THIS VOLUME IS DEDICATED TO THOSE SCHOLARS OF MAMMALS IN ACADEMIC institutions, governmental agencies, and nongovernmental organizations in countries of the South American continent. At a pivotal point in the worldwide biodiversity crisis, these individuals have rightly assumed the mantle for the exploration, discovery, description, and conservation of the mammals of their continent through the programs they have developed, the academic institutions and professional organizations they have established and populated, the front rank publication series they have initiated and are supporting, and the students they have trained and who will train those of future generations. There has been remarkable growth in these programs, especially over the past two to three decades, with an energy level and commitment to discovering, archiving, and understanding mammalian diversity in South America that is currently unsurpassed anywhere else in the world.

Sections and Authors

- Class Mammalia Linnaeus, 1758 1
- Order Rodentia Bowdich, 1821: by James L. Patton 1
- Suborder Sciuromorpha Brandt, 1855 1
 - Infraorder Sciurida Carus, 1868 1
 - Family Sciuridae G. Fischer, 1817: by Mario de Vivo and Ana Paula Carmignotto 1
 - Subfamily Sciurillinae Moore, 1959 3
 - Genus *Sciurillus* Thomas, 1914 3
 - Subfamily Sciurinae G. Fischer, 1817 9
 - Genus *Guerlinguetus* Gray, 1821 9
 - Genus *Hadroskiurus* J. A. Allen, 1915 15
 - Genus *Microsciurus* J. A. Allen, 1895 24
 - Genus *Notosciurus* J. A. Allen, 1914 32
 - Genus *Simosciurus* J. A. Allen, 1915 43
 - Genus *Syntheosciurus* Bangs, 1902 47
- Suborder Castorimorpha Wood, 1955: by James L. Patton 48
 - Infraorder Geomorpha Thaler, 1966 48
 - Superfamily Geomyoidea Bonaparte, 1845 48
 - Family Geomyidae Bonaparte, 1845: by Mark S. Hafner 49
 - Genus *Orthogeomys* Merriam, 1895 49
 - Family Heteromyidae Gray, 1868: by Robert P. Anderson 51
 - Genus *Heteromys* Desmarest, 1817 52
- Suborder Myomorpha Brants, 1855: by James L. Patton 58
 - Infraorder Myodonta Schaub, in Grassé and Dekeyser, 1955 58
 - Superfamily Muroidea Illiger, 1811 58
 - Family Cricetidae G. Fischer, 1817 58
 - Subfamily Neotominae Merriam, 1894 60
 - Genus *Isthmomys* Hooper and Musser, 1964: by James L. Patton 60
 - Genus *Reithrodontomys* Giglioli, 1874: by Elizabeth Arellano 61
 - Subfamily Sigmodontinae Wagner, 1843: by Guillermo D'Elía and Ulyses F. J. Pardiñas 63
 - Sigmodontinae *incertae sedis*: by Guillermo D'Elía 70
 - Genus *Abrawayaomys* F. Cunha and Cruz, 1979: by Ulyses F. J. Pardiñas, Pablo Teta, and Guillermo D'Elía 73
 - Genus *Andinomys* Thomas, 1902: by Jorge Salazar-Bravo and Jorge Pablo Jayat 75

- Genus *Chinchillula* Thomas, 1898: by Jorge Salazar-Bravo 78
- Genus *Delomys* Thomas, 1917: by Robert S. Voss 79
- Genus *Euneomys* Coues, 1874: by Janet K. Braun and Ulyses F. J. Pardiñas 83
- Genus *Irenomys* Thomas, 1919: by Pablo Teta and Ulyses F. J. Pardiñas 89
- Genus *Juliomys* E. M. González, 2000: by Enrique M. González, João A. de Oliveira, and Pablo Teta 92
- Genus *Neomicroxus* Alvarado-Serrano and D'Elía, 2013: by Diego F. Alvarado-Serrano and Guillermo D'Elía 96
- Genus *Neotomys* Thomas, 1894: by Pablo E. Ortiz and Jorge Pablo Jayat 99
- Genus *Phaenomys* Thomas, 1917: by Alexandre R. Percequillo 101
- Genus *Punomys* Osgood, 1943: by James L. Patton 103
- Genus *Wilfredomys* Avila-Pires, 1960: by Enrique M. González, João A. de Oliveira, and Ulyses F. J. Pardiñas 105
- Tribe Abrotrichini D'Elía, Pardiñas, Teta, and Patton, 2007: by Guillermo D'Elía, Ulyses F. J. Pardiñas, and Pablo Teta 107
- Genus *Abrothrix* Waterhouse, 1837: by Bruce D. Patterson, Margaret F. Smith, and Pablo Teta 109
- Genus *Chelemys* Thomas, 1903: by Pablo Teta, Ulyses F. J. Pardiñas, and Guillermo D'Elía 127
- Genus *Geoxus* Thomas, 1919: by Pablo Teta, Ulyses F. J. Pardiñas, and Guillermo D'Elía 132
- Genus *Notiomys* Thomas, 1890: by Pablo Teta and Ulyses F. J. Pardiñas 135
- Genus *Pearsonomys* B. D. Patterson, 1992: by Guillermo D'Elía 138
- Tribe Akodontini Vorontsov, 1959: by Guillermo D'Elía and Ulyses F. J. Pardiñas 140
- Genus *Akodon* Meyen, 1833: by Ulyses F. J. Pardiñas, Pablo Teta, Diego F. Alvarado-Serrano, Lena Geise, Jorge Pablo Jayat, Pablo E. Ortiz, Pablo R. Gonçalves, and Guillermo D'Elía 144
- Genus *Bibimys* Massoia, 1979: by Ulyses F. J. Pardiñas, Guillermo D'Elía, and Pablo Teta 204
- Genus *Blarinomys* Thomas, 1896: by Pablo Teta and Ulyses F. J. Pardiñas 208
- Genus *Brucepattersonius* Hershkovitz, 1998: by Júlio Fernando Vilela, Pablo R. Gonçalves, and João A. de Oliveira 211
- Genus *Deltamys* Thomas, 1917: by Ulyses F. J. Pardiñas and Pablo Teta 219
- Genus *Gyldenstolpia* Pardiñas, D'Elía, and Teta, 2009: by Ulyses F. J. Pardiñas and Alexandra M. R. Bezerra 222
- Genus *Juscelinomys* Moojen, 1965: by Louise H. Emmons 225
- Genus *Kunsia* Hershkovitz, 1966: by Alexandra M. R. Bezerra 228

- Genus *Lenoxus* Thomas, 1909: by James L. Patton 231
- Genus *Necromys* Ameghino, 1889: by Ulyses F. J. Pardiñas, Pablo Teta, Pablo E. Ortiz, Jorge Pablo Jayat, and Jorge Salazar-Bravo 232
- Genus *Oxymycterus* Waterhouse, 1837: by João A. de Oliveira and Pablo R. Gonçalves 247
- Genus *Podoxymys* Anthony, 1929: by Ulyses F. J. Pardiñas and Pablo Teta 268
- Genus *Scapteromys* Waterhouse, 1837: by Guillermo D'Elía and Ulyses F. J. Pardiñas 269
- Genus *Thalpomys* Thomas, 1916: by Ulyses F. J. Pardiñas and Pablo Teta 274
- Genus *Thaptomys* Thomas, 1916: by Pablo Teta, Ulyses F. J. Pardiñas, and Guillermo D'Elía 277
- Tribe Ichthyomyini Vorontsov, 1959: by Robert S. Voss 279
- Genus *Anotomys* Thomas, 1906 281
- Genus *Chibchanomys* Voss, 1988 282
- Genus *Ichthyomys* Thomas, 1893 284
- Genus *Neusticomys* Anthony, 1921 287
- Tribe Oryzomyini Vorontsov, 1959: by Marcelo Weksler 291
- Genus *Aegialomys* Weksler, Percequillo, and Voss, 2006: by Alexandre R. Percequillo 293
- Genus *Amphinectomys* Malygin, 1994: by Marcelo Weksler and Michael Valqui 298
- Genus *Cerradomys* Weksler, Percequillo, and Voss, 2006: by Alexandre R. Percequillo 300
- Genus *Drymoreomys* Percequillo, Weksler, and Costa, 2011: by Alexandre R. Percequillo and Marcelo Weksler 308
- Genus *Eremoryzomys* Weksler, Percequillo, and Voss, 2006: by Alexandre R. Percequillo 310
- Genus *Euryoryzomys* Weksler, Percequillo, and Voss, 2006: by Alexandre R. Percequillo 312
- Genus *Handleyomys* Voss, Gómez-Laverde, and Pacheco, 2002: by Marcela Gómez-Laverde, Robert S. Voss, and Víctor Pacheco 321
- Genus "*Handleyomys*": by Marcelo Weksler 323
- Genus *Holochilus* Brandt, 1835: by Pablo R. Gonçalves, Pablo Teta, and Cibele R. Bonvicino 325
- Genus *Hylaeamys* Weksler, Percequillo, and Voss, 2006: by Alexandre R. Percequillo 335

Díaz, and Rubén M. Barquez 1025
- Genus *Octodon* Bennett, 1832: by M. Mónica Díaz, Rubén M. Barquez,
and Diego H. Verzi 1029
- Genus *Octodontomys* Palmer, 1903: by Diego H. Verzi, M. Mónica
Díaz, and Rubén M. Barquez 1035
- Genus *Octomys* Thomas, 1920: by Diego H. Verzi, M. Mónica Díaz,
and Rubén M. Barquez 1038
- Genus *Spalacopus* Wagler, 1832: by Diego H. Verzi, M. Mónica Díaz,
and Rubén M. Barquez 1039
- Genus *Tympanoctomys* Yepes, 1942: by M. Mónica Díaz, Rubén M.
Barquez, and Diego H. Verzi 1043

Introduction

The science of Natural History is of so unbounded an extent, that perhaps I may be allowed, comparatively speaking, to say, that scarcely a day passes without an opportunity being afforded to zoologists of bringing to light unknown instances of its latent treasures.

JOSHUA BROOKES (1829:95), British anatomist and naturalist, in reference to his description of the Plains Viscacha, *Lagostomus*.

IN HIS INTRODUCTION to the first volume in this series, Alfred L. Gardner (2008) detailed the history of the intention that he, Sydney Anderson, and James L. Patton had to produce an updated reference to the mammals of South America, one that would provide a thorough review of knowledge about mammals dating from the mid-1700s through today. The goal was to document the rich nomenclatural history for all taxa (families, genera, and species); describe morphological and other traits that aid in identification, both in the field and museum; delimit species' distributions by listing and mapping marginal records confirmed by voucher specimens and the published literature; and summarize available observations on natural history. Gardner's volume 1, which covered marsupials, xenarthrans, shrews, and bats, set an exemplary standard of scholarship for this effort. This, the second volume in the series, is restricted to the single order Rodentia, the most diverse of all mammalian groups worldwide, accounting for more than 42% of species and 39% of genera (Wilson and Reeder 2005). All Recent and extant taxa are included; those known only from the fossil record or now extinct are not (e.g., *Megaoryzomys* from the Galapagos Islands, Ecuador; *Noronhomys*, from Ilha Fernando de Noronha, Brazil; *Dusimys*, from Curaçao, Caribbean Netherlands), nor are those introduced to the continent (such as beavers, *Castor canadensis*, and muskrats, *Ondatra zibethicus*, from North America, or the Old World rats [*Rattus* spp.] and mice [*Mus* spp.], family Muridae).

The first substantive review of South American rodents was Angel Cabrera's seminal *Catálogo*, the rodent part of which was published in 1961 after his death, thanks to the

efforts of Jorge Crespo. In the intervening 50 years, the recognized diversity of South American rodents at both the genus and species levels has increased by approximately 160%. Perhaps not surprisingly, many of the taxa at all categorical levels treated by Cabrera have also been re-ordered in fundamentally different ways. To illustrate, we use taxon diversity trends for the largest group of South American mammals: the rats and mice of the cricetid subfamily Sigmodontinae, which encompass some 62% of the generic diversity and 56% of the species diversity of rodents recognized in the accounts presented in this volume. Only about 34% of the genera and 39% of the South American rodent species we recognize today owe their discovery and description to scholars of the nineteenth century. The first two decades of the twentieth century saw an increase of another 25% to the totals of both genus- and species-group taxa, followed by a 50-year rather quiescent period (from 1921 until 1970) which saw only a modest growth in overall diversity at both taxonomic levels of less than 2% per decade. Tracing these trend lines up to the time when our project was initiated (in the 1970s), one might have surmised that most of the known taxonomic diversity of sigmodontines on the continent had already been discovered and described. Such a conclusion, however, could not have been further from reality. Indeed, in the last 30 years, the generic diversity in South American sigmodontines has increased by 27%, with 24 new genera added, and species diversity by 24%, with 56 new species described. And, in the few months since this book went into production, additional species descriptions have appeared in the literature (e.g., Gonçalves and Oliveira 2014). Fully one quarter of

all genera and species of this group of rodents that are recognized today have been described in the terminal three of the 25 decades since Linnaeus (1758) established the earliest currently accepted technical names, and the exploration of the biota of South America began (see the historical reviews of Neotropical mammalogy given by Hershkovitz [1987b] and the Introduction in A. L. Gardner [2008]).

The remarkable rate of recent discovery and description of South American sigmodontines is mirrored by most other rodent groups (as well as for mammals in general worldwide [e.g., Reeder et al. 2007] or those limited to the Neotropical Realm [e.g., B. D. Patterson 2000, 2001]). This increased rate owes its origin to many factors, perhaps the most important of which has been the establishment of exceptionally strong academic programs in systematic and evolutionary sciences, including mammalogy, in most countries on the continent, a development that has accelerated in the past two decades. Naturally coupled to expansion of academic programs has been the development of professional organizations wherein annual or biannual meetings bring together scholars of all academic stages to share knowledge and inspire further research. These two critical components in the development of the professional field of mammalogy have been directly tied to other factors underlying the increase in our knowledge of South America mammals, including but not limited to (1) substantially increased field research, especially into the remote areas of this ecologically diverse continent; (2) an increase in the diversity of survey methods for securing samples (particularly owl pellet analyses in Argentina and pitfall trapping in Brazil); (3) computer-driven analytical methodologies to evaluate characters, compare morphologies in multivariate space, and construct the trees upon which phylogenetic systematics depend; (4) the explosion of molecular-based methodologies, particularly DNA sequencing, which can be applied to historic specimens in museum collections as well as recently collected materials; (5) the requisite shift in systematic philosophy to one based on phylogenetic principles, with taxon definition appropriately based on relationships determined by shared-derived characters rather than overall similarity, and (6) the recognition, through both policy implementation and financial support, by governmental and nongovernmental agencies of the importance of basic systematic research as a key component of biodiversity assessment, which in turn underlies sound environmental policy and establishes conservation priorities. We intend that this volume and the others in our series will identify gaps in our current knowledge and encourage additional field, museum, and laboratory research to fill those gaps.

As noted by A. L. Gardner (2008) in his introduction to volume 1, we selected Cabrera's (1958–1961) catalog as the primary point of departure because of its strong empha-

sis on taxonomy and nomenclature. Our area of coverage includes nuclear South America as well as the continental islands of Trinidad and Tobago and the Caribbean Netherlands off the Venezuelan coast (Map 1). Along with extensive but not exhaustive synonymies, the accounts in this volume include identification keys and descriptions of each order, family, genus, and species. Each species account also includes comments on distribution; lists of selected localities that are plotted on maps; comments on subspecies and, in a few cases only, lists of subspecies and their synonyms and distributions; summaries of natural history information; and discussions of issues related to type localities, taxonomic interpretations, matters of nomenclatural importance, and karyotype, if known. As with volume 1, this one contains its own Gazetteer and Literature Cited sections, with the latter including all citations in the text as well as those cited in the references relating to dates of publication.

Also, as was the case for volume 1, the scope of individual contributions and thus authorship assignments is uneven. The authority and responsibility for a given contribution continue until a new author line is encountered; for example, some authors were responsible for all entries in a single family, while multiple individuals singly or in combination authored the accounts in other families. The Acronyms and Abbreviations, Literature Cited, and Gazetteer sections were compiled from information provided by each account author.

With a few exceptions, the taxonomy of higher categories follows McKenna and Bell (1997), and the sequence of family, genus, and species group taxa is based on the third edition of *Mammal Species of the World*, edited by Wilson and Reeder (2005). Documentation by reference to more recent literature is provided for deviations from either of these two general references, or is noted when based on the personal views of the contributing authors from their own, often unpublished, research. A. L. Gardner (2008:xvi) provided the guidelines followed herein for the synonymies, including citation of the original description and any unique name combination subsequently applied by any author for the first time to that taxon. Interested persons should see his written synopsis for details. We, as did Gardner (see his dedication in volume 1), relied heavily on the "scrapbooks" compiled by Remington Kellogg, the former curator of mammals and director of the U.S. National Museum, in constructing synonymies. Fortunately, much of the early eighteenth and nineteenth century literature is now available in digital form from the Biodiversity Heritage Library (<http://www.biodiversitylibrary.org/>), a truly remarkable resource. Finally, J. R. Ellerman is credited in this volume with the name combinations cited from his *The Families and Genera of Living Rodents*; however, if a name came from one of the lists and was available before 1937, in many cases either R. W. Hayman or G. W. C. Holt

compiled the individual list on which those name combinations are based.

This volume deviates from volume 1 in limited but important ways. First, we asked account authors to provide a description of each species beyond those characters that comprise the keys. Most rodents have not been monographed in recent decades or ever, and many species are known only from their initial description. Moreover, an increasing number of species have been defined in the past few decades by karyotypic data (diploid number and arm number of both autosomes and sex chromosomes) and/or DNA sequences. As important as these characters are, neither the karyotype nor sequence are available for the vast majority of specimens in museum collections nor for live animals captured during field studies. As a consequence, reliance on keys alone for identification in the field or museum can be problematic. We thus believe that descriptions of external and/or craniodental characters of each species is an important addition to this volume, one enhanced by multi-authored accounts for large, geographically widespread, and particularly vexing taxa, such as the sigmodontine genus *Akodon* or the echimyid genus *Proechimys*. Where possible, the authors have provided the standard external measurements of head and body length, tail length, hind-foot length, ear length, and/or mass, taken either from the literature or from labels of museum vouchers they examined as well as characters of the pelage (color, color pattern, details of hair types), appendages, and both soft and craniodental anatomy. However, these descriptions vary greatly in depth of detail owing to both the level of knowledge of individual and geographic variation available and an author's direct familiarity with specimens in museum collections. In some cases, our knowledge of a particular species is so poor that little beyond the original description is available.

Second, we have allowed authors liberty in delineating locality records beyond just those circumscribing the edge of a species' range. Many species of rodents are so poorly known that we believed it valuable to list and map virtually all known records in those cases. However, we caution users of metadata, such as marginal locality maps in global analyses of biodiversity, not to confuse a shaded range bounding locality records with actual occurrence throughout. Many species of rodents are habitat specialists and are certainly not evenly spread across the geographic landscape indicated by that shaded range. Shading surrounding the mapped localities is provided primarily to highlight those locality placements and not to identify actual geographic boundaries, although the maps are drawn with as much precision as possible given their scale. The ranges mapped also include locality records assembled over many decades; as a result, they do not accommodate any range shift or fragmentation that may have resulted from anthropogenic

landscape modification or other factors in recent decades. Nor should these range maps be viewed as static into even the near future, as continuing fieldwork in remote areas will invariably expand those ranges now known and global climate change continues to impact both distribution and presence (e.g., Malcolm et al. 2006; Urban et al. 2012). Finally, because the shapes of species' ranges are diverse, often linear or geographically restricted, we have not followed the uniform clockwise listing of localities, starting with *N* on a compass, employed in volume 1. Rather than explaining deviations from this scheme in so many individual cases, localities are simply listed alphabetically by country, department/province/state, and specific locality in all accounts. Virtually all locality records are based on vouchered specimen records where the identification could be verified, either literature records from revisionary accounts or the actual examination of a museum voucher. We note, however, that the advent of widespread camera traps and archives of verifiable digital photos—which have been used so successfully to document new records for large mammals—are beginning to provide insight even into smaller and often very secretive rodents (e.g., Blake et al. 2010). Although photos are unacceptable replacements for vouchered specimens in systematic research, a few accounts have included localities derived from unambiguous recent photographs of rare taxa with few records. Inset maps depicting the range of the genus are also provided in the maps for each species.

Third, there is also substantial unevenness in coverage of natural history and other information on population biology, ecology, reproduction, and other attributes across accounts. Some of this simply results from the actual quantity of information available, as so many species of rodents have never been studied in their natural habitats, but some also stems from whether existing or relatively recent synopses have already been published (e.g., the *Mammalian Species* accounts produced by the American Society of Mammalogists, <http://www.mammalsociety.org/publications/mammalian-species>).

Finally, the construction and use of vernacular names is a vexing problem in mammalogy, as there is no standard set of rules that apply to their formation (but see Duckworth and Pine 2003). This issue is exacerbated by the common application of English names (as given, for example, in Wilson and Cole [2000] for mammal species worldwide) rather than use of the larger number of common terms applied to those species by South American biologists, the lay public in each country, and/or indigenous groups. The common names employed herein are those of the account authors and may reflect either or both English and local terms or equivalents. Many of these follow Wilson and Cole (2000) and/or those of account authors in Wilson and Reeder (2005).

Map 1 Political map of the South American continent including the Caribbean Netherlands, Trinidad and Tobago, and the Galapagos Islands.

Acronyms and Abbreviations

The following acronyms and abbreviations are used in the text to identify collectors and museum collections.

- AMNH: American Museum of Natural History, New York, New York, United States
AL: Alfredo Langguth field numbers
AN: Andrea Nunes field numbers
APC: Ana Paula Carmignotto field numbers
ARG: Field numbers of uncataloged specimens in the Sam Noble Oklahoma Museum of Natural History, Norman, Oklahoma, United States
ARP: Alexandre R. Percequillo field numbers
BM: The Natural History Museum, London (NHM); formerly the British Museum (Natural History), London, United Kingdom
CAS: California Academy of Sciences, San Francisco, California, United States
CBF: Colección Boliviana de Fauna, Instituto de Ecología y Museo de Historia Natural, La Paz, Bolivia
CEM: Colección Elio Massoia, acquired by the Fundación de Historia Natural Félix de Azara, Buenos Aires, Argentina
CIT: Laboratório de Citogenética de Vertebrados, Universidade de São Paulo, São Paulo, Brazil
CLH: Christine L. Hice field numbers
CM: Carnegie Museum of Natural History, Pittsburgh, Pennsylvania, United States
CML: Colección Mamíferos Lillo, Universidad Nacional de Tucumán, Tucumán, Argentina
CML-PIDBA: Colección Mamíferos Lillo, Programa de Investigaciones de Biodiversidad Argentina, Universidad Nacional de Tucumán, Tucumán, Argentina
CMUFL: Mammal Collection, Universidade Federal de Lavras, Minas Gerais, Brazil
CNP: Colección de Mamíferos, Centro Nacional Patagónico, Puerto Madryn, Chubut, Argentina
CNP-E: Colección de Material de Egagrópilas y Afines “Elio Massoia,” Centro Nacional Patagónico, Puerto Madryn, Chubut, Argentina
CONN: University of Connecticut, Storrs, Connecticut, United States
CRB: Cibele R. Bonvicino field numbers
CUVLA: Colección de Vertebrados de la Universidad de Los Andes, Mérida, Venezuela
EBRG: Museo de la Estación Biológica de Rancho Grande, Maracay, Venezuela
EPN: Escuela Politécnica Nacional, Quito, Ecuador
FAG: Valéria Fagundes field numbers
FLMNH: University of Florida Museum of Natural History, Gainesville, Florida, United States
FMNH: Field Museum, Chicago, Illinois, United States
GD: Guillermo D’Elía field numbers
HGB: Helena de Godoy Bergallo field numbers
HTC: Departamento de Microbiología, Universidad del Valle, Cali, Colombia
IADIZA: Colección de Mastozoología del Instituto Argentino de Investigaciones de Zonas Áridas, Mendoza, Argentina
IAvH: Instituto Alexander von Humboldt, Cartagena, Colombia

- ICN: Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Bogotá, Colombia
- INDERENA: Instituto Nacional de los Recursos Naturales Renovables y del Ambiente, Bogotá, Colombia
- INEVH: Instituto Nacional de Enfermedades Virales Humanas, Pergamino, Buenos Aires, Argentina
- INPA: Instituto Nacional de Pesquisas da Amazônia, Amazonas, Manaus, Brazil
- JAO: João A. de Oliveira field numbers
- JPB: Jean-Phillipe Boubi field numbers; voucher specimens in INPA collection.
- JPJ: Jorge Pablo Jayat field numbers
- JRM: Jay R. Malcolm field numbers
- KU: Natural History Museum, University of Kansas, Lawrence, Kansas, United States
- LACM: Los Angeles County Museum of Natural History, Los Angeles, California, United States
- LAMAQ: Laboratório de Mamíferos Aquáticos, Universidade Federal de Santa Catarina, Florianópolis, Santa Catarina, Brazil
- LBCE: Laboratório de Biologia e Controle da Esquistossomose, Fundação Instituto Oswaldo Cruz (FIOCRUZ), Rio de Janeiro, Brazil
- LC (and LPC): Leonora Pires Costa field numbers
- LCM: Laboratorio de Genómica Evolutiva, Facultad de Medicina, Universidad de Chile, Santiago, Chile
- LF: Luiz Flamarion field numbers

The following abbreviations are used to identify statistical or other terms.

bp: base pairs (of DNA sequences)
FN: fundamental number
ft: feet
g: grams
ha: hectares
HPD: highest posterior density
IRBP: interphotoreceptor retinoid-binding protein
kg: kilograms
kya: thousands of years ago
m: meters
mm: millimeters
mtDNA: mitochondrial DNA
mya: millions of years ago
nucDNA: nuclear DNA
pg: picograms
s.d.: standard deviation
s.s.: *sensu stricto*
ybp: years before present

Acknowledgments

No treatise such as this can be completed without the input of many individuals, and not just those who authored the accounts herein. With apologies beforehand for excluding some who deserve mention, we single out several individuals for special recognition for aiding us in so many substantive ways. Specifically, Louise H. Emmons read through most of the completed manuscript in its several iterations, freely offering her vast knowledge, correcting parts, and updating others. Mere mention of her name here does not do justice to her insights and overall contributions. Michael D. Carleton offered expert advice on details of synonymy construction and reviewed large parts of the manuscript with the eye of an editor; his efforts are deeply appreciated. Carola Cañón (Chile), Hugo Mantilla-Meluck and Héctor Ramírez (Colombia), and Julio Torres (Paraguay) reviewed and corrected locality designations in the accounts and gazetteer; we are grateful to each for this very important contribution. Susan Abrams and Christie Henry, both senior editors at the University of Chicago Press over the gestation period of our project, deserve special recognition for their unflagging interest and incredible patience while encouraging us to complete this project, as do Abby Collier, Kyle Adam Wagner, and Amy Krynak, also at the University of Chicago Press, for help with the final stages of manuscript production.

Finally, we are especially grateful to Ronald H. Pine and Robert S. Voss for their careful, critical reviews of the entire manuscript; neither should be held responsible for the final product, but their nomenclatural expertise and especially their personal field and museum experience with many taxa have improved virtually every section.

Jim Patton acknowledges Alfred L. Gardner, whose editorship of volume 1 in this series set a standard of scholarship we can only hope to achieve. Gardner not only initiated Patton's career in mammalogy in the early stages of their respective graduate studies and introduced him to South America and its spectacular mammalian fauna (see Patton 2005c), but he also answered many queries quickly and concisely. Michael Carleton, Judith Chupasco, Robert Fisher, David Flores, Mark Hafner, Yuri Leite, João de Oliveira, Víctor Pacheco, Bruce Patterson, Mario de Vivo, and Robert S. Voss provided Patton with either direct access to the collections under their control, examined critical specimens for him, or sent him crucial specimen records or literature for inclusion in this volume; he thanks each for their professionalism and friendship. James Hanken at the Museum of Comparative Zoology of Harvard University and Mary Sears, librarian of the Mayr Collection of the Museum of Comparative Zoology's library, kindly provided a digital scan of an important historical document.

Ulyses Pardiñas acknowledges the economic support from Agencia Nacional de Promoción Científica y Tecnológica (PICT 2008-547), and Consejo Nacional de Investigaciones Científicas y Técnicas (PIPs 6179 and 2001-164). He is especially grateful to Pablo Teta and Carlos Galliari for many years of collaborative work in the field and museum on sigmodontines, and to Erika Cuéllar, whose love and unconditional support rescued him from unhappiness, and his son Joaquín, a tireless friend in the field, both of whom changed his life.

Guillermo D'Elía is grateful to those colleagues, teachers, and students who shared and discussed their views on

the evolutionary history and systematics of South American rodents, and gives special thanks to everyone who made this project possible.

Louise Emmons wishes to thank João Oliveira for providing a photograph of *Oxymycterus talpinus*, essential for her review of *Juscelinomys*.

Claudio Bidau acknowledges Julio R. Contreras, Patricia Miro, Jeremy B. Searle, Chris G. Faulkes, Enrique Lessa, Andrés Parada, Guillermo D'Elía, Ricardo Ojeda, Thales de Freitas, Yolanda Davies, Alonso Medina, Diego Verzi, Mabel D. Giménez, Claudia Ipucha, Pablo Suárez, Cecilia Lanzone, Joyce Bernardo, Pavel Borodin, Dardo Marti, Juan Luis Santos, and a large number of students during his years at the Universidad Nacional de Misiones, Universidade Estadual de Rio de Janeiro, and Fundação Oswaldo Cruz. He gives his special thanks to Valeria Ximena Rodríguez for her help and endless love.

Scott Steppan and Oswaldo Ramirez thank Jim Patton for substantial contributions to their *Phyllotis* account, and

they acknowledge the financial support of National Science Foundation grants DEB-0841447 and DEB-0108422.

Alexandra Bezerra thanks Manoel Santos-Filho and Maria Nazareth F. da Silva for discussions and clarifications regarding the correct identification of a specimen allocated to *Euryzygomatomys spinosus* in previous studies; Ana Paula Carmignotto and Roberta Paresque for sharing their unpublished karyotypic data for *Carterodon sulcidens*; Ulyses F. J. Pardiñas for providing key bibliographic references; and the CNPq (150599/2008-0) for postdoctoral support and Conservation International for grants to visit critical museum collections.

Mario de Vivo wishes to thank Dr. Robert S. Voss and the Mammal Department of the American Museum of Natural History in New York for postdoctoral advisorship and funding, respectively. He and Ana Paula Carmignotto would also like to extend their heartfelt thanks to Jim Patton “for everything, and more.”

Taxonomic Accounts

Class Mammalia Linnaeus, 1758

Order Rodentia Bowdich, 1821

NEW WORLD RODENTS

James L. Patton

KEY TO THE SUBORDERS OF RECENT SOUTH AMERICAN RODENTS:

1. Well-defined zygomatic plate anterior to zygomatic arch present; infraorbital foramen small and either piercing zygomatic plate or positioned on side of rostrum anterior to zygomatic plate; lower jaw sciurognathous, with origin of angular process directly ventral to sheath of lower incisor. 2
 - 1'. No zygomatic plate; infraorbital foramen greatly enlarged; lower jaw hystricognathous, with the root of the angular process deflected lateral to sheath of lower incisor. Hystricomorpha
 2. Zygomatic plate oriented anteriorly; infraorbital foramen small, transmitting only nerves and blood vessels; maxillary teeth number four or five 3
 - 2'. Zygomatic plate oriented more laterally; infraorbital foramen enlarged, narrow, but typically expanded dorsally, transmitting medial masseter muscle in addition to nerves and blood vessels; maxillary teeth number three or fewer Myomorpha
 3. Infraorbital foramen pierces zygomatic plate; cheek teeth number four or five, with molars brachydont, bunodont, with three transversely oriented crests Sciuromorpha

- 3'. Infraorbital foramen positioned on side of rostrum anterior to zygomatic plate; cheek teeth number four, either hypsodont, cylindrical, and planar (Geomyidae) or brachydont, bunodont, and cuspidate (Heteromyidae) Castorimorpha

Suborder Sciuromorpha Brandt, 1855

Infraorder Sciurida Carus, 1868

Family Sciuridae G. Fischer, 1817

Mario de Vivo and Ana Paula Carmignotto

Squirrels are ubiquitous inhabitants of all forest biomes throughout South America except the temperate forests, with all species adapted for life in the canopy, even though some forage on the ground. Specialized adaptations for climbing include elongate bodies, forefeet with four long toes with claws, hindfeet with five long toes with claws, large plantar pads on all feet, broad heads, large eyes, short ears, generally soft fur, long bushy tails, and elongated legs. The ankle joint is flexible, allowing the hindfoot to rotate sufficiently for headfirst descent of vertical tree trunks. Most species have enlarged, long incisors accompanied by correspondingly large jaw muscles, which enable them to gnaw through the hardest nuts. Some species specialize on hard-shelled seeds of tropical trees such as palms, but most are more omnivorous, feeding on a range of food types such as nuts, fruits, insects, fungi, and sometimes leaves, flowers, and bark (Emmons and Feer 1997). All South American squirrels are diurnal; as such, individuals can be easily

2 Mammals of South America

seen and often readily heard as they move about or gnaw on large nuts. They build round, ball-like nests of leaves and twigs in vine tangles or on tree limbs, or they nest in tree holes. Capuchin monkeys, *Cebus* [now *Sapajus*] *apella* (Galetti 1990), and both medium and large felids (Emmons 1978b) are known predators of South American squirrels.

Body size can be arranged into three broadly separable classes, with one pygmy squirrel (maximum head and body length about 115 mm, tail length 120 mm, and mass 45 g), many dwarf squirrels of intermediate size (head and body length 160–300 mm, tail length 150–280 mm, and mass 130–520 g), and a few large squirrels (head and body length 240–300 mm, tail length 240–340 mm, and mass 570–900 g; Thorington et al. 2012). The skull retains the same generalized shape in all South American species: braincase domed and rounded; interorbital region wide; post-orbital processes on both frontals and jugals prominent; rostrum relatively short but broad; zygomatic arches deep and stout; auditory bullae evenly rounded and relatively large but rarely excessively inflated, and divided by several transverse bony septa; incisive foramina short; cheek teeth brachydont and bunodont, with prominent cusps and transverse crests usually on molars; and dental formula I 1/1, C 0/0, PM 2–1/1, and M 3/3=20–22, with PM3 reduced or absent. Angular processes of the mandible are slightly inflected. A baculum is present in the phallus of males of all species.

Peterka (1937) and Bryant (1945), among others, have provided detailed descriptions of sciurid morphology. Only four taxa have been karyotyped: *Guerlinguetus brasiliensis brasiliensis* (Lima and Langguth 2002, $2n=40$, FN=76), *G. b. ingrami* (Fagundes et al. 2003, $2n=40$, FN=74), *Hadroskiurus spadiceus* (Lima and Langguth 2002, $2n=40$, FN=76), and *Notoskiurus granatensis* (Nadler and Hoffmann 1970, $2n=42$, FN=78).

Despite their broad range throughout much of the continent and local ubiquity in all forest types, South American squirrels remain poorly known in nearly all aspects of their life history and, in particular relevance to this volume, their evolutionary relationships and diversification history. There have been no revisionary studies published in the last half-century or longer. Furthermore, and in contrast to virtually all other South American rodent groups, students of molecular phylogenetics have largely bypassed the Sciuridae, except for the inclusion of a few species in the phyletic delineation of the major lineages in this nearly cosmopolitan family (Mercer and Roth 2003; Steppan, Storz, and Hoffmann 2004; Pecnerová and Martínková 2012). These studies have unambiguously identified two lineages among the South American representatives of the family. One of these contains the monotypic *Sciurillus*, which forms a

basal offshoot that diverged very early in the history of the family. Although Moore (1959) did recognize the uniqueness of *Sciurillus* by placing it in its own subtribe Sciurillina in the tribe Sciurini, molecular studies clearly document that *Sciurillus* has no phylogenetic affinity to other tree squirrels. Consequently, this genus is now uniformly placed in its own subfamily, the Sciurillinae (Steppan, Storz, and Hoffmann 2004; Thorington and Hoffmann 2005; Thorington et al. 2012). The basal position of *Sciurillus* in the family, moreover, suggests great age for its lineage, which Roth and Mercer (2008) estimated at about 30 mya, a divergence event only slightly younger than the 36-mya age for the family. In contrast, the entire radiation of all remaining tree squirrels in South America, now placed in the subfamily Sciurinae (Thorington and Hoffmann 2005; Thorington et al. 2012), appears to have descended from a single lineage, one that arrived on the continent subsequent to the closure of the Panamanian land bridge (Roth and Mercer 2008; Pecnerová and Martínková 2012).

The last revision of South American representatives was J. A. Allen's classic monograph *Review of the South American Sciuridae*, published in 1915 and thus now nearly a century old. Allen recognized nine genera, a number reduced to three or four by subsequent reviewers (e.g., Ellerman 1940, three genera [*Sciurillus*, *Microsciurus*, and *Sciurus*, divided into three subgenera]; Moore 1959, four genera [*Guerlinguetus*, *Microsciurus*, *Sciurillus*, and *Syntheosciurus*]; Cabrera 1961, three genera [*Microsciurus*, *Sciurillus*, and *Sciurus*, divided into two subgenera]; R. S. Hoffmann et al. 1993 and Thorington and Hoffmann 2005, three genera [*Microsciurus*, *Sciurillus*, and *Sciurus*, divided into three subgenera]). The number of species recognized in various treatments over the past 50 years has also differed, sometimes substantially. For example, J. A. Allen (1915a) divided South American squirrels into 25 species, Cabrera (1961) into 13, Emmons and Feer (1997) described and mapped 11, and R. S. Hoffmann et al. (1993) and Thorington and Hoffmann (2005; see also Thorington et al. 2012) listed 15. In part, differences in species boundaries recognized by these and other authors attest to the extreme variability often present geographically in color and color pattern. The concordance of both generic membership and categorical level across these treatments is limited, a fact also attesting to both the extensive variation in coloration that characterizes most of these taxa and the lack of critical reviews.

The lack of any comprehensive or even regional analysis of character variation for nearly all species of South American squirrels prompted us to examine most available specimens, including holotypes, to assess both genus- and species-level boundaries. As a result, we recognize seven genera and

a total of 19 species. These taxonomic hypotheses differ from previous treatments of South American squirrels, the most recent of which is that of Thorington et al. (2012), and they are ripe for testing by phylogenetic and phylogeographic analyses employing molecular data and methods.

