_2)$). For $LaMnO_3$, the characteristic nonstoichiometry isotherm, the curve of $3 \pm \delta$ vs. $Log(p(O_2)/p^0)$, is S-shaped as shown in Fig. 1b, with δ indicating the amount of oxygen excess ($+\delta$) or deficit ($-\delta$). Around the turning point, the composition is stoichiometric with an A/B/O ratio of 1/1/3. At higher (oxidation) or lower (reduction) $p(O_2)$, different defects dominate as indicated in Fig. 1a (top) with consequences for oxygen stoichiometry, oxygen vacancy concentration, and electronic conductivity as shown in the boxes in Fig. 1a.

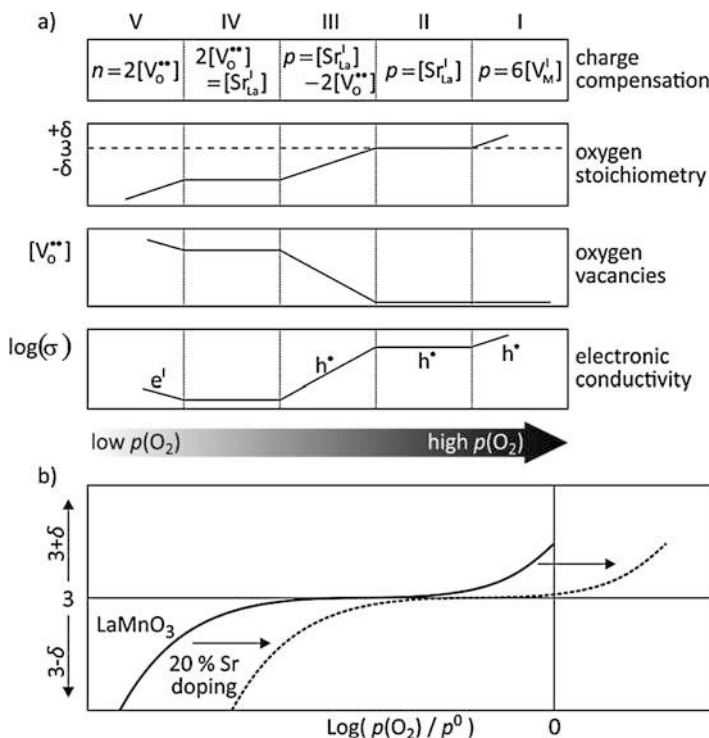
Under reducing conditions (low $p(O_2)$ and/or high T), which correspond to the $3 - \delta$ branch in Fig. 1b, perovskite oxides form oxygen vacancies, thus reducing the transition metal cations (defect regime V):


Fig. 1 Schematic diagram of defect chemistry in acceptor-doped perovskite oxides. (**a**) nonstoichiometry, oxygen vacancy concentration, and electronic conductivity as a function of $p(O_2)$, divided in five defect regimes. (**b**) Nonstoichiometry of $LaMnO_3$ (solid curve) and 20% Sr-doped $LaMnO_3$ (dashed curve) as a function of $Log(p(O_2))$. (Adapted from De Souza and Kilner 1998)

$$2Mn^x_{Mn} + O^x_O = 2Mn'_{Mn} + V^{\cdot\cdot}_o + \frac{1}{2}O_2 \tag{1}$$
In the case of $LaMnO_3$, Mn^{3+} is reduced to Mn^{2+}. Under oxidizing conditions (high $p(O_2)$ and/or low T), $LaMnO_3$ incorporates additional oxygen into the lattice by forming cation vacancies in equal proportion on A- and B-sites (defect regime I):

$$6\,Mn^x_{Mn} + \frac{3}{2}\,O_2 = V'''_{La} + V'''_{Mn} + 6\,Mn^{\cdot}_{Mn} + 3O^x_O \tag{2}$$
To compensate the high negative charge of the cation vacancies, 6 Mn^{3+} cations are oxidized to Mn^{4+}. The incorporation of additional oxygen is easily identified from the $3 + \delta$ branch as shown in Fig. 1b (solid line).

Doping $LaMnO_3$ with Sr^{2+} also leads to the formal oxidation of Mn^{3+} to Mn^{4+} (defect regime II):

$$Mn_{Mn}^x + La_{La}^x + Sr^{2+} = Mn_{Mn}^{\cdot} + Sr_{La}' + La^{3+} \tag{3}$$
The oxidation of manganese through Sr doping suppresses the formation of cation vacancies, thus shifting the nonstoichiometry curve to higher $p(O_2)$ (cf. Fig. 1b, dashed line). Twenty percent doping is sufficient to make the oxygen-excess region inaccessible at $T > 1300$ K Mizusaki Solid State Ionics 2000. However, the oxidation of Mn^{3+} to Mn^{4+} facilitates the formation of oxygen vacancies, $V_o^{\cdot\cdot}$ (defect regime III):

$$2Mn_{Mn}^{\cdot} + O_O^x = 2Mn_{Mn}^x + V_o^{\cdot\cdot} + \frac{1}{2}O_2 \tag{4}$$
The occurrence of different charge states of manganese, Mn^{2+}, Mn^{3+}, and Mn^{4+}, can be considered implicitly by introducing the charge disproportionation equilibrium:

$$2Mn_{Mn}^x = Mn_{Mn}' + Mn_{Mn}^{\cdot} \tag{5}$$

Defect regime IV does not occur in acceptor-doped $LaMnO_3$, as doping is compensated by Mn oxidation, rather than the formation of oxygen vacancies.

2.1 Formation of Oxygen Vacancies

Bulk oxygen vacancies play a crucial role for oxygen transport properties in SOFC cathodes and electrolytes. Surface oxygen vacancies have also been proposed as a decisive factor for the activity of LSM in the dissociation of O_2 (Mastrikov et al. (2018); Kuklja et al. 2013). At technologically relevant doping levels of 20%, 1 bar O_2, and 900 °C, the oxygen vacancy concentration is on the order of 10^{-8} (Berenov et al. 1999). As a result, LSM20 has a slow oxygen diffusivity in comparison with other transition metal perovskite-based MIECs like LSCF. Before considering the modeling of oxygen vacancies, experimental results for LSM shall be summarized first in order to assess the reliability of first-principles calculations.

2.1.1 Experimental Investigation of Oxygen Vacancies in LSM

For determining defect formation energies from experiments, there are two popular approaches. In the first, the reaction energy of a defect formation reaction is obtained by fitting the temperature dependency of the corresponding equilibrium constant. These equilibration constants can be obtained by fitting the defect concentrations to nonstoichiometry data obtained from experiments. The thus-obtained energy is not a pure vacancy formation energy, as several effects (ionic and electronic) occur simultaneously. Consider the oxygen vacancy formation (reduction) in Eq. 4. Using the bracket notation for site fractions, the equilibrium constant can be written as

$$K_{\text{red}} = \frac{\left[\text{Mn}_{\text{Mn}}^{\text{x}}\right]^2 \left[\text{V}_{\text{o}}^{\cdot\cdot}\right] p_{\text{O}_2}^{1/2}}{\left[\text{Mn}_{\text{Mn}}^{\cdot}\right]^2 \left[\text{O}_{\text{O}}^{\text{x}}\right] p_0^{1/2}} = e^{-\frac{\Delta_{\text{red}} G_0}{RT}} \text{, and} \tag{6}$$

$$-R\, T \ln\left(K_{\text{red}}\right) = \Delta_{\text{red}} H - T\, \Delta_{\text{red}} S. \tag{7}$$

Throughout the text, p_0 indicates the standard pressure (10^5 Pa), T the temperature, R the universal gas constant, and $\Delta_i H$, $\Delta_i S$, $\Delta_i G_0$, and $\Delta_i K$ the molar enthalpy, entropy, standard Gibbs enthalpy (at $p^0 = 10^5$ Pa), and equilibrium constant of reaction i. Only the reaction enthalpy can be measured in this fashion, but not individual defect formation energies. The result is strongly intertwined with the applied defect model, and different defect models can give very different values for the formation of the same type of defect or even a different dependency on the Sr-doping content.

The second approach involves determining the ion mobility in a tracer diffusion experiment, where the vacancy concentration is implicitly contained and can be determined by using an approximation (Berenov et al. 1999). Again, the defect formation energy can be obtained by considering the temperature dependency of the defect concentration in similar fashion.

Naturally, these two approaches do not necessarily give the same results, as the two approaches operate under very different conditions and apply different approximations. Tracer diffusion experiments are typically conducted at $p(\text{O}_2) = 1$ bar, resulting in very low oxygen vacancy concentrations in LSM (on the order of 10^{-8}). The resulting values may thus be considered as dilute oxygen vacancy formation energies. However, under these conditions, cation vacancies V_{A}''' dominate in LSM, especially for low Sr-doping content. This possibly results in reduced $\text{V}_{\text{o}}^{\cdot\cdot}$ formation energy due to opposing defect charges and favorable defect association.

In TGA, however, the nonstoichiometry is detected by mass change. For reasonably fitting a defect model to TGA data, the defect concentration must be at least a few percent. Common fitting approaches neglect defect-defect interactions, but they do play a role at defect concentrations in the percent range. For these reasons, there are systematic deviations between the results from tracer diffusion and TGA.

A comparison of oxygen vacancy formation energies determined by TGA (blue) and tracer diffusion (green) is shown in Fig. 2. The literature sources used to compile this figure are listed in Table 1 (dilute concentration) and Table 2 (high concentration).

For both methods, data are available from different literature sources for different Sr-doping levels. The results within the two groups (low and high concentration) are remarkably consistent, which allows us to treat the data obtained by these two methods as whole sets of data, regardless of source. The only exception within the high-concentration group is Mebane et al. (2008), which uses a very different fitting model and is thus plotted separately in Fig. 2 (yellow squares).

[a]V_O in center of slab, with Sr dopants in bulk
[b]V_O in center of slab, with Sr dopants at surface

For pure LMO, the oxygen vacancy formation energy at high concentration (blue dots) is about 3.6 eV. Tracer experiments at dilute concentration (green diamonds) give a much smaller value of 2.5 eV. This apparent discrepancy is resolved by the very different experimental conditions as outlined above.

However, both methods show remarkably similar dependence of E_{V_O} on Sr content: the oxygen vacancy formation energy decreases with increasing Sr content. This is consistent with the experimentally observed shift of the nonstoichiometry curve to higher $p(O_2)$ with increasing x(Sr) (Fig. 1b), which means that oxygen vacancies form more easily at higher Sr content.

The models used to fit nonstoichiometry data usually do not take into account the defect-defect interaction energy. The only exception is the TGA analysis by Liu and Mebane (orange curve), which introduces an interaction term describing the strain energy of close-by defects. As a result, the model gives very different values from other TGA analyses, as well as a much stronger dependency of the Sr content. Since there are only two points available, it is unclear if the relationship of E_{V_O} with x(Sr) is linear.

2.1.2 Modeling of Oxygen Vacancies by Density Functional Theory Calculations

Computations of the oxygen vacancy formation energy in LSM are also available (red triangles in Fig. 2). Compared to the experimental results, the computational values are remarkably inconsistent. Some of the inconsistencies can be explained

Table 4 Overview of computational parameters and resulting vacancy formation energies. Data are compiled from Curnan and Kitchin (2014)

Parameter	Range tested	A	$\left\lvert \Delta\left(E_{V_O}\right)\right\rvert$
Supercell[a]	$(1\times1\times1)$, $(1\times1\times2)$, $(2\times2\times1)$, $(2\times2\times2)$	La	0.5 eV
		Sr	0.5 eV
Space group	$Pm\bar{3}m$ (cubic), $R\bar{3}c$ (rhombohedral), $Pbnm$ (orthorhombic)	La	0.7 eV
		Sr	0.2 eV
Magnetism	FM, AFM	La	0.5 eV
		Sr	0.7 eV
U_{eff} (Mn 3d)	0–4.5	La	0.1 eV
		Sr	0.3 eV
O_2 correction	$E(O_2)$		$\frac{1}{2}\Delta E\,(O_2)$

[a]E_{V_O} usually decreases with increasing supercell size. In the study by Curnan and Kitchin (2014), the opposite was observed for the cubic crystal structure of $LaMnO_3$ (but not of $SrMnO_3$). This is unphysical and reflects the instability of the cubic structure, which is not a minimum on the potential energy surface for A = La.

by the use of different exchange functionals (generalized gradient approach (GGA) with Hubbard U correction (+U) or hybrid functionals), choice of the U parameter, assumed space group, choice of supercell size, and magnitude of O_2 overbinding (Wang et al. 2006) correction. Curnan et al. investigated the influence of these factors on the oxygen vacancy formation energies in $LaMnO_3$ and $SrMnO_3$. An overview of these results is shown in Table 4. These parameters influence the oxygen vacancy formation energies in various ways, which will be briefly discussed here.

The supercell size and shape dependency of E_{V_O} reflects the strength of defect-defect interactions. Within the examined range of supercell volumes (1–8 cubic unit cells), E_{V_O} scatters by about 0.5 eV for both $LaMnO_3$ and $SrMnO_3$, which is a large possible source of discrepancy when comparing different density functional theory (DFT) calculations with experiments but also when comparing different DFT studies with each other. It should also be kept in mind that $LaMnO_3$ has a rather low tolerance for oxygen vacancies. Pure $LaMnO_3$ decomposes already at a V_O concentration of about 5–10%, as inferred from TGA experiments, which corresponds to 1 vacancy in 3–7 unit cells. DFT calculations in smaller supercells do not reflect physical vacancy concentrations, thus overestimating the oxygen vacancy formation energy.

Structural distortions frequently occur in perovskites, reducing the symmetry from cubic to rhombohedral or orthorhombic. LSM is frequently modeled using cubic and orthorhombic space groups in DFT calculations, but their defect energetics are quite different. According to Curnan et al., the cubic structures usually show the lowest oxygen vacancy formation energies, regardless of A- and B-site cations. Introducing lattice distortions uniformly increases the oxygen vacancy formation energy, although the magnitude depends on the combination of A/B cations. For $LaMnO_3$, which is strongly distorted in the $R\bar{3}c$ and $Pbnm$ space groups due to the

Jahn-Teller distortion characteristic for Mn^{3+}, E_{V_O} is increased by up to 0.7 eV. In $SrMnO_3$, where no Jahn-Teller distortion occurs, the influence of lattice distortions on the oxygen vacancy formation energy is of a much smaller magnitude (up to 0.2 eV). It should be noted, however, that the cubic structure is not a minimum on the potential energy surface (PES) in some cases (such as LSM). Calculating vacancy formation energies for a structure that is not a minimum on the PES is not physically meaningful and should be avoided.

Magnetism plays a strong role in transition metal-based perovskite oxides, and the magnetic ground state often shows transitions within a series of compounds. Within the $La_{(1-x)}Sr_xMnO_3$ series, the ground state is ferromagnetic for $0.09 < x < 0.48$. For $x \leq 0.09$, a canted antiferromagnetic spin order is realized, and for $x \geq 0.48$ the ground state 0 K is antiferromagnetic (Tokura and Tomioka 1999). The magnetic state influences the redox properties of manganites. Neglecting magnetization or choosing an inappropriate magnetic state can cause errors of 0.5 eV–0.7 eV.

GGA+U can be employed to improve the computed properties of perovskite compounds by enhancing electron localization. U_{eff} is typically applied to the d-orbitals of transition metals. In the case of Mn compounds, the optimal choice of U_{eff} depends on the oxidation number (Lee and Morgan 2012). Values between 3 and 5 eV are typically found in the literature. The oxygen vacancy formation energy is not particularly sensitive to U_{eff}, as varying the parameter between 0 and 4.5 eV changes the oxygen vacancy formation energy only by up to 0.3 eV. However, U_{eff} should be chosen carefully, as some of the observed trends (such as relative stabilities of crystal structures) may change with U_{eff}.

The highest reported O_2 overbinding correction among the considered studies is 1.36 eV, so that over- or undercorrection of the O_2 energy constitutes a large possible influence (up to 0.7 eV) on the obtained oxygen vacancy formation energy.

These considerations allow us to put the inconsistencies between the theoretical results from the literature into better perspective and give a reference for the expected deviations between studies employing a slightly different computational framework.

2.2   Oxidizing Regime

A prominent feature of LSM at low Sr-doping content is oxygen superstoichiometry under oxidizing conditions (low temperature, high $p(O_2)$). The oxygen superstoichiometry is achieved not by oxygen interstitials but rather by cation vacancies following Eq. 2. The equilibrium constants for oxygen incorporation can be obtained by fitting a defect model to nonstoichiometry data obtained by TGA in the same principle fashion as previously outlined for oxygen vacancy formation. The cation vacancy formation energies are determined from the temperature dependency
Fig. 3 Overview of literature values for the cation vacancy formation energy. (The figure is compiled from data in references listed in Table 5)

of these equilibrium constants. A selection of experimentally determined cation vacancy formation energies is shown in Fig. 3.

However, this approach is quite error-prone for cation vacancies for several reasons. The range of temperatures and $p(O_2)$ where cation vacancies occur in LSM is rather limited, especially for higher Sr-doping contents. The experiments must be able to measure very small stoichiometry variations very accurately, which is not always the case. For large cation vacancy concentrations, however, computational results suggest that defect-defect interactions are quite strong (Lee and Morgan 2012), making defect models that do not consider such interactions less reliable. Strong defect-defect interactions also make the usually applied ideal configurational entropy a debatable point because the defect distribution is not random when interactions are strong. In addition, several different defects, as well as entropy, need to be considered simultaneously, which can give rise to parameter compensation. As a consequence, the experimentally determined cation vacancy formation energies scatter substantially between literature sources, as shown in Fig. 3.

Each individual set of data in Fig. 3 shows a clear trend of E_{V_M} with respect to the Sr-doping content, but some sets show a decrease of E_{V_M} with $x(Sr)$, while others show an increase. Intuitively, an increase of E_{V_M} with $x(Sr)$ is expected due to the equal charge of defect and dopant. The absolute deviation between the data sets can be as high as 5 eV.

Since most computational studies focus on oxygen vacancy formation with the goal of modeling the oxygen transport, investigations of cation vacancy formation are scarce in the literature. In the case of LSM (for $x(Sr) \leq 0.20$), however, cation vacancies are the dominant defect under typical fuel cell conditions (1300 K, $p(O_2) = 1$ bar), so they should be considered when modeling fuel cell materials.

Lee and Morgan examined cation vacancy formation with a DFT-based model, taking vacancy-vacancy interaction explicitly into consideration but neglecting the influence of Sr on the cation vacancy formation (Lee and Morgan 2012). They report $E_{V_M} = -4.07$ eV at zero concentration. To obtain the defect formation energy E_{def}, the interaction is added as a linear function of the V_M concentration c_{def}:

$$E_{def}\left(c_{def}\right) = E_{rxn} + I_{rxn}c_{def}, \tag{8}$$

where E_{rxn} is the zero-concentration defect formation energy and I_{rxn} is the interaction term. The cation vacancy-vacancy interaction is very high at 16.10 eV compared to the oxygen vacancy-vacancy interaction at 2.54 eV. This suggests that the cation vacancy formation is limited by vacancy-vacancy repulsion, rather than the availability of oxidizable Mn^{2+}/Mn^{3+} cations as implicitly assumed by the ideal mixing entropy approach applied in experimental studies when modeling nonstoichiometry data.

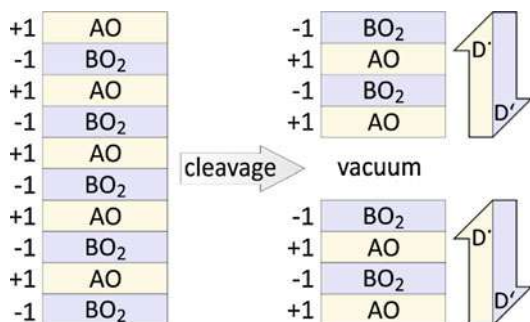
These results highlight that concentration-dependent defect formation energies should always be employed in computational studies in order to obtain reliable defect concentrations. However, at strong interactions, the use of the ideal mixing entropy is questionable due to correlations that arise in the distribution of defects. This can be overcome by using more accurate approaches, such as the quasichemical approximation or lattice-based Monte Carlo simulations.

3 Surfaces and Defect Segregation

Although the bulk properties of LSM are well-understood, thus allowing for systematic material optimization, the surface properties are not. The surface structure and composition change dynamically with temperature, oxygen partial pressure, and polarization. This often leads to significant deviations from the bulk properties in the boundary region close to the surface after annealing. Cation segregation as observed in aliovalently doped perovskites (such as $La_{1-x}Sr_xMO_3$ where M = Co, Mn, Fe) not only leads to the enrichment of dopant cations close to the surface (Druce et al. 2014) but also to the formation of Sr-enriched secondary phase precipitates at the surface that are non-conductive (electronically and ionically) (Chen et al. 2012) and severely impede the oxygen exchange on the surface, thus leading to degradation of the electrode (Wang and Jiang 2006; Jiang 2008). The fundamental understanding and tuning of the properties of the electrode-gas interface thus remains a major challenge.

3.1 Electronic Reconstruction at Polar Surfaces

LSM surfaces and interfaces suffer from the fundamental problem of surface polarity. The structure is comprised of AO and BO_2 layers stacked in [001] direction. In the host structure $LaMnO_3$, where the A and B cations both have a +3 charge, these AO and BO_2 layers have +1 and −1 net charge, respectively. Cleaving the structure as shown in Fig. 4 creates dipolar surfaces of Tasker type 3 (Tasker 1979) with diverging surface energy, which cannot be stable without undergoing significant charge rearrangement, defect segregation, or surface reconstruction. In materials like LSM, which can support a complex defect chemistry, the transition metal (TM) cation can change oxidation state, possibly reducing surface charge at a lower energy cost compared to ionic rearrangement. Such charge redistribution frequently occurs at polar surfaces of perovskite compounds, such as the $SrTiO_3(111)$ surface (Pojani et al. 1999), as well as at heterointerfaces of perovskite compounds with different charge types (Nakagawa et al. 2006). The MnO_2 termination of LSM undergoes a similar electronic reconstruction as discussed in the following.

Fig. 4 Cleavage of a 3–3 perovskite, e.g., $LaMnO_3$, forms two surfaces, terminated by AO and BO_2 layers. These terminations are polar, inducing segregation of defects with opposite charge to the surface and defects with equal charge into the bulk to reduce surface polarity


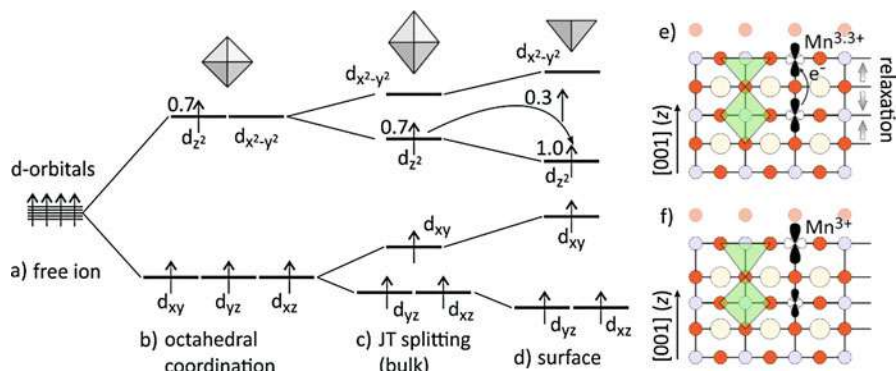


Fig. 5 Crystal field model of $Mn^{3.3+}$ in $La_{0.7}Sr_{0.3}MnO_3$. (**a**) Free Mn^{3+} ion, (**b**) crystal field splitting of $Mn^{3.3+}$ in octahedral coordination, (**c**) Jahn-Teller splitting as it occurs in bulk $La_{0.7}Sr_{0.3}MnO_3$, (**d**) approximation of undercoordinated Mn at the surface as a square-pyramidal complex. Since the $e_g\left(d_{z^2}\right)$ orbital energy is lowered compared to the underlying bulk-Mn, electron density is transferred from bulk to surface, reducing the surface-Mn to Mn^{3+} (Calderón et al. 1999; Zenia et al. 2005; Cui et al. 2014; Pesquera et al. 2012). (**e**) and (**f**) Surface and bulk coordination in LSM before (**e**) and after (**f**) relaxation of electronic and ionic structure (blue, Mn; yellow, La/Sr; red, O)

To understand the electronic reconstruction that occurs at the MnO_2 termination of LSM (Calderón et al. 1999; Zenia et al. 2005; Cui et al. 2014; Pesquera et al. 2012), consider first the electronic configuration of Mn in bulk LSM (Fig. 5b). For a Sr-doping level of 30%, LSM is ferromagnetic and semimetallic. The average oxidation number of Mn is +3.3. $Mn^{+3.3}$ is octahedrally coordinated, which splits the d-orbitals into t_{2g} (d_{xy}, d_{xz}, d_{yz}) and e_g ($d_{x^2-y^2}, d_{z^2}$) levels (Fig. 5b). In this high-spin $d^{3.7}$ configuration, Jahn-Teller splitting occurs in the bulk, which splits the t_{2g} and e_g levels (Fig. 5c). The energies of the antibonding d_{z^2} and $d_{x^2-y^2}$ levels are reduced and increased, respectively, which causes elongation of the bonds along the z direction (Jahn-Teller elongation).

At the surface, one O^{2-} is missing, so that the surface-$Mn^{3.3+}$ is approximately in a square-pyramidal coordination (Fig. 5c). This reduces the energy of the d_{z^2} orbital even further (Calderón et al. 1999). This reduction of the energy level allows the surface-Mn to accept 0.3 electrons from the subsurface layer, reducing the surface-Mn to Mn^{3+} while retaining the high-spin configuration. The subsurface-Mn is oxidized to $Mn^{3.6+}$, shortening its Mn-O bonds along the z direction upon subsequent ionic relaxation (Fig. 5e, f).

3.2   Segregation of Charged Defects

Since the surface-Mn is reduced to +3, the surface polarity persists despite this electronic reconstruction, which can attract or repel defects with opposing or equal charge, respectively. Similar considerations apply for other polar terminations, such as the pure LaO, mixed (La,Sr)O, and SrO terminations. These polar surface

terminations have been proposed to play an important role in dopant segregation and subsequent degradation of oxygen exchange activity through the formation of insulating areas on the electrode or precipitation of secondary phases.

Various computational studies have addressed defect segregation at (001) surfaces of perovskites, considering electrostatic and elastic driving forces for dopant segregation. The general conclusion drawn from these studies is that electrostatic contributions play the strongest role in defect segregation at polar surfaces (Harrison 2011; Lee and Morgan 2015; Lee et al. 2013). In a purely electrostatic picture, negatively charged defects (V_A''', V_B''', Sr_A', Mn_B') are drawn to the positively charged LaO termination in LSM, and positively charged defects $\left(V_o^{\cdot\cdot}, Mn_B^{\cdot}\right)$ are drawn to the negatively charged MnO_2 termination. Mn_B' and $Mn_B^{\cdot}$ represent Mn in 2+ and 4+ charge state, respectively. The previously discussed electronic reconstruction of the MnO_2 termination may be considered as such a segregation of electronic defects.

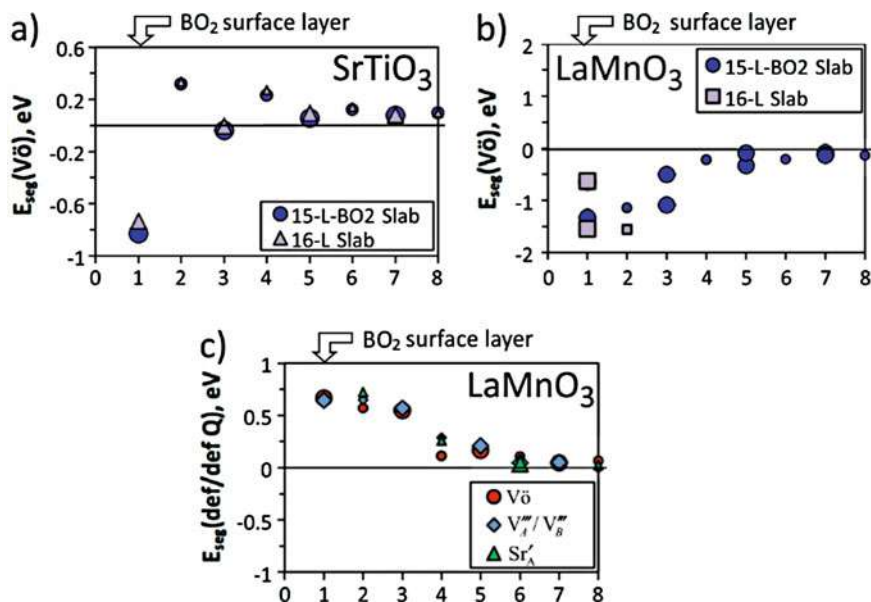
The electrostatic interaction is the dominant term in segregation at polar surfaces, as can be rationalized by comparing the oxygen vacancy segregation at nonpolar $SrTiO_3(001)$ surfaces with the polar $LaMnO_3(001)$ surfaces. The $V_o^{\cdot\cdot}$ segregation profiles at the BO_2 surfaces of $SrTiO_3(001)$ and $LaMnO_3(001)$ are reproduced in Fig. 6a and b from Lee and Morgan (2015). In the absence of a clear segregation trend, the profile for $SrTiO_3$ (a) shows a zigzag shape. The $V_o^{\cdot\cdot}$ segregation energy at $SrTiO_3(001)$ is strongly negative only for the termination layer. For deeper layers, the segregation energy is either close to 0 (for BO_2 layers) or slightly positive (for AO layers). The negative $V_o^{\cdot\cdot}$ segregation energy at the topmost BO_2 surface layers


Fig. 6 Defect segregation energies of $V_o^{\cdot\cdot}$ at BO_2 surfaces of (**a**) $SrTiO_3$ and (**b**) $LaMnO_3$. (**c**) Defect segregation energies normalized by charge. (Figure adapted from Lee and Morgan 2015)

indicates the additional degrees of freedom at the surface, which allow the lattice to relax and accommodate the vacancy more easily compared to the bulk. In the AO bulk layers, removing one O^{2-} constitutes a larger perturbation compared to the BO_2 layers, thus reflecting finite-size effects of the slab calculations, which are most likely artificial (Lee and Morgan 2015).

The BO_2 surface of $LaMnO_3$ has a negative polarity, thus attracting positively charged defects like $V_o^{\cdot\cdot}$. As a consequence, the $V_o^{\cdot\cdot}$ segregation profile at $LaMnO_3$ in Fig. 6b) shows a clear trend of increasingly negative segregation as the $V_o^{\cdot\cdot}$ is moved closer to the surface.

Similar trends are observed also for other defects at the BO_2 surface of $LaMnO_3(001)$. Normalizing the defect segregation energy by the formal defect charge Q reveals a unique profile for $V_o^{\cdot\cdot}$, $V_{A/B}'''$ and Sr_{La}', as shown in Fig. 6. This is indirect evidence that the defect segregation is mostly governed by the electrostatic interaction between the polar surface and the defect charge. This electrostatic interaction, however, can be enhanced or counterbalanced by the coexistence of other point defects of opposing or equal charge close to the surface (Lee et al. 2013), and the trend of the classic electrostatic energy for coexisting point defects

$$E_{elec} = \sum -\frac{Q_1 Q_2}{4 \pi \varepsilon R_{12}} \tag{9}$$

was found to correlate perfectly with the trends obtained by DFT calculations in $LaMnO_3$ and $SmMnO_3$ (Lee et al. 2013), with Q_1 and Q_1 indicating the charges of defect and surface, ε the dielectric constant, and R_{12} the distance between defect and surface. More recently, experimental tuning of the oxygen vacancy concentration at the surface was shown to correlate with enhancement in chemical stability and electrochemical activity on Sr-substituted $LaCoO_3$ (Tsvetkov et al. 2016). However, which defects coexist at the surface in stable configurations at a given set of chemical potentials and whether or how these defects are responsible for the precipitation of secondary phases are still a matter of debate.

The elastic contribution to the segregation energy is more straightforward and has been investigated computationally for different combinations of A^{2+}- (Lee and Morgan 2015; Kwon et al. 2016) and B- (Kwon et al. 2016) site cations, as well as strain (Han et al. 2011). The change in free volume ΔV_f upon doping was found as a suitable predictor for cation segregation (Kwon et al. 2016), revealing a linear relationship between ΔV_f and segregation energy. The free volume quantifies the exclusion volume of the unit cell after subtracting the ions, modeled as hard spheres with defined radii, and is expressed as

$$\Delta V_f = \left(a_{doped}^3 - a_{host}^3\right) - \frac{4}{3}\pi \left(r_{dopant}^3 - r_{host}^3\right), \tag{10}$$

where a_{doped}^3 and a_{host}^3 are the unit cell volumes of doped and host structure and r_{dopant} and r_{host} are the ionic radii of dopant and host cations, respectively.

3.3   Stable Surface Terminations of Perovskite Oxides

A perovskite lattice can be cleaved in various low-index miller planes with different concentration of A-site and B-site cations within the surface layer. Thus, the surface catalytic activity would depend on the particular plane and the exposure of A-sites and B-sites. Theoretical studies on $SrTiO_3$ have shown that AO-terminated (001) surfaces and BO_2-terminated (001) surfaces are characterized with identical surface energy and both should be observed experimentally. Oxygen reduction reactions were studied computationally on La_2NiO_4 La-/Ni-terminated surfaces, concluding that Ni ions exposed to the surface are beneficial for the catalytic activity (Zhou et al. 2013). These theoretical results, however, have been contradicted by the vast majority of experimental observations which reported that under SOFC operational conditions, the surfaces of Sr-containing perovskites show significant Sr segregation (Lee et al. 2015 Phys. Rev B; Lee et al. 2015 PCCP). Scanning tunneling microscopy studies have shown that as a result SrO surface layers and Sr-rich nanoparticles have been formed (Chen Energy Environ. Sci. 2012). As layered materials, perovskites are well-suited to be studied with the LEIS technique (Druce Energy Environ. Sci. 2014). Unlike other characterization techniques, i.e., X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), etc., LEIS offers direct measurement of the chemical composition of the outermost surface layer and also offers the facility to obtain layer-by-layer depth profile of the outermost 20 nm of the material. Thus, the technique is sensitive enough to provide accurate information of the chemical composition of the surface termination and reconstruction of perovskite materials.

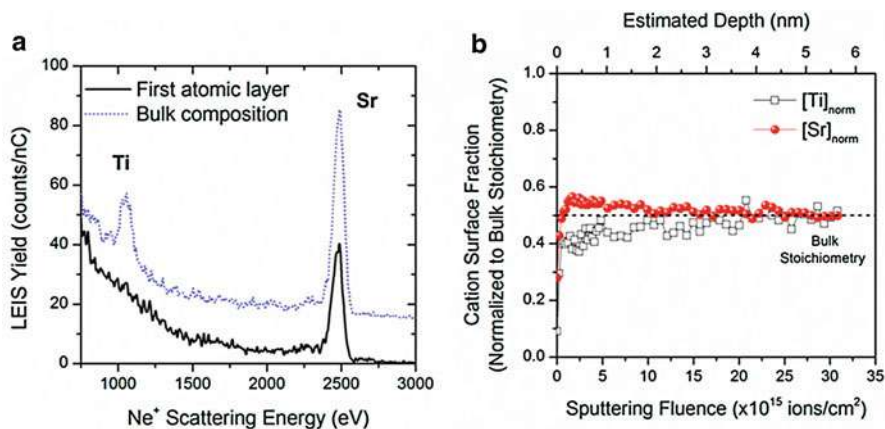
LEIS analysis of various functional perovskites used as electrodes in SOFCs at elevated temperatures has shown that all those materials are characterized by AO surface termination (Druce Energy Environ. Sci. 2014). Among the oxides investigated were $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ (LSCF113, single perovskite), $GdBaCo_2O_{5+\delta}$ (GBCO-1125, double perovskite), and $La_2NiO_{4+\delta}$ (LNO-214, Ruddlesden-Popper structure). All those compounds are industrially relevant materials for application in solid oxide devices. In addition, single crystal $SrTiO_3$ was investigated as a model perovskite material. High-sensitivity LEIS depth profiling was performed to characterize the surface and near-surface composition of polycrystalline ceramics representative of the most promising perovskite-based mixed ionic and electronic conducting materials for fuel cell applications. The LEIS measurements are performed after grinding and polishing of the ceramic materials to produce fresh surfaces. The samples were subjected to high-temperature annealing treatments of 1000 °C for 12 h to simulate operating conditions of solid oxide electrodes. In all cases, the AO surface termination was observed. The experimentally observed surface terminations contradict the assumptions often made in computational modeling studies of the surface structure and oxygen exchange reaction. In the vast majority of computational modeling papers, the surfaces are assumed to be either a mixed AO- and BO_2-terminated or a BO_2-dominated surface to facilitate electron transfer to reduce molecular O_2 (Zhou et al. 2013; Eglitis 2009; Cai et al. 2006; Eglitis 2015).


Fig. 7 Sequential LEIS spectra showing the evolution of the spectra with 500 eV Ar sputtering. The sample is a single crystal of $SrTiO_3$ after treatment at 1000 °C for 2 h in high purity oxygen. (Figure adapted from Staykov et al. 2015)

The investigated samples reveal through depth profile analysis that the very outermost surface is enriched in the A cation. Light sputtering reveals the B cations, which grow in intensity to show a second region which is slightly enriched in these species compared to the bulk stoichiometry. Finally, after sufficient sputtering, the bulk composition is reached, showing a plateau in the cation surface coverage, which was assumed to correspond to the bulk stoichiometry. An example set of spectra are shown in Fig. 7 for an $SrTiO_3$ sample heat-treated in oxygen (Staykov et al. 2015). The outermost layer shows an absence of the peak for the Ti cations, while the subsurface layers are Ti cations enriched. The bulk stoichiometry is observed after depths of 1–2 nm beneath the surface have been reached.

In addition to the information from surface analysis techniques, first-principles studies have shown AO-terminated surface reconstructions for polar perovskite surfaces, in particular $KTaO_3$ (Deacon-Smith et al. 2014; Setvin et al. 2018). The reason behind is that interlayer cation exchange stabilizes the polar perovskite surfaces. The Tasker theory for surface termination of ionic materials distinguishes between three possible surface types (Tasker 1979). Type one is characterized with planes containing positive and negative ions that completely compensate each other, and as a result, the individual planes are neutral. Type two is the result of alternation of one plane with either positive or negative charge followed by two planes characterized with half countercharge. Those surfaces should be cleaved in unit cells in order to avoid surface polarization. Type three surfaces are characterized with alternation of positively and negatively charged planes. As a result, a strong surface dipole moment arises which in reality is avoided by surface reconstruction, and if not compensated, it might lead to strong artificial effects in theoretical simulations. Woodley and co-authors have shown that cation exchange between the surface and subsurface layers of polar perovskites leading to AO surface termination and B-enriched sub-

surface region effectively eliminates the surface dipole momentum and is the natural mechanism to deal with surface polarity of ABO_3 perovskites (Deacon-Smith et al. 2014). The driving force for the cation exchange was the different electronic properties of the A- and B-site cations. A-site cations possess large ionic radii with usual charge of $+1$ or $+2$. In contrast B-site cations are characterized with small ionic radius and strongly localized point charge between $+3$ and $+5$. As a result, they build an octahedral symmetry coordination sphere with oxide ions which compensates the charge localization. When exposed to the surface, the B-site coordination sphere is broken, and surface-localized point charges give rise to dipole moments and high surface energies. By B-site/A-site cation exchange, the surface energy is minimized, the oxide coordination spheres of the B-site cations are restored, and the formation of a surface dipole is avoided (Deacon-Smith et al. 2014).

4 O_2 Activation on Perovskite Surfaces

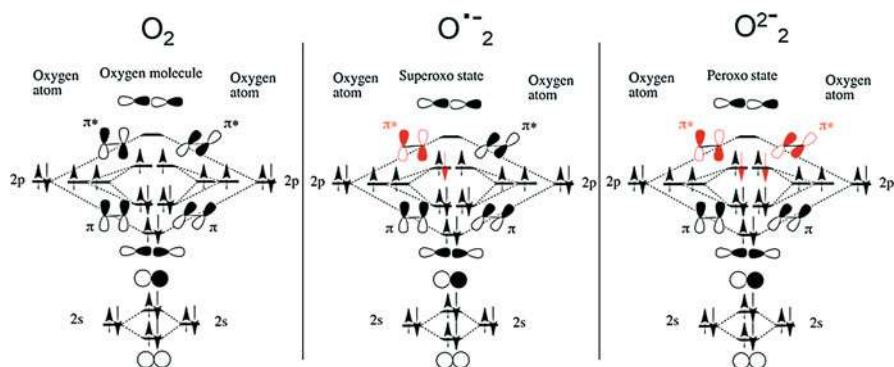
In the gas phase, the oxygen molecule is stable in its triplet ground state with two unpaired electrons occupying degenerate π-molecular orbitals with an orthogonal spatial distribution. Any dissociation of the oxygen molecule progresses through its activated states, i.e., singlet oxygen, superoxo state (O_2^-), or peroxo state (O_2^{2-}). The electron configurations of the oxygen molecule, the superoxo state, and the peroxo state are shown in Fig. 8. The oxygen activation requires significant interaction between the molecule and the catalytic surface and possible electron transfer. The activated states of the oxygen molecule are characterized by different spins and bond lengths. The superoxo state has radical character and O−O bond of 1.3–1.4 Å, while the peroxo state is singlet and is characterized with an O−O


Fig. 8 Molecular orbital diagrams of dioxygen molecule (left), superoxo state of oxygen (center), and peroxo state of oxygen (right). The molecular orbitals are constructed by the atomic orbitals of two isolated oxygen atoms. The orbitals in black are those of the dioxygen molecule. A red color denotes the additional electrons transferred from the surface to the molecule (in order to obtain superoxo and peroxo states), as well as the molecular orbitals, which receive those additional electrons

bond length of 1.4–1.6 Å. These can be distinguished computationally, as well as experimentally, using electron paramagnetic resonance (EPR) and infrared (IR) spectroscopy. The superoxo state is characterized with high catalytic activity toward the oxidation reaction due to its radical character, while the peroxo state is known as a mild oxidant. Both the superoxo and the peroxo states are precursors for the molecular oxygen dissociation reaction.

4.1   Oxygen Activation on the SrO-Terminated $SrTi_xFe_{1-x}O_{3-\delta}$ Surface

Dissociation of molecular oxygen starts with adsorption on the substrate. Two orientations of the oxygen molecule are possible: end-on, with a single oxygen atom facing the substrate (perpendicular to the surface); and side-on, with two oxygen atoms facing the substrate (parallel to the surface) (Akbay et al. 2016; Staykov et al. 2015, 2008). The adsorption geometry is important for the further reaction mechanism and activation barrier for oxygen dissociation. Often, end-on adsorption geometry is realized in homogeneous organometallic and enzymatic catalysis, while side-on adsorption is preferred in the heterogeneous surface catalysis. While in the end-on adsorption geometry the oxygen molecule is attached only to one center and the substrate geometry has only minor effect on the dissociation mechanism, in the side-on adsorption, the two oxygen atoms are linked to different centers from the substrate and the substrate geometry, i.e., bond lengths, lattice constants, etc. can be of major importance.

As shown in Sect. 3.3, the surfaces of relevant perovskite materials are AO-terminated under typical SOFC conditions. Thus, it is important to address the question of the surface reactivity and catalytic properties of AO-terminated perovskite surfaces. For this purpose, the mechanisms for oxygen reduction reactions on a model material such as $SrTiO_3$ and industrially relevant material La_2NiO_4 will be reviewed. The simulations were performed with periodic plane wave density functional theory (DFT) implemented in the Vienna ab initio simulation package (VASP). The Perdew−Burke−Ernzerhof exchange-correlation functional (PBE) was employed using projector augmented wave pseudopotentials (Kresse and Hafner 1993; Kresse and Furthmüller 1996a, b; Blöchl 1994). DFT+U was used when necessary to localize electrons at the d-orbitals of transition metals. The details of those simulations are provided in the original research articles (Akbay et al. 2016; Staykov et al. 2015).

Oxygen reduction on an SrO-terminated $SrTiO_3$ surface was estimated to be an energetically unfavorable endothermic process. The reason is in the strong ionicity of Sr^{2+} and O^{2-}. Those surface ionic species do not participate in electron exchange with the molecular oxygen. However, perovskite materials are characterized with a moderate concentration of oxygen vacancies, and the simulation results summarized in Fig. 9 show that oxygen vacancies are slightly stabilized within the surface layer by 0.15 eV (Staykov et al. 2015).

Fig. 9 Subsurface to surface migration mechanism of an oxygen vacancy in $SrTiO_3$. (Figure adapted from Staykov et al. 2015)
Fig. 10 Geometry of two neighboring Ti-octahedra in the subsurface layer of $SrTiO_3$, corresponding to the vacancy free case, the single oxygen vacancy case, and two neighboring oxygen vacancies. For simplicity, the Sr-ions are omitted in this representation. All distances are in Å. (The figure is compiled from data in Staykov et al. 2015)

The surface oxygen vacancy removes the apical oxygen in the terminating BO_6 octahedron and exposes the electronic density at a B-site cation center. This is important because it allows the surface adsorbed oxygen species to gain access to the partially delocalized electrons in the conducting –B–O–B– backbone network of the perovskites. Oxygen ion migration between the subsurface and the surface layers is characterized with an activation barrier of 0.44 eV. Interestingly, oxygen ion migration on the surface is characterized with a significantly higher activation barrier of 0.98 eV. The reason behind the higher activation energy necessary to transport vacancies on the surface compared to the bulk is that on the surface the Ti–O bond should be completely cleaved, while through the bulk the oxide ion shifts between different sites of the Ti coordination sphere, where one Ti–O bond is cleaved while another Ti-O bond is formed. Thus, the migrating oxide ion always shares electron density with Ti. Another important property of surface oxygen vacancies is that the energy is significantly decreased as vacancies occupy neighboring sites due to relaxation of the electron density due to decrease of the Ti–O–Ti angles close to the vacancy sites.

In Fig. 10, the Ti-O-Ti angle for vacancy free surface equals 168°. In the case of a single oxygen vacancy, the Ti ion is attracted away from the surface by the apical oxide ion below it, and the angle now equals to 156°. For two oxygen vacancies, both Ti ions are attracted below the surface resulting in an angle of 136° (Staykov et al. 2015). It is worth noting that the oxygen atom is in sp^3 hybridization with an optimal relaxed electron density when the four orbitals are pointing toward the apices of a tetrahedron. Two of those hybrid orbitals are occupied by electron pairs, and the other two give rise to the valence bonds of oxygen. Thus, the preferred
Fig. 11 Dissociation mechanism of oxygen molecule over a pair of surface oxygen vacancies on the SrO-terminated surface of SrTiO₃. (Figure adapted from Staykov et al. 2015)

oxygen valence bond geometry is V-shaped. The electron density around the oxygen atom is strongly strained in the perovskite lattice and is relaxed by coupling vacancies on the perovskite surface.

Having established the important electronic nature of the surface oxygen vacancy, it is now important to understand how this will interact with a gas-phase oxygen molecule. In contrast to the perfect surface, the oxygen molecule from the gas phase readily interacts with the surface oxygen vacancy. As a result, electron density is transferred from the B-O-B-O network, through the d_z^2 atomic orbital of the Ti, to the antibonding π^* orbital of the oxygen molecule (Staykov et al. 2018). As a result, the oxygen-oxygen bond is elongated to 1.5 Å, and oxygen is activated to its peroxo state. From the peroxo state, the oxygen molecule is dissociated as one oxygen atom occupies the lattice vacancy site and the second oxygen atom passes over a Sr-Sr bridge and occupies a nearby oxygen vacancy. The activation barrier for the oxygen dissociation is 0.5 eV, and the reaction is exothermic with 2.38 eV (Staykov et al. 2015). The dissociation mechanism is summarized in Fig. 11. In the case that a second surface vacancy is not available in the vicinity which can be occupied by the second oxygen atom, the surface oxygen exchange reaction can still occur, and a cross molecule can be formed between an oxygen atom from the gas phase and an oxygen from the surface.

From these results on the model system SrTiO₃, it is possible to infer that the same oxygen incorporation mechanism will be active in other perovskite materials, specifically those where bulk oxygen transport has been enhanced by the substitution on the A-site by Sr. Such materials can display very high values of the surface exchange coefficient (k) and have found extensive use as air electrodes and include the mixed ionic electronic conductors $La_{1-x}Sr_xCoO_{3-\delta}$, $La_{1-x}Sr_xMnO_{3-\delta}$, and $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$. As mentioned in Sect. 3.3, at the working temperature of these devices, the surfaces will be terminated by SrO; however, most of the materials will also have a substantial population of oxygen vacancies. Similar to SrTiO₃, the surface vacancies will provide access for the gas-phase oxygen molecules to the electronically conducting B-O-B network and hence the electron transfer needed for dissociation.

In a recent work on Sr-doped LaCoO₃, experimental evidence has been provided for the effect of surface oxygen vacancies and the exposure of the B-site of the

perovskite lattice for the activity of oxygen reduction reaction using real-time impedance spectroscopy (Rupp et al. 2017). They have successfully estimated that on SrO-terminated surface, oxygen reduction occurs at selected spots corresponding to surface oxygen vacancies and exposed Co ions. With an increase of both temperature and observation time, the surface was completely covered by Sr segregation leading to inert, inactive surface composition. As Co (Co_3O_4) was deposited to the surface, the catalytic activity was restored. The experiment of Rupp et al. clearly demonstrates that on the SrO-terminated perovskite surface, molecular oxygen dissociation occurs only on exposed B-site cations (Rupp et al. 2017). Thus, surface oxygen vacancies are crucial for the oxygen exchange reaction in such substituted perovskite materials.

4.2   Oxygen Activation on the LaO-Terminated La$_2$NiO$_{4+\delta}$ Surface

The oxygen vacancy facilitated oxygen dissociation mechanism on the SrO-terminated surface of $SrTiO_3$ leaves open the question about the large surface exchange coefficients observed on the LaO-terminated surface of $La_2NiO_{4+\delta}$ (Burriel et al. 2008; Tarancon et al. 2007; Skinner and Kilner 2000). $La_2NiO_{4+\delta}$ is a layered perovskite related to Ruddlesden-Popper oxide which has been observed to show the same AO termination as the simple perovskites after high-temperature exposure to O_2. The material is not Sr-substituted and is usually prepared as an oxygen-rich material where the oxygen excess is accommodated by oxygen interstitials. This high density of oxygen interstitials has the effect of suppressing the oxygen vacancy concentration through the Frenkel equilibrium, and thus the oxygen vacancy concentration is vanishingly small. In order to investigate this apparent contradiction in the earlier findings of the importance of the surface oxygen vacancy, a theoretical study of molecular oxygen dissociation on an LaO-terminated La_2NiO_4 surface was performed by Akbay et al. (2016). The simulation results show that unlike the AO termination in $SrTiO_3$, on the LaO surface, molecular oxygen can be dissociated without the support of surface oxygen vacancies. The dissociation mechanism is summarized in Fig. 12.

The oxygen molecule is chemisorbed over a La-La bridge on the LaO surface. Such an adsorption geometry was not observed on the SrO-terminated $SrTiO_3$. The La-O-O-La bridge geometry resembles the molecular oxygen adsorption on noble metals such as Pd (Staykov et al. 2008). In this geometry, the oxygen molecule is activated to the superoxo state upon electron transfer from the LaO surface to the antibonding π^* orbital of the oxygen molecule. The oxygen-oxygen bond is elongated to 1.33 Å. The chemisorption state is stabilized by 0.59 eV. The oxygen molecule is dissociated with an activation barrier of 1.1 eV, and the two surface oxygen species take the position of an La-O-La surface bridge. The charge on the surface oxygen species is -1. The overall reaction is slightly exothermic by 0.03 eV at 0 K. Under SOFC operating conditions, this process will proceed at an elevated temperature, and as a result, the activation barrier of 1.1 eV is feasible. In order to understand better the difference of the catalytic activity between the SrO and LaO
Fig. 12 Dissociation mechanism and electron density differences of oxygen molecule over the LaO-terminated surface of La_2NiO_4. (Figure adapted from Akbay et al. 2016)

surfaces, the electronic properties of La and Sr will be investigated. Bader charge analysis shows that Sr charge is close to $+2$ verifying that Sr is mostly fully ionized. However, the La charge was estimated to be also close to $+2$, which differs from its formal charge of $+3$. The reason for the deviation of the La charge from its formal charge is a partially covalent interaction between the d-levels of La and the p-levels of O. Such interaction is responsible for shared delocalized electron density between the A-sublattice and B-sublattice. As a result, the surface La is characterized with electronic density perpendicular to the surface plane (i.e., electron density similar to dangling bonds at the cleaved La-O bonds). Such electron density available on an LaO surface is responsible for the strong adsorption energy of the oxygen molecule and also stabilizes the oxo species after the dissociation of the molecular oxygen as it is summarized in Fig. 12.

The theoretical results described in Akbay et al. (2016), Staykov et al. (2015)) conclude that there is a fundamental difference in the oxygen reduction reaction mechanism on the SrO- and LaO-terminated perovskite surfaces. The reason behind this lies in the differences in electronic structure of Sr and La and, more generally, in the different electronic structure of earth alkaline elements and the lanthanoid series elements. While Sr, and in general all earth alkaline elements, contains two s elections in their valence shell which are easily ionized, La and most of the lanthanoids contain in addition d and f electrons whose ionization energy is rather different from that of s electrons. As a result, a significant deviation from the La formal charge in La_2NiO_4 was observed due to the partial covalent interaction between La and O. On the surface, it results in occupied d-levels of La which can interact with gas-phase molecular oxygen and lead to its dissociation. The lack of occupied d-levels in the valence shell of Sr leads to the inert properties of SrO toward molecular oxygen dissociation. Thus, surface oxygen vacancies in the $SrTiO_3$ lattice have been found essential for the oxygen dissociation. The dissociation mechanism includes electron transfer from the d-levels of Ti to the

oxygen antibonding π* orbital and the consequential cleavage of the oxygen-oxygen bond. A very similar mechanism is inferred for the common mixed ionic electronic conductors used extensively in high-temperature electrochemical devices. The alkaline earth dopants will provide a segregated outer surface layer which will be inert to the gas-phase molecules. The presence of surface oxygen vacancies will provide the catalytically active sites for the oxygen reduction reaction.

5   Summary

Perovskite materials have wide range of application as catalysts and electrocatalysts in energy conversion devices. Their flexibility is owing to the large number of compositions that can be synthesized, which allows for tuning the material's electronic, ionic, and catalytic properties to the desired applications.

The bulk properties, such as oxygen diffusivity, band gap, redox stability, and electronic conductivity, are governed by the bulk defect chemistry. Transition metal perovskites, such as $La_{1-x}Sr_xMnO_3$ (LSM) or $La_{(1-x)}Sr_xCoO_3$ (LSC), can often support a rich bulk defect chemistry with electronic and ionic defects. The dominant defect depends on $p(O_2)$ at a given temperature, and five defect regimes can be identified for perovskite oxides. For ionic defects, two major regimes can be distinguished: (1) the reducing regime, where oxygen vacancies dominate, and (2) the oxidizing regime, where incorporation of additional oxygen leads to the formation of metal vacancies.

The formation of oxygen vacancies is desirable for transport of oxygen through the bulk, as required by SOFC cathodes. The oxygen vacancy formation energy appears to be a good predictor for oxygen ion conductivity. While experimental methods to approximate the oxygen vacancy formation energy (such as tracer diffusion or thermogravimetric analysis) have been applied to SOFC materials for decades, computational methods are not yet routinely applied. For our example material, LSM, large scatter is present in the computational literature, and such large variability suggests limited reliability of computational studies in predicting the oxygen vacancy formation energy in this material. The observed scatter can be partially resolved by the choice of supercell size, crystallographic space group, magnetization, the Hubbard U parameter, as well as the magnitude of correction to the total energy of the O_2 molecule.

Only few perovskite materials exhibit the formation of cation vacancies under practical temperatures and $p(O_2)$. In LSM, however, cation vacancies occur in measurable concentrations under SOFC operating conditions, so that they need to be considered in reliable computational models of the SOFC cathode. Due to the uncertainty in fitting defect models to experimental TGA data, significant scatter between different literature sources can be observed. This can be rationalized by density functional theory, which suggests very strong interactions between close-by cation vacancies. As a consequence, the defect distribution cannot be assumed as random, so that the approximation of ideal mixtures usually applied when analyzing

the experimental data breaks down. Thus, more exact approaches, such as Monte Carlo simulations or the quasichemical approximation, are called for to treat cation vacancies in perovskite oxides.

The surfaces play a major role for many catalytic applications of perovskite oxides. However, the surface structure and composition adapt dynamically to the external conditions, which often leads to significant deviations from the bulk properties in the boundary regions. One major problem that arises in 3–3 perovskites like LSM and LSC is surface polarity. Dipolar surfaces are unstable due to diverging surface energy, so that electronic and ionic reconstructions frequently occur at such interfaces. For example, electronic charge can be transferred from the LSM subsurface to the surface in LSM, and defects of opposing charge segregate to the surface to compensate the surface dipole moment.

An extreme case of surface reconstruction is observed at the (001) surface of perovskite oxides. These surfaces are experimentally observed to be terminated exclusively by AO or, more specifically, by SrO in Sr-doped materials. This cation exchange between surface and subsurface essentially eliminates the surface dipole, thus improving surface stability. Also, the B-cation is more strongly destabilized by removal of oxide ions due to its highly localized point charge. The AO termination thus restores the favorable BO_6 coordination.

The dissociation of O_2 is an important step in many electrochemical and thermochemical reactions. For example, in SOFC cathodes, O_2 needs to be split and reduced in order to be incorporated into the perovskite surface. The electronic states of O_2 are distinguished in the dissociation of O_2: the neutral triplet O_2, which has diradical character, superoxide O_2^-, and peroxide O_2^{2-}. O_2 can adsorb terminally or side-on, resulting in either one or two metal-O bonds being formed upon adsorption. O_2 adsorption is considered at the AO and the BO_2 termination of perovskite oxides.

The AO termination is the stable termination of most perovskite oxides under typical SOFC conditions, so that O_2 dissociation at this surface is the main pathway for oxygen splitting and reduction at SOFC cathodes. The dissociation of O_2 on the SrO surface of $SrTiO_3$ was shown to strongly depend on the presence of double oxygen vacancies near the surface. Their role is twofold. At a surface oxygen vacancy, the underlying Ti is exposed, which gives the O_2 molecule access to the d_{z^2} orbital of Ti, which transfers electron density to the antibonding π^* orbital of O_2, thus weakening its internal bond and inducing dissociation. The second role is in incorporating the dissociated oxygen into the surface, thus completing the O_2 reduction.

In comparison to the SrO termination on $SrTiO_3$, where O_2 dissociation occurs only at oxygen vacancies, the LaO termination of Sr-free materials displays a much higher activity in O_2 reduction, as exemplified on $La_2NiO_{4+\delta}$, despite very low oxygen vacancy concentration. Computational results show that the La centers at the LaO termination are able to adsorb and split oxygen without exposed transition metal cations. This is possible because La has occupied d and f electrons, which facilitates the interaction of La with molecular O_2 and allows for O-O bond cleavage.

Surface Catalysis

A Decade of Computational Surface Catalysis

53

Karsten Reuter and Horia Metiu

Contents

Abstract

We briefly survey recent developments in surface catalysis modeling. The differentiated view on required level of accuracy established in the wake of multi-scale modeling approaches led to the emergence of high-throughput computational screening approaches. The large amounts of data created this way are now increasingly mined with machine learning techniques. We discuss status and challenges in this exciting mix of methodologies that describe catalytic systems from the electrons to the reactor. Next to the traditional focus on understanding and predicting catalytic activity, we argue that approaches to dynamical catalyst restructuring, to concomitant heat management, and to catalyst lifetime are important themes for the decade to come.

1   Introduction

When the first edition of the *Handbook of Materials Modeling* appeared in 2005 (Yip 2005), many chapters featured surface catalysis as an important application area. However, compared to the situation we have reached now, a bit over a decade later, this research was much more disjunct, focused on individual methods at their corresponding length and time scales. Multi-scale modeling was in its early days but then took off to become a lead theme in catalysis modeling. In bottom-up approaches, electronic structure theorists tried to extend the predictive-quality power of first-principles techniques to longer length and time scales, advancing ab initio thermodynamics and microkinetic models to capture effects of the reactive environment or ensemble effects arising in the interplay of elementary processes in the catalytic cycle. In top-down approaches, chemical engineers aimed at introducing a more detailed chemistry into traditional continuum descriptions of the macroscopic heat and mass transport in reactor models. Today, the gap between both types of approaches is still not closed, but it has narrowed substantially, forging an interdisciplinary community that is used to tackle the multi-physics challenges of surface catalysis with multi-method approaches.

Perhaps the most important implication of this new paradigm was a more differentiated view on accuracy and required level of detail. For a long time, consistent chemical accuracy had been seen as a prerequisite for predictive quality in first-principles calculations. More coarse-grained models were instead frequently motivated by the perception that microscopic details (and concomitant errors in their description) would in some way average out. Increasingly established sensitivity analyses in multi-scale modeling approaches scrutinized these views and revealed that it is in fact often a few microscopic parameters that critically control targeted macroscopic functionalities like activity or selectivities (Campbell 2017; Döpking et al. 2018; Medford et al. 2014; Meskine et al. 2009; Sutton et al. 2016). This laid the foundation for high-throughput computational screening approaches that focus on these microscopic parameters (then called descriptors), compute them for a wide range of materials, and thereby allow to search vast materials spaces for promising catalysts (Andersen et al. 2016, 2017a; Andersson et al. 2006; Besenbacher et al. 1998; Greeley and Mavrikakis 2004; Greeley et al. 2006; Linic et al. 2004; Loffreda et al. 2009; 2014; Toulhoat and Raybaud 2003). The large amounts of data created this way are now increasingly mined with machine learning techniques. This provides further insight into correlations between materials properties and (catalytic) function and carries the predictive first-principles power over to the in silico design of improved systems (Jinnouchi and Asahi 2017; Li et al. 2017; Ma et al. 2015; Ulissi et al. 2017a, b).

The emerging methodological triangle of detailed multi-scale modeling, high-throughput screening, and data sciences converts contemporary computational catalysis research into a powerhouse of possibilities and exciting developments. Many of these are driven by the urgent need to switch to alternative energy sources and establish their conversion through sustainable energy technologies. Among others, this has led to a strong boost in electrocatalysis modeling. Tackling the challenges

connected with the electrified solid-liquid interface will likely continue to be a major theme for the next decade. Another such theme will be the complexity gap between structural models presently feasible with atomistic approaches and real high-surface area catalysts in complex reactor geometries, connected with a description of catalyst degradation. In the following we will briefly survey some of these developments and challenges that are then discussed in more detail in the following chapters in this section. What will already become clear from this short overview is that the next decade of catalysis modeling will be at least as fast paced as was the past. In this respect, it is tantalizing to imagine what could be the content of the surface catalysis section in a future third edition of the *Handbook of Materials Modeling*.

2   Methods in Surface Catalysis Modeling

With its inherent focus on support through computational spectroscopy and a description of the reactive surface chemistry, first-principles electronic structure theory has always been a natural basis for any modeling in catalysis research. Density functional theory (DFT) and its ever more sophisticated and powerful computer packages like VASP (Kresse and Furthmüller 1996a, b) and others are presently the de facto standard for extended systems. For metallic catalysts and in lack of any even conceptual avenues for systematic improvements, low-rung generalized-gradient approximation (GGA) functionals are still prevalent and probably will be for quite a while (Burke 2012; Cohen et al. 2012; Feibelman 2010). The concomitant uncertainty in key energetic parameters like reaction barriers will therefore continue to be a crucial issue, in particular, when considering that computed reaction barriers (and their errors) enter exponentially into kinetic rate constants. For gap systems like most oxides, simple +U corrections to GGA functionals are still a minimalistic state of the art in more applied studies (Himmetoglu et al. 2014; Kulik 2015). Admixture of exact exchange in hybrid, screened hybrid, or diagrammatic functionals offers an alternative route for systematic improvements for these systems that sees increasing usage also in surface catalysis research (Goerigk and Grimme 2011; Pacchioni 2008; Ren et al. 2012; Schimka et al. 2010). The possibility to efficiently account for dispersive interactions either through van der Waals (vdW) correction schemes or vdW functionals has been of unparalleled value for all types of systems and has certainly opened the door to also treat larger reaction intermediates (Klimeš and Michaelides 2012; Liu et al. 2014; Maurer et al. 2016), e.g., in the context of Fischer-Tropsch catalysis. Solid-state embedding approaches concentrating the quantum mechanical calculations to a finite core region around a considered active site also begin to enable more extensive use of correlated wave-function-based electronic structure theory calculations, not least providing highly accurate reference values (Boese and Sauer 2013; Kubas et al. 2016; Libisch et al. 2014; Richter et al. 2013; Stodt et al. 2013).

Next to such concurrent multi-scale modeling techniques, it is in particular hierarchical multi-scale modeling approaches that are now largely employed in surface catalysis research and that have led to qualitative advances in comparison to

the situation a decade ago. In bottom-up approaches, quantities calculated by first-principles techniques enter into more coarse-grained models that thereby allow to address longer time scales and larger length scales. A most widespread approach is ab initio thermodynamics, in which first-principles calculated total energies or vibrational frequencies are used to determine thermodynamic potentials like Gibbs free energies (Reuter 2016). Representing a surrounding gas or liquid environment in the form of chemical reservoirs to or from which species or charges are given or taken, this approach yields, for instance, (approximate) insight into the surface structure and composition of the catalyst surface in the reactive environment (in heterogeneous catalysis denoted as surface phase diagrams, in electrocatalysis denoted as Pourbaix diagrams) and of nanoparticle shape during reaction conditions (Garcia-Mota et al. 2015; Ouyang et al. 2013; Wang et al. 2013), or it provides a first assessment of thermodynamic barriers along an assumed reaction path, as, for instance, discussed in ▶ Chap. 56, "Supercell Models of Brønsted and Lewis Sites in Zeolites," by Li and Schneider in this section.

For surface electrocatalysis, the breakthrough for such models came when Nørskov and coworkers realized that the (otherwise computationally hard to determine) chemical potentials of solvated species can be related to their gas-phase chemical potentials at standard conditions (Nørskov et al. 2004, 2005). This computational hydrogen electrode (CHE) or equivalent references for other species then allows to quickly obtain estimates of overpotentials and the rate-limiting steps causing them. In the original formulation, solvation effects on the surface energetics were not treated at the electronic structure level, leading among others to deficiencies in the description of pH effects. Efficient treatment of solvation effects is therefore a major topic in current research, with implicit solvation models (Andreussi and Marzari 2014; Mathew et al. 2014; Ringe et al. 2016; Sinstein et al. 2017), static ice layers (Chan and Nørskov 2015; Rossmeisl et al. 2008; Skúlason et al. 2010), or full explicit dynamical simulations (Chen et al. 2013; Mattioli et al. 2013; Quaranta et al. 2017; Stecher et al. 2016), representing three major strands of activities as discussed in more detail in ▶ Chaps. 60, "Fundamental Atomic Insight in Electrocatalysis," ▶ 59, "Structure of Electrode-Electrolyte Interfaces, Modeling of Double Layer and Electrode Potential," and ▶ 61, "Electrocatalysis Beyond the Computational Hydrogen Electrode," by Bagger et al., Groß, and Oberhofer, respectively, in this part.

The explicit calculation of reaction barriers is a first step to account for kinetic effects (Sabbe et al. 2012). In heterogeneous catalysis, corresponding calculations are predominantly carried out using transition state search algorithms like the nudged elastic band (Henkelman et al. 2000). While nominally a "plug-and-play" functionality in almost all major computer packages, in practice every student working with it still struggles in practice with poor convergence and large computational costs. For reactions at solid-liquid interfaces, the situation is even worse, as in principle even more demanding dynamical or free energy simulations are required (Chen et al. 2013; Groß et al. 2014; Li et al. 2014; Mattioli et al. 2013; Pinto et al. 2014; Schnur and Groß 2011; Quaranta et al. 2017; Stecher et al. 2016). Further complications arise presently in this electrocatalytic

context, as standard first-principles supercell approaches for extended systems are for constant charge and not for constant potential (Bonnet et al. 2012; Chan and Nørskov 2015; Filhol and Bocquet 2007; Otani and Sugino 2006; Rossmeisl et al. 2008, 2013; Surendrala et al. 2018), as discussed in detail by Groß in ▶ Chap. 59, "Structure of Electrode-Electrolyte Interfaces, Modeling of Double Layer and Electrode Potential." Research toward numerically efficient approaches allowing the reliable (quantitative or at least semiquantitative but with controlled error bars) calculation of reaction barriers is therefore a hot topic that will likely even increase in importance in the next years. In this respect, the quantification of Brønsted-Evans-Polanyi (BEP) relationships pioneered within the more general context of so-called scaling relations by Nørskov and coworkers has been a true game changer in surface catalysis research in the last decade (Greeley 2016; Nørskov et al. 2008, 2014). Through BEP relationships approximate barriers can be derived from much less demanding thermochemical calculations, while other scaling relations allow to derive corresponding energetic parameters for more complex reaction intermediates from data for their constituting elements, or they allow to extrapolate the energetics over different catalyst materials; see ▶ Chap. 54, "Energy Trends in Adsorption at Surfaces," by Raman and Vojvodic for more details.

The increasing availability of such (approximate) first-principles reaction energetics for elementary processes has strongly fueled the development of microkinetic simulations that evaluate the interplay of these elementary processes in the reaction network and yield the intrinsic catalytic activities (and increasingly also selectivities) as a function of applied reaction conditions (Sabbe et al. 2012; Reuter 2016; Sutton and Vlachos 2015). While mean-field microkinetic models in the form of rate equations still dominate the field (Nørskov et al. 2014; van Santen and Neurock 2006), cf. ▶ Chap. 57, "Microkinetic Modeling of Surface Catalysis" by Vlachos and Wittreich, more accurate kinetic Monte Carlo (kMC) simulations that account for the spatial distribution of reaction intermediates at the catalyst surface are quickly catching up (Stamatakis and Vlachos 2012; Reuter 2013, 2016). Especially when exploiting scaling-relation-based larger energetic databases, either type of microkinetic simulations is successfully and increasingly used to also address more complex reaction networks, for instance, leading to synthetic fuels. kMC simulations are thereby often still challenged by networks featuring very fast processes (prototypically diffusion at metal catalysts). This starts to be addressed in emerging accelerated kMC approaches (Andersen et al. 2017b; Chatterjee and Voter 2010; Dybeck et al. 2017).

A particularly intriguing development within the realm of microkinetic simulations is the realization that through the use of scaling and BEP relations, the dimensionality of the problem can be dramatically reduced. While in principle any given microkinetic model depends on all rate constants (aka reaction barriers) of all elementary processes, the complexity of these dependencies decreases significantly when exploiting that groups of rate constants all scale with one another. When furthermore making (in parts strong) assumptions about the reaction mechanism and rate-limiting steps, the overall dependencies of a microkinetic model can be

minimized (Nørskov et al. 2014). Often the catalytic activity (or selectivity) can then be discussed as a function of the rate constants of just one or two elementary processes and through BEP and scaling relations as a function of the adsorption energies of just one or two elemental reaction intermediates like O or C. This strand of catalysis research has substantially increased our understanding of trends in the past decade and is nowadays largely employed to "screen" for better catalysts by simply computing corresponding descriptors like the O or C binding energies for a multitude of catalyst materials and seeing whether these energies fall into a range yielding optimum activity according to the simplified microkinetic model (Andersen et al. 2016, 2017a; Besenbacher et al. 1998; Greeley and Mavrikakis 2004; Greeley et al. 2006; Linic et al. 2004; Loffreda et al. 2009; Nørskov 2014; Toulhoat and Raybaud 2003). An exciting new development in this context is the fusing with data sciences, using machine learning techniques to identify better descriptors or to extend and refine the energetic databases through regression techniques (Jinnouchi and Asahi 2017; Li et al. 2017; Ma et al. 2015; Quaranta et al. 2017; Stecher et al. 2016; Ulissi et al. 2017a, b).

To also account for macroscopic heat and mass transport effects in a given reactor, microkinetic models are integrated into continuum fluid dynamical simulations. This is more established for mean-field rate equation models (Janardhanan and Deutschmann 2012; Maestri and Cuoci 2013) but has recently also been extended to kMC-based microkinetic models (Matera and Reuter 2009, 2010; Matera et al. 2014). Such coupled simulations help in particular to analyze data from increasingly employed in situ and *operando* measurements, which are often heat and mass transport limited and where then the normal intrinsic activity provided by a microkinetic model cannot be used to relate to the experimental data (Sabbe et al. 2012; Reuter 2016). To date, the integration of first-principles based microkinetic models (either mean-field or kMC) into fluid dynamical simulations at reactor level is, however, limited to simple model catalysts, in fact essentially to single crystals. The reactive chemistry in more complex high-surface area real catalysts is instead described through effective kinetic models as discussed in ▸ Chap. 58, "Computational Fluid Dynamics of Catalytic Reactors," by Hettel, Wörner, and Deutschmann. For such structured catalysts, explicit or effective treatments of porosity, the emergence of turbulence, or complex reactor approaches like fluidized beds are instead challenging topics in fluid dynamics research itself.

3   Open Challenges

Due to the impressive methodological advances briefly highlighted above, modeling and simulation makes substantial contributions to surface catalysis research at all levels from the active site to the reactor. In fact, modeling and simulation is by now firmly integrated as an indispensable part of essentially any project, even in industrial settings. Despite these advances, modeling is still severely challenged by the complexity of real catalytic systems. The development of suitable model systems that still contain the essential features at largely reduced complexity remains one of

the core issues and tasks for the years to come (Sauer and Freund 2015). At the level of the active sites, prevalent approaches often focus on singular high-symmetry sites at individual facets of crystalline nanoparticles. This does not adequately address the complexity in particular of compound materials, which offer multiple such sites – with often little insight available which of these sites dominate the catalytic activity (Reuter et al. 2017). Furthermore, point or extended defects can generally play a crucial role, which in semiconducting materials can additionally exist in multiple charge states. *Operando* studies increasingly report strong morphological changes of the active particles, which severely question the prevalent approach to base any type of active site models simply on structures derived from cutting the crystal lattice of the nominal bulk catalyst material (Reuter 2016). There is also increasing evidence of a more dynamical nature of operating catalysts, suggesting continuous structural changes, maybe even reminiscent of a near liquid state (Newton 2008; Reuter 2016; Schlögl 2015). At present, such dynamics cannot be captured by prevalent microkinetic models, in particular not by generally still lattice-based kMC models (Reuter 2013). That such dynamics has not been "seen" in corresponding modeling is therefore no proof against its existence but simply a shortcoming of our present methodological capabilities.

A second core issue is that (in particular first-principles-based academic) computational catalysis research is still largely focused on catalytic activity as singular measure for a good catalyst. This neglects that in practice a catalyst is part of a complex system and one cannot evaluate a catalyst without considering the whole system. The catalyst needs to contain cheap materials, it needs to be cheap to make, it needs to tolerate contaminants in the feed, it needs to last for a long time, and it needs to avoid elaborate separation of the products. In addition, it must allow for inexpensive heat management. While some computational studies start to consider material cost, for instance, searching for pareto-optimal solutions in high-throughput screening using cost as additional descriptor (Andersson et al. 2006; Nørskov et al. 2009), this does not yet address the actual costs of making a catalyst out of the material. Recall that the reason why, for example, ruthenium still prevails over iron as industrial ammonia synthesis catalyst are the high costs of making an iron catalyst out of cheap iron (Ertl 1980). Computational studies have hitherto also not really aimed at evaluating the effect of trace impurities in the stream at predictive-quality level, neither in detailed microkinetic models nor by considering an optimized interplay of catalyst and contaminant in computational screening. "Poisoning" by impurities is thereby not always detrimental. Sometimes it is possible to poison selectively the surface sites on which an undesired reaction takes place. In partial oxidation reactions, one often tries to poison the surface sites on which complete oxidation occurs. In either case, the absolute effect can be enormous. In ammonia fabrication, the catalytic reactor accounts for about 1% of the cost of a plant. The main expense is generating clean hydrogen that is devoid of CO or sulfur contaminants. A radical improvement for this process would be finding a catalyst that is immune to impurities in the feed. Such a catalyst would prevail in practice, even if the reaction rate is smaller than that of the existing catalyst. The point is that high rate is a good criterion but in many cases it is

not the dominant factor. Similar examples and arguments could be made about the importance of heat management and catalyst degradation. The last decade of computational catalysis modeling is primarily characterized by establishing a comprehensive trend understanding of catalytic activity in terms of underlying materials properties. Compared to this trend understanding, our present insight, for instance, into microscopic heat dissipation channels (Rittmeyer et al. 2018), their role in, as well as sintering or other aging processes in general is essentially nonexistent. In this respect, catalyst lifetime, catalyst tolerance to contaminants, and embracing a possibly dynamical state of catalysts are certainly worthwhile themes for the decade to come.

Energy Trends in Adsorption at Surfaces

Contents

Abstract

Adsorption is a process of vital importance in surface science and heterogeneous catalysis, with early studies dating back to the days of Irving Langmuir. Over the last decades, the advent of first-principles methods coupled with increasing computing power has enabled generation of large data sets of the energetics describing the interaction between adsorbates with different solid surfaces. This has aided in the conceptualization of energy trends through scaling relations, originally obtained by empirical means, and primarily used for the ease of computational burden in chemical transformations involving adsorption. However, the use of scaling relations has now evolved beyond its original intended purpose, with their use in identifying descriptors for reactivity and activity, as well as extension to more complex adsorbates and surfaces beyond transition metals. This chapter traces the history of scaling relations from their inception, through their extension to enable the understanding of chemical transformations and aid in the design of better catalysts, ending with the challenges and an outlook.

1 Introduction

Adsorption is the phenomenon of adhesion of atoms, molecules, radicals, or ions from a gas or liquid onto a surface of a solid material, a nanoparticle, or a larger molecule. In this chapter, the focus is on the adsorption on solid surfaces. Adsorption is at the heart of any gas-surface and liquid-surface interaction found in, e.g., catalytic processes, growth, etc. and has been a vivid research area for decades. Studies of the interaction of atoms and molecules with surfaces go back to Irving Langmuir, considered to be one of the founders of surface science (Langmuir 1961). Over the last two decades, we have seen rapid changes in the fields of surface science and heterogeneous catalysis to a point where we have reached an understanding of the chemistry on surfaces at a level where we can start designing them for their chemical properties in a controlled and systematic way (Medford et al. 2015). The advent of density functional theory (DFT) coupled with increasing computational power has made it possible to gain a deeper understanding of surface processes while also providing the ability to computationally screen among existing, modified, and entirely new materials for complex heterogeneous catalytic processes involving many adsorption intermediates (Nørskov et al. 2009, 2011; Xu 2009; Christensen and Nørskov 2008). At the same time, first-principles atomistic thermodynamics-based approaches have made it possible to determine the relative stabilities of different surface facets and terminations under relevant experimental conditions, improving the accuracy and predictability power of computational methods (Bollinger et al. 2003; Reuter and Scheffler 2001, 2003; Reuter et al. 2004; Nørskov et al. 2006; Rossmeisl et al. 2006; Hansen et al. 2008; Inoğlu and Kitchin 2009; Bendavid and Carter 2013; Holby et al. 2009). An effective method to quantitatively calculate and ultimately predict adsorption energies for the many possible adsorbates that might be involved in chemical processes is highly desirable. With such a suite of data on hand, it allows for comparative studies of different surfaces, enabling the identification of trends in the adsorption energetics that ultimately can be captured by simpler adsorption models, rather than through time-consuming heavy first-principles calculations. Correlations known as energy scaling relations of the adsorption energies between chemically related species have become one of the most popular methods in achieving this. Initially, these relations emerged as a result of empirically fitting large enough computationally derived data sets and were then rationalized and explained for certain groups of materials based on electronic structure arguments, which we will return to in a later subchapter. These scaling relations serve multiple purposes, the most obvious being the reduction in the computational cost associated with the calculation of adsorption energies for a large number of reaction intermediates, when potentially the overall surface reactivity trend can be gauged from a single or a few adsorbate(s), which is discussed in further detail later in this chapter. This way, these scaling relations can aid in the reduction of the dimensionality of a chemical transformation problem, providing insights into the identification of effective descriptors for surface reactivity (Medford et al. 2015; Nørskov et al. 2014; Montemore and Medlin 2014; Greeley 2016). A plethora of papers on adsorption and reactivity, a few

reviews on scaling trends (Montemore and Medlin 2014; Greeley 2016), and a book (Nørskov et al. 2014) have been written on these topics. Therefore, we will here focus on introducing the concepts of adsorption and scaling trends, discussing their applicability, putting them in a larger perspective, and providing an outlook on what the future might bring.

2 Origin of Adsorption Scaling Relations

The origin of adsorption scaling relations for chemisorbed adsorbates can be traced back to the seminal paper by Abild-Pedersen et al. (2007), which in a systematic way established a linear correlation between the adsorption energies of simple hydrides (AH_n) and the corresponding central atom (A) on transition metal surfaces, as given by Eq. 1.

$$\Delta E_{AH_n} = \gamma_s(n)\Delta E_A + \xi,\qquad(1)$$

with the slope $\gamma_s(n)$ given by:

$$\gamma_s(n) = \frac{N-n}{N}\qquad(2)$$

where N is the maximum valency of the central atom A and $n \leq N$ are the number of bonds saturated by bonding to other atoms. For example, C, N, and O would have N equal to 4, 3, and 2, respectively, with CH_3 and CH_2 having n of 3 and 2, respectively. Conceptually, this can be rationalized by taking the N levels to be degenerate and linearly independent, thereby providing an equal contribution to the overall adsorption energy when the central atom A binds to a surface. Removing the contribution from the number of bonds saturated by other atoms (n) provides the number of bonds that the central atom can form with the surface (i.e., dangling bonds). Figure 1 shows the linear adsorbate scaling relationship for the CH_n, NH_n, OH_n, and SH_n species on different surfaces of unary elemental transition metals, respectively.

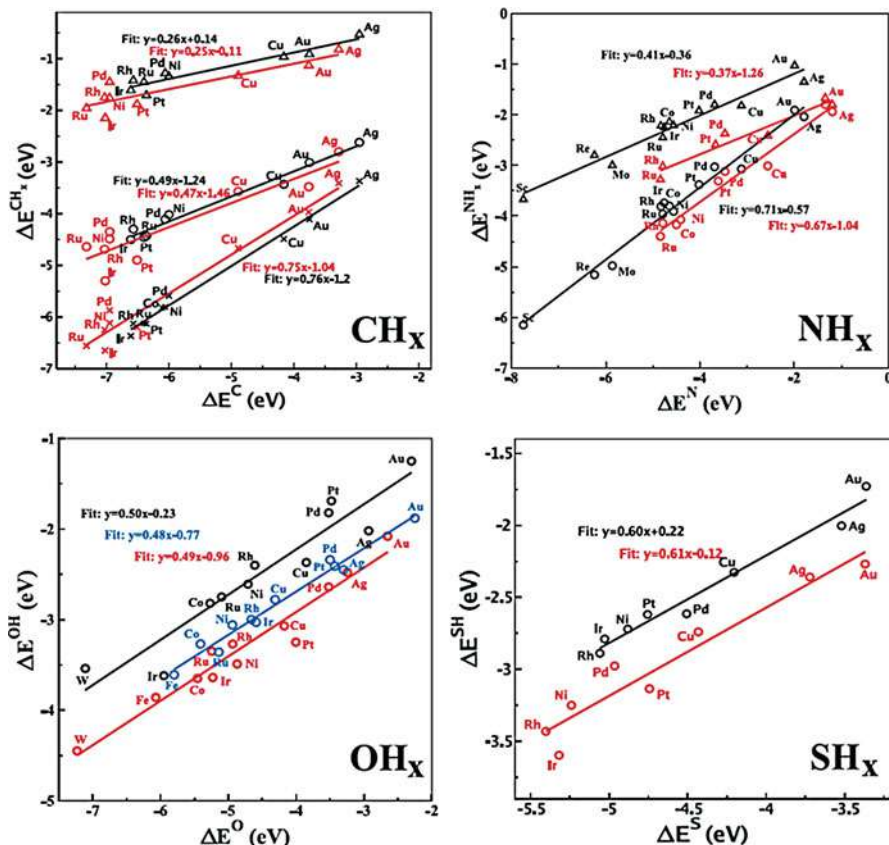
As is evident from Fig. 1, the slope or the scaling parameter $\gamma_s(n)$ in Eq. 1 is independent of the surface facet, while the intercept ξ is surface-facet dependent. This essentially arises from the fact that the adsorbate, at least to a first-order approximation, will form bonds with the surface commensurate with its degree of unsaturation, irrespective of the surface. On the other hand, the difference in the exact local coordination of the adsorption site at the surface affects the overall adsorption energy, resulting in the difference in the intercept ξ. While further modifications to account for more complex adsorbates, coverage effects, etc. have all been built on the scaling relationship given by Eq. 1, it should be noted that some scaling parameters can be determined from bond-order conservation models such as the UBI-QEP methods (Shustorovich 1986; Shustorovich and Bell 1988; van Santen 2010), which predate the use of DFT for adsorption energy calculations.


Fig. 1 Linear adsorption energy scaling relations for simple hydrides AH$_x$ on close-packed (black) and stepped (red) surfaces of different transition metals. (Adapted from Fig. 1 in Abild-Pedersen et al. (2007) based on DFT calculated data)

The simple scaling relationship scheme presented in Eq. 1 has been extended to account for more complex adsorbates. This can be done by first realizing that the adsorption energy of an AH_n species on a given metal can be rewritten in terms of a comparison of the central atom A on that given metal and a reference transition metal, as given below (Abild-Pedersen et al. 2007; Jones et al. 2008):

$$\Delta E_{AH_n;M_2} = \Delta E_{AH_n;M_1} + \gamma_s(n)\left(\Delta E_{A;M_2} - \Delta E_{A;M_1}\right) \tag{3}$$

where M_1 and M_2 represent the two different transition metals. Equation 3 provides the basis for a simple generalization to complex adsorbates, by simply summing over all the adsorbate atoms that bind to the surface, as given below (Abild-Pedersen et al. 2007; Jones et al. 2008):

$$\Delta E_{R;M_2} = \Delta E_{R;M_1} + \sum_i \gamma_i \left(\Delta E_{A_i;M_2} - \Delta E_{A_i;M_1} \right) \tag{4}$$

where R refers to any generic adsorbate and γ_i is redefined as:

$$\gamma_i = \frac{N - n_{intra}}{N} \tag{5}$$

where n_{intra} refers to the total number of intra-adsorbate bonds attached to the central atom A. This generalization has, for example, been used for unsaturated hydrocarbons (CH_x-CH_2), with x = (0,1,2) to successfully predict adsorption energetics on both close-packed and stepped surfaces of transition metals as a function of the adsorption energy of atomic carbon (Jones et al. 2011), as shown in Fig. 2. One finds that a single linear scaling is not enough; rather a piecewise scaling demarcates two separate independent regions, one corresponding to those transition metals that are reactive enough (including non-noble metals and some Cu surfaces) to alter the intramolecular bond of the adsorbate versus those that are not (including the metals Au, Ag, and certain Cu surfaces).

It should be noted that other bond-order-based approaches have been used for multicenter adsorbates, especially those belonging to the class of ethanol derivatives ($CH_xCH_yO_z$) (Ferrin et al. 2009; Salciccioli et al. 2010; Liu and Greeley 2013; Liu et al. 2015) with varying degrees of success on different transition metal surfaces. While scaling concepts based on the usual bond-order conservation approach can be used for such adsorbates, care must be taken when applying the principle to noble metals and potentially other systems with complex surfaces and adsorbates.
Fig. 2 Calculated adsorption energies for CH_x-CH_2 hydrocarbons, with x = (0,1,2) as a function of the adsorption energy of atomic carbon on close-packed (black) and stepped (red) surfaces of transition metals. (Adapted from Jones et al. (2011))

3   Adsorption Energies as Descriptors for Reactivity/Activity

While it is important to generalize the scaling relations to more complex adsorbates, it should also be realized that the true power of scaling relations goes beyond just easing computational effort. Understanding and quantifying surface reactivity has been the main goal of heterogeneous catalysis in order to provide a systematic design paradigm for superior catalysts, in contrast to the conventional trial and error approaches. To this end, the Sabatier principle (Sabatier 1913; Che 2013) provides a conceptual framework by suggesting that the optimal performing catalyst should bind the adsorbates with some intermediate strength, i.e., neither too weakly (activation limited) nor too strongly (desorption limited). This therefore establishes the typical "volcano-type" relation between rate (activity) and the bond strength, as shown in Fig. 3.

    While this provides a theoretical framework, it is not quantitative, as the physical quantity characterizing the "bond strength" is not described, and the value of the "bond strength" that describes the optimal catalyst is unknown. Therefore, to use the Sabatier principle in a predictive manner, descriptors characterizing a heterogeneous catalytic reaction are needed. Since adsorption plays a crucial role in heterogeneous catalysis, the adsorption energies of the relevant intermediates on a given surface of interest serve as descriptors that suitably characterize the reactivity and potentially the activity. To illustrate this, the ammonia synthesis activity on different transition metals is shown in Fig. 4 with two different descriptors: the bulk oxide heat of formation (Fig. 4a) and the calculated nitrogen adsorption energy (Fig. 4b).

    It is evident that the activity "volcano" is well defined when the descriptor is the nitrogen adsorption energy, since it provides a better description of the interaction between the adsorbate and the transition metal surface. While the adsorption of nitrogen is a key step in ammonia synthesis, there are several other elementary steps with multiple reaction intermediates whose adsorption energetics are vital for the overall reaction. What then distinguishes the adsorption of nitrogen as a single descriptor for ammonia synthesis? To illustrate this, the transition state energy for

Fig. 3 Representation of the Sabatier principle. (Adapted from Medford et al. (2015))
Fig. 4 Measured ammonia synthesis activity as a function of two suggested descriptors for the reaction: oxide heat of formation and nitrogen adsorption energy, of which the adsorption energy provides the most satisfactory explanation of the trends by ordering the elemental metal catalysts onto a volcano curve. (Adapted from Medford et al. (2015))

Fig. 5 Calculated transition state energy for nitrogen dissociation vs nitrogen adsorption energy on stepped transition metal surfaces. (Adapted from Medford et al. (2015))
dissociation of a nitrogen molecule is plotted against nitrogen adsorption energy and the rate of reaction computed using a mean-field kinetic model in Fig. 5. It is well established from both experiments and theory that the N_2 dissociation step is rate determining for certain elemental metal active catalysts (Schlögl 2003; Ertl 1980; Logadottir et al. 2001). According to the findings presented in Fig. 5, the transition state energy for the dissociation step scales linearly with the nitrogen adsorption

energy. This explains why the nitrogen adsorption energy would serve as a unique descriptor for ammonia synthesis.

More fundamentally, it is also clear that variations in transition state energies and adsorption energies are governed by the same physics, resulting in such correlations between the two (Plessow and Abild-Pedersen 2015). This enables the development of transition state scaling relations that effectively map the space of adsorption energies onto transition state energies, aiding in the prediction of surface activity (Logadottir et al. 2001; Plessow and Abild-Pedersen 2015; Nørskov et al. 2002; Liu and Hu 2001a, b; Michaelides et al. 2003; Bligaard et al. 2004). Even more remarkable is the similarity of the transition state scaling relationships for chemically and geometrically related molecules undergoing a similar mechanistic reaction step. For example, the transition state energies of simple diatomic molecules show a similar correlation with respect to their dissociative chemisorption energies, providing at least to a first-order approximation an adsorbate-independent way of estimating transition state energies and activation barriers (Nørskov et al. 2002). It should be noted that this correlation sometimes referred to as "universality" of the transition state scaling relations as shown in Fig. 6 is only valid for subsets of molecules on very similar surfaces and adsorption sites. Finally, it should be noted that the popular Brønsted-Evans-Polanyi (BEP) relations (Brønsted 1928; Evans

Fig. 6 Transition state scaling relations for dissociation of simple diatomic molecules on flat and stepped metal surfaces. (Adapted from Nørskov et al. (2002, 2014))
and Polanyi 1938) which have been used extensively for understanding trends in chemical reactions through linear correlations between the activation and reaction energies are simply a subset of the transition state scaling relations. This therefore establishes the importance of trends in adsorption energetics in quantifying surface activity.

4   Extensions to Other Systems Beyond Transition Metals

Considerable progress in the description of adsorption and chemical reactions of more complex systems has been made including scaling relations and extensions of similar ideas for systems beyond pure elemental transition metal surfaces. Adsorbate scaling relations have been established for metal alloys including near-surface metal alloys (Calle-Vallejo et al. 2012; Greeley et al. 2009). In addition to metal alloys, scaling relations have also been found for even more complex solid systems most prevalently for transition metal compounds, including certain surfaces of transition metal oxides, nitrides, carbides, sulfides, etc. (Fernández et al. 2008; Vojvodic et al. 2009, 2011; Rossmeisl et al. 2005; Man et al. 2011; Viñes et al. 2013). One of the earliest papers in this field by Fernandez et al. (2008) showed that linear scaling relations exist between OH, NH_x, and SH and the corresponding central atom, for adsorption on oxide, nitride, and sulfide surfaces, respectively. Further, Vojvodic et al. (2009) demonstrated scaling for NH_x intermediates and BEP relations for transition metal carbides, i.e., scaling relations for intermediates with a central atom having a different chemical component compared to the transition metal compound itself. When it comes to oxides, they have received a lot of attention, for example, with the aim of modeling the electrochemical oxygen evolution reaction, most notably for single metal oxides such as MO_2 oxides and binary metal oxides such as perovskites (Rossmeisl et al. 2005; Man et al. 2011). Versatile BEP relations were found for a range of transition metal oxides including rutiles and perovskites (Vojvodic et al. 2011), where the BEP relation depends on the type of oxide, the active site, and the dissociating molecule. A comparison between the different BEP relations for transition metal carbides and oxides with metals has also been performed (Viñes et al. 2013).

Challenges in modeling these complex solid surfaces arise, on one hand, due to complications in describing the structure and stoichiometries of these surfaces and, on the other hand, from possible limitations in our current description of the exchange-correlation in standard density functional theory (Bengone et al. 2000). Although there are numerous examples of excellent agreement between DFT calculations and experiments, our current description of the exchange and correlation may be insufficient when studying the surface chemistry of complex systems.

Up until now we have only discussed adsorption in the chemisorption limit; however, physisorption is another important class of adsorption. In many cases, physisorption arises from weak interactions due to the relatively long-ranged van der Waals forces between the adsorbate and the surface. These interactions can have

a strong dependence on the spatial extent of the adsorbate, implying that adsorbate correlations normalized to the corresponding active components can be established for comparable systems. This has been observed experimentally, for example, the physisorption of linear alkanes on a Pt (Hong et al. 2016) surface (Tait et al. 2006). Further, with the advent of exchange-correlation functionals that capture dispersion interactions (Dion et al. 2004; Grimme 2004, 2006; Tuma and Sauer 2006; Grimme et al. 2007, 2010; Román-Pérez and Soler 2009; Svelle et al. 2009; Hansen et al. 2010; Lee et al. 2010; Wellendorff et al. 2012; Berland et al. 2015), it is now feasible to computationally model physisorption in systems involving significant contributions from dispersion interactions. For example, the experiment by Tait et al. (2006) was rationalized by Londero et al. (2012). Physisorption in more complex systems such as zeolites, which constitute a large class of materials commonly employed in heterogeneous catalysis and surface science (Brogaard et al. 2012; Bukowski and Greeley 2016; Göltl et al. 2017; Liu et al. 2017), has also been illustrated, for example, see correlation for the physisorption enthalpy of n-alkanes on a zeolite H-ZSM-22 shown in Fig. 7.

In contrast to heterogeneous catalysts with active sites located at continuous surfaces, the active site of a homogeneous catalyst is often comprised of a transition metal center consisting of one or multiple metal atoms embedded in a metal-ligand complex. Homogeneous systems offer large chemical tunability through, e.g., ligand control and steric interactions, to promote or prevent specific chemical reactions. Early work by Bryndza et al. (1987) identified linear correlations between the ligand to transition metal complex interaction and the bond strength of a ligand to a hydrogen atom. Schock and Marks (1988) further investigated this through bond order and electronegativity aspects. More recently, examples of scaling relations for homogeneous systems (Wodrich et al. 2016; Wang et al. 2016) showing that
Fig. 7 Physisorption enthalpy of n-alkanes in a H-ZSM-22 zeolite. (Adapted from Brogaard et al. (2012))

thermodynamic descriptors and kinetic relations can be applicable beyond solid surfaces have been demonstrated.

5   Electronic Structure-Based Adsorption Models

The canonical model for understanding chemisorption on metal surfaces can be traced back to the Newns-Anderson model (Newns 1969; Grimley 1971, 1967a, b; Anderson 1961), which employs a simplified Hamiltonian that accounts for the dominant mechanisms involved in bond formation between the adsorbate and the metal surface. By studying the evolution in the electronic structure of the individual components and the combined system as the adsorbate approaches the metal surface, one can capture the interaction between the adsorbate and the metal through the adatom-projected density of states. This essentially leads to two adsorption limits known as the weak and strong chemisorption limits, classified based on the relative strength between the average coupling matrix element between adsorbate and surface, V, and the bandwidth of the surface states, W. When $V \ll W$, as would be the case when the adsorbate interacts with the sp band of the metal surface, the weak chemisorption limit is reached, and when $V \gg W$, as would be the case when the adsorbate interacts with the d-band of the metal surface, the strong chemisorption limit is reached. In the case of adsorption on a transition metal surface, which consists of a broad sp band and a narrow d-band, both these limits are encountered. The solution to the Newns-Anderson Hamiltonian in such a scenario is schematically illustrated in Fig. 8.

As can be seen in Fig. 8, the interaction between the sp band and an adsorbate results in a broadening of the adatom energy level, with a downward shift in the energy relative to the free adsorbate. The subsequent interaction between the shifted adatom state and the d-band splits the adatom energy level into a broadened
Fig. 8 Illustration of the changes in the adatom-projected density of states upon adsorption on a transition metal surface. (Adapted from Nørskov et al. (2014))

downward-shifted bonding state that is occupied, since it is positioned lower in energy than the lowest occupied metal state, and a broadened upward shifted antibonding state, which may be unoccupied or partly (or fully) occupied based on its position relative to the Fermi level. The region between them corresponds to what is sometimes referred to as a weak nonbonding state. Clearly, the strongest bond between the adsorbate and the metal surface occurs when all the bonding states are filled and all the antibonding states are empty. This provides a simplified fundamental understanding of the energetics involved in the interaction between an adsorbate and a transition metal surface.

6   Adsorption Model for Metals: *d*-Band Model

Since transition metals are vital to most of heterogeneous catalysis, the role played by the *d*-electrons must be carefully elucidated. To this end, the *d*-band model for adsorption on transition metal surfaces, proposed by Hammer and Nørskov (1995a, b), aims to systematically explain the energy trends seen in transition metals, building on the Newns-Anderson model discussed previously. The adsorption energy according to the *d*-band model is split into a contribution from the *sp* states and the *d*-states assuming the following expression:

$$E_{ads} = n_{deg} E_{sp-hyb} + n_{deg} E_{d-hyb} \tag{6}$$

where n_{deg} is the degeneracy of the adsorbate level and E_{sp-hyb} and E_{d-hyb} are the energy contributions resulting from the interaction between the adatom and the surface *sp* and *d*-bands, respectively. The energy contributions resulting from the interaction between the *sp* band and the adsorbate are shown to be very similar for the different transition metals, resulting in the adsorption energy trends being determined by the interaction with the *d*-band of the metal. Therefore, the *d*-band center, filling, and the coupling matrix element between the adsorbate and the *d*-band of the metal serve as important parameters that determine the strength of the bond formed between the adsorbate and the transition metal surface. To illustrate this, the adsorption of atomic oxygen on 4*d* transition metals, as a function of the *d*-band centers, is shown in Fig. 10. Moving from right to left in the periodic table, the *d*-band center moves up in energy, resulting in the antibonding states of the adsorbate becoming empty (see Fig. 9). This yields a stronger bond between the adsorbate and the transition metals toward the left of the periodic table.

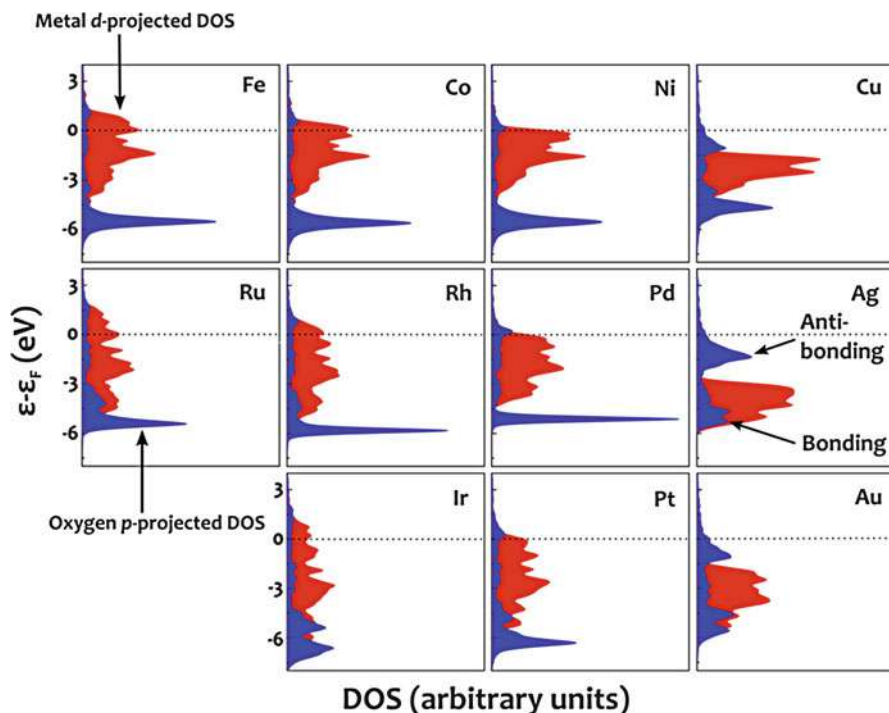
Generalized reactivity descriptors beyond the *d*-band center, i.e., the average energy of electronic *d*-states projected onto a surface metal atom, have been introduced. For example, the upper edge of the *d*-band was identified as an improved reactivity descriptor for pristine transition metals (Vojvodic et al. 2014a) taking into account the effects of the spread in energy on the position of adsorbate-metal antibonding states. In addition, the *d*-band shape of a metal site was shown to have an important role in determining the local surface reactivity of transition metal alloys (Xin et al. 2014). Numerous studies have over the last decades contributed


Fig. 9 Calculated density of states projected onto the *d*-states of the surface atoms of the transition metals and the *2p*-projected density of states of an adsorbed oxygen atom. (Adapted from Nørskov et al. (2014))

to understand the interaction between metal states including the *d*-states and an adsorbate state (Gajdoš et al. 2004; Hammer 2006; Roudgar and Groß 2003; Greeley and Mavrikakis 2004; Kitchin et al. 2004; Nikolla et al. 2009; Marković and Ross 2002; Tripa et al. 1999; Mills et al. 2003; Zhang et al. 2005; Kibler et al. 2005; Behm 1998; Schnur and Groß 2010; Menning and Chen 2009; Groß 2008; Liu et al. 2004; Inderwildi et al. 2007).