KEY TO THE SUBFAMILIES OF SOUTH AMERICAN SCIURIDAE (FROM MOORE 1959:199–200):

1. Lateral wall of cranium with squamosal extending dorsally to a point less than or equal to halfway from base of zygomatic process of squamosal to base of postorbital process of frontal; typically two transbullar septa; well-developed masseteric tubercle; maxilla contributing much less than half to the lateral side of rostrum; robust zygoma with a well-developed superior process Sciurinae
- 1'. Lateral wall of cranium with squamosal extending dorsally notably more than halfway between base of zygomatic process of squamosal and base of postorbital process of frontal; one transbullar septum; no masseteric tubercle; maxilla contributing much more than half of the lateral side of rostrum; slender zygoma lacking superior process. Sciurillinae

Subfamily Sciurillinae Moore, 1959

The subfamily Sciurillinae contains only the single genus and species *Sciurillus pusillus*. This is the smallest of the New World Sciuridae and one of the two most ancient lineages in the family, the other being the Ratuinae, or giant tree squirrels of southern Asia. In erecting this taxon, Moore (1959:180) delineated 12 diagnostic characters of the skull, including those listed in the key.

Cladistic analyses of both morphological (Roth 1996) and molecular characters (allozymes: M. S. Hafner et al. 1994; mitochondrial and nuclear DNA sequences: Mercer and Roth 2003; Herron et al. 2004; Roth and Mercer 2008) support the basal position of the Sciurillinae in the Sciuridae and refute the hypothesized phyletic link between *Sciurillus* and the Asian (*Nannosciurus*) and African (*Myosciurus*) pygmy squirrels proposed by G. S. Miller and Gidley (1918). Mercer and Roth (2003) estimated the split between the lineage leading to *Sciurillus* and all other sciurids (flying, ground, and tree squirrels) at about 36 mya, in the late Eocene. These authors also argued that the deep phylogenetic separation between *Sciurillus* and other South American sciurids, which formed a monophyletic assemblage, indicated separate invasions of the continent by squirrels. Because *Sciurillus* has no close relatives in the family, its place of origin and timing of entry to South America remain enigmas.

Genus *Sciurillus* Thomas, 1914

The genus *Sciurillus* is a tiny rainforest squirrel with three pairs of mammae, distributed in the Guianas and Amazon Basin. This is the smallest of the New World tree squirrels, with a head and body length averaging 113 mm, tail length 114 mm, hindfoot length 30 mm, and body mass 44 g (N=5). The ears are small and round, up to 14 mm long. The skull has a strongly convex dorsal profile, with the inflexion point at the middle of the frontals; the rostrum is long, more than one-third the skull length; the frontals are short, as wide or wider than their length; the braincase is relatively large and globose; the temporal part of the orbitotemporal fossa is completely obliterated, with the postorbital process extending posteriorly to almost coincide with a vertical plane at the posteriormost part of the squamosal zygomatic process; the anterior portion of the zygoma is nearly vertical, situated posterior to the first upper molar; a distinct semi-circular crest, originating at the infraorbital foramen, runs dorsally along the line of contact between the premaxilla and maxilla on each side; the anterior opening of the infraorbital foramen is positioned midway between the anteriormost part of the zygoma and the incisors, but the infraorbital canal is not conspicuously elongated; the parapterygoid fossa is deep, well delimited, and sometimes perforated by bilateral or unilateral vacuities; the posterior aperture of the alisphenoid canals is small, maximally one-third the width of the foramen ovale; the aperture of the transverse canal is distinctly visible in ventral view, and not covered by the posterior border of the pterygoid encircling the foramen ovale; a sphenopalatine foramen is situated above the third upper molar or, at most, over the region between the second and third molars; and only one bullar septum is present. Very short coronoid processes characterize the mandible. Temporal muscles are correspondingly unusually small for a squirrel, but the anterior deep masseters are enlarged and oriented to assist in retraction of the jaw (Ball and Roth 1995).

The dental formula is I 1/1, C 0/0 PM 2/1, M 3/3=22. Upper incisors are proodont. PM3 has one root; all remaining permanent cheek teeth have three roots. In occlusal view, the maxillary tooththrows form a more or less rounded to slightly oval arrangement. PM3 is small, with a simple, unicuspidate occlusal surface. PM4 is molariform, only slightly smaller than M1; M2 is the largest cheek tooth. PM4 through M2 lack a paraconule, metaconule, and ectostyle; the trigon of all maxillary teeth is shallow. The lower cheek teeth lack a paraconid and ectostylid, and a trigonid is obsolete or absent.

SYNONYMS:

[*Myoxus*]: Shaw, 1801:171; part (included “*le petit guerlinguet*” of Buffon 1789); not *Myoxus* Zimmerman, 1780.

Sciurus (*Macroxus*): Liais, 1872:503; part (inclusion of *pusillus*); not *Sciurus* Linnaeus, 1758.

Sciurus (*Microsciurus*): E. W. Nelson, 1899b:32; part (inclusion of *pusillus* and *kubli*); not *Microsciurus* J. A. Allen, 1895.

Microsciurus: E.-L. Trouessart, 1904:329; part (inclusion of *pusillus* and *kubli*); not *Microsciurus* J. A. Allen, 1895.

Sciurillus Thomas, 1914f:36 [1914f:415]; type species *Sciurus pusillus* Desmarest, 1817 (= *Sciurus pusillus* É. Geoffroy St.-Hilaire, 1803), by original designation.

REMARKS: Buffon (1789:261, plates 65 and 66, respectively) recognized the existence of two “squirrel-like” animals in the Guiana region, “*le grand guerlinguet*” (= *Sciurus aestuans* Linnaeus) and “*le petit guerlinguet*” (= *Sciurillus pusillus* É. Geoffroy St.-Hilaire). Buffon used the vernacular French term “*guerlinguet*” rather than “*écureuil*” because he was not convinced that the animals were “true” squirrels.

When É. Geoffroy St.-Hilaire (1803) named “*le petit guerlinguet*” as *Sciurus pusillus*, he implicitly allied the species with other known tree squirrels. Desmarest (1817c:109) redescribed Geoffroy St.-Hilaire’s *Sciurus pusillus* and, because many subsequent authors regarded the taxa proposed by É. Geoffroy St.-Hilaire (1803) as unavailable manuscript names, much of the nineteenth- and twentieth-century literature credited *Sciurus pusillus* to Desmarest (J. A. Allen 1915a; Ellerman 1940; Cabrera 1961; R. S. Hoffmann et al. 1993). Desmarest (1822:337) even coined a new common name for the species, calling it “*l’Écureuil nain*” or “dwarf squirrel,” probably to emphasize its similarity to the European forms and to abolish the distinctiveness suggested by “*guerlinguet*.” However, some authors continued to distinguish between “*guerlinguets*” and squirrels. F. Cuvier, in a series of papers dealing with the dentition of mammals, described and figured the dentition of “*le petit guerlinguet*” (F. Cuvier 1812:277, plate 15, Fig. 1), the distinctive dental characters being the size of the cheek teeth depicted and the presence of a diminutive upper third premolar, a feature present only in *Sciurillus pusillus* and not in *Sciurus aestuans*. Indeed, F. Cuvier did not mention “*le grand guerlinguet*” in his 1812 paper, but in a later publication (F. Cuvier 1819:248), he provided brief descriptions of the “*grand*” and “*petit*” *guerlinguets*, stating that “leurs

molaires [= cheek teeth] sont tout-à-fait semblables à celles des écureuils,” thus making them essentially equal in that respect (although “*le grand guerlinguet*” [= *Sciurus aestuans*] actually has a distinctive dentition that lacks third upper premolars).

Later, when F. Cuvier published a comprehensive account of mammalian dentition (1823c:161–162), he erected the genus *Macroxus*, characterized by (among other features) the presence of two upper premolars, and he included as species “*le guerlinguet*” and “*le toupaye*” (the latter an oriental squirrel). If his diagnosis is interpreted strictly and if reference is made to his 1812 publication, “*le guerlinguet*” would mean only the “*petit guerlinguet*.” However, as he clearly considered (incorrectly) that both “*guerlinguets*” had similar dentition (F. Cuvier 1819), it can be safely assumed that by “*guerlinguet*” Cuvier meant both *pusillus* and *aestuans*. Husson (1978:382–383) recognized this possible confusion and specifically designated the specimen described and figured by Buffon (1789:261, plate 66: “*le petit guerlinguet*”) as the lectotype of *Sciurus pusillus* É. Geoffroy St.-Hilaire. Earlier, Thomas (1898g:933) had designated *Sciurus aestuans* Linnaeus, 1766 as the type species of *Macroxus* F. Cuvier, 1823, thus making this name unavailable for *Sciurillus*.

The remaining generic names associated with *Sciurillus pusillus* (É. Geoffroy St.-Hilaire) clearly belong either to other rodent groups (e.g., *Myoxus* Zimmermann, Gliridae) or to other groups of sciurids (e.g., *Sciurus* Linnaeus) and need not be discussed further here.

Sciurillus pusillus (É. Geoffroy St.-Hilaire, 1803)

Neotropical Pygmy Squirrel

SYNONYMS:

Sciurus pusillus É. Geoffroy St.-Hilaire, 1803:177; type locality “Cayenne,” French Guiana.

Sciurus guianensis Goldfuss, 1809:122; based on Buffon’s (1789:261, plate 66) “*le petit guerlinguet*.”

Sciurus olivascens Illiger, 1815:69; *nomen nudum*.

Sciurus pusillus Desmarest, 1817c:109; renaming of *Sciurus pusillus* É. Geoffroy St.-Hilaire, 1803; based on Buffon’s (1789:261, plate 66) “*le petit guerlinguet*.”

Sciurus olivascens Olfers, 1818:208; part; not *olivascens* Illiger, 1815, *fide* Hershkovitz, 1959b:345.

Macroxus pusillus: Lesson, 1842:111; name combination.

[*Funambulus Pucheranii*] *pusillus*: Fitzinger, 1867a:487; part; name combination.

Macroxus kublii Gray, 1867:433; type locality “Brazil,” restricted by Thomas (1928c) to Pebas, Loreto, Peru.

Sciurus leucotis Gray, 1867:433; unavailable name published as a junior synonym and attributed to the French naturalist François de Caumont LaPorte, Comte de Castelnau (see Hershkovitz 1959b:345).

Sciurus (Macroxus) pusillus: Liais, 1872:503; name combination.

Sciurus aestuans var. *aestuans*: J. A. Allen, 1877:756, part; not *Guerlinguetus aestuans* (Linnaeus, 1766).

Macroxus aestuans: E.-L. Trouessart, 1897:428, part (inclusion of *pusillus* and *kublii* as synonyms); not *Guerlinguetus aestuans* (Linnaeus, 1766).

Sciurus (Microsciurus) pusillus: E. W. Nelson, 1899b:32; name combination.

Sciurus (Microsciurus) kublii: E. W. Nelson, 1899b:32; name combination and incorrect subsequent spelling of *Macroxus kublii* Gray.

Microsciurus pusillus: E.-L. Trouessart, 1904:329; name combination.

Microsciurus kublii: E.-L. Trouessart, 1904:329; name combination and incorrect subsequent spelling of *Macroxus kublii* Gray.

Microsciurus kublii: J. A. Allen, 1914a:162; name combination.

[*Sciurillus pusillus*] *kublii* Thomas, 1914b:575; incorrect subsequent spelling or invalid emendation of *Macroxus kublii* Gray.

Sciurillus pusillus: Thomas, 1914b:575; first use of current name combination.

Sciurillus pusillus glaucinus Thomas, 1914b:575, type locality “Great Falls of Demerara River, British Guiana,” = Ororo Marali, Upper Demerara–Berbice, Guyana.

Sciurillus pusillus pusillus: J. A. Allen, 1915a:197; name combination.

[*Sciurillus*]. *kublii*: Thomas, 1928c:291; name combination.

Sciurus pusillus Olalla, 1935:426; incorrect subsequent spelling of *Sciurus pusillus* É. Geoffroy St.-Hilaire.

Sciurillus pusillus kublii: Cabrera and Yepes, 1940:192; name combination.

Sciurillus pusillus hoehnei Miranda-Ribeiro, 1941:10; type locality “Rio Teles Pires (São Manoel), northern Mato Grosso,” Brazil (page number incorrectly given as 139 by Hershkovitz 1959b:346).

Sciurus aestuans: Rode, 1943:385; part; not *Sciurus aestuans* Linnaeus.

Microsciurus pusillus hoehnei: C. O. da C. Vieira, 1955:410; name combination.

Sciurillus guajanensis: Hershkovitz, 1959b:345; not *guajanensis* of Gmelin, 1788, nor *guajanensis* of Kerr, 1792.

Sciurillus pusillus Moore, 1959:204; incorrect subsequent spelling of *Sciurus pusillus* É. Geoffroy St.-Hilaire.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Sciurillus pusillus* is known from scattered localities in Guyana, Surinam, French Guiana, Amazonian Brazil in Amapá, Amazonas, Pará, and Mato Grosso states, and northeastern Amazonian Peru. Cuervo Díaz et al. (1986) and Rodríguez-Mahecha et al. (1995)

listed this species in their faunal compilations of Colombia but without locality or voucher specimen citations; Alberico et al. (2000) listed *S. pusillus* from the department of Caquetá in southeastern Colombia without providing an exact locality but referring to specimens in the IAvH and ICN in Bogotá. Jessen, Gwinn, and Koprowski (2013) included southeastern Colombia and Venezuela south of the Río Orinoco in the mapped range, without either literature or specimen documentation. The species has not been recorded from the fauna of either Ecuador (Tirira 2007) or Venezuela (O. J. Linares 1998).

SELECTED LOCALITIES (Map 2): BRAZIL: Amapá, Amapá (MPEG 1541), Oiapoque, upper Rio Oiapoque (MZUSP 20353); Amazonas, Andira, near Villa Bella da Imperatriz (AMNH 93154), Estirão do Equador, Rio Javari (MPEG 1557); Mato Grosso, São Manoel, Rio Teles Pires (type locality of *Sciurillus pusillus hoehnei* Miranda-Ribeiro); Pará, Boim, Rio Tapajós (MCZ 30216), Igarapé Amorim (AMNH 95727), Igarapé Brabo (= Bravo), left bank Rio Tapajós (AMNH 94743). FRENCH GUIANA: Cayenne (type locality of *Sciurus pusillus* É. Geoffroy St.-Hilaire), Inini, Arataye River (USNM 548447), Paracou (Voss et al. 2001), Tamanoir, Mana River (FMNH 21788). GUYANA: Upper Demerara–Berbice, Great Falls of Demerara River (type locality of *Sciurillus pusillus glaucinus* Thomas). PERU: Loreto, Estación Biológica Quebrada Blanco (Heymann and Knogge 1997), Pebas (BM 28.7.21.79), Quebrada Orán (M. S. Hafner et al. 1994), Santa Cecilia, Río Maniti (FMNH 87182), Sarayacu, Río Ucayali (AMNH 76185). SURINAM: Sipaliwini, Emmaketen [= Emma Ketten] (Husson 1978), Frederik Willem IV Falls, Corentyne River (FMNH 48419).

SUBSPECIES: Two (J. A. Allen 1915a) or three (Anthony and Tate 1935; Cabrera 1961; Thorington and Hoffman 2005) subspecies have generally been recognized. These include the nominotypical form (the Guianas and northeastern Brazil), *glaucus* Thomas (the Amazon Basin of central Brazil and interior Guyana), and *kublii* Gray (northeastern Peru and probably western Brazil and southwestern Colombia).

Anthony and Tate (1935), who studied specimens from French Guiana, Peru, and the region of the Rio Tapajós, Brazil, believed that three subspecies could be distinguished on the basis of color, having found no significant differences in cranial measurements, specifically: *S. p. pusillus*—ears black; head decidedly reddish when compared with the grayish dorsum; *S. p. glaucinus*—ears the same color as the head, which was not very distinct in color from the rest of the grayish dorsum; and *S. p. kublii*—like *glaucus* but more “saturated,” with “belly even more cinnamon” (p. 8) than in *pusillus* and with a darker back. However, our microscopic examination of the pinnae revealed

that the epithelium is pigmented (thus appearing black on dried skins) in specimens from the entire range of the genus. Moreover, the color of the head is variable in the series from the Rio Tapajós, as is the intensity of the orange mixed with gray in the belly. The number of specimens we have examined from Peru, the putative region of occurrence of *kublii*, is small, but a good series from Estirão do Equador, Rio Javari, Amazonas, which is geographically close to the Peruvian localities, cannot be distinguished from the larger series from the Rio Tapajós, and which has been ascribed to *glaucinus*. We have not seen the holotype of *Sciurillus pusillus hoehnei* from northern Mato Grosso, but nothing in the description supports it as a plausible valid taxon.

Mercer and Roth (2003) reported substantial sequence divergence in both mitochondrial and nuclear genes between two specimens from opposite ends of the geographic range of this species (USNM 578014 from French Guiana, and LSUMZ 27994 from Loreto department, Peru), positing a late Miocene divergence between these samples. Despite the extensive level of divergence and apparent deep age of the species, we are unable to find significant, geographically partitioned variation among the few samples available from this very large area; we provisionally regard *Sciurillus pusillus* as a monotypic species.

NATURAL HISTORY: Jessen, Gwinn, and Koprowski (2013) synthesized the few data available on ecology, behavior, and life history. Emmons and Feer (1990, 1997), Ball and Roth (1995), Roth (1996), Heymann and Knogge (1997), Voss et al. (2001:76), and Youlatos (2011) detailed observations of solitary individuals in trees in well-drained primary forest, primarily in *Inga* (French Guiana) and *Parkia* (Peru), both in the subfamily Mimosoideae. In both geographic areas, animals were observed gnawing on the bark, probably feeding either on cambium or on exudates (sap or gum), incising pieces of the upper bark layer, and leaving the trunk densely pockmarked. Heymann and Knogge (1997) recorded large amounts of bark chips that accumulated on the ground under one such tree. Emmons and Feer (1990:176) noted that individuals forage on trunks from near the ground to high in the canopy, “hopping and flitting from branch to branch,” and traveling from tree to tree high in the canopy.

Their small size makes individuals difficult to spot, but they are not wary of humans and can be easily observed. Youlatos (2011) observed five individuals using wide vertical substrates in the canopy, with locomotion primarily by claw climbing. Velhagen and Roth (1997) suggested that a decrease in bite force with decreasing size might account for a shift in diet of the pygmy squirrels, including *Sciurillus*, from hard fruits and nuts to gleaning bark. Because most sightings were of solitary individuals, Heymann and

Knogge (1997) also suggested that a solitary lifestyle was the dominant mode of sociospatial organization. Peres et al. (2003) reported four sightings, each averaging 1.5 individuals, in the headwaters of the Rio Arapiuns, Pará state, Brazil, and estimated their density at 0.023 individuals/ha. Dalecky et al. (2002) stated that home range size in French Guiana was small, which facilitated individual persistence in habitat islands created by flooding. Olalla (1935), Heymann and Knogge (1997), and Voss et al. (2001) observed this species only in noninundated or *terra firme* forest, and Olalla (1935) reported a litter size of two.

REMARKS: Due to the scarcity of specimens of *S. pusillus* from the time of its discovery in the late eighteenth century until the 1930s, the taxonomic history of this taxon has presented certain persistent problems. Most of the trouble relates to confusion between *Sciurillus pusillus* (or some junior synonym) and several other South American squirrels, usually *Sciurus aestuans* Linnaeus (herein *Guerlinguetus aestuans*). Because both of these species were first known from Guianan specimens, their respective taxonomic histories are entangled. We comment on all names, available or not, that have been associated with *Sciurillus pusillus*; however, new combinations and changes in specific versus subspecific status are not discussed because they can be easily followed in the synonymy provided earlier.

Sciurillus pusillus was the second squirrel to be known from the Guianan region, the first being *Sciurus aestuans*, described by Linnaeus in 1766. Ten years later, Buffon (1776:146–147) published his first report on a Guianan squirrel. The essential parts of Buffon’s report are translated as: “M. de la Borde, Physician of the King in Cayenne, said that there is *only one species* of squirrel in the Guyanne, that it lives in the forests, that *its fur is reddish*, that *it is not larger than the European rat* . . . I am not quite certain that this animal from the Guyanne, of which M. de la Borde *speaks*, is a true squirrel, because the latter are hardly found in excessively hot climates, such as that of the Guyanne” (emphases ours). This is a very uninformative account, but it is clear that Buffon did not have specimens to describe in 1776, only an oral or written account by de la Borde. It is also clear that Buffon believed that there was a single species of “squirrel-like” mammal in the Guiana region, and that it was not larger than the European *Rattus*. Such reference to size is vague, but it can be interpreted to mean an animal about the size of a Norway or black rat; because *Sciurillus* is so much smaller, we believe this feature would not go unnoticed even by an amateur such as de la Borde. Also, *Sciurillus pusillus* can hardly be described as having “reddish” fur, a character that could roughly be applied to *Sciurus aestuans*. Therefore, it is plausible that the animal reported by de la Borde

was *Sciurus aestuans*, by far the most common species found in the Guianas.

Later, Buffon (1789) was finally provided with specimens from French Guiana, which had been collected by M. Sonini de Manoncourt, and he was able to give firsthand information on the entire squirrel fauna of the region. The essential aspects of this later contribution are, first, that Buffon (1789:261–264, plates 45 and 46) believed the animals were not real squirrels (e.g., the European “écureuil” or *Sciurus vulgaris*), confirming his earlier prediction, and he called them “guerlinguets”; and, second, that he considered them two species, “le grand” and “le petit guerlinguet.” He then proceeded to reinterpret his own 1776 account of one species to accommodate the two he now had in front of him. Thus, the “petit guerlinguet” became the species “not larger than a rat,” and the “grand” one was compared in size to *Sciurus vulgaris*. Obviously, anything the size of *Sciurillus* is “not larger than a rat,” but then neither are its fleas. Buffon’s awkward adaptation of his earlier, vague size reference to the actual specimens collected by Sonini de Manoncourt allowed for some misinterpretation, mainly because other naturalists were also busy reporting and cataloging the Guianan sciurid fauna. It is now important to devote attention to a number of publications dealing with Guianan squirrels, which appeared before É. Geoffroy St.-Hilaire (1803) coined the name *Sciurus pusillus* for the “petit guerlinguet” of Buffon, because Hershkovitz (1959b) considered some of these names to have priority over *pusillus*.

The first of these is *Sciurus gujanensis*, coined by Gmelin (1788:152) for two squirrels from different reports concerning the Guianan region. One of these reports is that by de la Borde, which we discussed earlier and associated with *Sciurus aestuans* Linnaeus. The other report commented on by Gmelin was Bancroft’s (1769:143), taken from his account of the natural history of Guiana, where he states that the animal was close to the common English squirrel in size and morphology, and that it had a pale yellowish brown dorsum, white under parts, small white streaks on the sides of the body, and a tail similar in color to the dorsum but “variegated” with white and black. The presence of lateral white streaks does not fit with the color pattern of any known South American squirrel, and *Sciurus aestuans* does not have white under parts. Whichever squirrel Bancroft had in mind, however, both his description of the color pattern and size completely eliminate the possibility that his animal was *Sciurillus pusillus*.

Hershkovitz (1959b:345) ignored Gmelin’s name and its complete lack of correspondence with *Sciurillus pusillus*. He proposed that the valid name for the dwarf squirrel should be *Sciurillus guajanensis* (Kerr) and then organized a synonymy with that in mind. However, Kerr (1792:265)

both acknowledged that his usage derived from Gmelin and decided to keep the name *Sciurus guajanensis* (his different spelling of the name either is an unjustified emendation or a *lapsus calami*) for de la Borde’s animal, while creating the new name *Sciurus bancrofti* for the other “species.” As documented earlier, these two names have nothing to do with *Sciurillus pusillus* and do not belong in its synonymy. Hershkovitz (1959b:345) also stated that Turton (1802:94) employed the name *Sciurus guajanensis* based on the “petit guerlinguet” of Buffon. There is, however, no mention in Turton’s work of the French naturalist or of the “petit guerlinguet.” Indeed, Turton’s *General System* is only an updating of Kerr’s, which is entirely referable to Gmelin (1788).

Finally, Hershkovitz (1959b:345) cited yet another author (Goldfuss 1809:122) who used the name *Sciurus guianensis* for the “petit guerlinguet,” a publication that can be viewed in the same perspective as those by Kerr and Turton. However, as neither of us has personally seen the work by Goldfuss, we herein treat his *Sciurus guianensis* as a possible synonym of *Sciurillus pusillus*.

The first scientific name unequivocally associated with “le petit guerlinguet” is *Myoxus guerlingus* Var. (?), coined by Shaw (1801:171), which actually encompasses both Guianan squirrels, *Sciurus aestuans* Linnaeus and *Sciurillus pusillus* Thomas. Because we fix the type specimen of *Myoxus guerlingus* as the same as that of *Sciurus aestuans* (*guerlingus* had no type, being a name for both of Buffon’s guerlinguets; see the account for *Guerlinguetus aestuans*), Shaw’s name cannot be employed as the valid one for “le petit guerlinguet” and is not listed in the synonymy of *S. pusillus* as a result.

É. Geoffroy St.-Hilaire (1803:177) created the name *Sciurus pusillus* exclusively for “le petit guerlinguet,” making it the valid one for the species. He stated, however, that de la Borde had collected the specimen he studied. This made Husson (1978:382) question whether Geoffroy St.-Hilaire’s specimen was the same as that seen by Buffon, who obtained his material from Sonini de Manoncourt. The holotype of *Sciurus pusillus* É. Geoffroy St.-Hilaire in the Paris museum (MNHN 312, a mounted skin), however, has an old label bearing de la Borde’s name attached to its support. In our opinion, this is probably the same specimen seen by Buffon (1789), and de la Borde’s name is on the label because Buffon believed it represented the “guerlinguet” he reported. Husson (1978:382) never questioned that the holotype is really what is currently called *Sciurillus pusillus*, in spite of its somewhat deteriorated condition, but he felt the need to select a lectotype, which he indicated (1978:383) to be the same specimen described and figured by Buffon in 1789 (p. 261, plate 46). Husson’s act, however, was unnecessary, as the specimen (MNHN 312)

is the holotype of *Sciurus pusillus* É. Geoffroy St.-Hilaire, as the name is applied today, and is characterized by the small and rounded pinnae and the small size of the feet. It is not the young of a *Sciurus aestuans* as proposed by Rode (1943:385).

Another early name resurrected by Hershkovitz (1959b:345) was *Sciurus olivascens*, placed in the synonymy of *Sciurillus guajanensis* (Kerr) [= *Sciurillus pusillus*], which he attributed to Olfers, 1818. According to Hershkovitz (1959b:345), Olfers erected the name after a manuscript usage by Illiger, purportedly based on “*le petit Guerlinguet*” of Buffon, but of this Olfers himself was not completely sure because he added a question mark after the French vulgar name. Illiger (1815:69) published the name *Sciurus olivascens* in a list of mammals from South America without diagnosis or description, and he made no subsequent reference to this name in his brief discussion of South American squirrels (pp. 74–75). It thus seems clear that *olivascens* is unavailable from Illiger (1815) in the meaning of the International Code of Zoological Nomenclature (ICZN 1999). The same name was again mentioned in yet another list of South American mammals (Minding 1829:89), also unavailable for the same reasons. Given that Olfers (1818:208) only questionably associated “*Sc. olivascens* Ill.” to Buffon’s “*le petit guerlinguet*,” and that both Illiger’s (1815) original usage of this name and the subsequent usage by Minding (1829) are *nomina nuda*, it seems to us that the name continues to be unavailable. But even if Olfers’s usage were judged available, *olivascens* would remain a junior synonym of *Sciurus pusillus*, being antedated by E. Geoffroy St.-Hilaire’s name by 15 years.

For some decades, no new specimens other than the one(s) in the Paris museum were reported until Gray (1867:433) listed and described *Macroxus pusillus* and *Macroxus kublii*, the latter a new species said to have been collected by Castelnau in “Brazil.” The name *Sciurus leucotis* was also given by Gray (1867:433) in the synonymy of *kublii* and attributed to Castelnau (manuscript); *leucotis*, having never been employed as valid, is not available under the International Code of Zoological Nomenclature (ICZN 1999). Gray’s (1867:433) descriptions are not good, but one of us (MdV) has seen the holotype of *Macroxus kublii* (BM 51.7.3.7, skin and skull); the skin is in bad shape, with extensive loss of hair in the region immediately posterior to the crown, legs, tail, throat, and chest, and with small losses in other scattered areas. Nevertheless, what is left of the animal is very similar to the specimen from Cayenne (BM 45.5.1.3) that probably served as basis for Gray’s account of *Macroxus pusillus*. Thomas (1920f:276) assigned two specimens from Villa Braga on the Rio Tapajós, Pará, Brazil, to *S. pusillus* but noted that these were “quite like” the type of *Macroxus kublii* and suggested that the latter likely

came from the same region in Brazil. He later restricted the type locality of *kublii* Gray to Pebas, Loreto, Peru (Thomas 1928c:291). Because we consider *Sciurillus pusillus* to be a monotypic species, the matter of the correct type locality of *Macroxus kublii*, a junior synonym, is not critical. However, because *kublii* has been considered by Anthony and Tate (1935) to be a valid subspecies (and may even be a species separate from *pusillus*, as suggested by the deep molecular divergence of western and eastern Amazonian samples; Mercer and Ross 2003), validation of Thomas’s restriction of the type locality to Peru is warranted.

J. A. Allen (1877:756–757), without examining specimens of the dwarf squirrel, placed both *pusillus* and *kublii* as junior synonyms of his excessively broad *Sciurus aestuans* var. *aestuans*, believing they could be young specimens of the larger animal. Alston (1878:670) immediately corrected Allen, considering *Sciurus pusillus* a valid species with *Macroxus kublii* as a junior synonym. Most subsequent authors were convinced of the validity of *pusillus* but placed the species in the genus or subgenus *Microsciurus* (e.g., E. W. Nelson 1899b; E.-L. Trouessart 1904; J. A. Allen 1914a). Any remaining doubts regarding the distinctiveness of *pusillus* were finally dispelled when Thomas (1914b,f) erected the genus *Sciurillus*, completely divorcing it from the larger squirrels of the genus *Microsciurus*.

Thomas (1914b:575) described *Sciurillus pusillus glaucinus* from Guyana (former British Guiana), thus adding a third species group taxon to the picture. Anthony and Tate’s (1935) review of *Sciurillus* took advantage of the first relatively large series of specimens available at any museum; they recognized three subspecies, namely, *Sciurillus p. pusillus*, *S. p. glaucinus*, and *S. p. kublii*. They restricted the

Map 2 Selected localities for *Sciurillus pusillus* (●). Contour line = 2,000 m.

nominotypical subspecies to French Guiana, *glaucinus* to British Guiana (= Guyana) south to the lower Rio Tapajós, Pará, Brazil, and *kublii* to northeastern Amazonian Peru. Another subspecies, *Sciurillus pusillus hoehnei*, was posthumously published by Miranda-Ribeiro (1941), from northern Mato Grosso, Brazil. For reasons discussed earlier, we consider *Sciurillus pusillus* to be a monotypic species, with *kublii*, *glaucinus*, and *hoehnei* as junior synonyms.

Subfamily Sciurinae G. Fischer, 1817

Species in the subfamily Sciurinae are the “typical” tree squirrels, with members distributed on all continents save Antarctica and Australia. South American representatives include taxa allocated by Moore (1959) to his subtribes Sciurina and Microsciurina. Both groups are now collectively placed in the Sciurinae (Thorington and Hoffmann 2005). Species in some genera (e.g., *Hadroskiurus*, *Microsciurus*, *Notoskiurus*) are characterized by an ear patch colored differently than the top of the head, neck, and shoulders; typically, this patch is continuous from the distal part of the medial surface of the pinna to just behind the ear (herein referred to as a postauricular patch). In a few cases, the colored hairs of the patch protrude above the rim of the ear. In species of *Simoskiurus*, some hairs may extend from the dorsal edge of the pinnae, but none of these resemble a tuft, such as that characterizing the European *Sciurus vulgaris* (see Thorington et al. 2012).

Phylogenetic relationships among the genera and species we recognize are very incompletely known, as few of these taxa have been included in any of the surprisingly small number of molecular phylogenetic studies to date. The most comprehensive analysis of sciurid phylogeny (Mercer and Roth 2003) included only three South American taxa of “*Sciurus*” and *Microsciurus*. Assuming an entry into South America at or subsequent to the closure of the Panamanian seaway some 3–4 mya, the net rate of diversification of tree squirrels was exceedingly rapid, more than twice that for any other continental assemblage (Roth and Mercer 2008).

KEY TO THE GENERA OF SOUTH AMERICAN SCIURINAE:

- 1. Mean head and body length of adults <160 mm; orbito-temporal fossa of skull, in dorsal view, unevenly divided by the postorbital process of the frontals, resulting in nearly obliterated temporal fossa; generally with two upper premolars, the anteriormost very small. *Microsciurus*
- 1'. Mean head and body length of adults >160 mm; orbito-temporal fossa of skull, in dorsal view, evenly divided by the postorbital process of the frontals, resulting in

- nearly equal-sized orbital and temporal fossa; always with only one upper premolar 2
- 2. Mean head and body length of adults between 160 and 180 mm; ears small and rounded *Syntheosciurus*
- 2'. Mean head and body length of adults >160 mm; ears relatively large and pointed. 3
- 3. Adult females with three pairs of mammae; distinctive postauricular patch of different color than that of top of head usually present *Notoskiurus*
- 3'. Adult females with four pair of mammae; postauricular patch may or may not be present 4
- 4. Pelage coarse; distribution west of the Andes in Ecuador and Peru; pinnae hirsute, with somewhat long hairs, but not quite forming a tuft *Simoskiurus*
- 4'. Pelage normal to soft; distribution east of the Andes; pinnae hirsute, covered with very short hairs 5
- 5. Size medium, mean head and body length between 175 and 180 mm *Guerlinguetus*
- 5'. Size large, mean head and body length >215 mm *Hadroskiurus*

Genus *Guerlinguetus* Gray, 1821

Guerlinguetus is a tropical tree squirrel genus occurring from eastern Colombia, Venezuela, and the Guianas, south throughout the lowland Amazonian rainforest, then through the Atlantic Forest of eastern and southern Brazil to northeastern Argentina. It is not known to occur in neighboring Paraguay and Bolivia, where the genus is replaced by the morphologically very similar *Notoskiurus*. Although widespread in Amazonian Brazil, *Guerlinguetus* is not known from south of the Rio Solimões, between the Rio Javari and Rio Madeira. It is absent from all but the broad gallery forests at the periphery of the Cerrado biome in central Brazil and mesic forest enclaves in the Caatinga of eastern Brazil (Carmignotto et al. 2012). Species of *Guerlinguetus*, as is true of all other South American squirrels, are exclusive forest dwellers. The genus is mostly parapatric with *Notoskiurus*, except in the general region of the Río Marañón in Peru.

Guerlinguetus is easily distinguished from other South American squirrels by its size (larger than *Microsciurus*, *Sciurillus*, and *Syntheosciurus*, but smaller than *Hadroskiurus* and *Simoskiurus*). In comparison with *Notoskiurus*, which has an approximately similar size range, *Guerlinguetus* is unique in the possession of four pairs of mammae instead of three and typically by the absence of a differentially colored postauricular patch. Cranially, the genus can be distinguished by an orbitotemporal fossa that is equally divided by a well-developed postorbital process and an upper second molar with two parallel, buccolingual crests perpendicular to the anteroposterior axis of the skull.

We recognize only two species in *Guerlinguetus*: *G. aestuans*, a Guianan and Amazonian species, and *G. brasiliensis*, from eastern Amazonia to eastern and southern Brazil and northern Argentina. Although there are more publications on aspects of the natural history of these species than for any other South American squirrels, details of ecology, behavior, and other aspects of population biology remain unknown. *Guerlinguetus* appears to rely heavily on small palm fruits, using several palm genera through its distribution. Several regional Brazilian vernacular names are used for these squirrels, without distinction as to species, including *esquilo*, *serelepe*, *caxinguelê*, and *quatipuru*, the last used exclusively in the Brazilian Amazon. In Argentina, where only *G. brasiliensis* occurs, the local name is *ardilla gris* or *ardilla misionera*.

SYNONYMS:

Sciurus: Brisson, 1762:107; part (inclusion of *brasiliensis*); not *Sciurus* Linnaeus, 1758; rejected for nomenclatural purposes (ICZN 1998:Opinion 1894).

Myoxus: Shaw, 1801:171; part (included “*le grand guerlinguet*” of Buffon as species); not *Myoxus* Zimmermann, 1780.

Guerlinguetus Gray, 1821:304; type species *Sciurus guerlinguetus*, by tautonomy (“*le grand guerlinguet*” of Buffon, 1789=*Myoxus Guerlingus* Shaw, 1801=*Sciurus guerlinguetus* Gray, 1821=*Sciurus aestuans* Linnaeus, 1766. Gray [1821] writes “*Gerlinguet, Guerlinguetus, sciurus guerlinguetus*. Lin.”).

Macroxus F. Cuvier, 1823c:161; type species *Sciurus aestuans* Linnaeus designated by Thomas (1898g:933).

[*Funambulus*]: Fitzinger, 1867a:486; part (listing of *aestuans*); not *Funambulus* Lesson, 1835.

[*Sciurus*] (*Guerlinguetus*): Ellerman, 1940:322, 340; as subgenus.

REMARKS: The first available generic name for this group of medium-sized South American squirrels is *Guerlinguetus* Gray, 1821, with type species *Sciurus guerlinguetus*. Gray attributed *S. guerlinguetus* to Linnaeus, a name that is actually a *nomen nudum* because Gray’s usage was not followed by any description or plate. However, Gray’s generic name *Guerlinguetus* is clearly identifiable to the French vernacular “*guerlinguet*,” which Buffon (1789:261, plates 65, 66) used for the squirrels of the Guianas, for which he recognized two varieties, a larger “*le grand guerlinguet*” [= *Guerlinguetus aestuans* (Linnaeus)], and a smaller “*le petit guerlinguet*” [= *Sciurillus pusillus* (E. Geoffroy St. Hilaire)]. Since Gray (1821), the name *Guerlinguetus* has been either ignored or variously employed for a full genus or subgenus, but at either categorical level it broadly encompassed most medium-sized South American squirrels, some now placed in other genera. J. A. Allen (1915a) was the first to restrict the con-

cept of *Guerlinguetus*, a view that is very close to ours herein.