7   Outlook

Even though the existence of energy scaling relations which together with activity maps and the *d*-band model has enabled a quantitative understanding and a faster discovery of new catalyst materials (Medford et al. 2015; Nørskov et al. 2011, 2014), recently it has been discovered (Vojvodic and Nørskov 2015; Koper 2013; Seh et al. 2017) that their existence also sets limitations. Under the assumption that each group of reaction intermediates binds to the same type of active site for a given type of material facet, it has been found for several catalytic reactions that the activity
of the surface has an upper theoretical limit, for example, the thermal ammonia synthesis (Vojvodic et al. 2014b), electrochemical ammonia synthesis (Montoya et al. 2015), oxygen evolution reaction, oxygen reduction reaction (Koper 2013; Viswanathan et al. 2012; Nørskov et al. 2004), CO_2 reduction reaction (Peterson and Nørskov 2012; Hansen et al. 2013), and catalytic hydrogenation of carbon monoxide (Cheng and Hu 2008) to name a few. It has been argued that for us to overcome these limitations, we need to find systems where the scaling relations are very different from the systems that we have discovered so far or find systems where the scaling relations do not apply. Several schemes that might be used to circumvent the scaling relations have been suggested; see, for example, a summary in Vojvodic and Nørskov (2015), where both tuning of properties internal to the material, as well as external means are discussed. One of the ideas is to either change how different intermediates are binding to the surfaces, in that way changing the adsorbate scaling relations, while others suggest how one could change the transition state relative to the thermodynamic intermediates, in that way possibly decoupling the kinetics and thermodynamics or finding more favorable BEP relations. So far, only a couple of these strategies have been computationally explored, for example, bifunctional

catalysts through alloying, doping, or defects (Hong et al. 2016; Halck et al. 2014) and 3D active sites as can be found in a confined space (Doyle et al. 2015, 2017). In other words, many possible routes for tuning the surface chemistry remain unexplored, while others might already have been observed but not identified as separate phenomena. There is a long way to go for us to model and design more complicated catalytic systems comprised of multiple components and more intricate details of the material and the environment it is interacting with, for example, understanding the solid-liquid interfaces is a necessity for us to gain a full picture of electrode-electrolyte interactions present in electrochemical systems. Besides this more applied direction for research to progress, there is the more fundamental one that we should be concerned with.

Despite considerable progress, a theoretical understanding of the reactivity of transition metal oxides is less established than that of pure transition metals. As a matter of fact, a complete underlying electronic structure theory is still lacking for complex solid surfaces beyond metals. Vojvodic et al. (2009) showed that the electronic structure descriptor to be considered for an adsorption model for transition metal compounds, as was illustrated for carbides, is more intricate than the one for metals. This approach was applied to a doped oxide system as well (García-Mota et al. 2013) and was found to be able to describe the adsorption trends. Other descriptors have been suggested as well, including the simple one being the number of d-electrons of a system (Bockris and Otagawa 1984; Mun et al. 2005; Calle-Vallejo et al. 2013), the e_g filling of the d-electrons of the bulk system if such are present (Suntivich et al. 2011), e_g or t_{2g} filling of the active surface metal site for a specific surface facet (Vojvodic and Nørskov 2011; Montoya et al. 2018), d-band center, and the p-band center of O in the bulk (Lee et al. 2016) system if present (Hong et al. 2015) or of the surface O near the active site (Montoya et al. 2018), all with different level of success. In addition, coordination-based descriptors have emerged in the literature for complex metal systems including nanoparticles (Jiang et al. 2009; Calle-Vallejo et al. 2014, 2015a, b; Wang et al. 2018; Ma and Xin 2017). Also, recently relationships between adsorbate binding energies and the stability of individual metal surface sites have been considered as descriptors (Roling and Abild-Pedersen 2017). The key thing for us to show is how transferable these are, not only between different materials but also between different surfaces. Ultimately, the goal is to identify suitable descriptor(s), potentially electronic structure-based descriptor(s), that can be used to rationalize the different adsorption trends on these surfaces and help in the endeavor of designing new materials.

Contents

Abstract

This chapter reviews some aspects of computational work on the catalytic chemistry of oxides. The difficulties of using density functional theory in calculations are explained. Different ways of structural or chemical modifications aimed at improving catalytic activity are reviewed. The reaction mechanism of partial oxidation reaction catalyzed by oxides is discussed. The focus is on

qualitative design rules rather than on obtaining highly accurate computational results.

1 Introduction

The number of publications on oxide catalysts is enormous and we can only attempt to provide a summary of those properties that seem to be common to classes of oxide catalysts and/or for classes of reactions. The main subject of this section is what computations teach us about catalysis by simple oxides having the formula M_xO_y. We do not discuss compounds having two cations such as perovskites, spinels, vanadates, etc. Most zeolites are oxides of Si and Al with peculiar, porous structures. We do not examine them here since their catalytic chemistry is different from that of ordinary oxides. Within these self-imposed limitations, we will discuss pure oxides, doped oxides, submonolayers of oxides supported on oxides, and oxide submonolayers supported on metals. Among reactions, we will mention oxidative dehydrogenation and methane oxidative coupling. The topic is so vast that more is left unsaid than is presented.

Oxide catalysts are used industrially for the synthesis of sulfuric acid, the conversion of hydrogen sulfide to sulfur, of methanol to formaldehyde, of o-xylene to phthalic anhydride, of ethylbenzene to styrene, and of propane to propylene.

2 Mars–van Krevelen Mechanism

In the majority of reactions catalyzed by oxides, the gaseous feed contains a reductant and an oxidant. Hydrocarbons, alcohols, CO, H_2, etc. are reductants, and O_2 N_2O or CO_2 are oxidants. There is extensive evidence that oxidation reactions catalyzed by oxides take place through a Mars–van Krevelen mechanism. This postulates that the reductant in the feed reacts with the surface oxygen atoms, removing them and creating oxygen vacancies on the surface; the oxidant reoxidizes the surface. For example, in the reaction $CO(g) + 1/2\,O_2(g) \rightarrow CO_2(g)$, CO reduces the oxide surface to form CO_2 and oxygen vacancies; one oxygen atom in the CO_2 molecule originates from the surface of the oxide. The role of the gas-phase oxygen is to reoxidize the surface. In a slightly more complicated reaction, such as $CH_3OH + \frac{1}{2}\,O_2(g) \rightarrow CH_2O + H_2O$ the oxygen in the water molecule is taken from the oxide surface and, after water desorbs (thus removing an oxygen atom from the surface), the gaseous oxygen reoxidizes the surface. The oxygen in the aldehyde is the oxygen atom contained in the methanol feed.

Transient kinetics experiments, experiments using $^{18}O_2$, and Density Functional Theory (DFT) calculations, all support the Mars–van Krevelen mechanism. However, it is bad practice to assume uncritically that all oxides work according to a Mars–van Krevelen mechanism, for all reactions, under all conditions. In some cases, the oxide might activate the adsorbed oxygen and this oxidizes the reductant.

According to the Mars–van Krevelen mechanism, the reductant removes oxygen from the surface of the oxide and the oxidant puts it back. Because of this, at steady state, there is a constant concentration of oxygen vacancies at the surface. The catalyst is the partially reduced oxide, not the stoichiometric oxide. For a given reductant, the surface of the catalyst is less reduced if the oxidant is O_2 and more reduced if the oxidant is CO_2. In many experiments using oxygen, it has been observed that the steady-state reaction rate is independent of the partial pressure of the oxygen. This indicates that the reoxidation of the surface by gaseous oxygen is much faster than the other reaction steps. This independence of the rate on the oxygen partial pressure does not mean that the reaction will proceed without gaseous oxygen. If the feed does not contain oxygen, the oxide will be reduced until the degree of reduction is so high that the oxide will stop providing oxygen and the oxidation reaction stops. At high temperature, this reduction may go all the way to the formation of the metal, an undesirable outcome unless one is a metallurgist.

3   Irreducible and Reducible Oxides

The Mars–van Krevelen mechanism suggests a classification of the oxide into those that provide oxygen easily (reducible oxides) and those do not (irreducible oxides). Examples of irreducible oxides are alkali oxides, alkali earth oxides, La_2O_3, Sm_2O_3, Y_2O_3, Sc_2O_3, ZrO_2, Ta_2O_5, etc. The term "irreducible" indicates that the oxide is difficult to reduce. It is reasonable to assume that an oxide that is difficult to reduce is not a good oxidant. This is why irreducible oxides are used as catalysts for partial-oxidation reactions at high temperature. An example is the oxidative methane coupling, $2 CH_4 + 1/2 O_2 \rightarrow C_2H_4 + H_2O$, which takes place at $\sim 800\,°C$ (Zavyalova et al. 2011). At this temperature, a reducible oxide will combust methane to CO_2 and water, or to CO and H_2, depending on the working conditions. A characteristic common to all irreducible oxides is that their cation does not make stable oxides having different cation-to-oxygen ratios. For example, in the case of La_2O_3, La does not make stable LaO or LaO_2 oxides. However, as in many cases in chemistry, the rules have exceptions. The fact that a cation forms only one oxide is not necessarily an indication that the oxide is difficult to reduce: for example, NiO and ZnO do not form an oxide containing Ni^+ or Zn^+ but they can be reduced much more easily than, for example, MgO.

Reducible oxides, such as TiO_2, CeO_2, V_2O_5, MoO_3, Mn_3O_4, WO_3, CrO_2, are grouped together because they are better oxidants than the other oxides. In other words, it is easier to partially reduce them by making oxygen vacancies on their surface. The elements in these oxides are able to make oxides having a lower oxygen content (per cation), such as Ti_2O_3, Ce_2O_3, V_2O_3, VO_2, MnO_2, Mn_2O_3, MoO_2, WO_2, Cr_2O_3. Some of them form a large number of crystalline oxides of intermediate stoichiometry. For example, vanadium forms V_nO_{2n+1} ($n = 3, 4, 5$) and V_nO_{2n-1} ($n = 4, 5, 6, 7, 8, 9$). Similar compounds are formed by Mo, Ce, and Ti. The existence of such compounds suggests that it is easy to induce these cations to release oxygen and lower their valence.

4 Oxides Whose Cations Have an Incomplete d- or f-Electronic Shell

There is another important classification of oxides, based on whether the d-shell or the f-shell of the cation is filled. The cations in rows 1, 2, and 11–16 in the periodic table have filled d- or f-shells. The rest of the cations do not, and this causes difficulties: calculations using the generalized gradient approximation of DFT (GGA-DFT) make substantial, qualitative errors. A well-studied example of an oxide having a cation with an incomplete d-shell is TiO_2; equally well studied is CeO_2, in which Ce has an incomplete f-shell. A number of things go wrong when GGA-DFT is used to calculate the properties of these oxides. (1) The d-band (or the f-band) is much too wide (i.e., the energy of the d- or f-orbitals changes substantially when the wave vector is changed) whereas experiments show them to be narrow. The narrow band detected by experiments indicates the d (or the f) electrons are localized on the cations. GGA predicts the opposite: electrons located in d orbitals are delocalized. (2) GGA does not accurately describe processes in which one or two electrons are donated to the oxide. Such donation takes place, for example, when radicals such as H or CH_3 bind to the oxide, or when an oxygen vacancy is formed. Experiments indicate that the donated electrons are localized on one cation while GGA predicts that they are delocalized. (3) In most processes in which one or two electrons are donated to the surface, GGA-DFT predicts that the energy of the orbital in which such electrons are located is at the bottom of the valence band. However, ultra-violet photoelectron spectroscopy (UPS) experiments show that their energy is in the band gap. No such difficulties are encountered when GGA is used for oxides with a complete d- or f-shell (e.g., MgO).

This tendency of GGA to delocalize electrons is attributed to a flaw in the DFT method. The DFT energy contains a term in which each electron interacts with itself. This energy is diminished if the electron distribution is diffuse rather than localized. Hence, the variational procedure will lower the energy by spreading out the electron distribution.

To correct the behavior of GGA, when one calculates the properties of such oxides, one introduces in the DFT energy a term U designed to increase the energy when more than one d or f electron is present on a cation. As a result, the d or f electrons are localized on the cations, as they should be. The theory containing this term, called GGA + U, is an improvization that does not have a firm theoretical foundation and does not provide a reliable prescription for the magnitude of U. U is determined to fit some property of interest. Chemist may pick U to give correct energy of formation of the oxide. People interested in photochemistry at the surface pick U to obtain the experimentally measured band gap. There are also recipes for calculating U from the atomic properties of the cation, but they are approximate. In some cases, people adjust the value of U, in GGA + U, to give results close to the results of hybrid functionals (e.g., B3LYP or HSE), which are deemed to be more accurate. In general, it is prudent, when using GGA + U, to perform calculations for several values of U in order to confirm that at least the qualitative conclusions of the study are independent of the magnitude of U.

The hybrid density functionals (e.g., B3LYP, HSE) give more reliable results than GGA + U. These methods add a fractional amount of Hartree–Fock exchange energy to the ordinary exchange term in the Kohn–Sham equation. This diminishes, to some extent, the self-interaction error that plagues GGA-DFT. The fraction of Hartree–Fock exchange has been determined by fitting a data set. The method works well for molecules and the consensus is that hybrid functionals are more reliable than GGA + U, when applied to oxides. Unfortunately, hybrid functional calculations require substantially more computer time than GGA + U. Since the study of a catalytic process requires many calculations, on systems having many electrons, the hybrid functionals are not used in "production runs." It is more common to use them to validate (or not) some essential step in a reaction mechanism predicted by GGA + U.

5   Oxygen Vacancy Formation

The Mars–van Krevelen mechanism assumes that the reductant in the feed reacts with surface oxygen, making oxygen vacancies. One would expect that oxides for which the energy of oxygen vacancy formation is the lowest are the best oxidation catalysts. Such oxides are likely to be the better oxidants, but they are not necessarily the best partial oxidation catalysts. For example, one would not try to use HgO as a catalyst; it reacts vigorously with reductants but it does not reoxidize easily. Nevertheless, barring a few exceptions, the energy of vacancy formation is not a bad descriptor for a preliminary screening of an oxide catalyst for partial or total oxidation.

It is very difficult to obtain reliable experimental information about the energy of oxygen vacancy formation at the surface of an oxide. Our search of the experimental literature, for the energy of oxygen-vacancy formation for CeO_2, found that numerous values between 0.5 and 4.5 eV have been proposed. There are several reasons for the discrepancies between various measurements. (1) The energy of vacancy formation seems to depend on crystallite size. Therefore, different methods of oxide preparation give different results for the energy of vacancy formation. (2) The energy of oxygen vacancy formation ought to depend strongly on vacancy concentration. As one removes a few oxygen atoms, one expects that the cations will bind more tightly the remaining oxygen. (3) The energy of vacancy formation is affected by the presence of small dopant concentrations. Even research grade oxides have 99.99% purity. In the semiconductor industry, the presence of 0.01% dopants is considered unacceptable since it could dramatically change some properties (e.g., the electrical conductivity). Calculations show that the presence of dopants whose valence is lower than that of the cations they substitute will lower substantially the energy of oxygen-vacancy formation.

Given the paucity of conclusive experimental data, the calculation of the energy of oxygen-vacancy formation plays an important role in our qualitative understanding of the properties of oxide catalysts. While the absolute values of the calculated energy are unreliable, it is likely that they can be used to compare

the oxidative power of different oxides. The calculated energy of oxygen-vacancy formation, when done properly, is consistent with the oxidizing activity observed in experiments.

When an oxygen atom is removed from the oxide surface, it leaves behind (formally) two electrons that used to be tied in the bonds between the oxide and the oxygen atom being removed. The energy of vacancy formation depends on the strength of metal–oxygen chemical bond and on the fate of these "stranded electrons." If the oxide is reducible, these two electrons will reduce two cations. For example, in the case of TiO_2 the removal of an oxygen atom creates two Ti^{3+} ions. We are using here what inorganic chemists call "formal charges," a term that facilitates communication but should not be taken literally. The calculated Bader charge on a Ti atom, in TiO_2, is not 4+ nor is the charge on oxygen equal to -2. A more precise statement is that when an oxygen vacancy is formed the Bader charge on two Ti ions increases by almost one electron. The Ti^{3+} ion, together with the distortion of the oxygen atom surrounding it, is called a *polaron*. Polaron formation lowers the energy of the system (as compared to the case in which the electrons are stuck in the vacancy). It is expected that in all reducible oxides, the formation of an oxygen vacancy, at the surface or in the bulk, is accompanied by the formation of two polarons. This phenomenon has been documented for TiO_2, CeO_2, MoO_3, V_2O_5, and WO_3.

The energy of the polarons formed when an oxygen vacancy is created depends on the nature of the oxide, the position of the polarons with respect to the vacancy site, and the positions of the polaron with respect to each other. This means that to determine the lowest energy for oxygen-vacancy formation, one must study all possible locations of the two polarons.

Polarons do not form spontaneously when an oxygen atom is removed to form an oxygen vacancy. If the oxygen atom is removed and the energy is minimized, two Ti^{3+} ions are formed at the vacancy site. To form a polaron on a specific Ti ion, one must push the nearest oxygen atoms away from the cation and optimize the energy with these oxygen atoms held fixed. When a minimum energy is reached, one releases the oxygen atoms that were held in place during the first optimization, and one optimizes the geometry again. This will form a polaron at the desired location. If DFT + U is used, polarons are generally stable if U is larger than 2.5 eV (or thereabouts, depending on the oxide). The larger the value of U, the more stable is the polaron.

When DFT + U is used, the energy of the orbital involved in the polarons is in the band gap, in agreement with photoelectron experiments. Stoichiometric, pure TiO_2 has a large band gap and does not conduct electricity. However, if oxygen vacancies are created the material becomes an n-conductor. It is widely accepted that in the case of TiO_2 the electric conductivity of the oxide is due to polaron hopping from site to site. The energy barrier of site-to-site hopping has been calculated (Deskins and Dupuis 2007) to be ~ 0.25 eV. This is consistent with conductivity experiments. The band gap of TiO_2 is ~ 2 eV and the states in the gap are below the conduction band by ~ 0.7 eV. Therefore, the electrical conductivity is not due to thermal promotion of an electron from a state in the gap to the conduction band.

The only possible explanation for the conductivity by n-carrier is the mobility of the polarons. This is also true if electrons are injected in the material by a cathode: the electron will form a Ti^{3+} with a polaronic distortion and the electric conductivity is due to polaron migration. The polarons caused by oxygen-vacancy formation have been detected by electron paramagnetic resonance (EPR) spectroscopy.

Experiments in Moskovits's group (Zhang et al. 2004) measured the conductivity of a SnO_2 nanowire that was reduced by CO and reoxidized by O_2. The measurements have shown that reduction increases the electrical conductivity of the wire and oxidation reduces it, as expected if polarons are formed during reduction. We are not aware of a computational study of oxygen vacancies in this oxide, which differs from TiO_2 because Sn^{3+} is unlikely to be formed.

Why is this relevant to surface chemistry? Polaron formation explains why it is much easier to form oxygen vacancies on reducible oxides. This in turn explains why such oxides are better oxidants than the irreducible ones. Furthermore, the polaron are strong Lewis bases (electron donor). Their presence facilitates the adsorption of Lewis acids, such as Au atoms, O_2, Cl_2, Br_2, and I_2.

Polarons are also invoked (in the case of reducible oxides) when H adsorption or CH_3 adsorption is studied. The binding energy of these species to reducible oxides is increased by the fact that they donate an electron and form a polaron.

The formation of oxygen vacancies on irreducible oxides does not result in polaron formation. The "stranded electrons" remain at the vacancy site where they act as strong Lewis bases, which bind Lewis acids strongly.

6 Two-Step Oxidation–Reduction

There has been quite a bit of experimental work studying the possibility of a two-step process for conversion of methane to syngas. It turns out that at high temperature many oxides react with methane to produce syngas and a reduced oxide. In a second step, the oxide can be regenerated by reacting with water, to produce H_2 and a fully oxidized oxide. An alternative second step will oxidize the reduced oxide with CO_2 to produce a stoichiometric oxide and CO. The degree of reduction must be monitored carefully to remove only a few layers of oxygen atoms from the surface of each oxide nanoparticle, so that the surface does not become purely metallic. This partial reduction will avoid coarsening and the cracking of the solid particles due to the stress created by a large change of density when cycling between a stoichiometric oxide and a strongly reduced one.

7 The Lewis Acid–Base Rule

The catalytic chemistry of oxides is very complex and it is therefore useful to have some design rules that give general guidance regarding how one might modify an oxide surface to change its catalytic chemistry. Useful in this regard is the Lewis acid–base rule that is stated below. The interaction energy between two species

adsorbed on an oxide surface is increased substantially if one species can function as a Lewis acid (electron acceptor) and the other as a Lewis base (electron donor). A consequence of this rule is that two species that have several options for binding sites (e.g., could bind to the cation or to the oxygen) would prefer the binding configuration that allows one to be a Lewis acid and the other a Lewis base. For example, if they are alone on an oxide surface, H or CH_3 each prefers to bind to an oxygen atom. However, when they are coadsorbed, the energy is lower if H binds to O and donates an electron to a CH_3 bound to the cation. In this case, H is a Lewis base and CH_3 is a Lewis acid. This acid–base rule seems to be general: it has been documented by numerous calculations for the dissociative adsorption of CH_4, H_2, HX and X_2 (X = Cl or Br), on the surface of a variety of oxides (e.g., MgO, La_2O_3, CaO, TiO_2, CeO_2).

8   Doped Oxides

This acid–base rule suggested a number of strategies for modifying oxide surface to make them better oxidants. One of them is doping (Metiu et al. 2012; McFarland and Metiu 2013; Nilius and Freund 2015): replacing some of the cations near or at the surface of the oxide with cations having a lower valence (e.g., MgO doped with Li). This creates a deficit of electrons in the oxide, making the surface an electron acceptor (Lewis acid), which enhances the ability of the surface to bind Lewis bases such as H and CH_3. The chemistry of the doped oxide does not involve the dopant directly. By not supplying the oxide with enough electrons, the dopant weakens the bond of one of the surface oxygen atoms to the oxide, making the atom more reactive. The use of a higher-valence dopant (e.g., MgO doped with La) has the opposite effect. Formally, the dopant is capable of donating three electrons but the oxide will only use two of them (because we replace a divalent cation in oxide with a trivalent element). The unwanted electron is stuck on to the dopant, making it a good Lewis base. According to the acid–base rule, this site will adsorb well a Lewis acid such as oxygen. In this example, the oxygen becomes negatively charged and is chemically more active than neutral O_2.

It is difficult to prove by experiments with powder catalysts that these concepts work as expected, mainly because one is not certain where the dopants are located (in the surface layer, in the second layer, in the bulk?). It is also not known whether the dopant is oxidized during reaction to form an isolated oxide cluster (the oxide of the dopant). Resolving this issue is made difficult, among other reasons, by the fact that the chemistry of a submonolayer of oxidized dopant will not behave chemically like the bulk oxide of the dopant. In a few experiments, electron microscopy has detected isolated dopants but the mechanism through which they act as catalyst cannot be verified experimentally. Most experiments find that the use of lower valence doping does make the oxide a better oxidant. Careful experiments in Freund's laboratory, working in ultra-high vacuum, with well-defined systems characterized by scanning tunneling microscopy (STM) are generally in agreement with the acid–base rules.

9   Oxides Supported on Other Oxides

Several recent articles (Wachs 2013, 2005; Stacchiola et al. 2013; Carrero et al. 2014; Freund et al. 2014) have reviewed catalysis by systems consisting of an oxide submonolayer supported on another oxide. Any oxide can be used as a submonolayer if it "wets" the support. Broadly speaking the strategy is the same as in doping: create a new bonding scheme in the system, with the goal of changing reactivity. Of course, not every new bonding is beneficial and a central goal of research is to find the ones that are. Experience indicates that the catalytic chemistry is more interesting if the submonolayer is a reducible oxide (e.g., vanadium or molybdenum oxide) but this is not an absolute rule. We examine, as an example, systems in which the submonolayer is V_xO_y. We use this symbol because we are not certain about the stoichiometry of the submonolayer. An exception is provided by experiments (Price et al. 2014) in which mass-selected V_xO_y clusters are deposited, in ultra-high vacuum, on $TiO_2(110)$ surface, and are examined in situ, by scanning tunneling microscopy (STM). Thermal desorption experiments were performed on these systems to determine the catalytic conversion of methanol to formaldehyde for different V_xO_y stoichiometry. Experiments on well-defined systems (Freund et al. 2014; Nilius and Freund 2015) are particularly important when comparison with computations is desired.

The qualitative idea in the design of these submonolayer systems is to force some oxygen atoms to have an unusual bonding. For example, in V_xO_y supported on TiO_2, some oxygen atoms form -Ti-O-V- groups (the lines indicate chemical bonds). The reactivity of these "bridging oxygen atoms" should be different from that of the oxygen atoms in TiO_2 or in V_2O_5. Experiments show that they are. By studying the oxidative dehydrogenation of propane to propylene (Carrero et al. 2014), or of methanol to formaldehyde (Wachs 2013), the following conclusions were drawn. (1) The V_xO_y submonolayer is more active than V_2O_5 powder or TiO_2 powder. The catalytic activity decreases when the amount of vanadium used in the preparation of the catalyst is sufficient to build a second vanadium oxide layer. Moreover, the selectivity changes: pure V_2O_5 is a good total combustion catalyst, while supported V_xO_y is effective for propane or methanol oxidative dehydrogenation. (2) The effect of the support is surprisingly strong. The turnover frequency on VO_x supported on CeO_2 or on TiO_2 is roughly three orders of magnitude higher than that on VO_x supported on silica or alumina. (3) One can prepare a catalyst having a very low concentration of vanadium, in which case one has isolated VO_4 clusters on the surface. Adding more vanadium leads to the formation of clusters having several V atoms connected by -V-O-V- bridges. The oxygen atoms in these bridges do not seem to have high reactivity. (4) Under working conditions, at atmospheric pressure, the catalyst is covered with reactant, intermediate, and product molecules, in addition to having an unknown and probably inhomogeneous morphology. Possible adsorbed species are C_3H_8, C_3H_7, C_3H_6, hydroxyls, oxygen vacancies, and all the intermediates of the combustion of carbon-containing species. This complexity, in surface composition and morphology, makes it difficult to obtain a detailed understanding of these catalysts (oxide submonolayer on oxide).

An important task is to develop a qualitative understanding of the V_xO_y interaction with the support.

10   Inverse Catalysts

Many catalysts used in industry or research consist of metal nanoparticles supported on an oxide. In many cases, the oxide support confers mechanical stability, inhibits coarsening, helps create a large surface for the metal catalyst, etc. In some cases, the oxide support affects the performance substantially. For example, the best support for the Ag catalyst for ethylene epoxidation is α-alumina or SiC. Other supports, such as SiO_2, MgO, TiO_2, Y_2O_3, ZrO_2, have been tried and found inadequate. Even Ag supported on γ-Al_2O_3 has poor performance because γ-alumina is more acid than α-alumina. In some cases, the oxide support covers the metal particle with a thin oxide layer. Often it seems that catalysis takes place at the border between the oxide support and the metal nanoparticle. It is natural therefore to try to create such a border differently, by using an oxide nanoparticle supported on a metal. Catalysts designed in this way are called inverse catalysts and their properties have been studied and reviewed in several publications (Hornes et al. 2010; Rodriguez and Hrbek 2010; Senanayake et al. 2010; Freund et al. 2014; Pan et al. 2014; Rodriguez et al. 2017). Inverse here means opposite to the more common catalysts that consist of metal particles on an oxide support.

11   Summary and Outlook

Several facts make computational studies of real catalysts, oxides or otherwise, difficult. In spite of great advances in in situ electron microscopy and the spectroscopy of catalysts under working conditions, we do not know in detail the morphology (steps, kink, facets) and the composition of the surface of working catalysts. At atmospheric pressure the surface is covered with reactants, products, and intermediates, which compete for surface sites and often interact strongly with each other. For example, the adsorption of O_2 is enhanced substantially by the presence of hydroxyls. While the hydroxyls might not participate in the mechanism of an oxidation reaction, they might influence it through their effect on oxygen adsorption. In many cases the support of the catalyst is important and it is possible that the border between the oxide catalyst and the support is catalytically active. Modeling such a border is difficult. The models we use to study catalysts are almost always a simplified version of reality. The divorce from reality is amplified by the fact that almost all practical catalysts contain small amounts of promoters of the desired reaction and inhibitors of unwanted reactions. Such small additives make a very substantial difference in a catalyst's performance.

A study of catalysis requires the examination of systems with many atoms, which could have a great variety of positions. Because of this, computational efficiency is an essential requirement. That requirement is the reason GGA-DFT + U is the

workhorse in the field. Hybrid functionals require substantially more computer power and are mostly used to recalculate some of the critical steps in a mechanism derived by using GGA calculations. The validation of these calculations by experiment is difficult: there are few groups that can perform experiments with well-defined, single-crystal, oxide surfaces in ultra-high vacuum. Careful measurements of adsorption isotherms, for real catalysts, would be helpful but they are out of fashion. Validation of the DFT calculations by using high-accuracy quantum chemistry methods is, in principle, possible; however, modeling catalysts requires dealing with a large number of electrons and a large number of geometries, and demands too much computer time. Modeling a catalyst by a very small cluster, for which high-quality calculations are possible, is often not satisfactory. Progress in the near future is likely to come from the development of new functionals designed specifically for dealing with oxides. Another promising possibility is the development of embedded cluster methods, to accurately treat a critical group of atoms and more poorly (by DFT or classical potentials) treat the rest.

One might think that the morphology and the composition of the surface could be determined by finding the structure having the lowest energy. However, catalysis is performed at steady state and the morphology and the composition of the surface under working conditions is controlled by kinetics, not by thermodynamics. Kinetic Monte Carlo simulations could be attempted but the number of rate events is very large and the calculated rate constants are likely to have substantial errors. DFT calculations of activation energies are not accurate and unfortunately the Arrhenius formula amplifies the errors.

To summarize: if we intend to study real catalysts, we are forced to use an inaccurate computational method (DFT), in order to examine inaccurate models of systems that experiments do not describe in detail. One might have to give up, temporarily, the dream of performing a complete ab initio description of a catalytic process and accept that computation is one of the tools we have along with spectroscopy and kinetics. This frees the computational chemist to focus on those questions of the catalytic process that the experiments cannot settle. A great strength of the theory is that it has a complete control of morphology and composition. Rather than try to imitate real catalysts, theory should create, on the computer, new structures and new compositions to find the ones that have very promising properties.

Supercell Models of Brønsted and Lewis Sites in Zeolites

56

Sichi Li and William F. Schneider

Contents

Abstract

Zeolites are three-dimensional, crystalline silicate-based materials of interest for catalysis and separations. Computational models of zeolites must capture their three-dimensional structure, the intrinsic microscopic heterogeneity introduced by heteroatom substitutions that underlie their interesting chemical behavior, and the dynamic nature of reactive sites within the pores of molecular dimensions. Here we describe the use of supercell density functional theory (DFT) models for tackling these problems, focusing primarily on Brønsted acidic and Cu-exchanged chabazite (CHA) zeolites and their chemistry related to the catalytic

chemistry of nitrogen oxides (NO_x). We describe considerations important in model construction, applications of *ab initio* molecular dynamics to structure annealing and accurate computations of reaction and activation free energies, first-principles thermodynamics approaches for predicting site compositions at realistic conditions, and approaches for incorporating heteroatom distributions into material models.

1 Introduction

Zeolites are a general class of crystalline silicate-based materials (Auerbach et al. 2003). The presence of micropores and voids of fixed, molecular dimension and the ability to tailor through chemical functionalization make them broadly useful as catalysts ranging from fluid catalytic cracking (Corma 1989) to hydrocarbon oligomerization (Nicholas 2017) to selective catalytic reduction (SCR) of NO_x with NH_3 (Paolucci et al. 2016a). The primary building unit of a zeolite is an SiO_4 tetrahedron (or T-site), which can be linked together at the corners to create a variety of secondary building units, including rings and cages of various sizes, that are further organized into distinct three-dimensional, periodic structures. The topology of a zeolite determines the sizes and dimensionalities of pores that permit molecular access into the interior of the zeolite as well as the sizes and interconnectivities of any cages. The identity of a zeolite is further nuanced by its chemical composition, including the types, concentrations, and locations of any framework or extra-framework heteroatoms. Depending on the synthesis method and treatment history, heteroatoms can be distributed in different ways, e.g., substituting framework Si (Lopez et al. 1993; Matsubayashi et al. 1996), cationically charge-compensating anionic framework blocks (Sherry 1966; Colella 1996), or even forming aggregated metal clusters or metal oxides inside the zeolite cages (Melson et al. 1983). Substitution of framework Si by Al is the most common chemical modification of a zeolite. Due to the 3+ oxidation state of Al, each substitution of a 4+ Si introduces a negatively charged site that can in principle host an extra-framework cation, e.g., a proton, alkali metal, or transition metals. These substituents introduce distinct chemical functionality into the zeolite, such as Lewis acidity or basicity, Brønsted acidity, and/or redox activity, all relevant to catalysis by enhancement of adsorption and/or bond activation of reactant(s) and intermediate(s). How to accurately model the electronic properties of different cations in zeolites from first-principles has been a popular topic in the computational catalysis community for many years (Sauer et al. 1980; Trout et al. 1996; Schneider et al. 1998; Gonzales et al. 1998; Sierka and Sauer 2001; Tuma and Sauer 2006; Paolucci et al. 2016b).

The two common approaches to represent a zeolite within an atomistic simulation are cluster and supercell models. The basic idea of cluster model is to excise the relevant portion of the zeolite framework (a cluster) out of the three-dimensional structure. These cluster representations are amenable to treatment with standard local-basis-set quantum mechanical (QM) methods (Kramer et al. 1991). To recover the effect of zeolite confinement on chemistry, larger models are often created in

which the central cluster containing the chemically relevant active site is treated with QM and a surrounding silicate cage is treated at some lower level of theory (Sherwood et al. 1997; Sierka and Sauer 2005). Such hybrid quantum mechanics-molecular mechanics (QM/MM) methods potentially offer computational efficiency combined with the accuracy of general QM methods. These models take some care to construct and are not well suited to problems in which the site of interest is not well known or well localized. A more natural approach to modeling a zeolite is to apply a supercell approach in which periodic boundary conditions (PBC) are used to naturally recover the dimensionality of a zeolite structure (Rozanska et al. 2003; Hafner 2008). The periodic nature of a supercell model is well suited to plane-wave density functional theory (DFT) treatment and also enables ready implementation of ab initio molecular dynamics (AIMD) simulations to study dynamics behavior of the material (Hass et al. 1998). In this contribution, several common static DFT and state-of-the-art dynamics approaches as well as systematic strategies to model exchanged cation properties in Al-substituted zeolites using supercell model are described. Emphases are placed on methodologies used to probe Brønsted acidity, reactivity of exchange protons, Lewis acidity, siting preference, and redox thermodynamics of exchanged metal cations.

2   Brønsted Acid Site Modeling

A proton is the simplest form of an exchanged cation present in a zeolite, typically residing at one of the tetrahedrally coordinated oxygen atoms around the Al center. Exchanged protons contribute to the Brønsted acidity of a zeolite, which is vital to a broad spectrum of acid-catalyzed reactions. The Brønsted acid strength can influence catalytic activity and is determined by the local environment and accessibility of the protons, as determined by framework topology, type of T-site, different framework oxygen adjacent to each T-site, etc. For example, the MFI zeolite framework contains 12 symmetry-distinct T-sites with 4 first-shell oxygen atom for each, yielding in principle 48 different types of Brønsted acid sites in total, which can all be captured by an orthorhombic supercell as shown in Fig. 1. Experimentally observed Brønsted acid properties are generally an ensemble-average among all possible sites. In order to build the structure-property relationship of Brønsted acids, it is more straightforward and unambiguous to simulate each site explicitly through first-principles modeling than deconvolution from experimental observations.

2.1   Deprotonation Energy

One fundamental electronic property of a Brønsted acid site is the interaction strength between the proton and the anionic framework block, which can be quantified by a deprotonation energy (DPE), defined as the energy to move a proton from a Brønsted acid site into a noninteracting environment. DPE is therefore a

Fig. 1 Orthorhombic MFI zeolite supercell with 12 structural-unique T-sites highlighted and indexed. Four possible Brønsted acid site structures associated with single T-site Al are illustrated. (Adapted from Hernandez-Tamargo et al. 2016)
direct descriptor of the acid strength of a Brønsted acid site. Here we adopt the common "Z" shorthand as a symbol for an Al-substituted tetrahedral site in a zeolite. DPE formally corresponds to the energy of the reaction

$$DPE = E_{Z^-} + E_{H^+} - E_{ZH} \qquad (1)$$

where E_{Z^-}, E_{H^+}, and E_{ZH} are DFT-computed 0-K energies of the anionic zeolite framework after deprotonation, an isolated proton, and neutral zeolite framework with a Brønsted acid site, respectively. Comprehensive studies of DPE for a variety of zeolite frameworks have been reported by several authors (Jones and Iglesia 2015; Rybicki and Sauer 2015). It is worthy to note that within the PBC, supercell model, calculations on the charged anionic zeolite framework or gaseous proton suffer from electrostatic interactions between the periodic images that can lead to erroneous DFT energies without appropriate corrections. One should use caution while trying to compare Brønsted acid strength using PBC DFT-computed DPE values across zeolite framework topologies because the degree of periodic image interaction artifact depends on supercell size as well as void fraction of the cell (Jones and Iglesia 2015).

2.2 Probe Molecule Binding

An alternative approach to quantify Brønsted acid strength is to calculate binding strength of a basic probe molecule, commonly NH_3, to the acid site. It is noteworthy that, unlike deprotonation energy, probe molecule binding strength is not determined only by the acid strength but also the local environment of the acid site through van der Waals interaction and/or hydrogen bonding with the zeolite framework (Jones and Iglesia 2015). Consequently, the net binding strength is the summation
Fig. 2 DFT-optimized structures of ZH and ZNH_4. Only eight-membered rings and adsorbates are illustrated. Distances are given in Å. Equation of NH_3 binding energy calculation is inserted (Li et al. 2017)

of acid-base interaction and other weak interactions that are sensitive to framework pore and ring structure surrounding the Al substituted T-site.

Figure 2 presents an example in which NH_3 is used to probe the Brønsted acid strength of chabazite (CHA) zeolite (Li et al. 2017). The CHA lattice contains only one type of symmetry-distinct T-site, and the entire structure can be representing within a 12-T-site supercell. In a first step, DFT calculations were performed to search for the lowest energy structures of each species, including searches over the four distinct first-shell oxygen atoms adjacent to a substituted Al where a proton can locate. To identify the most favorable proton position, DFT geometry optimization calculations were performed for ZH structures with various proton positions. When NH_3 is placed close to a Brønsted acid, the location of energy minima becomes more challenging, as NH_3 extracts the H^+ from the framework to create an NH_4^+ that exhibits multiple local minima that are close in energy. In such situations, AIMD simulations at elevated temperatures are useful for sampling the potential energy surface. Low energy structures visited in the AIMD trajectory can be further relaxed to their ground states to collect local and, ideally, the global minimum. The binding energy can be calculated as the reaction energy of moving an adsorbed NH_3 to a noninteracting gas-phase environment, formulated by the equation shown in Fig. 2, where E_{ZNH_4}, E_{ZH}, and E_{NH_3} are DFT-computed energies of a zeolitic Brønsted acid with, without NH_3 adsorbate, and isolated gaseous phase NH_3, respectively. Binding energies are typically found to be in the range of $130 \, kJ \, mol^{-1}$.

2.3   AIMD Potentials of Mean Force

Raw DFT-computed probe molecule binding energies include only the 0-K electronic contributions to binding. While typically good reporters of chemical reactivity, comparisons with experimental observations, such as observed NH_3 temperature programmed desorption profiles, are facilitated by the incorporation of finite temperature effects, including the temperature-dependent entropic and enthalpic contributions to the binding free energy. The most common model to incorporate finite temperature effects is the harmonic oscillator (HO) approximation, appropriate for species that exhibit little conformational flexibility. The HO approximation breaks down when adsorbate motions contain significant anharmonicities or are approximately free translators and/or rotators. Improper treatment of these translational and rotational entropies can lead to underestimation of binding free energies and thus of adsorbate coverages and desorption temperatures (Campbell and Sellers 2012; Paolucci et al. 2014). One approach for incorporating these finite temperature, dynamical effects within a supercell model is AIMD coupled with the potential of mean force (PMF) algorithm, a MD-based umbrella sampling method (Wong and York 2012; den Otter 2013). In the PMF simulation, a relevant reaction coordinate is first defined. For adsorbate binding, the reaction coordinate is most naturally the interatomic distance between adsorbate and adsorbent. MD simulations are performed along the one-dimensional grid of the defined reaction coordinate. For any points on the grid that are away from the equilibrium state, constraint forces are present along the reaction coordinate. The Helmholtz free energy to desorb to the center of the cage is determined by integrating the ensemble-averaged constraint forces along the reaction coordinate from the equilibrium to the desorbed state (Li et al. 2018):

$$\Delta A(T) = -\int_{r_{eq}}^{r_{max}} \langle F(r, T) \rangle \, dr \tag{2}$$

Taking NH_3 binding to a Brønsted acid site in CHA zeolite again as an example (Li et al. 2017), a reaction coordinate was defined as the interatomic separation between the proton and the NH_3 nitrogen center (d_{H-N}), as shown in Fig. 3. Grid points are selected to be sufficiently close to ensure a smooth integration of Eq. (2.3) and sufficiently far to keep computational expense manageable. Twenty discrete values of d_{H-N} were chosen in the range from 0.9 to 4.5 Å. At each distance, 40 ps of AIMD were performed at 473 K using the CPMD code, and the constraint forces averaged over the second half of trajectories. As the AIMD simulations are rather computational demanding but the simulation quality greatly depends on the sampling time, to estimate the statistical errors, multiple replicate simulations with different initial atomic coordinates were performed at each d_{H-N}. The free energy surface (FES) at 473 K was constructed through integration of constraint forces along d_{H-N}. As suggested by the location of the minimum in the FES, the equilibrium $d_{H-N} \approx 1.0$ Å, and at distances less than or greater than this separation,
Fig. 3 Free energy profiles for chemisorption of NH_3 to a Brønsted acid site in CHA from PMF simulations (error bars included). Color scheme: O, red; H, pink; Si, yellow; N, blue; Al, green (Li et al. 2017)

the constraint forces are repulsive or attractive, respectively. The FES plateaus as d_{H-N} approaches 4.5 Å, suggesting the NH_3 becomes noninteracting with the Brønsted acid at this separation. To assure that the probe is not perturbed by the framework, the rotational and vibrational dynamics at the end of the constraint path can be compared with those of the free gas. The NH_3 binding free energy at the simulated temperature is the difference between the minimum value and the flat region value in the FES plus the free energy associated with moving the adsorbate from the cage center to outside the zeolite, which is readily estimated (Li et al. 2018).

2.4   Metadynamics Simulations of Brønsted Acid Reactions

The strengths of a Brønsted acid and its local framework environment are both potential factors governing their influence on the rate of an acid-catalyzed reaction. To explore relationship between the nature of a Brønsted acid site and its catalytic function, the intermediates(s) and transition state(s) along the path need to be explicitly identified. The nudged elastic band (NEB) algorithm (Jónsson et al. 1998) and the further refined climbing image NEB (Henkelman et al. 2000) are the most common tools used to locate transition states and minimum energy paths for reactions within the supercell model. As with the geometry optimizations discussed above, these static NEB methods report on the 0-K electronic energy of a particular reaction path and when combined with the harmonic approximation can be used to extract harmonic transition state theory rate constants for use in further microkinetic modeling. However, these static methods are less satisfactory for reactions that

have loosely bound, anharmonic reactant, transition, or product states. A PMF approach is an appropriate alternative when a single reaction coordinate can be clearly identified, but for more complex concerted reactions, the more flexible metadynamics approach is more suitable (Iannuzzi et al. 2003; Laio et al. 2005).

The underlying principle of metadynamics is to supplement the intrinsic DFT potential energy surfaces with a series of Gaussian-shaped biasing potentials accumulated during the course of the AIMD trajectory. These biasing potentials, if introduced as small perturbations through the course of a dynamics trajectory, can smoothly drive the system away from one equilibrium state toward some other region of configuration space of interest. These biasing potentials are applied along predefined collective variables (CV) that can be as simple as a single distance or as complex as a linear combination of many internal degrees of freedom, contributing to the overall flexibility of the method. As with a PMF, metadynamics accelerates the sampling of higher free energy parts of the PES and in particular accelerates the crossing of energy barriers. The collection of biasing potentials accumulated over the course of the simulation reports on the underlying free energy surface, including both the enthalpic and entropic parts of the reaction. The FES of the reaction can be recovered by summing up the biasing potentials added in the defined grid of CV space. To ensure that a particular metadynamics simulation proceeds along a productive direction and to enhance simulation efficiency, CVs should be chosen that are directly relevant to the bond breaking and formation events associated with the reactants and products. Several applications of metadynamics for constructing FES within a supercell model have been reported (Brüssel et al. 2011; Moors et al. 2013; Erichsen et al. 2015).

Here we use the reaction between a Brønsted acid site and two nitrogen oxides (NO_x), a reaction relevant to the Brønsted-acid-catalyzed fast selective catalytic reduction (SCR) of NO_x with NH_3, to illustrate a practical application of metadynamics for a catalytic process (Li et al. 2017). The reactants and products are shown in Fig. 4b. The desired reaction coordinate involves proton (H^+) transfer from a framework oxygen (O_f) to one oxygen of an approaching NO_2 molecule (O_{NO_2}) and concerted adsorption of a NO molecule to an O_f through its N center (N_{NO}). One complication in modeling such a process is that NO at the product stage can potentially coordinate with any one of O_f adjacent to Al and, to obtain a smooth FES and avoid bias, must be included on an equal footing into the CVs. For this purpose one can define a generalized coordination number:

$$\sum_{j \neq i}^{n_{\text{list}}} \frac{1 - \left(\frac{d_{ij}}{d_0}\right)^p}{1 - \left(\frac{d_{ij}}{d_0}\right)^q}, \tag{3}$$

Here d_{ij} is the distance between atoms i and j, and d_0 is a reference distance corresponding to the approximate bond distance between atoms, and p and q are parameters that determine the balance between sampling bound and unbound regions of the FES. In the simulation illustrated in Fig. 4a, CV1 was set to the
Fig. 4 (**a**) Time evolution of CVs in single run of metadynamics simulation for reaction between NO_x and a Brønsted acid site in CHA at 473 K. (**b**) Free energy surface projected on the two auxiliary collective variables (CV1 and CV2) from metadynamics simulation. Structures of reactants and products are superimposed. Color scheme: O, red; H, pink; Si, yellow; N, blue; Al, green (Li et al. 2017)

$H-O_{NO2}$ CN and CV2 to the O_f-N_{NO} CN, averaged over all four O_f. CV trajectories during the course of the metadynamics simulation are plotted in Fig. 4a. Near the beginning of the simulation, both CVs fluctuate around 0.1, corresponding to a region of configuration space in which $H-O_{NO_2}$ and O_f-N_{NO} are unbound and a system in the ZH, NO, NO_2 reactant well. As time progresses, the metadynamics biasing algorithm pushes the system to explore regions of higher CV space. Near 42 ps, both CV1 and CV2 attain values associated with the product state, suggestive of a first crossing of the reaction barrier and formation of ZNO and nitrous acid

HONO. The simulation can be terminated at this point if the purpose is solely to quantify the activation free energy, which corresponds to the depth of the reactant basin in the constructed FES. If the goal is to simulate the full FES including reactant and product basins, simulations are continued until the CV values return to the reactant region so that product free energy basin is well sampled and filled, as shown in Fig. 4b. Metadynamics can in principle be applied to any reactions of interest and is particularly powerful for those reactions with only limited knowledge on the reaction pathways, because CVs are generally loosely defined and the system still retains a high degree of freedom that allows the reaction to proceed through the most favorable pathway on the fly. On the other hand, really free energies depend on careful selection of the parameters that control the rate of addition and size of the biasing potentials.

2.5   Interaction Between Brønsted Sites

We have discussed to this point the properties of an isolated Brønsted site within a zeolite, taking CHA as an example. In real zeolite materials, Al T-sites are generally not ordered, and the silicon to aluminum ratio (SAR) is typically such that there is always some probability for two Al-containing T-sites to be in sufficient proximity to influence chemistry (Paolucci et al. 2017). The distribution of Al within a zeolite framework can in principle be dependent on the types of symmetry-distinct T-sites as well as any interactions between the sites that prevail at the time of synthesis. "Löwenstein's rule," for instance, is the empirical observation that two Al are generally not found in adjacent T-sites. This observation suggests that there may be some energetic interaction between T-sites. This idea has been explored in supercell simulations of paired Brønsted sites in CHA zeolite (Fletcher et al. 2017).

The size of the zeolite supercell determines the maximum unique Al−Al pair combinations that can be represented. Figure 5 shows a representative 36-T-site supercell for CHA. This supercell nominally contains 35 distinct Al−Al pair combinations and, considering that each T-site has 4 distinct associated framework O, 560 Brønsted acid pair configurations. Because of PBC considerations, the actual number of unique combinations is reduced. Figure 5 shows DFT-computed energies for all possible combinations within the 36-T-site supercell. Results are plotted against Al−Al separation and normalized to the energy at infinite Al separation:

$$2\,HSi_{35}AlO_{72} \longrightarrow H_2Si_{34}Al_2O_{72} + Si_{36}O_{72} \tag{4}$$
The broad distribution of energies at any separation reflects the strong dependence of relative energy on proton location. At any given separation, energies span the infinite separation baseline. Further, this range broadens with decreasing Al−Al separation. Energy is minimized at the first-nearest-neighbor separation, suggesting that an Al−O−Al configuration is particularly low in energy when protons are the charge-compensating species and thus that this energy landscape cannot account for Löwenstein's rule. Further, the results suggest that Brønsted acid strength

Fig. 5 Relative energy of Brønsted acid site pair against framework aluminum separation for H-SSZ-13 (Fletcher et al. 2017)
is sensitive to the proximity of an acid site to a neighbor. In general, these findings highlight the importance of considering the influence of heterogenous site distributions in zeolite material simulation.

3 Cationic Metal Site Modeling

3.1 Metal Cations Anchored to Isolated Al T-Sites

Metals that can exist as monovalent cations, e.g., alkali metals and some transition metals, are similar to protons in their ability to charge-compensate isolated Al T-sites in zeolites. The same methodologies discussed above can be applied to study the electronic and chemical properties of these cationic metal sites, which are typically Lewis acidic (Thang et al. 2014). For metals that exhibit more than one oxidation state, redox characteristics become relevant. For instance, Cu exists in both 1+ and 2+ oxidation states and thus can in principle charge-compensate one or two Al within a zeolite. Even in the 2+ state, the presence of additional charge-compensating ligands (OH^-) will alter the net charge of the Cu complex and thus its interaction with a zeolite host. Redox cycling between oxidation states has been demonstrated to be key to the performance of Cu-exchanged SSZ-13 zeolites in the standard SCR of NO_x by ammonia (Paolucci et al. 2014, 2017; Gunter et al. 2015). Thus, first-principles models of metal exchange in zeolites become significantly more rich and challenging than that of monovalent Brønsted sites.

3.2   Polyvalent Metal Cations Anchored to Paired Al T-Sites

Because of its relevance to SCR, Cu exchange in CHA zeolites has received
considerable computational attention. Figure 6 shows a representation of the CHA
cage structure, illustrating the various rings and voids within the zeolite that can host
a metal ion (Paolucci et al. 2016b). All T-sites within this structure are equivalent.
DFT calculations report that an isolated Cu^I ion charge-compensating a single Al
T-site seeks a twofold coordinate site, near one O_f adjacent to Al and one one-
site removed. Two Al are required to charge-compensate a ligand-free Cu^{II}, and
the structure and stability thus becomes a function of the proximity of the two Al.
Figure 7 reports DFT-supercell-computed structures of a nominally Cu^{II} ion in a
variety of Al pair sites present in CHA, including a second-nearest-neighbor (2NN)
Al pair in a four-membered ring (4MR), third-nearest-neighbor (3NN) pairs in six
(6MR)- and eight-membered rings (8MR), and fourth-nearest-neighbor (4NN) pairs
in an 8MR (Verma et al. 2014). All structures were optimized within a 12-T-site
rhombohedral CHA supercell and some repeated in a doubled, 24-T-site supercell to
test the sensitivity of computed energies on supercell size. Bader charge analysis on
Cu confirms that all Cu are in the same (formally 2+) oxidation state. The structural
preference for Cu^{II} for higher coordination is evident in the computed structures,
particularly in structure (b).

   Computed DFT energies are summarized in Table 1. Relative energies span
approximately 1.5 eV and are generally insensitive to supercell size, and among
the six configurations explored, configuration (b), corresponding to a Cu^{II} in
the 6MR, is substantially lower in energy than other combinations. This energy
preference likely reflects the ability of the 6MR to comfortably accommodate the
fourfold coordination preference and preferred $Cu^{II}-O$ distances with minimal
lattice strain. These energies convolute the energy of interaction of the Cu^{II} ion
with the zeolite framework and the energy difference between different $Al-Al$
Fig. 6 Side view of the CHA cage structure and computed structures of Cu^I and Cu^{II} ions
attached to the zeolite framework and solvated by H_2O (Paolucci et al. 2016b)
Fig. 7 Relaxed structures of an isolated exchanged Cu^{II} ion in CHA (Verma et al. 2014). Distances between O_f and Cu indicated in Å. (**a**) $2 \times 1 \times 1$ supercell 2NN Al pair in 4MR. (**b**) $2 \times 1 \times 1$ supercell 3NN Al pair in 6MR. (**c**) $2 \times 1 \times 1$ supercell 4NN Al pair in 8MR. (**d**) $1 \times 1 \times 1$ supercell 4NN Al pair in 8MR. (**e**) $1 \times 1 \times 1$ supercell 3NN Al pair in 8MR. (**f**) $1 \times 1 \times 1$ supercell 2NN Al pair in 8MR. Color scheme: O, red; Si, yellow; Cu, gray; Al, green

pair combinations. These two factors are not directly separable, and one can only make comparisons on the basis of some balanced reaction involving other charge-compensating species. One can define, for instance, an exchange energy between different sites as

$$Z_2H_{2\,config1} + Z_2Cu_{config2} \longrightarrow Z_2H_{2\,config2} + Z_2Cu_{config1} \qquad (5)$$
Table 1 Raw and relative energies of isolated Cu^{II} ions at different Al pair locations in CHA. All energies in eV (Verma et al. 2014)

Al-pair sites	From $2 \times 1 \times 1$ supercell		From $1 \times 1 \times 1$ supercell	
	Raw energy	Relative energy	Raw energy	Relative energy
2NN in 4MR	-574.622	-0.37	-284.155	-0.37
3NN in 6MR	-575.751	-1.51	-285.203	-1.42
4NN in 8MR	-574.246	0	-283.783	0
3NN in 8MR	N/A	N/A	-283.550	0.23
2NN in 4MR	N/A	N/A	-284.030	-0.25

which convolves the energies shown in Table 1 with those reported in Fig. 5. Exact results depend on site, but it is evident that the 1.5 eV advantage of the 6MR site over others for Cu^{II} overwhelms the $\ll 0.4$ eV difference between various Z_2H_2 configurations. Thus, on the basis of this exchange reaction, Cu^{II} will preferentially populate 2Al 6MR sites over other sites, when exchange occurs against the Brønsted form of the zeolite.

3.3   Cu Exchange Siting Between 1Al and 2Al Sites in CHA

As a redox-active ion, Cu^{II} can be present in the zeolite in more than one chemical form. Figure 6 shows the computed structure of ZCuOH, a formally Cu^{II} ion charge-compensated by both a single Al T-site plus an extra-lattice OH^-. DFT calculations show that the addition of this OH^- ligand to an isolated Cu^I moves the Cu center from the center of a 6MR up into an adjacent 8MR (Fig. 6), illustrating how Cu location is both a function of the Al site and additional Cu coordination.

In a typical Cu ion exchange experiment, Cu^{II} is introduced to the zeolite as an aqueous solution, Cu is absorbed, and the material is then heated to drive off H_2O. In principle every Al T-site could host a Cu^{II} ion as ZCuOH, leading to a Cu/Al ratio of 1. Ionic Cu uptake in Cu-CHA is typically observed to saturate at Cu/Al ratios lower than unity, however, likely reflecting the competition between 1Al (ZCuOH) and 2Al (Z_2Cu) sites for Cu^{II}. The relative energies of these two types of sites can only be compared by constructing a stoichiometric reaction that connects the two. A variety of choices are possible, but one that is consistent with the conditions of Cu exchange is

$$Z_2Cu^{II}H_2O + ZH \longrightarrow Z_2H_2 + ZCu^{II}OH \qquad (6)$$
where H_2O Lewis-bound to Z_2Cu is used to balance the overall reaction and the same Al pair site is implied on both sides of the reaction. The Z_2CuH_2O structure and energy can be evaluated using a computational approach analogous to that described above for NH_3 on a Brønsted site, including AIMD annealing followed

by a relaxation. The H_2O binding energy to a 6MR Z_2Cu evaluated this way is computed to be approximately 0.8 eV (Paolucci et al. 2016b). The overall energy of Eq. (6) can then be computed either in separate single Al and paired Al supercells or in one, larger, supercell that contains both types of sites of interest. Tests indicate that for Cu in CHA, both approaches give similar results and for two Al 3NN in a 6MR give an energy of about 0.6 eV, reflecting an energetic preference for populating these Z_2Cu sites over ZCuOH sites.

Predicting the equilibrium fraction of Z_2Cu and ZCuOH sites in a particular zeolite requires knowledge both of these exchange preferences and the distribution of Al with the framework. This Al distribution is in general a function of the Si to Al ratio (Si/Al) and the zeolite synthesis conditions and cannot be predicted, for instance, from the relative energies of Brønsted sites (Fig. 5). Because CHA contains only a single T-site type, a simple model for the Al distribution is that Al are distributed randomly on the CHA lattice subject to the empirically observed constraint that Al avoid 1NN sites (Löwenstein's rule). This model can be exercised in numerical simulations to predict the distribution of Al as a function of Si/Al. Combining this distribution with a rule derived from Eq. (6) that exchanged Cu^{II} populates 6MR 2Al sites preferentially before populating residual isolated Al sites as ZCuOH leads to the composition phase diagram shown in Fig. 8 (Paolucci et al. 2016b). The white line represents the saturation limit of Z_2Cu sites, and the colored range the relative $ZuOH/Z_2Cu$ fraction. A variety of chemical probes can be used to compare these predictions with observation, including residual Brønsted site density, spectroscopic observation of the ZCuO−H intensity, and chemical titrations using probes sensitive only to paired Al. Paolucci et al. found that these predictions matched experimental observations for Cu-CHA samples of a wide range of Si/Al and Cu/Al ratios prepared under the same conditions.
Fig. 8 Predicted Cu site compositional phase diagram versus Si/Al and Cu/Al ratios. Color scale indicates predicted fraction of $ZCu^{II}OH$. White line demarcates transition from Z_2Cu^{II}-only region to mixed $Z_2Cu^{II}/Cu^{II}OH$ region. White circles indicated compositions of synthesized Cu-SSZ-13 samples (Paolucci et al. 2016b)

These results illustrate the potential richness of metal ion exchange in zeolites introduced by polyvalency, extra-lattice ligands, and Al distributions. Cu exchange in CHA is a relatively simple example in which these factors can all be accounted for through DFT evaluation of energies combined with stochastics. These problems become more challenging for lower symmetry zeolites and for metal ions that exhibit more complex exchange chemistry.

3.4   Thermodynamics of Cu Speciation in CHA

Heterogeneous catalytic reactions at metal surfaces are understood in terms of the adsorption, dissociation, rearrangement, and desorption of species at a relatively constant metal (or metal oxide) surface. Metal-exchanged zeolites, while technically heterogeneous catalysts at the macro level, exhibit many of the characteristics of homogeneous catalysts at the atomic scale. As shown in panel C of Fig. 6, isolated Z_2Cu or ZCuOH sites can adsorb multiple ligands (H_2O, in the example shown) and in the process become detached from the zeolite framework itself and move into the void space of the zeolite cage (Kwak et al. 2014; Psofogiannakis et al. 2015; Paolucci et al. 2016b). In the process, Cu centers evolve from a rather static into a dynamic state. Figure 9 compares the volume of space visited during 90 ps of AIMD at 298 K of "dry" and fully hydrated Cu^{II} ions in the CHA cage (Paolucci et al. 2016b); hydration substantially increases this space even at this ambient temperature.
Fig. 9 Volume of space visited by the Cu center during 90 ps of 298 K AIMD as a function of the Cu oxidation and coordination states (Paolucci et al. 2016b)

To compare with and rationalize experimental observations, it is important to be able to predict the equilibrium state of the Cu sites as a function of external conditions, including temperature and pressures of various gases. A first-principles thermodynamic approach is well suited to this problem. In this approach, the various states of a catalyst site are written in terms of formation reactions with respect to some base state of the site and some combination of relevant reactive species. Under hydrothermal conditions, for instance, this formation reaction can be written as

$$Z_*\text{Cu} + \frac{x}{2}\left(H_2O - \frac{1}{2}O_2\right) + \frac{y}{2}O_2 \xrightarrow{\Delta G_f} Z_*\text{CuH}_xO_y \tag{7}$$
where $Z_*\text{Cu}$ represents either a single or paired Al site and H_2O and O_2 are used as reference species for the various ligands that may cover the Cu ion or associate with the lattice itself. Application of this strategy presents two significant challenges: first, to generate a comprehensive list of product species and second, to relate DFT-computed energies to finite temperature free energies. Because the number of candidate species involved is potentially quite large, the AIMD-based free energy approaches of Sects. 2.3 and 2.4 become prohibitively expensive. In such cases, chemical intuition combined with judicious AIMD-based annealings are currently the best alternative. Paolucci et al. used this approach to identify the structures and compute the energies of more than a dozen different candidate combinations of H_xO_y ligands on both 1Al and 6MR 2Al sites in Cu-CHA (Paolucci et al. 2016b). Further, they used correlations derived from PMF simulations on a limited number of ligands (Paolucci et al. 2014; Li et al. 2018) to estimate the entropic contributions to the free energy. These PMF simulations suggest that adsorbates retain approximately $1/2$ of their gas-phase entropy upon adsorption at the highly dynamic Cu sites.

Figure 10 shows the composition phase diagram as a function of O_2 pressure and temperature at a fixed 0.02 bar H_2O for Cu exchanged near single and paired Al sites. These conditions determine the chemical potentials needed to evaluate the free energy of reaction (7):

$$\Delta G_f^{Z_*\text{CuH}_xO_y}(T, P_{O_2}, P_{H_2O}) = \left(E_{\text{DFT}}^{Z_*\text{CuH}_xO_y} - E_{\text{DFT}}^{Z_*\text{Cu}}\right) - T\left(S^{Z_*\text{CuH}_xO_y} - S^{Z_*\text{Cu}}\right)$$

$$- \frac{x}{2}\mu^{H_2O}(T, P_{H_2O}) - \frac{y - x/2}{2}\mu^{O_2}(T, P_{O_2}) \tag{8}$$

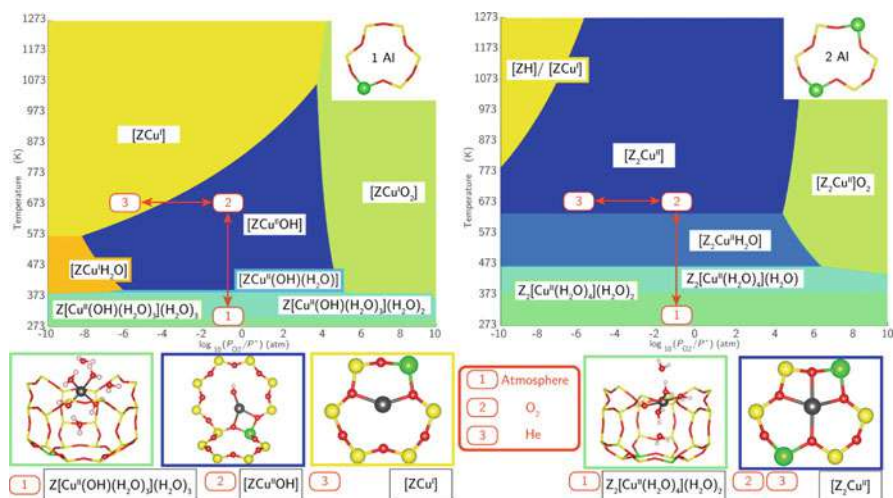
and the figure reports the composition that minimizes free energy at the specified conditions. These diagrams are a powerful tool for predicting the evolution of sites as a function of conditions. For instance, in Fig. 10, both Cu ions are seen to evolve from a fully hydrated, Cu^{II} state at ambient conditions (state 1) to a fully dehydrated, zeolite-bound state at elevated temperature (state 2). Thermal "autoreduction" to a Cu^{I} state is predicted to occur for the ZCuOH sites but not the Z_2Cu sites. All these observations are in good agreement with experiment, in particular X-ray spectroscopic characterization of oxidation states and coordination numbers


Fig. 10 Ex situ Cu speciation phase diagrams based on HSE06-Tsvdw calculations on 1Al (left) and 2Al (right) Cu exchange sites. Regions indicate site composition that minimizes free energy at 2% H_2O and given T and P_{O_2}. Labeled on the phase diagram and illustrated below are minimum free energy species at (1) ambient (298 K, 20% O_2), (2) oxidizing (673 K, 20% O_2), and (3) inert (673 K, 10^{-6} atm O_2 in He) (Paolucci et al. 2016b)

(Paolucci et al. 2016b). A similar strategy applied to these sites under conditions representative of standard NO_x SCR reveals the role of NH_3 both as a Cu ion ligand and a reductant in this redox chemistry.

4   Outlook and Challenges

The structural and chemical diversity of zeolites presents a rich set of challenges for first-principles computations. We have focused here on the chemistry of Brønsted and Lewis (Cu ion) sites in CHA as two examples for which computational models are well developed and have led to significant insights. The dynamic nature of both types of sites motivates careful consideration of the state of these sites at finite temperature and in the presence of reactive gases. The three-dimensional structure of CHA can be captured in supercells small enough to be amenable to AIMD, but zeolites of lower symmetry and larger supercell volumes remain a challenge for fully first-principles models, as do models able to reliably predict free energy changes upon adsorption and reaction at highly dynamic sites. Zeolite chemistry is closely associated with framework-substituted heteroatoms. While we have focused here on Al, other types of iso- and aliovalent dopants are possible. Further, as we have seen, the distribution of these heteroatoms can itself have an influence on zeolite chemistry by creating local sites and ensembles of differing reactivity, and similar ensemble effects likely are related to zeolite hydrothermal stability as

well. Computational models must account for potential ensemble and environmental effects in any robust comparisons with experiment. For instance, recent experiments demonstrate that ZCuOH but not Z_2Cu sites participate in the selective oxidation of methane to methanol over Cu-CHA (Pappas et al. 2017), a conclusion quite different from that for NO_x SCR (Paolucci et al. 2016b). In fact, recent results highlight the coupled role of Al spatial distributions and adsorbate-induced active site diffusion and pairing in controlling the rate of the O_2-consuming step in standard NO_x SCR (Paolucci et al. 2017). Thus, computational descriptions of zeolite structure and dynamics present a coupled challenge and opportunity for both understanding and predicting heterogeneous catalytic performance.

Abstract

Microkinetic modeling (MKM) breaks down a reaction mechanism into all known elementary steps making no a priori assumptions about dominant reaction paths, rate determining steps, and most abundant reactive intermediates. Instead this information emerges from the solution of the model. Aside from mechanistic understanding, MKM can be utilized to optimize reaction conditions and/or reactor configuration and provide guidelines for catalyst design. This chapter focuses on describing the basics of mean-field MKM. It also details how first-principles calculations or fast-screening methods can be used in conjunction with transition state theory and statistical mechanics to derive kinetic and thermodynamic parameters that abide to thermodynamic consistency constraints. Finally, the chapter covers analysis techniques that provide key insights into the reaction mechanism. We focus primarily on the ammonia decomposition chemistry as an illustrative example.

1 Introduction

In 1864, Waage and Guldberg first proposed mass action kinetics where reaction rates are proportional to the concentration of the reactants (Lund 1965). In 1884, Van't Hoff published his now famous work "Etudes de dynamique chimique" (van't Hoff 1884) where he described how to determine reaction orders and to link equilibrium to thermodynamics. Deriving simplified rate equations and estimating reaction rate and equilibrium constants is still a main activity of chemical reaction engineering today. For a simple bimolecular reaction, one has

$$
\begin{aligned}
&A + B \rightarrow C \\
&r_{\text{eff}} = k_{\text{eff}}[A]^x[B]^y \\
&k_{\text{eff}} = A_{\text{eff}} e^{\frac{-E_{a,\text{eff}}}{RT}}
\end{aligned}
\tag{1}
$$

Here r_{eff} is the observed reaction rate, k_{eff} is the associated rate constant, [A] and [B] the concentrations of the reactants with x and y the observed reactions orders for each reactant, A_{eff} is the pre-exponential factor, and $E_{a,\text{eff}}$ is the reaction barrier.

In the early 1900s, researchers proposed more complex rate expressions. In 1913, Michaelis and Menten recognized that enzymatic reaction rates depend on a reversible reaction between an enzyme and a substrate producing the activated form of the enzyme (Cornish-Bowden 2015). The Langmuir-Hinshelwood-Hougen-Watson (LHHW) mechanism proposed in the 1920s considers the following elementary steps, namely, adsorption of a gas-phase molecule onto a heterogeneous catalyst surface, subsequent reaction between adsorbed species, and finally desorption of the resulting product(s) from the surface. Instead of reactions between adsorbed species, the Eley-Rideal (ER) mechanism formulated in the 1930s proposes an elementary step where a gas-phase species reacts directly with an adsorbed surface

species. Finally, the Mars-van Krevelen (MvK) mechanism describes a surface redox reaction where oxygen is provided by the metal oxide catalyst to an adsorbate reducing the metal oxide which is subsequently oxidized by adsorbed oxygen to complete the cycle. These reaction schemes form the backbone of modern surface reaction mechanisms. Because several elementary steps are postulated in these mechanisms, this modeling approach requires parameters for each step, including activation energies, pre-exponential factors, sticking coefficients for adsorption, and catalyst site densities. In early years, closed-form LHHW or ER rate expressions were derived by postulating the quasi-steady-state approximation (QSSA), partially equilibrated reactions, rate-determining step(s) (RDS), and most abundant surface intermediates (MASI). Regression to experimental data is still commonly used to estimate the parameters of these overall rate expressions. These reduced rate equations avoid the estimation of a large number of unknown parameters, but they are usually less predictive than full microkinetic models because their assumptions are often not valid over a broad range of reaction conditions.

The birth of microkinetic modeling (MKM) is often attributed to Dumesic and Rudd due to their 1993 book of "The Microkinetics of Heterogeneous Catalysis" (Dumesic and Rudd 1993). MKM breaks down a reaction mechanism into all known elementary steps without the aforementioned a priori assumptions. Instead, the rate constants of all elementary steps are estimated and the governing equations for surface and fluid (gas- or liquid-phase) species are numerically solved. Determining accurately the many kinetic parameters is a limiting factor of this modeling approach. In the early days of MKM, this requirement limited the application of MKM to simple reactions, like CO and H_2 oxidation, where enough experimental data was available to estimate individual parameters. In the late 1990s, the bond-order conservation (BOC) method (Shustorovich 1986, 1990) was employed for the first time in parametrizing MKMs (Park et al. 1999; Aghalayam et al. 2000). BOC estimates activation energies from heats of adsorption and even allows for the estimation of molecular heats of adsorption from the atomic ones, such as C, O, N, H, and S. These atomic heats of adsorption are in essence descriptors of thermochemistry and activation energies. In addition, due to the possible dependence of heats of adsorption on coverage (the fraction of surface sites occupied by a species), BOC provides a systematic way of incorporating coverage effects (non-idealities) on the activation energies and obtaining insights into reactivity (Park et al. 1999; Aghalayam et al. 2000).

BOC is a simple but empirical method whose accuracy remains (in most cases) unknown until tested against experimental data. The accuracy of this method becomes even more questionable for complex species (dehydrogenated intermediates, multifunctional molecules) anchoring on a surface in many, often multi-dentate configurations. These shortcomings obviously limit BOC's applicability. With the parallel evolution of both computing power and computational techniques, such as density functional theory (DFT), first-principles-based MKM is flourishing. Parameterization of moderate size reaction mechanisms using DFT is now possible; yet, parameterization of large reaction mechanisms remains a challenge (Sutton and Vlachos 2015). MKM results enable clear assessment of reaction paths, MASI,

RDS, and provide guidelines for catalyst design that promote desired reaction paths with the ultimate goal to improve catalyst selectivity and activity.

This chapter focuses on describing the basics of MKM. It also details how kinetic and thermodynamic parameters are derived from first principles using transition state theory and statistical mechanics while also addressing thermodynamic consistency. Finally, the chapter covers analysis techniques that provide key insights into the reaction mechanism. We focus primarily on the ammonia decomposition chemistry as an illustrative example.

2   Reaction Mechanism

A reaction mechanism, composed of elementary steps, is key to MKM. As an example, the overall ammonia synthesis reaction from nitrogen and hydrogen is written as

$$N_2 + 3H_2 \rightleftarrows 2NH_3 \tag{2}$$

An elementary step is a reaction that describes a molecular event and cannot be broken down into more steps. In the case of ammonia synthesis, one starts with the adsorption of each of the reactants on the active site of the catalyst surface:

$$N_2 + * \rightleftarrows N_2^* \qquad\qquad H_2 + * \rightleftarrows H_2^* \tag{3}$$

Here * represents an unoccupied active site while N_2^* and H_2^* represent the adsorbed hydrogen and nitrogen molecules on the surface. Subsequently, each species dissociates from its molecular form to its atomic form

$$N_2^* + * \rightleftarrows 2N^* \qquad\qquad H_2^* + * \rightleftarrows 2H^* \tag{4}$$

Hydrogen atoms are then added sequentially to nitrogen

$$NH_{x-1}^* + H^* \rightleftarrows NH_x^* + * \tag{5}$$

Ammonia finally desorbs from the surface

$$NH_3^* \rightleftarrows NH_3 + * \tag{6}$$

Alternative reaction paths may also be considered. For example, does molecular hydrogen associate directly with N* to form adsorbed NH_2? Does H_2 physisorb or dissociate directly? Previous studies have shown that hydrogen dissociates rapidly on active metal surfaces, and thus, the hydrogen adsorption is taken as dissociative

$$H_2 + 2^* \rightleftarrows 2H^* \tag{7}$$

As another example, the CO_2 formation in the water-gas-shift reaction was assumed in early days to proceed via water dissociation to oxygen followed by oxidation of CO: $H_2O \rightarrow OH + H$, $OH \rightarrow O + H$, and $CO + O \rightarrow CO_2$. It was subsequently realized that the carboxyl pathway, following partial water dissociation, i.e., $H_2O \rightarrow OH + H$, $CO + OH \rightarrow COOH \rightarrow CO_2 + H$, is in fact the key (preferred) path that was missing in early mechanisms (Mhadeshwar and Vlachos 2004). These examples underscore the diversity of possible reaction schemes and showcase the experience required in assembling a valid reaction mechanism.

An implicit assumption of the above mechanisms is the presence of a single type of active site. As is often the case for heterogeneous catalysts, multiple sites of different activity usually exist on a catalyst. For example, ruthenium (Ru), a well-known ammonia synthesis catalyst, has at least two well-described sites; terrace sites on planes of low Miller indices and B5 step sites located at the edges of nanocrystals. Representing both site types requires parallel sets of elementary steps.

Terrace Sites

$$N_2 + *(t) \underset{k^t_{1_b}}{\overset{k^t_{1_f}}{\rightleftarrows}} N_2(t)$$

$$N_2(t) + *(t) \underset{k^t_{2_b}}{\overset{k^t_{2_f}}{\rightleftarrows}} 2N(t)$$

$$H_2 + 2^*(t) \underset{k^t_{3_b}}{\overset{k^t_{3_f}}{\rightleftarrows}} 2H(t)$$

$$N(t) + H(t) \underset{k^t_{4_b}}{\overset{k^t_{4_f}}{\rightleftarrows}} NH(t) + *(t)$$

$$NH(t) + H(t) \underset{k^t_{5_b}}{\overset{k^t_{5_f}}{\rightleftarrows}} NH_2(t) + *(t)$$

$$NH_2(t) + H(t) \underset{k^t_{6_b}}{\overset{k^t_{6_f}}{\rightleftarrows}} NH_3(t) + *(t)$$

$$NH_3(t) \underset{k^t_{7_b}}{\overset{k^t_{7_f}}{\rightleftarrows}} NH_3 + *(t)$$

Step Sites

$$N_2 + *(s) \underset{k^s_{1_b}}{\overset{k^s_{1_f}}{\rightleftarrows}} N_2(s)$$

$$N_2(s) + *(s) \underset{k^s_{2_b}}{\overset{k^s_{2_f}}{\rightleftarrows}} 2N(s)$$

$$H_2 + 2^*(s) \underset{k^s_{3_b}}{\overset{k^s_{3_f}}{\rightleftarrows}} 2H(s)$$

$$N(s) + H(s) \underset{k^s_{4_b}}{\overset{k^s_{4_f}}{\rightleftarrows}} NH(s) + *(s)$$

$$NH(s) + H(s) \underset{k^s_{5_b}}{\overset{k^s_{5_f}}{\rightleftarrows}} NH_2(s) + *(s)$$

$$NH_2(s) + H(s) \underset{k^s_{6_b}}{\overset{k^s_{6_f}}{\rightleftarrows}} NH_3(s) + *(s)$$

$$NH_3(s) \underset{k^t_{7_b}}{\overset{k^t_{7_f}}{\rightleftarrows}} NH_3 + *(s)$$

Diffusion (Step ↔ Terrace)

$$N_2(t) + *(s) \underset{k^{s \to t}_{1_b}}{\overset{k^{t \to s}_{1_f}}{\rightleftarrows}} N_2(s) + *(t)$$

$$N(t) + *(s) \underset{k^{s \to t}_{2_b}}{\overset{k^{t \to s}_{2_f}}{\rightleftarrows}} N(s) + *(t)$$

$$H(t) + *(s) \underset{k^{s \to t}_{3_b}}{\overset{k^{t \to s}_{3_f}}{\rightleftarrows}} H(s) + *(t)$$

$$NH(t) + *(s) \underset{k^{s \to t}_{4_b}}{\overset{k^{t \to s}_{4_f}}{\rightleftarrows}} NH(s) + *(t)$$

$$NH_2(t) + *(s) \underset{k^{s \to t}_{5_b}}{\overset{k^{t \to s}_{5_f}}{\rightleftarrows}} NH_2(s) + *(t)$$

$$NH_3(t) + *(s) \underset{k^{s \to t}_{6_b}}{\overset{k^{t \to s}_{6_f}}{\rightleftarrows}} NH_3(s) + *(t)$$

$$(8)$$

The simple ammonia synthesis reaction is represented by 14 reversible adsorption, surface, and desorption reactions, and six reversible diffusion steps between sites (these represent the overall process; the distance among sites can also be important). In total, there are 20 distinct gas and surface species. Bimolecular reactions between species in adjacent but different sites, e.g., a terrace and a step site, entail interfacial reactions that require different parameters compared to reactions between species on the same type of site. An example of such study revealing this complexity is the water-gas shift reaction (Stamatakis et al. 2011). As a result, while consideration of multiple sites is in principle

straightforward, the number of reactions and species in these multisite or multifunctional catalysts increases greatly, making the parameterization task more demanding.

3   Mean-Field Approximation

A common assumption in MKM is the so-called mean-field approximation. In mean-field MKM, all the surface species and active sites are assumed to be uniformly distributed at the nanometer scale; this does not imply a fully spatially uniform system. Indeed, nonuniformity over larger, reactor scales can easily be handled in the mean-field framework using a spatially distributed reactor model. Reaction-diffusion partial differential equations-based (mean-field) models on catalyst surfaces have also been employed to describe long-range patterns, e.g., traveling waves (Raimondeau and Vlachos 2003). The application of Fickian diffusion is often another approximation in these diffusion-reaction models.

In mean-field modeling, rate constants depend on the "mean," i.e., the average, coverage, rather than the microscopic distribution of adsorbates and catalyst sites. This does not preclude the ability to define different catalyst sites or diffusion from one type of site to another; rather this is done based on the average density of each site type. In contrast, kinetic Monte-Carlo (KMC) methods describe surface species and catalyst sites with atomic resolution and explicitly account for nanoscale inhomogeneities (Stamatakis and Vlachos 2012). The large computational demand and need for expert knowledge of statistical mechanics for data analysis make currently widespread use of KMC simulation rather limited. In this chapter, we present the mean field approach because it is instructive and the only viable method for large mechanisms. In a later section, there is a discussion about adding lateral interactions (coverage effects). For the interested reader, other approximations for the distribution of adsorbates are discussed in Hill (1962). What is important is that all these methods for spatially averaging microscopic information allows us to compute the reaction rate at different levels of accuracy. In mean-field, we use a uniform distribution of adsorbates; in KMC, we solve for the exact distribution of adsorbates (within numerical accuracy of the stochastic method) subject to the overall kinetics imposed as constraints (this is not an equilibrium Monte Carlo calculation typically taught in statistical mechanics books; rather it is often far from equilibrium conditions).

4   Mass-Action Kinetics

Once the reaction mechanism is described in elementary steps, mass-action kinetics is typically used to describe each step. The rate (r_i) of a single elementary step i can be written as:

$$r_i = k_i \prod_j \theta_j^{\alpha_{ij}} \tag{9}$$

where k_i is the rate constant of elementary step i, while θ_j are the coverages of surface species j with α_{ji} their stoichiometric coefficients in elementary step i.

5   Transition-State Theory (TST)

TST assumes that for any activated elementary step, there exists equilibrium between reactants and the activated complex. In 1910, French chemist Marcelin proposed that the rate constant is proportional to the exponential of the change in standard Gibbs free energy from reactant to transition state ($\Delta G^{\circ}{}_i^{\ddagger}$) with the pre-exponential factor as the proportionality constant (Laidler and King 1983)

$$k_i \propto e^{-\left(\frac{\Delta G^{\circ \ddagger}_i}{k_B T}\right)} \qquad\qquad A_i = \frac{k_B T}{h} \tag{10}$$

The pre-exponential part of this expression ($k_B T/h$), where k_B is Boltzmann's constant, h is Planck constant and T is temperature, approximates the contribution from the frequency associated with the negative curvature of the potential energy surface in the direction of the reaction coordinate (Salciccioli et al. 2011). By breaking down the Gibbs free energy change to its enthalpic and entropic contributions (see Fig. 1), the above equation can be rewritten as

$$k_i = \left(\frac{k_B T}{h}\right) e^{-\left(\frac{\Delta G^{\circ \ddagger}_i}{k_B T}\right)} = \left(\frac{k_B T}{h}\right) e^{\left(\frac{-\Delta H^{\circ \ddagger}_i}{k_B T}\right)} e^{\left(\frac{\Delta S^{\circ \ddagger}_i}{k_B}\right)} \tag{11}$$

Fig. 1 Schematic of reaction coordinate. (Taken from Salciccioli et al. (2011))
As will be explained later, the resulting equation connects first-principles DFT and statistical mechanics to the rate constant. TST is applied to all surface processes that are activated. Examples of such processes include Langmuir-Hinshelwood surface reaction, desorption, and surface diffusion.

6   Collision Theory and Adsorption Rate

Unlike activated processes described using TST (see above), adsorption is often nonactivated. Collision theory defines the molecular flux (N_j) of adsorbing gases on a catalyst surface

$$N_{j,collisions} = \frac{P_j}{\sqrt{2\pi m_j k_B T}} \ [=] \left(\frac{1}{m^2 \cdot s}\right) \tag{12}$$

Here P_j is the partial pressure of species j, m_j is the molecular weight of species j, k_B is the Boltzmann constant, and T is the temperature. Since not all collisions result in a molecule adsorbing on the surface, the adsorption rate (r_j) is obtained by the product of the incident molecular flux and a dimensionless probability factor known as the sticking coefficient ($0 \leq \gamma \leq 1$)

$$r_j = N_{j,collisions} \cdot \gamma_j = \frac{P_j \gamma_j}{\sqrt{2\pi m_j k_B T}} \tag{13}$$

The adsorption rate constant (k_j) can then be expressed as

$$k_j = \frac{\gamma_j}{\sqrt{2\pi m_j k_B T}} \ [=] \left(\frac{1}{Pa \cdot m^2 \cdot s}\right) \tag{14}$$

An assumption implicit in the sticking coefficient is that it is much less than one (Coltrin et al. 1996; Motz and Wise 1960). That suggests that the gases near the surface behave randomly and are not impacted by surface reactions. As the sticking coefficient nears one, the implicit Maxwell velocity distribution becomes distorted and the rate of adsorption increases. To correct for this, the simple sticking coefficient is replaced with a Motz-Wise corrected sticking coefficient

$$\gamma_{j,corrected} = \frac{\gamma_j}{1 - \gamma_j/2} \tag{15}$$

The corrected versus uncorrected sticking coefficient is shown in Fig. 2. For activated adsorption, the rate constant is multiplied by a Boltzmann factor to account for the reduced probability of incoming molecules to overcome the adsorption barrier and stick to the surface.

Fig. 2 Comparison of an uncorrected sticking coefficient with the Motz-Wise corrected sticking coefficient. (Motz and Wise 1960; Coltrin et al. 1996)
7 Thermodynamic Consistency

A microkinetic model for heterogeneous catalysis involves both gas and surface species. As thermodynamic data are developed for each phase often separately, it is critical to ensure thermodynamic consistency between surface and gas-phase. This constraint is illustrated with the thermodynamic cycle of Fig. 3. Since DFT is not very accurate for gas-phase species, use of DFT for estimation of gas-phase thermochemistry can lead to inaccurate free energies and large errors in overall equilibrium constants. Instead, high-level ab initio or experimental methods (see NIST database) are used to estimate – with chemical accuracy – gas-phase thermochemistry. On the other hand, surface thermochemistry is typically calculated at the DFT theory level since the investigated surface models are of considerable size and higher-level theoretical methods are often not applicable due to the very unfavorable scaling of computational costs. The use of a different methodology for each phase causes a mismatch between gas and surface thermochemistries. There are two ways to remedy this mismatch.

7.1 Adjusting Surface Reaction Properties

The surface reaction state properties can be related to those of the corresponding gas-phase reactions by a thermodynamic cycle (Fig. 3)

$$\zeta_{i,surf}(T,\theta) = \zeta_{i,gas}(T) + \Delta\zeta_{i,ads}(T,\theta) \tag{16}$$

Here ζ is a surface or gas species thermodynamic (state) property (i.e., enthalpy, entropy, or free energy) of reaction i and $\Delta\zeta_{i,ads}$ is the difference in the correspond-

ing adsorption properties of products from those of reactants for reaction i. Such thermodynamic cycles can be written for each reaction.
Practically, temperature dependent (NASA) polynomials, describing the thermochemistry of gas-phase species, are commonly used as given below. Surface thermochemistry is described by similar polynomials with the same coefficients a_1-a_5. The coefficients $a_{6,surf}$ and $a_{7,surf}$ of surface species are related to those in the gas a_6 and a_7 as follows (it can easily be shown that this choice yields thermodynamic consistency).

$$\frac{C_p^\circ}{R} = a_1 + a_2 T + a_3 T^2 + a_4 T^3 + a_5 T^4$$

$$\frac{H^\circ}{RT} = a_1 + a_2 \frac{T}{2} + a_3 \frac{T^2}{3} + a_4 \frac{T^3}{4} + a_5 \frac{T^4}{5} + \frac{a_6}{T} \qquad \begin{aligned} a_{6,surf} &= a_{6,gas} + \frac{\Delta H^\circ_{ads}(T,\theta)}{R} \\ a_{7,surf} &= a_{7,gas} + \frac{\Delta S^\circ_{ads}(T,\theta)}{R} \end{aligned}$$

$$\frac{S^\circ}{R} = a_1 \ln T + a_2 T + a_3 \frac{T^2}{2} + a_4 \frac{T^3}{3} + a_5 \frac{T^4}{4} + a_7$$

$$(17)$$

Here ΔH°_{ads} and ΔS°_{ads} are the standard heat and entropy of adsorption, respectively. When adsorption data are well-known, e.g., from experiments, one estimates $a_{6,surf}$ and $a_{7,surf}$. Then the surface reaction thermochemistry is estimated. A more detailed discussion is found in Mhadeshwar et al. (2003).

7.2   Adjusting Adsorption Properties

It is generally accepted that DFT is more accurate in estimating surface reaction properties due to cancelation of errors. Given this fact, one can estimate the surface thermochemistry via DFT and adjust the adsorption properties to close the thermodynamic cycles (Fig. 3). The thermodynamic properties of the surface species are determined by regressing the heat capacity DFT data computed via

statistical mechanics for the surface species. To achieve thermodynamic consistency, a reference set of gas species is selected as a basis such that (1) all the atoms in the surface species are represented in the reference set, (2) there are at least as many gas species in the reference set as the different atoms in the reference set, and (3) the reference gas species have well-known formation energies. These reference gases form the basis set upon which the surface species thermochemistry data is referenced to achieve thermodynamic consistency. The difference in formation energy of a gas species in the basis set computed by DFT from its experimental or high-level ab initio value represents the error in the formation energy of the adsorbed species. This difference is attributed to each atom of the reference species via least squares fit. Adding the total correction for each species to the $a_{6,surf}$ and $a_{7,surf}$ coefficients results in a surface species thermodynamic polynomial with the same reference state as the gas species (Nicolaides et al. 1996; Wijaya et al. 2003).

The error introduced by the least squares fitting in this approach can be quantified by a fourfold cross-validation. Using this methodology, a root mean squared error of ~1.65 kcal/mol is found for a reference set of 13 gas-phase molecules (C_2H_4, C_2H_6, CH_4, H_2, H_2O, $(CH_2)_4O$, $(CH_3)_2CO$, C_4H_{10}, C_5H_{12}, C_5H_{10}, C_3H_8, $C_2H_5OCH_3$, CH_3OCH_3). This value is a good indicator of the order-of-magnitude of the error introduced.

8   Surface Species Lateral Interactions

One of the shortcomings of the mean-field model is that it ignores many-body interactions. To correct this deficiency, the enthalpy of a surface species is modified based on the coverage of each adsorbate. DFT is used to calculate the adsorption energy versus coverage. The change in adsorption energy is regressed and used in the MKM. An example is shown in Fig. 4.

Fig. 4 N-N (self) pair lateral interaction adsorption energy [kcal/mol] versus N coverage varying linearly (blue) or piecewise with a zero-effect below 0.25 coverage of N (orange). (Nørskov 1993; Guo and Vlachos 2013, 2015a)
9   Kinetic and Thermodynamic Parameter Estimation

9.1   Partition Functions

The translational, rotational, vibrational, electronic, and nuclear partition functions contribute to the overall as

$$Q_{tot} = q_{trans} \cdot q_{rot} \cdot q_{vib} \cdot q_{elect} \cdot q_{nuclear} \qquad (18)$$

The model often uses the first three partition functions since the electronic and nuclear contributions are much smaller than the uncertainty in the first three. The translational partition function is defined as

$$q_{trans} = \frac{V}{\Lambda^3}, \text{ where} \left. \begin{array}{l} V \text{ is the volume in which the molecule is contained} \\ \Lambda \text{ is the de Broglie } wavelength \text{ and defined as } \Lambda = \sqrt{\frac{h^2}{2\pi m k_B T}} \end{array} \right.$$
$$h = \text{Planck}'s \text{ constant}; \quad k_B = \text{Boltzmann}'s \text{ constant};$$
$$m = \text{mass of } a \text{ molecule}; \quad T = \text{temperature}$$
$$(19)$$

The relationship can be further simplified for a gas adsorbing on the surface of a heterogeneous catalyst into

$$q_{trans} = q_{trans,2D} \cdot \ell_z \cdot \frac{\sqrt{2\pi m k_B T}}{h}; \quad (\ell_z \text{ distance of the gas from the surface})$$
$$q_{trans,2D} = A_{st} \cdot \frac{2\pi m k_B T}{h^2}; \quad \left(\begin{array}{l} A_{st} = \text{the effective area of the site } (s) \\ \text{where the reaction takes place.} \end{array} \right)$$
$$(20)$$

The rotational molecular partition function for a linear molecule is

$$q_{rot} = \frac{8\pi^2 I k_B T}{\sigma h} \qquad (21)$$

For a nonlinear molecule with three moments of inertia, one has

$$q_{rot} = \frac{\left(\pi \cdot I_x \cdot I_y \cdot I_z \right)^{1/2}}{\sigma} \left(\frac{8\pi^2 k_B T}{h^2} \right)^{\frac{3}{2}} \qquad (22)$$

where σ is the number of indistinguishable orientations (i.e., symmetry number) of the molecule and I is the moment of inertia. Lastly, the vibrational contribution is the product of the contribution of each vibrational mode.

$$q_{vib,ZPE} = \prod_k \frac{\exp\left(-\frac{h \cdot \nu_k}{2 \cdot k_B \cdot T}\right)}{1-\exp\left(-\frac{h \cdot \nu_k}{k_B \cdot T}\right)}; \quad \text{where} \left.\begin{array}{l}\\ \end{array}\right\} \quad \begin{array}{l} \nu_k = \text{Each of the vibration frequencies of} \\ \qquad \text{that molecular configuration } \left(s^{-1}\right) \end{array}$$

$$E_{ZPE} = \sum_k \frac{h \cdot \nu_k}{2}$$

Set zero-point energy to 0 in the vibrational partition function and account for it in the *activation* energy.

$$q_{vib} = \prod_k \frac{1}{1-\exp\left(-\frac{h \cdot \nu_k}{k_B \cdot T}\right)}$$

$$(23)$$

9.2   Thermodynamic-Temperature Relationships

Thermodynamic quantities such as heat capacity, enthalpy, and entropy expressed as a function of temperature (Eq. 17) are necessary to estimate reverse rate constants. While it is possible to calculate these quantities directly using the statistical mechanics equations while solving the MKM, it is more efficient and common to use simple polynomial relationships. The statistical mechanics treatment is found in more detail in books, e.g., Sandler (2010) and Hill (1962). The relevant quantities are calculated as follows.

Heat Capacity

Linear molecules

$$\frac{C_p}{R} = \underbrace{\sum_i \left(\frac{\Theta_{v,i}}{T}\right)^2 \frac{e^{-\Theta_{v,i}/T}}{\left(1-e^{-\Theta_{v,i}/T}\right)^2}}_{\substack{\text{Vibrational} \\ \text{contribution}}} + \underbrace{\frac{3}{2}}_{\substack{\text{Rotational} \\ \text{contribution}}} + \underbrace{1}_{\substack{\text{Translational} \\ \text{contribution}}} + \underbrace{1}_{\substack{C_v \text{ to } C_p \\ C_v = C_p + R \\ \frac{C_v}{R} = \frac{C_p}{R} + 1}}$$

$$(24)$$

Non-linear molecules

$$\frac{C_p}{R} = \underbrace{\sum_i \left(\frac{\Theta_{v,i}}{T}\right)^2 \frac{e^{-\Theta_{v,i}/T}}{\left(1-e^{-\Theta_{v,i}/T}\right)^2}}_{\substack{\text{Vibrational} \\ \text{contribution}}} + \underbrace{\frac{3}{2}}_{\substack{\text{Rotational} \\ \text{contribution}}} + \underbrace{\frac{3}{2}}_{\substack{\text{Translational} \\ \text{contribution}}}$$

$$(25)$$

$$+ \underbrace{1}_{\substack{C_v \text{ to } C_p \\ C_v = C_p + R \\ \frac{C_v}{R} = \frac{C_p}{R} + 1}}$$

Enthalpy

Linear molecules

$$\frac{H}{RT} = \underbrace{\sum_i \frac{\Theta_{v,i}}{2T} + \frac{\Theta_{v,i}}{T} \frac{e^{-\Theta_{v,i}/T}}{1 - e^{-\Theta_{v,i}/T}}}_{\substack{\text{Vibrational} \\ \text{contribution}}} + \underbrace{\frac{3}{2}}_{\substack{\text{Rotational} \\ \text{contribution}}} + \underbrace{1}_{\substack{\text{Translational} \\ \text{contribution}}}$$

$$+ \underbrace{RT}_{\substack{\text{Convert U to H} \\ H = U + PV}} + \underbrace{E_{\text{zero point}} + E_{\text{dft total}}}_{\text{Energies from DFT}}$$

(26)

Non-linear molecules

$$\frac{H}{RT} = \underbrace{\sum_i \frac{\Theta_{v,i}}{2T} + \frac{\Theta_{v,i}}{T} \frac{e^{-\Theta_{v,i}/T}}{1 - e^{-\Theta_{v,i}/T}}}_{\substack{\text{Vibrational} \\ \text{contribution}}} + \underbrace{\frac{3}{2}}_{\substack{\text{Rotational} \\ \text{contribution}}} + \underbrace{\frac{3}{2}}_{\substack{\text{Translational} \\ \text{contribution}}}$$

$$+ \underbrace{RT}_{\substack{\text{Convert U to H} \\ H = U + PV}} + \underbrace{E_{\text{zero point}} + E_{\text{dft total}}}_{\text{Energies from DFT}}$$

(27)

Entropy

Linear molecules

$$\frac{S}{R} = \underbrace{\sum_i \frac{\Theta_{v,i}}{T} \frac{e^{-\Theta_{v,i}/T}}{1 - e^{-\Theta_{v,i}/T}} - \ln\left(1 - e^{-\Theta_{v,i}/T}\right)}_{\substack{\text{Vibrational} \\ \text{contribution}}} + \underbrace{1 + \ln\frac{T}{\sigma \Theta_r}}_{\substack{\text{Rotational} \\ \text{contribution}}}$$

$$+ \underbrace{\frac{5}{2} + \ln\left[\left(\frac{2\pi \sum_i m_i k_B T}{h^2}\right)^{\frac{3}{2}} \frac{1}{P}\right]}_{\substack{\text{Translational} \\ \text{contribution}}}$$

(28)

Non-linear molecules

$$\frac{S}{R} = \underbrace{\sum_i \frac{\Theta_{v,i}}{T} \frac{e^{-\Theta_{v,i}/T}}{1 - e^{-\Theta_{v,i}/T}} - \ln\left(1 - e^{-\Theta_{v,i}/T}\right)}_{\substack{\text{Vibrational} \\ \text{contribution}}} + \underbrace{\frac{3}{2} + \ln\left(\frac{\sqrt{\pi}}{\sigma}\sqrt{\frac{T^3}{\Theta_x\Theta_y\Theta_z}}\right)}_{\substack{\text{Rotational} \\ \text{contribution}}}$$

$$\underbrace{+\frac{5}{2} + \ln\left[\left(\frac{2\pi \sum_i m_i k_B T}{h^2}\right)^{\frac{3}{2}} \frac{1}{P}\right]}_{\substack{\text{Translational} \\ \text{contribution}}}$$

where the vibrational and inertial temperatures are defined as

$\Theta_{v,i} = \frac{v_i h}{k_B}$; $v_i = i^{\text{th}}$ vibrational frequency $\left[s^{-1}\right]$

$\Theta_k = \frac{8\pi^2 I_k k_B}{h^2}$; $I_k =$ moment of inertia in the k-plane

$$(29)$$

Gas species include all three molecular partition functions while surface species often include only the vibrational component. Also, since PV is omitted for surface species (Reuter and Scheffler 2001; Mhadeshwar et al. 2004), the terms that convert C_V to C_P and U to H are not included in the calculation for surface species

$$H = U + PV; \quad \text{If } PV \ll 1 \quad \therefore \quad U \approx H;$$
$$U = \int C_V dT \quad and \quad H = \int C_P dT$$
$$\int C_V dT = \int C_P dT \quad \therefore \quad C_V = C_P$$

$$(30)$$

The heat capacity NASA fourth-order polynomial (Eq. 17) is commonly used and fitted to heat capacity-temperature data over a desired temperature range. Depending on the size of the temperature range and the goodness of the fit, it may be appropriate to divide the polynomial into two temperature ranges while ensuring that there is no discontinuity between the two.

9.3 Activation Energy and Pre-exponential Factor

Activation energies are calculated from the heats of formation of the transition state [TS] and the reactants as

$$E_a = \Delta E^{\ddagger} = FE\,[\text{TS}] - FE\,[\text{Reactants}]$$

$$FE\,[\text{TS}] = E_{DFTE}\,[\text{TS}] + E_{ZPE}\,[\text{TS}] - E_{DFTE}\,\big[\text{Catalyst Surface}\big]$$
$$\quad - \sum_i E\,[\text{Gas}_i]$$

$$FE\,[\text{Reactants}] = \sum_i \big(E_{DFTE}\,[\text{Reactant}_i] + E_{ZPE}\,[\text{Reactant}_i]$$
$$\quad - E_{DFTE}\,\big[\text{Catalyst Surface}\big] - E\,[\text{Gas}_i]\big) \tag{31}$$

$$FE = \text{Formation Energy};\ E_{DFTE} = \text{DFT\ Energy};$$

$$E_{ZPE} = \sum_k \frac{h \cdot v_k}{2} = \text{Zero Point Energy}$$

$$E\,[\text{Gas}] = \text{Reference gas DFT computed energy including zero}$$
point energy.

The rate constant for Langmuir-Hinshelwood surface reactions between two adsorbed species ($X^* + Y^* \to Z^* + ^*$) can be written as

$$k_{surf}^{fwd} = \underbrace{\frac{q_{vib}^{\ddagger}}{q_{vib,X} \cdot q_{vib,Y}} \cdot \frac{k_B \cdot T}{h}}_{\text{Pre-exponential factor}} \exp \underbrace{\left(-\frac{\Delta E^{\ddagger}}{k_B \cdot T}\right)}_{\Delta E^{\ddagger} = \ \text{Activation Energy}} \ \big[\sec^{-1}\big] \tag{32}$$

$$k_{surf}^{rev} = \frac{q_{vib}^{\ddagger}}{q_{vib,Z}} \cdot \frac{k_B \cdot T}{h} \exp\left(-\frac{\Delta E^{\ddagger} - \Delta E_{rxn}}{k_B \cdot T}\right) \ \big[\sec^{-1}\big]. \tag{33}$$

It is worth noting that surface species often have no translational or rotational degrees of freedom and have instead vibrational degrees of freedom (mobile species exist when adsorption is weak).

The expression for the rate constant of ER reactions ($X_{gas} + Y^* \to Z^*$) is

$$k_{\text{Eley-Rideal}}^{fwd} = \frac{q_{vib}^{\ddagger}}{Q_{gas} \cdot q_{vib,Y^*}} \cdot \frac{p_{gas} A_{st}}{\sqrt{2\pi m_X k_B T}} \exp\left(-\frac{\Delta E^{\ddagger}}{k_B T}\right) \ \big[\sec^{-1}\big] \tag{34}$$

$$Q_{gas} = q_{trans2D,X_{Gas}} \cdot q_{rot,X_{Gas}} \cdot q_{vib,X_{Gas}}$$

$$k_{\text{Eley-Rideal}}^{rev} = \frac{q_{vib}^{\ddagger}}{q_{vib,Z^*}} \cdot \frac{k_B T}{h} \exp\left(-\frac{\Delta E^{\ddagger} - \Delta E_{rxn}}{k_B T}\right) \ \big[\sec^{-1}\big] \tag{35}$$

These equations depend on the 2D-translational partition function and the effective area of the reaction site(s) (A_{st}) which is the area of the catalyst site on which adsorption takes place.