KEY TO THE SPECIES OF *GUERLINGUETUS*:

1. Ventral coloration orange, or, if mostly orange, only the throat has white or grayish-white hairs; tail color lined with orange *Guerlinguetus aestuans*
- 1'. Ventral coloration heavily grizzled with white or grayish-white, either along the entire venter or else only in throat, chest, and inguinal areas; tail color either lined with orange or grayish white *Guerlinguetus brasiliensis*

Guerlinguetus aestuans (Linnaeus, 1766)

Guianan Squirrel, Quatipuru

- Sciurus [(Guerlinguetus)] aestuans poaiae*: Cabrera, 1961:361; name combination.
- Sciurus [(Guerlinguetus)] aestuans quelchii*: Cabrera, 1961:361; name combination.
- Sciurus (Guerlinguetus) aestuans georgibernandezi* Barriga-Bonilla, 1966:492; type locality “Margen derecha del río Vaupés, cerca de Mitú, Vaupés, Colombia, altura 240 m.s.n.m.”
- Sciurus (Guerlinguetus) aestuans*: Eisenberg, 1989:331; name combination.
- Sciurus (Guerlinguetus) gilvicularis*: Eisenberg, 1989:331; name combination.

DESCRIPTION: Adult body weight averages 174 g (N=28), head and body length 176 mm (N=235), tail length 177 mm (N=205), hindfoot length 47 mm (N=245), and ear length 22 mm (N=83). Dorsal color uniformly brown to olive brown, heavily streaked with orange throughout, including the upper parts of the legs; ventral color highly variable, with throat orange to grayish white and remaining parts orange, sometimes with dark gray hairs interspersed; inner parts of forelimbs colored similarly to chest and belly; inner parts of hindlimbs darker than belly; area immediately circumscribing mammae not distinct from remainder of venter, and tail color indistinct from dorsum. Postauricular patches absent, except for some specimens from Guianan highlands.

DISTRIBUTION: *Guerlinguetus aestuans* occurs throughout Amazonia, in northeastern Peru, eastern Colombia, Venezuela south of the Río Orinoco, and Brazil north of the Rio Amazonas and west of the Rio Xingu, and throughout the Guianan region.

SELECTED LOCALITIES (Map 3): BRAZIL: Amapá, Cachoeira de Santo Antônio, Rio Jari (MPEG 21804), Mazagão, Rio Vila Nova (MPEG 438), Vila Velha do Cassiporé, Oiapoque (MPEG 6742); Amazonas, Igarapé Auará, Rio Madeira (AMNH 91831), Santo Isidoro, Tefé (AMNH 78949); Mato Grosso, Cachoeira Dardanelos, right bank Rio Aripuanã (MPEG 8786), Estação Ecológica Serra das Araras (MPEG 15272); Pará, Aramapucu, Rio Parú do Oeste (MPEG 10019), Cussary (AMNH 37453), Foz do Rio Curuá, right bank Rio Amazonas (MZUSP 4601), Rio Jamanxim, right bank Rio Tapajós (MPEG 453); Rondônia, Cachoeira Nazaré, left bank Rio Ji-Paraná (MPEG 20825), Ouro Preto d'Oeste (MPEG 20529). COLOMBIA: Vaupés, La Providencia, Río Apaporis (Barriga-Bonilla 1966), right bank Río Vaupés, near Mitú (Barriga-Bonilla 1966). FRENCH GUIANA: River Iracoubo (MNHN 1983/350), River Oyapock (MNHN 1983/346). GUYANA: Essequibo Islands–West Demerara, Supinaam River (BM 10.5.4.12); Upper Takutu–Upper Essequibo, Kanuku Mountains

(type locality of *Sciurus Quelchii* Thomas). PERU: Loreto, Orosa, Río Amazonas (AMNH 73917), Sarayacu, Río Ucayali (AMNH 75277). SURINAM: Para, Zanderij (BM 52.1102). VENEZUELA: Amazonas, Monduapo, right bank upper Río Orinoco (BM 99.9.11.29–30); Bolívar, Ciudad Bolívar, Suapure, Río Caura valley (AMNH 16128), El Yagual, lower Río Caura (AMNH 16948).

SUBSPECIES: We recognize two subspecies, namely, *G. a. aestuans* (Linnaeus, 1766) and *G. a. gilvicularis* (Wagner, 1845). Distributions and coat color variation of each are discussed in the Remarks section.

NATURAL HISTORY: There are very few published field observations of the ecology or behavior of this species in the wild. It ranges throughout lowland rainforest and, marginally, into the dry forests of Mato Grosso state, Brazil. In French Guiana, and likely throughout this broad range, seed-caching behavior plays an important role in the demography of understory palms such as *Astrocaryum sciophilum* (see Sist 1989) and other large-seeded plants such as *Carapa procera* (Forget 1996). Forget (1991) reported that this species did not forage at ground level even when seeds were available. In French Guiana, this squirrel may persist on small and medium-sized islands produced by flooding after dam construction, which suggests that their home range size is relatively small (Dalecky et al. 2002). Peres et al. (2003), from a site in the headwaters of the Río Arapiuns, Pará state, Brazil, estimated density of 0.444 individuals/ha, with sightings of seven solitary individuals. Voss et al. (2001) observed animals perched in trees at heights of 3–30m above the ground, with most individuals solitary. Individuals these authors captured came primarily from primary forest at both well-drained and swampy sites as well as from somewhat disturbed habitats.

REMARKS: Use of the name *Sciurus aestuans* Linnaeus by almost all authors from the late eighteenth and early nineteenth centuries (e.g., Gmelin 1788:151; Turton 1802:93; Illiger 1815:75; Thunberg 1823:2; Minding 1829:29; Schinz 1840:144; P. Gervais 1841:37, 1854:308; Gray 1843b, 1867; Chenu 1850:34) to the present (e.g., Emmons and Feer 1997; Eisenberg and Redford 1999; Thorington and Hoffmann 2005) includes both *G. aestuans*, as we restrict this species herein, and *G. brasiliensis* (next section) or even species we allocate to *Notosciurus* (e.g., Alston 1878:668).

Geographic variation of coat color across the distribution of *G. aestuans* has led authors to name distinct taxa based on slight variations, all of which names we regard either as applying to subspecies or as synonyms. Here, we summarize the geographic variation of characters to justify our recognition of a single species. There

are no qualitative cranial distinctions along the entire distribution; in fact, the species is cranially indistinct from *G. brasiliensis*.

We recognize two subspecies. The nominotypical form occurs in the Guianas, adjacent Venezuela, Amazonian Brazil, in the states of Roraima, Amazonas (to the north of the Río Solimões–Amazonas axis), Amapá, Pará (except on the south bank of the Río Amazonas, to the east of the Río Xingu, where the other species of *Guerlinguetus* occurs), in northern Peru from scattered localities along the Río Marañón, and in Colombia near its border with Brazil. By contrast, *G. a. gilvicularis* (Wagner, 1845) occurs in Brazil, in the Río Tapajós and Río Madeira basins, and from there southward to the states of Rondônia and western Mato Grosso. These two taxa can be distinguished by the color of their ventral surfaces, *aestuans* with a grayish white throat but orange or yellowish chest and belly, and *gilvicularis* with an entirely orange or yellowish venter. Specimens from the Río Negro region in Amazonas, Brazil, exhibit a ventral color pattern characteristic of both subspecies, suggesting that this area is a zone of intergradation between *aestuans* and *gilvicularis*. Dorsally, all animals are very similarly colored.

One important aspect of morphological variation in the distribution of *G. a. aestuans* is that some animals collected in the highlands of the Guianas and Venezuela possess postauricular patches whereas in the adjacent lowlands such patches are either inconspicuous or absent altogether. The presence of a patch is associated with the names *guianensis* Peters, 1864, and *macconnelli* Thomas, 1901, both of which we regard as synonyms to *Guerlinguetus aestuans aestuans* (Linnaeus, 1766).

DESCRIPTION: Adult mass averages 193 g (N=33), head and body length 180 mm (N=175), tail length 183 mm (N=171), foot length 46 mm (N=177), and ear length 22 mm (N=143). Dorsal color uniform brown to olive brown, heavily streaked with orange throughout body, including upper parts of forelegs and hindlegs; ventral color

highly variable, with throat always white to grayish white, with white hairs sometimes extending to chest and/or belly and/or inner sides of arms and legs; area immediately around mammae lighter than rest of venter; and dorsal color of tail either indistinct from dorsum or, if distinct, grizzled with whitish bands on hairs. Postauricular patches absent.

DISTRIBUTION: This species is distributed in Amazonian Brazil east of the Iriri and Xingu rivers and south of the lower Amazon in Pará, Maranhão, Tocantins, and Mato Grosso states, and extends throughout northeastern and southwestern Brazil from the states of Ceará to Rio Grande do Sul and from there to Misiones in Argentina. The species appears to occupy two disjunct areas, one corresponding to the Amazonian subspecies *G. b. paraensis* and the other to the two subspecies *G. b. brasiliensis* and *G. b. ingrami*, which occur continuously from northeastern to southern Brazil and Argentina.

SELECTED LOCALITIES (Map 4): ARGENTINA: Misiones, Eldorado (BM 26.2.11.1), Santa Ana (FMNH 49885). **BRAZIL:** Alagoas, Usina Sinimbu, Mangabeiras (Manimbu) (MZUSP 7532); Bahia, Ilhéus (MZUSP 3501), Macaco Seco, Monte Andaraí, Rio Paraguaçu (FMNH 20424), Senhor do Bonfim [= Villa Nova] (MZUSP 2608); Ceará, Serra do Castelo (BM 20.7.1.7); Espírito Santo, Colatina, right bank Rio Doce (type locality of *Guerlinguetus aestuans garbei* O. M. O. Pinto), Rio Itaúnas (MZUSP 7071), Rive [= Engenheiro Reeve] (BM 3.9.4.44); Maranhão, Aldeia Gurupiúna, Reserva Indígena Alto Turiaçú (MPEG 21981), Estreito, right bank Rio Tocantins (MPEG 2444), São Bento (BM 25.5.21.6); Mato Grosso, Serra do Roncador, 264 km N of Xavantina (BM 79.203–207); Minas Gerais, Rio das Velhas, near Lagoa Santa (FMNH 20733); Pará, Belém (MPEG 710), Gradaús, right bank Rio Fresco (MZUSP 20399), mouth of Rio Bacajá, right bank Rio Xingú (MZUSP 25455), Portel, Rio Procupi (MPEG 606), Rio Riosinho, left bank Rio Fresco (MPEG 1039), Santa Júlia, Rio Iriri (BM 20.7.1.6), Urumajó, Arabóia, east of Bragança, Estrada de Ferro de Bragança (MZUSP 20398); Paraíba, Mamanguape, Camaratuba (MZUSP 8241); Pernambuco, São Lourenço (type locality of *Sciurus Roberti* Thomas); Rio de Janeiro, Sepetiba (NMW B1393), Terezópolis (NMW 1693); Rio Grande do Sul, Colônia do Mundo Novo (Ihering 1892:107); Santa Catarina, Joinville (BM 13.7.8.1); São Paulo, Ilha de São Sebastião (type locality of *Sciurus ingrami sebastiani* P. Müller and Vesmanis), Ilha do Cardoso (MZUSP 3905), Porto Cabral, Rio Paraná (MZUSP 6021), Presidente Epitácio, left bank Rio Paraná (MZUSP 3733), Santos (MZUSP 3699), Serra da Juréia (MZUSP 12835).

SUBSPECIES: *Guerlinguetus brasiliensis* is polytypic: *G. b. brasiliensis* (Gmelin) occurs in northeastern Brazil, in the states of Ceará, Rio Grande do Norte, Paraíba, Per-

nambuco, Alagoas, Sergipe, and Bahia; *G. b. paraensis* (Goeldi and Hagmann) is distributed in eastern Brazilian Amazonia, in the states of Pará, the south of the Rio Amazonas from the Rio Xingu basin eastward to eastern Maranhão, Tocantins, and eastern Mato Grosso states; and *G. b. ingrami* (Thomas), which is found in coastal Brazil from Espírito Santo state south to Rio Grande do Sul, and extending to Misiones in Argentina. See Remarks for comments on the geographic variation of these subspecies.

NATURAL HISTORY: Although the distribution suggests that *G. brasiliensis* inhabits several distinct biomes in eastern South America, from Amazonian rainforest to the central Brazilian savannas (Cerrado), northeastern Brazil dry forests (Caatinga), and Atlantic rainforest, we believe this species is restricted to forest habitats and does not occur in open vegetation communities. In the Amazonian and Atlantic rainforests, this species is common, and specimens are well represented in collections. In contrast, the species appears to be rare in the Cerrado and Caatinga, where it is restricted to marginal gallery forests and isolated pockets of mesic vegetation, respectively. One of us (MdV) has observed solitary individuals or groups of up to four animals in the wild, but there are literature reports of associations of up to eight animals (Solórzano-Filho 2006).

As with other tree squirrels, *G. brasiliensis* is an arboreal specialist, shot, trapped, or observed typically at 5–12 m in the midstratum layer (Grelle 2003) where it builds nests made of moss, twigs, leaves, and plant fibers on the outside and exclusively of fibers internally; nest circumference averages 56 cm, and nests are usually placed at midcanopy (Alvarenga and Talamoni 2005). The diurnal activity pattern was represented by two peaks, one in the morning and other during the afternoon (Bordignon and Monteiro-Filho 2000). Fixed routes between the nests and food resources have been observed, and animals mark territories with urine and head-gland rubbing against the substrate. Foods include lichens, bryophytes, mushrooms, leaves, fruits, insects, and bird eggs (L. F. Ribeiro et al. 2009). At some sites, coconuts may be the most consumed item, comprising up to 70% of the diet; foods also include exotic plant seeds such as *Pinus*, demonstrating this species' ability to occupy altered habitats (Bordignon and Monteiro-Filho 1999; Alvarenga and Talamoni 2006). Several studies have discussed the role of *G. brasiliensis* as either a seed predator and/or disperser, especially of palm species with large seeds and hard endocarps (e.g., Paschoal and Galetti 1995; G. S. Silva and Tabarelli 2001; Pimentel and Tabarelli 2004; Donatti et al. 2009).

Alvarenga and Talamoni (2005) and T. G. Oliveira et al. (2007) presented evidence of reproduction associated with the onset of the rainy season, but Bordignon and Monteiro-Filho (2000) captured pregnant females during two peaks,

one in the winter and the other during the summer; the latter investigators also estimated a population density of 0.89 squirrels/ha, with males occupying larger areas during the winter mating period.

REMARKS: The name for the Brazilian Squirrel is *Guerlinguetus brasiliensis*, and its author is Gmelin (1788). The name was published as a synonym of his *Sciurus aestuans* and was attributed to G. Marcgraf (1648). Lesson (1838) recognized the species as valid, stating that F. Cuvier in Buffon's *Supplement*, Tome I, had provided the name; however, in this work, F. Cuvier (1831) does not employ a binomial designation for Marcgraf's squirrel. According to the International Code of Zoological Nomenclature (ICZN 1999:Arts. 11.6.1 and 50.7), the authorship of such a name must be attributed to the first publisher of the name, even if it was given as a junior synonym. Gmelin (1788) gave the type locality as "Brasilia et Guiana," but as other authors have argued for the species first reported by Marcgraf (1648), we restrict it here to Recife, Pernambuco, Brazil.

There is considerable geographic variation in the wide distributional range of this species, and some of this variation has been recognized at the species or subspecies level. The material examined does allow us to recognize three valid subspecies in *G. brasiliensis*. The typical subspecies, *G. b. brasiliensis*, occurs in northeastern Brazil, from the states of Ceará to Bahia, where the color of the venter is generally white on the throat, chest, belly, and inner parts of forelegs and hindlegs, and the tail is grizzled. To the

south of this area, intermediate forms between the nontypical subspecies and *G. b. ingrami* appear in the state of Espírito Santo (the form to which O. M. O. Pinto [1931] gave the name *garbei*), with specimens having less white and more yellowish under parts but retaining grizzled tails. Farther to the south as well as west of Espírito Santo, animals show white only at the throat and chest, sometimes also at the posterior and inguinal parts of the venter; the tail is never grizzled and is always punctuated with orange or red. The third subspecies, *G. b. paraensis* from eastern Brazilian Amazonia, resembles *ingrami* but has less gray on the belly; individuals also appear to have shorter pelage and are slightly smaller. Current records suggest that *G. b. paraensis* is not contiguous with the other two subspecies because *G. b. brasiliensis* is known only from forest pockets in the otherwise open formation of the Caatinga and *G. b. ingrami* occurs in the Atlantic Forest, which is mostly separated from Amazonia by open savannas of the Cerrado, a biome without any squirrel records (Carmignotto et al. 2012).

Genus *Hadroskiurus* J. A. Allen, 1915

Hadroskiurus contains the largest of the South American squirrels, distributed in Venezuela south of the Orinoco, Colombia, Ecuador, and Peru east of the Andes, western Brazilian Amazonia, and western central Brazil, Bolivia, and northern Paraguay.

This genus can be distinguished from most other South American sciurid genera by their size, except for the similar-sized *Simosciurus*, which differs from *Hadroskiurus* by its distinctly coarser pelage, ears covered by longer hairs, shorter skull with a broader rostrum, and a trans-Andean distribution. Individuals of some species of *Notosciurus* reach sizes that overlap the lower size limits of *Hadroskiurus*, but the two genera can be distinguished because the latter exhibits four pair of mammae instead of three.

Hadroskiurus, like other South American squirrels, exhibits considerable variation in external morphology and especially in color. Mass varies from 450 to 750 g, head and body length from 215 to 320 mm, tail length from 220 to 330 mm, hindfoot length from 50 to 75 mm, and ear length from 20 to 40 mm. A well-developed postorbital process equally divides the orbitotemporal fossa of the skull.

The genus includes three polytypic species, namely, *Hadroskiurus igniventris*, with three subspecies, *Hadroskiurus pyrhrinus*, with two subspecies, and *Hadroskiurus spadiceus*, with three subspecies. These three species present an interesting pattern of sympatry, with their large-scale ranges overlapping along the lower Solimões and lower Purús rivers, the only region where museum specimens document the presence of all three. All remaining

Map 4 Selected localities for *Guerlinguetus brasiliensis* (●). The likely disjunct distributions of Amazonian, Caatinga, and coastal populations are emphasized. Contour line = 2,000 m.

sympatry records are for pairs of species, with *H. igniventris* and *H. spadiceus* broadly sympatric in Ecuador and northern Peru; *H. pyrrhinus* and *H. spadiceus* sympatric along the middle and lower Rio Juruá in western Brazil; and *H. pyrrhinus* and *H. igniventris* sympatric along the lower Rio Negro, also in Brazil. It is somewhat surprising that so few localities have yielded sympatric species of squirrels, if we consider that, at least potentially, the area of sympatry at map scale covers much of central Peru and a vast area of the Brazilian western Amazonia. Patton et al. (1982) and Lemke et al. (1982) documented sympatry for *H. igniventris* and *H. spadiceus* in northern Peru and southern Colombia, respectively.

SYNONYMS:

Sciurus: Olfers, 1818:208; part (listing of *spadiceus*); not *Sciurus* Linnaeus, 1758.

Macroxus: Gray, 1867:428; part (listing of *langsдорffii*); not *Macroxus* F. Cuvier, 1823.

Guerlinguetus: Miranda-Ribeiro, 1914:36; part (listing of *langsдорffii*); not *Guerlinguetus* Gray, 1821.

Mesosciurus (*Histriosciurus*) J. A. Allen, 1915a:213; type species *Sciurus gerrardi* Gray, by original designation; part; all species-level taxa in this genus belong to *Notosciurus* J. A. Allen except for J. A. Allen's *Mesosciurus pyrrhinus*.

Hadrosociurus J. A. Allen, 1915a:265; type species *Sciurus flammifer* Thomas, by original designation.

Urosociurus J. A. Allen, 1915a:267, type species *Sciurus tricolor* Tschudi, by original designation.

Sciurus (*Urosociurus*): Thomas, 1926f:635; name combination.

Sciurus (*Hadrosociurus*): Thomas, 1928b:259; name combination.

[*Sciurus*] (*Guerlinguetus*): Ellerman, 1940:340; as subgenus (among the included species is *Sciurus pyrrhinus* Thomas).

Guerlinguetus (*Hadrosociurus*): Moore, 1959:177; name combination.

REMARKS: Our concept of *Hadrosociurus* mirrors that of Thomas (1928b), who suggested that *Sciurus* (*Hadrosociurus*) encompassed all the largest squirrels east of the Andes, but this concept requires more detailed clarification. As new species of squirrels were added to the roster of taxa from South America, J. A. Allen (1915a), acting as the first true reviewer of the family for the continent, recognized several distinct genera and subgenera, many of which he described as new. For the largest squirrels, Allen described two new genera: *Hadrosociurus*, containing only *H. flammifer*, and *Urosociurus*, with several species, including *U. langsдорffii*, *U. igniventris*, *U. pyrrhonotus*, and others. He also created the genus *Mesosciurus* for many species and subspecies in the *Sciurus granatensis* complex, in which he included *Sciurus*

pyrrhinus Thomas as a species—*Mesosociurus* (*Histriosociurus*) *pyrrhinus*.

However, Thomas (1927a) suggested that Allen's genera were "very intangible" and decided to change the status of many by placing them as subgenera of *Sciurus*. In this same work, Thomas allied *pyrrhinus* with *igniventris*, thus, for all practical purposes, removing *pyrrhinus* from *Mesosociurus*. Shortly thereafter, Thomas (1928b) realized that *Sciurus flammifer*, the type and only species of Allen's *Hadrosociurus*, belonged together with all the other large squirrels in a single taxonomic entity and that, having been described a few pages earlier than *Urosociurus*, the former would be the proper generic name for these squirrels, with *Urosociurus* as a junior synonym. Except for a few specific and subspecific taxa not yet known at the time of Thomas's publication, the content he assigned to *Hadrosociurus* is the same as ours.

Ellerman (1940) did not subscribe to Thomas's views and rearranged the specific contents of Thomas's *Sciurus* (*Hadrosociurus*), placing *pyrrhinus* with most other South American squirrels in his *Sciurus* (*Guerlinguetus*). Moore (1959) arranged all non-dwarf South American squirrels in the genus *Guerlinguetus*, with *Hadrosociurus* as a subgenus. Subsequent authors, for example, Thorington and Hoffmann (2005), believed that Moore (1959) had additionally recognized *Urosociurus* J. A. Allen as a subgenus of his *Guerlinguetus*. However, Moore (1959:177, 198) included *Sciurus igniventris* Wagner, the type species of *Urosociurus* J. A. Allen, as *Guerlinguetus* (*Hadrosociurus*) *igniventris*, thus treating *Urosociurus* as a junior synonym. Because Cabrera's (1961) work was published posthumously, he probably never saw Moore's (1959) arrangement and so employed Thomas's scheme for the genus. The current practice of regarding *Urosociurus* as a valid generic name for the large South American squirrels has resulted from a misreading of Moore's intentions.

Hershkovitz (1959b) expanded the discussion of cranial characters initiated by J. A. Allen (1915a) by recognizing two groups of large South American squirrels, which he treated as distinct species based on a characterization of the skull as either "short and broad" (*Sciurus igniventris*) or "long and narrow" (*Sciurus spadiceus*). Patton (1984) performed a morphometric study of Peruvian samples, agreed with Hershkovitz (1959b) that two distinct skull morphotypes could be recognized in the area, and resurrected *Urosociurus* as a subgenus of *Sciurus*.

At present, we cannot ascertain how the three species and subordinated subspecies that we have recognized in the genus *Hadrosociurus* can be distinguished by the cranial characters described by Hershkovitz (1959b) and Patton (1984), particularly because the presence of these characters has not been tested throughout the entire distribution of the genus. We employ *Hadrosociurus* as a full genus to keep

what seems to us a distinct group of species—distinguished mainly by their large size from other South American taxa—and to separate these squirrels from *Sciurus*, a near cosmopolitan taxon. We wish to emphasize that the differences in skull morphology demonstrated by Patton (1984) are quite substantive, contrary to what some previous authors believed (such as Oldfield Thomas). Indeed, we have not found such trenchant character differences in other South American squirrels, and it seems highly unlikely that strongly bimodal distribution is populational or merely geographical. *Hadroskiurus* might, with further study, be justifiably split into distinct taxonomic groups based on their skull morphology alone.

KEY TO THE SPECIES OF *HADROSKIURUS*:

1. Dorsum black or dark brown background streaked with red, orange, or yellow (dark hairs with red, orange, or yellow subterminal bands) 2
- 1'. Dorsum brownish red to reddish orange with little or no streaking; postauricular patch small, but distinct. *Hadroskiurus pyrrhinus*
2. Forelimbs uniformly orange or red, differently colored from dorsum; postauricular patch rarely present *Hadroskiurus igniventris*
- 2'. Forelimbs similar to that of anterior dorsum; postauricular patch always absent. . . . *Hadroskiurus spadiceus*

Hadroskiurus igniventris (Wagner, 1842)

Northern Amazon Red Squirrel, Quatipuru-açú

SYNONYMS: See under subspecies.

DESCRIPTION: Large, with head and body length 246–300 mm (N=117 adults), tail length 236–310 mm (N=118), hindfoot length 58–75 mm (N=111), ear length 29–40 mm (N=73), and mass 453–700 g (N=12). Dorsum dark, distinctly punctuated by light subapical bands to hairs, with background color from dark brown to black, and light bands from pale yellow to orange and red. Presence of distinct postauricular patches variable geographically; if present, pale orange in color. Forelimbs, and sometimes the hind legs, homogeneously orange to red; ventral color from white to reddish orange or orange yellow; base of tail colored like dorsum, with the terminal portion distinctly orange. Completely or partially melanistic individuals common.

DISTRIBUTION: The species occurs in northwestern Amazonia from the right bank of the Río Orinoco in Venezuela southward to the Río Negro and Río Solimões in Brazil and westward to Colombia, Ecuador, and northern Peru east of the Andes. The record of two specimens (MPEG 21807, 21808) from the Brazilian state of Amapá (Cachoeira do Santo Antonio, Rio Jari) is likely in error because there are no other records between this locality and the easternmost known distributional limit of the species

in Roraima, Brazil, about 1,000 km to the west. Cláudia Regina da Silva (pers. comm. to MdV) has conducted extensive mammal inventories in Amapá and has never encountered this species in the wild, nor has she ever heard locals refer to such a squirrel.

SELECTED LOCALITIES (Map 5): BRAZIL: Amazonas, Canabuco, Paraná do Jacaré (SMF 6918), Igarapé de Alvarães, right bank Rio Solimões (MZUSP 18921), Paraná do Aiapuá, Rio Purus (MZUSP 20357), Paraná do Manhãna, between Rio Japurá and Rio Solimões (MZUSP 6141); Roraima, BR 174, frontier between Brazil and Venezuela, frontier mark 8 (MZUSP 22347), lower Rio Mucajá, south of Boa Vista (MZUSP 9779); Roraima, Rio Catrimani (MZUSP 13688). COLOMBIA: Boyacá, Río Lengupa (AMNH 38407); Caquetá, Florencia, Río Bodoquera (AMNH 33691); Cundinamarca, Sabana Grande, lowlands near Bogotá (type locality of *Sciurus igniventris taedifer* Thomas); Meta, La Macarena, Río Yerli (FMNH 87954). ECUADOR: Loja, El Porotillo San José (MNHN 1934/1207); Morona-Santiago, Chiguaza (FMNH 54287), Mendéz Sur (MNHN 1960/3790); Orellano, Río Cotapino (FMNH 47600); Pichincha, Quito (MNHN 1937/893). PERU: Cajamarca, Chaupe (AMNH 64047); Loreto, Pebas (AMNH 98426), Santa Elena, Río Samiria (FMNH 87158), Santa Rita, Iquitos (FMNH 87148), Yurimaguas, Río Huallaga (FMNH 19674); San Martín, about 35 mi W of Moyobamba, Río Negro (AMNH 73214). VENEZUELA: Amazonas, Nericagua (Caño Usate), Río Orinoco (BM 99.9.11.26), Raya 32 km SSE of Puerto Ayacucho (USNM 409801); Bolívar, Ciudad Bolívar (AMNH 16127), El Yagual, lower Río Caura (AMNH 16940).

SUBSPECIES: We recognize three subspecies of *H. igniventris*. See Remarks for a description of the geographic variation.

H. i. cocalis (Thomas, 1900)

SYNONYMS:

Sciurus cocalis Thomas, 1900e:138, type locality “Mouth of Coca River, Upper Rio Napo,” Orellana, Ecuador.

Uroskiurus igniventris cocalis: J. A. Allen, 1915a:273; name combination.

Sciurus (Hadroskiurus) igniventris: Thomas, 1928c:289; part.

Sciurus [(Hadroskiurus)] igniventris cocalis: Ellerman, 1940:345; name combination.

Sciurus igniventris cocalis: Soukup, 1961:244; name combination.

Sciurus [(Uroskiurus)] igniventris [cocalis]: Thorington and Hoffmann, 2005:762; name combination.

This subspecies occurs in Ecuador east of the Andes, and in Peru in the departments of Loreto, Cajamarca, and San Martín.

H. i. igniventris (Wagner, 1842)

SYNONYMS:

Sciurus igniventris Wagner, 1842c:360; type locality "Rio Negro"; restricted by Wagner (1850:277) to "Marabitanos, überhaupt vom Rio negro" [= Marabitanas], right bank of the upper Rio Negro, Amazonas, Brazil.

Sciurus Morio Wagner, 1850:275, type locality "Marabitanos, überhaupt vom Rio negro" [= Marabitanas], right bank of the upper Rio Negro, Amazonas, Brazil.

(?) *Macroxus fumigatus* Gray, 1867:428, type locality "Brazil, Upper Amazon"; identity uncertain as holotype is almost entirely melanistic.

(?) *Macroxus brunneo-niger* Gray, 1867:429, type locality "Brazil"; identity uncertain as holotype is almost entirely melanistic.

Sciurus igniventer Gray, 1867:433; incorrect subsequent spelling of *Sciurus igniventris* Wagner.

Sciurus igniventris niger Fitzinger, 1867a:479; type locality "Am. Brasilien, Rio negro, Marabitanas," Amazonas, Brazil.

Sciurus igniventris taedifer Thomas, 1903b:487, type locality "Sabaña Grande, near Bogota," Cundinamarca, Colombia.

Sciurus tricolor morio: E.-L. Trouessart, 1904:328; name combination.

Sciurus brunneo-niger: E.-L. Trouessart, 1904:328; name combination.

Sciurus duida J. A. Allen, 1914d:594, type locality "Rio Cunucunumá (altitude 700 feet), base of Mount Duida, [Amazonas,] Venezuela."

Sciurus igniventris zamorae J. A. Allen, 1914d:594, type locality "Zamora (altitude 2,000 feet), [Zamora-Chinche], Ecuador."

Urosciurus duida: J. A. Allen, 1915a:270; name combination.

Urosciurus igniventris igniventris: J. A. Allen, 1915a:271; name combination.

Urosciurus igniventris taedifer: J. A. Allen, 1915a:272; name combination.

Urosciurus igniventris zamorae: J. A. Allen, 1915a:274; name combination.

S[ciurus]. (*Hadrosociurus*) *igniventris*: Thomas, 1928c:290; name combination.

Hadrosociurus igniventris igniventris: Tate, 1939:176; name combination.

Hadrosociurus igniventris duida: Tate, 1939:176; name combination.

Hadrosociurus igniventris: Cabrera and Yepes, 1940:195; name combination.

Sciurus [(*Hadrosociurus*)] *duida*: Ellerman, 1940:344; name combination.

Sciurus [(*Hadrosociurus*)] *igniventris igniventris*: Ellerman, 1940:344; name combination.

Sciurus [(*Hadrosociurus*)] *igniventris taedifer*: Ellerman, 1940:344; name combination.

Sciurus [(*Hadrosociurus*)] *igniventris zamorae*: Ellerman, 1940:345; name combination.

Hadrosociurus igniventris manhanensis Moojen, 1942:24, type locality "Paraná do Nanhana [= Manhana; Paynter and Traylor 1991], entre o Rio Japurá e o Amazonas, Amazonas," Brazil.

Hadrosociurus pyrrhonotus purusianus Moojen, 1942:31, type locality "Lago Aiapuá, Baixo Purús, Estado do Amazonas," Brazil.

Sciurus [(*Hadrosociurus*)] *igniventris manhanensis*: W. P. Harris, 1944:12; name combination.

Sciurus [(*Hadrosociurus*)] *igniventris purusianus*: W. P. Harris, 1944:12; name combination.

Sciurus igniventris igniventris: Sanborn, 1949b:285; name combination.

Sciurus igniventris manhanensis: Moojen, 1952b:30; name combination.

Sciurus pyrrhonotus purusianus: Moojen, 1952b:31; name combination.

Sciurus (Hadrosociurus) pyrrhonotus purusianus: C. O. da C. Vieira, 1955:408; name combination.

Guerlinguetus (Hadrosociurus) igniventris: Moore, 1959:203; name combination.

Sciurus [(*Urosciurus*)] *igniventris*: Patton, 1984:53; name combination.

The nominotypical subspecies occurs in Colombia east of the Andes in Cundinamarca, Meta, and Caquetá departments; along the Río Napo in Loreto, Peru; in Amazonas department of Venezuela; and in Roraima state in Brazil, on the left bank of the Rio Branco, and in Amazonas state, along the Rio Solimões and Rio Negro.

H. i. flammifer (Thomas, 1904)

SYNONYMS:

Sciurus flammifer Thomas, 1904d:33, type locality "La Union, Caura district, Lower Orinoco," Bolívar, Venezuela.

Hadrosociurus flammifer: J. A. Allen, 1915a:266; name combination.

S[ciurus (Hadrosociurus)] flammifer: Thomas, 1928c:290; name combination.

Guerlinguetus (Hadrosociurus) flammifer: Moore, 1959:203; name combination.

This subspecies is distributed from the Venezuelan department of Bolívar, south of the Orinoco and west of Río Caroní, to the Brazilian border at Serra de Pacaraima.

NATURAL HISTORY: Emmons and Feer (1997) noted that individuals are diurnal, arboreal, territorial, and

solitary, although several may feed together in a single fruiting tree. Primary foods include large palm nuts and other tree nuts and fruits. Silvius (2002) reported individuals feeding on beetle larvae as well as the endocarp of the palm *Attalea maripa*. The species is largely limited to closed-canopy rainforest, either mature or disturbed (Emmons and Feer 1997). Youlatos (1999) reported that individuals used all forest heights, preferring tree crowns and lianas, with an ability to walk, leap, and bound along small horizontal supports. Jessen, Palmer, and Koprowski (2013) reported a nest for an unidentifiable melanistic female of either *H. igniventris* or *H. spadiceus* from Loreto, Peru, built at 3.6 m above ground with two offspring.

REMARKS: *Hadroskiurus igniventris cocalis* is a large squirrel with orange forelimbs, which differs from the nominotypical subspecies by a dark to almost black dorsal color streaked with orange or dark red, the presence of conspicuous orange postauricular patches, and a yellowish orange venter.

Hadroskiurus igniventris igniventris is also a large squirrel with orange to red forelimbs, with hindlimbs colored as the forelimbs or dorsum; head blackish above, with an orange muzzle diluted with black and with no conspicuous eye-ring; ears brown to almost black on both sides; postauricular patches, if present, inconspicuous;

dorsum black to dark brown heavily streaked with orange or red; venter red, with same color extending to undersides of legs; and tail dark, mostly black over the proximal third, with some orange distally. J. A. Allen (1915a:267–268) placed *Sciurus igniventris* Wagner in his new genus *Urosciurus*.

Hadroskiurus igniventris flammifer is similar to *H. i. igniventris*, with orange to red limbs and a black dorsum heavily streaked with pale yellow to orange, but the former differs from the latter by having conspicuous pale orange postauricular patches and a white venter. The genus *Hadroskiurus* was created by J. A. Allen (1915a), with *Sciurus flammifer* as its type and only species.

Hadroskiurus pyrrhinus (Thomas, 1898)

Junín Red Squirrel, Quatipuru-açu

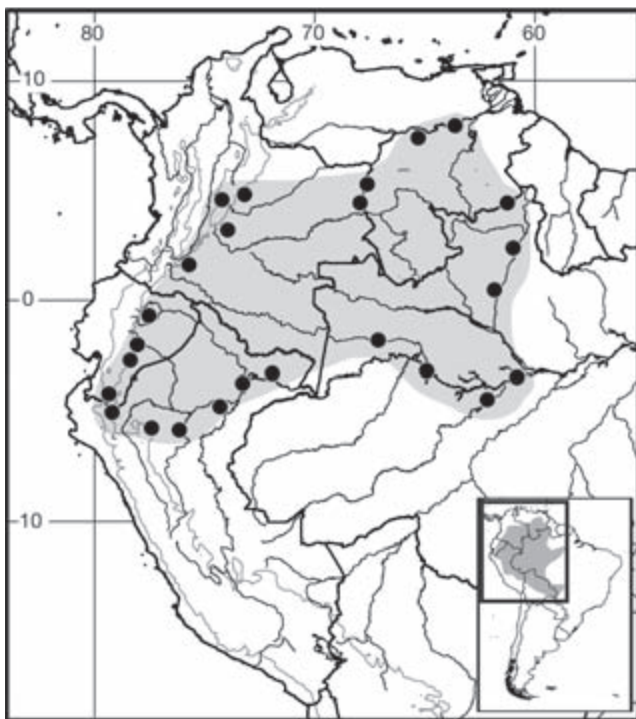

SYNONYMS: See under subspecies.

DESCRIPTION: Equivalent in size to *H. igniventris*, with head and body length 220–290 mm (N=44 adults), tail length 252–305 mm (N=42), hindfoot length 60–70 mm (N=40), and ear length 31–35 mm (N=19). Color of dorsum, forelimbs, and hindlegs uniform dark red to brownish red, without streaking by hairs with light apical or subapical bands. Conspicuous postauricular patches present, generally pale yellow or light orange throughout most of range but inconspicuous in specimens from upper Rio Negro area of Brazil at Colombian border. Venter white to pale red, mixture of both colors in some individuals; when white, transition from venter to torso, limbs, and head demarcated by a red strip.

DISTRIBUTION: This species occurs from the eastern Andean slopes of central Peru to western Brazilian Amazonia, probably limited by the Purus river basin on the east and Negro basin on the north.

SELECTED LOCALITIES (Map 6): BRAZIL: Amazonas, between Cajutuba and Airão, Rio Jaú, Rio Negro (syntype of *Sciurus igniventris* Wagner), Codajás, left bank Rio Solimões (MZUSP 4202), Dejedá, Rio Juruá (type locality of *Urosciurus nigratus* O. M. O. Pinto), Estirão do Equador, right bank Rio Javari (MPEG 1807), Manaus (syntype of *Sciurus igniventris* Wagner), Santo Antônio do Içá, left bank Rio Içá (MZUSP 20384), Tauhuapunto (Tauá), Rio Vaupés, left bank (AMNH 78620). PERU: Cusco, San Juan Grande, Quincemil, Quispicanchis (FMNH 75208); Huánuco, Tingo Maria, Río Huallaga (FMNH 24112); Junín, Tarma, 2 mi NW of San Ramón (AMNH 231771); Pasco, Puerto Bermudez (FMNH 24110).

SUBSPECIES: We tentatively recognize two subspecies of *H. pyrrhinus*, which we compare in the Remarks section.

Map 5 Selected localities for *Hadroskiurus igniventris* (●). Contour line=2,000m.

H. p. fulminatus (Thomas, 1926)

SYNONYMS:

Sciurus [(*Urosciurus*)] *igniventris fulminatus* Thomas, 1926f:637; type locality “Manacapuru,” Rio Solimões, Amazonas, Brazil.

Sciurus. (*Urosciurus*) [*igniventris*]. *fulminatus*: Thomas, 1928c:290; name combination.

Urosciurus nigratus O. M. O. Pinto, 1931:309; type locality “Rio Juruá (Amazonas),” Brazil.

Sciurus [(*Hadrosociurus*)] *nigratus*: Ellerman, 1940:344; name combination.

Sciurus [(*Hadrosociurus*)] *igniventris fulminatus*: Ellerman, 1940:345; name combination.

Hadrosociurus igniventris fulminatus: Moojen, 1942:22; name combination.

Sciurus igniventris fulminatus: Moojen, 1952b:29; name combination.

Sciurus (*Hadrosociurus*) *pyrrhonotus fulminatus*: Avila-Pires, 1964:15; name combination.

This subspecies occurs primarily in Amazonas state, Brazil; it is also known from a single locality in Cusco department, Peru.

H. p. pyrrhinus (Thomas, 1898)

SYNONYMS:

Sciurus pyrrhinus Thomas, 1898f:265; type locality “Gartal del Sol, Vitoc, [Junín,] Peru.”

Mesosociurus [(*Histriosociurus*)] *pyrrhinus*: J. A. Allen, 1915a:252; name combination.

Sciurus [(*Urosciurus*)] *pyrrhinus*: Thomas, 1927a:369; implicit allocation to subgenus due to accepted resemblance to *S. igniventris*.

Sciurus [(*Guerlinguetus*)] *pyrrhinus*: Ellerman, 1940:342; name combination.

Sciurus (*Hadrosociurus*) *pyrrhinus*: Cabrera, 1961:378; name combination.

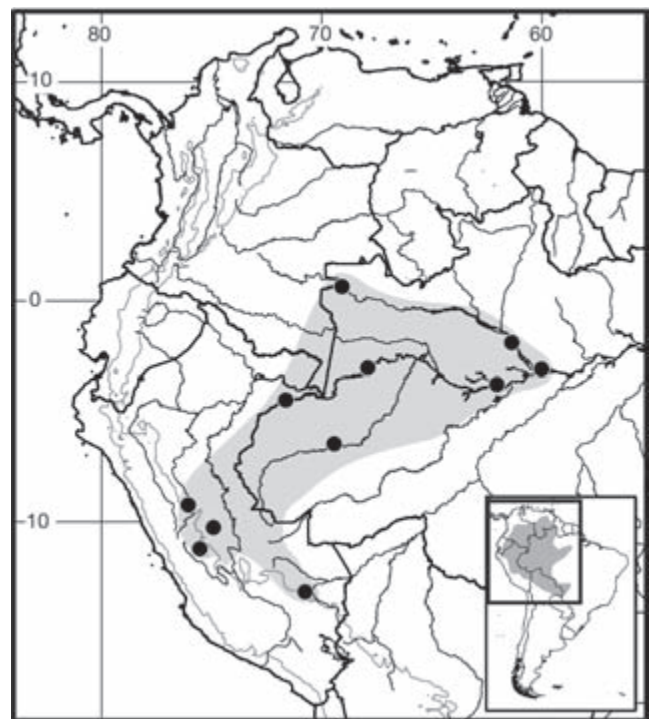

The nominotypical subspecies occurs on the eastern slopes of the Andes in the Peruvian departments of Huánuco, Junín, Pasco, and Ucayali.

NATURAL HISTORY: Emmons and Feer (1997) stated that this species inhabits montane forests across an elevational range from 600 to 2,000 m, but it occurs at less than 300 m elevation at localities in the central Amazon.

REMARKS: The taxonomic history of *Hadrosociurus pyrrhinus* (Thomas) is marked by its erroneous allocation to a group of Andean and peri-Andean taxa allied to *Notosciurus granatensis* by J. A. Allen (1915a). Although it is superficially similar to these squirrels, its distribution on the eastern slopes of the central Peruvian Andes only added to the confusion. The alliance of *pyrrhinus* to other large South American squirrels we include in *Hadrosociurus* be-

comes clear when it is considered together with its sister subspecies, as we shall do.

Hadrosociurus pyrrhinus fulminatus is similar to *H. p. pyrrhinus* except that dorsal tones are paler, duller red; pale orange postauricular patches are conspicuous; the venter is uniformly yellow to orange. This taxon occurs sympatrically with two other forms in the genus (namely *H. i. igniventris* and *H. spadiceus pyrrhonotus*) in the region of the lower Rio Solimões and Rio Purus in the Brazilian state of Amazonas. In this area of sympatry, *H. pyrrhinus* can be distinguished from *H. i. igniventris* by its uniform dull dark red dorsal color with very little streaking (which results from a pale band near the tip of the hairs) and the possession of conspicuous postauricular patches. *Hadrosociurus pyrrhinus* is distinguished from *H. spadiceus pyrrhonotus* by presence of distinct postauricular patches, a less vivid red dorsum with less streaking, and yellowish orange as opposed to white venter. Since its description, *fulminatus* has been allied to *Sciurus igniventris*, and since Thomas (1927a) transferred *pyrrhinus* to the *igniventris* complex, both have been usually treated as distinct subspecies under *igniventris*. The similarity in coat color between *pyrrhinus* and *fulminatus* made us consider a probable affinity, here inferred at the subspecific level.

Map 6 Selected localities for *Hadrosociurus pyrrhinus* (●). Contour line=2,000 m.

Hadroskiurus spadiceus (Olfers, 1818)

Southern Amazon Red Squirrel, *Quatipurú-açu*

SYNONYMS: See under subspecies.

DESCRIPTION: Slightly larger than other species in the genus, with head and body length 215–316 mm (N=78 adults), tail length 225–325 mm (N=78), hindfoot 50–75 mm (N=76), ear length 20–35 mm (N=36), and mass 650–750 g (N=3). Highly variable species, as apparent from several subspecies we recognize (see Remarks for distinctive characters of each subspecies). Dorsum dark, with black background color, strongly streaked with pale yellow, yellow, orange, or red; specimens from Peru have darker mid-dorsal strip. Alternatively, the dorsum may be mostly or entirely red, or divided into relatively distinct anterior and posterior regions, with posterior part uniformly colored orange but anterior portion dark and streaked. Dorsal sides of forelimbs and hindlimbs colored same as adjacent region of upper body; in southeastern portion of distribution, hindlegs divided into paler anterior and darker posterior regions. Differently colored postauricular patches absent. Ventral color variable: white in specimens from Brazilian Amazon and parts of Bolivia, white to yellow in those from Peru, and red in west-central Brazil, central Bolivia, and northern Paraguay.

DISTRIBUTION: The species occurs from southern Colombia, Ecuador, and Peru east of the Andes, eastward into Amazonian Brazil, where it is limited to the region south of the Rio Solimões-Amazonas system, from the Rio Tapajós west to the Peruvian border, and south to west-central Brazil in the states of Mato Grosso and Mato Grosso do Sul as well as across the lowlands of Bolivia to northern Paraguay.

SELECTED LOCALITIES (Map 7): BOLIVIA: La Paz, Chimate (BM 1.2.1.7); Santa Cruz, Santa Cruz de la Sierra (FMNH 21420). BRAZIL: Acre, Oriente (= Seringal Oriente), near Taumaturgo, Rio Juruá (MPEG 725); Amazonas, Eirunepé, left bank Rio Juruá (MZUSP 4634), Lago do Batista, Ilha de Tupinambarama, right bank Rio Amazonas (MZUSP 4567), Lago do Mapixi, east of Rio Purus (FMNH 38881), Manaqueri, Rio Solimões (NMW B 1533), mouth Rio Guariba, left bank Rio Aripuanã (MPEG 8785); Mato Grosso, Mato Grosso (= Vila Bela da Santíssima Trindade) (NMW B 1520), Palmeiras (MZUSP 6338), Villa Maria, NNW of Cáceres (NMW B 1518); Mato Grosso do Sul, Urucum (type locality of *Sciurus langsdorffii urucumus* J. A. Allen); Pará, Flexal, Itaituba–Jacareacanga road, km 212, left bank Rio Tapajós (MPEG 10165), Rio Arapiuns, left bank Rio Tapajós (MPEG 424), Sumaúma, left bank Rio Tapajós (MZUSP 20365); Rondônia, Ouro Preto d'Oeste, Rio Paraíso (MPEG 12411). COLOMBIA: Meta, Cabaña Duda, junction of Río Duda and Río Guayabero (Lemke et al. 1982), Fundo “Guami,” Piñalto (Lemke et al. 1982).

ECUADOR: Morona–Santiago, Río San José (AMNH 68264); Napo, mouth of Río Coca, upper Río Napo (BM 0.6.3.2), boca del Río Lagarto Cocha (AMNH 72231); Pastaza, Mera (AMNH 67674). PARAGUAY: Alto Paraguay, Estancia Kambá Aka, Parque Nacional Río Negro (D'Elia, Mora et al. 2008). PERU: Cajamarca, Huarandosa (AMNH 67095); Huánuco, Tingo Maria, Río Huallaga (FMNH 24113); Loreto, boca del Río Curaray (AMNH 72177), Río Apayacu (AMNH 74389), San Fernando, Río Yavari (FMNH 88967); Puno, Pauquiplaya, below San Ignacio, Río Tambopata (FMNH 79903).

SUBSPECIES: We tentatively recognize four subspecies of *H. spadiceus*, as follows.

H. s. castus (Thomas, 1903)

SYNONYMS:

Sciurus castus Thomas, 1903b:488, type locality “Chimate, [La Paz,] Bolivia, . . . on the Upper Rio Beni.”

Urosciurus pyrrhonotus castus: J. A. Allen, 1915a:276; name combination.

Hadroskiurus pyrrhonotus castus: Cabrera and Yepes, 1940:195; name combination.

Sciurus [(*Hadroskiurus*)] *pyrrhonotus castus*: Ellerman, 1940:345; name combination.

Hadroskiurus langsdorffii rondoniae Moojen, 1942:39; type locality “Cabeceiras do Rio Aripuanã, Rondonia, Mato-Grosso,” Brazil.

Sciurus [(*Hadroskiurus*)] *langsdorffii rondoniae*: W. P. Harris, 1944:12; name combination.

Sciurus langsdorffii rondoniae: Moojen, 1952b:32; name combination.

Sciurus pyrrhonotus castus: Soukup, 1961:244; name combination.

This subspecies is known from Rondônia state, Brazil, and an isolated locality in La Paz department, Bolivia. It is quite similar morphologically to the nominotypical form, differing primarily by more extensive white on the venter and the lack of a conspicuous eye-ring. The head is black, mixed with orange on the crown; the rostrum also black and orange; the ears brown on both sides; postauricular patches are absent; the dorsum black, finely streaked with vivid yellow; forefeet and limbs the same color as the dorsum, only slightly lighter distally; hindfeet orange streaked with black; bicolored legs—their anterior portion the same color as the sides but darker orange posteriorly; venter entirely white to white with some yellow from throat to chest, white extending to the undersides of fore and hind limbs almost to the feet, with the color near the feet the same as dorsal parts of the legs; and the proximal quarter to third of the tail is dark, and also turning black with an orange tip. *Hadroskiurus langsdorffii rondoniae* Moojen,

from west-central Brazil, is identical to *castus* and thus is placed as a synonym.

H. s. pyrrhonotus (Wagner, 1842)

SYNONYMS:

Sciurus pyrrhonotus Wagner, 1842c:360, type locality “Borba,” Amazonas, Brazil.

Urosciurus pyrrhonotus pyrrhonotus: J. A. Allen, 1915a:275; name combination.

Urosciurus pyrrhonotus: O. M. O. Pinto, 1931:303; name combination.

Sciurus [(*Hadrosociurus*)] *pyrrhonotus pyrrhonotus*: Ellerman, 1940:345; name combination.

Hadrosociurus pyrrhonotus pyrrhonotus: Moojen, 1942:26; name combination.

Sciurus pyrrhonotus pyrrhonotus: Moojen, 1952b:30; name combination.

Sciurus pyrrhonotus Alho, 1982:144; incorrect subsequent spelling of *Sciurus pyrrhonotus* Wagner.

The range of *H. s. pyrrhonotus* is limited to Amazonas state, Brazil, south of the Rio Amazonas–Solimões along the lower and middle courses of the Rio Purus and Rio Madeira. Specimens typically have a black head but orange rostrum, and lack a conspicuous eye-ring. The ears are red on both sides. Postauricular patches are absent. The dorsum is red, slightly darker on the midline. The forelimbs and feet are the same color as the dorsum, only slightly lighter distally. The hindlegs and feet are reddish. The venter is white, with the white extending to the undersides of arms and legs almost to the feet. The color near forefeet and hindfeet is the same as dorsal parts of the legs. The tail is dark over the proximal third of its length, with red predominating in the middle section and black predominating distally. Some specimens of this subspecies have the dorsum partially divided into anterior and posterior sections with slightly distinct hues of red and distinct amounts of banding of the hairs, but the dorsal color is always red, and the venter is white.

H. s. spadiceus (Olfers, 1818)

Sciurus [*Sciurus*]. *spadiceus* Olfers, 1818:208; type locality restricted by Hershkovitz (1959b:346) to Cuiabá, Mato Grosso, Brasil.

Sciurus langsdorffii Brandt, 1835:89, type locality “Brazil,” restricted to Cuiabá, Mato Grosso, Brazil by Wagner (1850:275).

Sciurus Langsdorffii Gray, 1843b:137; incorrect subsequent spelling of *Sciurus langsdorffii* Brandt.

Sciurus langsdorffii Var. *rufa* Wagner, 1844:plate CCXV; preoccupied by *Sciurus rufus* Kerr, 1792.

Sciurus Langsdorffii: E.-L. Trouessart, 1897:429; name combination and incorrect subsequent spelling of *Sciurus langsdorffii* Brandt.

Sciurus Langsdorffii: Thomas, 1900e:137; name combination and incorrect subsequent spelling of *Sciurus langsdorffii* Brandt.

Sciurus langsdorffii urucumus J. A. Allen, 1914d:595; type locality “Urucum, (altitude 400 feet), Rio Paraguay (at mouth of Rio Tacuari), [Mato Grosso do Sul,] Brazil.”

Sciurus langsdorffii steinbachi J. A. Allen, 1914d:596; type locality “Santa Cruz de La Sierra, [Santa Cruz,] Bolivia.”

Guerlinguetus langsdorffii: Miranda-Ribeiro, 1914:36; name combination and incorrect subsequent spelling of *Sciurus langsdorffii* Brandt.

Urosciurus langsdorffii langsdorffii: J. A. Allen, 1915a:276; name combination.

Urosciurus langsdorffii urucumus: J. A. Allen, 1915a:278; name combination.

Urosciurus langsdorffii steinbachi: J. A. Allen, 1915a:279; name combination.

Urosciurus langsdorffii urucumus: J. A. Allen, 1916d:572; name combination.

Hadrosociurus langsdorffii urucumus: Cabrera and Yepes, 1940:196; name combination.

Hadrosociurus langsdorffii steinbachi: Cabrera and Yepes, 1940:196; name combination.

Sciurus [(*Hadrosociurus*)] *langsdorffii langsdorffii*: Ellerman, 1940:345; name combination.

Sciurus [(*Hadrosociurus*)] *langsdorffii urucumus*: Ellerman, 1940:345; name combination.

Sciurus [(*Hadrosociurus*)] *langsdorffii steinbachi*: Ellerman, 1940:345; name combination.

Hadrosociurus langsdorffii langsdorffii: Moojen, 1942:36; name combination.

Sciurus langsdorffii langsdorffii: Moojen, 1952b:32; name combination.

Guerlinguetus (*Hadrosociurus*) *urucumus*: Moore, 1959:203; name combination.

Guerlinguetus (*Hadrosociurus*) *spadiceus*: C. T. Carvalho, 1965:52; name combination.

Sciurus [(*Urosciurus*)] *spadiceus*: Patton, 1984:53; name combination.

Sciurus (*Hadrosociurus*) *spadiceus*: Eisenberg, 1989:335; name combination.

Sciurus [(*Urosciurus*)] *spadiceus* [*steinbachi*]: Thorington and Hoffmann, 2005:763; name combination.

Urosciurus spadiceus: J. A. Oliveira and Bonvicino, 2006:350; name combination.

The nominotypical subspecies occurs in the southern part of Mato Grosso and northwestern Mato Grosso do Sul states, Brazil, and extends west to Santa Cruz department, Bolivia. Specimens are characterized by a black head mixed with orange on the crown, a black and orange muzzle, a conspicuous eye-ring, ears brown on both

sides; no postauricular patches; dorsum black finely lined with yellow and slightly darker on the midline; forefeet and limbs the same color as dorsum, only slightly lighter distally; black hindfeet streaked with orange; bicolored hindlegs, anteriorly the same pale orange as the sides but posteriorly darker reddish; venter yellowish orange, with some white on the throat and with color extending to the undersides of forelegs and hindlegs, almost to the feet; color near feet same as dorsal parts of legs; and proximal quarter of tail dark, becoming black before terminating in an orange tip.

H. s. tricolor (Tschudi, 1845)

SYNONYMS:

Sciurus [*Sciurus*]. *tricolor* Tschudi, 1845:156, plate XI; type locality "Peru"; restricted to "Maynas, in the angle between the lower Huallaga and the Marañon [Loreto]" (Thomas 1900e:137).

Urosciurus tricolor: J. A. Allen, 1915a:269; name combination.

Sciurus (*Urosciurus*) *pyrrhonotus taparius* Thomas, 1926f:635; type locality "Uricurituba, Santarem [= Santarém]," Pará, Brazil.

Sciurus [(*Urosciurus*)] *pyrrhonotus juralis* Thomas, 1926f:636, type locality "Juruá River," Amazonas, Brazil.

Sciurus (*Urosciurus*) *tricolor*: Thomas, 1927f:599; name combination.

Sciurus (*Hadrosciurus*) *tricolor*: Thomas, 1927f:599; name combination.

Hadrosciurus tricolor: Cabrera and Yepes, 1940:195; name combination.

Sciurus [(*Hadrosciurus*)] *pyrrhonotus taparius*: Ellerman, 1940:345; name combination.

Sciurus [(*Hadrosciurus*)] *pyrrhonotus juralis*: Ellerman, 1940:345; name combination.

Hadrosciurus pyrrhonotus taparius: Moojen, 1942:30; name combination.

Hadrosciurus pyrrhonotus juralis: Moojen, 1942:34; name combination.

Sciurus pyrrhonotus taparius: Moojen, 1952b:30; name combination.

Sciurus pyrrhonotus juralis: Moojen, 1952b:31; name combination.

Sciurus [(*Urosciurus*)] *spadiceus* [*tricolor*]: Thorington and Hoffmann, 2005:763; name combination.

This subspecies occurs east of the Andes in Colombia south through Ecuador and Peru to central Bolivia, extending to the east to Acre and Amazonas states in Brazil, and south of the Rio Solimões along the upper course of the Rio Juruá and Rio Purus. There is an apparent gap in the distribution, as the taxon is also known from the Rio Aripuanã,

a tributary on the right bank of the middle Rio Madeira, Amazonas, Brazil, and from there to Pará state west of the Rio Tapajós.

Melanistic individuals of *H. s. tricolor* are common, with some individuals entirely black, others only partially so. The color pattern for non-melanistic specimens includes a black head with orange rostrum, no conspicuous eye-ring, reddish brown to brownish black ears on both sides; no postauricular patches; dorsum generally black, sometimes darker red posteriorly, but heavily streaked with orange; forefeet and limbs same color as the dorsum, only slightly paler distally; hindfeet and limbs reddish orange, with or without black streaking; venter white, extending to undersides of forelegs and hindlegs almost to the paws, color near hands and feet the same as dorsal parts of the legs; proximal third of the tail dark, with red predominating in the middle section and orange and black predominating distally.

NATURAL HISTORY: Gwinn et al. (2012) compiled information on the natural history of this species. Peres, Barlow, and Haugaasen (2003) reported an estimated density of 0.08 individuals/ha at a site in the headwaters of Rio Arapiuns, Pará state, Brazil; they observed solitary individuals twice. H. Gómez et al. (2003) reported a larger average density for a site in the department of La Paz, Bolivia, with 0.122 individuals/ha. Patton et al. (2000) recorded scrotal males in the headwaters of the Rio Juruá, Amazonas state, Brazil, in September and February. They also collected a lactating female with three placental scars in February. Anderson (1997) reported litter sizes ranging from two to four in August from Bolivia. These very limited data suggest breeding in both wet and dry seasons. According to sources cited in Gwinn et al. (2012), the species is mostly seen at ground level, using the canopy when the forest is flooded. Nuts of four genera of trees (the palms *Astrocaryum*, *Attalea*, and *Scheelea*, and the legume *Dipteryx*) comprise the majority of its diet. Della-Flora et al. (2013) reported the association of this species with mixed-species bird flocks in western Brazil.

REMARKS: The distributions of three subspecies (*H. s. castus*, *H. s. tricolor*, and *H. s. spadiceus*) approach one another in Bolivia. Here, those specimens we assign to *tricolor* differ from both *spadiceus* and *castus* in dorsal color, with the dorsum black streaked with red or orange, not the pale yellow characteristic of the latter two subspecies. However, Bolivian *tricolor* also differ from their counterparts east of the Andes in Ecuador and Peru, where specimens typically exhibit a mid-dorsum darker than the sides, a characteristic not present in Bolivian *tricolor*. Samples from the western Brazilian Amazon, in the states of Acre and Amazonas, also differ from typical *tricolor*, with the mid-dorsum not markedly darker than the sides and the venter tending to white, with some orange. The dorsum of

these Brazilian samples also varies from being uniformly colored from front to back or divided between a more orange posterior section and a black grizzled with orange anterior section; this phenotype has an available name, *Sciurus pyrrhonotus juralis* Thomas, with type locality on the middle Rio Juruá, Amazonas, Brazil.

There are few samples from the east and northeast along the Rio Amazonas, but those from the Rio Aripuanã, in southeastern Amazonas state, as well as those from the left bank of the Rio Tapajós, Pará state, are similar to those from the Juruá region, except that the top of the head is paler. As is usual for most color variants of South American squirrels, there is a name available for these squirrels, namely, *Sciurus (Urosciurus) pyrrhonotus taparius* Thomas. If taken in isolation, specimens from central Peru and from the Rio Tapajós are quite distinct from each other and could be distinguished as valid taxa. We do not do so, however, because we cannot presently establish clear geographical limits to this variation. We believe that the taxon we are recognizing here is a complex and will probably be split into a number of distinct, valid taxa with a deeper study of geographical variation.

Sciurus langsdorffi steinbachi J. A. Allen, described from Santa Cruz de la Sierra, Bolivia, is identical to our concept of *H. s. spadiceus*, and we treat it as a junior synonym. In the southern portion of the geographical distribution of *spadiceus*, specimens from the Serra do Urucum and Cáceres, Mato Grosso do Sul, Brazil, are identical to typical *spadi-*

Map 7 Selected localities for *Hadroskiurus spadiceus* (●). Contour line = 2,000 m.

ceus in color but average distinctly smaller in size. J. A. Allen (1914d) described these specimens as *Sciurus langsdorffii urucumus*; we have placed *urucumus* as a junior synonym of *S. spadiceus* because there is an overlap in size between the largest specimens of *urucumus* and the smallest of *spadiceus*.

Genus *Microsciurus* J. A. Allen, 1895

Microsciurus is a genus of small tree squirrels distributed in Central and South America. Among neotropical squirrels, *Microsciurus* species are intermediate in size between the diminutive *Sciurillus* and the slightly larger *Syntheosciurus*, with mass ranging from 80–120 g and external measurements of head and body length of 112–170 mm, tail length 82–165 mm, hindfoot length 28–45 mm, and ear length 8–19 mm. The ears are small and rounded. Females possess three pairs of evenly spaced mammae. Except for a few taxa, the color pattern is very conservative, usually some shade of brown finely streaked with orange or red on the dorsum, and with a paler ventrum. Several species have colored postauricular patches. High-elevation populations typically have longer and denser fur than lowland ones, and the tail is never very bushy.

The skull has a strongly curved dorsal profile with an inflection point at the middle of the frontals. From the inflection point to the anteriormost portion of skull, the rostrum maintains a straight or even slightly concave profile. The rostrum is short, at most one-third the length of the skull. The frontals are longer than they are wide, and the braincase is globose. The temporal portion of the orbitotemporal fossa is greatly reduced but not obliterated; the postorbital process extends posteriorly almost to a vertical plane passing through the internal (anterior) portion of the squamosal zygomatic process in the fossa. The maxillary process of the zygomatic arch is oblique in lateral view, originating anterior to the cheek teeth and above the infraorbital foramen. The sphenopalatine foramen is situated above the second molar or the contact between the second and third molars. There are two complete bullar septa, and rarely a third incomplete septum. The mandible has a very short coronoid process.

The dental formula is I 1/1, C 0/0, PM 2–1/1, M 3/3 = 20–22; PM3 is absent in some populations, particularly those of *M. flaviventer*. When present, PM3 is simple, small, unicuspidate, and has one root; all remaining permanent cheek teeth possess three roots. PM4 is molariform but varies in size, from one-third smaller to only slightly smaller than M1. M1 and M2 are subequal, but M3 is distinctly smaller in size. Paraconule, metaconule, and ectostyle are absent or vestigial; the trigon is shallow. Only pm4 has a vestigial paraconid, a structure absent in all remaining lower cheek teeth. The trigonid is vestigial.

SYNONYMS:

- Macroxus*: Gray, 1867:432; part (description of *flaviventer*); not *Macroxus* F. Cuvier.
Sciurus: J. A. Allen, 1877:750; part (inclusion of *rufoniger*); not *Sciurus* Linnaeus.
 [*Sciurus*] (*Microsciurus*) J. A. Allen, 1895b:332; type species *Sciurus (Microsciurus) alfari*, by original designation.
Microsciurus: E.-L. Trouessart, 1897:429; elevation to generic status.
Microsciurus (Microsciurus): Moore, 1959:179; name combination.

REMARKS: J. A. Allen (1895b) described *Microsciurus* as a subgenus, designating *Sciurus (Microsciurus) alfari* J. A. Allen as the type species. Being quite easily diagnosable in terms of size and a number of cranial characters from other squirrels, the taxonomic history of *Microsciurus* is relatively unproblematic. The only major taxonomic changes subsequent to Allen's description were E.-L. Trouessart's (1897) elevation to full genus and Thomas's (1914b,f) placement of *Microsciurus pusillus (sensu J. A. Allen 1914a)* in its own genus, *Sciurillus*. Moore (1959) used the name in a broader sense, including several genera and subgenera in it, but his subgenus *Microsciurus* is equal to the genus *Microsciurus* of other authors and ourselves.

We recognize 11 species of *Microsciurus*, three in Central America (*M. alfari*, *M. boquetensis*, and *M. venustus*) and eight in South America (*M. flaviventer*, *M. isthmius*, *M. mimulus*, *M. otinus*, *M. sabanillae*, *M. santanderensis*, *M. similis*, and *M. simonsi*). Only the South American species are detailed herein. Both Hall (1981) and Thorington et al. (2012) extended the range of *boquetensis* into extreme northwestern Colombia (as a subspecies of *M. mimulus*).

KEY TO THE SOUTH AMERICAN SPECIES OF *MICROSCIURUS*:

1. Postauricular patch present 2
- 1'. Postauricular patch absent 3
2. Dorsum brown, streaked with red
 *Microsciurus flaviventer*
- 2'. Dorsum dark brown, with mid-dorsal dark stripe
 *Microsciurus santanderensis*
3. Dorsum dark brown streaked with red to reddish orange tones 4
- 3'. Dorsum dark brown streaked with yellow to pale yellow tones 5
4. Venter orange, mixed with brown on belly
 *Microsciurus isthmius*
- 4'. Venter washed with red on throat and chest; mixed brown, dark gray, and red on belly *Microsciurus otinus*
5. Basal third of hairs of venter gray
 *Microsciurus mimulus*
- 5'. Hairs of ventrum without gray basal third 6

6. Venter with predominantly red tones 7
6. Ventral color variable, dark gray, pale gray, or pale yellow on throat, and dark gray to dark brown and yellow on chest and belly *Microsciurus simonsi*
7. Venter red to mixed red and gray on throat and chest, dark gray to dark brown punctuated with red on belly *Microsciurus similis*
- 7'. Venter brown washed with red on throat and chest, dark gray and red on belly *Microsciurus sabanillae*

Microsciurus flaviventer (Gray, 1867)

Amazon Dwarf Squirrel

SYNONYMS:

- Macroxus flaviventer* Gray, 1867:432; type locality "Brazil."
Sciurus aestuans: Alston, 1878:668 part (inclusion of *flaviventris* [= *flaviventer*]); not *aestuans* Linnaeus.
Macroxus flaviventris Alston, 1878:668; incorrect subsequent spelling of *Macroxus flaviventer* Gray.
Sciurus chrysurus: Thomas, 1893a:337; part; not *chrysurus* Pucheran.
Sciurus (Microsciurus) peruanus J. A. Allen, 1897c:115; type locality "Guayabamba, alt. 4000 feet," = Santa Rosa de Huayabamba, Amazonas, Peru.
Sciurus (Microsciurus) peruanus napi Thomas, 1900f:295; type locality "Mouth of Coca River, Upper Rio Napo," Orellana, Ecuador.
Sciurus peruanus: Ihering, 1904:420; name combination.
Microsciurus peruanus: E.-L. Trouessart, 1904:329; name combination.
Microsciurus peruanus napi: E.-L. Trouessart, 1904:329; name combination.
Microsciurus brevirostris J. A. Allen, 1914a:147; *nomen nudum*; indicated as a new species in a list but with no further description or reference to a description or illustration, likely a *lapsus calami* for *M. rubrirostris*, described in the same paper.
Microsciurus napi: J. A. Allen, 1914a:163; name combination.
Microsciurus rubrirostris J. A. Allen, 1914a:163; type locality "Chanchamayo, [Junín,] central Peru; altitude 2000 m."
Microsciurus florenciae J. A. Allen, 1914a:164; type locality "Florencia (altitude 1000 feet), Caquetá district, Colombia."
Microsciurus avunculus Thomas, 1914b:574; type locality "Gualaquiza; alt. 2500'," Morona-Santiago, Ecuador.
Microsciurus rubricollis Thomas, 1914b:574; incorrect subsequent spelling of *Microsciurus rubrirostris* J. A. Allen.
Microsciurus manarius Thomas, 1920f:275; type locality "Acajutuba, Rio Negro, near its mouth," Amazonas, Brazil.

Microsciurus flaviventer: Thomas, 1920f:275; first use of current name combination.

Microsciurus mannarius: O. M. O. Pinto, 1931:284; inadvertent subsequent spelling of *Microsciurus manarius* Thomas.

Microsciurus [(*Microsciurus*)] *napi*: Moore, 1959:203; name combination.

Microsciurus flaviventer flaviventer: Cabrera, 1961:355; name combination.

Microsciurus flaviventer napi: Cabrera, 1961:356; name combination.

Microsciurus flaviventer peruanus: Cabrera, 1961:357; name combination.

Microsciurus flaviventer rubrirostris: Cabrera, 1961:357; name combination.

DESCRIPTION: Adult mass 80–111 g (N=16); head and body length 124–170 mm (N=76), tail length 115–165 mm (N=79), hindfoot length 30–44 mm (N=76), and ear length 13–19 mm (N=65). Dorsal color brown streaked with red; most samples have yellowish to white postauricular patches; venter of mixed colors, with throat and chest yellowish orange and belly slightly darker.

DISTRIBUTION: *Microsciurus flaviventer* occurs widely in western Amazonia, from southern Colombia through eastern Ecuador, Peru, and northeastern Bolivia, then eastward to the Brazilian states of Amazonas, Acre, and Rondônia. It ranges in elevation from 100 to 1,500 m.

SELECTED LOCALITIES (Map 8): **BOLIVIA:** Pando, left bank Río Madre de Dios near Santa Elena (Salazar-Bravo, Yensen et al. 2002). **BRAZIL:** Acre, Oriente (= Seringal Oriente), near Taumaturgo, Rio Juruá (MZUSP 20351); Amazonas, Acajutuba, Rio Negro (type locality of *M. manarius* Thomas), Codajás, left bank Rio Solimões (MZUSP 4207), Eirunepé, left bank Rio Juruá (MZUSP 4621), Estirão do Equador, right bank Rio Javari (MZUSP 20350), Lago do Mapixi, east of Rio Purus (FMNH 38880), Manacapuru, Rio Solimões (BM 26.5.5.36), Paraná do Aiapuá, Rio Purus (BM 27.8.11.61); Rondônia, Cachoeira Nazaré, left bank Rio Ji-Paraná (MPEG 20826). **COLOMBIA:** Caquetá, Florencia (type locality of *M. florenciae* J. A. Allen); Putumayo, La Tagua, Tres Troncos, Río Caquetá (FMNH 71118); Vaupés, Río Vaupés, in front of Tahuapunto (AMNH 78625). **ECUADOR:** Loja, El Porotillo, San José (MNHN 1934/1210); Morona-Santiago, Mendez Sur, Oriente (MNHN 1987/338); Napo, Archidona (MNHN 1932/2876), San José abajo (AMNH 66792). **PERU:** Amazonas, Guayabamba (AMNH type locality of *Sciurus* (*Microsciurus*) *peruanus* J. A. Allen), near Huampani, Río Cenepa (MVZ 154929), 12 km E of La Peca Nueva (LSUMZ 21876); Cusco, Quincemil (FMNH 75210); Junin, Chanchamayo (type locality of *Microsciurus rubrirostris* J. A. Allen); Loreto, boca Río Curaray (AMNH

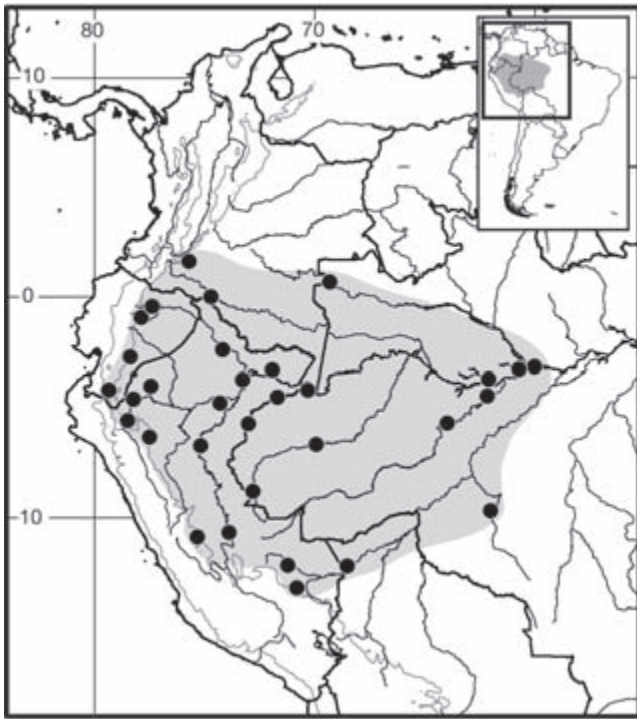

71606), Hacienda Santa Elena, ca. 35 km NE of Tingo Maria (LSUMZ 17720), left bank at mouth of Río Yaquerana, alto Río Yavari (FMNH 88991), Pebas. Río Amazonas (BM 28.7.21.74–78), Quebrada Pushaga, left bank Río Morona, alto Río Amazonas (FMNH 88984), San Fernando, left bank Río Yavari (FMNH 88990), Santa Rita, Iquitos (FMNH 87178), Sarayacu, Río Ucayali (AMNH 75279); Madre de Dios, Altamira, Manu (FMNH 98067); Ucayali, Lagarto, upper Río Ucayali (AMNH 76538).

SUBSPECIES: We regard *M. flaviventer* as monotypic (but see Remarks). Thorington and Hoffmann (2005) recognized seven subspecies, and Thorington et al. (2012) listed eight, three and four of which, respectively, we regard herein as full species.

NATURAL HISTORY: This species is found only in evergreen rainforest (Emmons and Feer 1997). Surprisingly, few ecological, reproductive, behavioral, or other natural history data are available for this wide-ranging squirrel. Emmons and Feer (1997) stated that individuals search actively over the trunks of large trees, on vines, and in tree-falls, apparently searching for insects, but that they also feed on substances scraped from tree bark such as gum (as was suggested by A. C. Smith [1999], who observed two solitary individuals moving through the subcanopy). Youlatos (1999) noted that individuals primarily used the subcanopy or canopy at heights above 5 m. Emmons and Feer (1997) recorded ball nests of leaves lined with fibers in the top of palms. Eisenberg (1989) reported a litter size of two offspring. Buitron-Jurado and Tobar (2007) reported on associations between individuals of this species and bird flocks, with squirrels actively searching for insects at heights of 2–10 m in the company of birds.

REMARKS: *Microsciurus flaviventer* has a wide distribution, from the eastern slopes of the Andes to central Amazonia. In this vast area, authors have distinguished several taxa, all listed in the previous synonymy. Our study of material deposited in many collections revealed that this variation is real, but we have not been able to decide how much of it is of taxonomic value. There are important differences in size (Andean forms such as *napi* are large, for example). And the upper third premolar may be present or absent in different samples. The fur is also longer and denser in Andean samples, and the color, especially that of ventral surfaces, varies regionally. We believe that recognizing a single species for the whole of the samples examined is, in this case, a decision of convenience. It is quite possible that further study of this material will reveal the existence of additional taxa, either to be recognized as valid subspecies or as full species.