Finally, the rate constant for both activated and non-activated adsorption of gases to/from the catalyst surface described by the LHHW mechanism ($X_{gas} + * \rightarrow X*$) is calculated as

$$k^{fwd}_{\text{Activated adsorption}} = \frac{q^{\ddagger}_{vib}}{Q_{gas}} \cdot \frac{A_{st}}{\sqrt{2\pi m_X k_B T}} \exp\left(-\frac{\Delta E^{\ddagger}}{k_B T}\right) \quad \left[\sec^{-1} \cdot \text{pressure}^{-1}\right]$$

$$Q_{gas} = q_{trans2D,X_{Gas}} \cdot q_{rot,X_{Gas}} \cdot q_{vib,XGas} \tag{36}$$

$$k^{rev}_{\text{Activated adsorption}} = \frac{q^{\ddagger}_{vib}}{q_{vib,Z^*}} \cdot \frac{k_B T}{h} \exp\left(-\frac{\Delta E^{\ddagger} - \Delta E_{ads}}{k_B T}\right) \quad \left[\sec^{-1}\right] \tag{37}$$

$$k^{fwd}_{\text{Non-activated adsorption}} = \frac{A_{st}}{\sqrt{2\pi m_X k_B T}} \quad \left[\sec^{-1} \cdot \text{pressure}^{-1}\right]. \tag{38}$$

Alternatively, the reverse rate constant for the aforementioned reactions can also be calculated from the equilibrium constant, which in turn is calculated from the Gibbs free energy

$$K_{eq} = \frac{k^{fwd}}{k^{rev}} \qquad\qquad K_{eq} = e^{\frac{-\Delta G}{RT}} = e^{\frac{-(\Delta H - T\Delta S)}{RT}} = e^{-\left(\frac{\Delta H}{RT} - \frac{\Delta S}{R}\right)} \tag{39}$$

10   Brønsted–Evans–Polanyi (BEP) Relationships

DFT calculations become impractical for large reaction networks. To overcome this challenge, BEP relationships can be used as they enable the prediction of reaction barriers from the heat of reactions for an entire homologous series of reactions (i.e., reactions with similar transition states). A BEP describes the reaction barrier $\Delta E_{a,i}$ of reaction i as a linear function of its heat of reaction

$$\Delta E_{a,i} = \omega \Delta H_{rxn,i} + \Delta E_0 \tag{40}$$

Here ω is the proximity factor (0–1) indicating the reaction coordinate position of the TS relative to the reactant and products (0 implies reactant-like whereas 1 product-like). The intercept ΔE_0 is called the intrinsic reaction barrier. Typical BEP relationships for NH_3 chemistry are shown in Fig. 5 (Falsig et al. 2014; Vojvodic et al. 2014). BEPs for common homologous series are available (Sutton and Vlachos 2012; Vojvodic et al. 2014; Guo and Vlachos 2015b). For new reactions, DFT calculations for a handful reactions of a homologous series can be carried out to build the BEP.

Fig. 5 BEP relationships for NH₃ decomposition. (Falsig et al. 2014; Vojvodic et al. 2014; Guo and Vlachos 2015a, b)
10.1   Linear Scaling Relationships (LSRs)

Linear scaling relationships (LSRs) relate the thermodynamic properties of surface species on one metal catalyst surface to those on another (reference) surface. Small adsorbates, such as AH_x, scale with the adsorption energy Q of the surface species A as

$$Q^{AH_x} = \alpha\,(x)\,Q^A + \beta \quad \alpha\,(x) = \frac{x_{\max} - x}{x_{\max}} \tag{41}$$

α is related to the valency of the species where $x_{\max}$ (C = 4, N = 3, O = 2, etc.) is the maximum number of ligands the central heteroatom can take and x is the actual number of ligands of the bound atom (Abild-Pedersen et al. 2007; Fernndez et al. 2008; Jones et al. 2008). Extended LSRs apply this relationship for small adsorbates to large, more complex, potentially multidentate (n = # dentates, j) species.

$$Q_{i,new} = Q_{i,ref} + \sum_{j=1}^{n} \gamma_{i,j} \left(Q_{new}^{ref\ species,j} - Q_{ref}^{ref\ species,j} \right) \tag{42}$$

Here $Q_{i,new}$ refers to the adsorption energy of the ith large species on a surface from a reference energy on another metal $Q_{i,ref}$, and the parenthesis is the corresponding difference for the heteroatoms via which adsorption occurs. The summation extends over all binding atoms (i) and dentates (j). This approach enables one to transfer thermochemistry from one metal to another without relying on expensive DFT calculations. An example where the surface reference species is N* (step) and the reference metal surface is Pt is shown in Fig. 6. These LSRs together with the aforementioned BEPs are used to parameterize the MKM discussed below.
Fig. 6 LSR relationships for ammonia surface species on step sites with Pt as a reference metal and N* adsorption on terrace sites as the reference surface species. (Abild-Pedersen et al. 2007; Falsig et al. 2014)

11   Reactor Equations

The dynamic and steady-state operation of ideal reactors (e.g., batch, continuous stirred-tank reactor [CSTR], or plug flow reactor [PFR]) combines the surface reactions described earlier in this chapter with a series of equations (e.g., ODE's or algebraic) that describe the concentrations of each gas and surface species and unoccupied active catalyst sites. The general extensive property conservation equation is

$$\rho \frac{\partial \overline{\omega}}{\partial t} + \rho \mathbf{u} \cdot \nabla \overline{\omega} = -\nabla \cdot \widehat{\mathbf{J}} + \widehat{\sigma} \tag{43}$$

where $\overline{\omega}$ is an extensive property, ρ the density, $\mathbf{u}$ the velocity vector, $\widehat{\mathbf{J}}$ the diffusive flux vector, and $\widehat{\sigma}$ the source/sink terms. Here the first term on the left is accumulation followed by inflow/outflow by convection and the first term on the right is inflow/outflow by diffusion followed by a generation term (i.e., reactions). This equation is further simplified for a CSTR where the diffusion term is not required and due to perfect mixing, the convective inflow/outflow gradient is just the mass flow in/out. Using the ammonia synthesis/decomposition mechanism described in Eq. 8, and focusing on catalyst step sites with a specific catalyst active-site density (Γ [=] mol_active_sites/area) and catalyst loading (A/V [=] area/volume) results in the following rate expressions (a compact vector notation can be used but we provide an introductory presentation herein for illustration purposes).

$$
\begin{aligned}
R1_f &= k_{1_f} [N_2][*] & R1_b &= k_{1_b} \left[N_2^*\right] \\
R2_f &= k_{2_f} \left[N_2^*\right][*] & R2_b &= k_{2_b} \left[N^*\right]^2 \\
R3_f &= k_{3_f} [H_2]\left[*\right]^2 & R3_b &= k_{3_b} \left[H^*\right]^2 \\
R4_f &= k_{4_f} \left[NH_3^*\right][*] & R4_b &= k_{4_b} \left[NH_2^*\right]\left[H^*\right] \\
R5_f &= k_{5_f} \left[NH_2^*\right][*] & R5_b &= k_{5_b} \left[NH^*\right]\left[H^*\right] \\
R6_f &= k_{6_f} \left[NH^*\right][*] & R6_b &= k_{6_b} \left[N^*\right]\left[H^*\right] \\
R7_f &= k_{7_f} [NH_3][*] & R7_b &= k_{7_b} \left[NH_3^*\right]
\end{aligned}
\tag{44}
$$

A set of ordinary differential equations (ODEs) describe the time-dependent concentration of each species in the reaction mechanism:

$$
\begin{aligned}
\frac{d\left[N_2^*\right]}{dt} &= R1_f + R2_b - R1_b - R2_f \\[6pt]
\frac{d\left[N^*\right]}{dt} &= 2R2_f + R6_f - 2R2_b - R6_b \\[6pt]
\frac{d\left[H^*\right]}{dt} &= 2R3_f + R4_f + R5_f + R6_f \\
&\quad - 2R3_b - R4_b - R5_b - R6_b \\[6pt]
\frac{d\left[NH_3^*\right]}{dt} &= R4_b + R7_f - R4_f - R7_b \\[6pt]
\frac{d\left[NH_2^*\right]}{dt} &= R4_f + R5_b - R4_b - R5_f
\end{aligned}
$$

$$
\begin{aligned}
\frac{d\left[NH^*\right]}{dt} &= R5_f + R6_b - R5_b - R6_f \\[6pt]
\frac{d[N_2]}{dt} &= R1_b - R1_f + \frac{Q_{in}}{V_{reactor}}[N_2]_{feed} - \frac{Q_{out}}{V_{reactor}}[N_2] \\[6pt]
\frac{d[H_2]}{dt} &= R3_b - R3_f + \frac{Q_{in}}{V_{reactor}}[H_2]_{feed} - \frac{Q_{out}}{V_{reactor}}[H_2] \\[6pt]
\frac{d[NH_3]}{dt} &= R7_b - R7_f + \frac{Q_{in}}{V_{reactor}}[NH_3]_{feed} - \frac{Q_{out}}{V_{reactor}}[NH_3] \\[6pt]
\frac{d[*]}{dt} &= R1_b - R1_f + R2_b - R2_f + 2R3_b \\
&\quad - 2R3_f + R4_b - R4_f + R5_b - R5_f \\
&\quad + R6_b - R6_f + R7_b - R7_f
\end{aligned}
\tag{45}
$$

The concentration of surface species above is expressed in [mol/vol] but often as surface coverage by dividing the adsorbate concentrations with the total site concentration ($\Gamma \times A/V$). The gas species ODEs also include terms to account for their volumetric inlet and outlet flow rate (Q_{in} and Q_{out}). While the inlet flow rate of gases is specified, the outlet flow rate must be determined and depends on how the reactor is operated, e.g., isochoric or isobaric. Using the same ammonia equations, the total exit flow rate of the CSTR is written as:

$$
Q_{out} = Q_{in} + \left[\frac{\left(R1_b - R1_f\right)_{N_2} + \left(R3_b - R3_f\right)_{H_2} + \left(R7_b - R7_f\right)_{NH_3}}{[N_2] + [H_2] + [NH_3]} \cdot V_{reactor} \right]
\tag{46}
$$

Here the term in square brackets represents the rate of volume change due to the changing number of moles of the reactant and products and can be excluded for an isochoric reactor or included for an isobaric reactor.

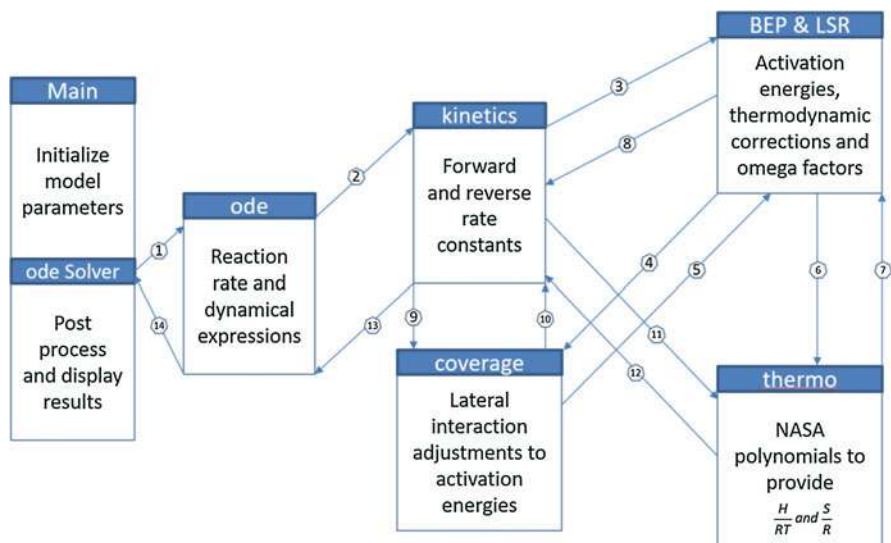
If the flow $Q_{in} = 0$, then the equations represent a batch reactor. A PFR model can similarly be written. In this example, only the material balance is considered (the reactor is assumed to be isothermal).


Fig. 7 Typical microkinetic model solution program flow

The system of ODEs is usually stiff, and its solution requires an implicit numerical method. A typical solution flow might look like Fig. 7 where key functions such as ODE solver, thermodynamics, kinetics, lateral interactions and BEP/LSR relationships are modularized and the modules pass relevant information of the model. The modules allow for simple troubleshooting. A module can easily be rewritten and inserted into the model to change the model capability without impacting other modules.

12 Microkinetic Model Data Analysis

The solution of the MKM yields the concentration of gaseous species, coverages of surface species, and reaction rates as well as conversion and selectivity. In addition, analysis of the MKM results can provide significant insights into the mechanism. The following sections describe such analysis tools focusing on the ammonia chemistry as a model example. (Ammonia decomposition simulation examples were performed in a Matlab based MKM using an NH_3 feed and Ru (step sites) catalyst. Model parameters: P = 1 atm, τ = 1 sec, Γ_{total} = 2.6 $\times$ 10^{-9} mol catalyst sites/cm^2, Γ_{step} = 4.4385 $\times$ 10^{-10} mol catalyst sites/cm^2, A/V = 1500 cm^3/cm^2. Kinetic parameters derived from BEP and LSR relationships. Complete model details and Matlab MKM code is found at https://github.com/VlachosGroup/NH3-Matlab-Microkinetic-Model.)
Fig. 8 Surface species coverage and conversion versus temperature for the decomposition of ammonia on ruthenium catalyst in a CSTR

12.1 Species Concentrations

The steady-state ammonia decomposition reaction MKM results versus temperature are shown in Fig. 8. The MASI changes from NH_2^* at very low temperatures to N_2^* and N^* at intermediate temperatures, to N^* and vacancies at sufficiently high temperatures.

12.2 Reaction Path Analysis (RPA)

In more complex reaction mechanisms, there are multiple paths from reactants to products and by-products. Understanding the primary paths and why one path is favored over another allow design of experiments to interrogate the mechanism and potentially predict new catalysts. The ammonia synthesis or decomposition involves only one key path. In the case of ammonia synthesis, this involves N_2 activation followed by subsequent hydrogenation and desorption. The forward, reverse and net reaction rates are computed for each elementary step and path. The net reaction rates (red bars) of all steps are all when balanced by the stoichiometric coefficients of the overall reaction. This simple comparison indicates that the solution obeys mass conservation. The large yellow and blue bars (from top to bottom in Fig. 9) for NH_3 adsorption, NH_2 dehydrogenation, NH dehydrogenation, H_2 desorption, and N_2 desorption indicate these steps are much faster than others, e.g., 2N* association
Fig. 9 Comparison of steady-state forward, reverse, and net reaction rates for ammonia decomposition at 750 K

and the first NH$_3$* dehydrogenation and will be most likely equilibrated. We will return to this point next but it suffices to state that the RDS is one or both of the two latter reaction steps.

12.3 Partial Equilibrium Analysis

It is often useful to understand which reaction steps are nearly in equilibrium since those steps tend not to be the RDS. A formal partial equilibrium analysis computes the partial equilibrium index (PEI) from the forward and backward reaction rates (Samant and Vlachos 2005).

$$PEI = \frac{R^{fwd}}{R^{fwd} + R^{rev}} \qquad (47)$$

Heuristically, it has been found that a reaction step with a PEI between 0.45 and 0.55 is in partial equilibrium. Again, using the ammonia decomposition as an example, it is clear that the nitrogen association reaction is non-equilibrated, whereas the first dehydrogenation reaction is nearly out of equilibrium. These steps are the likely RDS for this reaction. Analysis of partial equilibrium combined with MASI can be used to perform systematic mechanism reduction (Mhadeshwar and Vlachos 2004; Deshmukh and Vlachos 2007) (Fig. 10).
Fig. 10 Steady-state partial equilibrium index for ammonia decomposition at 750 K

12.4 Sensitivity Analysis

A sensitivity analysis reveals the RDS by intentionally varying the rate constant of each reaction by a differential factor and determining its impact on the overall reaction rate (e.g., represented by conversion). This is accomplished by multiplying both the forward and backward pre-exponential factors of each reaction step by the same small factor. The normalized sensitivity coefficient (NSC) is calculated from

$$NSC = \frac{d\,(\ln X)}{d\,(\ln A)} \approx \frac{\Delta\,(\ln X)}{\Delta\,(\ln A)} \tag{48}$$

where $d(\ln A)$ is a differential change in the pre-exponential factor of a specific reaction step and $d(\ln X)$ is the differential response of the system, in this case, the conversion; other quantities of interest can also be used.

Figure 11 shows that most reaction steps are kinetically irrelevant. The nitrogen association reaction is the most sensitive at all temperatures, while the first dehydrogenation reaction is relevant at temperatures above 750 K. At low temperatures, NH* dehydrogenation is significant too. The results are consistent with the partial equilibrium analysis. It is important to note that the RDS is not a single elementary reaction, but often a pair of reactions and the significance of these reactions can change with operating conditions, e.g., temperature, and the catalyst. MKM provides a systematic way of determining the RDS. Given that H abstraction can be kinetically significant, isotopically labeled ammonia can be used at various conditions to confirm model predictions. A kinetic isotope effect is expected at low and high temperatures but not one at 700–800 K. These model predictions can be assessed with experiments.

Fig. 11 Normalized sensitivity coefficients for ammonia decomposition on Ru catalyst over a range of temperatures
12.5   Potential Energy Diagram

The potential energy diagram is often presented at the zero-coverage limit, and the step with the highest barrier is typically assumed to be RDS. This oversimplification can lead to incorrect conclusions as the rate of the reaction depends on the coverage of species participating in a reaction and these coverages are often the result of local equilibrium of partially equilibrated reactions. MKM can provide coverages under reaction conditions (similar to "operando" spectroscopy) and correct the potential energy diagram.

The potential energy diagram for the ammonia decomposition mechanism on a clean catalyst surface and at steady-state coverages shows the significant impact of species coverages on the energetics for this reaction (orange and blue lines in Fig. 12, respectively). Specifically, the reaction barrier for the nitrogen association is significantly increased to 1.8 eV due to repulsive interactions and becomes the dominant reaction barrier to overcome at typical surface coverages. In contrast, the zero-coverage potential energy diagram shows the last dehydrogenation and 2N* association having comparable barriers. Furthermore, energetics alone cannot explain why the NH_3* and NH* dehydrogenation steps can be kinetically significant given the relatively low barrier of these reactions.

13   Concluding Remarks

Microkinetic models are an essential tool for understanding a reaction mechanism and an important link to reactor modeling and design as well to catalyst prediction. Advances in computing power and DFT functionals have both improved the speed and accuracy of producing first-principles based data, which are essential for the estimation of key kinetic and thermodynamic parameters required for a microkinetic
Fig. 12 Potential energy diagram with activation barriers for ammonia decomposition at 750 K at zero-coverage (orange) and at a typical coverage under reaction conditions (blue)

model. Alternatively, BEPs and LSRs can be used to estimate the parameters of large mechanisms. These fast estimation methods can be combined with first-principles calculations to enable building large models at low cost while ensuring DFT accuracy of key thermodynamic and kinetic parameters. This chapter has provided the approach, theory, equations, and examples necessary to use these tools. An example of a microkinetic software is given on Github at https://github.com/VlachosGroup/NH3-Matlab-Microkinetic-Model.

Abstract

Today, the challenge in chemical and material synthesis is not only the development of new catalysts and supports to synthesize a desired product, but also the understanding of the interaction of the catalyst with the surrounding flow field. Computational Fluid Dynamics (CFD) is the analysis of fluid flow, heat and mass transfer, and chemical reactions by means of computer-based numerical simulations. CFD has matured into a powerful tool with a wide range of applications in industry and academia. From a reaction engineering perspective, main advantages are reduction of time and costs for reactor design and optimization, and the ability to study systems where experiments can hardly be performed, e.g., hazardous conditions or beyond normal operation limits. However, the simulation results will always remain a reflection of the uncertainty in the underlying models and physicochemical parameters so that in general a careful experimental validation is required.

This chapter introduces the application of CFD simulations in heterogeneous catalysis. Catalytic reactors can be classified by the geometrical design of the catalyst material (e.g. monoliths, particles, pellets, washcoats). Approaches for modeling and numerical simulation of the various catalyst types are presented. Focus is put on the principal concepts for coupling the physical and chemical processes on different levels of details, and on illustrative applications. Models for surface reaction kinetics and turbulence are described and an overview on available numerical methods and computational tools is provided.

1 Introduction

Today, the challenge in chemical and material synthesis is not only the development of new catalysts and supports to synthesize a desired product but also the understanding of the interaction of the catalyst with the surrounding reactive flow field. Often, only the exploitation of these interactions can lead to the desired product selectivity and yield. Hence, a better understanding of gas-solid, liquid-solid, and gas-liquid-solid flows in chemical reactors is understood as a critical need in chemical technology calling for the development of reliable simulation tools that integrate detailed models of reaction chemistry and computational fluid dynamics (CFD) modeling of macroscale flow structures.

The ultimate objective of CFD simulations of catalytic reactors is (1) to understand the interactions of physics (mass and heat transport) and chemistry in the reactor, (2) to support reactor design and engineering, and, (3) eventually, to find optimized operating conditions for the maximization of the yield of the desired product and minimization of undesired side products or pollutants.

This chapter introduces the application of CFD simulations to obtain a better understanding of the interactions between mass and heat transport and chemical reactions in reactors for chemical and materials synthesis, in particular in the presence of catalytic surfaces. Catalytic reactors are generally characterized by the complex interaction of various physical and chemical processes. Bundles or tubular fixed bed reactors can serve as an example. They are widespread in chemical industry and in particular used for reactions with large heat release or supply. Figure 1 illustrates typical time scales and length scales within such a catalytic tube bundle reactor.

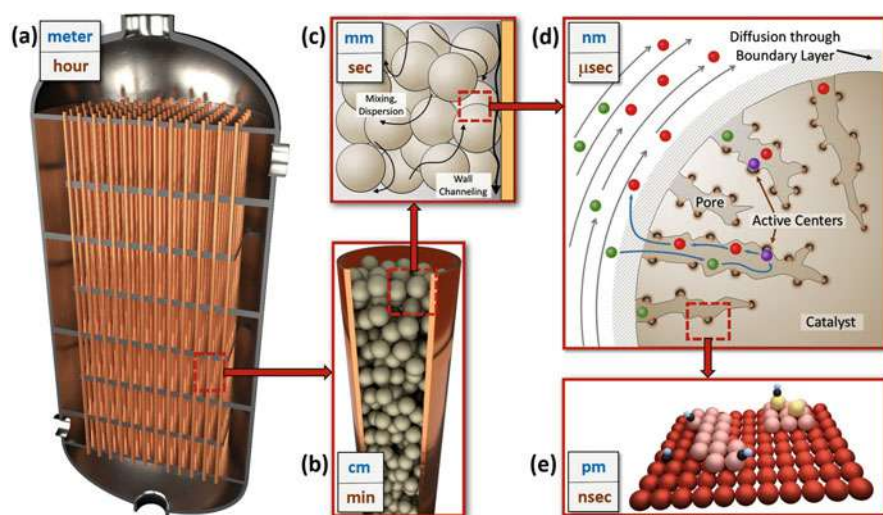
Computational fluid dynamics (CFD) is able to predict complex flow fields, even combined with heat transport, due to the recently developed numerical algorithms and the availability of fast computer hardware. The consideration of detailed models for chemical reactions, in particular for heterogeneous reactions, however, is still very challenging due to the large number of species mass conservation equations,


Fig. 1 Typical length scales (blue text) and length time scales (brown text) in a catalytic bundled tube reactor. (**a**) Principle of the reactor. The mixture flows from top to bottom through a bundle of tubes where the conversion takes place. The tubes are bathed by a fluid (gaseous or liquid) which is guided around the tubes in a crossflow arrangement. This fluid serves as a cooling or heating agent depending on the type of reaction (exothermic or endothermic). The tubes (**b**) are filled with catalytic particles. In each tube, the transport of momentum, energy, and chemical species occurs not only in flow direction but also into radial direction. Channeling in the near-wall region (**c**) affects the radial heat transfer; radiation plays a significant role at higher temperatures; local kinetics influence local transport phenomena and vice versa; reaction rates are limited due to film diffusion. The catalyst material is often dispersed in porous structures like washcoats or pellets (**d**). Mass transport in the fluid phase and chemical reactions are superimposed by diffusion of the species to the active catalytic centers in the pores. The temperature distribution depends on the interaction of heat convection and conduction in the fluid, heat release due to chemical reactions, heat transport in the solid material, and thermal radiation. The chemical reaction itself takes place at active sites on the inner surface of the porous catalyst structure (**e**)

their highly nonlinear coupling, and the wide range of time scales introduced by the complex reaction networks.

In the following, concepts for modeling and numerical simulation of catalytic reactors are presented, which describe the coupling of the physical and chemical processes in detail. The elementary kinetics and dynamics as well as ways for modeling the intrinsic chemical reaction rates (micro kinetics) by the mean field approximation (MF) and by lumped kinetics are discussed. It is assumed that models exist that can compute the local heterogeneous, but also homogeneous reaction rate, as a function of the local conditions such as temperature and species concentration in the gas phase and of the local and temporal state of the surfaces. These chemical source terms are here coupled with the fluid flow and used to numerically simulate the chemical reactor.

The focus is on the principal ideas and the potential applications of CFD in heterogeneous catalysis; textbooks and specific literature are frequently referenced for more details. Specific examples taken from literature in combination with own work will be used for illustration of the state-of-the-art CFD simulation of chemical reactors with heterogeneously catalyzed reactions.

2 Governing Equations of Multicomponent Single-Phase Flows

As long as a fluid can be treated as a continuum, the most accurate description of the flow field of multicomponent mixtures is given by the transient three-dimensional (3D) Navier-Stokes equations coupled with the mass continuity, energy, and species transport equations, which will be summarized in this section. More detailed introductions into fluid dynamics and transport phenomena can be found in a number of textbooks (Bird et al. 2001, Kee et al. 2003, Warnatz et al. 1996, Hayes and Kolaczkowski 1997). Other alternative concepts such as the Lattice-Boltzmann method are not discussed here, because the state of development does not allow a broad application.

Governing equations, which are based on conservation principles, can be derived by consideration of the fluid flow for a differential control volume. The principle of mass conservation leads to the mass continuity equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho \cdot u_i)}{\partial x_i} = 0, \tag{1}$$

with ρ being the mass density, t the time, x_i ($i = 1,2,3$) are the Cartesian coordinates, and u_i the velocity components. The principle of momentum conservation for Newtonian fluids leads to three scalar equations (Navier-Stokes Equations) for the momentum components ($\rho \cdot u_i$):

$$\frac{\partial (\rho \cdot u_i)}{\partial t} + \frac{\partial \left(\rho \cdot u_i \cdot u_j\right)}{\partial x_j} + \frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j} = \rho \cdot g_i, \tag{2}$$

where p is the static pressure, τ_{ij} is the stress tensor, and g_i are the components of the gravitational acceleration. The above equation is written for Cartesian coordinates. The stress tensor is given as

$$
\tau_{ij} = -\mu \cdot \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) + \left(\frac{2}{3}\mu - \kappa \right) \delta_{ij} \cdot \frac{\partial u_k}{\partial x_k}.
\tag{3}
$$

Here, κ and μ are the bulk viscosity and mixture viscosity, respectively, and δ_{ij} is the Kronecker delta, which is unity for $i = j$, else zero. The bulk viscosity vanishes for low-density mono-atomic gases and is also commonly neglected for dense gases and liquids. The coupled mass continuity and momentum equations have to be solved for the description of the flow field.

In multicomponent mixtures, not only the flow field is of interest but also mixing of the chemical species and reactions among them, which can be described by an additional set of partial differential equations. Here, the mass m_i of each of the N_g gas-phase species obeys a conservation law that leads to

$$
\frac{\partial (\rho \cdot Y_i)}{\partial t} + \frac{\partial (\rho \cdot u_j \cdot Y_i)}{\partial x_j} + \frac{\partial (j_{i,j})}{\partial x_j} = R_i^{\text{hom}},
\tag{4}
$$

where Y_i is the mass fraction of species i in the mixture ($Y_i = m_i/m$, with m as total mass) and R_i^{hom} is the net rate of production due to homogeneous chemical reactions. The components $j_{i,j}$ of the diffusion mass flux caused by concentration and temperature gradients are often modeled by the mixture-average formulation:

$$
j_{i,j} = -\rho \cdot \frac{Y_i}{X_i} \cdot D_i^{\text{M}} \cdot \frac{\partial X_i}{\partial x_j} - \frac{D_i^{\text{T}}}{T} \cdot \frac{\partial T}{\partial x_j}.
\tag{5}
$$

D_i^{M} is the effective diffusion coefficient of species i in the mixture; D_i^{T} is the thermal diffusion coefficient, which is significant only for light species; and T is the temperature. The molar fraction X_i is related to the mass fraction Y_i using the species molar masses M_i by

$$
X_i = \frac{1}{\sum_{j=1}^{N_g} Y_j/M_j} \cdot \frac{Y_i}{M_i}.
\tag{6}
$$

Heat transport and heat release due to chemical reactions lead to spatial and temporal temperature distributions in catalytic reactors. The corresponding governing equation for energy conservation is commonly expressed in terms of the specific enthalpy h:

$$
\frac{\partial (\rho \cdot h)}{\partial t} + \frac{\partial (\rho \cdot u_j \cdot h)}{\partial x_j} + \frac{\partial j_{q,j}}{\partial x_j} = \frac{\partial p}{\partial t} + v_j \cdot \frac{\partial p}{\partial x_j} - \tau_{jk} \cdot \frac{\partial v_j}{\partial x_k} + S_{\text{h}},
\tag{7}
$$

with S_h being the heat source, for instance, due to chemical reactions. In multicomponent mixtures, diffusive heat transport is significant due to heat conduction and mass diffusion, hence

$$j_{q,j} = -\lambda \cdot \frac{\partial T}{\partial x_j} + \sum_{i=1}^{N_g} h_i \cdot j_{i,j}. \tag{8}$$

λ is the thermal conductivity of the mixture. The temperature is then related to the enthalpy by the definition of the mixture specific enthalpy:

$$h = \sum_{i=1}^{N_g} Y_i \cdot h_i(T), \tag{9}$$

with h_i being the specific enthalpy of species i, which is a monotonic increasing function of temperature. The temperature is then commonly derived from Eq. (9) for known h and Y_i.

Heat transport in solids such as reactor walls and catalyst materials can also be modeled by an enthalpy equation

$$\frac{\partial (\rho \cdot h)}{\partial t} - \frac{\partial}{\partial x_j} \left(\lambda_s \cdot \frac{\partial T}{\partial x_j} \right) = S_h, \tag{10}$$

where h is the specific enthalpy and λ_s the thermal conductivity of the solid material. S_h accounts for heat sources, for instance, due to electric or radiative heating of the solid.

This system of governing equations is closed by the equation of state to relate the thermodynamic variables density ρ, pressure p, and temperature T. The simplest model of this relation for gaseous flows is the ideal gas equation:

$$p = \frac{\rho \cdot R \cdot T}{\sum\limits_{i=1}^{N_g} X_i \cdot M_i}, \tag{11}$$

with the universal gas constant $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$.

The transport coefficients of the fluid μ, D_i^M, D_i^T, and λ appearing in Eqs. (3, 5, and 8) depend on temperature and mixture composition. They are derived from the transport coefficients of the individual species and the mixture composition by applying empirical approximations.

The specific enthalpy h_i is a function of temperature and can be expressed in terms of the heat capacity:

$$h_i = h_i\,(T_{\text{ref}}) + \int\limits_{T_{\text{ref}}}^{T} c_{p,i}(T)\;\mathrm{d}T, \tag{12}$$

where $h_i\,(T_{\text{ref}})$ is the enthalpy at reference conditions ($T_{\text{ref}} = 298.15$ K, $p_0 = 1$ bar) and $c_{p,i}$ is the specific heat capacity at constant pressure.

3   Coupling of the Flow Field with Heterogeneous Chemical Reactions

Depending on the spatial resolution of the different catalyst structures, e.g. flat surface, gauzes, and pellets, embedded in porous media, the species mass fluxes due to catalytic reactions at these structures are differently coupled with the flow field.

3.1   Modeling of Fluid above Nonporous Catalytic Surfaces

In the simplest case considered, the catalytic surface consists of a single nonporous homogeneous material, e.g. wires or plates made of platinum. The chemical processes at the surface are then coupled with the surrounding flow field by boundary conditions for the species continuity equations, Eq. (4), at the gas-solid interface:

$$\vec{n} \cdot \left(\vec{j}_i + \rho \cdot \vec{u}_{\text{Stef}} \cdot Y_i \right) = R_i^{\text{het}}. \tag{13}$$

Here, $\vec{n}$ is the outward-pointing unit vector normal to the surface, $\vec{j}_i$ is the diffusion mass flux of species i as discussed in Eq. (4), and R_i^{het} is the heterogeneous surface reaction rate, which is given per unit geometric surface area (kg m^{-2} s^{-1}). It should be noted that in this case the *catalytic surface* (red outline in Fig. 2, left)
Fig. 2 Left: Definition of surface areas for a nonporous catalyst. Right: Definition of surface areas for porous catalysts (or porous layers such as washcoats)

corresponds to the *geometrical surface* (green outline in Fig. 2, left) of the fluid-solid interphase of the flow field simulation.

The Stefan velocity $\vec{u}_{\text{Stef}}$ occurs at the surface if there is a net mass flux between the surface and the gas phase:

$$\vec{n} \cdot \vec{u}_{\text{Stef}} = \frac{1}{\rho} \cdot \sum_{i=1}^{N_g} R_i^{\text{het}}. \tag{14}$$

At steady-state conditions, this mass flux vanishes unless mass is deposited on the surface, e.g. chemical vapor deposition, or ablated, e.g. material etching. Equation (13) basically means that for $\vec{u}_{\text{Stef}} = 0$, the amount of gas-phase molecules of species i, which are consumed/produced at the catalyst by adsorption/desorption, have to diffuse to/from the catalytic wall (Eq. 5).

3.2   Fluid Flow above Porous Catalysts

Most catalysts exhibit a certain structure, for instance, they may occur as dispersed particles on a flat or in a porous substrate. Examples are thin catalytically coated walls in honeycomb structures, foams, disks, plates, and well-defined porous media (e.g. particles). A representative is a washcoat (Fig. 3), which is a thin layer of supporting material where small particles of the catalytic active material (e.g. precious metals) are embedded in a supporting material (Fig. 2, right). The numerical grid resolves only the flow region bounded by the geometrical structure of the catalyst. The simplest way to account for the active catalytic surface area consists in scaling the intrinsic reaction of Eq. (14) in the following form:

$$R_i^{\text{het}} = \eta \cdot F_{\text{cat/geo}} \cdot M_i \cdot \dot{s}_i. \tag{15}$$

Here, $\dot{s}_i$ is the molar net production rate of gas-phase species i, given in mol m^{-2} s^{-1}. The area now refers to the actual *catalytically active surface area* (red outline in Fig. 2, right). The parameter $F_{\text{cat/geo}}$ represents the amount of *catalytically*
Fig. 3 Washcoat on a channel of a monolith with typical length scales

active surface area in relation to the *geometric surface area* of the fluid-solid interphase (green outline in Fig. 2, right). Depending on porosity of the support and the dispersion (e.g. of particles of precious metals), this factor can range up to the order of hundred. The *catalytically active surface area* is the surface area (layer on which we find adsorbed species) of the catalytic active particles exposed to the ambient gas (fluid) phase. This area can be determined experimentally (e.g. by chemisorption) with sample molecules such as CO and hydrogen. The *catalytically active surface area* should not be confused with the BET (Brunauer-Emmett-Teller) surface area representing the *total inner surface area* of a porous structure (blue outline in Fig. 2, right).

The simplest model to include the effect of internal mass transfer resistance for catalyst dispersed in a porous media is the effectiveness factor η based on the Thiele modulus (Hayes and Kolaczkowski 1997). The effectiveness factor of species i, η_i, is defined as

$$\eta_i = \frac{\dot{s}_{i,\text{mean}}}{\dot{s}_i} \tag{16}$$

with $\dot{s}_{i,\text{mean}}$ as mean surface reaction rate in the porous structure. Assuming a homogeneous porous medium, time-independent concentration profiles, and a rate law of first order, the effectiveness factor can be analytically calculated in terms of

$$\eta_i = \frac{\tanh(\Phi_i)}{\Phi_i} \tag{17}$$

with Φ_i as Thiele module defined as

$$\Phi_i = L \cdot \sqrt{\frac{\dot{s}_i \cdot \gamma}{D_{\text{eff},i} \cdot c_{i,0}}}. \tag{18}$$

Here, L is the thickness of the porous medium (washcoat), γ is the ratio of catalytic active surface area to washcoat volume, and $c_{i,0}$ are the species concentrations at the fluid/porous media interface (geometrical surface in Fig. 2, right). The Thiele module is a dimensionless number. The value in the root term of Eq. (18) represents the ratio of intrinsic reaction rate to diffusive mass transport in the porous structure. Since mass conservation has to be obeyed (Eq. 15), the same effectiveness factor has to be applied for all chemical species. Therefore, this simple model can only be applied at conditions at which the reaction rate of one species determines overall reactivity. Furthermore, this model then implies that mass diffusion inside the porous media can be described by the same diffusion coefficient for all species.

In fixed bed reactors with large numbers of catalytic pellets or for catalyst dispersed in porous media, the structure of the catalyst cannot be resolved geometrically. In those cases, the catalytic reaction rate is expressed per volume, which means R_i^{het} is now given in kg m^{-3} s^{-1}; the volume here refers to the volume of

a computational cell in the geometrical domain of a discretized flow region. Then R_i^{het} simply represents an additional source term on the right side of the species continuity equation, Eq. (4), and is computed by

$$R_i^{\text{het}} = \eta \cdot S_{\text{V}} \cdot M_i \cdot \dot{s}_i, \tag{19}$$

where S_{V} is the active catalytic surface area per volumetric unit, given in m^{-1}, determined experimentally or estimated. $F_{\text{cat/geo}}$ as well as S_{V} can be expressed as a function of the position inside a reactor and time to account for inhomogeneously distributed catalysts and loss of activity, respectively.

3.3   Porous Catalyst as a Homogeneous Media

The aforementioned approach fails at conditions under which the reaction rate and diffusion coefficient of more than a single species determine overall reactivity. Hence, the interaction of diffusion and reaction demands more adequate models if mass transport in the porous media is dominated rather by diffusion than by convection. Contrary to the approaches shown above, not only the fluid region has to be discretized but also the porous solid region that is considered as a homogeneous media.

Concentration gradients inside the porous media result in spatial variations of the surface reaction rates $\dot{s}_i$. In thin catalyst layers (washcoats), these are primarily significant in normal direction to the fluid/washcoat boundary. Therefore, one-dimensional reaction-diffusion equations are applied with their spatial coordinate in that direction. Each chemical species leads to one reaction-diffusion equation, which is written in steady state as

$$\frac{\partial}{\partial x} \left(-D_i^{\text{eff}} \cdot \frac{\partial c_i^{\text{W}}}{\partial x} \right) - S_{\text{V}} \cdot \dot{s}_i = 0. \tag{20}$$

Here, c_i^{W} denotes the species concentration inside the washcoat. D_i^{eff} is the effective diffusion coefficient, which can account for the different diffusion processes in macro- and micropores.

Eq. (20) is coupled with the surrounding flow field, Eq. (5), at the interface between open fluid and catalytic layer/pellet. In this model the species concentrations, catalytic reaction rates, and surface coverages do not only depend on the position of the catalytic layer/pellet in the reactor but also vary inside the catalyst layer/particle leading to CPU-time-consuming computations.

Fluxes within porous media which are driven by gradients in concentration and pressure, i.e. diffusion and convection, can be described by the dusty gas model (DGM) (Kerkhof and Geboers 2005). This model, which is also applicable for three-dimensional and larger porous media, leads to more sophisticated computational efforts.

3.4   Resolved Modeling of Porous Catalyst

If a catalytic layer is porous (e.g. washcoat in Fig. 3), the effective catalyst surface area is often significantly larger than the geometrical surface area. The multiplicative factor is $F_{\text{cat/geo}}$ (see above). Albeit with knowledge of measured properties such as porosity, BET surface area, and chemisorption characteristics, the effective catalyst area is usually adjusted empirically. Moreover, $F_{\text{cat/geo}}$ is often taken to be a constant, independent of changes in reactor operating conditions or age of the catalyst.

Karakaya et al. 2016 performed a detailed analysis of reaction-diffusion processes within a porous rhodium-alumina catalyst washcoat based on a reconstruction of the actual catalyst-support microstructure. In this case, the total surface of a washcoat was used as the catalytic surface area (blue outline in Fig. 2, right). The catalytic chemistry was represented simply as a first-order irreversible reaction A→B, with a rate constant of k. The molar net production rate of the gas-phase species B is therefore

$$R_B^{\text{het}} = F_{\text{total}} \cdot k \cdot c_A, \tag{21}$$

where F_{total} is the total surface of the solid (see Fig. 2, right). They showed that characteristics such as effective area and pore effectiveness are strong functions of the reaction chemistry and the pore microstructure. The results depend greatly on the Damköhler number, which defines the ratio of the diffusive time scale to the reaction time scale. At relatively high Damköhler numbers, the reaction is mainly concentrated at the pore openings leaving most of the catalytic area deeper in the pores underutilized. However, as the Damköhler number decreases, the reaction is able to penetrate further into the pores. In this case, the net reaction can depend on local diffusion resistances, such as small necking regions (see Figs. 4 and 5). In the work of Blasi et al. (2016), the results from the microscale reconstructed pore volumes from the work of Karakaya et al. (2016) were used to develop macroscale models that can be applied at larger length scales.

4   Numerical Methods and Computational Tools

There are a variety of methods to solve the coupled system of partial differential and algebraic equations (PDE), which were presented in the previous sections for modeling catalytic reactors. Very often, the transient three-dimensional governing equations are simplified (no time dependence, symmetry conditions, preferential flow direction, infinite diffusion etc.) as much as possible but still taking care of all significant processes in the reactor. Simplifications often are not straightforward and need to be conducted with care. Special algorithms were developed for special types of reactors to achieve a converged solution or to speed up the computation solution.

4.1   Numerical Methods for the Solution of the Governing Equations

An analytic solution of the PDE system is only possible in very limited special cases; for all practical cases, a numerical solution is needed. A numerical solution means that algebraic equations are derived approximating the solution of the PDE system at discrete points of the geometrical space of the reactor only at discrete points in time. The way of selection of these grid points and the derivation of algebraic

equations, which are finally solved by the computer, is called discretization. The grid points are representatives for small flow regions, which are now represented by the cells of a computational grid. Since the solution of the discretized equations is only an approximation of the solution of the PDE system, an error analysis (e.g. a study of grid independency) is an essential feature of the interpretation of every CFD simulation.

4.2   Turbulence Models

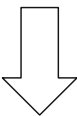
Turbulent flows are characterized by continuous fluctuations of velocity, which can lead to fluctuations in scalars such as density, temperature, and mixture composition. Turbulence can be desired in catalytic reactors to enhance mixing and reduce mass transfer limitations but is also unwanted due to the increased pressure drop and energy dissipation. An adequate understanding of all facets of turbulent flows is still missing.

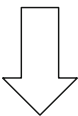
Today, the engineer or scientist can choose one of the numerous commercial or public CFD codes including a wide variety of turbulence models. However, the complexity of the codes and the bandwidth of potential applications are enormous, and almost nobody is able to overlook all aspects of a modern CFD code. Even scientists often confine themselves to improve numerical algorithms or to develop models for the description of physical or chemical sub-processes and use the other parts of the codes in good faith of their accurateness. The idea that turbulence or turbulent reaction models may be used without knowledge of the underlying theory is misleading.

This section should give the reader an overview of numerical turbulence and reaction modeling. For a deeper insight, some basic additional literature should be mentioned: turbulence (Wilcox 1998; Pope 2000; Lemos 2006), numerical methods (Patankar 1990; Oran and Boris 1987; Fox 2003; Versteeg and Malalasekera 2007), and combustion modeling (Libby and Williams 1994; Peters 2000; Poinsot and Veynante 2001).

4.2.1   Length and Time Scales of Turbulent Reacting Flows

The length scales of turbulent flows range from the size of Kolmogorov eddies η up to the size L_t (integral length scale) of the large energy-containing eddies. In technical applications, L_t is typically one order smaller and η typically three orders smaller than the characteristic size of the flow system. Corresponding to the length scales – via a characteristic flow velocity – there exist time scales, accordingly. The time scales of the turbulent flow range from the lifetime of the fine-grained Kolmogorov eddies up to the characteristic lifetime τ_t of the large energy-containing eddies. On the chemical conversion side, the time scales of reactions range from very small time scales (formation of radicals) up to large time scales (e.g., formation of NO_X), and thus, many time scales exist, which are able to interact with those of turbulent mixture.

4.2.2   Calculation of the Flow Field




For the calculation of multidimensional turbulent flows, different methods with various levels of detail exist. The most common methods used in CFD are listed in Table 1. The more universal a method is, the larger is the computational effort. Besides that, there are numerous specialized methods which are only applicable to distinct flow problems. The acceptable level of complexity is restricted by the available computer capacity.

Direct numerical simulations (DNS) solve the time-dependent Navier-Stokes equations without using any turbulence model. For technical applications, there are at least three orders of magnitude between the size L of the flow system and the mesh size Δ needed to resolve the smallest scales. In 3D, this would result in at least 10^9 grid points. As the length scale of the small vortices decreases with the Reynolds number of the flow, the number of grid cells needed to resolve also the small structures increases. Therefore, DNS is still out of reach as a method to predict even isothermal turbulent flows for practical engineering applications (high Reynolds number) for many years to come. Therefore, this method is restricted to either flows with small Reynolds number (e.g., in the order of some thousands or laminar flows) or to higher Reynolds number but only small calculation domains (in the order of centimeters).

Consequently, turbulent flow configurations are generally modeled with other approaches, i.e., Reynolds-averaged Navier-Stokes simulations (RANS) or large eddy simulations (LES). Within these two basic approaches, the balance equations are filtered in time or space, respectively. All flow variables are subdivided into a resolved part and an unresolved part. Both approaches introduce additional terms, which have to be modeled to achieve closure, in the Navier-Stokes equations.

The balance equations for RANS techniques are obtained by time averaging the instantaneous balance equations. If the turbulent flow is steady state in the sense that there is no overall time scale of the transient process (statistically steady-state flow, e.g. no periodic variations), the calculation yields only the time-averaged quantities. The most popular model is the k-ε model, which solves two additional transport equations (partial differential equations) for the quantities k (turbulent kinetic energy) and ε (turbulent dissipation). These two variables are used to determine the turbulent viscosity $\mu_t \sim k^2/\varepsilon$ representing the effect of the turbulent fluctuations on the exchange of momentum in the flow. This quantity is dependent on the local conditions of turbulence and is no property of the medium. The RANS

Table 1 Methods for the calculation of fluid dynamics

Universalism	Method	Resolution, Effort
	1. Solving the Reynolds-averaged Navier-Stokes Equations (RANS-approach) 2. Solving the Space-filtered Navier-Stokes Equations (LES: Large-Eddy-Simulation) 3. Solving of the Navier-Stokes Equations (DNS: Direct-Numerical-Simulation)	

technique is still the standard approach used for the calculation of catalytic reactors with turbulent flow.

LES is always formulated in a transient way, which makes it a time-consuming calculation. In deriving the basic LES equations, the instantaneous balance equations are spatially filtered with a filter size, which usually is the size of the grid. The objective of LES is explicitly to compute the largest structures of the flow field (typically structures larger than the mesh size), whereas the effects that are dependent on the motion of the smallest eddies are modeled using subgrid closure rules (employing length-scale separation). The evolving local subgrid eddy viscosity μ_t has to be modeled.

Compared to RANS simulations, LES simulations are expensive in time and storage space. As modeling is only applied on the smaller unresolved scales, the results are usually less sensitive to modeling assumptions such as RANS models. However, usual simplifications, which can be applied by RANS as symmetry conditions or two-dimensional flows, cannot be retained. The solution has to be time-dependent, even for statistically steady-state flows.

Figure 6 shows schematically the temporal variation of the velocity u at a fixed spatial position in a statistically steady-state flow for different modeling approaches. The DNS claims to predict the same spatial and temporal variations inside the flow as a measurement would yield. The concept of LES implies that the determination of the flow will be the better the finer the grid is. Asymptotically, this leads to a DNS solution. In the frame of a RANS model, the velocity is constant and represents the time averaged value.

The fluid flow in small-scaled flow regions (in the order of cm and below) is highly affected by particle surfaces and reactor tube walls, respectively. Consequently, the turbulence intensity is also changed by the presence of a near wall. Getting closer to a wall, the tangential velocity fluctuations are diminished by viscous damping, and the normal fluctuations are damped by kinematic blocking. Therefore, it is important to use appropriate models for the flow laminarization at the solid surfaces. The traditional $k-\varepsilon$ model is not suited for near-wall velocity

Fig. 6 Temporal variation of velocity u at one position in a statistically steady-state flow for different modeling approaches
calculation, since the damping in this region is not accounted for. This and some other RANS models are based on wall functions, so that the sublayer and buffer layer do not have to be resolved. This is often enough if the flow region is large scaled with respect to the dimensions of the near wall regions. As a consequence, turbulence models that are based on the resolution of the near-wall zones have to be used for small-scaled (strongly confined by walls) flow regions. These are termed low-Reynolds number models such as the Spalart-Allmaras and $k - \omega$ model, where ω is a typical frequency of turbulence. Sometimes the flow region consists of distinct laminar and turbulent zones. An example is an automotive converter, where the flow inside the channels of the monolith is laminar whereas the flow upstream and downstream of the monolith is turbulent. RANS models cannot predict the laminarization in front of and the transition to turbulence behind the monolith.

Contrary, the LES approach is able to resolve the near-wall turbulence as well as laminarization and transition processes. Dixon et al. (2011) investigated different RANS turbulence models on a single sphere in terms of drag coefficient and heat transfer Nusselt number. As a reference case, large eddy simulations (LES) were carried out showing good agreement with correlations from literature. However, the small time step and fine mesh required are unpractical for entire bed simulations. The authors suggest using the shear-stress transport (SST) $k - \omega$ turbulence model, which is capable to predict heat transfer accurately. Cornejo et al. (2018) calculated the gas flow inside an entire automotive converter applying the porous body approach and using a RANS model. The decay of the turbulence inside of the single channels of the monolith was investigated using a LES model.

4.2.3 Turbulence and Chemistry

Turbulence implies a large range of both length scales and time scales. This is valid for both flow and chemical reactions. A basic concept for the development of turbulent reaction models is the physical principle stating that the probability of the interaction of scales decreases with the amount of scale separation. There are many circumstances where only limited ranges of chemical and turbulent time scales are involved and where the overlap of these ranges is small. According to Damköhler, the interaction of time scales can be expressed by the ratio of the typical times scales of chemical conversion τ_c and turbulence τ_t called the Damköhler number: $Da = \tau_c / \tau_t$.

Classical turbulent reaction models describing homogeneous reactions (e.g. combustion) explicitly or implicitly assume scale separation (fast chemistry). If the turbulent mixing is relatively fast or the chemistry is relatively slow (Damköhler number < 1), there is no time-scale separation. In this case, PDF approaches are claimed. Here, probability density functions (PDFs) (Warnatz et al. 1996), either derived by transport equations or empirically constructed, are used to consider the turbulent fluctuations when calculating the chemical source terms. In combination with RANS models for turbulence, these combustion models yield the time-averaged chemical reaction rates (Warnatz et al. 1996; Libby and Williams 1994). The realization of homogeneous reaction in the LES approach is handled in a similar

way for the subgrid scales. As the reaction is determined by molecular mixing, reaction takes place only on this dimension of scales.

There is a lack in literature with respect to the modeling of systems where turbulence and heterogeneous chemistry concur. To the best knowledge of the authors, no paper can be found where the impact of turbulence on the chemical conversion on a surface is discussed with respect to the interaction of time scales.

4.3   CFD Software

The three major approaches of discretization are the finite difference method (FDM), the finite volume method (FVM), and the finite element method (FEM). Today, nearly all commercial CFD codes are based on the FVM; only few use the FEM. Currently available multipurpose commercial CFD codes can simulate very complex flow configurations including turbulence and multicomponent transport. However, CFD codes still have difficulties to implement complex models for the chemical processes. One problem is the insufficient number of reactions and species the codes can handle. An area of recent development is the implementation of detailed models for heterogeneous reactions.

Several software packages have been developed for modeling complex reaction kinetics in CFD such as CHEMKIN, CANTERA, and DETCHEM, which also offer CFD codes for special reactor configurations such as channel flows and monolithic reactors. These kinetic packages and a variety of user written subroutines for modeling complex reaction kinetics have meanwhile been coupled to several commercial CFD codes. Aside from the commercially widespread multipurpose CFD software packages such as FLUENT, STAR-CD, FIRE, CFD-ACE+, and CFX, a variety of multipurpose and specialized CFD codes have been developed in academia and at research facilities. A widespread CFD code is the tool OpenFOAM (OpenFOAM 2017). By being open-source, OpenFOAM offers users complete freedom to customize and extend its existing functionality.

5   Reactor Simulations

From the modeling point of view, catalytic reactors can be classified by the geometrical design of the catalyst material. This is the main characteristic, because the numerical calculation needs a spatial discretization of the fluid region and of the solid material (surface or whole body). Therefore, it is essential how the catalyst is shaped and if it is immobile or not.

On the one hand, the catalyst can consist of one single continuous solid material that is penetrated by regularly distributed straight channels (as in monoliths or honeycomb structures) or by randomly distributed and shaped voids (as in foams). Here, the catalyst material is mostly deposited on the surface of the support material as a washcoat (see Fig. 3). This is a thin layer of supporting material where small particles of the catalytic active material (e.g. precious metals) are embedded.

On the other hand, the catalyst can consist of single particles with undefined form (e.g. crushed material) or pellets showing a defined geometrical shape (e.g., spheres or cylinders). The single elements itself can consist of a coated supporting material or can be built up of the catalyst material itself. In a packed bed, the particles/pellets are immobile. They touch each other in distinct contact points (for spheres) or contact lines/areas (for pellets) only. In a fluidized bed, the particles are moved by the flow and touch only frequently due to collisions.

This section explores the modeling of catalytic reactors. It starts with an approach where the solid structure is considered as a porous media. This model needs the smallest effort in computer capacities (memory and time) and can be applied for all of the configurations where the catalyst is immobile. The discretization of both the fluid and the solid structure is more complex and is called *resolved modeling* in the following. For each of the basic macroscopic morphologies of the catalyst (monolith, foam, fixed bed), some of the most used modeling methods will be presented consecutively. The simulation of mobile catalysts (e.g., fluidized beds) and reactors with multiple fluid phases demands special methods and is discussed afterward. Various special types of catalysts (e.g., wire gauzes) will not be discussed here.

For all the methods presented for the modeling of a reactor, it holds that the microscopic structure of the active part of the catalyst (washcoat or pelleted material) is not resolved by the numerical grid. This is because the morphology of the catalyst layer itself implies very small length scales. The thickness of washcoats is in the order of 0.1 mm (Fig. 3); the typical size of pores in this material is in the order of nm and below. However, the modeling of a small part of a reactor (e.g., one channel of a monolith) including the resolved washcoat can lead to very valuable insights in the interaction of processes (see Sect. 3.4).

5.1   Modeling of Immobile Catalyst as a Porous Media

A permeable structure can be seen as a multiphase system with one of the phases being a solid matrix. It is considered as a continuous media consisting partially of fluid and partially of solid (monolith, foam, fixed bed). Within this approach, the whole region of the porous body itself is discretized with a numerical grid. That means the real geometry of the flow region or the solid structure is not reproduced by the grid. The volumetric ratio between fluid and solid structure defines the porosity. Using volume averaging leads to a loss of information at the microlevel but provides insight into the macroscopic effects (e.g., flow maldistribution), which are needed for the full understanding of the system operation.

The flow of fluids through consolidated porous media and through beds of granular solids is similar, both having the general function of pressure drop versus flow rate. Transition from laminar to turbulent flow is gradual. Depending on the Reynolds number based on length scales of the macroscopic pores (e.g. diameter of channels in a monoliths/foams or particle diameter of a fixed bed), four distinct flow regimes can be observed (Dybbs and Edwards 1984): Darcy or creeping flow,

steady laminar inertial flow, unsteady laminar flow, and highly unsteady and chaotic flow regime. If the Reynolds number is very small, the empirical Darcy's law is applied traditionally for the determination of the pressure loss of the flow. For larger Reynolds number, the models of Ergun, Brinkman, and Forchheimer followed by numerous extended models were developed (Lemos 2006). The pressure loss may be strongly anisotropic, depending on the structure of the solid (e.g. for monoliths).

The properties of the porous medium (e.g. heat conductivity) which is a combination of the fluid and the solid part have to be deduced with additional models. Heat transport in porous media involves conductive heat transfer both in solid struts and in the fluid phase as well as convective heat transport due to the flow. The overall conductive heat transport depends on the material and structural properties of the solid and on the properties of the working fluid. Under the assumption of a local thermal equilibrium between fluid and solid phases, mixture models are used traditionally for heat conduction in porous media. By this, the temperatures of solids and fluids are assumed to be the same locally, and the heat conduction equations for the solid and fluid phase are lumped together. If the solid and fluid are in thermally non-equilibrium state, the heat conductions in the fluid and solid phases have to be considered with two separate balance equations. For heat exchange between fluid and solid structure, Nusselt number correlations are needed. If the temperature is high, the radiative heat transport has to be included.

The prediction of the mass transfer of species between flow and surface in the case of catalytic reactions demands additional models (Sherwood number correlations or effectiveness factor approaches). Within the porous media approach, the catalytic surface is parametrized as a specific area (square meter surface per volume porous body).

The modeling of a monolith as a continuous porous medium can be found in Hayes et al. (2012) and Porter et al. (2016). By pre-computing the required data at the micro- and mesoscales and storing them in a look-up table, small-scale effects (such as washcoat diffusion) can be captured in a macroscale model that executes with practicable execution times (Nien et al. 2013). A multiscale model for a fixed bed catalytic reactor is given in Park (2018). The macroscale part is for the transport across the reactor, and the microscale part is for the intra-particle transport and reaction. The effects of pellet size, intra-pellet diffusivity and conductivity on the reactor yield, and catalyst effectiveness factor are investigated.

5.2 Resolved Modeling of Monoliths (Honeycomb-Structured Catalysts)

In environmental catalysis (e.g., automotive catalytic converters, high-temperature catalysis, catalytic combustion and reforming), honeycomb-structured catalysts are often applied. Reactors that are based on monolithic structures include many equally sized small channels. To resolve these structures with CFD methods in detail, grids with high spatial resolution are needed, which leads to large numbers of grid cells and very large simulation times. To reduce the computer resources needed for

modeling of structured catalytic reactors, several strategies with various levels of complexity and accuracy have been developed.

One possibility is to model only one representative channel of the whole monolith in 1D/2D/3D with or without inclusion of diffusion effects in the catalytic coating (washcoat). This approach is successful if only one channel is a good representative for all other channels of the monolith. However, a typical monolith consists of thousands of channels running in parallel, and the operational conditions for each of them might vary significantly. If the conditions inside the monolith are inhomogeneous, it is far better to calculate a certain number of channels and assume that each of those channels is a representative for a group of them (Tischer and Deutschmann 2005; Sharma and Birgersson 2016; Hettel et al. 2015). Another approach is to exclude the channels of the catalyst from the CFD domain and to solve them using 1D/2D grids applying a second solver (Hettel et al. 2015; Sui et al. 2016).

Studies where all channels of a real converter are resolved by the numerical grid include restrictions in dimensionality, complexity of models, or in the number of channels considered. Either the number of channels resolved is large (some thousands) and there is no chemistry involved or the number of channels is small (some hundreds) and global chemistry or reduction in dimensionality is used.

Publications presenting the calculation of multichannel systems resolving the 3D geometry and using detailed chemistry are scarce in literature. Some papers focus on numerical methods and computer resources (Kumar and Mazumder 2010); others are using new computer architectures (Choudary and Mazumder 2014). Generally, there is a lack of publications where the results of numerical calculations are compared to spatially resolved experimental data from inside the channels. In the work of Hettel et al. (2018), the 3D modeling of a quarter of a CPOX (catalytic partial oxidation) reformer (diameter 20 mm) including two monoliths with ca. 300 channels each is discussed (Figs. 7 and 8). Detailed chemistry was applied, and radiation effects between the two solids were considered. The results are compared to detailed measured data.

5.3   Resolved Modeling of Foams

The application of ceramic foams as catalyst carriers represents a promising alternative to fixed beds or structured packings. Ceramic foams are characterized by their low specific pressure drop, high mechanical stability at relatively low specific weight, enhanced radial transport, as well as a high geometric surface area. Their open-cell structure consists of stiff, interconnected struts building a continuous network. In literature, these structures are typically named as foams or sponges. They can be found in a wide range of technical apparatuses, such as molten metal filters, burner enhancers, soot filters for diesel engine exhausts, and biomedical devices.

Several catalytic applications have been investigated during the last decades (combustion, exhaust gas treatment, syngas production). Maestri et al. (2005)
Fig. 7 Temperature field of the fluid part and the two solids (the left monolith is uncoated; the right one is coated). Additionally, some streaklines are plotted. Only the slice at the end of the calculation domain shows the distribution of the velocity into z-direction. (Hettel et al. 2018, reprinted with permission from Elsevier)

compared by simulation the performance of three different catalyst supports for the CPOX of methane, i.e., honeycomb, foam, and fixed bed reactor. The authors conclude that the foam catalyst support shows the best performance regarding transport properties, syngas selectivity, and pressure drop.

The sponge-like structure consists of solid edges and open faces through which fluid can pass. The irregularly shaped strut network can be expressed by its morphological parameters, i.e., cell and window diameter, strut thickness, and porosity. However, industrial manufacturers often use pores per inch (PPI) as a value of characterization, ranging typically between 10 and 100, and porosity values greater than 75%. One of the most import properties of ceramic foams is the specific surface area, which is significant for the transport of momentum, energy, and mass.

An alternative to transport correlation-based models (see sect. 5.1) are structure-resolved 3D CFD simulations. With such detailed simulations, quantitative descriptions can be made of transport phenomena within complex structures without a priori assumptions. Numerical 3D simulations of foam structures can be divided into real foam models and model structures of different complexity. The first type is carried out by converting the actual geometry by means of 3D computer tomography (CT) or 3D magnetic resonance imaging (MRI) into CAD data appropriate for 3D simulations. These models are limited to the scanned structure that is determined by its morphological characteristics. The procedures are time and cost intensive and include several consecutive steps of preparation.
Fig. 8 Intersection through the midplane of only the central channel of the coated monolith. Distributions of temperature and species. (Hettel et al. 2018, reprinted with permission from Elsevier)

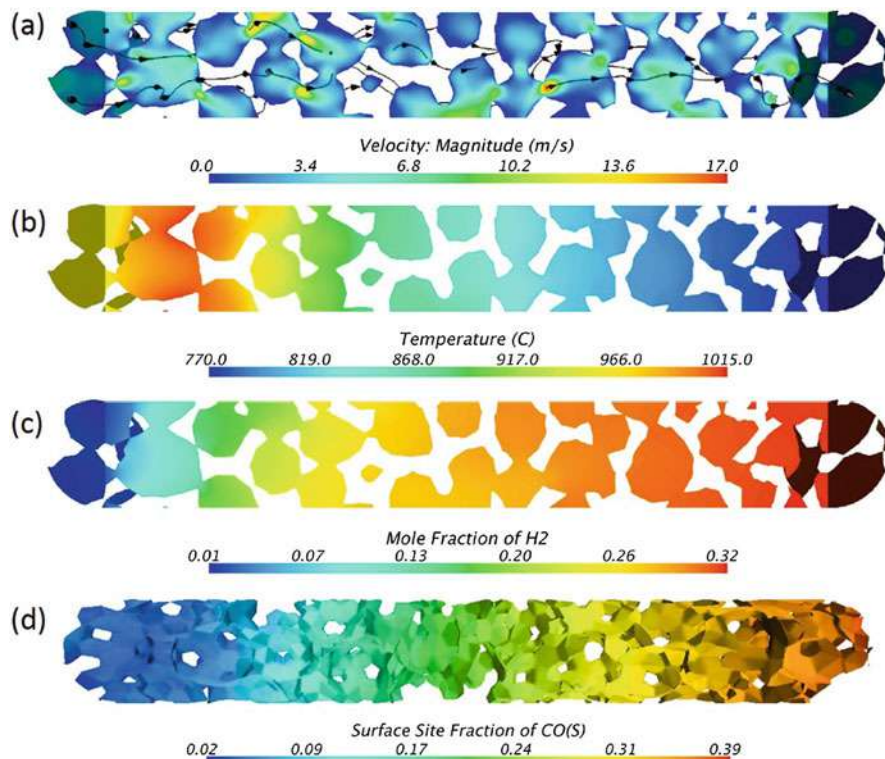
Model structures can be separated into deterministic models (e.g. unit cells) and stochastic models. An artificial foam modeler is able to generate structures that can be varied in terms of the most significant morphological characteristics, i.e., porosity, specific surface area, and strut dimensions. The modeler does not have to use scanned data but generates the structure automatically, as well as it generates a format that is ready to use for a CFD simulation. However, the usage of idealized unit cells does not account for random variations typical for natural foam structures. This leads to preferable flow directions in the cell structure. The second type of model structures applies stochastic approaches. For example, a perfectly ordered cell structure can be randomized by relocating nodes with a stochastic algorithm. However, the prediction of pressure drop or residence time is still unsatisfactory. Habisreuther et al. (2009) demonstrated that the parameters porosity and specific


Fig. 9 Modeling of CPOX on a foam coated with rhodium. (**a**) Velocity magnitude with streamlines, (**b**) temperature, and (**c**) hydrogen mole fractions on a plane cut through the CPOX foam. (**d**) Adsorbed C* on the foam surface. (courtesy of G. Wehinger, related papers are Wehinger 2016 and Wehinger et al. 2016)

surface alone are insufficient to describe the transport phenomena in such complex geometries.

Works showing the modeling of foams including surface reactions are very scarce. Figure 9 shows examples of the calculation of CPOX in a tubular reactor filled with a foam (see also Wehinger 2016; Wehinger et al. 2016).

5.4 Particle Resolved Modeling of Fixed Bed Reactors

A fixed bed reactor is based on a container filled with randomly positioned particles. The understanding of fluid dynamics and their impact on conversion and selectivity in fixed bed reactors is still very challenging. For large ratios of reactor width to pellet diameter, simple porous media models are usually applicable. This simple approach becomes questionable as this ratio decreases. At small ratios, the individual local arrangement of the particles and the corresponding flow field are significant

for mass and heat transfer and, hence, the overall product yields. Therefore, the method of direct numerical simulation (DNS) is the most promising approach. Over the last years, researchers have used particle-resolved CFD simulations to model this kind of packed-bed arrangement more rigorously (Dudukovic 2009). The concept is to take into account the actual shape of each individual particle inside the reactor. Consequently, the fluid flow field is determined by the particles it has to pass by. The advantage is the absence of transport correlations, which are necessary in pseudo-homogeneous or heterogeneous models to describe the transport of momentum, heat, and mass. Even though the governing equations are relatively simple for laminar flows, this approach can usually be applied for small and periodic regions of the reactor only, which is caused by the huge number of computational cells needed to resolve all particles.

Several authors used detailed fluid dynamics in combination with pseudo-homogeneous kinetics due to the small number of reaction equations and species (Kuroki et al. 2009). However, these kinetics are often limited to a certain range of process parameters and could therefore not be applied to other flow regimes or reactor types. Especially, the species distribution inside fixed bed reactors is often insufficiently reproduced with such kinetics in contrast to the exit concentrations (Korup et al. 2011).

For a first-principles approach, modeling spatially resolved fluid dynamics must be combined with reliable kinetics, i.e., microkinetics. Additionally, the diffusion and reaction of the species within the catalyst pellets, which may be made up of microporous materials, have to be considered. More recently, a larger bed of catalytic spheres was investigated both experimentally and by particle-resolved CFD simulations (Wehinger 2016; Wehinger et al. 2016b). Figures 10 and 11 depict some typical results.

5.5   Modeling of Mobile Catalyst with one Fluid Phase

At the present, gas-fluidized beds (FBs) find a widespread application in the petroleum, chemical, metallurgical, and energy industries. The large increase in computational resources during recent decades made theoretical approaches for the investigation more applicable, since the governing equations describing FBs can now be solved within accessible time scales. Hence, theoretical modeling of FBs with CFD has become a trend in the field. Three different types of simulation approaches can be distinguished: direct numerical simulations (DNS), Eulerian-Eulerian (EE), and Eulerian-Lagrangian (EL) models. Contrary to DNS, the flow field is not resolved at the particle level in the last approaches mentioned, and consequently closures need to be applied, e.g., for fluid-particle interaction forces.

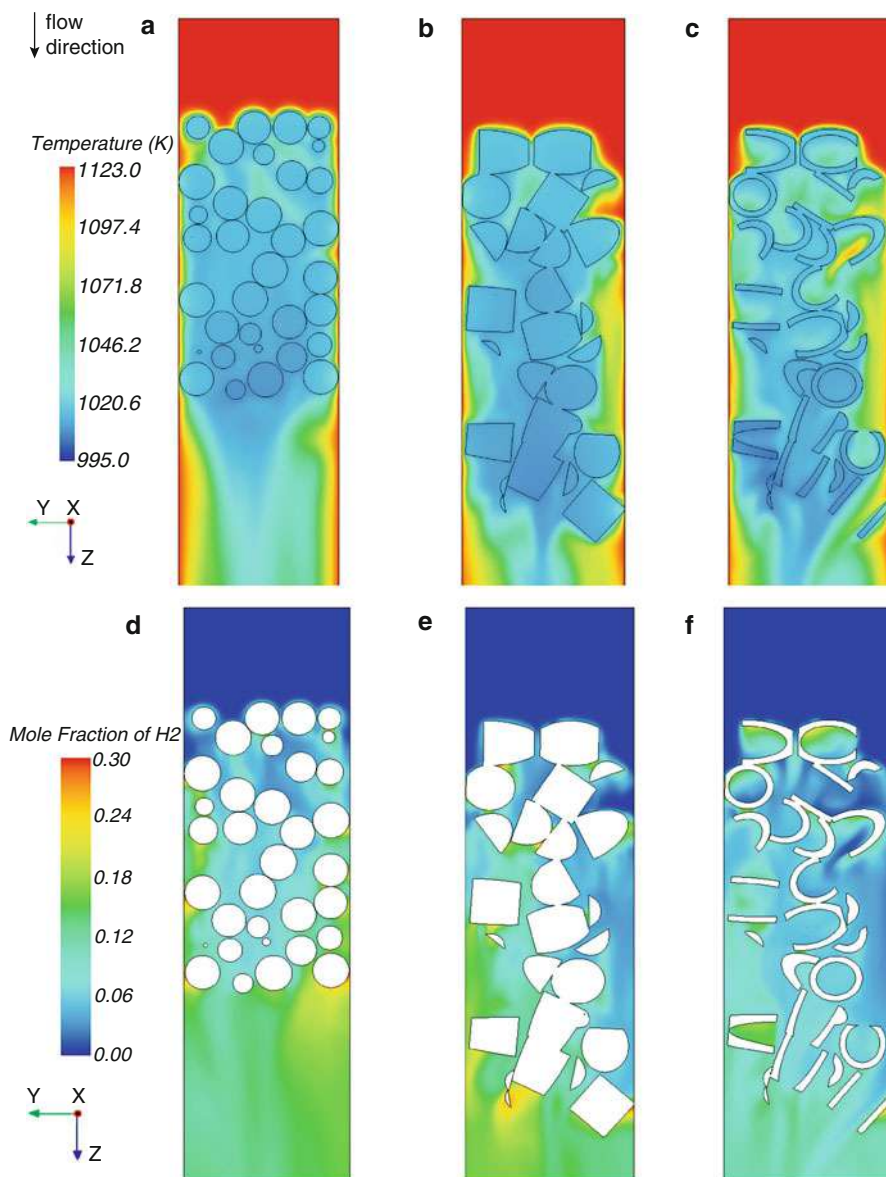
In DNS, the incompressible Navier-Stokes equations are solved for the gas phase, and the flow in the interstices of the particles bed is directly computed. DNS is the most popular tool for developing closure relations required in the averaged models mentioned below. Unfortunately, these simulations are restricted to a few thousand particles. In Eulerian-Eulerian (EE) models, in contrast, the particulate and the gas


Fig. 10 Modeling of dry reforming of methane in a resolved fixed bed using three different particle shapes. Plane cut through the fixed bed. Temperature distribution: (**a**) spheres, (**b**) cylinders, (**c**) 1-hole cylinders. Mole fraction of hydrogen: (**d**) spheres, (**e**) cylinders, (**f**) 1-hole cylinders. (courtesy of G. Wehinger, related paper is Wehinger 2016)
Fig. 11 Streamlines colored with temperature inside the bed of cylinders. (courtesy of G. Wehinger, related paper is Wehinger et al. 2016b)

phase are considered as interpenetrating continua, necessitating additional closure laws. EE models are preferred for the simulation of large-scale devices. Figure 12 shows an example for the EE modeling of an industrial scale fluidized bed for olefin polymerization. The height of the calculation domain is about 5 m.

The use of an Eulerian-Lagrangian (EL) model (e.g., the discrete particle model, DPM) holds a much greater promise when it comes to the full-physics simulations of heterogeneous reactors. EL models describe the particle phase with discrete entities, e.g., using the discrete element method (DEM) where every particle is tracked individually. EL approaches typically compute the particle-phase interactions directly and hence do not require complex rheological models and boundary conditions for the granular phase. This opens the door for the application to systems involving non-spherical and irregular particles. While a large number of work focused on inert systems, CFD-DEM calculations accounting for chemical reactions are relatively scarce. The latter are mainly found in the field of biomass and coal conversion (for a recent review, see Zhong et al. (2016)). Typically, the employed model assumes a homogeneous concentration and temperature distribution within the particle. This is unrealistic in situations involving fast chemical reactions, small pore diameters, or in case depositions form on the surface of the particles. CFD-DEM calculations accounting for intra-particle transport phenomena are even more rarely done; recently universal open-source tools were developed (Radl et al. 2015). Figure 13 shows an example of the calculation of a fluidized bed including surface reactions with an EL approach. In the left plot, the temperatures of the particles are shown and in the right plot (Hettel et al. 2016) the burst of particles at the upper surface of the bed. Additionally, a part of the CFD grid on the surrounding wall is shown.
Fig. 12 Snapshots of the solids volume fraction. The time interval between two consecutive pictures is $\Delta t = 0.1$s. (Schneiderbauer et al. 2015, reprinted with permission from Elsevier)

5.6   Modeling of Catalytic Reactors with Multiple Fluid Phases

The catalytic reactors considered so far contain a solid phase (the catalyst and its supports) and one fluid phase (i.e. a gas or a liquid). However, there are also various classes of reactions performed in catalytic reactors containing multiple fluid phases (usually a gas and a liquid or less often two immiscible liquids) (Önsan and Avci 2016). Examples for heterogeneously catalyzed gas-liquid reactions are hydrogenations, oxidations, hydroformylations, and Fischer-Tropsch synthesis (FTS). The corresponding reactors can be classified in types with immobile catalyst (e.g. fixed beds, trickle beds, solid sponges, monoliths, and other structured reactors) and types with significant motion of the catalyst (i.e. slurry reactors such as bubble columns or stirred tanks).

Relevant phenomena in three-phase catalytic reactors arise on multiple scales reflecting multiple physics. The dimensions range from catalyst pores to single particles/bubbles/drops and over particle/bubble clusters to reactor internals toward the entire vessel. Gas-to-liquid processes such as FTS are frequently carried out in slurry reactors (Wang et al. 2007). There, the catalyst particles (diameter 1 to 100 μm) are suspended in the liquid phase while the injected gas rises in the form of
Fig. 13 Modeling of a two-zone fluidized bed reactor for the conversion of butane to butadiene. Left: Snapshot of the particle temperature in a 2D domain (white, T = 710 K; black, T = 700 K). Diameter/number of particles: 70 µm/250,000 (courtesy of Prof. S. Radl, University Graz, Austria). Right: Snapshot of the particle velocity in a 3D domain. Diameter/number of particles: 200 µm/2,500,000. (Hettel et al. 2016)

bubbles (diameter 1 to 10 mm) providing the mixing and catalyst suspension within the vessel (height up to 25 m). Coupling of hydrodynamics, heat and mass transfer, and reaction kinetics takes place at molecular and particle levels where conductive and convective transfer and diffusion within the internal pores of the catalyst are accompanied by the adsorption, surface reaction, and desorption of reactant and product on the surface.

Full interface-resolving multiphase CFD simulations of at least some of the relevant phenomena listed above are only possible for small sections of large-scale reactors and for microreactors. In the general case, multidimensional CFD approaches relying on a time averaging (Ishii and Hibiki 2006) or volume averaging procedure are indispensable instead (Jakobsen 2008). Mathematically, the averaging of the single-phase conservation equations for mass, momentum, and energy for all phases yields the Eulerian multi-fluid model, where the phases are represented as interpenetrating continua. For slurry reactors, the liquid and catalyst particles may optionally be represented by one slurry phase with the gas as additional phase.

As the system of averaged Eulerian multi-fluid equations is not closed, constitutive relations must be provided to model turbulence as well as momentum/heat/mass transfer between the phases. Interfacial transfer models (e.g. for the drag force and interfacial heat/mass transfer) are well established for dilute disperse flows (Sommerfeld et al. 2008), however, often relying on idealized situations (e.g. isolated particles moving through stagnant fluid). The development of interfacial transfer and turbulence models for non-dilute and non-disperse flow regimes which are valid in a wide range of operating conditions is actually a larger scientific

challenge than the numerical solution of the set of averaged multi-fluid equations themselves (Hjertager 2007).

In its standard form, the Euler-Euler model (two-fluid model) requires input of a (mean) particle/bubble/drop diameter. For narrow size distributions, the Sauter mean diameter may serve well for this purpose. For wider size distributions, which are standard rather than exceptional in technical reactors, various types of population balance approaches are available taking into account, e.g., bubble breakup/coalescence (Yeoh et al. 2014; Marchisio and Fox 2013).

A conceptually different approach for disperse flows is the Euler-Lagrange (EL) model, where the continuous phase is still represented in the Eulerian manner while the disperse elements (i.e., particles/drops/bubbles) are described in a Lagrangian way (Sommerfeld 2017; Crowe et al. 2011). There, an equation of motion is solved for a large number of particles or computational parcels yielding particle trajectories. The EL approach is often used for disperse two-phase flows (e.g., bubbly flow or sprays). The interaction between the phases is modeled depending on the disperse volume fraction α_P (see Fig. 14). For very dilute conditions ($\alpha_P < 5 \cdot 10^{-4}$), one-way coupling is sufficient, where the continuous phase affects the disperse phase but not vice versa. As α_P increases, two-way and four-way coupling are required, where in the latter case also the effects of particle-particle interactions are accounted for. For volume fractions $\alpha_P > 0.1$, the particle transport is no longer flow/collisions-driven but contact-driven. Such situations are frequently encountered in fluidized beds; they are best described by the discrete element method, in potential combination with CFD (see above).

Three-phase reactors with immobile catalyst are conceptually simpler to model by CFD since the solid domain is invariant in time. The hydrodynamics thus reduces to the simulation of the two-fluid flow coupled with the solid domain by boundary conditions reflecting the conjugate heat transfer and heterogeneous reactions. By a porous body approach (see above), such reactors may be computed on a large scale by the Eulerian multi-fluid model as well. However, reactor details such as a single monolith channel, a section of a trickle bed, a representative part of structured reactors, a portion of a solid foam, etc. are well amenable nowadays for interface-resolving simulation of the two-phase flow.

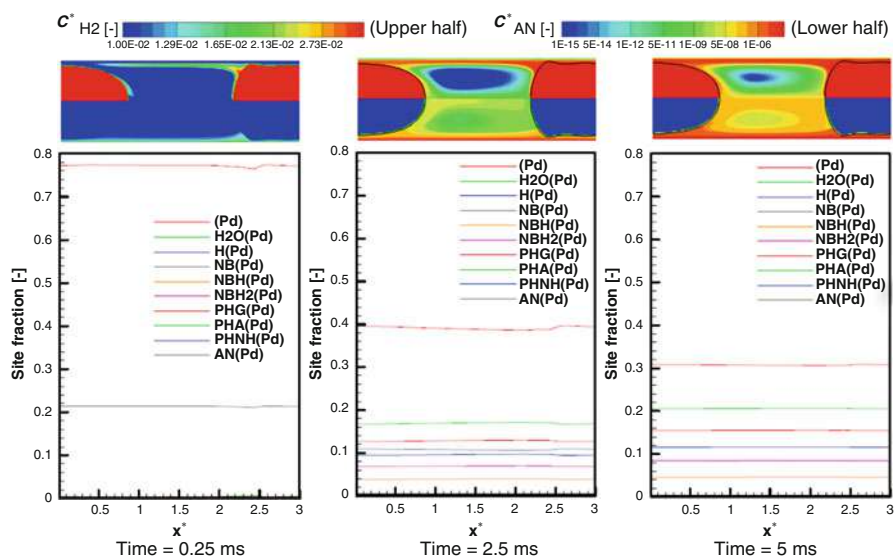
Fig. 14 Regimes of dispersed two-phase flows in terms of transport phenomena; left, dilute flow dominated by fluid transport of particles; middle, dense flow regime dominated by interparticle collision; right, dense flow regime that is particle contact dominated. (Sommerfeld 2017, reprinted with permission from Springer Nature)
In recent years, microfluidic systems operated in continuous multiphase flows have emerged as useful platforms for synthesizing micro- and nanoparticles with controlled shape and size distribution. They have yielded particles of organic polymers, oxides, semiconductors, and metals as well as hybrid structures combining multiple materials and functionalities (Marre and Jensen 2010). A detailed review on numerical methods for interface-resolving multiphase CFD simulations in microfluidics and microprocess engineering (including the widely used volume-of-fluid and level set methods) along with an overview on related applications is given in Wörner (2012). While the number of computational studies combining two-phase hydrodynamics with mass transfer is increasing (especially for segmented gas-liquid flow), numerical studies incorporating chemical kinetics in microreactors in which the catalyst is dispersed on the solid wall are still rare. Here, the study of Woo et al. (2017) on the hydrogenation of nitrobenzene to aniline in gas-liquid Taylor flow within a single channel may serve as an example. The authors first computed the quasi-steady bubble shape and velocity field by a 2D simulation of a single flow unit cell (consisting of one Taylor bubble and liquid slug). Using these (frozen) hydrodynamics, they computed the transient mass transfer of hydrogen from the gas into the liquid phase toward the catalytic wall, where a detailed kinetic mechanism adapted from a density functional theory study is employed, consisting of four bulk species and ten surface species. Figure 15 illustrates the temporal evolution of educts and product in the bulk phases in combination with wall profiles of all intermediates.


Fig. 15 Top row: Normalized instantaneous concentration distributions of hydrogen (upper half of channel) and aniline (lower half of channel) in gas-liquid Taylor flow. Bottom row: Instantaneous wall profiles of intermediate species. (Woo et al. 2017)

Even though the adequate modeling of physical complexity is challenging for multiphase CFD simulations, computations are a promising tool to achieve a better understanding of three-phase catalytic reactors.

6   Conclusions and Outlook

Computational fluid dynamics (CFD) is the analysis of systems involving fluid flow, heat transfer, and associated phenomena such as chemical reactions by means of computer-based numerical simulations. The technique is powerful and spans a wide range of industrial and nonindustrial applications. The advantages of CFD simulations over experiment-based approaches for reactor system design and optimization are the substantial reduction of development times and costs, the ability to study systems where experiments are difficult or impossible, the ability to study systems under hazardous conditions or beyond their normal performance limits, and the practically unlimited level of detail of results.

From a reaction engineering perspective, CFD simulations have matured into a powerful tool for understanding mass and heat transport in catalytic reactors. Initially, CFD calculations focused on a better understanding of mixing, mass transfer to enhance reaction rates, diffusion in porous media, and heat transfer. Over the last decade, the flow field and heat transport models have also been coupled with models for heterogeneous chemical reactions. So far, most of these models are based on the mean field approximation, in which the local state of the surface is described by its coverage with adsorbed species averaged on a microscopic scale. There is a gap between the length and time scales on the microscopic level and the length and times scales which can be resolved by a computational grid. This gap is bridged with models (e.g., mean field approximation). In the future, the gap will be shortened due to improved models, the combination of existing and advanced numerical approaches (e.g., Monte-Carlo simulations), and extended computer resources (higher discretization level). The currently increasing research activities on surface reactions at practical conditions will certainly boost the application of CFD codes that combine fluid flow and chemistry. New insights into the complexity of heterogeneous catalysis, however, will also reveal the demand for more sophisticated chemistry models. Their implementation into CFD simulations will then require robust numerical algorithms.

The simulation results will always remain a reflection of the models and physical parameters applied. Various commercial and open-source codes are available including a sometimes confusing number of methods and models. The careful choice of the submodels (turbulence, diffusion, species, reactions involved, etc.) and the physical parameters (boundary conditions, properties, etc.) is a precondition for reliable simulation results. Only the use of appropriate models and parameters, which describe all significant processes in the reactor, can lead to reliable results. Numerical algorithms never give the exact solution of the model equations but only an approximated solution. The solution is always dependent on the calculation grid (calculation domain, discretization level, grid type). Hence, error estimation is

needed. Moreover, the practical experience shows that the results from two different codes for the same complex physical problem are not equal.

CFD calculations require careful validation using experimental data or analytical solutions. Not till the model is evaluated, operational conditions or other parameters should be varied or extended to regions where no data is available. Owning the resources of a CFD program and computer hardware only is worthless. Qualified people having long experience in the field of modeling are needed to run the codes and to analyze and interpret the results. The understanding of the physics of fluid flow and the fundamentals of the numerical algorithms is a prerequisite. Having these crucial issues in mind, CFD can really serve as a powerful tool in understanding the behavior in catalytic reactors and in supporting the design and optimization of reactors and processes.

Structure of Electrode-Electrolyte Interfaces, Modeling of Double Layer and Electrode Potential

59

Axel Groß

Contents

Abstract

Our current understanding of the structure of electrode-electrolyte interfaces and double layers will be presented from a theoretical point of view. Furthermore, recent attempts to consider varying electrode potentials in theoretical studies will be discussed. Although there have been significant advances in recent years as far as the modeling of electrode-electrolyte interfaces is concerned, still further progress is needed to get a more complete understanding of these scientifically interesting and technologically relevant systems.

1 Introduction

There is a growing interest in the structure of electrochemical electrode-electrolyte interfaces because of their importance for a sustainable future energy technology

A. Groß (✉)

Institute of Theoretical Chemistry, Ulm University, Ulm, Germany
e-mail: axel.gross@uni-ulm.de

(Schlögl 2010). Electrochemical energy storage and conversion processes occur at these interfaces in devices such as batteries, fuel cells, or electrolyzers. Still, there is a long tradition of studying solid-electrolyte interfaces (Schmickler and Santos 2010). They correspond to the interface between an electron conductor (the electrode) and an ionic conductor (the electrolyte) (Schmickler and Santos 2010). At these interfaces, so-called electrical double layers (EDL) form. From a theoretical point of view, the double layers were first described in a continuum approach in which the electrolyte was represented by a dielectric medium, while atomistic aspects such as the orientation of the molecules directly at the electrode were taken into account in an empirical manner. The atomistic modeling of these interfaces is theoretically and numerically rather demanding, in particular for liquid electrolytes, as a proper description requires to perform statistical averages over the many possible configurations of the electrolyte. Furthermore, instead of total energies, free energies need to be evaluated, taking entropy effects into account.

A complete elucidation of the structure of electrode-electrolyte interfaces still requires an atomistic understanding, in particular if one is interested in charge-transfer processes or electrocatalytic reactions at these interfaces. Due to the ever-increasing computer power and the development of more efficient algorithms, an atomistic description of electrode-electrolyte interfaces has become possible. First, such studies were based on parameterized interaction potentials, but nowadays a quantum chemical first-principles modeling is feasible. At the same time, experimental electrochemical tools with atomistic resolution have been developed making an electrochemical surface science approach (Kolb 2002) possible.

Still, it is fair to say that our atomistic understanding of the structure of electrode-electrolyte interfaces is still far from being complete. Experimental techniques based on the scattering and diffraction of electronic beams are typically not operative in solution. As far as theory is concerned, apart from the requirement to take the disordered structure of the liquid electrolyte into account, it is important to note that structures and properties of electrode-electrolyte interfaces are strongly influenced by the electrode potential. This adds considerable complexity to the theoretical treatment (Schnur and Groß 2009) as varying the electrode potential changes the excess charge at the interface. Consequently, even such a seemingly simple issue as the structure of water layers at close-packed metal electrodes is still a matter of debate (Schnur and Groß 2009; Michaelides 2006).

We will now discuss some basic properties of electrode-electrolyte interfaces using the schematic drawing shown in Fig. 1. Any electrolyte contains ions to make it conductive. In principle, any aqueous electrolyte also contains protons and/or hydroxide, depending on the given pH value. Typically concentrations are below the 1 M level. Recall that a concentration of 1 M corresponds to 1 ion per 55 water molecules. Still, at the electrode-electrolyte interface, the concentration of ions can be much higher because of the strong ion-electrode interaction. This is illustrated in Fig. 1 for the anions. Typically, anions interact more strongly than cations with electrodes. Hence anions often adsorb *specifically* to the electrode, which means that their solvation shell becomes broken up upon adsorption. In contrast, the more weakly interacting cations usually adsorb *non-specifically* with their solvation shell still intact.
Fig. 1 Schematic drawing of an electrode-electrolyte interface between a metal electrode (lower part) and an aqueous electrolyte (upper part). The gray-shaded balls represent water molecules; the arrows denote their dipole moment. Solvated cations are illustrated by the white balls with a plus sign and anions in the electrolyte by white balls with a minus sign. Anions can either adsorb specifically at the electrode or non-specifically with their solvation shells still intact. In the electrode, the only charge carriers are the electrons, denoted by white balls with a minus sign. Their explicit presence at the electrode-electrolyte interface just illustrates that the electron density at the interface differs from the bulk metal density

The arrows in Fig. 1 denote the dipole moment of the water molecules. In the drawing, it is assumed that all the water molecules directly at the electrode surface are aligned which is the basis of the Stern layer described below. However, ab initio molecular dynamics simulations suggest that the first water layer at metal electrodes is not ordered (Schnur and Groß 2009). Still there might be a preferential orientation of the water molecules in the first layer at the electrode. At oxide electrodes, water molecules are rather bound through direct covalent bonds to the electrode (Cheng and Sprik 2014; Bonthuis and Netz 2013). Here a picture as shown in Fig. 1 might be more appropriate.

In this contribution, the structure of electrode-electrolyte interfaces will be addressed from a theoretical point of view. We will first determine the surface coverage of adsorbed ions within a thermodynamic picture in a grand-canonical approach. Even if within this approach the presence of the electrolyte at the electrode is not explicitly taken into account, still meaningful results can be derived. Then continuum models of electrode-electrolyte interfaces will be discussed. Atomistic studies of aqueous electrolytes at electrodes will be presented in which statistical averaging can be done via molecular dynamics simulations. Finally, recent approaches to incorporate varying electrode potentials into the theoretical description will be introduced. This chapter will show that further progress is needed in order to obtain a more complete picture of electrode-electrolyte interfaces. Still, this is an exciting field of research which is not only scientifically very interesting but also technologically rather relevant.

2   Thermodynamic Considerations

The structure of electrode-electrolyte interfaces is determined by the interaction between the electrode and electrolyte which seems to be a trivial statement. However, in a thermodynamics sense, the interface corresponds to an open system in contact with a reservoir. As mentioned above, electrolytes contain solvated ions in order to make them electrically conducting. In thermodynamic equilibrium, these ions are characterized by their (electro-)chemical potential. The adsorption of an ion species at the electrode can be thermodynamically stable (Reuter and Scheffler 2001) if the Gibbs free energy of adsorption $\Delta\gamma$ of adsorbates bound to a surface area A_s:

$$
\begin{aligned}
\Delta\gamma(T, c) &= \gamma(T, c, N_{\text{ads}}) - \gamma_{\text{clean}}(T, p, 0) \\
&= \frac{1}{A_{\text{S}}}\big(G_{\text{surf,ads}} - G_{\text{surf,0}} - \sum_i n_i \tilde{\mu}_i\big)
\end{aligned}
\tag{1}
$$

is negative. Here, $G_{\text{surf,ads}}$ and $G_{\text{surf,0}}$ are the Gibbs free energies of the adsorbate-covered and the clean surface, respectively, n_i is the number of adsorbed atoms of type i per surface area A_{S}, and $\tilde{\mu}_i$ is the corresponding electrochemical potential:

$$
\tilde{\mu}_i = \mu_i + q_i eU,
\tag{2}
$$

of adsorbate species i where q_i is the charge of the particle and U is the electrode potential. The chemical potential μ_i contains all solvation effects of the species. However, in order to evaluate solvation energies, computationally demanding thermodynamic integration schemes are necessary (Leach 2001).

Concentrating first on solvated protons, these efforts can be avoided by realizing (Nørskov et al. 2004, 2005) that at standard conditions (pH= 0, $p = 1$ bar, $T = 298$ K, $U = 0$), there is an equilibrium between protons in aqueous solution together with an electron at the Fermi level of the electrode $H^+(\text{aq}) + e^-$ and hydrogen in the gas phase, $\frac{1}{2}H_2(\text{g})$. In addition, the variation of the electrochemical potential of the proton and the electron change with proton concentration and electrode potential is well-known (Schmickler and Santos 2010):

$$
\tilde{\mu}(H^+(\text{aq})) + \mu(e^-) = \frac{1}{2}\mu(H_2(\text{g})) - eU_{\text{SHE}} - k_{\text{B}}T\ln(10)\text{pH},
\tag{3}
$$

where U_{SHE} is the electrode potential with respect to the standard hydrogen electrode (SHE). This approach is now referred to as the computational hydrogen electrode (CHE) (Nørskov et al. 2004, 2005); it is equivalent to the concept of ab initio thermodynamics for heterogeneous catalysis at the solid-gas interface (Reuter and Scheffler 2001).

It is not only applicable for hydrogen and protons; it works also for any redox couple such as $\frac{1}{2}A_2 + e^- \rightleftharpoons A^-$ (Hansen et al. 2010) where A_2 can be, for example, a halogen molecule, resulting in an electrochemical potential:

$$\tilde{\mu}(A^-(aq)) - \mu(e^-) = \frac{1}{2}\mu(A_2(g)) + e(U_{SHE} - U^0) + k_B T \ln a_{A^-}, \qquad (4)$$

where U^0 is the reduction potential of the corresponding halide vs. U_{SHE} and a_{A^-} its activity coefficient. Furthermore, this concept can also be extended to more than one solvated species in the electrolyte (Gossenberger et al. 2016).

Up to here the whole derivation is exact. Typically, the electrochemical potential $\tilde{\mu}_i$ is taken as a parameter characterizing the electrochemical conditions of the system. Still, Eq. 1 requires to evaluate surface free energy differences which is computationally very demanding. In heterogeneous catalysis where adsorption occurs at the solid-gas interphase, the dependence of the free energy of the adsorbate-covered surfaces is typically only rather weakly dependent on the environment represented by partial pressures of the gas phase species and temperature (Reuter and Scheffler 2001). Furthermore, changes in entropy and zero-point energies upon adsorption are typically small (Reuter and Scheffler 2001) so that they can be neglected. Hence surface free energies are often replaced by surface total energies (Todorova et al. 2003; Rogal et al. 2007).

At electrochemical interfaces, typically corresponding approximations are made, i.e., the presence of the electrolyte, entropy effects, and varying electrode potentials is neglected, so that the surface free energy is expressed as

$$\Delta\gamma = \frac{1}{A_S}\Big(E_{ads} - \sum_i n_i \Delta\tilde{\mu}_i(T, a_i, U)\Big). \qquad (5)$$

where E_{ads} is the total energy of adsorption in the absence of the electrochemical environment and $\Delta\tilde{\mu}_i(T, c_i, U)$ is the contribution to the electrochemical potential that depends on temperature, concentrations c_i, and electrode potential.

Hence the whole dependence on the particular electrochemical conditions is only taken into account with respect to the solvated species in the electrolyte. This seems to be a very rough approximation. Still, this approach has been rather successful in reproducing and explaining observed trends in electrocatalytic reactions such as oxygen reduction (Nørskov et al. 2004; Keith et al. 2010) and hydrogen evolution (Nørskov et al. 2005) on metal electrodes. This is most probably a consequence of the good screening properties of metallic electrodes which make binding energies hardly dependent on applied electric fields (Nørskov et al. 2004; Rossmeisl et al. 2006; Wang and Liu 2009; Jinnouchi et al. 2014). In addition, water typically interacts rather weakly with metal electrodes (Gohda et al. 2008).

We will now illustrate the power of this approach with respect to the equilibrium coverage of halides on metal electrodes (Gossenberger et al. 2015, 2016; Lin et al. 2016). Experimentally a competitive adsorption of protons and chloride adsorption on Pt(111) was observed (Garcia-Araez et al. 2005a, b), which means that as a function of increasing electrode potential, hydrogen adsorbed on Pt(111) is replaced by chlorine. Similar observations were also made in bromide and hydrogen co-adsorption (Garcia-Araez et al. 2006; Garcia-Araez and Koper 2010).
Fig. 2 Equilibrium phases of co-adsorbed chlorine and hydrogen on Pt(111) as a function of the electrochemical potential of hydrogen and chlorine (Gossenberger et al. 2016). The green areas denote hydrogen-containing adsorbate structures, the blue areas chlorine-containing structures, and the cyan areas correspond to mixed structures of both hydrogen and chlorine. The effect of increasing the concentration of the species individually is illustrated by the yellow arrows, whereas the red double arrow shows the effect of varying the electrode potential for fixed concentrations. (Reprinted from Gossenberger et al. (2016), with permission from Elsevier)

Using Eq. 5, the free energies of adsorption of hydrogen and chloride on Pt(111) were determined as a function of their electrochemical potential (Gossenberger et al. 2016). In total, the adsorption energies of 117 adsorbate structures were evaluated. Thus the phase diagram shown in Fig. 2 was derived. Interestingly enough, over a wide range of electrochemical potentials either pure hydrogen or pure chlorine adsorption phases or the clean electrode surface are stable. Naively, one would expect that adsorbed anions (chloride) and cations (protons) experience an attractive interaction. However, there is only a relatively small pocket at positive electrochemical potentials where both hydrogen and chlorine form a stable co-adsorbate structure. Usually one would assume that the adsorption of anions leads to a work function decrease, but in fact chlorine adsorption on Pt(111) causes an anomalous decrease of the work function for chlorine coverage below $\Theta_{Cl} = 0.5$ because of the strong polarization of chlorine upon adsorption (Gossenberger et al. 2014; Roman et al. 2014). This causes an effective dipole-dipole repulsion between hydrogen and chlorine upon co-adsorption, making co-adsorbate structure energetically unfavorable.
Fig. 3 Calculated electrochemical Gibbs energy of adsorption as a function of electrode potential on a Pt(111) surface under standard conditions (Gossenberger et al. 2016). The structure with the lowest energy as a function of electrode potential corresponds to the thermodynamical equilibrium structure. (Reprinted from Gossenberger et al. (2016), with permission from Elsevier)

Note that a phase diagram as shown in Fig. 2 cannot be directly compared to experiment as in electrochemical experiments the electrochemical potentials are not controlled but rather the electrode potential and the concentration of the solvated species. However, electrochemical potentials are a function of the electrode potential and the concentration (see Eqs. 3 and 4). A pure variation of the electrode potential for given concentrations corresponds to a change parallel to the red double arrow included in Fig. 2. At standard conditions, i.e., for an activity $a_{A^-} = 1$, the free energy of adsorption for a halide can be expressed as a function of the electrode potential according to

$$\Delta\gamma(U_{SHE}) = \frac{N_{ads}}{A_s}\left(E_{ads} - e(U_{SHE} - U^0)\right). \qquad (6)$$

For other concentrations of the species A^- in the electrolyte, the corresponding electrode potential needs to be shifted by $k_B T \ln a_{A^-}$ which at room temperature is equivalent to approximately 60 meV when the activity is changed by one order to magnitude.

The Gibbs energy of adsorption for hydrogen and chlorine on Pt(111) as a function of electrode potential is plotted in Fig. 3. This diagram shows the stable phases along the red double arrow in Fig. 2, but it also provides information about the free energies of adsorption for unstable phases. At low electrode potentials
Fig. 4 Calculated Pourbaix diagram showing the stable phases of co-adsorbed chlorine and hydrogen on Pt(111) as a function of pH and electrode potential. The chlorine concentration corresponds to an activity of 0.1. (Reprinted from Gossenberger et al. (2016), with permission from Elsevier)

for which the electrode becomes negatively charged, the adsorption of cations is favored. Consequently, in this region the electrode is hydrogen-covered. As Fig. 3 shows, up to electrode potentials of about 0.45 V hydrogen adsorption is in principle thermodynamically stable with respect to hydrogen evolution. However, already below 0.45 V chlorine adsorption is energetically more favorable. Hence the adsorbed hydrogen atoms will be replaced by chlorine atoms, and the so-called underpotential deposition (upd) of hydrogen is shifted to lower potentials due to the replacement by chlorine. This example shows that phase diagrams based on the concept of the computational hydrogen electrode can successfully reproduce experimental findings with respect to the competitive character of hydrogen and chlorine adsorption on Pt(111) (Garcia-Araez et al. 2005a, b).

Figure 3 shows the stable phases for standard conditions, i.e., for pH = 0. The stable phases as a function of both the electrode potential and pH are plotted in Fig. 4. Such a so-called Pourbaix diagram can directly be compared with experimental finding. Note however that all this information is already implicitly included in Fig. 2, i.e., it corresponds to a transformation of the phase diagram as a function of the electrochemical potentials of the solvated species.

3   Continuum Models of Electrode-Electrolyte Interfaces

In the previous section, the ionic adsorption at electrode-electrolyte interfaces in equilibrium was addressed. However, the presence of the electrolyte was in fact not taken into account in the explicit calculations. We will now consider the properties and structure of the electrode-electrode interface at the first-principles level in more detail. We start by describing the interface in a continuum approach. At this interface, the so-called electrical double layer forms. One layer consists of ions on the electrode surface due to the chemical interaction between the ions and the electrode. This layer is then screened by a charge redistribution in the electrolyte. As this charge is locally not well confined, it is called the diffuse layer. In a simplified picture, the whole charge distribution can be regarded as being formed by two capacitor plates.

Helmholtz is given credit for being the first to realize that the charge distribution in the solution is realized as a single layer of ions adsorbed at the surface (Helmholtz 1853). The potential within this *Helmholtz layer* exhibits a linear behavior as a function of distance from the electrode. Early in the twentieth century, Gouy (1910) and Chapman (1913) refined this model by allowing for a diffuse thermal distribution of the ions.

Applying Boltzmann statistics to the distribution of both anions and cations of absolute charge $|ze|$ with a bulk density of n_0 yields the *Poisson-Boltzmann equation* (Schmickler and Santos 2010) for the potential $\phi(x)$:

$$\frac{d^2\phi}{dx^2} = -\frac{zen_0}{\varepsilon\varepsilon_0}\left(\exp\left(-\frac{ze\phi(x)}{k_BT}\right) - \exp\left(\frac{ze\phi(x)}{k_BT}\right)\right). \tag{7}$$

The exponentials can be linearized for $ze\phi(x)/k_BT \ll 1$, yielding an exponentially decreasing electric potential:

$$\phi(x) = \frac{\sigma}{\varepsilon\varepsilon_0\kappa}\exp(-\kappa z), \tag{8}$$

where σ is the surface charge density of the electrode and

$$\kappa = \left(\frac{2(ze)^2 n_0}{\varepsilon\varepsilon_0 k_BT}\right)^{1/2}, \tag{9}$$

is the inverse *Debye length*. Note that this formulation is rather close to the macroscopic treatment of the interface between an electron conducting n-type and a hole conducting p-type semiconductor, resulting in the formation of a space charge layer. The Gouy-Chapman model, however, does not take into account that ions

Fig. 5 Illustration of the Stern model describing the electric double layer in a continuum picture
can adsorb specifically at the electrode surface immobilizing them. Therefore it does not allow to describe highly charged double layers. As a consequence, the Gouy-Chapman theory predicts that the capacity always has its minimum at the potential of zero charge. Still, at higher electrolyte concentrations, the capacity exhibits a much more complex dependence on the potential (Schmickler and Santos 2010).