Microsciurus flaviventer is one of the two Colombian species of the genus occurring east of the Andes, the other being *M. santanderensis*. Their known distributions are interrupted

Map 8 Selected localities for *Microsciurus flaviventer* (●). Contour line=2,000m.

by a large gap in the eastern Andes, a region well sampled for other squirrels, and this gap likely represents a true disjunction. Salazar-Bravo, Yensen et al. (2002) extended the range of this species into northern Bolivia, reidentifying a specimen that S. Anderson (1997:397) originally assigned to *Sciurus ignitus* (= *Notosciurus pucheranii* herein).

Microsciurus isthmius (E. W. Nelson, 1899)

Isthmian Dwarf Squirrel

SYNONYMS:

(?) *Sciurus aestuans* var. *rufoniger*: J. A. Allen, 1877:757; part.

Sciurus (Microsciurus) isthmius E. W. Nelson, 1899a:77; type locality "Truando River [= Río Truandó], [Chocó,] Colombia."

Microsciurus isthmius: E.-L. Trouessart, 1904:329; name combination.

Sciurus (Microsciurus) palmeri Thomas, 1909:234; type locality "Sipi, Rio Sipi, Rio San Juan, Chocó, western Colombia."

Microsciurus isthmius vivatus Goldman, 1912b:4; type locality "near Cana, (altitude 3,500 feet), in the Pirri range of mountains, [Darién,] eastern Panama."

Microsciurus isthmius isthmius: J. A. Allen, 1914a:57; name combination.

Microsciurus palmeri: J. A. Allen, 1914a:160; name combination.

Microsciurus [(Microsciurus)] isthmius: Moore, 1959:203; name combination.

Microsciurus flaviventer isthmius: Cabrera, 1961:355; part; name combination.

Microsciurus mimulus isthmius: Handley, 1966:778; part; name combination.

DESCRIPTION: Adult mass 120g (one female); head and body length 120–165 mm (N=41), tail length 98–150 mm (N=36), hindfoot length 32–45 mm (N=39), and ear length 10–19 mm (N=20). Dorsum dark brown to black, heavily speckled with yellow; postauricular patches absent; venter not sharply distinct from dorsum, generally orange in color but with mixture of orange and brown on belly.

DISTRIBUTION: *Microsciurus isthmius* occurs in rainforests west of the Andes in northwestern Colombia and adjacent Panama; in Colombia, it ranges in elevation from sea level to 800m.

SELECTED LOCALITIES (Map 9; South America only): COLOMBIA: Antioquia, Alto Bonito, upper Río Sucio (AMNH 37645), Murindó (FMNH 44855); Cauca, Río Saija (FMNH 90210); Chocó, Bagadó (AMNH 34132), Baudó (AMNH 33812), Nóvita, Río Tamaná (BM 9.7.17.26), Río Nuqui, base of Baudó Mts. (USNM 292132), Río Truandó (type locality of *Sciurus [Microsciurus] isthmius* E. W. Nelson), Sipí, Río Sipí, Río San Juan (type locality of *Sciurus [Microsciurus] palmeri* Thomas); Nariño, Buenavista (AMNH 34158), La Guayacana (FMNH 89518); Valle Del Cauca, Mechenquito (ROM 63217), Río Mechengue (FMNH 90201), San José (AMNH 31680).

SUBSPECIES: We treat *M. isthmius* as monotypic.

NATURAL HISTORY: Goldman (1920: 144) reported specimens from about 1,150m on Cerro Pirre, Darién, Panama (his *M. isthmius vivatus*), collected from lower branches or the trunks of trees in cloud forest.

REMARKS: Variation in the coat color is limited to the amount of black on the crown and rest of dorsum, which is slightly more pronounced in some specimens. J. A. Allen (1877:756–763) recognized five species of squirrels in South America, among which was *Sciurus aestuans* and in which he listed "aestuans" and "rufoniger" as two "varieties." These together encompassed all of the then-known smaller South American squirrels. This was a very broad concept, and even Allen himself (1914a, 1915) did not succeed in settling all the synonymic implications of his earlier lumping effort. E. W. Nelson (1899a:77–78) subsequently described *Sciurus (Microsciurus) isthmius* based on the material collected at the Río Truandó, Chocó, Colombia.

Cabrera (1961) proposed a new arrangement for the species level taxa in the genus *Microsciurus*, one in which *isthmius* E. W. Nelson and all other South American taxa

Map 9 Selected localities for *Microsciurus isthmius* (●). Range in Panama from Hall (1981). Contour line=2,000m.

were placed as subspecies, or synonyms, of a single species, namely, *M. flaviventer* (Gray). Cabrera's arrangement, however, was not uniformly followed (e.g., see Handley 1966; Hall 1981; and Honacki et al. 1982). Thorington et al. (2012) retained *isthmius* as a subspecies in their concept of *M. mimulus*.

Microsciurus mimulus (Thomas, 1898)

Western Dwarf Squirrel

SYNONYMS:

Sciurus (*Microsciurus*) *mimulus* Thomas, 1898f:266; type locality "Cachavi [= Cachabí], [Esmeraldas,] N. Ecuador, alt. 167 m."

Microsciurus mimulus: E.-L. Trouessart, 1904:329; first use of current name combination.

Microsciurus [(*Microsciurus*)] *mimulus*: Moore, 1959:203; name combination.

Microsciurus flaviventer mimulus: Cabrera, 1961:356; name combination.

DESCRIPTION: Head and body length 114–159 mm (N=17), tail length 90–125 mm (N=17), hindfoot length 30–38 mm (N=16), and ear length 13–16 mm (N=8). Dorsum dark brown to black, speckled with red or orange, sometimes with mid-dorsal dark stripe; postauricular

patches absent; venter not sharply distinct from dorsum, with color ranging from orange to pale yellow with basal third of hairs gray, with belly orange to pale yellow with some brown.

DISTRIBUTION: *Microsciurus mimulus* occurs in rainforests west of the Andes in northwestern Ecuador and southwestern Colombia, at elevations from sea level to 1,000 m.

SELECTED LOCALITIES (Map 10): COLOMBIA: Nariño, Barbacoas (AMNH 34159), La Guayacana (USNM 309028). ECUADOR: Esmeraldas, Cachabí (type locality of *Sciurus* [*Microsciurus*] *mimulus* Thomas), Carondelet (USNM 113310); Imbabura, Lita (BM 1.1.6.3).

SUBSPECIES: *Microsciurus mimulus* is monotypic.

NATURAL HISTORY: We have found no information about the natural history of this species.

REMARKS: Thomas (1898f:266–267) described *Sciurus* (*Microsciurus*) *mimulus* based on three specimens from northwestern Ecuador. This was the first name applied to dwarf squirrels from South America west of the Andes. Cabrera (1961:356) considered *M. flaviventer* to be the only South American species in the genus, using all other names either for subspecies (including *mimulus* Thomas) or as synonyms. As in many occasions throughout his catalog of South American mammals, this decision was based on the literature and on his own (limited, in this case) experience with the group. Handley (1966:777) considered *M. mimulus* to be a good species, and although he did not provide a reason for this decision, his arrangement

Map 10 Selected localities for *Microsciurus mimulus* (●). Contour line=2,000m.

met with wide acceptance and has been adopted by most subsequent authors (e.g., Emmons and Feer 1997; Thorington and Hoffmann 2005). Our concept of *M. mimulus* is more restricted geographically than that espoused by these authors, generally equivalent to that given by Thorington et al (2012:35) for the nominotypical form of their polytypic *M. mimulus*.

Some specimens from Nariño, Colombia, show individual variation in belly color, from almost black punctuated with orange to brown mixed with orange. The type series of *M. mimulus* and other specimens from northwestern Ecuador have a black mid-dorsal stripe continuing to the crown (Thomas 1898f; J. A. Allen 1914a). This character, however, while present in Ecuadorean material, is variable in specimens from farther to the north in Nariño, Colombia, with only one specimen in five presenting it fully.

Microsciurus otinus (Thomas, 1901)

White-eared Dwarf Squirrel

SYNONYMS:

Sciurus (Microsciurus) otinus Thomas, 1901c:193; type locality “Medellin, [Antioquia,] Colombia.”

Microsciurus otinus: E.-L. Trouessart, 1904:329; first use of current name combination.

Microsciurus flaviventer otinus: Cabrera, 1961:357; name combination.

DESCRIPTION: Head and body length 120–141 mm (N=15), tail length 95–132 mm (N=12), hindfoot length 35–39 mm (N=13), and ear length 11–16 mm (N=6). Dorsum dark brown streaked with pale yellow; postauricular patches absent but ears tipped with white; throat and chest washed with reddish orange, belly mixed brown, dark gray, and red; tail frosted whitish.

DISTRIBUTION: *Microsciurus otinus* occurs west of the Andes, in rainforests in the Colombian departments of Antioquia, Bolívar, and Córdoba, at elevations from 200 to 1,500 m.

SELECTED LOCALITIES (Map 11): COLOMBIA: Antioquia, La Tirana, 25 km S and 22 km W of Zaragoza (USNM 499515), Medellín (type locality of *Sciurus [Microsciurus] otinus* Thomas), Purí, above Caceres (FMNH 70046), Valdívía, right bank of lower Río Cauca (AMNH 37640); Bolívar, 15 mi W of Simiti, 6 mi above Santa Rosa (USNM 282755); Córdoba, Socorré, upper Río Sinú (FMNH 69034).

SUBSPECIES: *Microsciurus otinus* is monotypic.

NATURAL HISTORY: Rojas-Robles et al. (2008) reported on the importance of a species of *Microsciurus* in the short-distance dispersal (typically <50 m) of the large seeds of *Oenocarpus bataua*, a subcanopy and canopy palm in premontane humid forest. Because their study site

Map 11 Selected localities for *Microsciurus otinus* (●). Contour line = 2,000 m.

was on the Río Porce in the Cordillera Central of Antioquia department, Colombia, the taxon they studied was likely *M. otinus*, not *M. mimulus* as they originally reported. Otherwise, little information is available on this species.

REMARKS: Thomas (1901c) contrasted *M. otinus* with the geographically adjacent *M. isthmius*, noting that the two were similar in all external aspects except that *otinus* had white pinnae. Although we recognize *M. otinus* here as a valid species, this scheme needs to be tested by additional collecting and comparisons of existing specimens. Thorington et al. (2012) included *otinus* as a subspecies of *M. flaviventer*.

Microsciurus sabanillae Anthony, 1922

Sabanilla Dwarf Squirrel

SYNONYMS:

Microsciurus sabanillae Anthony, 1922: 2, type locality “Sabanilla, Prov. de Loja, Ecuador; altitude 5700 feet.”

Microsciurus flaviventer sabanillae: Cabrera, 1961:357; name combination.

DESCRIPTION: Head and body length 134–151 mm (N=3), tail length 140–148 mm (N=3), and hindfoot

length 40–42 mm (N=3). Dorsum dark brown to black streaked with red; postauricular patches absent; throat and chest washed with red, belly mixed dark gray and red.

DISTRIBUTION: *Microsciurus sabanillae* is known from Ecuador and adjacent northwestern Peru, in midelevation forests on the eastern Andean slope, at an elevational range from 600 to 1,750 m.

SELECTED LOCALITIES (Map 12): ECUADOR: Loja, Sabanilla, near Río Destrozo, a small tributary of Río Zamora (type locality of *Microsciurus sabanillae* Anthony); Napo, Río Napo (BM 54.406). PERU: Amazonas, Santa Rosa (AMNH 69237).

SUBSPECIES: *Microsciurus sabanillae* is monotypic.

NATURAL HISTORY: Nothing has been published on the ecology of this species.

REMARKS: Contra Thorington et al. (2012), we recognize *M. sabanillae* as a species distinct from *M. flaviventer* on the basis of details of ventral coloration, the lack of the postauricular patch, and partial sympatry. However, as in the case of *M. otinus*, this kind of variation has to be considered in the context of the highly variable *M. flaviventer*. The validity of supposed species-level taxa such as *M. sabanillae*, *M. otinus*, and several other forms here treated as synonyms of *M. flaviventer* requires additional study and further collecting efforts.

Map 12 Selected localities for *Microsciurus sabanillae* (●). Contour line = 2,000 m.

Microsciurus santanderensis
(Hernández-Camacho, 1957)

Santander Dwarf Squirrel

SYNONYMS:

Sciurus pucheranii santanderensis Hernández-Camacho, 1957: 219, type locality “Meseta de los Caballeros, 5 km NW of La Albania, San Vicente de Chururí [= San Vicente de Chucurí], Santander, Colombia.”

Microsciurus santanderensis: Hernández-Camacho, 1960: 360; first use of current name combination.

DESCRIPTION: (The following summarized from the original description, which was based on five specimens; no specimens seen by us.) Head and body length 133–160 mm, tail length 136–152 mm, hindfoot length 42–45 mm, and ear length 15–18 mm. Dorsum dark brown, with mid-dorsal black stripe; pale ochraceous postauricular patches present; venter with mixed colors, but predominantly light ochraceous salmon.

DISTRIBUTION: This species occurs in the rainforests on the western slopes of the eastern Cordillera, and from the right bank of the middle Río Magdalena, in the vicinity of Barrancabermeja and San Vicente de Chucurí, Santander, Colombia. Thorington et al. (2012) extended the range west and northwest to include the upper portion of the Cordillera Occidental, but did not cite specific localities.

SELECTED LOCALITIES (Map 13): COLOMBIA: Santander, Barancabermeja (Hernández-Camacho 1960), Meseta de Los Caballeros, 5 km NW of La Albania, San Vicente de Chucurí (type locality of *Sciurus pucheranii santanderensis* Hernández-Camacho).

SUBSPECIES: *Microsciurus santanderensis* is monotypic.

NATURAL HISTORY: Little is known about the ecology of this species, other than its distribution in humid forests in the low to mid elevations in the Cordillera de La Paz, Colombia (Hernández-Camacho 1960). Thorington et al. (2012) included marshlands and montane forests (at an elevational range of 2,700–3,800 m) among habitats this species occupies.

REMARKS: Variation in this species has not been studied beyond what Hernández-Camacho (1957, 1960) presented in his original description and subsequent redescription. It appears to be a valid species because it differs from similarly colored squirrels occurring east of the Andes. For example, *M. santanderensis* differs from *M. flaviventer* by the possession of a mid-dorsal dark stripe and from *M. sabanillae* by its possession of postauricular patches. Although originally described as a subspecies of *Notosciurus pucheranii* (as *Sciurus pucheranii santanderensis*) by Hernández-Camacho, he (1960) subsequently transferred *santanderensis* to *Microsciurus*, as more specimens became available.

Map 13 Selected localities for *Microsciurus santanderensis* (●). Contour line = 2,000 m.

The remarkable distribution gap between this species and *M. flaviventer*, which happens to be in a region of Colombia well sampled for squirrels in general, and this species' resemblance to *Notosciurus pucheranii*, may indicate that *M. santanderensis* does not belong in the genus *Microsciurus*. Because we have not seen specimens (and, so far as we know, neither has anyone but the author of the name), we keep it among the dwarf squirrels, but with this cautionary note.

Microsciurus similis (E. W. Nelson, 1899)

Chocó Dwarf Squirrel

SYNONYMS:

Sciurus (Microsciurus) similis E. W. Nelson, 1899a:78; type locality "near Cali, Cauca Valley, [Valle de Cauca,] Colombia (alt. 6000 ft.)."

Microsciurus similis: E.-L. Trouessart, 1904:329; first use of current name combination.

Sciurus (Microsciurus) similis fuscus Thomas, 1910d:503; type locality "Juntas, Rio San Juan. Alt. 400', Chocó, W. Colombia."

Microsciurus similis similis: J. A. Allen, 1914a:153; name combination.

Microsciurus similis fuscus: J. A. Allen, 1914a:154; name combination.

Microsciurus [(Microsciurus)] similis: Moore, 1959:203; name combination.

Microsciurus flaviventer similis: Cabrera, 1961:357; name combination.

Microsciurus alfari fuscus: Handley, 1966:777; name combination.

DESCRIPTION: Head and body length 112–147 mm (N=23), tail length 82–133 mm (N=17), hindfoot length 28–38 mm (N=21), and ear length 8–16 mm (N=17). Dorsum dark brown to black punctuated with red; postauricular patches absent; venter not sharply distinct from the dorsum, colored red to mixed red and dark gray on throat and chest but dark gray to dark brown heavily streaked with red on belly.

DISTRIBUTION: *Microsciurus similis* occurs in rainforests west of the Andes in western Colombia, across an elevational range from 130 to 2,200 m.

SELECTED LOCALITIES (Map 14): COLOMBIA: Antioquia, Alto Bonito, upper Río Sucio (AMNH 37643); Cauca, Munchique (FMNH 86788), Río Munchique (FMNH 90200); Chocó, Baudó (AMNH 33184, 33186), Juntas de Tamaná (type locality of *Sciurus [Microsciurus] similis fuscus* Thomas), Río Jurubidá, Baudó Mts.

Map 14 Selected localities for *Microsciurus similis* in South America (●). Contour line = 2,000 m.

(USNM 292134), Río San Juan (BM 10.7.16.1); Nariño, Ricaurte (USNM 309027); Risaralda, Siató, Río Siató, San Juan (FMNH 18877); Valle del Cauca, Albán (= Salencio) (AMNH 32852), Cali (BM 99.9.6.56).

SUBSPECIES: We treat *M. similis* as monotypic, although Thomas (1910d) differentiated specimens from Chocó in western Colombia as *M. s. fuscus*.

NATURAL HISTORY: We found no information about the natural history of this species.

REMARKS: *Microsciurus similis*, on the scale of Maps 9 and 14, appears to broadly overlap the range of *M. isthmus*. The two species, however, occupy separate elevational ranges in the Colombian Andes, with limited overlap. The lowest elevation recorded for *M. similis* is 150m, and the highest for *M. isthmus* is 800m. This species is also sympatric with *M. mimulus* in Nariño department in southwestern Colombia.

Microsciurus simonsi (Thomas, 1900)

Simons's Dwarf Squirrel

SYNONYMS:

Sciurus (Microsciurus) simonsi Thomas, 1900f:294; type locality "Porvenir, near Zaparal, Province of Bolívar, Ecuador. Altitude 1500m."

Microsciurus simonsi: E.-L. Trouessart, 1904:329; first use of current name combination.

Microsciurus similis fuscus: Lönnberg, 1913:26; not *fuscus* Thomas.

Microsciurus flaviventer simonsi: Cabrera, 1961:358; name combination.

DESCRIPTION: Head and body length 126–154 mm (N=10), tail length 104–124 mm (N=10), hindfoot length 32–37 mm (N=11), and ear length 14–16 mm (N=11). Dorsum dark brown streaked with orange; postauricular patches absent; ventrum mixture of dark gray, pale gray, pale yellow on throat, dark gray to dark brown and yellow on chest and belly.

DISTRIBUTION: *Microsciurus simonsi* occurs west of the Andes in the Ecuadorean provinces of Bolívar and Pichincha, at elevations from 250 to 1,500m.

SELECTED LOCALITIES (Map 15): ECUADOR: Bolívar, Porvenir (type locality of *Sciurus [Microsciurus] simonsi* Thomas); Pichincha, Ila, 36 mi SW of Santo Domingo (BM 15.1.1.25), Mindo, Río Blanco (BM 13.10.24.36), Santo Domingo (BM 15.1.1.23–24).

SUBSPECIES: *Microsciurus simonsi* is monotypic.

NATURAL HISTORY: Nothing has been published on the ecology or behavior of this species.

REMARKS: *Microsciurus simonsi* is the southernmost species of the genus west of the Andes. Each of the four trans-Andean species can be distinguished mainly by its ventral coloration and the color of the subterminal band of dorsal guard hairs. Thorington et al. (2012) in-

Map 15 Selected localities for *Microsciurus simonsi* (●). Contour line=2,000m.

cluded *simonsi* as a subspecies of a highly polytypic *M. flaviventer*.

Genus *Notosciurus* J. A. Allen, 1914

Notosciurus is a genus of medium-sized Central and South American squirrels occurring from eastern Costa Rica through Colombia, Venezuela, Ecuador, Peru, western Amazonian Brazil, and Bolivia, to northernmost Argentina. In South America, its distribution is mostly associated with the Andean Cordillera, but in western Colombia, eastern Peru, and neighboring areas of Brazil, it is also found in lowland evergreen forests. The distribution of the genus is largely parapatric to that of *Guerlinguetus*, but both genera may be found living together at the margins of their ranges, particularly in the Marañón, Solimões, and Madeira river basins of Amazonia and possibly also in northwestern Mato Grosso state in Brazil.

Species of *Notosciurus* can be distinguished from all other South American squirrels except for *Guerlinguetus* by their size (larger than species of *Microsciurus*, *Sciurillus*, and *Syntheosciurus*, but smaller than those of *Hadrosociurus* and *Simosciurus*). Compared with the similarly sized *Guerlinguetus*, *Notosciurus* possess three pairs of mammae instead of four and typically have orange postauricular patches, which are generally lacking in *Guerlinguetus*. *Notosciurus* is highly variable in size and mass, varying from 136–418.5 g (N=31 adults). The head and body length range from 151–262 mm (N=469), tail length from 134.5–265 mm (N=459), hindfoot length from 34–65 mm (N=455), and

ear length from 15–32 mm (N=359). The skull has the orbitotemporal fossa equally divided by a well-developed postorbital process, and an upper second molar with two parallel, buccolingual crests. These crests are obliquely oriented relative to the anteroposterior axis of the skull.

We recognize two polytypic species: *Notosciurus granatensis* with six subspecies (five in South America), and *N. pucheranii* with four subspecies. Our concept of both species is considerably different from that of previous authors, most recently Thorington et al. (2012). These authorities, for example, recognized 32 subspecies for *granatensis*, 29 in South America. They also treated the trans- and cis-Andean populations of our *N. pucheranii* as separate species.

SYNONYMS:

Sciurus: Pucheran, 1845:336; part (description of *rufoniger* and *chrysurus*); not *Sciurus* Linnaeus, 1758.

Funambulus: Fitzinger, 1867a:487; part (listing of *pucheranii* and *chrysurus*); not *Funambulus* Lesson, 1835.

Macroxus: Gray, 1867:429; part (description of *ignitus*); not *Macroxus* F. Cuvier, 1823.

Sciurus (*Guerlinguetus*): J. A. Allen, 1899b:217; part (description of *quebradensis*); not *Guerlinguetus* Gray, 1821.

Notosciurus J. A. Allen, 1914d:585; type species *Notosciurus rhoadsi* J. A. Allen, 1914, by original designation.

Guerlinguetus: J. A. Allen, 1914d:587; part (description of *pucheranii salentensis*, *hoffmanni quindianus*, *hoffmanni manavi*, and *griseimembra*); not *Guerlinguetus* Gray, 1821.

Leptosciurus J. A. Allen, 1915a:199; type species *Sciurus rufoniger* Pucheran, 1845 (preoccupied by *Sciurus rufonigra* Gray, 1842:263, replaced by *Funambulus pucheranii* Fitzinger, 1867).

Mesosciurus J. A. Allen, 1915a:212; type species *Sciurus aestuans* var. *hoffmanni* Peters, 1864, by original designation.

Histrosciurus J. A. Allen, 1915a:213, 236; as subgenus; type species *Sciurus gerrardi* Gray, 1861, by original designation (p. 236).

Mesosciurus (*Mesosciurus*): J. A. Allen; 1915a:216; name combination.

Guerlinguetus (*Mesosciurus*): J. A. Allen; 1915a:228; name combination, but *lapsus calami*.

Mesosciurus (*Histrosciurus*): J. A. Allen; 1915a:236; name combination.

Sciurus (*Mesosciurus*): Thomas, 1921k:609; name combination.

Sciurus (*Leptosciurus*): Anthony, 1923a:5; name combination.

Sciurus [(*Notosciurus*)]: Ellerman, 1940:344; name combination.

REMARKS: The midsized South American squirrels with three pairs of mammae were organized with all other

South American species until J. A. Allen (1915a) created new genera to accommodate the several groups of apparently related species he was able to recognize. Among the new genera were *Leptosciurus* (type species *Sciurus rufoniger* Pucheran, 1845) and *Mesosciurus* (type species *Sciurus aestuan* var. *hoffmanni* Peters, 1864), the latter with two subgenera: the nominotypical one and *Histrosciurus* (type species *Sciurus gerrardi* Gray). Allen did not compare *Leptosciurus* and *Mesosciurus* with each other, except in his key for the genera; in his characterizations, he chose to compare both only to *Guerlinguetus*, and quite superficially. Furthermore, he distinguished between *Leptosciurus* and *Mesosciurus* only on the basis of size, which overlapped slightly in his own key (J. A. Allen 1915a:187).

However, a year earlier, J. A. Allen (1914d) had described a new genus and species based on a single specimen from Ecuador, which he named *Notosciurus rhoadsi*. We have not seen the holotype of this taxon, but Hershkovitz (1947:8) identified it as a young specimen of *Sciurus hoffmanni soederstroemi* Stone. Thorington and Hoffmann (2005:761) also listed Allen's *rhoadsi* as a synonym of *soederstroemi* Stone, which they regarded as a subspecies of a polytypic *Sciurus granatensis* Humboldt. These authors also included *chrysuos* Pucheran and *hoffmanni* Peters as additional subspecies of *S. granatensis*. Because we consider *soederstroemi* Stone to be a synonym of *chrysuos* Pucheran and we treat *granatensis* Humboldt as a species in the genus we discuss here, *Notosciurus* J. A. Allen takes priority over *Leptosciurus* J. A. Allen as the generic name for these squirrels.

We do not recognize subgenera in *Notosciurus*, as all species share the presence of three pairs of mammae; additionally, most of the included species and subspecies possess postauricular patches, both characteristics that distinguish our concept of *Notosciurus* from *Guerlinguetus*. These two genera, as here recognized, are largely parapatric, with marginal sympatry in parts of western Brazil and eastern Peru. See the discussion on the validity of the presently recognized supraspecific groups in the family account.

KEY TO THE SPECIES OF *NOTOSCIURUS*:

1. Size smaller, head and body length approximately 150–210 mm; ventral hairs of various colors but usually with a gray base (except in Bolivia and Argentina) *Notosciurus pucheranii*
- 1'. Size larger (but overlapping; in eastern Andean Colombia, where both species occur in sympatry [*N. g. chrysuos* and *N. p. pucheranii*], they diverge greatly in size), head and body length approximately 170–265 mm; ventral hairs of various colors but usually of a single color throughout (species does not occur in Bolivia or Argentina) *Notosciurus granatensis*

Notosciurus granatensis (Humboldt, 1811)

Red-tailed Squirrel

SYNONYMS: See under subspecies.

DESCRIPTION: Highly variable species, with head and body length 169–262 mm (N=348 adult specimens), tail length 145–265 mm (N=342), hindfoot length 40–65 mm (N=330), ear length 17–32 mm (N=250), and mass 190–420 g (N=25). We briefly describe each subspecies following its synonymy.

DISTRIBUTION: This species ranges from Costa Rica to Colombia, Ecuador, and Venezuela. In South America, *N. granatensis* is essentially linked to the Andes, but may also occur in adjacent lowlands and coastal areas at sea level.

SELECTED LOCALITIES (Map 16): COLOMBIA: Antioquia, Puerto Valdivia (type locality of *Mesososciurus (Histriososciurus) gerrardi valdiviae* J. A. Allen), Sonsón (USNM 239942); Bolívar, Cartagena (type locality of *Sciurus granatensis* Humboldt); Cauca, Cocal (type locality of *Sciurus milleri* J. A. Allen); Cesar, Colonia Agrícola de Caracolicito (type locality of *Sciurus granatensis agricolae* Hershkovitz); Chocó, Baudó (type locality of *Mesososciurus (Histriososciurus) gerrardi baudensis* J. A. Allen), Río Salaquí (type locality of *Sciurus gerrardi salaquensis* J. A. Allen); Córdoba, Catival, upper Río San Jorge (FMNH 69008), Socorré, upper Río Sinú (FMNH 68987); Cundinamarca, Bogotá (type locality of *Sciurus chrysuros* Pucheran and *Sciurus hyporrhodus* Gray); Huila, La Palma (AMNH 33669); La Guajira, Laguna de Junco (USNM 271318), Puerto Estrela (USNM 216696); Magdalena, Don Diego (AMNH 23317); Meta, Villavicencio (USNM 241350); Nariño, Guayacana (USNM 309034); Norte de Santander, El Guayabal, 10 mi from San José de Cucuta (type locality of *Sciurus gerrardi cucutae* J. A. Allen), San Calixto, Río Tarra (type locality of *Sciurus granatensis tarrae* Hershkovitz); Valle del Cauca, Río Frio, Río Cauca (type locality of *Guerlinguetus hoffmanni quindianus* J. A. Allen), Río Raposo, (USNM 334696). ECUADOR: Carchi, Atal, 5 mi SE of San Gabriel (type locality of *Sciurus candelensis carchensis* W. P. Harris and Hershkovitz); Chimborazo, Chunchi (type locality of *Notosciurus rhoadsi* J. A. Allen); Esmeraldas, Panbilar (USNM 113314); Manabí, Manaví, Río de Oro (type locality of *Guerlinguetus hoffmanni manavi* J. A. Allen); Napo, Sumaco abajo (AMNH 68159); Pichincha, Mt. Pichincha (type locality of *Sciurus hoffmanni soederstroemi* Stone). TRINIDAD AND TOBAGO: Tobago, Runnemedede (USNM 461886); Trinidad, Carenage (AMNH 14008), Diego Martin (AMNH 188365). VENEZUELA: Anzoátegui, Cantaura (USNM 283879); Apure, Nulita, 3 km N of Nula (USNM 442011), Tama (type locality of *Sciurus griseogena tamae* Osgood); Barinas, Hato Corozal, Caño Tutumito, Arismendi (type locality of *Sciurus [Guerlinguetus] granatensis llanensis* Mondolfi

and Boher); Carabobo, Urama, E of Yaracuy (AMNH 130289); Guárico, Guárico (AMNH 32877); Mérida, Es-corial, Sierra de Mérida (type locality of *Sciurus griseogena meridensis* Thomas); Monagas, near San Agustín, 2 km N and 4 km E of Caripe (USNM 409776); Nueva Esparta, El Valle, Isla de Margarita (type locality of *Sciurus nesaesus* G. M. Allen); Sucre, Cristobal Colón (AMNH 36156), Nevera (AMNH 69911); Vargas, Galiparé, Cerro del Ávila, near Caracas (type locality of *Sciurus griseogena klagesi* Thomas); Zulia, El Panorama, Río Aurare (type locality of *Sciurus granatensis maracaibensis* Hershkovitz), Hacienda Platanal, 18 km N and 49 km W of Maracaibo (USNM 442017), Novita, 3.1 km S and 19 km W of Machiquos (USNM 442013).

SUBSPECIES: We recognize six subspecies of *N. granatensis*, with five in South America. A sixth subspecies, *N. g. hoffmanni*, occurs only in Costa Rica and western Panama. For comparison with South American taxa, specimens of *hoffmanni* possess postauricular patches, a reddish dorsum streaked with orange or yellow but without a dark mid-dorsal area, an orange venter with gray-based hairs, and a homogeneously colored tail fringed and/or streaked with orange.

N. g. chapmani (J. A. Allen, 1899)

SYNONYMS:

Sciurus chapmani J. A. Allen, 1899a:16, type locality “Caparo, Trinidad,” Trinidad and Tobago.

Sciurus (Guerlinguetus) aestuans quebradensis J. A. Allen, 1899b:217, type locality “Quebrada Secca [= Quebrada Secca, = Villarroel], [Sucre,] Venezuela.”

Sciurus (Guerlinguetus) chapmanni E.-L. Trouessart, 1904: 327; name combination, and incorrect subsequent spelling of *Sciurus chapmani* J. A. Allen.

Sciurus tobagensis Osgood, 1910:27, type locality “Tobago Island, Caribbean Sea,” Trinidad and Tobago.

Mesososciurus (Mesososciurus) chapmani: J. A. Allen, 1915a: 230; name combination.

Mesososciurus (Mesososciurus) chapmani tobagensis: J. A. Allen, 1915a:232; name combination.

Sciurus [(Guerlinguetus)] chapmani chapmani: Ellerman, 1940:341; name combination.

Sciurus [(Guerlinguetus)] chapmani tobagensis: Ellerman, 1940:341; name combination.

Sciurus granatensis chapmani: Hershkovitz, 1947:37; name combination.

Sciurus granatensis tobagensis: Hershkovitz, 1947:37; name combination.

Sciurus (Guerlinguetus) granatensis chapmani: Goodwin, 1953:277; name combination.

Sciurus (Guerlinguetus) granatensis: Eisenberg, 1989:331; part; name combination.

Notosciurus g. chapmani occurs on the islands of Trinidad and Tobago as well as neighboring coastal Venezuela, including both lowlands and coastal ranges. Specimens on the islands average slightly smaller than those on the mainland but are otherwise indistinguishable. Top of head and dorsum dark brown streaked with orange or pale orange; postauricular patches absent (the only case of this, along with *N. g. morulus*, in the genus); venter differently colored than sides, being washed with orange to reddish orange on the throat, chest, and belly (hairs with a short, gray base and orange on the remainder); and tail colored like the dorsum, but the distal tips of hairs are washed with red.

N. g. chrysueros (Pucheran, 1845)

SYNONYMS:

- Sciurus chrysueros* Pucheran, 1845:337, type locality "Columbia (Santa-Fé de Bogota)," Cundinamarca, Colombia.
- Sciurus chrysurus*: Wagner, 1850:272; unnecessary Latinization of *chrysueros* Pucheran.
- Sciurus hyporrhodus* Gray, 1867:419; type locality "Santa Fé de Bogotá," Cundinamarca, Colombia.
- Macroxus griseogena* Gray, 1867:429; type locality given as a number of localities from Mexico to Colombia and Venezuela.
- [*Funambulus*] *chrysurus*: Fitzinger, 1867a:487; name combination, and incorrect Latinization of *chrysueros* Pucheran.
- Sciurus griseogenys* Alston, 1878:667; unjustified emendation of *griseogena* Gray.
- Sciurus rufo-niger*: Alston, 1878:669; part.
- Sciurus aestuans*: Thomas, 1880:400; part; not *aestuans* Linnaeus, 1766.
- Macroxus chrysueros*: E.-L. Trouessart, 1897:427; part; name combination.
- Sciurus griseogena*: W. Robinson and Lyon, 1901:144; name combination.
- Sciurus griseogena meridensis* Thomas, 1901c:192; type locality "Escorial, Sierra de Merida. Alt. 2500 m," Mérida, Venezuela.
- Sciurus griseogena tamae* Osgood, 1912:48; type locality "Paramo de Tama, [Norte de Santander,] Colombia. Alt. 6000–7000 ft."
- Sciurus hoffmanni*: J. A. Allen, 1912:90; part; name combination.
- Notosciurus rhoadsi* J. A. Allen, 1914d:585; type locality "Pagma Forest, Chunchi (altitude 6300 feet), [Chimborazo,] Ecuador."
- Sciurus hoffmanni söderströmi* Stone, 1914:14; type locality "Mt. Pichincha," Pichincha, Ecuador.
- Sciurus griseogena klagesi* Thomas, 1914d:240; type locality "Galifaré, Cerro del Avila [= Pico Ávila], near Caracas, [Vargas,] Venezuela. Alt. 6500'."
- Guerlinguetus griseimembra* J. A. Allen, 1914d:589; type locality "Buena Vista (altitude 4500 ft.), eastern slope of Eastern Andes, about 50 miles southeast of Bogotá," Meta, Colombia.
- Guerlinguetus candelensis* J. A. Allen, 1914d:590; type locality "La Candela (altitude 6500 ft.), near San Agustín, Huila, Colombia."
- Sciurus gerrardi cucutae* J. A. Allen, 1914d:592; type locality "El Guayabal, 10 miles north of San José de Cucuta, [Norte de Santander,] Colombia (near Venezuela boundary)."
- Mesosciurus hoffmanni hoffmanni*: J. A. Allen, 1915a:216; part; name combination.
- Mesosciurus (Mesosciurus) hoffmanni hyporrhodus*: J. A. Allen, 1915a:223; name combination.
- Mesosciurus (Mesosciurus) griseogena griseogena*: J. A. Allen, 1915a:226; name combination.
- Guerlinguetus (Mesosciurus) griseogena meridensis*: J. A. Allen, 1915a:228; name combination.
- Mesosciurus (Mesosciurus) griseimembra*: J. A. Allen, 1915a:233; name combination.
- Mesosciurus (Mesosciurus) candelensis* J. A. Allen, 1915a:235; name combination and incorrect subsequent spelling of *Guerlinguetus candelensis* J. A. Allen.
- Mesosciurus (Histriosciurus) gerrardi cucutae*: J. A. Allen, 1915a:247; name combination.
- Mesosciurus ferminae* Cabrera, 1917:49; type locality "Baeza (Ecuador oriental)," Napo, Ecuador.
- Mesosciurus candelensis sumaco* Cabrera, 1917:51; type locality "San José, al pie del monte Sumaco, [Napo,] Ecuador oriental."
- Sciurus gerrardi imbaburae* W. P. Harris and Hershkovitz, 1938:1; type locality "Peñaherrera (Intag) western subtropical part of Imbabura Province, Ecuador; altitude, approximately 1500 meters."
- Sciurus candelensis carchensis* W. P. Harris and Hershkovitz, 1938:3; type locality "Atal, about five miles southeast of San Gabriel, Montúfar, Carchi Province, Ecuador, in the cold temperate rainforests of the western slopes of the eastern cordillera of the Andes. Altitude about 2900 meters."
- Mesosciurus griseogena meridensis*: Cabrera and Yepes, 1940:194; name combination.
- Mesosciurus caudeleusis carchensis*: Cabrera and Yepes, 1940:194; name combination and incorrect subsequent spelling of *Guerlinguetus candelensis* J. A. Allen.
- Mesosciurus gerrardi imbaburae*: Cabrera and Yepes, 1940:195; name combination.
- Mesosciurus gerrardi cucutae*: Cabrera and Yepes, 1940:195; name combination.

- Sciurus* (*Guerlinguetus*) *granatensis tarrae*: Cabrera, 1961:369; name combination.
- Sciurus* (*Guerlinguetus*) *granatensis llanensis* Mondolfi and Boher, 1984:312, type locality "Hato Corozal, Caño Tutumito, Arismendi, Barinas, Venezuela."
- Sciurus* (*Guerlinguetus*) *granatensis*: Eisenberg, 1989:331, part; name combination.
- Sciurus* (*Guerlinguetus*) *granatensis soederstroemi*: Thorington and Hoffmann, 2005:761; name combination; required replacement of diacritical marks used in original description (ICZN 1999:Art. 32.5.2.1).
- Notosciurus g. chrysueros* is the name for the taxon occurring on the eastern slopes of the Andes, from Venezuela to Ecuador. Crown of the head brown to dark brown streaked with pale yellow to dark red; dorsum uniformly colored brown to dark brown streaked with yellow, grayish yellow to red, sometimes with black on midline; pale orange but inconspicuous postauricular patches present; venter reddish orange on the throat, chest, and belly, with white spots on the chest in some specimens. Tail colored like dorsum on its proximal quarter to third, and washed with reddish orange succeeded by a black tip on some specimens; in others, tail may have an intermediate section washed with red and a black distal portion.
- N. g. granatensis* (Humboldt, 1811)
- SYNONYMS:
- Sciurus granatensis* Humboldt, 1811:8, 13, plate III; type locality "Carthagène [= Cartagena]," Bolívar, Colombia.

Sciurus (Guerlinguetus) granatensis norosiensis: Thorington and Hoffmann, 2005:761; name combination.

Sciurus (Guerlinguetus) granatensis variabilis: Thorington and Hoffmann, 2005:761; name combination.

The nominotypical subspecies is parapatric to *N. g. morulus*, occurring at high elevations in the western Andes of Colombia to the Sierra de Santa Marta, and across the central and eastern cordilleras of Colombia to western Venezuela. This subspecies also extends into the intervening lowlands, including the area around Lake Maracaibo. Average size larger than for all other subspecies; postauricular patches present; dorsal color an “agouti” pattern, mostly brown streaked with orange or red, or uniformly completely orange; posterior dorsum may exhibit dark patterning, ranging from a spot near the base of the tail to larger area; dorsal orange or red tones may appear merely as a scapular patch or extend farther posteriorly. Ventral color ranges from entirely red to orange with white spots (of varying sizes) on chest and belly to entirely white; white ventral spots may also extend as continuous lines across body at midventer. Entirely orange or red individuals with a white venter predominate in the northern parts of the range, on the slopes of the Serra de Santa Marta; the “agouti” dorsal pattern with a mostly or entirely red venter is most common in southern samples.

N. g. morulus (Bangs, 1900)

SYNONYMS:

Sciurus variabilis morulus Bangs, 1900b:43, type locality “Loma del Leon, Panama.”

Sciurus versicolor Thomas, 1900g:385: type locality “Cachabi [= Cachabí], Prov. Esmeraldas, N Ecuador, alt. 160m.”

Sciurus milleri J. A. Allen, 1912:91; type locality “Cocal (altitude 4000 ft.),” Cauca, Colombia.

Sciurus variabilis choco Goldman, 1913:4, type locality “Cana (altitude 3500 feet). [Darién,] Eastern Panama.”

Guerlinguetus hoffmanni manavi J. A. Allen, 1914d:589, type locality “Manavi [= Manabí] (Rio de Oro, near sea-level), Ecuador,” [= sea port of Bahía de Caráquez, Manabí province; see Paynter 1993:15].

Sciurus gerrardi salaquensis J. A. Allen, 1914d:592, type locality “Rio Salaqui, [Chocó,] northwestern Colombia.”

Mesosciurus (Mesosciurus) hoffmanni manavi: J. A. Allen, 1915a:221; name combination.

Mesosciurus (Histriosciurus) gerrardi milleri: J. A. Allen, 1915a:241; name combination.

Mesosciurus (Histriosciurus) gerrardi versicolor: J. A. Allen, 1915a:242; name combination.

Mesosciurus (Histriosciurus) gerrardi choco: J. A. Allen, 1915a:244; name combination.

Mesosciurus (Histriosciurus) gerrardi salaquensis: J. A. Allen, 1915a:245; name combination.

Mesosciurus (Histriosciurus) gerrardi baudensis J. A. Allen, 1915a:308; type locality “Baudo [= Serranía de Baudó] (alt. 3500 ft.), [Chocó,] coast region of western Colombia.”

Sciurus (Guerlinguetus) variabilis choco: Elliot, 1917:19; name combination.

Sciurus (Guerlinguetus) gerrardi choco: Goldman, 1920:139; name combination.

Sciurus (Guerlinguetus) gerrardi morulus: Goldman, 1920:140; name combination.

Sciurus gerrardi inconstans Osgood, 1921:40, replacement name for *Sciurus versicolor* Thomas, 1900, said to be preoccupied by *Sciurus versicolor* Zimmermann, 1777; Hershkovitz (1947:36) stated that Zimmermann’s name was invalid, but without specifying a reason.

Sciurus (Mesosciurus) gerrardi leonis Lawrence, 1933:369, replacement name for *Sciurus milleri* J. A. Allen, 1912, preoccupied by *Sciurus epomophorus milleri* H. C. Robinson and Wroughton, 1911.

Sciurus [(Guerlinguetus)] hoffmanni manavi: Ellerman, 1940:340; name combination.

Sciurus [(Guerlinguetus)] gerrardi leonis: Ellerman, 1940:341; name combination.

Sciurus [(Guerlinguetus)] gerrardi inconstans: Ellerman, 1940:341; name combination.

Sciurus [(Guerlinguetus)] gerrardi morulus: Ellerman, 1940:341; name combination.

Sciurus [(Guerlinguetus)] gerrardi choco: Ellerman, 1940:341; name combination.

Sciurus [(Guerlinguetus)] gerrardi salaquensis: Ellerman, 1940:342; name combination.

Sciurus [(*Guerlinguetus*)] *gerrardi baudensis*: Ellerman, 1940:342; name combination.

Sciurus granatensis salaquensis: Hershkovitz, 1947:35; name combination.

Sciurus granatensis leonis: Hershkovitz, 1947:36; name combination.

Sciurus granatensis versicolor: Hershkovitz, 1947:36; name combination.

Sciurus granatensis manavi: Hershkovitz, 1947:36; name combination.

Sciurus (*Guerlinguetus*) *granatensis salaquensis*: Goodwin, 1953:275.

Sciurus (*Guerlinguetus*) *granatensis leonis*: Goodwin, 1953:276; name combination.

Sciurus (*Guerlinguetus*) *granatensis manavi*: Goodwin, 1953:276; name combination.

Sciurus (*Guerlinguetus*) *granatensis choco*: G. S. Miller and Kellogg, 1955:257; name combination.

Sciurus (*Guerlinguetus*) *granatensis morulus*: G. S. Miller and Kellogg, 1955:257; name combination.

Sciurus (*Guerlinguetus*) *granatensis versicolor*: Cabrera, 1961:370; name combination.

Notosciurus g. morulus is the oldest available name for the subspecies occurring from the Panama Canal Zone to western Colombia and northwestern Ecuador. Individuals lack postauricular patches over most of this range, except in Ecuador, where traces of a patch are present on specimens. The mid-dorsum slightly to more strongly darker than in other races, a characteristic more pronounced in Colombian specimens than those of central and eastern Panama; venter red, with hairs lacking a grayish base; tail usually divided into three differently colored sections: a dark proximal portion, a large middle red section, and a dark (black) distal terminus.

N. g. nesaeus (G. M. Allen, 1902)

SYNONYMS:

Sciurus nesaeus G. M. Allen, 1902:93; type locality "El Valle, Margarita Island, [Nueva Esparta,] Venezuela."

Mesosciurus (*Mesosciurus*) *nesaeus*: J. A. Allen, 1915a:233; name combination.

Sciurus [(*Guerlinguetus*)] *nesaeus*: Ellerman, 1940:341; name combination.

Sciurus granatensis nesaeus: Hershkovitz, 1947:37; name combination.

Sciurus (*Guerlinguetus*) *granatensis nesaeus*: Cabrera, 1961:367; name combination.

Notosciurus g. nesaeus is an insular subspecies known only from Isla Margarita, Venezuela. It is easily distinguished from mainland samples, but we have decided not to recognize it as a distinct species on the same grounds as Hershkovitz (1947); that is, the color pattern fits a general geograph-

ical trend. Head and back uniformly colored brown, heavily streaked with orange; inconspicuous orange postauricular patches present; ventral coloration sharply set off from the dorsolateral coloration, with uniform reddish orange throat, chest, and belly (hairs are entirely reddish orange). Coloration of tail variable, similar to that of dorsum on its proximal quarter to third but washed with reddish orange distally.

NATURAL HISTORY: Nitikman (1985) summarized the data on form and function, ontogeny and reproduction, ecology, behavior, and genetics of *N. granatensis*, with most studies focused on Panamanian populations (e.g., Heaney 1978; Glanz et al. 1982; Glanz 1984).

REMARKS: Samples referred to *N. granatensis* range from Costa Rica to Panama, and then south to Andean South America, from western Venezuela to northern Ecuador. As the synonymies for each subspecies indicate, dozens of names have been proposed for squirrels from this vast area (Cabrera 1961, for example, listed 28 subspecies in his concept of this polytypic species). One could easily conclude that the diversity of squirrels in this region is extensive simply by reading the original descriptions of these taxa. Indeed, based on our own examination of hundreds of specimens deposited in the major U.S. and European museums as well as most of the type material, both the nongeographic and geographic variation exhibited by these samples is staggering. In fact, many subspecies have been described from localities very close to one another, without even a separation by elevation or river basin. Hershkovitz (1947) personally collected dozens of specimens in Colombia and described several new subspecies, some of them with identical provenance! Other authors have frequently described series in which different

Map 16 Selected localities for *Notosciurus granatensis* (●). Contour line = 2,000 m.

specimens from the same locality could be assigned to separate subspecies.

Here, we offer a brief summary of geographic trends expressed in *N. granatensis*, and we attach names that we believe best represent the major axes of this variation. In so doing, we reduce the number of subspecies to only five for the South American part of the species' distribution. The description we provide above for each one can, with benevolence, be termed "impressionistic." However, we cannot accept a single name for all such squirrels at the risk of obscuring a most baffling but manifest evolutionary phenomenon. In fact, Hershkovitz (pers. comm. to MdV) first devised his "metachromism theory" (Hershkovitz 1968, 1970a) because he wanted to explain the color variation he saw in Colombian squirrels. Keeping at least some of the plethora of names as "valid" will, we hope, encourage researchers to study these squirrels further and discover how and why they vary so much.

Notosciurus pucheranii (Fitzinger, 1867)

Pucheran's Squirrel, Ardija, Quatipuru

SYNONYMS: See under subspecies.

DESCRIPTION: Variable squirrel of medium size, with head and body length 151–212 mm (N=121 adult specimens), tail length 135–225 mm (N=117), hindfoot length 34–58 mm (N=125), ear length 15–29 mm (N=109), and mass 136–242 g (N=6). Dorsal color of head and back brown, streaked with orange, sometimes with defined mid-dorsal black stripe, and darker than that of sides; cheeks brownish orange; orange eye-ring present, and orange postauricular patches conspicuous. Ventral surfaces distinct in color from dorsolateral region, with throat white or the same white, yellow, or orange color as chest; belly orange; ventral hairs usually have gray base. Didier (1955) illustrated the baculum for specimens from eastern Peru.

DISTRIBUTION: *Notosciurus pucheranii* is a polytypic species of primarily Andean distribution, ranging from the central and eastern Andean forests of Colombia to the eastern Andes of Peru, and from the Peruvian lowlands to western Amazonian Brazil, Bolivia, and northwestern Argentina. Their ecological range spans upper montane forests, lowland rainforest, and lowland seasonally dry forests, across a broad elevational range from 100 to 3,200 m. A geographic gap in this range is apparent between the Nariño department in southern Colombia and the Loreto department in northern Peru, with no specimens as yet recorded from Ecuador. It is unclear whether this gap is real or the result of inadequate sampling. Most collecting localities are Andean or situated in Andean foothills; there are fewer localities at lower elevations east of the Andean slopes.

SELECTED LOCALITIES (Map 17): ARGENTINA: Jujuy, Higuierilla (type locality of *Sciurus [Mesosciurus] argentinius* Thomas). BOLIVIA: Beni, Totaisal, 1 km SW of Estación Biológica del Beni (AMNH 261917); Chuquisaca, Sud Cinti, 15.6 km N of El Palmar, above Río Santa Marta (LHE 1310); Cochabamba, Incachaca (FMNH 35224); Río Chapare (FMNH 21547); La Paz, Charuplaya (BM 2.1.1.17), Mapiri (BM 1.1.1.58); Santa Cruz, Buenavista (FMNH 21423), Santiago, Chiquitos (FMNH 105927); Tarija, pié Sierra Santa Rosa, Itau (BM 25.2.1.18–23), Vermejo [= Bermejo] (AMNH 38994). BRAZIL: Acre, Manoel Urbano (MZUSP 11235), Oriente, near Taumaturgo (MPEG 758), Plácido de Castro (type locality of *Sciurus ignitus iquiriensis* Vieira), Rio Branco (AMNH 149145); Amazonas, Igarapé Grande [= Eirunepé], left bank Rio Juruá (MZUSP 4581); Mato Grosso, São João, cabeceiras do Rio Aripuanã (type locality of *Guerlinguetus rufus* Moojen); Rondônia, Ouro Preto d'Oeste (MPEG 20529), Samuel (MPEG, field number 402–8557). COLOMBIA: Antioquia, 4 km NE of Bellavista, above Río Ponce (FMNH 70038), Urrao, Río Aná (FMNH 71106), 15 km E of Río Negrito, Sonsón (FMNH 70043), 10 km S of Valdivia (FMNH 70048); Boyacá, Miraflores (AMNH 32173); Cauca, Salento, west Quindio Andes (AMNH 32850); Cundinamarca, El Roble, above Fusugasugá, east Andes (AMNH 34622), Panamá (AMNH 34680); Huila, Andalucáa, eastern Andes (AMNH 33700), La Candela (AMNH 33699), San Adolfo, Acevedo (FMNH 71110); Nariño, La Laguna (AMNH 42358); Valle del Cauca, vicinity of Palmira, central Andes (AMNH 32175). PERU: Cusco, Cosñipata, Hacienda Cadena (FMNH 65673), Ocabamba, near Cusco (type locality of *Sciurus aestuans cuscinus* Thomas), Río San Miguel (BM 22.1.1.21); Huánuco, Agua Caliente, Río Pachitea (FMNH 55407), Tingo Maria (FMNH 24116); Junín, Perené (AMNH 61814); Loreto, Puerto Punga, Río Tapiche (AMNH 99203), Quebrada Pushaga, Río Morona, upper Río Amazonas (FMNH 88974), San Fernando, Río Yavari (FMNH 88981), Santa Cecilia, Río Maniti (FMNH 87173), Sarayacu, Río Ucayali (AMNH 76442); Madre de Dios, Altamira, Manu (FMNH 98060), Río Inambari (AMNH 16562); Pasco, Rumicruz (AMNH 60599); Puno, Pampa Grande, Sandia (FMNH 79902); Ucayali, Lagarto, upper Río Ucayali (AMNH 78943).

SUBSPECIES: We recognize the four subspecies of *N. pucheranii*.

N. p. argentinius (Thomas, 1921)

SYNONYMS:

Sciurus (Mesosciurus) argentinius Thomas, 1921k:609, type locality "Higuierilla, 2000 m., in the Department of Valle Grande, about 10 km. east of the Zenta range and 20 km. of the town Tilcara," Jujuy, Argentina.

Sciurus argentinius: Thomas, 1925b:577; name combination.
Leptosciurus argentinius: Cabrera and Yepes, 1940:193; name combination.

Sciurus [sic] [(*Guerlinguetus*)] *ignitus argentinius*: Cabrera, 1961:370; name combination.

This subspecies occurs in extreme southern Bolivia and adjacent northwestern Argentina.

N. p. boliviensis (Osgood, 1921)

SYNONYMS:

Macroxus leucogaster Gray, 1867:430, type locality “Bolivia, Santa Cruz de la Sierra”; preoccupied by *Sciurus leucogaster* F. Cuvier, 1831:300 (= *Sciurus aureogaster* F. Cuvier, 1829c).

Leptosciurus leucogaster: J. A. Allen, 1915a:207; name combination.

Sciurus boliviensis Osgood, 1921:39, replacement name for *Macroxus leucogaster* Gray, 1867, which is preoccupied by *Sciurus leucogaster* F. Cuvier, 1831.

Sciurus [(*Guerlinguetus*)] *boliviensis*: Ellerman, 1940:344; name combination.

Sciurus sanborni Osgood, 1944:191; type locality “La Pampa, between Rio Inambari and Rio Tambopata, about twenty miles north of Santo Domingo, Madre de Dios, Peru. Altitude about 1900 feet.”

Sciurus ignitus boliviensis: Sanborn, 1951:18; name combination.

Sciurus [(*Guerlinguetus*)] *ignitus boliviensis*: Cabrera, 1961:371; name combination.

Sciurus [(*Guerlinguetus*)] *sanborni*: Cabrera, 1961:373; name combination.

Notosciurus p. boliviensis is distributed from southern Peru to central Bolivia.

N. p. ignitus (Gray, 1867)

SYNONYMS:

Macroxus ignitus Gray, 1867:429, type locality “Bolivia.”

Macroxus irroratus Gray, 1867:431, type locality “Brazil, Upper Ucayali.”

Sciurus aestuans cuscinus Thomas, 1899a:40, type locality “Ocabamba, Cuzco,” Peru.

[*Sciurus*]. *irroratus*: Thomas, 1899a:40; name combination.

Sciurus cuscinus: Thomas, 1902b:129; name combination.

Sciurus irroratus: Ihering, 1904:420; name combination.

[*Sciurus* (*Guerlinguetus*)] *aestuans cuscinus*: E.-L. Trouessart, 1904:327; name combination.

[*Sciurus* (*Guerlinguetus*)] *irroratus*: E.-L. Trouessart, 1904:328; name combination.

Sciurus cuscinus ochrescens Thomas, 1914a:362, type locality “Bolivia, in upperparts of Beni and Mamoré Rivers. Type from Astillero, [La Paz,] 67°W, 16°S. Alt. 2700 m.”

Leptosciurus ignitus ignitus: J. A. Allen, 1915a:204; name combination.

Leptosciurus ignitus irroratus: J. A. Allen, 1915a:206; name combination.

Sciurus irroratus ochrescens: Osgood, 1916:204; name combination.

Sciurus ignitus irroratus: Thomas, 1927f:599; name combination.

Sciurus [(*Guerlinguetus*)] *ignitus ignitus*: Ellerman, 1940:344; name combination.

Sciurus [(*Guerlinguetus*)] *ignitus irroratus*: Ellerman, 1940:344; name combination.

Guerlinguetus rufus Moojen, 1942:14; type locality “S. João [São João] (cabeceiras do Aripuanã) M. [Mato] Grosso,” Brazil; preoccupied by *Sciurus rufus* Kerr, 1792.

Sciurus (*Guerlinguetus*) *rufus*: W. P. Harris, 1944:12; name combination.

Sciurus rufus: Moojen, 1952b:28; name combination.

Sciurus ignitus ignitus: Sanborn, 1951:18; name combination.

Sciurus ignitus iquiriensis C. O. da C. Vieira, 1952:28, type locality “Placido de Castro, Rio Abunã, Acre,” Brazil.

Sciurus [sic] *ignitus*: Didier, 1955:423; name combination, but typographic error.

Sciurus (*Guerlinguetus*) *ignitus iquiriensis*: C. O. da C. Vieira, 1955:408; name combination.

Sciurus cabrerai Moojen, 1958:50; replacement name for *Guerlinguetus rufus* Moojen, 1942.

Sciurus [(*Guerlinguetus*)] *ignitus cabrerai*: Cabrera, 1961:372; name combination.

Sciurus [(*Guerlinguetus*)] *ignitus*: R. S. Hoffmann, Anderson, Thorington, and Heaney, 1993:441; name combination.

Guerlinguetus ignitus: J. A. Oliveira and Bonvicino, 2006:348; name combination.

This subspecies occurs on the eastern Andean slopes and in the Amazon Basin from northern to southern Peru, extending eastward to the states of Acre and Amazonas in Brazil.

N. p. pucheranii (Fitzinger, 1867)

SYNONYMS:

Sciurus rufoniger Pucheran, 1845:336; type locality “Colombie (Santa-Fé de Bogotá),” Cundinamarca, Colombia; preoccupied by *Sciurus rufonigra* Gray, 1842 [see Fitzinger 1867a].

Funambulus Pucheranii Fitzinger, 1867a:487; replacement name for *Sciurus rufoniger* Pucheran [preoccupied by *Sciurus rufonigra* Gray, 1842]; type locality given as “Am. Columbien.”

Macroxus griseogena Gray, 1867:429; at least in part; no explicit type locality was given, but “Santa Fé de Bogotá” was listed among the several localities cited.

- Macroxus tephrogaster* Gray, 1867:431; probably part (?); while no explicit type locality was given, “Bogotá” was listed among the several localities cited. Thorington and Hoffman (2005) treated *tephrogaster* as a synonym of *S. deppei*.
- Macroxus medellinensis* Gray, 1872:408; type locality “Medellin, Antioquia,” Colombia.
- Sciurus*. *aestuans* var. *rufoniger*: J. A. Allen, 1877:669; part.
- Sciurus tephrogaster*: J. A. Allen, 1877:763; name combination.
- Sciurus griseogenys*: Alston, 1878:667, part; name combination.
- Sciurus deppei*: Alston, 1878:668, part; name combination.
- Sciurus rufo-niger*: Alston, 1878:669; name combination.
- Sciurus aestuans rufo-niger*: True, 1884:595, part; name combination.
- Sciurus*. *Pucherani*: Thomas, 1898f:266; name combination and incorrect subsequent spelling of *Funambulus pucheranii* Fitzinger.
- Sciurus*. [(*Guerlinguetus*)] *caucensis* E. W. Nelson, 1899a:79, type locality “Lima River, upper Cauca Valley, [Valle del Cauca?; see Paynter 1997:252,] Colombia (alt. 6000 feet).”
- [*Sciurus*] *medellinensis*: E.-L. Trouessart, 1904:327; name combination.
- [*Sciurus* (*Guerlinguetus*)] *caucensis*: E.-L. Trouessart, 1904:328; name combination.
- Guerlinguetus pucheranii salentensis* J. A. Allen, 1914d:587, type locality “near Salento (altitude 9000 ft.), Central Andes, [Cauca,] Colombia.”
- Leptosciurus pucheranii pucheranii*: J. A. Allen, 1915a:200; name combination.
- Leptosciurus pucheranii medellinensis*: J. A. Allen, 1915a:202; name combination.
- Leptosciurus pucheranii caucensis*: J. A. Allen, 1915a:203; name combination.
- Leptosciurus pucheranii salentensis*: J. A. Allen, 1915a:203; name combination.
- Sciurus* (*Leptosciurus*) *pucheranii medellinensis*: Anthony, 1923a:5; name combination.
- Leptosciurus pucherani*: Cabrera and Yepes, 1940:192; name combination and incorrect spelling of *pucheranii* Fitzinger.
- Sciurus* [(*Guerlinguetus*)] *pucherani pucherani*: Ellerman, 1940:343; name combination and incorrect spelling of *pucheranii* Fitzinger.
- Sciurus* [(*Guerlinguetus*)] *pucherani medellinensis*: Ellerman, 1940:343; name combination and incorrect spelling of *pucheranii* Fitzinger.
- Sciurus* [(*Guerlinguetus*)] *pucherani salentensis*: Ellerman, 1940:343; name combination and incorrect spelling of *pucheranii* Fitzinger.
- Sciurus aestuans rufoniger*: Rode, 1943:384; name combination, and required elimination of hyphen used in original description (ICZN 1999:Art. 32.5.2.2).
- Sciurus pucherani caucensis*: Goodwin, 1953:277; name combination, and incorrect subsequent spelling of *Funambulus pucheranii* Fitzinger.
- Sciurus pucheranii salentensis*: Goodwin, 1953:277; name combination.

- Sciurus* [(*Guerlinguetus*)] *pucheranii*: Eisenberg, 1989:333; name combination.

The nominotypical subspecies is distributed in the Andean cordilleras of central and southern Colombia. It is geographically separated by a large gap from the cis-Andean distributions of the other three subspecies, as noted previously.

NATURAL HISTORY: Leonard et al. (2009) summarized the natural history, behavior, and other aspects of the biology of this species, restricting their compilation to the trans-Andean Colombian populations. Otherwise, little has been published on this species, surprisingly so given its broad cis-Andean range. Emmons and Feer (1997) provided a few ecological and behavioral details for *argentinus*, *ignitus*, and *sanborni*, which they regarded as separate species.

REMARKS: Both *Funambulus pucheranii* Fitzinger and *Macroxus ignitus* Gray were published in 1867, but Fitzinger’s paper appeared in March (“21 März 1867”) and Gray’s in December. The species name *pucheranii* Fitzinger thus has priority over *ignitus* Gray.

Notosciurus pucheranii is highly variable throughout its range, and many supposed species and subspecies have been described that we treat either as subspecies rather than species or as junior synonyms. All names proposed have been largely based on coat color, which, although variable, presents a reasonably defined geographical trend, as follows. Animals with denser and longer fur are found at higher elevations, while specimens with less dense and shorter pelage come from lower elevations. In northern Colombia

(Antioquia and Quindío departments), most specimens have a well-defined mid-dorsal black stripe (characteristic of *N. p. pucheranii*), but in samples from Cundinamarca, Huila, and Nariño this stripe becomes less pronounced and in some series disappears entirely. In Peru, from Loreto department southward, the *N. p. ignitus* phenotype predominates, with animals having dark brown dorsal parts, without a mid-dorsal stripe, and a grayish white throat and orange chest and belly, with ventral hairs gray at the base. This same phenotype extends to adjacent Brazil, in the states of Amazonas and Acre. Specimens from localities in central and southern Peru have the same general color as typical *N. p. ignitus*, but with less demarcation of the throat from that of the chest and belly, and an overall ventral color ranging from pale yellow to orange.

Southern Peruvian and adjacent Bolivian samples are generally similar, although some Bolivian samples have more white on the venter. By central Bolivia, this general trend of lightening of the venter reaches the extreme, where specimens have white bellies but with hairs still

with a gray base; this is the phenotype of *N. p. boliviensis*. The name *Sciurus sanborni* Osgood has been applied to animals with this color pattern; we treat this name as a junior synonym of *boliviensis*. Southern Bolivian and northern Argentinean samples belong to *N. p. argentinius*, with the main distinction between them and *N. p. boliviensis* being in the color of the venter, which is self-colored orange in the former and white with a gray base in the latter. Specimens from Bermejo, Tarija department, Bolivia, have a white venter (characteristic of typical *boliviensis*), but this locality is situated in the middle of the range of *N. p. argentinius*.

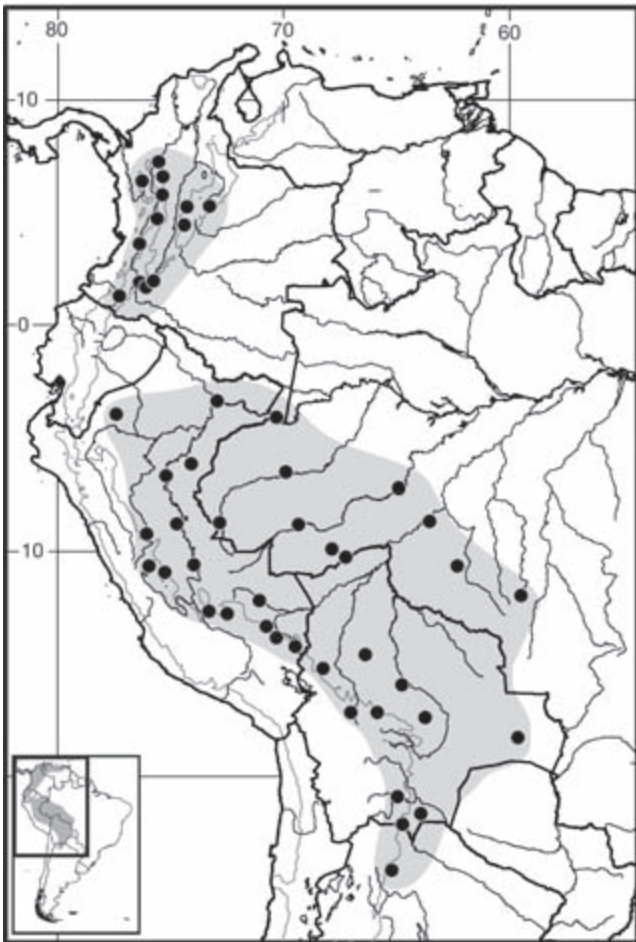

The reason that we recognize four subspecies in *N. pucheranii* rather than a single, monotypic species or four separate species is that the characters that would identify distinct taxa do not segregate in a clear-cut manner. Samples frequently contain specimens with mixed characteristics in regions where one subspecies replaces another.

Throughout its distribution, specimens of *N. pucheranii* possess postauricular patches and three pairs of mammae. However, L. H. Emmons (pers. comm. to MdV) collected a female with four pairs of mammae from Sud Cinti, Chuquisaca, Bolivia (LHE 1313). Because all females of *Notosciurus* we have examined have three pairs of mammae, Emmons's specimen may be an anomaly or perhaps has been misidentified.

Genus *Simosciurus* J. A. Allen, 1915

Simosciurus is a genus of large, trans-Andean squirrels that occurs in western Ecuador and northwestern Peru. We recognize two species, both of which inhabit dry to moist forests from sea level to about 2,300 m. *Simosciurus* can be distinguished from most South American squirrels by their coarser pelage and larger size (relative to *Sciurillus*, *Microsciurus*, *Guerlinguetus*, *Notosciurus*, and *Syntheosciurus*). Although comparable in size, *Simosciurus* is distinguished from *Hadrosociurus* by its very short and broad rostrum and distinctly coarse fur. The rostral character is difficult to quantify, but it can be visualized most readily in dorsal view comparisons. Not only are the nasals wider but also the premaxillae remain visible distally to the tip of the rostrum. In *Hadrosociurus*, the premaxillae are narrower and disappear from view before the rostral tip. The respective trans- versus cis-Andean distributions of the two genera circumvent the possibility of their misidentification based on geography alone.

J. A. Allen (1915a) erected the genus *Simosciurus* to include *Sciurus stramineus* P. Gervais, with three subspecies (*neboxii* I. Geoffroy St.-Hilaire; *guayanus* Thomas; and *zarumae* J. A. Allen) in addition to the nominotypical form. Moore (1959) retained *stramineus* in *Simosciurus* (as a subge-

Map 17 Selected localities for *Notosciurus pucheranii* (●); cis- and trans-Andean distributions are mapped as disjunct (see Remarks). Contour line = 2,000 m.

nus of *Microsciurus*), but Ellerman (1940), Cabrera (1961), and Thorington and Hoffmann (2005) placed the species in *Sciurus*, subgenus *Guerlinguetus*. Allen (1915a:280–281) recognized that two of these taxa had a white nuchal patch (*nebouxii* and *zarumae*) and two did not (*stramineus* and *guayanus*). Emmons and Feer (1997) suggested that animals possessing the nuchal patch were only a highland color variant, a position that supported Allen's initial recognition of a single species. Our study of more than 140 specimens, however, indicates clear geographical separation of specimens with and without a distinct nuchal patch. We interpret this pattern as indicative of species, rather than subspecies, and thus recognize *S. nebouxii* I. Geoffroy St.-Hilaire and *S. stramineus* P. Gervais. No measurements of mass are available in the material we examined, but the two species are of similar size, with an average head and body length of 260 mm, tail of about 294 mm, ear of 35 mm, and hindfoot of 63 mm.

The vernacular name “Guayaquil Squirrel” (or *ardilla de Guayaquil*, Tirira 2004, 2007) has been used in the recent accounts that recognize a single species of these trans-Andean squirrels. However, because the main difference between the two species we recognize lies in the presence (in *S. nebouxii*) or absence (in *S. stramineus*) of a nuchal patch, we refer to the former as the “White-naped Squirrel,” the English equivalent of the local Spanish name, *ardilla de nuca blanca* (Tirira 2007).

SYNONYMS:

Macroxus: Lesson, 1842:112, part (listing of *stramineus*); not *Macroxus* F. Cuvier, 1823.

Sciurus: I. Geoffroy St.-Hilaire, 1855:165; part (inclusion of *nebouxii*); not *Sciurus* Linnaeus, 1758.

Echinosciurus E.-L. Trouessart, 1880a:292; part (listing of *stramineus*); proposed as a subgenus of *Sciurus*; type species *Sciurus hypopyrrhus* Wagler, 1831, a synonym of *Sciurus aureogaster* F. Cuvier, 1829.

Simosciurus J. A. Allen, 1915a:280; type species *Sciurus stramineus* P. Gervais, 1841.

[*Sciurus*] (*Guerlinguetus*): Ellerman, 1940:343; name combination.

Sciurus (*Simosciurus*): Goodwin, 1953:278; name combination.

Microsciurus (*Simosciurus*): Moore, 1961a:15, table 2; name combination.

Guerlinguetus (*Simosciurus*): Moore, 1961b:15; name combination.

REMARKS: J. A. Allen (1915a) proposed the genus *Simosciurus* with type species *Sciurus stramineus* P. Gervais, 1841 (a name often attributed to Eydoux and Souleyet, 1841, but see Remarks under the *Simosciurus stramineus*). The name *Echinosciurus* E.-L. Trouessart actually predates *Simosciurus*, but the type species of *Echinosciurus* is *Sciurus hypopyrrhus* Wagler, 1831. E.-L. Trouessart (1880a)

thought that J. A. Allen's (1877) *Sciurus hypopyrrhus* was the same as the Ecuadorean taxon, an error probably resulting from the unusually coarse pelage of *Simosciurus*, which resembles that of some North American species and is completely different from that of any other South American form. Because *Sciurus hypopyrrhus* is firmly in the synonymy of *Sciurus aureogaster* F. Cuvier, 1829 (Thorington and Hoffmann 2005), the name *Echinosciurus* is not available for this genus of squirrels.

KEY TO THE SPECIES OF *SIMOSCIURUS*:

1. Nuchal patch present, colored white to pale gray, slightly tinged with very pale yellow; dorsal color strongly streaked with yellowish gray anteriorly (same color as nuchal patch) and more vivid pale yellow posteriorly; head about the same color as other anterior parts of body; venter mostly pale yellowish gray. *Simosciurus nebouxii*
- 1'. No nuchal patch; dorsal color usually brown heavily streaked anteriorly with gray, sometimes yellowish gray posteriorly; head distinctly darker than rest of dorsum, with brownish tones; venter dark brown, sometimes with tinge of gray *Simosciurus stramineus*

Simosciurus nebouxii (I. Geoffroy St.-Hilaire, 1855)

White-naped Squirrel

SYNONYMS:

Sciurus Nebouxii I. Geoffroy St.-Hilaire, 1855:165, plate 12, a–d; type locality “Pérou, à Payta [= Paita], [Piura].”

Sciurus stramineus: Alston, 1878:664; part; *S. nebouxii* I. Geoffroy St.-Hilaire placed in synonymy.

Macroxus nebouxii: E.-L. Trouessart, 1897:428; name combination, and incorrect subsequent spelling of *Sciurus nebouxii* I. Geoffroy St.-Hilaire.

Sciurus stramineus nebouxii: Thomas, 1900a:151; name combination.

Sciurus stramineus nebouxii: E.-L. Trouessart, 1904:326; name combination, and incorrect subsequent spelling of *Sciurus nebouxii* I. Geoffroy St.-Hilaire.

Sciurus nebouxii: Neveu-Lemaire and Grandidier, 1911:8; incorrect subsequent spelling of *Sciurus nebouxii* I. Geoffroy St.-Hilaire.

Sciurus stramineus zarumae J. A. Allen, 1914d: 597; type locality “Zaruma, [El Oro,] southwestern Ecuador; altitude 6000 ft.”

Simosciurus stramineus nebouxii: J. A. Allen, 1915a:280; name combination.

Simosciurus stramineus zarumae: J. A. Allen, 1915a:284; name combination.

Sciurus [(*Guerlinguetus*)] *stramineus nebouxii*: Ellerman, 1940:343; name combination, and incorrect subsequent spelling of *nebouxii* I. Geoffroy St.-Hilaire.

Sciurus [(*Guerlinguetus*)] *stramineus zarumae*: Ellerman, 1940:343; name combination.

Simosciurus stramineus zaruma: Cabrera and Yepes, 1940: 196; name combination.

Sciurus (*Simosciurus*) *stramineus zarumae*: Goodwin, 1953: 278; name combination.

Sciurus (*Guerlinguetus*) *stramineus*: Cabrera, 1961:373; part; placed *S. neboxii* I. Geoffroy St.-Hilaire and *S. s. zarumae* J. A. Allen in synonymy.

Sciurus neboxiii: Soukup, 1965:360; incorrect subsequent spelling of *Sciurus neboxii* I. Geoffroy St.-Hilaire; placed in synonymy of *S. stramineus* P. Gervais.

DESCRIPTION: Medium-sized squirrel with head and body length 230–281 mm (N=52), tail length 264–330 mm (N=52), hindfoot length 52–70 mm (N=53), and ear length 26–43 mm (N=24). Body color light gray, with posterior dorsum and posterior parts of forelegs and hindlegs pale yellow; head, including cheeks, same color as body; ears distinctly darker than head, pinnae rimmed with elongated black hairs; nuchal patch present, white to grayish white; forefeet and distal parts of forelimbs darker than body; hindfeet and distal parts of hindlegs dark brown; venter yellow streaked with gray. Tail black to light gray, except near yellowish base.

DISTRIBUTION: This species ranges from extreme southwestern Ecuador, in El Oro and Loja provinces, to northwestern Peru, in Lambayeque, Tumbes, and Piura departments, from sea level to 2,300 m. Jessen et al. (2010) reported the presence of this species (as *S. stramineus*) in and around Lima, Peru, but considered these animals a probable human introduction.

SELECTED LOCALITIES (Map 18): ECUADOR: El Oro, Arenillas (FMNH 53258), Río Pindo (AMNH 60474), Zaruma (type locality of *Sciurus stramineus zarumae* J. A. Allen); Loja, Guainche [not located; see Paynter 1993] (AMNH 61375), Los Posos (AMNH 67680), Malacatos (FMNH 54285). PERU: Lambayeque, Chongoyape, Cabache (FMNH 80995); Piura, Cerro Prieto, Lancones, Encuentros (FMNH 83437), Hacienda Bigotes, Salitral (FMNH 80908), Le Payta [= Paita] (type locality of *Sciurus neboxii* I. Geoffroy St.-Hilaire), Monte Grande, 14 km N and 25 km E of Talara (MVZ 135638), near Talara, Pariñas Valley (FMNH 53864), Palambra (AMNH 63701); Tumbes, Huasimo (FMNH 80991).