Stern suggested a combination of the Helmholtz and Gouy-Chapman models in order to improve the description of the double layer (Stern 1924), as illustrated in Fig. 5. It consists of an internal Stern layer (i.e., a Helmholtz layer) in which the potential drops linearly and an outer diffuse layer (i.e., a Gouy-Chapman layer) in which the potential falls off exponentially. This yields the following expression for the capacity C:

$$\frac{1}{C} = \frac{1}{C_{GC}} + \frac{1}{C_H}. \tag{10}$$

C_{GC} is the Gouy-Chapman capacity and C_H the Helmholtz capacity which is independent of the electrolyte concentration.

This description yields a phenomenological macroscopic model of the electrode-electrolyte interface. It is very useful in order to understand and analyze general trends of the capacity at electrochemical interfaces. Still, a more quantitative theory of solid-electrolyte interfaces is needed, taking into account the atomistic structure of the interface in order to fully understand structures and processes at these interfaces.

4   Atomistic First-Principles Description of Solid/Water Interfaces

A more realistic picture of the structure of electrode-electrolyte interfaces requires an atomistic modeling associated with performing statistical averages over many different configurations. This calls for numerical efficient methods based on inter-atomic potentials which avoid to solve the quantum mechanical electronic structure problem. In fact, structural properties of aqueous electrolytes can be rather well reproduced by parameterized classical interaction potentials (Siepmann and Sprik 1995; Crozier et al. 2000; Bukowski et al. 2007). Such potentials have also been used quite frequently in molecular dynamics studies addressing the structure of the electrode-electrolyte interfaces at finite temperatures (Spohr 1989, 1997; Raghavan et al. 1991; Xia and Berkowitz 1995). Important insights into the structure of electrode-electrolyte interfaces have been gained from these studies.

However, interatomic potentials usually do not reproduce water *and* metal properties satisfactorily at the same time. On the one hand, force fields do not describe metals well. On the other hand, covalent bonding can typically not been appropriately reproduced by interpolation schemes including many-body effects such as the embedded atom method (EAM) (Daw and Baskes 1984; Daw et al. 1993) that are well suited to reproduce metallic properties. In addition, classical interaction potentials usually fail in describing bond breaking and bond making which would be required to treat electrocatalytic processes at electrode-electrolyte interfaces. Reactive force fields based on bond-order concepts (Goddard et al. 2003; Fantauzzi et al. 2014) allow to treat chemical reactions, but their training effort rises exponentially with the number of elements considered in the parameterization.

Modern machine learning techniques such as interpolation schemes based on artificial networks (Lorenz et al. 2006; Morawietz and Behler 2013; Behler 2014) are able to yield a reliable description of the structural properties of liquid water (Morawietz et al. 2016) and of water-metal interfaces (Natarajan and Behler 2016). However, as no chemical insights enter their construction procedure, their fitting usually requires large training sets (Lorenz et al. 2006).

Due to the ever-increasing computer power and the development of efficient algorithms, first-principles electronic structure methods based on density functional theory (DFT) can now be applied to describe the properties of electrode-electrolyte interfaces (Schnur and Groß 2009; Sakong et al. 2016). DFT calculations combine numerical efficiency with sufficient accuracy (Groß 2002; Hafner et al. 2006; Michaelides 2006). Thus also statistical averages can be performed using ab initio molecular dynamics (AIMD) simulations (Schnur and Groß 2009; Marx and Hutter 2009) in which the forces necessary to integrate the classical equations of motion are determined "on the fly" by DFT calculations. Based on DFT studies, we will first discuss the structure of water layers on close-packed metal electrodes and then later also turn to oxide electrodes.

Although DFT calculations yield often sufficient accuracy for materials properties, it should be noted that the popular PBE functional (Perdew et al. 1996) leads to

an overstructuring of liquid water (Fernández-Serra and Artacho 2004; VandeVondele et al. 2005; Liu et al. 2009), which means that the pair distribution functions are too much peaked compared to the measured distribution function (Soper 2007), i.e., the shell structure of PBE water is too pronounced.

As a simple solution of this problem, PBE water simulations have been run at a higher temperature of 350 K (Fernández-Serra and Artacho 2004; VandeVondele et al. 2005; Liu et al. 2009) which is, however, not a truly satisfactory approach. Recently, there was significant progress concerning the incorporation of the van der Waals interaction into DFT approaches by the development of reliable dispersion-corrected DFT functionals (Grimme 2004; Grimme et al. 2010; Tkatchenko and Scheffler 2009) and the improvement of van der Waals DFT functionals (Dion et al. 2004). It turns out that it is critical to include the van der Waals interaction in DFT calculations addressing water properties (Santra et al. 2007, 2008). The inclusion of dispersion does not only improve the description of liquid water (Zhang et al. 2011; Lin et al. 2012; Forster-Tonigold and Groß 2014; Sakong et al. 2016), but it also yields the correct wetting behavior of water on metal electrodes (Tonigold and Groß 2012; Carrasco et al. 2011, 2013).

For pure water simulations, DFT hybrid functionals including a certain amount of exact Hartree-Fock exchange are rather popular (Do and Besley 2012). However, for metal-water interfaces, they are not appropriate as the inclusion of exact exchange worsens the description of metal properties (Paier et al. 2007). Here the RPBE functional (Hammer et al. 1999) together with the so-called D3 dispersion corrections of Grimme (Grimme et al. 2010) yields a rather satisfactory description of the water-water (Forster-Tonigold and Groß 2014; Imoto et al. 2015; Sakong et al. 2016; Morawietz et al. 2016) and the water-metal interaction (Tonigold and Groß 2012) as it replaces the overestimated directional hydrogen bonds of PBE by nondirectional van der Waals bonds (Forster-Tonigold and Groß 2014).

Another source of error in the description of water is the possible role of nuclear quantum effects because of the low mass of hydrogen atoms. There are conflicting results with respect to the effect of these nuclear quantum effects on the properties of liquid water (Morrone and Car 2008; Chen et al. 2003; Habershon et al. 2009; Fritsch et al. 2014). As AIMD simulations of liquid water including dispersion corrections yield pair distribution function very close to the experiment (Forster-Tonigold and Groß 2014; Sakong et al. 2016), it is still unclear whether the incorporation of nuclear quantum effects is really necessary.

We will now discuss the structure of water adsorbed on metal electrodes using Fig. 6 as an illustration where the structure of a hexagonal icelike structure on a $Pt_1Ru_2/Pt(111)$ surface alloy is depicted (Fischer et al. 2016). Isolated water monomers typically bind in an almost flat configuration via their oxygen atom in an on-top configuration to metal surfaces with the hydrogen and oxygen atoms of the water molecules almost at the same height (Michaelides 2006; Schnur and Groß 2009, 2011), similar to the water molecules adsorbed on the Ru atoms of the $Pt_2Ru_1/Pt(111)$ surface alloy (Fischer et al. 2016) shown Fig. 6. The adsorption energy of water monomers on metals is relatively weak, ranging from -0.1 to -0.4 eV. Their binding energy on typical late transition metal surfaces is ordered
according to Au<Ag<Cu<Pd<Pt<Ru<Rh (Michaelides 2006). The weak interaction of water with metal surfaces is also reflected by the fact that the electronic local density of states of the metal atoms at the surfaces is not substantially altered upon water adsorption (Gohda et al. 2008; Schnur and Groß 2009). As a consequence, the binding energy of specifically adsorbed species to late transition metal electrode surfaces is hardly influenced by the presence of water (Roudgar and Groß 2005a, b; Sakong et al. 2015).

It is important to note that the rather nondirectional water-metal interaction is of the same magnitude than the directional water-water interaction mediated by hydrogen bonds. Hence the minimum energy structure of water layers adsorbed on metal electrodes corresponds to a compromise between the attractive water-metal and water-water interaction (Groß et al. 2014). As for close-packed hexagonal metal surfaces, icelike hexagonal rings fit rather nicely on top of them. However, in order to build a hexagonal icelike network, not all water molecules can bind in the optimum configuration through their oxygen atom to the metal atoms. In fact, there are two different possible configurations for the water molecules not bound via their O atom to the metal, namely, the so-called H-down and H-up structures with one hydrogen atom either pointing toward or away from the surface. Figure 6 depicts an H-down structure; the H-down hydrogen atom is actually not visible in the top view. The H-down and H-up structures are rather close in energy, and both structures can be stable depending on the particular choice of the metal: the H-up structure is more stable on Ni(111), Cu(111), and Ru(0001), whereas on Rh(111), Ag(111), Pt(111), Pd(111) (Michaelides 2006), and Pd/Au(111) (Roudgar and Groß 2005b), the H-down structure is energetically favorable. As far as the hexagonal

icelike layer shown in Fig. 6 is concerned, it is obvious that the water molecules interacting more strongly through their O atom with the metal are located above the Ru atom which reflects the stronger interaction of Ru with water monomers compared to Pt mentioned above.

The interaction of water, in particular, with noble metal surfaces such as Ag(111) and Au(111) is so weak that in fact it is more stable to form a three-dimensional ice cluster (Carrasco et al. 2011; Tonigold and Groß 2012), i.e., water does not wet these surfaces. In contrast, on Pt(111) and Pd(111), wetting layers form.

In spite of the weak interaction of intact water molecules with metal surfaces, water can still adsorb dissociatively on metals (Feibelman 2002; Michaelides 2006). On Ru(0001) a half-dissociated water layer should be preferred according to DFT calculations (Feibelman 2002) where every second water molecule is dissociated to OH. Ru is not the only metal where half-dissociated water layers should form; also on Rh and Ni, half-dissociated water layers should be energetically favorable (Michaelides 2006). Still, the water dissociation is associated with relatively high barriers so that the formation of the half-dissociated layer is kinetically hindered.

Up to now we have only considered minimum energy structures of water on close-packed metal electrodes. Still the question remains whether at room temperatures these water structures are really crystalline or rather liquid-like. In order to address this question, a systematic AIMD study of the structure of two water layers on Ag(111), Au(111), Pt(111), Pd/Au(111), and Ru(0001) at room temperature was performed (Schnur and Groß 2009). The simulations were started with the icelike bilayer as the initial configuration and then run for 10 ps. Figure 7 shows snapshots of the AIMD trajectories at 8 ps.

According to Fig. 7 for water on the noble metal surfaces Ag(111) and Au(111), there is almost no indication of the initial hexagonal geometry anymore after 8 ps. Also on Pd/Au(111) that is even more strongly interacting with adsorbates than Pd(111) (Roudgar and Groß 2003a, b) but has a larger lattice constant, the water structure is broken. On Pt(111) and Ru(0001), there is still some hexagonal water structure discernible which might be an artifact of the relatively small $2\sqrt{3} \times 2\sqrt{3}$ unit cell chosen. However, the orientation of the water molecules seems to be rather random; there is no indication of either the H-up or the H-down structure. Only the half-dissociated water structure on Ru(0001) stays rather fixed which is due to the fact that the hydroxyl groups strongly interact with the metal substrates and thus pin the water network.

Figure 7 suggests that at room temperature, water layers on close-packed metal electrodes are disordered, at least as far as the orientation of the water molecules is concerned. Experimentally, at the moment it is not really possible to directly monitor the orientation of water molecules in a water film on electrode surfaces. However, the work function change of electrodes upon water adsorption sensitively depends on the orientation of the water molecules. Because of opposite dipole orientation, the H-up and H-down water structures cause work function changes that differ by about 2 eV (Schnur and Groß 2009, 2011; Filhol and Bocquet 2007), as is shown in Fig. 8. The comparison with the experimentally measured work function changes
Fig. 7 Snapshots of AIMD simulations of two water layers on (**a**) Ag(111), (**b**) Ag(111), (**c**) Pt(111), (**d**) Pd/Au(111), and (**e**) Ru(0001) at 300 K. Only the first water layer is shown (Schnur and Groß 2009). In addition, a snapshot of a half-dissociated water layer on Ru(0001) is shown (panel f). The size of the surface unit cell used in the simulations is shown in panel c. (Reprinted from Schnur and Groß (2009) ©IOP Publishing Ltd and Deutsche Physikalische Gesellschaft. Reproduced by permission of IOP Publishing. CC BY-NC-SA)

for Au(111) (Heras and Viscido 1980), Pt(111) (Langenbach et al. 1984; Kiskinova et al. 1985), or Ru(0001) (Hoffmann and Benndorf 1997; Lilach et al. 2001) also shown in Fig. 8 reveals a large discrepancy. In fact, the experimentally observed work functions for these systems lie in between those calculated for the H-up and H-down structures.

In Fig. 8, also calculated work function changes averaged over AIMD runs for water on Au(111), Pt(111), and Ru(0001) at 150 and 300 K are shown. In fact, the discrepancy between measured and calculated work function changes is strongly reduced when the thermal disorder in the orientation of the water molecules is taken into account through AIMD simulations (Schnur and Groß 2009, 2011) because then the preferential orientation of the water molecules and thus of their dipole moments is significantly reduced. This yields strong evidence that indeed water layers at close-packed fcc(111) electrodes are disordered at room temperature and not aligned, as assumed in Fig. 1.

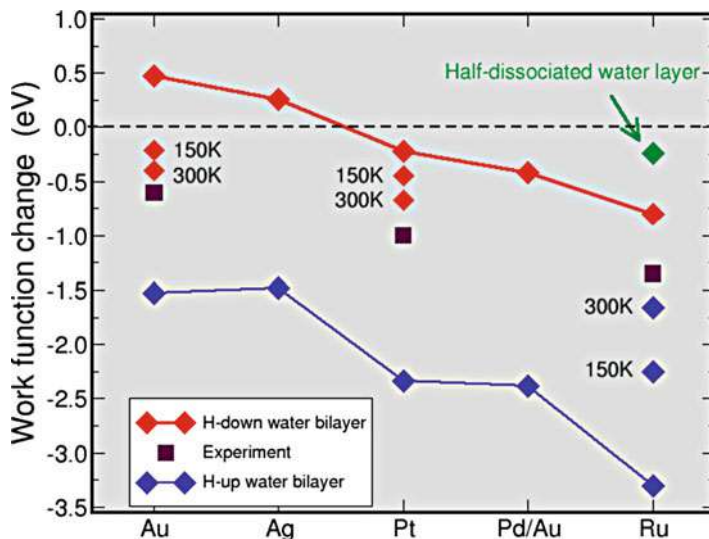
The determination of the work function is not only important to derive the mean orientation of adsorbed water molecules, it is also directly related to the electrode potential (Trasatti 1995) in electrochemical systems. For example, the so-called potential of zero charge (pzc) is given by the work function of an electrode


Fig. 8 Work function change induced by the presence of H-up and H-down water bilayers on Au(111), Ag(111), Pt(111), Pd/Au(111) and Ru(0001) according to DFT calculations (Schnur and Groß 2009). For Ru, also the work function change induced by the half-dissociated water layer is included. Furthermore, the average work function change determined in AIMD runs with at 150 and 300 K is compared to experimental results for Au(111) (Heras and Viscido 1980), Pt(111) (Langenbach et al. 1984; Kiskinova et al. 1985) and Ru(0001) (Hoffmann and Benndorf 1997; Lilach et al. 2001). (Reprinted from Schnur and Groß (2011), with permission from Elsevier)

covered by a pure, ion-free water film (Trasatti 1986, 1991; Tripkovic et al. 2011). In order to evaluate the pzc of Pt(111), ab initio molecular dynamic simulations of six water layers on a five-layer Pt(111) slab within a 3×3 unit cell were run for more than 30 ps (Sakong et al. 2016). In Fig. 9, the work function calculated along this run for the first 30 ps is plotted. On short time scales, the work function can vary by ± 1 eV because of the still rather small size of the surface unit cell. The red line in Fig. 9 corresponds to smoothened values averaged over 5 ps. The overall distribution of the work function along the AIMD run is plotted in the inset of Fig. 9. A necessary but not sufficient condition for performing thermal averages in the canonical ensemble is that the quantities of interest exhibit a Gaussian distribution which is satisfactorily fulfilled in this case. A Gaussian fit to the simulation results yields a mean value of the work function of 4.88 V which is in rather good agreement with the experimentally observed absolute pzc of 4.9 V measured using the CO adsorption technique (Trasatti 1991; Weaver 1998; Cuesta 2004; Petrii 2013). This also lends credibility to the simulation results. Assuming a value of 4.44 V for the absolute standard hydrogen electrode (SHE) potential as suggested by both theory and experiments (Tripkovic et al. 2011; Trasatti 1983, 1986; Reiss and Heller 1985), a calculated pzc of 0.44 V versus SHE is obtained. In Fig. 9, still an overall drift in the work function is observable. Yet, running the
Fig. 9 Calculated work function of the water-covered Pt(111) slab along an AIMD trajectory of six explicit water layers on Pt(111) (Sakong et al. 2016). The red line corresponds to values each averaged over 5 ps. The distribution in the work function is shown together with a Gaussian fit that is presented in the inset. (Courtesy of Dr. Sung Sakong)

simulations for further 10 ps does not influence the results significantly (Sakong et al. 2016).

The AIMD simulations can also be used to analyze the water structure as a function of the distance from the Pt(111) electrode (Sakong et al. 2016). The distributions of the oxygen and the hydrogen atoms of the water molecules in the AIMD simulations are shown in Fig. 10a, b, respectively. In the middle of the water film, the mean spatial distribution becomes already rather flat as in bulk water. This suggests that the water film is thick enough to include a region that is bulk water-like and that water above Pt(111) becomes liquid-like from the third water layer on.

Up to now we only considered clean metal electrodes. However, as shown in Sect. 2, metal electrodes such as Pt(111) are typically covered by hydrogen at low electrode potentials and by anions at high electrode potentials. This will also have a consequence as far as the water structure at these electrode-electrolyte interfaces is concerned. AIMD simulations of water layers on hydrogen-covered Pt(111) (Roman and Groß 2013) have shown that the presence of hydrogen on Pt(111) weakens the interaction between water and Pt. As a consequence, the lowest water layer is about 1 Å farther away from the surface than in the case of the clean electrode. Thus one could say that the adsorption of hydrogen on Pt(111) leads to a passivation of the Pt-electrode.

Furthermore, the weakening of the water-metal interaction also leads to a strengthening of the water-water interaction which can be explained invoking the

concept of bond-order conservation (Groß et al. 2014). This leads to a more
structured distribution of the water molecules in the first two layers above the
hydrogen-covered Pt(111) electrode (Roman and Groß 2013).

Besides metal electrodes, oxide electrodes are also of strong interest in electro-
chemistry and electrocatalysis, in particular as catalysts for the oxygen evolution
reaction (Halck et al. 2014; Mom et al. 2014). However, in contrast to metal
electrodes, oxide electrodes often have a more complex surface structure due to
the covalent nature of the bonding (Groß 2009). In particular, many oxide surfaces
become hydroxylated in the presence of water which then has a significant influence
on the bonding of water to these electrodes. In a DFT study, it was found that out-of-
plane hydroxyl groups act as H-bond donors, whereas in-plane hydroxyl groups are
H-bond acceptors (Gaigeot et al. 2012) and thus define a patterning of the interfacial
water structure.
Fig. 11 Side and top views of the structure of water bilayer taken from the AIMD simulations of water at 140 K on β-Ni(OH)$_2$(001), β-NiOOH(001) terminated with 50% OH and 50% O, and β-NiOOH(001) terminated with 75% OH and 25% O. (2017) with permission from the PCCP Owner Societies)

In another DFT study, the adsorption of water layers on nickel(oxy)hydroxides was addressed (Eslamibidgoli et al. 2017). Figure 11 shows the top and side views of water bilayers at a coverage of 2/3 monolayers (ML). On β-Ni(OH)$_2$(001) and β-NiOOH$_{75/25}$(001), i.e., a surface terminated with 75% OH and 25%O, hexagonal water layers form. In contrast, on β-NiOOH$_{50/50}$(001), only an incomplete hydrogen bond network is stable (Eslamibidgoli et al. 2017). However, the lattice constant of β-Ni(OH)$_2$(001) is about 7.5% larger than the one of the β-NiOOH(001) surfaces, resulting in a weaker water-water interaction on β-Ni(OH)$_2$(001). In addition, on β-Ni(OH)$_2$(001) also the surface-water interactions are weaker as due to the surface structure, no favorable adsorption configuration with the water molecule bound through the oxygen to the surface can be realized. Consequently, a temperature of 140 K leads to a disordered structure, as the lower panel of Fig. 11 demonstrates.

As shown above, for selected systems the statistical averages necessary to determine the properties of systems including liquid electrolytes can nowadays be obtained from first principles using AIMD simulations. Still, in spite of the development of efficient algorithms and the ongoing progress in computer power, AIMD simulations are numerically rather costly. This represents a severe obstacle for the first-principles modeling of electrode-electrolyte interfaces, in particular, when many different configurations are needed to be calculated, as, for example, in the description of electrocatalytic reaction networks.

As a computationally attractive alternative, the electrolyte can be represented in an implicit solvent model (Mathew et al. 2014; Andreussi et al. 2012; Andreussi and Marzari 2014; Sakong et al. 2015), i.e., the solvent is treated as a continuous dielectricum. This approach is justified when the averaged behavior of many highly dynamic solvent molecules can be approximated by a potential of mean force (Leach 2001), but critical issues are a suitable short-range cavity parameterization and an appropriate treatment of the nonlinearity in the ionic response (Sundararaman and Schwarz 2017). Still, qualitative trends can be well reproduced by using implicit solvent models, as was recently shown for the methanol electrooxidation on Pt(111) (Sakong and Groß 2016, 2017).

Experimentally, it was shown that on a Pt(111) electrode in an electrochemical environment, methanol is initially predominantly converted to hydroxymethyl (H_2COH) involving the breaking of one of the C-H bonds of the methyl group of methanol (Franaszczuk et al. 1992). In contrast, at the Pt-vacuum interface, methanol also decays to methoxy (CH_3O) associated with the breaking of the O-H bond (Franaszczuk et al. 1992). Calculations with and without the presence of an implicit solvent show that the presence of the implicit solvent favors isomers with a hydrophilic hydroxyl group. This also increases the barrier for the O-H bond breaking in the dehydrogenation from methanol to methoxy in the presence of the solvent as the molecule loses its hydrophilic hydroxyl group along the reaction path (see Fig. 12). Thus the selectivity toward the initial C-H bond breaking with regard to the initial O-H bond breaking is increased by three orders of magnitude in the
Fig. 12 Energy minimum curves of the initial methanol dehydrogenation on Pt(111) in vacuum (dashed lines) and in implicit water (solid lines) along a reaction path coordinate. The blue lines represent the formation of H_2COH involving the breaking of a C-H bond, while the red lines correspond to the creation of CH_3O involving the breaking of an O-H bond. presence of a solvent (Sakong and Groß 2016, 2017), confirming the experimental findings (Franaszczuk et al. 1992).

5 Explicit Consideration of Varying Electrode Potentials

It was already shown in Sect. 2 how varying electrode potentials can be implicitly included in the grand-canonical description of electrode-electrolyte interfaces through the dependence of the electrochemical potentials on the electrode potential. However, fundamentally this is not a satisfactory approach as typically the explicit dependence of the properties on the electrode potential is not taken into account.

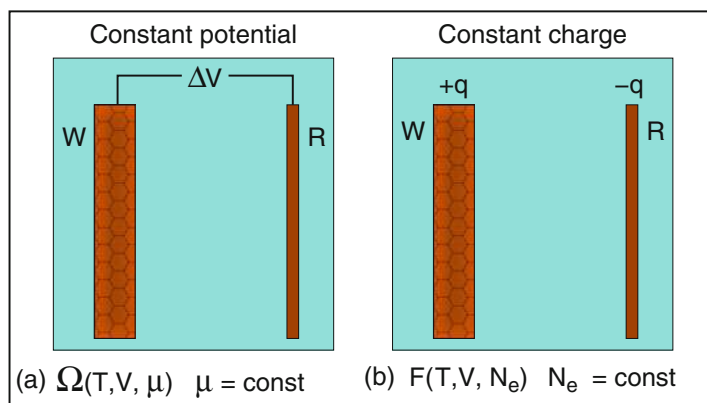
Let us have a look at how electrochemical experiments are performed which is illustrated in Fig. 13a. Typically the electrode potential of a working electrode W with respect to a reference electrode R is specified. When processes occur at the working electrode that would change the charge distribution at the interface and thus the specific electrode potential, a charge is flowing between working and reference electrode that keeps the electrode potential constant. This leads to different excess charges on the electrodes at a given constant potential which for slabs of finite thickness in a periodic DFT, ansatz can be achieved by varying the number of electrons and keeping the chemical potential μ of the electrons constant, i.e., the grand-canonical formulation of DFT (Mermin 1965) needs to be invoked. This requires a self-consistent field procedure in which the number of electrons is allowed to vary such that the Fermi level stays at a preset value (Lozovoi et al. 2001). However, a straightforward implementation of a feedback loop leads to oscillatory instabilities (Bonnet et al. 2012; Schneider and Auer 2014).


Fig. 13 Illustration of (**a**) the constant chemical potential ($\mu = const$) and (**b**) the constant charge ($N_e = const$) mode to treat electrochemical cells within periodic DFT calculations. The corresponding thermodynamic potentials to describe a slab together with a reference electrode are the grand potential Ω and the Helmholtz free energy F, respectively

These problems can be avoided by connecting the system to a fictitious potentiostat (Bonnet et al. 2012). The potentiostat functions analogously to a thermostat (Nosé 1984). The total electronic charge of the system becomes a dynamical variable through the exchange of electronic charge with an external potentiostat at a specified potential. This leads to dynamical equations for the total electronic charge such that the calculated trajectory samples the grand-canonical distribution at a given electrode potential.

Another constant potential scheme was developed for a nonperiodic finite DFT setup (Schneider and Auer 2014) which avoids the introduction of compensating countercharges. Still, a straightforward implementation of a grand-canonical DFT scheme leads to numerical instabilities also in this finite setup so that a numerical evaluation of $d\mu/dN$ is employed in order to estimate the correct number of electrons N.

It is fair to say that both of these constant potential implementations have so far not been routinely employed to describe structures and processes at electrochemical solid-electrolyte interfaces, probably because of their high numerical demand. In fact, most of the first-principles studies performed for different electrode potentials so far have been performed in the constant charge mode depicted in Fig. 13b with the corresponding electrode potential derived in an a posteriori fashion.

In contrast to calculations for a finite setup, in a periodic setup, only charge-neutral supercells can be employed because otherwise the electrostatic energy diverges. Hence any excess charge on an electrode has to be compensated by an oppositely charged counter electrode. This counter electrode can, for example, be realized, as illustrated in Fig. 14, by a localized planar charge distribution (Fu and Ho 1989; Bohnen and Kolb 1998; Lozovoi and Alavi 2003; Che and Chan 2003; Zhao et al. 2007; Schnur and Groß 2011) in the form of a Gaussian profile perpendicular to the surface:

$$\rho_{ce}(\mathbf{r}) = \frac{q}{\sqrt{2\pi}\alpha} \exp\left\{ \left(-\frac{z - z_0}{2\alpha} \right)^2 \right\}, \tag{11}$$

where q is the total charge of the counter electrode and z_0 corresponds to the position of the counter electrode.

In Fig. 14, laterally averaged one-electron potentials are plotted for different excess electron numbers per unit cell for a symmetric slab covered by one water layer on each side. Variations in the electron number cause a shift in the Fermi energy whose range is indicated $\Delta\varepsilon_F$. The counter electrode has to be positively charged for negatively charged slabs which in fact makes it attractive for electrons. This causes artificial electron transfer from the slabs to the counter electrode when the one-electron potential in the counter electrode drops below the Fermi energy for a sufficiently large positive countercharge. Consequently the range toward negative charges on the slabs corresponding to low electrode potentials is limited.

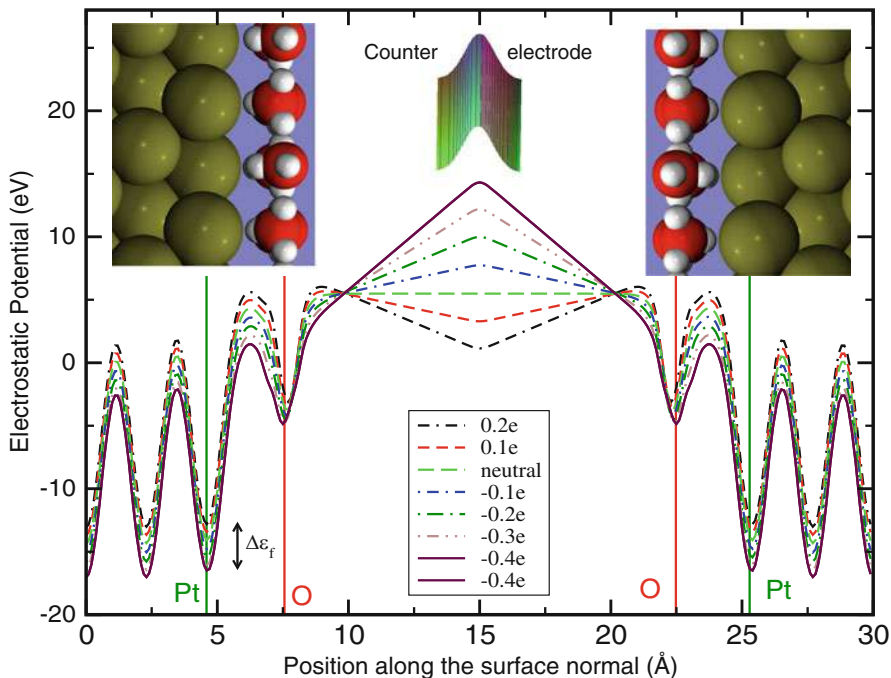
Note that a countercharge needs to be introduced in order to compensate the excess charges on the electrodes, but it has no physical relevance. Nevertheless there


Fig. 14 Illustration of the implementation of an explicit Gaussian-shaped counter electrode in a periodic DFT setup. The laterally averaged one-electron potential of a symmetrically constructed metal-water slab along the surface normal is plotted for various charges of the slab (Schnur and Groß 2011). (Reprinted and adapted from Schnur and Groß (2011), with permission from Elsevier)

is an additional direct electrostatic interaction between the electrons and the ion cores with the counter electrode which needs to be corrected for by integrating the electrochemical potential μ over the applied charge (Taylor et al. 2006), i.e.:

$$E = \int_0^q \mu \, dQ = E_{\text{DFT}} + \int_0^q \left[\int \frac{V_{\text{tot}}}{\Omega} d^3 x \right] dQ. \tag{12}$$

Furthermore, the total grand-canonical free energy of the electrons has to be expressed as

$$E_{\text{free}} = E + \mu q, \tag{13}$$

in order to take the varying number of electrons in each system into account. Here E is the total energy given by Eq. 12, i.e., the energy E_{DFT} from the DFT calculations corrected for the electrostatic interaction with the counter electrode, and q is the total charge of the explicit electron-ion system.

In order to derive the electrode potential related to a certain charge state of the electrode, in principle the corresponding work function needs to be evalu-

ated (Lozovoi et al. 2001; Taylor et al. 2006; Schnur and Groß 2011). This requires to determine the vacuum level of the one-electron energy. However, as Fig. 14 demonstrates, for $q \neq 0$ there is no field-free region in the supercell, so that the work function and hence the electrode potential cannot be specified. One might relate the charge to the electrode potential via experimentally derived capacities (Bohnen and Kolb 1998); however, this introduces an empirical component to the approach.

Still, following the procedure of Lozovoi et al. (2001), the work function can be derived by determining the one-electron potential v at a point z' where the potential is linear using:

$$\Phi = v\left(z'\right) - (z' - z_{\text{ref}}) \left.\frac{dv}{dz}\right|_{z=z'} - \varepsilon_F, \qquad (14)$$

where z_{ref} is a point where the vacuum level in the one-electron potential has been reached in the field-free case. As Fig. 14 illustrates, there is a very convenient reference point z_{ref} for this particular system where all one-electron potentials cross and where the electrode potential in the neutral case already assumes its vacuum level. Choosing $z' = z_{\text{ref}}$, the work function can be derived using

$$\Phi = v\left(z_{\text{ref}}\right) - \varepsilon_F \qquad (15)$$

In fact, defining the counter electrode as a localized planar distribution still requires to modify the electronic structure codes. However, when no explicit counter electrode is implemented, then upon charging the system, i.e., when the number of electrons does not equal the total positive charge of all ion cores, the excess charge is automatically compensated by a uniform charge background. This is because in the Fourier transform of the electrostatic energy, the monopole term is omitted as it would lead to a diverging energy. This approach has in fact also been used to realize the counter electrode in periodic DFT calculations, addressing electrochemical electrode-electrode interfaces (Filhol and Neurock 2006; Taylor et al. 2006). In this method it is even more complex to derive the electrode potential a posteriori because in the vacuum region, the one electrode potential exhibits a quadratic behavior for charged situations (Taylor et al. 2006). This also leads to erroneous field effects at the electrode surface. They do not appear when the vacuum region is filled with explicit water molecules (Taylor et al. 2006), but still no work function can directly be derived.

As a solution of this problem, the so-called double-reference method was developed (Filhol and Neurock 2006; Taylor et al. 2006). In a first step, a DFT calculation with a well-defined vacuum region is performed by constructing a solvated slab with a vacuum region introduced in the middle of the unit cell between the slabs. Note that electric fields do not penetrate into perfect metallic conductors. Hence the potential inside of the metal slab representing the metal electrode taken with respect to the vacuum level is taken as the first reference point.

Then a second set of calculations for varying charges q is performed in which the regions between the metal slabs are filled with explicit water. The water

configuration in a region far from the electrode is fixed in its $q = 0$ arrangement, and the one-electron potential $\phi_0(w)$ at this site is used as the second reference point. For $q \neq 0$, the remaining system is relaxed under the influence of the excess charge, and the potential at all other positions is shifted with respect to the second reference point. The absolute electrode potential is then taken, for example, with respect to the standard hydrogen electrode (SHE).

We will use Fig. 15 to illustrate how results as a function of the electrode potential can be derived from constant charge calculations. In Fig. 15a, results with respect to the oxygen dissociation on Pt(111) obtained with the double-reference method are shown (Wasileski and Janik 2008). As a first step, initial, transition, and final state of the O_2 dissociation on Pt(111) in the explicit presence of water molecules were calculated for five different charge states ranging from $-1e$ to $+1e$ per supercell. For each configuration, the corresponding electrode potential was determined a posteriori, and the energies were plotted as a function of the electrode potential. Points that are roughly above each other have been obtained for the same charge. In fact, if the electrode potential had been constant along the dissociation path for each particular charge, the points would have been exactly above each other. The variation shows how much the electrode potential varies along the reaction path at a given charge.

The dissociation barrier is given by the difference between the transition state and the initial state, which corresponds to the O_2 molecule adsorbed on Pt(111). This difference has to be taken at the same potential. As the points are not exactly above each other, the energies as a function of the electrode potential had to be interpolated, in this case by a quadratic spline. Then for any given electrode potential, the dissociation barrier can be read off from the quadratic fits. These barriers are plotted for constant potential (μ constant) as the red symbols in Fig. 15b. Not only results for pure water but also with co-adsorbed Na atoms are shown.

In addition, the barriers are also plotted derived from the differences in the energies at constant charge (q constant). For low electrode potentials, where the corresponding points in Fig. 15a are almost directly aligned above each other, there is not a significant difference between the barriers at constant charge and at constant potential. However, for positive electrode potentials, the corresponding points are no longer above each other, and the difference between the barriers obtained at constant charge and at constant potential becomes larger than 0.2 eV, which is in fact a consequence of the small unit cells that have to be used in periodic DFT calculations. Thus the change of the dipole distribution along a reaction path causes significant changes in the work function which then alter the corresponding electrode potential. If for a large surface unit cell the studied reaction takes place only on a small portion of the surface unit cell, then the associated work function change, which corresponds to an average over the whole surface unit cell, will only be small, even if locally the dipole moments change substantially.

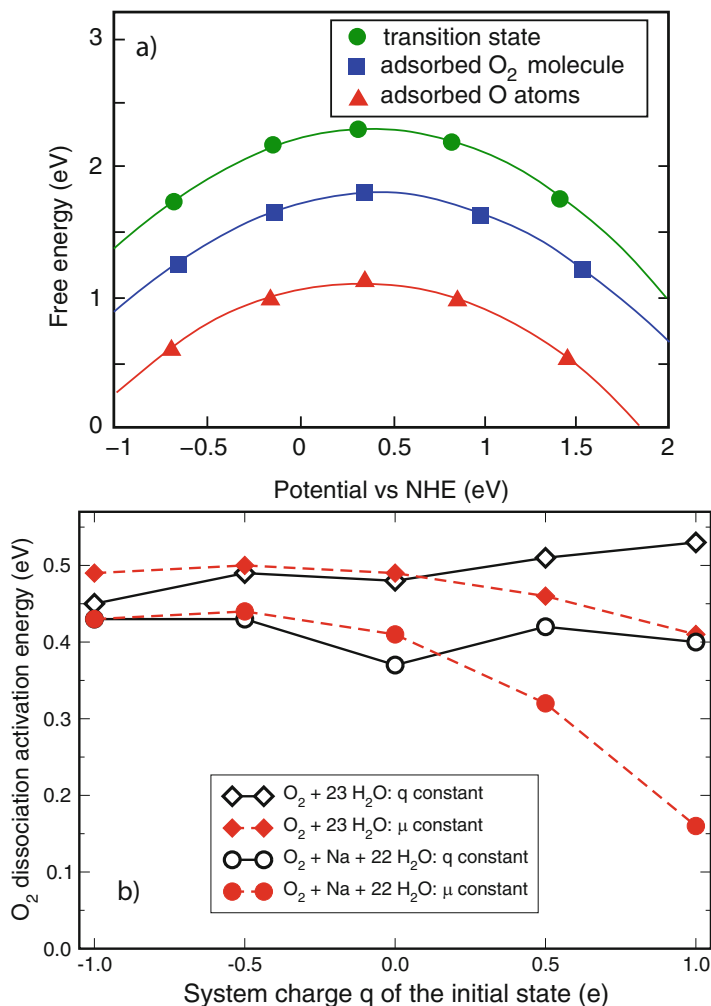
In the discussion so far, we only had focused on electronic effects upon changing the electrode potential. However, when the electrode potential changes, also the electric double layer will rearrange, water molecules might adjust their preferential orientation, and the density of solvated ions in the double layer can be altered. Hence


Fig. 15 (**a**) Calculated free energies as a function of potential for the initial, transition, and final state of O_2 dissociation on solvated Pt(111) obtained with the double-reference method (Taylor et al. 2006). The symbols correspond to the results obtained for different charge states of the Pt electrode, whereas the solid curves are quadratic fits to the results. (**b**) Dissociation barrier of O_2 on solvated Pt(111) without and with Na co-adsorption, respectively, for various constant system charges q of the system and for constant potential, kept at the corresponding value of the initial state. (Adapted from Wasileski and Janik 2008)

in fact the change of the electrode potential can also be represented by a change of the concentration of the ions at the electrode surface which modifies the dipole distribution and consequently the work function and also the electrode potential.

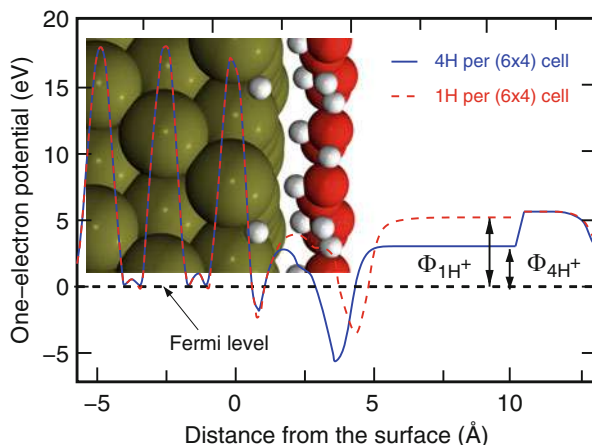
These considerations have been the basis for the model illustrated in Fig. 16 (Skúlason et al. 2007; Rossmeisl et al. 2008). The electrode potential is


Fig. 16 Illustration of how the work function and thus the electrode potential is changed by varying the number of counterions at the electrode-electrolyte interface. The one-electron potential is changed by varying the number of hydrogen atoms in the water layer at Pt(111) within a (6×4) geometry. In the vacuum layer, there is a potential drop due to the presence of a dipole layer. (Adapted from Skúlason et al. 2007). The inset illustrates the structure of the interface with additional protons

varied by introducing hydrogen atoms in the water layer close to the metal electrode. The added hydrogen atoms change the work function of the electrode-electrolyte system and thus the corresponding electrode potential, as demonstrated for one and four hydrogen atoms per (6×4) surface unit cell in Fig. 16. Within this approach, the whole unit cell remains neutral so that the introduction of a counter electrode is not needed.

The hydrogen evolution reaction on Pt(111) has been addressed using this method (Skúlason et al. 2007). As only integer numbers of hydrogen atoms can be added, the electrode potential cannot be changed continuously; however, an extrapolation method to infinite unit cell sizes has been developed which fixed this problem (Skúlason et al. 2007). As far as the calculation of reaction barriers is concerned, this ansatz faces the same problem as constant charge simulations, namely, that the configurations along the reaction path correspond to different dipole moments and thus to different electrode potentials.

However, in principle also calculations in the constant potential mode should take into account that the work function cannot only be adjusted by changing the number of electrons in the systems but also by rearranging the structure of the electrical double layer. Hence any realistic method addressing electrochemical electrode-electrolyte interfaces for varying electrode potentials should take into account both changes in the excess charge of the electrode and the structural rearrangement of the electrolyte within the double layer.

The fact that every surface configuration along a AIMD run in the constant charge mode corresponds in general to a different electrode potential can actually

be used as an advantage. By running long trajectories and monitoring the work function, different configurations can be binned according to their work function. This can also be done for different numbers of ions and adsorbates, thus creating a grand-canonical ensemble of states for a certain electrode potential range (Rossmeisl et al. 2013; Hansen et al. 2017). This so-called generalized computational hydrogen electrode approach was, for example, used to derive atomic-scale quantities of the Au(111)/water interface (Hansen and Rossmeisl 2016). However, this method still suffers from the problem that the sampling is rather inefficient.

6   Conclusions

There is a strong focus on electrochemical electrode-electrolyte interfaces at the moment as they are crucial for our understanding of structures and processes in electrochemical energy conversion and storage. Still, the theoretical description of these interfaces is quite challenging and demanding, as described in this chapter, because, in particular, for liquid electrolytes a sufficient statistical sampling is required, and furthermore a proper treatment of the effect of the electrode potential is necessary. Thus in spite of the complexity of the systems, quantum chemical approaches are needed that properly take electronic structure effects into account which on the other hand make numerical studies computationally very demanding.

There have been many theoretical and numerical efforts to describe electrode-electrolyte interfaces, but still it is fair to say that this field is far from being mature. There is, for example, no complete atomistic picture of the electric double layer even for simple systems. As far as the theoretical methods are concerned, there is no common approach that is widely used except for the grand-canonical ansatz within the concept of the computational hydrogen electrode. Applications of this concept typically use rather severe approximations, but the reliability of these approximations cannot easily be assessed as there are hardly any true benchmark calculations. There are attempts to perform quantum chemical electronic structure calculations of electrode-electrolyte interfaces in the constant potential mode, but obviously there is a certain disillusion with respect to these methods as there are no widespread applications of them.

In spite of these reservations, there has recently been significant progress in the theoretical description of solid-electrolyte interfaces, and it is now clear that the electrochemical environment has to be properly taken into account in theoretical and numerical studies, as illustrated in this contribution. Researchers are aware of all the pitfalls of present approaches and are actively pursuing strategies to overcome the limitations of the methods. Progress in this field is certainly required because of the technological importance of electrochemical energy conversion and storage for our future sustainable energy supply and because of severe problems that still need to be overcome. In addition, there are many interesting scientific problems on a fundamental level that need to be addressed.

The still incomplete status of our knowledge about the microscopic nature of structures and processes at the electrode-electrolyte interface and in the double

layer on a quantitative level makes this research field rather demanding, sometimes frustrating, but at the same time it also makes it exciting and rewarding with lots of opportunity for further progress, both as far as methodological development and applications of numerically efficient schemes that will deepen our knowledge about electrode-electrolyte interfaces are concerned. Hence this is certainly still a promising and emergent field that offers great opportunities.

advances in technology, atomic-scale simulations are needed to provide insight and fundamental understanding of the electrocatalytic reactions. Thus electronic structure calculations relevant for electrocatalysis have attracted a lot of attention in the last decade. However, it is not straightforward to translate state-of-the-art simulations into electrocatalysis. These simulations normally are done at constant number of ions and electrons rather than at constant potential and constant pH, which represent the real physical conditions. In fact, due to this, the electrochemical interface presents one of the frontiers for electronic structure simulations.

In this chapter we describe how standard simulations can provide atomic-scale understanding of electrocatalytic reactions. We introduce the computational version of reference electrodes, which are key in the interpretation of simulations. Furthermore, the reference electrodes are used to create phase diagrams and reaction free energy diagrams for electrocatalytic reactions. The chapter will focus on simulations which can be done without any special implementation of the electronic structure method. This means that we focus on explicit solvent and charge-neutral interfaces. The connection to the electrode potential is introduced in the analysis of the simulations rather than in the simulations themselves.

1   Introduction

Electrochemistry holds the promise to transform society from being based on petro-fuel and petro-chemical to being based on renewable energy. Chemicals and fuels are today by far mostly derived from fossil molecules, oil and gas. Oil is however a limited resource, and in a not too distant future, the chemical industry will have to transform. The transformation toward electrification is further undertaken as the price of electricity from renewable sources is decreasing and in some cases it is actually the most economically viable choice.

Electrochemical energy conversion can convert stable molecules into chemicals with a high-energy content. The source of energy is electricity (direct current) and the feedstock can be abundant molecules from air or water. Thus, chemicals and fuels could be produced using safe, cheap, environmental friendly, and more abundant reactants than today. Furthermore, the products could be provided on demand at the place where they are needed, reducing expensive and hazardous transport of chemicals. Electrocatalysis is, however, not yet established for chemical and fuel production, even though it has the potential to be a disruptive technology. Today, only a few chemicals are produced electrochemically on a huge industrial scale. The electrochemical chlor-alkali process is one of the largest chemical reactions worldwide. Another example is production of aluminum, which is a huge and very energy intense industry based on electrochemical reduction via the Hall–Héroult process (Charles 1889).

Electrochemical energy storage and conversion is related to charge transfer reactions between ion-conducting electrolytes and electron-conducting electrodes. It is at this charged interface between the electrode and the electrolyte that the

energy conversion takes place. These interfaces are ubiquitous in electrochemical devices, and the lifetime and efficiency of the electrochemical devices are often related to the performance of the interfaces. The complexity of the interface provides a severe impediment against its experimental elucidation, and currently there are no atomic-scale simulations or analyses that capture all the essential parts of the electrochemical interface. Fundamental atomic-scale insight is needed to understand and improve the interfaces for energy conversion and storage, and the charged solid/liquid interface represents one of the frontiers of atomic-scale simulations.

The aim of this chapter is to provide an overview of the current state of the art for ab initio quantum mechanical simulations of the electrochemical interface. Implicit electrochemical interface models may require special implementation (Lozovoi et al. 2001; Hamada et al. 2013; Jinnouchi and Anderson 2008a, b; Andreussi et al. 2012; Dupont et al. 2013; Sakong and Gross 2016). The focus here is on methods and analysis, which can be performed without any special requirements for the electronic structure code. Therefore, we focus on explicit water and charge-neutral simulations, with the idea that the analysis here can be performed by people with experience with electronic structure simulations. Many of the results shown here have been obtained using the open-source GPAW and ASE codes (Mortensen et al. 2005; Larsen et al. 2009, 2017; Enkovaara et al. 2010).

2 The Electrochemical Cell

A typical electrochemical cell is sketched in Fig. 1. Overall a cell consists of the electrolyte, at least two electrodes, the ion conductor, the electron conductor, and the potential control. In this case, the ion conductor is shown to conduct protons; however, it could also conduct OH^- groups or other ions. The reactions on the electrodes are determined by the potential applied, and the name *Anode* is given to the oxidizing electrode and *Cathode* is the reducing electrode, and these labels can be switched around by tuning the potential to a different range.

In Fig. 1, BH and A are the reactants and B and AH are the products of a redox reaction. The cathode reduces reactants and the anode oxidizes reactants, and the generalized reaction scheme for an electrochemical cell is:

$$\text{Overall: A} + \text{BH} \longleftrightarrow \text{AH} + \text{B} \tag{1}$$

$$\text{Cathode: A} + (H^+ + e^-) \longleftrightarrow \text{AH} \tag{2}$$

$$\text{Anode: BH} \longleftrightarrow \text{B} + (H^+ + e^-). \tag{3}$$
As the above is a generalized reaction scheme for an electrochemical cell, the proton-electron transfer can be utilized for different reactions. As an example, the relevant reaction for the hydrogen evolution reaction (HER) or the hydrogen oxidation reaction (HOR) (Nørskov et al. 2005; Strmcnik et al. 2013), the oxygen reduction reaction (ORR) or the oxygen evolution reaction (OER)
Fig. 1 Illustration of an electrochemical cell with separated electron and ion conductor to emphasize that the two electrodes can in principle be separated at arbitrary distance. The potential control sets up the potential difference to create the oxidizing anode and reducing cathode. BH indicates a reactant to be oxidized (e.g., H_2, methanol), and A indicates a reactant to be reduced (e.g., O_2, CO_2, CO). Note that reactions can be reversed by changing the potential

(Marković et al. 2001; Man et al. 2011; Busch et al. 2016), and the CO_2 reduction reaction (CO_2RR) (Hori et al. 1989; Peterson et al. 2010; Bagger et al. 2017a) or CO oxidation reaction can be written as reduction reaction schemes:

$$2(H^+ + e^-) \longleftrightarrow H_2, \tag{4}$$

$$O_2 + 4(H^+ + e^-) \longleftrightarrow 2H_2O, \tag{5}$$

$$CO_2 + 2(H^+ + e^-) \longleftrightarrow CO + H_2O. \tag{6}$$
These different reactions require multiple proton-electron transfers, and this indicates that intermediate steps between the reactant and the product exist.

2.1   Reaction Intermediates

Different reaction intermediates which have different atomic composition bind in different ways or adsorb on different sites on the electrode surface. The general reduction scheme of the reactant A can be considered through the intermediate A*, where * indicates a surface site and A* denotes that A binds to the electrode surface:

$$\text{Proton-Electron reaction: } {}^* + A \longleftrightarrow A^* + (H^+ + e^-) \longleftrightarrow AH^*. \tag{7}$$

When a proton and an electron are transferred to the adsorbate A* simultaneously, the reaction is called a proton-electron coupled reaction.

The overall reactions (4), (5), and (6) are proton-electron coupled; however, the intermediate steps in (7) can be observed as coupled, uncoupled, or anywhere in between. Determining the transfer of the electron(s) is difficult as partial charge
Fig. 2 The Pourbaix diagram shows the three different types of reaction: proton reaction (8), electron reaction (9), and proton-electron reaction (7). The proton reaction, as a typical buffer or acid reaction, only depends on pH (pK_a). The electron reaction, as a typical ionization reaction, depends only on the applied potential. The proton-electron reaction is constant on U_{RHE} scale and thus has a constant slope on absolute scale (U). The stability of the intermediate can be influenced by the interface region (shown by red and blue dashed lines)

of an intermediate is not a physical observable. Instead the continuum of electron transfer states can be accessed quantum mechanically by measuring the dipole of the interface or the work function.