SUBSPECIES: We treat *Simosciurus neboxii* as monotypic. J. A. Allen (1915a:280) distinguished *zarumae*, which he named from southwestern Ecuador, from the nominotypical form from adjacent Peru on the basis of dorsal and ventral color differences. Our examination of larger series fails to substantiate this geographic segregation.

NATURAL HISTORY: Little is known about the ecology and population biology of this species. One specimen (FMNH 53864) was found in a grass nest on a canyon wall.

REMARKS: We regard *Simosciurus stramineus* and *S. neboxii* as distinct species based on their different color patterns and separate geographic ranges. However, since Alston (1878:665) first noted the appearance of “irregular tufts of pure white hairs, . . . and sometimes uniting in larger patches,” others have viewed these differences as constituting individual variation rather than species-group characters (e.g., Emmons and Feer 1997). Individuals of both color patterns have been obtained at the same locality in southern Ecuador (Arenillas, El Oro province; specimens in FMNH). Two of the three specimens available possess the nuchal patch characteristic of *S. neboxii*, but the third has no nuchal patch, as is diagnostic of *S. stramineus*.

Arenillas is the northernmost locality for *S. neboxii*, and this mixture of characters may be due to unusual polymorphism, may indicate intergradation with the northern *S. stramineus*, or may actually represent an area of distributional overlap between the two species. Nevertheless, a gap of more than 150 km exists in the known ranges of two species between Arenillas in the south (*neboxii*) and the Guayaquil area in the north (*stramineus*). Collecting efforts directed to this region, including the application of molecular genetic methods, will aid in determining the degree of intergradation, if any, and ultimately the proper number of species to recognize.

Map 18 Selected localities for *Simosciurus neboxii* (●). Contour line=2,000 m.

Simosciurus stramineus (P. Gervais, 1841)

Guayaquil Squirrel

SYNONYMS:

Sciurus stramineus P. Gervais, 1841:37, plate 9; type locality “Omatopé, ou Pérou” [= Amotape, Piura, Peru]; here corrected to Guayaquil, Guayas, Ecuador (see Remarks, below).

Macroxus stramineus: Lesson, 1842:112; name combination.

Macroxus fraseri Gray, 1867:430; type locality given as “Republic of Ecuador.”

Sciurus hypopyrrhus: J. A. Allen, 1877:746; part (material from Guayaquil, Ecuador).

Sciurus tephrogaster: J. A. Allen, 1877:763; part (*Macroxus fraseri* Gray treated as a synonym).

Sciurus variabilis: J. A. Allen, 1877:768; part (*Sciurus stramineus* P. Gervais treated as a synonym).

Sciurus (Echinosciurus) stramineus: E.-L. Trouessart, 1880b:202; name combination.

Sciurus stramineus guayanus Thomas, 1900a:150; type locality “Balzar mountains, upper Río Palenque, [Manabí,] Ecuador.”

Sciurus stramineus stramineus: Thomas, 1900a:151; name combination.

Simosciurus stramineus stramineus: J. A. Allen, 1915a:281; name combination.

Simosciurus stramineus guayanus: J. A. Allen, 1915a:283; name combination.

Sciurus [(Guerlinguetus)] stramineus stramineus: Ellerman, 1940:343; name combination.

Sciurus [(Guerlinguetus)] stramineus guayanus: Ellerman, 1940:343; name combination.

Simosciurus stramineus: Moore, 1959:204; name combination.

Sciurus (Guerlinguetus) stramineus: Cabrera, 1961:373; part.

Microsciurus (Simosciurus) stramineus: Moore, 1961a:15, table 2; name combination.

Guerlinguetus (Simosciurus) stramineus: Moore, 1961b:15; name combination.

DESCRIPTION: Similar in size to *S. neboxii*, with head and body length 241–327 mm (N=40), tail length 250–380 mm (N=40), hindfoot length 50–69 mm (N=40), ear length 20–38 mm (N=7). Body color brownish gray, with posterior dorsum and posterior parts of forelegs and hindlegs yellowish; crown, cheeks, and ears distinctly darker than body; no nuchal patch; forefeet and distal parts of forelimbs from darker than body to whitish gray; hindfeet and distal parts of hind legs dark brown; venter brownish gray; tail black and gray, except for the yellowish base.

DISTRIBUTION: Central Ecuador west of the Andes, where it ranges from sea level to about 300 m, in Manabi, Los Ríos, and Guayas provinces.

SELECTED LOCALITIES (Map 19): ECUADOR: Guayas, Chongoncito (AMNH 60548), Daulé (AMNH 34684), Guayaquil (type locality of *Macroxus fraseri* Gray); Los Ríos, Hacienda Pijigal, Vices (AMNH 62886), Pimocha, Río Babahoyo (MNHN 1932/2893); Manabí, Balzar Mountains, upper Río Palenque (type locality of *Sciurus stramineus guayanus* Thomas); Tama [= Jama] (FMNH 53256); Santa Elena, Cerro Manglar Alto [= Manglaralto, placed at Cerros de Colonche following Painter 1993] (AMNH 66640).

SUBSPECIES: We treat *Simosciurus stramineus* as monotypic. However, J. A. Allen (1915a:281, 284) recognized two subspecies among those geographic samples without a nuchal patch, with *guayanus* Thomas “much lighter colored throughout than true *stramineus*.”

NATURAL HISTORY: Tirira (2007) summarized the natural history attributes of this species; however, his map of *S. stramineus* also included the range of *S. neboxii*, so his account possibly includes both species. *Simosciurus stramineus* inhabits both primary and secondary forests and disturbed areas, including both coffee and citrus plantations where individuals cause damage to crops. The natural habitat is primarily dry forest, but the species can be found in adjoining humid forests as well. This species is diurnal and arboreal, and in contrast with the solitary nature of most other squirrels, this species may be found in groups of three to five individuals. They feed on a variety of seeds taken directly from trees but occasionally eat insects, fungi, green leaves, and tree bark. Their activity is concentrated in the early daylight hours. They take refuge in treetops, in hollow logs, or in foliage. Their nests are made from leaves and twigs.

REMARKS: P. Gervais (1841) described *stramineus* as a member of the genus *Sciurus*. The name, however, has been commonly attributed to the naturalists J. F. T. Eydoux and L. F. A. Souleyet (e.g., J. A. Allen 1915a; Cabrera 1961; Thorington and Hoffmann 2005; Thorington et al. 2012), although these authors explicitly stated that Paul Gervais both identified and described all mammals obtained during the voyage of French corvette *La Bonite* (Eydoux and Souleyet 1841:ii; 3, footnote).

P. Gervais (1841:39) gave the type locality of *Simosciurus stramineus* as “Omatopé, Pérou.” There is no locality with this spelling in Peru; the locality referred to is most likely Amotape, Piura, Peru, about 25 km northeast of the port town of Paita (= Payta as given in Eydoux and Souleyet 1841). “Omatopé” (= Amotape) is also the type locality of *Eptesicus innoxius* (P. Gervais 1841), collected on the same expedition (see A. L. Gardner 2008:449). However, Amotape is located in the center of the geographic range of *Simosciurus neboxii* I. Geoffroy St.-Hilaire, and all specimens that we have examined of this species have the nuchal

Map 19 Selected localities for *Simosciurus stramineus* (●). Contour line = 2,000 m.

patches. But P. Gervais's (1841:38–39) detailed description of color characteristics of his *Sciurus stramineus* includes no mention of this very distinctive character. As can be seen in Maps 18 and 19, the two species of *Simosciurus* we recognize are allopatric, with their ranges apparently separated by about a 150-km gap. Therefore, we believe that the locality of the type specimen was originally recorded in error or that some other mistake occurred during the voyage and/or after arrival of the specimens in Paris. The ship *Le Bonite* remained anchored at Paita for a few days and then proceeded to Guayaquil, further north, where it stayed for several more days before departing. Because Guayaquil is an area inhabited by *Simosciurus stramineus*, we hereby designate Guayaquil, Provincia de Guayas, Ecuador as the type locality of the species (ICZN 1999:Art. 76A).

P. Gervais (1841:38–39) described the species as if he had an actual specimen in hand, but the holotype could not be located by one of us (MdV) in the Muséum National d'Histoire Naturelle in Paris in 1992, nor has any other author reported on the holotype since the original description. It may have been lost.

Genus *Syntheosciurus* Bangs, 1902

Syntheosciurus is a genus of small squirrels known until now by the single species *S. brochus* from Central America. We report what is likely an undescribed species from San

Martín department, Peru, the first record of the genus for South America. *Syntheosciurus brochus* occurs in evergreen montane forests of the Cordillera Talamanca of Costa Rica and Panama at elevations above 1,700 m. The Peruvian specimen was taken at a single locality in Parque Nacional Río Abiseo, an area covered by montane rainforest at elevations above 1,500 m on the eastern slope of the Andes (S. C. Ramirez and Vela 2003). The large geographic hiatus between the known localities of the Central American *S. brochus* and the Peruvian record appears to be real, because intervening areas in the northern Andes of Ecuador and Colombia with the appropriate habitat and elevations have been extensively collected, with large series of other taxa of squirrels recorded with no *Syntheosciurus* taken.

Syntheosciurus can be distinguished from other South American squirrels by the following combination of characteristics: size intermediate between that of *Microsciurus* and *Guerlinguetus*, with head and body length approximately 180 mm and tail length 150 mm; the single weight available among specimens we examined was that of an adult male, recorded as 244 g. Externally, *Syntheosciurus* is distinguished by its small ears, which are, on average, about 15 mm in length. Females have three pairs of mammae. The temporal portion of the orbitotemporal fossa is similar to that of the larger South American squirrels, with the postorbital process more or less equally dividing it from the orbital portion. This is different from the condition in *Microsciurus*, in which the temporal portion of the orbitotemporal fossa is greatly reduced, and from that in *Sciurillus*, in which it is obliterated. The incisors are clearly proodont, PM3 is present, and the cristae of PM4 to M3 are oriented obliquely. In the original description of the genus, Bangs (1902:25) stated that the incisors have well-developed grooves on the buccal surface; this characteristic is present in the holotype of *S. brochus* but is absent in other specimens examined (Goodwin 1943; Heaney and Hoffmann 1978).

SYNONYMS:

Syntheosciurus Bangs, 1902:25; type species *Syntheosciurus brochus*, by monotypy.

Synthetosciurus Elliot, 1904:91; incorrect subsequent spelling of *Syntheosciurus* Bangs.

Sciurus: Goodwin, 1943:1, part (description of *poasensis*).

Syntheosciurus (*Syntheosciurus*): Moore, 1959:179; name combination.

Syntheosciurus Villalobos and Cervantes-Reza, 2007:31; incorrect subsequent spelling of *Syntheosciurus* Bangs.

REMARKS: Phylogenetic relationships of *Syntheosciurus* to other American squirrels remain unclear, but Mercer and Roth (2003) proposed that *Syntheosciurus* was a sister group to *Microsciurus*, based on DNA sequence analyses. This hypothesis agrees with the earlier, more superficial assessments of Bangs (1902) and Hall (1981). Moore

(1959) included *Syntheosciurus* in his subtribe Microsciurina, together with *Microsciurus* and *Leptosciurus* [= *Notosciurus* herein] (*sensu* J. A. Allen 1915a) and *Simosciurus*. A phylogenetic hypothesis based on 57 morphological characters (Villalobos and Cervantes-Reza 2007) placed *Syntheosciurus* in a group with other Central American taxa, and separate from squirrels with more obvious South American affinities such as *Microsciurus* and *Notosciurus*.

In keeping with our adoption of most of J. A. Allen's (1915a) arrangement for the genera of South American Sciuridae, we employ *Syntheosciurus* as the generic name for these animals. See Hall (1981) for a list of synonyms and distributional records for the Central American *S. brochus*.

KEY TO THE SPECIES OF *SYNTHEOSCIURUS*:

1. Body color brown punctuated with orange; belly pale orange; eye-ring present and conspicuous; no postauricular patch *Syntheosciurus brochus*
- 1'. Body color brown punctuated with ochraceous; belly orange red; no eye-ring; postauricular patch present. *Syntheosciurus* sp.

Syntheosciurus sp.

Peruvian Montane Squirrel

SYNONYMS: None.

DESCRIPTION: In comparison to Central American *S. brochus*, the Peruvian specimen has longer palmar pads; belly tinted more reddish than orange; tail hairs fringed with orange; dorsum brown streaked with ochraceous rather than orange; no eye-ring, but postauricular patch present. Skull shorter in length, and bullae have two well-separated rather than closely appressed and parallel septa.

DISTRIBUTION: This species is only known from a single locality in Andean montane forest at 2,800 m in northern Peru.

SELECTED LOCALITIES (Map 20): PERU: San Martín, Vilcabamba del Pajate, 31 km NE of Pataz [La Libertad] (USNM [MML 279]).

SUBSPECIES: None.

NATURAL HISTORY: Nothing is known about the ecology or other aspects of the natural history of this animal. The single known locality is in upper montane forest (S. C. Ramirez and Vela 2003).

REMARKS: This species is here reported thanks to the late Dr. Charles O. Handley Jr., then at the Smithsonian Institution, National Museum of Natural History, Washington D. C., who showed a single specimen to one of us (MdV). Mariella Leo collected this specimen in 1989 during an inventory in the Parque Nacional del Río Abiseo (see S. C. Ramirez and Vela 2003). In that report, made to support a management plan for the park, the specimen was identi-

Map 20 Single known locality for *Syntheosciurus* sp. (●). Contour line=2,000 m.

fied as *Microsciurus* sp., and it was similarly listed in recent compilations of the mammal fauna of Peru (Pacheco et al. 1995, 2009). Several additional specimens may exist in Peruvian collections (V. Pacheco, pers. comm.).

Suborder Castorimorpha Wood, 1955
 Infraorder Geomorpha Thaler, 1966

Superfamily Geomyoidea Bonaparte, 1845

James L. Patton

Superficially dissimilar in body form and habits, the pocket gophers (Geomyidae) and kangaroo rats and pocket mice (Heteromyidae) have been united as a recognizable monophyletic assemblage for many decades. All genera share external fur-lined cheek pouches, four cheek teeth (dental formula I 1/1, C 0/0, PM 1/1, M 3/3=20) with a bilophodont or more simplified occlusal pattern, and an infraorbital foramen positioned anterior to the zygomatic plate on the side of the rostrum, opening anterolaterally in the Geomyidae,

but laterally, completely piercing the rostrum, in the Heteromyidae. The fossil record extends to the Oligocene, with the rapidly expanding diversification of living genera correlated with the general drying trend of the early to mid-Miocene.

McKenna and Bell (1997) grouped geomyids, heteromyids, and the fossil Entotychinae as subfamilies in the Geomyidae, following earlier suggestions of Shotwell (1967) and Lindsay (1972). Although the hierarchical rank of the pocket gophers and kangaroo rats and mice and pocket mice is partly a matter of taxonomic philosophy (Patton 2005a,b), it is also a decision that stems from the phylogenetic placement of the fossil entotychines. The sister relationship between entotychines and living pocket gophers, documented by both Wahlert (1985, 1988) and Korth (1994), supports the traditional separation of the Geomyidae (including the Entotychinae) as a family distinct from the Heteromyidae.

KEY TO THE FAMILIES OF GEOMYOIDEA:

1. Body bauplan adapted for subterranean living, with fusiform body, short powerful limbs, forefeet with elongated and strong claws, small eyes, very short ear pinnae, and short and nearly naked tail; skull blocky with strong zygomatic arches, heavy ridging, broad incisors, and euhypsodont cheek teeth consisting of simple prismatic columns and flattened occlusal surfaces Geomyidae
- 1'. Body bauplan adapted for bounding terrestrial gait or bipedal saltatorial locomotion, with elongated hind limbs and feet; forefeet with shortened but strong claws; tail elongated, often with both terminal crest and pencil; eyes large; ear pinna projecting above dorsal surface of skull; hair soft or often with imbedded spines; skull variable, some genera with hugely enlarged auditory bullae expanded onto the dorsal side of the skull; cheek teeth cuspidate, bunodont, and brachydont, or hypsodont and columnar Heteromyidae

Family Geomyidae Bonaparte, 1845

Mark S. Hafner

The family Geomyidae (pocket gophers) includes six extant genera and approximately 40 extant species of fossorial rodents distributed from southern Canada to northwestern Colombia. Pocket gophers are known from the lower Oligocene of North America (Wahlert 1985); both fossil (Russell 1968; Korth 1994) and molecular (Spradling et al. 2004) evidence suggest that modern genera radiated from a common ancestor approximately 5 mya.

All pocket gophers are characterized by numerous adaptations for subterranean life. Their bodies are fusiform, which facilitates movement in the narrow tunnels they

excavate while foraging for roots, tubers, or other plant parts. Their external appendages are short relative to body length, and they use their muscular forelimbs for digging and for pushing excavated soil to the surface. The cranium is robust and features prominent ridges for attachment of powerful temporal muscles. The mouth can be closed behind the large, procumbent incisors to prevent entry of soil when the incisors are used for digging. The incisors and cheek teeth are ever-growing, and the latter have simplified crown patterns consisting of dentine pools surrounded by enamel rings or transverse enamel plates.

Pocket gophers range in size from approximately 100–1,000 g, and they live in a wide variety of soils types. They rarely occupy shallow soils (<0.5 m) or soils prone to flooding. In addition to their principal diet of underground plant foods, many species of pocket gophers also forage opportunistically on surface vegetation near to their burrow entrances. Their preference for certain cultivated crops, including alfalfa, banana roots, and yuca (*Manihot*) make pocket gophers serious agricultural pests over parts of their geographic range. Their subterranean habits make them difficult to control, and they can cause significant damage to the small food plots of subsistence farmers.

Detailed descriptions of geomyid morphology can be found in Merriam (1895a) and Russell (1968), and a review of the taxonomic history of pocket gophers is available in Patton (2005b). Systematic revisions of pocket gopher taxa, appearing since the publication of *Mammal Species of the World* (Wilson and Reeder 2005), include M. S. Hafner et al. (2004, 2005, 2009, 2011), Sudman et al. (2006), D. J. Hafner et al. (2008), M. S. Hafner and Hafner (2009), and Mathis et al. (2013). Only one genus of pocket gopher (*Orthogeomys*) occurs in South America.

Genus *Orthogeomys* Merriam, 1895

Species of the genus *Orthogeomys* are medium to large pocket gophers (200–1,000 g). The skull is heavy and broad, with most of the breadth owing to extreme lateral expansion of robust zygomatic arches. The nasals and rostrum also are relatively broad and heavy, and the angular process of the dentary is short relative to overall length of the mandible. The anterior surface of each upper incisor has a broad longitudinal groove located either medially or near the inner edge of the tooth. The premolars consist of two columns united at their midpoints to yield a figure-8-shaped occlusal surface. The pelage generally is sparse and coarse in species living at low elevations and long and dense in high-elevation forms. Dorsal pelage markings (either a white head spot or a white lumbar belt) are present in all, or nearly all, specimens of some species, while others are characterized only by a low to moderate frequency of

individuals with head blazes or lumbar belts, which can occur on either the left, right, or both sides of the body (M. S. Hafner and Hafner 1987). Fossils attributed to the genus *Orthogeomys* (subgenus *Heterogeomys*) are known from Late Pleistocene deposits (San Josecito Cave local fauna) of Nuevo León, Mexico (Russell 1960).

SYNONYMS:

Orthogeomys Merriam, 1895a:172; type species *Geomys scalops* Thomas, 1894, by original designation.

Heterogeomys Merriam, 1895a:179; type species *Geomys hispidus* Le Conte, 1852, by original designation.

Macrogeomys Merriam, 1895a:185; type species *Geomys heterodus* Peters, 1865, by original designation.

REMARKS: Russell (1968) revised the genus and included *Heterogeomys* and *Macrogeomys* as subgenera. The genus includes 10 recognized species, including two in the subgenus *Heterogeomys*, six in *Macrogeomys*, and two in *Orthogeomys*. One species, *O. (Macrogeomys) dariensis*, occurs in South America.

Orthogeomys dariensis (Goldman, 1912)

Darién Pocket Gopher

SYNONYMS:

Macrogeomys dariensis Goldman, 1912b:8; type from “Cana (altitude 2,000 feet), in the mountains of eastern [Darién] Panama.”

Orthogeomys (Macrogeomys) dariensis: Russell, 1968:532; first use of current name combination.

Orthogeomys thaeleri Alberico, 1990:104; type locality “ca. 7 km S. Bahía Solano, Municipio Bahía Solano, Departamento de Chocó, Colombia, ca. 100 m.”

DESCRIPTION: Head and body length 210–278 mm (Goldman 1912b; Alberico 1990). Dorsal color reddish brown to dull chocolate brown, or nearly pure black in fresh pelage in some individuals; venter and inner sides of limbs sparsely haired, with scattered hairs grayish to light brown; vibrissae white to pale brown; upper surfaces of forefeet and hindfeet as well as tail either brownish, dark pinkish, or nearly white. Skull large (greatest length of holotype 71 mm), elongated, and with anteriorly spreading zygomatic arches, narrow braincase, and narrow rostrum (Goldman 1912b; Alberico 1990).

DISTRIBUTION: *Orthogeomys dariensis* occurs in forests and cultivated regions of eastern Panamá and the lowlands and western foothills of the Serranía de Baudó in extreme northwestern Colombia. It also may occur on the eastern slopes of the Serranía de Baudó (Alberico 1990). The species ranges in elevation from 10 to approximately 1,200 m. *Orthogeomys dariensis* is known only from the Recent.

SELECTED LOCALITIES (Map 21): COLOMBIA: Chocó, ca. 7 km S of Bahía Solano (type locality of *Orthogeomys thaeleri* Alberico), Parque Nacional Natural

Utría, Ensenada de Utría (LSUMZ 30057), Santa Marta (Alberico 1990).

SUBSPECIES: I treat *Orthogeomys dariensis* as monotypic.

NATURAL HISTORY: *Orthogeomys dariensis* occupies a wide variety of habitat types but is most common in forested areas or in small clearings in forests. Like other subterranean mammals, *O. dariensis* requires well-drained soils that are not prone to flooding and are of sufficient depth to prevent easy access to their burrows by digging predators. Alberico (1990) reported that the tunnels produced by *O. dariensis* in the clayey lateritic soils of the Chocó are shallower (only a few centimeters below the surface) than those typically produced by large pocket gophers. The diet of *O. dariensis* consists primarily of roots and tubers, although surface vegetation in the immediate vicinity of the burrow opening occasionally is consumed.

REMARKS: Intensive search for *O. dariensis* in the foothills of the northern Andes and near the headwaters of the Atrato and San Juan rivers (the most likely path of colonization of the northern Andes by a fossorial mammal) produced no evidence of pocket gophers (Alberico 1990). Thus, it appears that *O. dariensis* has not crossed the Bolívar Trough, which represents the geological (but not political) dividing line between Central and South America.

Alberico (1990:106) recognized specimens of *O. dariensis* from Chocó department, Colombia, as a distinct species, *O. thaeleri*, based on subtle craniodental character differences and because the chewing lice he collected from the type series “do not appear to be specifically related to *Geomydoecus dariensis* reported for *O. dariensis* from Panama” by Price and Emerson 1971. However, Sudman and Hafner (1992) sequenced a portion of two mitochondrial genes (16S rDNA and cytochrome-*b*) in a specimen of *O. thaeleri* from near its type locality in Colombia and compared the sequences with those from a specimen of *O. dariensis* from near its type locality in Panamá. These authors found only three transitional differences between *O. thaeleri* and *O. dariensis* in the 929 base pairs examined (0.3% uncorrected sequence divergence) and concluded that *O. thaeleri* likely represents only a geographic variant of *O. dariensis*.

My comparison of the study skin and skull of a near-topotypic specimen of *O. thaeleri* (LSUMZ 30057) with the skins and skulls of three topotypes (or near topotypes) of *O. dariensis* (LSUMZ 25434–25436) revealed no differences beyond those consistent with normal geographic variation in a species of pocket gopher. Dorsal pelage coloration in the two supposed species was indistinguishable to the naked eye, and two of the three specimens of *O. dariensis* had interorbital constrictions >10 (considered a diagnostic trait of *O. thaeleri* by Alberico 1990). The

Map 21 Selected localities for *Orthogeomys dariensis* (●). Range in Panama from hall (1981). Contour line = 2,000 m.

height of the external auditory meatus in all three specimens of *O. dariensis* exceeded 2.3 mm, which also was considered diagnostic of *O. thaeleri* by Alberico (1990). The fact that *O. thaeleri* and *O. dariensis* have been collected within 100 km of each other in what appears to be continuous habitat suitable for pocket gophers leads me to conclude that *O. thaeleri* is simply a southward extension of *O. dariensis*.

Family Heteromyidae Gray, 1868

Robert P. Anderson

Three subfamilies comprise the Heteromyidae, but only one of them occurs in South America. Whereas the Dipodomysinae (kangaroo rats and kangaroo mice) and Perognathinae (pocket mice, both silky and coarse-haired) occur exclusively in North America, the Heteromyinae (spiny pocket mice) range from southern Texas, United States, to central Ecuador (Patton 2005a). Heteromyines represent a well-defined monophyletic group distinct from the two other subfamilies (M. S. Hafner 1981; J. C. Hafner and Hafner 1983; Wahlert 1991; J. C. Hafner et al. 2007). Of the two currently recognized genera of

heteromyines, only the genus *Heteromys* inhabits South America.

Modern usage of the genera *Heteromys* and *Liomys* began a century ago. After a rather turbulent taxonomic history of the subfamily during the nineteenth century (see account of the genus *Heteromys*), Merriam (1902) espoused recognition of two genera: *Heteromys* Desmarest, and *Liomys*, which he described. Soon thereafter, Goldman (1911b) accomplished the first comprehensive revision of the subfamily, providing emended diagnoses of the two genera and using these to place previously described species into their appropriate genera. Subsequent twentieth-century authors reviewing the taxonomy of heteromyines (e.g., Genoways 1973; Hall and Kelson 1959; Hall 1981; D. F. Williams et al. 1993; Patton 1993, 2005a) continued to recognize the two genera, which can be identified based on several diagnostic characters and which inhabit markedly different habitats, with species of *Heteromys* generally found in wetter, denser forests (R. P. Anderson et al. 2006).

However, substantial morphological diversity exists in *Liomys* (Genoways 1973), and recent phylogenetic studies have recovered three clades in the subfamily (*Heteromys*; the *adpersus-salvini* clade of *Liomys*; and the *irroratus-pictus-spectabilis* clade of *Liomys*), based on mtDNA sequences (Rogers and Vance 2005; J. C. Hafner et al. 2007) and allozymes and morphology (R. P. Anderson et al. 2006). Although some of these studies indicated the paraphyly of *Liomys*, all documented the monophyly of species previously allocated to *Heteromys*. Whereas some authors have suggested that all heteromyines should be placed in the genus *Heteromys* to avoid recognition of a paraphyletic *Liomys* (J. C. Hafner et al. 2007), I continue to recognize *Liomys* until conclusive studies with multiple independent data sources (e.g., unlinked nuclear markers) are completed, allowing for a comprehensive reevaluation of the generic-level taxonomy of the subfamily (see R. P. Anderson et al. 2006:1227). Notably, available generic-level names exist for each of the three clades recovered in the subfamily, allowing for the possible designation of three genera, which would acknowledge the substantial morphological and ecological distinctiveness of each clade and maximally promote nomenclatural stability in the subfamily (see R. P. Anderson and Gutiérrez [2009] for discussion of *Schaeferia* Lehmann, described in Lehmann and Schaefer [1979]).

Three unique synapomorphies of the genus *Heteromys* are unreversed in the family Heteromyidae: optic foramen small, with posterior border generally formed by a strong bar of bone; anterior margin of posterior loph of permanent upper premolar [PM4] with a long fold; and permanent lower premolar [pm4] with three or more lophids (R. P. Anderson et al. 2006). In addition, the lateral termi-

nations of the lophs of the upper molars and lophids of the lower molars tend to be smooth in species of *Heteromys*, but generally are pointed in all other heteromyids.

Genus *Heteromys* Desmarest, 1817

Species of *Heteromys* are medium-sized heteromyids (approximately 40–130 g in adults) that constitute an easily recognizable element of the mammalian fauna of South America. Like all members of the superfamily Geomyoidea, they possess external fur-lined cheek pouches. Except for pocket gophers of the family Geomyidae (the sister group to the Heteromyidae), species of *Heteromys* represent the only South American mammals with such cheek pouches. In contrast to the subterranean pocket gophers (which evolved short, broad limbs and large claws for digging), *Heteromys* (like other heteromyids) have small claws and long, thin forelimbs; the hindlimbs are characteristically well developed. In addition to their characteristic cheek pouches, most adult *Heteromys* (like other heteromyines) have spiny dorsal pelage, with dark brown or black spines intermixed with soft and generally slightly paler brown or gray hairs, creating a grizzled effect. However, the dorsal pelage of juveniles of all species and even adults of some populations of some species is soft and more uniform in color. As in the rest of the subfamily, the ventral pelage of individuals of all ages lacks spines and is white, sharply demarcated from the dark pelage of the dorsum. A faint, narrow ventral stripe of dark hairs occurs in some individuals of some species in the midsagittal plane of the throat, chest, and/or abdominal regions. The tail is long—as long as or longer than the length of the head and body. As in other heteromyines, reproductively active adult male *Heteromys* possess extremely large testes, with the scrotal sac extending well posterior and lateral to the base of the tail and creating a distinctive outline in dorsal, ventral, and lateral views.

SYNONYMS:

Mus: Thompson, 1815:161; part (description of *anomalous*); not *Mus* Linnaeus, 1758.

Cricetus: Desmarest, 1817e:180; part (listing of *anomalous*); not *Cricetus* Leske, 1779.

Heteromys Desmarest, 1817e:181; type species *Mus anomalous* Thompson, 1815, by monotypy.

Sacomys F. Cuvier, 1823c:186; type species *Sacomys anthophile* F. Cuvier, 1823d:422, by subsequent designation.

Loncheres: Kuhl, 1820:72; part (listing of *anomala*, presumably a mandatory change of spelling of *anomalous* to match gender of genus).

Dasynotus Wagler, 1830:21; type species *Mus anomalous* Thompson, 1815, by monotypy.

Cricetomys: Schinz, 1845:204; part (listing of *anomalous*); not *Cricetomys* Waterhouse, 1840.

Perognathus: Gray, 1868:202; part (description of *bicolor*); not *Perognathus* Wied-Neuwied, 1839.

Xylomys Merriam, 1902:43; type species *Heteromys (Xylomys) nelsoni* Merriam, 1902, by original designation (subgenus).

REMARKS: F. Cuvier (1823d) described *Sacomys anthophile*, with type locality unknown, based on a single fluid-preserved specimen. This specimen, however, is apparently lost, as no holotype for the species appears in Rode (1945). The same specimen may have been the one in the Muséum National d'Histoire Naturelle in Paris studied by Desmarest (1817e) and considered by him to be conspecific with *Mus anomalous* Thompson. Ellerman (1940:472) stated “the type species of *Sacomys* is presumably unidentifiable.” The illustrations in F. Cuvier (1823d) show dental and external characters that allow placement of the *Sacomys anthophile* in *Heteromys*, but I concur that neither these illustrations nor the extensive textual description are sufficient to associate the specimen with any particular species of the genus. Given the presently available information, I consider *S. anthophile* to be a *nomen dubium*. Note relevant listings by various subsequent authors: *Sacomys anthophilus* Wagler, 1830:22 (incorrect subsequent spelling of *anthophile* F. Cuvier); *H[eteromys]. anthophilus* Alston, 1880b:119 (name combination and incorrect subsequent spelling of *anthophile* F. Cuvier); and *Sacomys anthophilus* Ellerman, 1940:472 (incorrect subsequent spelling of *anthophile* F. Cuvier).

The species-level taxonomy of *Heteromys* remains highly problematic in Mexico and Central America, but South American species have received recent revisionary study. Just over two decades ago, only six (D. F. Williams et al. 1993) or seven (Patton 1993) species were recognized in the genus. However, karyotypic and allozymic studies indicate that the widespread *Heteromys desmarestianus* (currently considered to range from southern Mexico to northwestern Colombia) is composite (Rogers 1989, 1990; Mascarello and Rogers 1988). In addition, morphological studies have revealed several new species, bringing the number of currently recognized species in the genus to 10 (R. P. Anderson and Jarrín 2002; R. P. Anderson 2003; R. P. Anderson and Timm 2006; R. P. Anderson and Gutiérrez 2009). Whereas the species limits of *Heteromys* in Central America remain unclear (in particular in what currently is considered *H. desmarestianus*), the recent revisionary studies of South American species allow the current accounts, which remain subject to evaluation with molecular data.

Even compared with other genera of rodents, specimens from many populations of *Heteromys* are extremely difficult to identify to species, especially when only one or a few specimens are available from a single locality. Vast age-

related cranial variation exists in size and shape, coupled with substantial ontogenetic changes in pelage; hence, age must be taken into account for valid comparisons and reliable identifications (Rogers and Schmidly 1982). Direct comparison with previously identified specimens from large series at single localities (in which age-related variation can be appreciated) is highly desirable and often necessary to ensure correct identification.

KEY TO THE SOUTH AMERICAN SPECIES
OF *HETEROMYS*:

1. Braincase narrow relative to length of skull; interorbital constriction narrow relative to length of skull 2
- 1'. Braincase wide relative to length of skull; interorbital constriction wide relative to length of skull 3
2. Size diminutive (rostral length <13.4 mm in adults); little or no dark coloration present on dorsal and external surfaces of forelimbs. *Heteromys oasicus*
- 2'. Size typical for genus (rostral length >13.4 mm in adults); patch of moderately dark coloration present on dorsal and external surfaces of forelimbs
. *Heteromys anomalus*
3. Rostrum short; dorsal coloration chocolate brown
. *Heteromys desmarestianus crassirostris*
- 3'. Rostrum typical in length for genus; dorsal coloration dark slate gray or black 4
4. Braincase distinctly inflated. *Heteromys australis*
- 4'. Braincase not inflated, or only moderately so 5
5. Zygomatic arches wide and bowed . . . *Heteromys teleus*
- 5'. Zygomatic arches not distinctly bowed, but rather parallel sided, or nearly so *Heteromys catopterus*

Heteromys anomalus (Thompson, 1815)

Caribbean Spiny Pocket Mouse

Heteromys [(*Heteromys*)] *anomalus anomalus*: Ellerman, 1940:475; name combination, listed as nominotypical subspecies.

[*Heteromys* (*Heteromys*)] *melanoleucas* Ellerman, 1940:475; incorrect subsequent spelling of *Heteromys melanoleucus* Gray.

Heteromys (*Heteromys*) *anomalus hershkovitzii*: Hernández-Camacho, 1956:3; type locality "Volcanes, cerca a la cabecera del corregimiento de Córdoba, Municipio de Caparrapí, Departamento de Cundinamarca; vertiente occidental de la Cordillera Oriental, Colombia. Alt. 250 metros." See also R. P. Anderson (1999:618).

DESCRIPTION: Adults with following combination of characters (R. P. Anderson 2003; R. P. Anderson and Gutiérrez 2009; see also R. P. Anderson 1999): Dorsal pelage typically pale brown, strongly grizzled, with thin ochraceous hairs intermixed with spines, but occasionally almost uniformly dark slate gray, nearly uniform to moderately grizzled (in wet lowlands of Zulia state, Venezuela, in some parts of Cordillera de Mérida, in mesic areas of Monagas and Sucre states, Venezuela, and on islands of Trinidad and Tobago); weak patch of dark coloration present on dorsal and external surfaces of forelimbs; ears distinctively rounded, brown to gray and large relative to body size; orange band on flanks absent; plantar surface of hindfeet naked. Skull variable in size geographically, average to large for genus (occipitonasal length 31.1–39.0 mm in adult specimens of age class 4 of Rogers and Schmidly [1982]); rostrum moderately long and moderately tapered anteriorly, without anterodorsal flare; anterior portion of premaxillary convex (inflated), forming a smooth (not stepped) lateral border of rostrum; interorbital constriction narrow; braincase narrow and not inflated; interparietal variable in size and shape; tubercle or swelling at posteroventral border of infraorbital foramen absent; mesopterygoid fossa formed by long, thin

hamular processes of pterygoids; optic foramen especially small, with posterior margin formed by strong bar of bone. PM4 with straight, moderately long fold in anterior margin of posterior loph; pm4 with three lophids.

DISTRIBUTION: This species is found in low elevations along Caribbean coast of Colombia and Venezuela (east of Río Atrato), upper Río Magdalena valley of Colombia, gallery forests of *llanos* (savannas) of Venezuela north of Río Orinoco, and up to middle elevations on adjacent slopes of Sierra Nevada de Santa Marta, Cordillera Central (of Colombia; eastern versant only), Cordillera Oriental (of Colombia; western versant only), Serranía de Perijá, Cordillera de Mérida, Cordillera de la Costa (of Venezuela), and other coastal ranges; it also inhabits the Caribbean islands of Margarita, Trinidad, and Tobago; the known elevational range is from near sea level to 2,430 m, but most occurrences are from sea level to approximately 1,600 m (R. P. Anderson and Soriano 1999; R. P. Anderson 2003; R. P. Anderson and Gutiérrez 2009).