The reactions which only involve a proton (acid-base reaction) or only the electron (ionization reaction) can be written as:

$$\text{Proton reaction: AH} \longleftrightarrow A^- + H^+ \qquad (8)$$

$$\text{Electron reaction: A} \longleftrightarrow A^+ + e^-. \qquad (9)$$
These reactions can be illustrated in a Pourbaix diagram (Pourbaix 1974) as shown in Fig. 2. Here the absolute potential (U) is plotted versus the pH. It shows how the electron and proton reactions (8) and (9) are only dependent on the potential and pH, respectively, while the proton-electron reaction (7) is dependent on both. As it is indicated by the blue and red dashed lines, the electrochemical reduction reaction of A* can be dominated mostly by protons (blue line) or mostly by electrons (red line).

One has to consider the interface between the electrolyte and the electrode as the reaction intermediate can extend into the electrolyte, as is shown in Fig. 3a. The distance from the electrode has been divided into three different regions of interest: the surface region, the interface region, and the electrolyte region.

In the surface region, which is close to the working electrode, the energy of the reaction intermediate is almost unaffected by the electrolyte environment. This would mean that the reaction would be a complete proton-electron reaction

(a) Regions from the electrode.

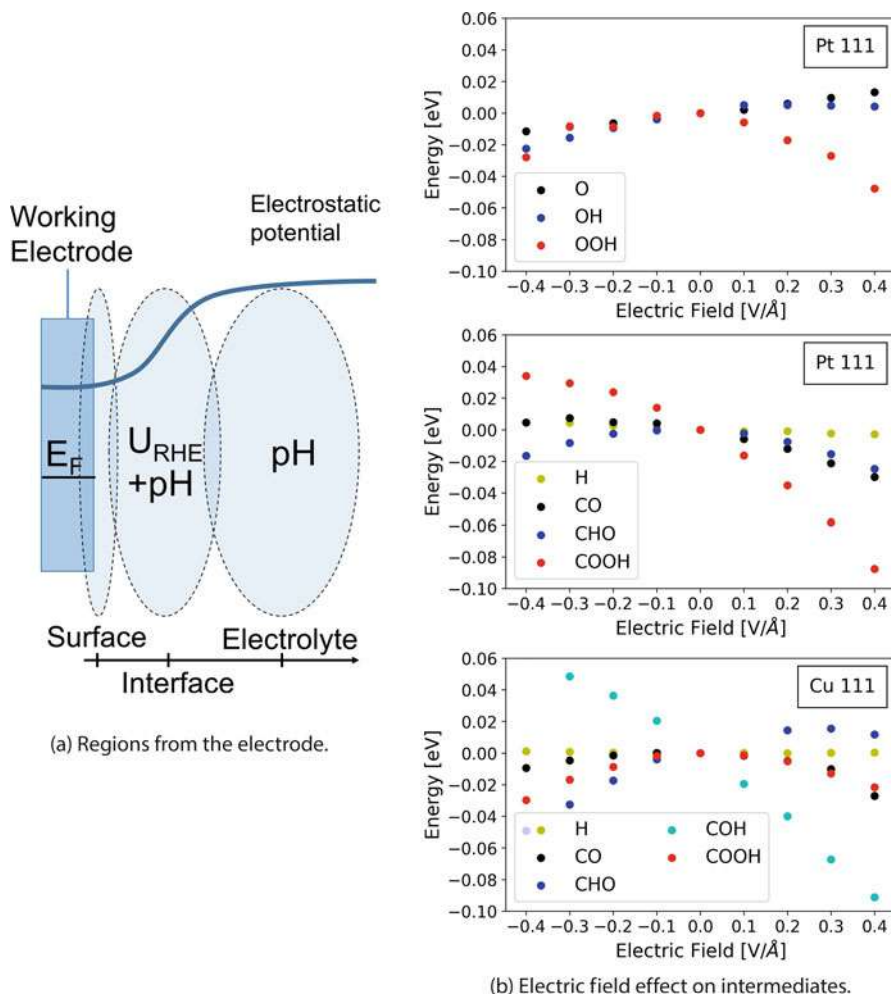
(b) Electric field effect on intermediates.


Fig. 3 (**a**) shows the three regions on the direction normal to the electrode: the surface, the interface, and the electrolyte. Reactions in the surface region are dominated by the potential, while far away from the electrode, the conventional pH equilibrium dominates. The interface region requires a control of both the potential and pH. (**b**) shows small, medium, and large intermediates as a function of electric field. Negligible affect of electric field is observed on small intermediates, while medium and larger intermediates, sticking out into the interface region and having a large dipole, are affected more by the electric field

following the black dashed line in Fig. 2, no matter the ions in the electrolyte and the pH.

In the interface region, the intermediates that are affected by the environment are either larger or adsorbs in a more electrolyte exposed position on the surface. Hence the intermediate extends into the interface region, and reducing or oxidizing

this intermediate may deviate from the ideal proton-electron transfer reaction. The electrostatic potential is determined by the absolute potential and an intermediate extending into the interface region with a dipole will interact with the electrostatic field in this region (see Fig. 3a). Lastly, far away from the electrode, in the electrolyte region, acid-base reactions are dominated by the pH only, as the average electrostatic potential is constant regardless of the potential of the working electrode.

The binding energy of an adsorbate is obtained from DFT calculations as:

$$\Delta E_A = E_{slab,A*} - E_{slab} - E_{A(g)}, \tag{10}$$

where the ΔE_A is the binding energy of the intermediate A, $E_{slab,A*}$ is the energy of the slab with A adsorbed, E_{slab} is the bare slab energy, and $E_{A(g)}$ is the energy of the chosen gas-phase reference. Choosing a good reference without functional dependent errors can be challenging; however, methods to remove systematic reference errors can be used (Christensen et al. 2015).

From the DFT-calculated binding energy, ΔE_A, the Gibbs free energy for a given reaction can also be calculated (Reuter and Scheffler 2001, 2003):

$$\Delta G_A = \Delta E_A - T\Delta S + \int_0^T C_p dT + \Delta ZPE \tag{11}$$

where ΔS is the entropy, $\int_0^T C_p dT$ is the heat capacity, and ΔZPE is the zero-point energy correction of the reaction. The adsorption free energy upon different metals for different reactions can be calculated with this equation. But the electrochemical reactions which also involve a proton-electron reaction require additional treatment as given in Sect. 3.

The electrostatic potential can affect the adsorption energies. This can be estimated by adding simple electric field to the binding energy calculation (Karlberg et al. 2007a). The electric double-layer thickness is around $\sim 3\,\text{Å}$, and the electric field effect due to the electrode is approximately on the order of $-0.2\,\text{V/Å}$(Rossmeisl et al. 2006).

Figure 3b shows relevant intermediate binding energies calculated for ORR/OER, HER, and CO2RR as a function of electric field strength on Pt (111) and Cu (111) facets. The graphs show how the intermediate binding energies depend on the electric field. The effect due to the electric field is shown to be very small. However, a solvated ion in the interface have been shown to possibly give local enhancements of the electric field effect up to $-1.0\,\text{V/Å}$ (Chen et al. 2016), and defected structures may also allow for a stronger dependency of the electric field for the binding energy (Mistry et al. 2017).

We note that there is not a direct mapping from the electrochemical potential and the electric field added in these calculations. The field will not be zero, when the potential is zero and different adsorbates does not need to have zero potential at similar fields.

2.2 Reference Electrodes

A requirement to compare the performances of catalysts is that a proper reference electrode is used. The standard hydrogen electrode (SHE) reference electrode is defined as 0 V at pH = 0:

$$(H^+ + e^-) \longleftrightarrow \tfrac{1}{2} H_2(g). \tag{12}$$
The SHE reference electrode, which is independent on the electrode material, has a potential of $U_{SHE} = -4.44$ eV with respect to the absolute potential, which is defined as electrons at rest in vacuum (Trasatti 1986). Experimentally, the reference electrode used is typically Pt; however, it could easily also be all other kinds of materials. The main advantage of using the Pt as reference electrode is simply that the kinetics of the proton reaction is very fast and equilibrium of (12) is obtained quickly.

A problem when using the U_{SHE} scale is that the activity of the protons change with pH (left side of Eq. (12)). Comparing catalysts in two different electrolytes and pH requires a shift with respect to the change in concentration of protons. The reversible hydrogen electrode (RHE) potential does not change with pH. The RHE scale is simply normalized by the activity of the protons, and the SHE and RHE scale are linked together by:

$$U_{RHE} = U_{SHE} - \frac{k_B T}{ne} \log\left(\frac{a_{H^+}}{\sqrt{p(H_2)}}\right) = U_{SHE} - 0.059V \cdot pH \tag{13}$$

where k_B is the Boltzmann constant, T is the temperature, n is the number of electrons transferred in the reaction, a_{H^+} is the proton activity, and $p(H_2)$ is the pressure of hydrogen at 1 bar. At room temperature the absolute potential change becomes 0.059 V per pH value.

3 The Computational Hydrogen Electrode (CHE)

In electrochemical reactions protons and electrons are transferred. The reaction energy will depend on the chemical potential of the protons and electrons. In the computational hydrogen electrode (CHE) (Rossmeisl et al. 2006; Hansen et al. 2008), the simplification of a combined chemical potential of protons and electrons is made. The CHE is based upon three assumptions:

(1) The bulk of the electrolyte is in equilibrium.
(2) The surface where the reactions take place is in equilibrium with the electrodes and the bulk of the electrolyte.
(3) The adsorption energy is independent on the electrostatic field.

The two first assumptions are used directly when deriving the CHE, and the last is a result of the minor electrostatic effect observed in the dependence between the adsorption energy and field shown in Fig. 3b. This implicitly assumes a proton-electron coupled reaction, and adding or subtracting hydrogen atoms in an electrochemical reaction can be carried out by considering the combined chemical potential of the proton-electron pair. The chemical potential of the proton depends on the pH, and the chemical potential of the electron depends on the potential of the cell. The free energy in an electrochemical reaction of adding and subtracting electrons and protons is:

$$\Delta G = \Delta E - T\Delta S + \int_0^T C_p dT + \Delta ZPE - n \cdot (\mu_{H^+} + \mu_{e^-}), \qquad (14)$$

where μ_{H^+} and μ_{e^-} are the chemical potentials of the protons in solution and the electrons at the Fermi level of the working electrode. These chemical potentials will depend on electrolyte and potential applied for the cell, and a reference for the theoretical calculated electrochemical reaction energy is needed. The hydrogen reference electrode, shown to the left in Fig. 4, is in equilibrium with hydrogen at standard conditions and with electrons and protons. This equilibrium condition can be written as:

$$\tfrac{1}{2}\mu_{H_2} = \mu_{H^+}^{ref} + \mu_{e^-}^{ref} \qquad (15)$$

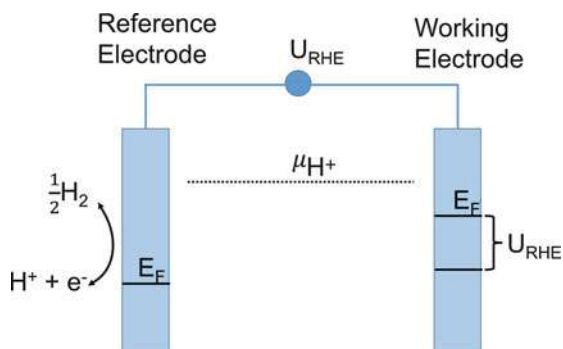
where μ_{H_2} is the chemical potential of hydrogen gas at standard conditions and superscript *ref* denotes chemical potential of electrons and protons at the reference electrode. Figure 4 illustrates that μ_{e^-} is related to the reference electrode potential at arbitrary pH as:


Fig. 4 Illustration of the computational hydrogen electrode (CHE). The hydrogen reaction is in equilibrium with the reference electrode. The protons for both the working and the reference electrode have the same chemical potential, while the electrons at the working electrode are affected by the applied potential (U_{RHE}). In this case U_{RHE} is negative

$$\mu_{e^-}^{ref} = \mu_{e^-} + eU_{RHE} \qquad (16)$$

where U_{RHE} is the potential difference between the working and reference electrode, in this case the reversible hydrogen electrode. Further, we can make the assumption that protons at the reference electrode are in equilibrium with protons everywhere in the electrolyte:

$$\mu_{H^+}^{ref} = \mu_{H^+}. \qquad (17)$$

Computationally, hydrogen can easily be calculated and then referenced back to the chemical potentials of the electrons and protons in solutions. One simply needs to calculate the hydrogen molecule energy and then add the potential U_{RHE} to the equation as follows for the adsorption total energy ΔE_{CHE} and free energy ΔG_{CHE}:

$$\Delta E_{CHE}(n, U_{RHE}) = E(n) - E(n = 0) - n \cdot (\tfrac{1}{2}\mu_{H_2} - eU_{RHE}), \qquad (18)$$

$$\Delta G_{CHE}(n, U_{RHE}) = \Delta E - T\Delta S$$
$$+ \int_0^T C_p dT + \Delta ZPE - n \cdot (\tfrac{1}{2}\mu_{H_2} - eU_{RHE}), \qquad (19)$$

where n is the number of proton-electron transferred and ΔG_{CHE} and ΔE_{CHE} are then a function of both potential and proton-electron pair transfers. The thermodynamic contributions to ΔG_{CHE} from the metal are typically neglected, and only the contributions from the gas phase and vibrational entropy of the adsorbate are included.

The simplicity of the computational hydrogen electrode is obtained by the choice of references and the assumption of electrolyte and electrode in equilibrium. As will be shown in the next sections, the CHE is applicable for calculating many interesting properties in electrochemical reactions, such as surface Pourbaix diagrams, isotherms, and free energy diagrams. Later on, the generalized computational hydrogen electrode (GCHE), where the chemical potentials of the electrons and protons are separated, will be introduced.

3.1   Surface Pourbaix Diagrams

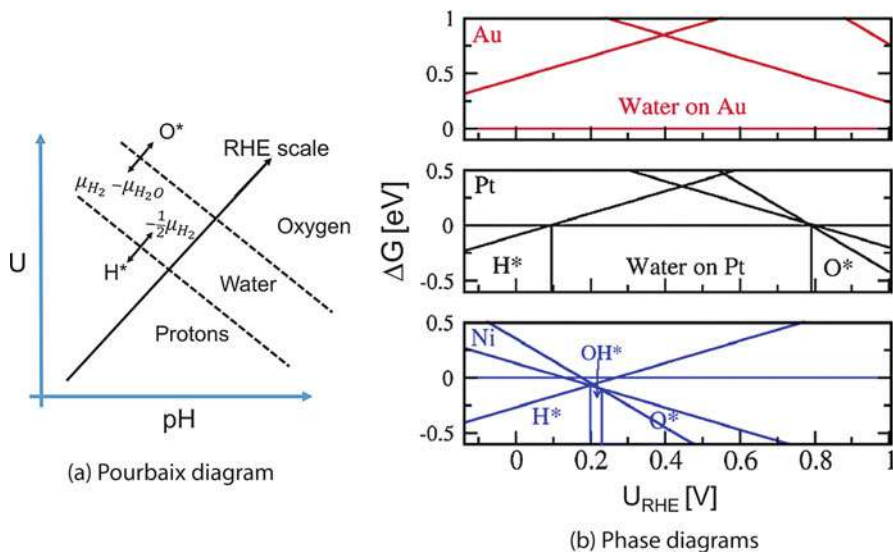
Many factors have to be considered when calculating reaction energies in electrocatalysis. The potential has the effect of changing the coverage on the surface. Reactions can, in fact, be very different if they occur on a clean metal or on a surface with species preadsorbed. The surface Pourbaix diagrams give information on the


Fig. 5 (**a**) shows a sketch of a Pourbaix diagram with the RHE scale drawn. Where the slope of the RHE scale is 0.059 V/pH at room temperature. (**b**) shows phase diagrams of water on Au(111), Pt(111), and Ni(111) on RHE scale. The thermochemically most stable phase corresponds to the lowest line. (Figure from Rossmeisl et al. 2006)

coverage of a surface in a similar way as the classical Pourbaix diagrams provide an understanding in the phase transition in bulk systems (Persson et al. 2012; Castelli et al. 2014).

The starting point, to construct a Pourbaix diagram, is to consider all possible states that a surface can have. In the example chosen here, four states have been considered: water-, hydrogen-, hydroxyl-, and oxygen-covered surfaces. Where the coverage energy is calculated from the CHE as a function of potential and shown in Fig. 5. The Pourbaix diagrams show the coverages on Au(111), Pt(111), and Ni(111). Au is the noblest of the metals, and therefore it binds adsorbates only at very high or low potentials. Pt is more reactive, and it has hydrogen adsorbed at low potential (typically called hydrogen under potential deposition H$_{upd}$), oxygen at high potential, and a water layer (clean surface) in between. Ni is very reactive and always has adsorbates covering the surface.

This approach is very simple and in particular it can be applied to screening projects and to study trends. On the other side, it fails when large dipole moments are involved because ΔE is influenced by electric fields in the out of place direction of the surface. This issue is addressed by the generalized computational hydrogen electrode (GCHE) in Sect. 4. Further, the surface Pourbaix diagrams assume that no reaction occur, i.e., hydrogen coverage becomes limited if hydrogen is over potential deposited on metals such as Au, Ag, or Cu as hydrogen is evolved.

3.2   Integrated Cyclic Voltammograms

The surface Pourbaix diagrams derived by the use of the CHE depicts when intermediate species are stable on the surface. The presence of intermediates on the metal surface from a proton-electron coupled reaction is a quantity that can be measured experimentally: i.e., the under potential deposited hydrogen (H_{upd}) H* intermediate from the reaction $H^+ + e^- \rightarrow H^*$ or the creation of an OH* from the reaction $H_2O \rightarrow OH^* + H^+ + e^-$ is proportional to the current measure as a function of potential. Experimentally the current for the reactions can be measured by Cyclic Voltammetry (CV), and the integration of the CV over time corresponds to the coverage of charge on the surface, which is related to adsorption isotherms.

The CHE can be used to calculate the differential energy of adding multiple H* or OH* on the surface, where the differential adsorption energy will include the adsorbate-adsorbate interaction. A more simple assumption for intermediate coverages on the surface is to include the differential configurable entropy of non-interaction particles given as:

$$-T\Delta S_{conf} = -k_b T \ln\left(\frac{1-\theta}{\theta}\right) \tag{20}$$

where θ is defined as the coverage on the surface. Adding this entropy term to the CHE, it becomes a function of both potential and coverage:

$$\Delta G(\theta, U_{RHE}) = \Delta G_{CHE}(n=1, U_{RHE}) - k_b T \ln\left(\frac{1-\theta}{\theta}\right) \tag{21}$$

where $\Delta G_{CHE}(n = 1, U_{RHE})$ is the calculated free energy of H* or OH*. Assuming that the coverage on the surface is in equilibrium at all potentials, the coverage can be found as a function of potential:

$$\theta(U_{RHE}) = \frac{1}{1 + \exp\left(\frac{\Delta G_{CHE}(n=1, U_{RHE})}{k_b T}\right)} \tag{22}$$

The coverage of none interacting intermediates on the surface is now defined as a function of potential, which is the Langmuir isotherm expression.

The calculated coverage found by the Langmuir isotherm can be directly compared with the experimental integrated CV (see Fig. 6). In Fig. 6a the isotherms for H* on Pt (111) and Pt (100) are given in the top, and the calculated coverages are given in the bottom. Specifically in these calculations, a mean field interaction between the H* has been included corresponding to a Frumkin isotherm (see Karlberg et al. 2007b). In Fig. 6b similar treatment for the OH* intermediate is shown on Pt and Pt_3Ni for experiment (dashed lines) and for calculation (solid lines).
(a) Pt (111) & Pt (100) integrated H* CV
(b) Pt (111) integrated OH* CV

Fig. 6 (**a**) Experimental integrated CV on Pt (111) and Pt (100) for H* (top) compared with the calculated coverage/isotherm (bottom). (**b**) Experimental integrated CV on Pt (red dashed) and Pt$_3$Ni (black dashed) compared with the calculated coverage/isotherm from the 1/3 monolayer OH* binding energy for the two structures (solid lines). (Figures from Karlberg et al. 2007b, Rossmeisl et al. 2009)

For both H* adsorption and OH* adsorption, the calculated coverages compare well with the integrate CVs in the low coverage regime. Since the H* and OH* are reaction intermediates, only the low overpotentials can be compared, since at too high driving forces H$_2$ or O$_2$ start to evolve.

3.3   Understanding Electrocatalytic Reactions and Trends

Another comparison with experiments is the thermodynamically calculated free energy diagram. The free energy diagram allows to interpret different reaction pathways, by calculating the reaction intermediates, and most importantly it gives a "theoretical onset potential." The theoretical onset potential is defined as the potential at which all reaction steps become exergonic, and it allows for a comparison of the overpotential, $\eta = |U^{\Theta} - U^{Theoretical}|$, with experiments. Even if, in experiments, the onset potential is not well defined, the trends in calculated and measured potentials can be compared. It is important to note that the comparison has to be carried out at low currents, as the model assumes equilibrium and this is only a valid approximation at low current densities. Furthermore, the free energies calculated for the free energy diagram can be used to find scaling relations and construct Sabatier activity volcanoes as a function of reactivity descriptors. This framework will be explained here from an OER and ORR perspective.

Free Energy Diagrams

Two key reactions are the four coupled electron proton reactions OER and ORR, which are two reversed sequence reactions. The OER reaction mechanism proceeds through the OH*, O*, and OOH* intermediates:

$$* + H_2O \rightarrow OH^* + H^+ + e^- \tag{23}$$

$$OH^* \rightarrow O^* + H^+ + e^- \tag{24}$$

$$O^* + H_2O \rightarrow OOH^* + H^+ + e^- \tag{25}$$

$$OOH^* \rightarrow O_2 + H^+ + e^- \tag{26}$$
The CHE can be used to calculate the energy of each step of the reaction, with respect to the previous step. Thus, the calculation can be given for only one proton-electron transfer for each calculated ΔG as shown by Eq. (19):

$$\Delta G_1(1, U_{RHE}) = G_{OH^*} - G_{H_2O^*} + \left(\tfrac{1}{2}\mu_{H_2} + eU_{RHE}\right), \tag{27}$$

$$\Delta G_2(1, U_{RHE}) = G_{O^*} - G_{OH^*} + \left(\tfrac{1}{2}\mu_{H_2} + eU_{RHE}\right), \tag{28}$$

$$\Delta G_3(1, U_{RHE}) = G_{OOH^*} - G_{O^*} - G_{H_2O^*} + \left(\tfrac{1}{2}\mu_{H_2} + eU_{RHE}\right), \tag{29}$$

$$\Delta G_4(1, U_{RHE}) = G_{O_2} - G_{OOH^*} + \left(\tfrac{1}{2}\mu_{H_2} + eU_{RHE}\right). \tag{30}$$

The calculated ΔGs can now be plotted in a free energy diagram, as shown in Fig. 7a. For the ideal catalyst, the proton-electron can take place at the equilibrium potential of $U_{RHE} = 1.23\,\text{eV}$ for OER and ORR. This means that the ideal catalyst should bind OH*, O*, and OOH* such that $\Delta G_1 = \Delta G_2 = \Delta G_3 = \Delta G_4 =$
Fig. 7 Free energy diagram for the oxygen evolution reaction at zero potential ($U_{RHE} = 0$ eV), at equilibrium potential ($U_{RHE} = 1.23$ eV) and at the potential where all steps are favorable. (**a**) is the ideal catalyst, and (**b**), (**c**), and (**d**) are the strong, intermediate, and weak binding catalyst. (Figure from Man et al. 2011)

1.23 eV. However, the free binding energy for three perovskite materials shown in (b), (c), and (d) indicates that either the catalyst binds to strongly, weakly, or even on the catalysts with intermediate binding; it is not possible to obtain equal values of each step.

Scaling Relations

The constrains found for the free energy diagram in Fig. 7 are due to the linear relations between the OOH* and OH* as shown in Fig. 8a for various systems (perovskites, rutiles, anatase, Mn_xO_y, Co_3O_4, and NiO oxides). The linear relations between adsorbates are called *scaling relations* and have been found between C-, N-, S-, and O-derived adsorbates on catalyst surfaces (Fernández et al. 2008). The scaling relations limit reactions which have intermediates that bind through the same atom and on the same site (on top, bridge, or hollow). This indicates a limitation in achieving better catalysts. As the scaling relation limits the properties of catalyst, *breaking the scaling* is a hot topic, and different suggestions have been proposed to circumvent this (Halck et al. 2014; Montoya et al. 2015; Doyle et al. 2015). The particular difficult scaling to *break* is the one for OER and ORR, where OOH* and OH* both binds to the on top site and through the oxygen and the two energies scale as:

$$\Delta G_2 + \Delta G_3 = 3.2 \pm \sigma, \tag{31}$$

where σ notes that there are some minor spread around the scaling relation shown in Fig. 8a.

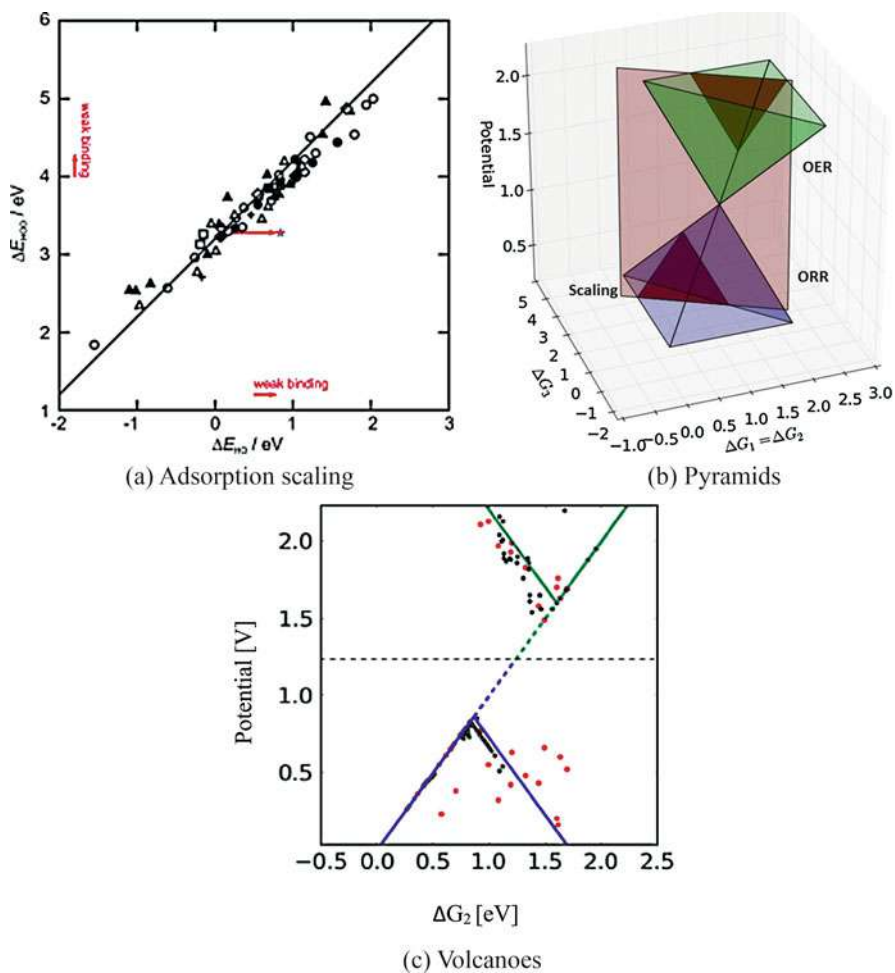
On the other hand, one way of using the scaling relations, without breaking them, is to utilize the fact that instead of having a catalyst with all three types of sites (on top, bridge, or hollow), porphyrin structures (single site catalyst) may have a structural advantages of simply not having the hollow site (Bagger et al. 2017b). This can be utilized to control the ORR mechanics toward H_2O_2 by removing the hollow oxygen binding possibility (Siahrostami et al. 2013). Or in CO_2RR, the competitive HER can be limited by not having the hollow site (Bagger et al. 2017b; Ju et al. 2017).


Fig. 8 (**a**) shows scaling relation between OOH* and OH*, (**b**) shows the three-dimensional pyramids of the OER/ORR parameter space, and (**c**) shows calculated transition metal and nitrogen-doped carbon catalyst materials to follow the scaling relation constrain and have different performance as OER or ORR catalyst. Each surface will have ΔG_1 and ΔG_2 values, which will correspond to a theoretical overpotential for ORR and OER read of the pyramids in (**b**). For normal surfaces the ΔG_1 and ΔG_2 values are related via scaling in (**a**), which means that most catalyst are constrained to the red plane in (**b**) constructing the volcanoes in (**c**). (Figures from Man et al. 2011; Busch et al. 2016)

Volcano Plots

The catalytic volcano plots are based on the Sabatier principle (Nørskov et al. 2014), which states that the interaction between the catalyst surface and the adsorbate/intermediate should be just right. The adsorbate should bind strongly enough to be brought to the surface, but not too strongly so that the product cannot

get off the catalyst and consequently an optimal catalyst binds just right. With the scaling relations the Sabatier principle can now be put on a quantitative form, and for electrochemistry reactions typically a binding free energy of intermediates is used for the x-axis. The volcano illustrates the theoretical overpotential that has to be paid to make the reaction run with all reaction steps being exergonic.

The ideal theoretical Sabatier volcano for OER and ORR is shown as three-dimensional pyramids in Fig. 8b. The most promising OER and ORR catalyst would be at the intersect of the two volcanoes. The scaling relation gives the constraint between the OOH* and OH*. This constraint will restrict catalysts to lie in the red plane. The red plane shows that obtaining the ideal catalyst at the intersect of the two pyramids ($U_{RHE} = 1.23$ eV) is not possible when fulfilling the scaling. Furthermore the sliced 2D plane is shown in Fig. 8c with calculated data (Man et al. 2011; Viswanathan et al. 2012). The two volcanoes show that if one material is good for OER, then it will be poor for ORR and vice versa. Furthermore, none of the two volcanoes reach the thermodynamic limit, and a large over potential has to be paid for all OER and ORR catalysts, which also has been observed experimentally (Seh et al. 2017).

3.4   Electrochemical Barriers

The comparisons of free energies and volcano plots with experiments are based on thermodynamics. To obtain kinetics of reactions, the barrier between reaction steps must be estimated. For heterogeneous catalysis the theoretical barriers can be calculated using the nudged elastic band (NEB) method (Jónsson et al. 2011; Henkelman et al. 2000; Henkelman and Jonsson 2000). Although similarities clearly exist between heterogeneous barriers and electrochemical barriers, the latter is not straightforward to obtain and to add to the electrochemical free energy diagram.

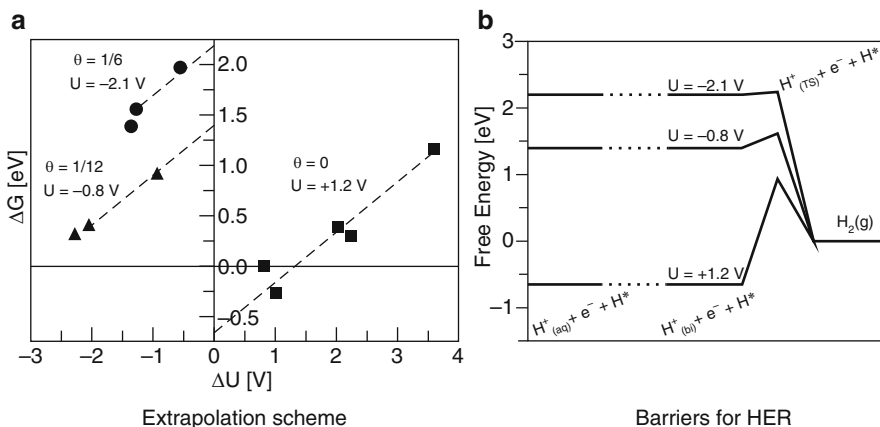
Correct electrochemical barriers are notoriously difficult to calculate, since the DFT-calculated unit cell has a constant charge (and changing potential), while in real experiments the potential is constant (and current/charge changes). This is shown in Fig. 9, where barriers are calculated for the Heyrovsky reaction on three different unit cells with different area. The Heyrovsky reaction is the reaction of a hydrogen on the surface (H*) and a proton (H^+) in the double layer creating H_2. Due to the translation of the proton in the double layer, the reaction involves a transfer of charge. From the NEB calculations, the energetic barriers (black) and the changes in dipole (red) can be plotted against the reaction coordinate. As the charges move, the measured dipole changes from initial state to final state by more than 3 V for the small cell and for about 0.5 V at the largest unit cell shown here. Since the dipole is directly proportional to the work function which is the potential of the electrode, the potential changes during the calculation of the reaction path. If the area of the interface gets bigger, the change in work function related to transferring one charge becomes smaller. In the limit of a very large area, the change in work function becomes neglectable. However, this is not possible, simply due to the practical size of the unit cell and a finite size problem present. The issue is that a charge transfer
Fig. 9 Barriers calculated for the Heyrovsky reaction $H^+ + e^- + H^* \rightarrow H_2$ in three different unit cell sizes of Pt (111). The energy is plotted together with the calculated dipole of the slab, where the dipole is directly proportional to the work function. The changes on the dipole along the reaction coordinate illustrate the problem of constant charge in the calculation. (Figures from Skulason et al. 2009)


Fig. 10 (**a**) The free energy barriers of the reaction Heyrovsky reaction are plotted versus the change in electrode potential and for minimum three different unit cell sizes; the barriers are extrapolated unto zero potential change. (**b**) Free energy diagram with electrochemical barriers added at three different potential for Pt(111). (Figures from Rossmeisl et al. 2008)

step changes the potential as the charge species interact with the potential setup by itself and thereby effecting the energy of itself.

In order to handle the finite size problem and obtain an electrochemical barrier at a constant potential, an extrapolation scheme has been developed (Skulason et al. 2007; Rossmeisl et al. 2008). This scheme applies the observed results from Fig. 9, in which the same reaction is calculated for different unit cell sizes and this allows to obtain barriers as a function of changing electrode potential (Skulason et al. 2010). An extrapolation to $\Delta U = 0$ is possible by plotting these barriers versus the changing electrode potential, and the barriers can be estimated as shown in Fig. 10.

Recently, advances have been made to calculate electrochemical barriers in a simple way, by using only one NEB calculation for each barrier (Chan and

Nørskov 2015). This new scheme uses the assumption of a decoupled chemical and electrostatic contribution to the calculation. This has been used to calculate barriers in particularly for the CO_2RR (Shi et al. 2016; Liu et al. 2017).

Furthermore, a proton shuttling scheme has be made to calculated the barriers. This is carried out by transferring a proton from the surface to the electrolyte, while transferring a proton from the electrolyte to the surface, which could then ensure an approximate constant potential in the calculation. This method has also been used to investigate the kinetics of the CO_2RR (Nie et al. 2014).

These schemes allow the dipole of the interface to stay constant, and the barriers may be considered at constant electrochemical conditions: pH and potential. However, it is still limited by only being referred to the RHE scale. Even if the barriers can give some insight, the structure of the interface may not be the relevant one at realistic conditions. Finding the relevant structure of the electrochemical interface region may be important to obtain more accurate electrochemical barriers. Determining stable structures at given pH and potential is the subject in the next section.

4 The Generalized Computational Hydrogen Electrode (GCHE)

The CHE was derived by applying three assumptions (see Sect. 3). The assumption (3) *the adsorption energy is independent of the electrostatic field* does not apply if intermediates have a strong dipole or interacts strongly with the electrolyte. In that case, the simulation of the intermediate binding energy must include the interface region (Fig. 3a), and the assumption (3) can be replaced by:

(4) The interface region is charge neutral and large enough to screen all charges (Hansen and Rossmeisl 2016).

For the CHE model, the U_{RHE} was defined as the potential difference between the reference and the working electrode no matter the chemical potential of the protons. To create the generalized computational hydrogen electrode (GCHE) (Rossmeisl et al. 2013), the proton and electron chemical potentials have to be referred to two reference electrodes using the Born-Haber cycle by two paths (Fig. 11): (1) the RHE reference through $\mu_{H^++e^-}$ (eU_{RHE}) or (2) through the

Fig. 11 The Born-Haber cycle, which allows two pathways to obtain the chemical potential of protons and the electrode potential
Fig. 12 (**a**) Illustration of the generalized computational hydrogen electrode (GCHE), which includes both the proton work function (ϕ_{H+}) and the electron work function (ϕ_{e+}). (**b**) The standard hydrogen electrode (SHE) scale and the absolute potential scale as comparison, to understand how to include ions into the interface region.

vacuum state of the proton H^+ and the electron e^-. Now two reference points can be obtained: the reference electrode and the near field vacuum electron work function (Fig. 12a). From these two references, the electrode potential and pH can be measured separately, which is shown next.

Using the Born-Haber cycle, we can obtain U_{RHE} in the following way:

$$eU_{RHE} = \mu_{H^+ + e^-} = \Delta_d G + \Delta_i G - \phi_{H^+} - \phi_{e^-}, \tag{32}$$

where $\Delta_d G$ is the hydrogen molecule dissociation energy, $\Delta_i G$ is the hydrogen atom ionization energy, ϕ_{H^+} is the proton work function, and ϕ_{e^-} is the electron work function (defined as $\phi_{e^-} = E_{e^-} - E_{E_F}$). For pH = 0 and $U_{RHE} = 0$ eV, this expression is equal to zero:

$$0 = \Delta_d G + \Delta_i G - \phi_{H^+}^0 - \phi_{SHE}, \tag{33}$$

where $\phi_{H^+}^0$ is the energy difference between H^+ at rest in vacuum and H^+(aq) at pH = 0. Further, ϕ_{e^-} has changed to ϕ_{SHE}, which is an experimental value between 4.44 and 4.85 eV (Trasatti 1986; Kötz et al. 1986). The pH-dependent proton work function can be obtained by the relation:

$$\phi_{H^+} - \phi_{H^+}^0 = 2.3 k_B T p H. \tag{34}$$

Combining these equations, the eU_{RHE} in the CHE can be replaced to include terms from both the electrode potential and pH. The free energy for the GCHE for adding or subtracting hydrogens from the interface is obtained:

$$\Delta G_{GCHE}(n, \phi_{e^-}, pH) = E(n, \phi_{e^-}) - E(n = 0) - n\frac{1}{2}\mu_{H_2}^0$$

$$- ne \overbrace{(\phi_{SHE} - \phi_{e^-} - 2.3 k_B T p H)}^{U_{RHE}}, \tag{35}$$

Fig. 13 shows the ΔG_{GCHE} energy as a function of work function and eU_{RHE}, with planes representing specific pH values (gray planes) and a plane for adding a proton (yellow plane) or creating a hydroxy (blue plane) and water (red plane)
Fig. 14 shows the GCHE setup in a side view of a DFT unit cell with four Au metals layers and three waters layers to the right of the Au slab. From this setup the work function ϕ can be measured together with the energy. (Figures from Hansen and Rossmeisl 2016)
where $E(n, \phi_{e^-})$ can be obtained from DFT with added or subtracted number of hydrogens, $E(n = 0)$ is a reference energy, $\mu_{H_2}^0$ is the hydrogen energy including ΔZPC and $-T\Delta S$ for the hydrogen molecule, ϕ_{SHE} is the SHE work function (Fig. 12b), ϕ_{e^-} is the calculated work function (Fig. 14), and the last term defines the energy with respect to the pH of the electrolyte.

It can be very illustrative to think of the GCHE in terms of a three-dimensional plot as shown in Fig. 13. This figure shows how the ΔG_{GCHE} energy is related to eU_{RHE} and the work function ϕ_{e^-}. In the three-dimensional plot, the pH planes of pH = 0, 7, and 14 are drawn (gray vertical planes) together with a plane for when a hydrogen is added (yellow) or removed (blue) leaving an OH$^-$ and a pure water simulation (red). The intermediate planes are displayed linearly (following RHE); however, they could also have a curvature (interface region). Note, for these planes, that our usual surface Pourbaix diagram corresponds to a projection into the ΔG_{GCHE} and eU_{RHE} plane.

To simulate the correct electrochemical environment, one may need to include charged ions. For this purpose the GCHE equation (35) needs to be modified from the proton reaction ($2H^+ + 2e^- \rightarrow H_2(g)$) to the ionization reaction of the charged ions. The ionization potentials for (positive) potassium and for (negative) chlorine ions are shown as an example on the SHE scale and absolute scale in Fig. 12b. Here ϕ_{ion} relates the ionization potential to the absolute potential scale, and the GCHE equation becomes:

$$\Delta G_{GCIE}(n_{ion}, \phi_{e^-}, [A]) = E(n_{ion}, \phi_{e^-}) - E(n = 0) - n_{ion}\mu_{ion}^0$$
$$- n_{ion}e\left(\phi_{ion} - \phi_{e^-} - 2.3k_B T ln\left(\frac{[A]}{[A]^0}\right)\right) \quad (36)$$

where $[A]$ is the reference ion concentration in the electrolyte, $[A]^0$ is the standard condition of 1 M, and G_{GCIE} refers to the fact that this is now a generalized computational ion electrode. Furthermore, it should be noted that in Eq. (36) the last term changes sign for the chlorine ionization reaction path compared to the proton and potassium reaction in Fig. 12b.

4.1   Practical and Technical Aspects of the GCHE

The CHE method has usually been applied to find one binding energy for each intermediate. The GCHE method measures the energy and the corresponding work function of the specific structure of the interface. For one structure, only one energy and work function is available, which for the GCHE means that interface energy is only found at one absolute potential. Hence we should sample the interface region of the electrochemical cell with the electrolyte (water molecules, ions, adsorbates, etc.) at some fixed temperature and generate an ensemble of states with different work functions to obtain an ensemble of energies in the wanted potential range. This sampling can be carried out by molecular dynamics (MD) simulations, which exist at various different levels of treating the electrolyte and metal (Spohr 1989; Sergeev et al. 2017; Merlet et al. 2014; Liang et al. 2014; Yeh et al. 2013; Larentzos and Criscenti 2008). Ab initio MD (AIMD) (Schnur and Groß 2009; Herron et al. 2016) uses electronic structure codes, and the values of interest can be directly obtained from this.

An example of ab initio MD simulation (i.e., where DFT is combined with MD) to measure the energy and work function is shown for Au (111) with four water layers in Fig. 14. The three water layers closer to the Au slab are allowed to move, while the outermost layer is fixed in hexagonal structure to keep the water density constant. The energy and the ϕ_{e^-} can be measured as the MD simulation is kept at room temperature, and adding or subtracting hydrogens allows to find the H* or OH* coverage on Au (111) as function of pH and potential.

This methodology is a simple brute force approach, which is impractical. Currently this can be carried out only on the proof of concept level due to the high computational cost required to sample enough structures. Future advances in algorithms and resources may be needed to leverage further advances from the methodology.

4.2   Electrolyte and pH

Here we show how the water interface structure, which can exist at a specific potential and pH, can be found in the case of pure water and with the limitations of the DFT setup (functional, PAW setup, etc.). To do this the GCHE is applied to a set of water structures obtained from MD with the calculation environment shown in Fig. 14. The pure water is sampled together with systems adding or removing up to six extra hydrogen atoms. The subtraction or addition can be written as n/N, where N = 12 is the number of surface atoms in the unit cell. In total this sampling requires 13 temperature equilibrated MD simulations, which is very computational consuming (one equilibrations currently takes approximately 5000 cpu hours).

From the MD structures, the energies, work functions, and number of protons are saved. In this way the interface energy can be calculated by using the GCHE equation (35), and the result are plotted in Fig. 15a for pH = 0 (left) and pH = 14 (right). These plots are equivalent to Fig. 5, but here each point is at a particular potential instead of extrapolating one point to all potentials. In the plots each line corresponds to a trajectory with n/N protons. To obtain the water structure at a given potential, one can manually select the minimum energy states from the plot or apply a Monte Carlo algorithm, which has been used to find the structures at finite temperature as shown in Fig. 15b.

Similar GCHE, MD ensembles, and Monte Carlo treatment have been carried out on Pt (111) (Hansen et al. 2017), where the Pt (111) interface model is of particular interest in the electrocatalytic proton exchange reactions. A difference from the previous CHE calculated integrated CV, and the experimental integrated CV is shown in Fig. 6b. The binding energy used was obtained from a coverage of 1/3 monolayer of OH. By using the GCHE framework, a stable 5/12 monolayer OH* structure was found and shown in Fig. 16. This shows that combining GCHE with MD ensembles and Monte Carlo, we may access unknown states and put them on an energy scale to find the most stable interface structure as a function of pH and potential.

5   Additional Considerations

Until now, we have described how to calculate various electrochemical properties on metallic surfaces. For the metallic surfaces, the calculations of the absolute level of the electronic states have been avoided, since the binding on metals is much better described with, e.g., DFT than the absolute positions of the electronic states.

The inset shows a snapshot of the 5/12 ML OH* chemisorbed layer structure corresponding to the experimental integrated cyclic voltammogram from Fig. 6b. (Figure from Hansen et al. 2017)

(a) Energy diagram of metal and electrolyte levels.

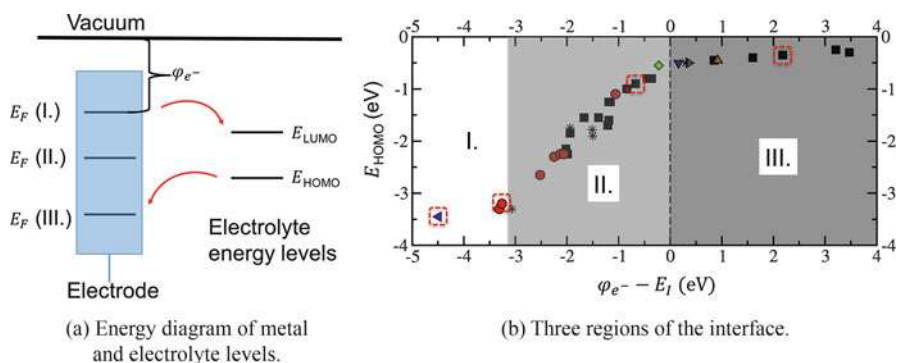
(b) Three regions of the interface.


Fig. 17 (**a**) Illustration of how the metal Fermi level should be aligned between the electrolyte HOMO and LUMO levels (II.). When this is the case, the pinning of the HOMO energy level is avoided as shown in (**b**). (Figures from Björketun et al. 2013)

However, we will give two examples where the energy of the electronic states will play a role. This represents situations where the previous described approach may not be sufficient: (1) interface alignment of electronic states and (2) calculation of binding energies on semiconductors.

A critical issue when calculating interface models is the alignment of the electrode and molecular water electronic energy levels (Cheng and Sprik 2010; Björketun et al. 2013), as shown in Fig. 17a. The issue occurs when the work function of the metal is either above the lowest unoccupied molecular level (LUMO) of the electrolyte, labeled (I.), or below the electrolyte highest occupied molecular level (HOMO), labeled (III.). In both these cases, the Fermi level will be pinned, by either electron transfer from the Fermi energy to the LUMO in case (I.) or electron transfer from the HOMO to the Fermi energy in case (III.). Only if the Fermi energy of the electrode is in between the electrolyte HOMO and LUMO energy levels, proper potentials can be obtained (none-pinned). Calculations of the HOMO level as a function of the difference between the metal work function and electrolyte ionization potential is presented in Fig. 17b. These results directly show how the HOMO level becomes pinned with respect to the metal Fermi energy in region (I.) and (III.), while a proper interface region can be simulated in (II.). As seen in the pinned regions, the work function will not change even if more charge is added to the electrode.

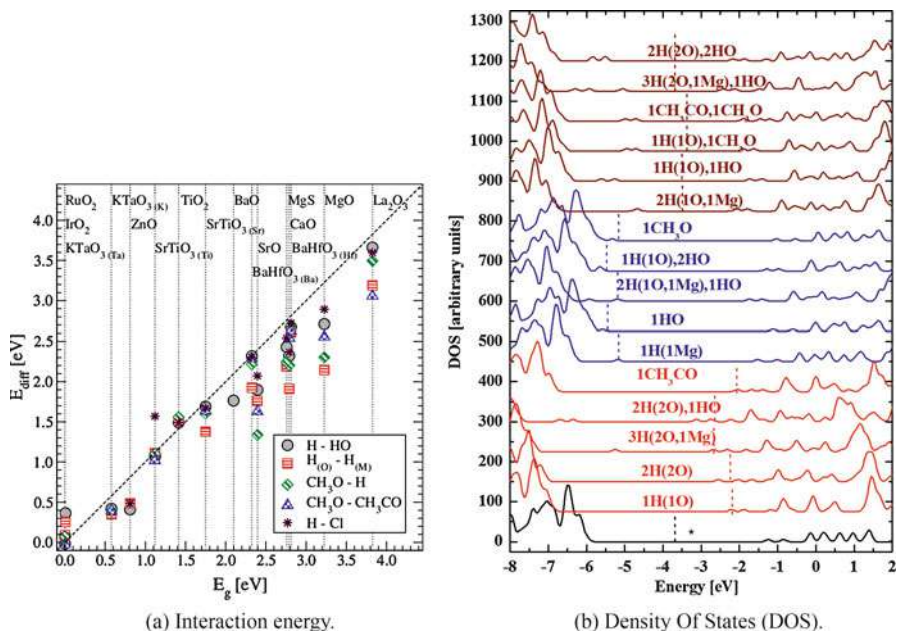
The adsorption properties on semiconductors carry similar problems, where the positions of the bands of the semiconductor force a charge transfer to or from the adsorbate. This is shown by the densities of states calculation on MgO in Fig. 18b. In an intrinsic semiconductor, the Fermi level is placed in the middle of the band gap (black line and labeled as *). When an electron donor is adsorbed (red lines), an electron charge transfers to the conduction band of the slab and the Fermi level shifts up. In the opposite case, if an electron acceptor is adsorbed (blue lines), the


Fig. 18 (**a**) Interaction energy, E_{diff}, as a function of the band gap, E_g, for different fragments on various surfaces. The one-to-one relation between the interaction energy and the band gap is indicated by a dashed line. (**b**) DOS of various fragments on MgO. The electron donors are indicated in red, the electron acceptors in blue, and an electron acceptor-donor pair in brown. (Figures from Castelli et al. 2017)

charge moves from the valence band to the fragment and the Fermi level shifts down. When an electron donor-acceptor pair is formed (brown lines), the shift of the Fermi level is close to zero because the charge donated from one fragment and is accepted by the other and this happens through the surface. This phenomenon is called *cooperative adsorption* or *interaction energy* and has been shown to happen on semiconductors (Broqvist et al. 2002; Ménétrey et al. 2007; Metiu et al. 2012; Hu and Metiu 2012; Li and Metiu 2012). The band gap of the clean surface has been identified as a simple descriptor for the interaction energy. As shown in Fig. 18a for various fragments and surfaces, there is a one-to-one relation between the band gap of the clean surface and the interaction energy. The binding energy of an electron donor-acceptor pair, $\Delta E_{\text{A,D}}$, is equal to:

$$\Delta E_{\text{A,D}} = \Delta E_{\text{A}} + \Delta E_{\text{D}} + \Delta E_g \tag{37}$$

where ΔE_{A} and ΔE_{D} are the binding energies of the A and D fragments calculated alone in the unit cell (Castelli et al. 2017).

6 Summary

In this chapter first principle models of the electrochemical cell have been elucidated. The electrochemical environment has been included by posterior analysis of ab initio calculations.

The computational hydrogen electrode (CHE) has been derived and the assumptions of it explained. Key results obtained by applying the CHE together with state-of-the-art DFT calculations have allowed to derive surface Pourbaix diagrams, integrated CVs, free energy diagrams, Sabatier volcanoes, and electrochemical barriers. Trends in these properties can be compared with trends in experiments.

To decouple the combined chemical potential of protons and electrons, the generalized computational hydrogen electrode (GCHE) has been derived. This allows one to obtain the most stable states with a decoupled dependency on pH and potential. Because of this the GCHE relies on measuring the energy and work function together, allowing only one energy per calculated system and one to obtain an ensemble of states. This generalized setup can be used to derive many interesting properties of the electrocatalytic interface region such isotherms, specific capacities calculated from the differential isotherms, potential of maximum entropy, atomic distance distributions to the surface and atomic pair correlation functions of the interface, and more.

Finally, additional considerations have been made upon systems that are not straightforward to calculate and how correct band alignment must be existing to obtain correct energetics of the interface.