SELECTED LOCALITIES (Map 22): **COLOMBIA:** Antioquia, Hacienda Barro, 12 km S of Caucasia (R. P. Anderson 2003), Urabá, Río Currulao (R. P. Anderson 2003); Atlántico, Ciénaga de Guájaro, Sabana Larga (R. P. Anderson 2003); Cundinamarca, Volcanes, Municipio de Caparrapí (type locality of *Heteromys* [*Heteromys*] *anomalous hershkovitzi* Hernández-Camacho); Huila, Camp Coscorón, Hacienda San Diego, 17 km SE of Villavieja (R. P. Anderson 2003); La Guajira, Las Marimondas, Fonseca (R. P. Anderson 2003); Magdalena, Mamatoca (R. P. Anderson 2003); Norte de Santander, Guamalito, near El Carmen (R. P. Anderson 2003), Finca La Palma, Durania (R. P. Anderson 2003). **TRINIDAD AND TOBAGO:** Tobago, Pigeon Peak, Tobago Forest Reserve, 2.5 km SSW of Charlotteville (R. P. Anderson and Gutiérrez 2009); Trinidad, Botanic Gardens, behind St. Anne's barracks (type locality of *Mus anomalous* Thompson), Mayaro (R. P. Anderson and Gutiérrez 2009). **VENEZUELA:** Anzoátegui, Paso Los Cocos, Río Caris, S of El Tigre (R. P. Anderson and Gutiérrez 2009), Pekín Abajo, Río Neverí (R. P. Anderson and Gutiérrez 2009); Falcón, Cerro la Danta, Sierra de San Luis, Parque Nacional J. C. Falcón (R. P. Anderson 2003); Guárico, Fundo Pecuario Masaguaral, 45 km (by road) S of Calabozo (R. P. Anderson and Gutiérrez 2009); Miranda, Estación Experimental Río Negro (R. P. Anderson and Gutiérrez 2009); Monagas, Caripito (R. P. Anderson and Gutiérrez 2009); Nueva Esparta, San Juan, Cerro Copey (R. P. Anderson and Gutiérrez 2009); Portuguesa, Cogollal, near Guanarito (R. P. Anderson 2003); Sucre, población de Macuro, Distrito Valdez (R. P. Anderson and Gutiérrez 2009), entre Cariaco y Chacopata (R. P. Anderson and Gutiérrez 2009); Táchira, Urbante,

Map 22 Selected localities for *Heteromys anomalous* (●) and *Heteromys desmarestianus crassirostris* (○). Range of *H. desmarestianus* in Panama follows Hall (1981). Contour line = 2,000 m.

Río Potosí (R. P. Anderson 2003); Zulia, El Panorama, Río Anaure (type locality of *Heteromys anomalous brachialis* Osgood).

SUBSPECIES: A thorough review of geographic variation in this relatively widespread species has yet to be undertaken, and I do not recognize subspecies at this time (but see D. F. Williams et al. 1993 and Patton 2005a for recognition of four subspecies).

NATURAL HISTORY: *Heteromys anomalous* inhabits both primary and secondary forests, as well as some low-intensity agricultural settings (R. P. Anderson 1999, 2003; R. P. Anderson and Gutiérrez 2009). Most localities are in evergreen and deciduous forests; the available information for records in landscapes dominated by nonforested vegetation indicates that the species is restricted to areas of denser vegetation (e.g., gallery forests) in such situations (Osgood 1912; August 1984; Soriano and Clulow 1988; R. P. Anderson 2003; R. P. Anderson and Gutiérrez 2009). Mark-recapture studies at Bush Bush Forest on Trinidad documented limited movement for individuals of the species (<300 ft [ca. 90 m]; Worth et al. 1968). Eisenberg (1963) reported some behavioral information for the species.

REMARKS: The karyotype is characterized by $2n=60$ and $FN=68$ (Engstrom et al. 1987).

Heteromys australis Thomas, 1901

Southern Spiny Pocket Mouse

SYNONYMS:

Heteromys australis Thomas, 1901c:194; type locality "St. [San] Javier, Lower Cachabi River [Río Cachaví], [Esmeraldas,] N[orthern]. Ecuador. Alt. 20 m."

Heteromys lomitisensis J. A. Allen, 1912:77; type locality "Las Lomitas, Cauca [now Valle del Cauca], Colombia . . . Altitude 5000 feet [1,524 m], west slope of Western Andes."

Heteromys australis consicus Goldman 1913:8; type locality “Cana (altitude 2000 feet [610 m]), [Darién,] Eastern Panama.”

Heteromys australis australis: Goldman, 1913:8; name combination, listed as nominotypical subspecies; see also Goldman (1913:9).

Heteromys australis lomitensis: Goldman, 1913:8; name combination, listed as subspecies; see also Goldman (1913:9).

Heteromys australis pacificus Pearson 1939:4; type locality “Amagal, [Darién,] eastern Panama, altitude 1000 feet [305 m]”.

Heteromys lomitansis Cabrera, 1961:513; incorrect subsequent spelling of *Heteromys lomitensis* J. A. Allen.

DESCRIPTION: Adults characterized by (R. P. Anderson 1999, 2003, R. P. Anderson and Jarrín 2002; see also R. P. Anderson et al. 2006) dorsal coloration of dark slate gray or black, nearly uniform or moderately grizzled with thin ochraceous hairs intermixed with spines; distinctive patch of dark coloration present on dorsal and external surfaces of forelimbs; ears black and small; orange band on flanks absent; plantar surface of hindfeet naked. Skull average to small for genus (occipitonasal length 32.1–36.0 mm in specimens of age class 4 of Rogers and Schmidly [1982] from Ecuador and southwestern Colombia; see also R. P. Anderson [1999]); rostrum unremarkable for genus, but moderately tapered anteriorly, without anterodorsal flare; anterior portion of premaxillary convex (inflated), forming smooth (not stepped) lateral border of rostrum; interorbital constriction wide; braincase wide and distinctly inflated; interparietal wide; tubercle or swelling at posteroventral border of infraorbital foramen absent; mesopterygoid fossa formed by long, thin hamular processes of pterygoids; optic foramen especially small, with posterior margin formed by strong bar of bone. PM4 with straight, moderately long fold in anterior margin of posterior loph; pm4 with three lophids.

DISTRIBUTION: Low elevations along Pacific coast of northwestern South America, from northwestern Ecuador through western Colombia to eastern Panama, and up to middle and high elevations on adjacent slopes of the Cordillera Occidental (of Ecuador), Cordilleras Occidental and Central (of Colombia), Cordillera Oriental (of Colombia; western versant only), and Cordillera de Mérida (Río Uribante drainage only, apparently disjunct) in western Venezuela. The known elevational range is from near sea level to 2,450 m, but most occurrences are found from sea level to approximately 2,000 m (R. P. Anderson 1999; R. P. Anderson and Jarrín 2002).

SELECTED LOCALITIES (Map 23; from R. P. Anderson 1999, except as noted): COLOMBIA: Antioquia, Alto Bonito, Purí, above Cáceres; Chocó, Bagadó,

Unguía, upper Río Ipetí; Córdoba, Socorré, upper Río Sinú; Cundinamarca, Paime; Huila, near San Adolfo, Río Aguas Claras, Río Suaza; Nariño, Barbaças (R. P. Anderson and Jarrín 2002); Valle del Cauca, Bahía Málaga, Quebrada Valencia, road to Quebrada Alegría, Reserva Forestal Yotoco. ECUADOR: Carchi, El Pailón (Anderson and Jarrín 2002); Esmeraldas, San Javier, Río Cachaví (type locality of *Heteromys australis* Thomas); Pichincha, Cooperativa Salcedo Lindo, on road from Pedro Vicente Maldonado to Encampamento de CODESA (R. P. Anderson and Jarrín 2002). VENEZUELA: Táchira, Presa La Honda, 10 km SSE of Pregonero (R. P. Anderson 2003).

SUBSPECIES: A thorough review of geographic variation in this relatively widespread species has yet to be undertaken, and I do not recognize subspecies (but see D. F. Williams et al. 1993 and Patton 2005a for recognition of three subspecies).

NATURAL HISTORY: *Heteromys australis* inhabits very wet, unseasonal evergreen forests, but very little additional information regarding its natural history is available (R. P. Anderson 1999; R. P. Anderson and Jarrín 2002).

Map 23 Selected localities for *Heteromys australis* (●) and *Heteromys teleus* (○). The disjunct locality of *H. australis* in the Cordillera de Mérida of Venezuela is mapped separately from the remainder of the species' distribution; its range in Panama follows Hall (1981). Contour line = 2,000 m.

REMARKS: The karyotype is unknown. Populations in central Colombia may be specifically distinct from *H. australis* (R. P. Anderson 1999:620).

Heteromys catopterus R. P. Anderson and Gutiérrez, 2009

Overlook Spiny Pocket Mouse

SYNONYMS:

Heteromys anomalus: Tate, 1947:66; part; first name combination applied.

Heteromys catopterus R. P. Anderson and Gutiérrez, 2009:40; type locality "Venezuela: Aragua: Rancho Grande, near Biological Station, 13 km NW Maracay, at 3576 ft [1,090 m]."

DESCRIPTION: Adults with following combination of characters (R. P. Anderson and Gutiérrez 2009): dorsal coloration dark slate gray or black, moderately grizzled with thin ochraceous hairs intermixed with spines; distinctive patch of dark coloration present on dorsal and external surfaces of forelimbs; ears dark gray to black and medium in size; orange band on flanks absent; plantar surface of hindfeet naked. Skull average to large for genus (occipito-nasal length 34.7–38.7 mm in adult specimens of age class 4 of Rogers and Schmidly [1982]); rostrum long and wide, only slightly to moderately tapered anteriorly, without anterodorsal flare; anterior portion of premaxillary convex (inflated), forming a smooth (not stepped) lateral border of rostrum; interorbital constriction wide; braincase wide and moderately inflated; interparietal wide; tubercle or swelling at posteroventral border of infraorbital foramen absent; mesopterygoid fossa formed by long, thin hamular processes of pterygoids; optic foramen especially small, with posterior margin formed by strong bar of bone. PM4 with straight, moderately long fold in anterior margin of posterior loph; pm4 with three lophids.

DISTRIBUTION: Middle-to-high elevations of the Cordillera de la Costa of Venezuela. The known elevational range is from 350 to 2,425 m, but most records are above approximately 700 m (R. P. Anderson and Gutiérrez 2009).

SELECTED LOCALITIES (Map 24; from R. P. Anderson and Gutiérrez 2009). VENEZUELA: Aragua, Campamento Rafael Rangel, Loma de Hierro [= Minas de Niquel], 10 km (by road) WNW [NNE] of Tiara; Carabobo, Campamento La Justa, Río Morón; Miranda, 25 km (by road) N of Altagracia de Orituco, Hacienda Las Planadas; Monagas, 2 km N and 4 km W of Caripe, near San Agustín.

SUBSPECIES: *Heteromys catopterus* is monotypic.

NATURAL HISTORY: *Heteromys catopterus* inhabits wet montane forests, particularly cloud forests with many palms, and has been collected in both primary and second-

Map 24 Selected localities for *Heteromys catopterus* (●) (note disjunct range, with absence from the lowlands of the Depresión de Unare on the coast) and *Heteromys oasicus* (○). Contour line=2,000 m.

ary forests (R. P. Anderson and Gutiérrez 2009). Rood (1963) and Rood and Test (1968) provided substantial information regarding the reproduction, development, diet, and behavior for the species.

REMARKS: The karyotype is characterized by $2n=60$ and $FN=72$ (Schmid et al. 1992). However, the FN reported by those authors included the four arms of the female sex chromosomes; thus, the autosomal FN is actually 68 (R. P. Anderson and Gutiérrez 2009). The Y chromosome of this species shows exceptional quinacrine-positive heterochromatin, indicating a preponderance of AT-rich sequences (Schmid et al. 1992).

Heteromys desmarestianus Gray, 1868

Desmarest's Spiny Pocket Mouse

SYNONYMS: [Synonymy for forms from Mexico and elsewhere in Central America not included; see Hall 1981; D. F. Williams et al. 1983.]

Heteromys desmarestianus Gray, 1868:204; type locality "Coban [Cobán]," Departamento de Alta Verapaz, Guatemala.

Heteromys crassirostris Goldman, 1912b:10; type locality "near head of Río Limón [Río Limón] (altitude 5,000 feet [1,524 m]), Mount Pirri [= Cerro Pirre], [Darién], eastern Panama."

Heteromys desmarestianus crassirostris: Goldman, 1920: 115; name combination, listed as valid subspecies; see also Goldman (1920:117–118).

Heteromys d[esmarestianus], *acutirostris* R. P. Anderson, 1999:623; incorrect subsequent spelling of *Heteromys crassirostris* Goldman; editor's error.

DESCRIPTION: (For *H. desmarestianus crassirostris*, see Remarks.) Adults with following combination of characters (R. P. Anderson 1999; see also R. P. Anderson and Timm 2006 and R. P. Anderson et al. 2006): dorsal pelage chocolate brown, only moderately grizzled with thin ochraceous hairs intermixed among spines; distinctive patch of dark coloration present on dorsal and external surfaces of forelimbs; ears small; orange band on flanks absent; plantar surface of hindfeet naked. Skull small for genus (occipitonasal length 32.2–35.1 mm in adult specimens of age classes 4 and 5 of Rogers and Schmidly [1982; published data for age class 4 not available]); rostrum distinctively short, wide, and strongly tapered anteriorly, without anterodorsal flare; anterior portion of premaxillary convex (inflated), forming smooth (not stepped) lateral border of rostrum; interorbital constriction wide; braincase wide and moderately inflated; interparietal moderately wide; tubercle or swelling at posteroventral border of infraorbital foramen absent; mesopterygoid fossa formed by long, thin hamular processes of pterygoids; optic foramen small, with posterior margin formed by strong bar of bone. PM4 with bent, extremely long fold in anterior margin of posterior loph; pm4 with three lophids.

DISTRIBUTION: Definitive distribution of this species of the *H. desmarestianus* species complex is only confirmed for extreme northwestern Colombia and eastern Panama along the Serranía del Darién and associated mountain chains (R. P. Anderson 1999; R. P. Anderson et al. 2006).

SELECTED LOCALITIES (Map 22, in South America): COLOMBIA: Chocó, Alto de Barrigonal, Serranía del Darién (R. P. Anderson 1999).

SUBSPECIES: *Heteromys desmarestianus*, as currently conceived, is polytypic, with 12 subspecies recognized (D. F. Williams et al. 1993; Patton 2005a). As presently understood, only *H. d. crassirostris* Goldman extends into South America (see Remarks).

NATURAL HISTORY: This form is known from cloud forests along the Colombian-Panamanian border, where it is locally common (R. P. Anderson 1999). The contents of cheek pouches have included a variety of seeds, nuts, and other items (R. P. Anderson 1999).

REMARKS: Morphological, karyological, and allozymic data indicate that, as currently conceived, *Heteromys desmarestianus* represents a complex of several species (Mascarello and Rogers 1988; Rogers 1989, 1990; R. P. Anderson and Timm 2006; R. P. Anderson et al. 2006). Detailed specimen-based studies of alpha-level taxonomy are needed to elucidate the species in this complex, and current knowledge does not permit definitive conclusions

regarding the valid name for the species present in extreme northwestern Colombia. These populations are provisionally referred to here as *H. d. crassirostris* (following R. P. Anderson 1999; R. P. Anderson et al. 2006). A karyotype for these populations is unknown.

Heteromys oasicus R. P. Anderson, 2003

Paraguana Spiny Pocket Mouse

SYNONYMS:

Heteromys anomalus: Bisbal-E., 1990:180; first name combination applied.

Heteromys oasicus R. P. Anderson, 2003:9; type locality "Venezuela: Estado Falcón: 49 km N, 32 km W of Coro, Cerro Santa Ana, at 550 m."

DESCRIPTION: Adults have following combination of characters (R. P. Anderson 2003). Dorsal pelage very pale brown, strongly grizzled with thin ochraceous hairs intermixed with spines; little or no dark coloration on dorsal and external surfaces of forelimbs; ears pale brown and large relative to body size; orange band on flanks absent; plantar surface of hindfeet naked. Skull diminutive for genus (occipitonasal length 29.7–31.2 mm in adult specimens of age class 4 of Rogers and Schmidly [1982]); rostrum short and strongly tapered anteriorly, without anterodorsal flare; anterior portion of premaxillary convex (inflated), forming a smooth (not stepped) lateral border of rostrum; interorbital constriction narrow; braincase narrow and not inflated; interparietal moderately wide and rounded laterally; tubercle or swelling at posteroventral border of infraorbital foramen absent; mesopterygoid fossa formed by long, thin hamular processes of pterygoids; optic foramen especially small, with posterior margin formed by strong bar of bone. PM4 with straight, moderately long fold in anterior margin of posterior loph; pm4 with three lophids.

DISTRIBUTION: Low-to-middle elevations of Cerro Santa Ana and Fila de Monte Cano on the Península de Paraguana in northwestern Venezuela; known elevational range from 90 to 700 m (R. P. Anderson et al. 2012).

SELECTED LOCALITIES (Map 24): VENEZUELA: Falcón, 49 km N and 32 km W of Coro, Cerro Santa Ana (type locality of *Heteromys oasicus* R. P. Anderson).

SUBSPECIES: *Heteromys oasicus* is monotypic.

NATURAL HISTORY: *Heteromys oasicus* inhabits small, isolated areas of forests, especially evergreen vegetation on the upper slopes of Cerro Santa Ana, but it also has been captured in riparian vegetation at lower elevations (i.e., on the lower slopes of Cerro Santa Ana and along the Fila de Monte Cano; R. P. Anderson 2003).

REMARKS: The karyotype is unknown.

Heteromys teleus R. P. Anderson and Jarrín, 2002

Ecuadorian Spiny Pocket Mouse

SYNONYMS:

Heteromys australis: Albuja, 1992:125; first name combination applied.

Heteromys teleus R. P. Anderson and Jarrín, 2002:6; type locality “Ecuador: Provincia Guayas [now Santa Elena]: Cerro Manglar Alto, western slope . . . 2000 ft [610 m].”

DESCRIPTION: Adults with following combination of characters (R. P. Anderson and Jarrín 2002; see also R. P. Anderson et al. 2006): dorsal coloration dark slate gray or black, nearly uniform or moderately grizzled with thin ochraceous hairs intermixed with spines; distinctive patch of dark coloration on dorsal and external surfaces of forelimbs; ears black and small to medium in size; orange band on flanks absent; plantar surface of hindfeet naked. Skull size average to large for genus (occipitonasal length 35.5–38.3 mm in adult specimens of age class 4 of Rogers and Schmidly [1982]); rostrum extremely wide and only slightly to moderately tapered anteriorly, without anterodorsal flare; anterior portion of premaxillary convex (inflated), forming smooth (not stepped) lateral border of rostrum; interorbital constriction moderately wide; braincase moderately wide and not inflated; interparietal narrow and rounded laterally; tubercle or swelling at posteroventral border of infraorbital foramen absent; mesopterygoid fossa formed by long, thin hamular processes of pterygoids; optic foramen especially small, with posterior margin formed by strong bar of bone. PM4 with straight, moderately long fold in anterior margin of posterior loph; pm4 with three lophids.

DISTRIBUTION: Low elevations along the Pacific coast of central-western Ecuador, and up to middle elevations on adjacent slopes of Cordillera Occidental and Cordillera de Chongón-Colonche of Ecuador. The known elevational range is from near sea level to 2,000 m, but most records are from sea level to approximately 600 m (R. P. Anderson and Jarrín 2002).

SELECTED LOCALITIES (Map 23; from R. P. Anderson and Jarrín 2002): ECUADOR: Cotopaxi, San Francisco de las Pampas, Reserva Bosque Nublado Otonga; Esmeraldas, Quinindé; Los Ríos, Estación Biológica Pedro Franco Dávila, Jauneche; Santa Elena, Cerro Manglar Alto, western slope (type locality of *Heteromys teleus* R. P. Anderson and Jarrín).

SUBSPECIES: *Heteromys teleus* is monotypic.

NATURAL HISTORY: *Heteromys teleus* inhabits evergreen but seasonal forests and is tolerant of moderate levels of disturbance (R. P. Anderson and Jarrín 2002). In the region near the type locality, almost all specimens were captured on the banks of small streams (R. P. Anderson and Jarrín 2002). R. P. Anderson and Martínez-Meyer (2004) provided an estimate of the species' potential geographic distribution and a preliminary conservation assessment.

REMARKS: The karyotype is unknown.

Suborder Myomorpha Brants, 1855

James L. Patton

Infraorder Myodonta Schaub, in Grassé and Dekeyser, 1955

Superfamily Muroidea Illiger, 1811

Family Cricetidae G. Fischer, 1817

The muroid rodents of the suborder Myomorpha comprise three subfamilies of the Cricetidae in South America. Two of these, the Neotominae and Tylomyinae, are North or Middle American lineages of which a single genus of the latter and two of the former extend into northwestern South America. The third, the Sigmodontinae, are highly diverse and largely autochthonous to that continent, with a few members extending north into Middle America and reaching a northern limit in the northeastern United States. These three groups, together with the Holarctic Arvicolinae and Old World Cricetinae, are currently included in the Cricetidae (e.g., Musser and Carleton 2005). Initial molecular analyses (e.g., Jansa and Weksler 2004; Stepan, Adkins, and Anderson 2004) failed to recover robust phylogenetic relationships among the three subfamilies that occur in South America. However, three recent taxon and gene-expanded studies (Parada et al. 2013; Schenk et al. 2013; J. F. Vilela et al. 2013) supported a sister relationship between the Tylomyinae and Sigmodontinae; the latter authors posited the split between the two subfamilies at about 18 mya based on a time-calibrated ultrametric tree analysis.

Musser and Carleton (2005) detailed the long and tortuous history of the concept of the Muroidea, answering the question these two authors had posed in 1984 about the number of families to recognize and the family-group ranks for those lineages recognized in the New World, specifically South America. Although refinements to what is known of phyletic relationships and group membership will continue, particularly with the future expansion of molecular analyses, the three subfamilies of Cricetidae now recognized as part of the native fauna of South America will likely remain stable into the foreseeable future (see Schenk et al. 2013).

The Sigmodontinae comprise the vast majority of cricetid rodents in South America, representing a large radiation (approximately 84 genera and nearly 380 species), with representatives occupying virtually all habitats from sea level to the high Andes, and from evergreen rainforests of the Amazon to some of the world's most xeric communities along the Pacific coast from central Peru to northern Chile. Only single species of *Reithrodontomys* and of *Isthmomys* of the otherwise highly diverse and mostly North

or Middle American Neotominae (16 genera, 124 species; Musser and Carleton 2005), and of *Tylomys* of the much less diverse Middle American Tylomyinae (four genera, 10 species; Musser and Carleton 2005), extend into South America. Neotomine and tylomyine taxa are limited to western Colombia and adjacent Ecuador; throughout the remainder of the continent, only members of the Sigmodontinae are found.

Craniodental, skeletal, and soft anatomical traits for representative genera of each of the three subfamilies of Cricetidae that occur in South America are described and illustrated in Carleton (1980), Stepan (1995), Pacheco 2003), and Weksler (2006). Focus should be on those trans-Andean genera in the northwestern part of the continent, the only region where members of the three subfamilies may be found together or in close proximity: *Tylomys*, the sole member of the Tylomyinae in South America, *Isthmomys* and *Reithrodontomys* of the Neotominae, and 25 genera of the Sigmodontinae.

Only a few obvious traits are needed to distinguish *Tylomys* from *Reithrodontomys* and *Isthmomys*, or the latter two from each other. Distinguishing each of these three from the array of trans-Andean sigmodontine genera, however, is more challenging, both because of phyletic diversity (these 25 genera belong to five of the nine currently recognized tribes) and because of disparate morphologies resulting from adaptation to the very wide array of occupied environments. The key emphasizes characters that readily distinguish *Tylomys* from *Reithrodontomys* and *Isthmomys*, and it pairs these comparisons only with the few co-occurring sigmodontine genera that share one or more character sets.

KEY TO THE SOUTH AMERICAN SUBFAMILIES OF CRICETIDAE (LIMITED TO THOSE GENERA IN TRANS-ANDEAN REGION OF ECUADOR AND COLOMBIA):

1. Upper incisors either ungrooved or grooved; lower third molar medium to large (>25% mandibular toothrow length); glans penis lacks dorsal papilla and lateral bacular mounds (cartilaginous baculum with single, medial digit), with crater absent or only incipiently developed; male accessory reproductive glands include no or only single pair of preputials; vesiculars variable but not J-shaped 2
- 1'. Upper incisors uniformly ungrooved (except for *Sigmodon alstoni*); lower third molar small (<23% mandibular toothrow length); glans penis of males with dorsal papilla, lateral bacular mounds (cartilaginous baculum tridigitate), and deep crater; male accessory reproductive glands include one or two pairs of preputials; vesiculars J-shaped Sigmodontinae

2. Body size relatively large (>100g); tail naked, scales large and conspicuous; anterocone bifurcated by deep anteromedian flexus dividing two equally large cusps; cusps arranged in opposite pattern; upper incisors smooth, ungrooved; supraorbital region with well-developed ledges that extend across the parietals to the lambdoidal crest as pronounced ridges; glans penis short and broad, the bony baculum short and broad, not extending beyond tip of glans, with long cartilaginous tip, crater incipiently developed; male accessory reproductive glands include a single pair of preputials, long and intestiniform vesiculars Tylomyinae (*Tylomys*)
- 2'. Body size smaller (<50g); tail thinly haired, scales not conspicuous; anterocone undivided or bifurcated by weak flexus dividing two small conules; cusps weakly alternate in pattern; upper incisors with or without single groove on anterior face; interorbital region smooth to slightly beaded; temporal ridges absent; glans penis elongated, and baculum long and thin, extending beyond glans tip, without cartilaginous tip, crater absent; male accessory reproductive glands lack preputials but include J-shaped vesiculars 3
3. Body size diminutive (head and body length 70–90 mm); upper incisors with longitudinal groove on anterior face. Neotominae (*Reithrodontomys*)
- 3'. Body size larger (head and body length 150–200 mm); upper incisors with smooth anterior face Neotominae (*Isthmomys*)

REMARKS: *Sigmodon alstoni* is the only sigmodontine in trans-Andean northwestern South America that shares with *Tylomys* the wide supraorbital ledges that extend across the parietals as distinct ridges and end at the lambdoidal crest. These two taxa, however, do not occur in the same area, and they are distinct in habitat (lowland grasslands versus montane forest, respectively). Cranially the two can be easily distinguished by their (respectively) planar versus cuspidate teeth, narrow (< rostral breadth) versus broad (> rostral breadth) interorbital regions, broad zygomatic plates with pronounced spines and deep zygomatic notches (when viewed from above) versus narrow zygomatic plates without spines and thus imperceptible zygomatic notches, among a number of other easily observed craniodental differences.

Externally, *Sigmodon* has a well-furred, dorsoventrally bicolored tail, elongated hindfeet, and coarse, hispid fur. *Tylomys* has a naked, anteroposteriorly bicolored tail, short and broad hindfeet, and soft fur. *Sigmodon alstoni* and *Reithrodontomys* also share grooved upper incisors, but these two are also readily separable externally by size (large versus small) and tail length (shorter than versus longer than head and body), and cranially also by planar

versus cuspidate molars, ledged versus smoothly rounded interorbital edges, and zygomatic plates with and without dorsal spines.

Subfamily Neotominae Merriam, 1894

Musser and Carleton (2005:1048) reviewed the concept and taxonomic history of the Neotominae, a group in which Merriam (1894) originally included only the North American woodrats (genus *Neotoma*) and certain South American fossils with high-crowned molars (*Ptyssophorus* and *Tretomys*, both now regarded as synonyms of the extant genus *Reithrodon*; see Pardiñas 2000 and that account here). Today, the subfamily includes all North and Middle American Cricetidae, excluding the Arvicolinae, the four genera of Middle American Tylomyinae, and the few genera of Sigmodontinae that extend north of the Panama-Colombia border. Two genera of neotomines, *Isthmomys* and *Reithrodontomys*, extend into South America.

KEY TO THE SOUTH AMERICAN GENERA OF NEOTOMINAE:

1. Upper incisors conspicuously sulcate, with a single longitudinal groove on anterior enamel face *Reithrodontomys*
- 1'. Upper incisors smooth, without conspicuous groove *Isthmomys*

Genus *Isthmomys* Hooper and Musser, 1964

James L. Patton

This genus includes two species, only one of which extends into extreme northwestern Colombia (*I. pirrensis*). *Isthmomys* was diagnosed originally (Hooper and Musser 1964) to reflect conspicuous penile differences from the remainder of *Peromyscus*. Carleton (1989:125–126) subsequently provided an expanded diagnosis that included the following morphological attributes: Beaded supraorbital edges and weakly developed temporal ridges; subsquamosal fenestra absent or minute, postglenoid foramen small and narrow; sphenopalatine vacuities tiny or absent; M1 strongly ovate, narrow anterocone deeply bifurcate; posteroflexid on m3 isolated as fossetid; entepicondylar foramen absent; stomach with edges of discoglandular zone partially infolded (incipient pouch); phallus long and broad distally, baculum longer than length of glans penis, spines long and heavy, urinary meatus open almost terminally through large mound of nonspinous, soft tissue; preputials and lateral ventral prostates absent, cephalic border of vesiculars with lobulated folds; postaxial pair of mammae absent.

SYNONYMS:

Megadontomys: Bangs, 1902:27; part (description of *flavidus*); not *Megadontomys* Merriam, 1898.

Peromyscus: Osgood, 1909:221 (listing of *flavidus*); part; not *Peromyscus* Gloger, 1841.

Isthmomys Hooper and Musser, 1964:12; type species *Megadontomys flavidus* Bangs, by original designation; as subgenus of *Peromyscus*.

REMARKS: Hooper and Musser (1964) proposed *Isthmomys* as a subgenus of *Peromyscus*. Hooper (1968) maintained this rank, but Carleton (1980, 1989) subsequently provided an emended diagnosis and accorded generic status. Pine et al. (1979:357), citing Article 13:1.1 of the Code, argued that the generic name as proposed by Hooper and Musser (1964) was a *nomen nudum*. Subsequently, Pine (in Honaki, Kinman, and Koepl 1982:421) wrote that Carleton (1980:124) may have made *Isthmomys* available. Neither Carleton (1989) nor Musser and Carleton (1993, 2005) accepted Pine's position, and continued to list Hooper and Musser (1964) as the author of the name.

Although the placement of *Isthmomys* in the Neotominae is noncontroversial, its phylogenetic relationship to other genera remains ambiguous. Carleton (1980) grouped *Isthmomys* in a clade with *Megadontomys*, based on a number of shared morphological characters. Alternatively, Rogers et al. (2004), using 25 allozyme loci, hypothesized a phyletic relationship between *Isthmomys* and *Reithrodontomys*, a result supported by subsequent analyses of the mtDNA cytochrome-*b* gene (Bradley et al. 2007), although not by other mitochondrial sequences (Engle et al. 1998). Two species (*I. flavidus* and *I. pirrensis*) are currently recognized (Hall 1981; Musser and Carleton 2005). Middleton (2007), in an unpublished M.S. thesis, examined morphometric relationships between them, confirming their phenotypic distinction.

Isthmomys pirrensis (Goldman, 1912)

Mount Pirri Deer Mouse

SYNONYMS:

Peromyscus (*Megadontomys*) *pirrensis* Goldman, 1912b:5; type locality "near head of Rio Limon (altitude 4,500 feet), Mount Pirri, [Darién,] eastern Panama."

[*Peromyscus*] *Isthmomys pirrensis*: Hooper and Musser, 1964:13; name combination.

[*Isthmomys*] *pirrensis*: Carleton, 1980:124; first use of current name combination.

DESCRIPTION: Size large (total length 342–376 mm, tail length 185–204 mm, hindfoot length 36–36.5 mm); upper parts dark brownish cinnamon to cinnamon rufous lined with black, becoming grayish brown on head and more rusty on rump; sides brighter, more rufescent; venter dull buffy white with gray basal color of fur apparent throughout; tail brownish and nearly unicolored.

DISTRIBUTION: Extreme eastern Panama and adjacent Colombia.

SELECTED LOCALITIES (Map 25; South America only): **COLOMBIA:** Chocó, Alto de Barrigonal, Serranía del Darién (Voss 2014).

SUBSPECIES: *Isthmomys pirrensis* is monotypic.

NATURAL HISTORY: This is a terrestrial species found in evergreen forest (tropical pluvial and tropical rainforest) at an elevational range from 100–500 m (Handley 1966; Alberico et al. 2000; Cuartas-Calle and Muñoz-Arango 2003).

REMARKS: Alberico et al. (2000:63) included *I. pirrensis* in their list of Colombian mammals, citing Cuervo et al. (1986) as their source and identifying the IAvH as the collection presumptively housing one or more vouchers. Neither publication, however, provided a specific locality or catalog number(s) as confirmation. Cuartas-Calle and Muñoz-Arango (2003) included the species, as a probable occurrence, in their list of mammals from Antioquia, Colombia, based on Alberico et al. (2000). Voss (2014) confirmed the presence of this species in Colombia when he examined specimens from the Serranía del Darién in Chocó department, then in the INDERENA collection in Bogotá, during a visit there in 1984.

Map 25 Single known South American locality for *Isthmomys pirrensis* (●). Panama distribution from F. A. Reid (2009). Contour line=2,000 m.

Genus *Reithrodontomys* Giglioli, 1874

Elizabeth Arellano

The genus *Reithrodontomys*, with 20 species (Bradley et al. 2004a; Musser and Carleton 2005), covers an extensive geographic and elevational range from the southwestern portions of Canada to western Colombia and Ecuador (Hall 1981; Eisenberg 1989). Fossils are known from Pleistocene deposits of North America. The elevational range extends from below sea level in Death Valley, California, to over 4,000 m in the mountains of Mexico, Central, and South America (Hooper 1952; Hall 1981). Ecologically, these mice are associated with a variety of habitats and local climates, including grass and shrub lands, both marine and freshwater marshlands, well-drained uplands in temperate climates, arid zones with xerophytic vegetation, tropical forest in humid lowlands, and conifer forests up to the timber line on high mountains (Hooper 1952).

Harvest mice are small rodents with proportionally long tails. They are distinguished from other members of the tribe Reithrodontini (*sensu* Musser and Carleton 2005, including *Habromys*, *Isthmomys*, *Megadontomys*, *Neotomodon*, *Onychomys*, *Osgoodomys*, *Peromyscus*, and *Podomys*) by the possession of grooved upper incisors (Le Conte 1853). This character alone distinguishes these mice from species of similar body size in other genera that co-occur in that part of the range that extends into South America (e.g., *Microryzomys* and *Oligoryzomys*).

The genus is divided into the two subgenera *Reithrodontomys* and *Aporodon*, which differ from each other in characteristics of the molars (A. H. Howell 1914; Hooper 1952) and other features (summarized by Carleton 1980), allozymes (K. Nelson et al. 1984; Arellano et al. 2003), satellite DNA (Hamilton et al. 1990), and DNA sequences (Bell et al. 2001; Bradley et al. 2004b; Arellano et al. 2006).

SYNONYMS:

Reithrodon Le Conte, 1853:413; type species *Mus LeContii* Audubon and Bachman [= *Mus humulis* Audubon and Bachman]; not *Reithrodon* Waterhouse.

R[eithrodon]: Saussure, 1860:109; part (description of *mexicanus*); not *Reithrodon* Waterhouse.

Reithrodontomys Giglioli, 1874:326; type species *Reithrodon megalotis* Baird, designated by A. H. Howell (1914:13).

Ochetodon Coues, 1874:184; no type species selected among those listed (*humulis* Audubon and Bachman, *longicauda* Baird, *mexicanus* Saussure, *montanus* Baird, and *sumichrasti* Saussure).

Aporodon A. H. Howell, 1914:63; type species *Reithrodontomys tenuirostris* Merriam, by original designation.

Cudahyomys Hibbard, 1944:725; type species *Cudahyomys moorei* Hibbard, by original designation.

REMARKS: See A. H. Howell (1914:13) for why *Mus lecontii* Audubon and Bachman (= *Reithrodontomys humilis*) was incorrectly selected as the type species of the genus *Reithrodontomys* by G. S. Miller and Rehn (1901:95). Merriam (1892:26, footnote) was the first to recognize that *Reithrodontomys* Giglioli had date of publication priority over *Ochetodon* Coues, a position more thoroughly detailed by Hooper (1952:32, footnote).

Only a single species, *R. mexicanus*, is known to occur in South America, but Alberico et al. (2000) listed *R. darienensis* Pearson as a probable resident of Colombia in the region adjacent to Panama (see also Musser and Carleton 2005:1081). Furthermore, analyses of molecular, morphological, and ecological data suggest elevation of at least two of the three subspecies of *mexicanus* in Ecuador to species status (D. Chávez, unpubl. data; see below), and phylogenetically couple these harvest mice to *R. darienensis* rather than to *R. mexicanus*. When published, these analyses will result in substantial changes in the taxonomy and biogeographic history of harvest mice in South America.

Reithrodontomys mexicanus (Saussure, 1860)

Mexican Harvest Mouse

SYNONYMS (only as applied to South American taxa; additional synonyms under subspecies):

Mus tazamaca Gray, 1843a:79; *nomen nudum* (see Alston 1880a:152).

R[eithrodon]. *mexicanus*: Saussure, 1860:109; “mts. of Veracruz,” restricted to “Mirador, Veracruz, Mexico” (Hooper 1952:140).

Ochetodon mexicanus: Coues, 1874:186; name combination.

Reithrodontomys mexicanus: J. A. Allen, 1894a:319; name combination.

DESCRIPTION: Moderate to large for genus; tail much longer than head and body (about 130–160% of head and body length); body coloration varies geographically from uniform dark brown to blackish, basic color of upperparts tawny or orange-cinnamon, with slight variation in tone; upper parts of intensely pigmented races (such as *mexicanus* and *soederstroemi*) heavily covered with black over tawny ground color; upper parts of paler races nearly pure tawny; venter varies from whitish to pale cinnamon or orange-cinnamon; epidermis of ears fuscous and sparsely covered with black hairs; duskiness of tarsus extends onto foot as a longitudinal stripe of varying width and length, and in northern races covers most of upper surface of hindfoot, leaving only narrow rim of white; in more southern populations, this stripe narrower and wedge shaped, with

apex not extending to base of toes; dusky stripe in some specimens entirely lacking, and upper surface of hindfoot whitish or pale cinnamon; toes in all races whitish (Hooper 1952). Tirira (1999:lamina 21, 7) provided a color photo of a specimen from Ecuador.

DISTRIBUTION: *Reithrodontomys mexicanus* in South America occurs in the western and central Andes of Colombia to as far south as Quito, Ecuador, across an elevational range of 1,200 to nearly 4,000 m (A. H. Howell 1914; Hershkovitz 1941; Hooper 1952; Eisenberg 1989; Voss 2003). Humid tropical broadleaf forests are the typical habitat, but specimens have been collected in dry deciduous forests (Hooper 1952) and at the edge of grassy páramo (Voss 2003). This species exceeds all others in the subgenus *Aporodon* in the extent of geographic (including elevational) range as well as in expressed morphological variability. The South American populations of this species are apparently disjunct from those in Middle America, as a distributional gap in the range extends from northwestern Colombia at least to western Panama (Hall 1981; F. A. Reid 2009).

SELECTED LOCALITIES (Map 26): COLOMBIA: Antioquia, Guapantal (FMNH 71684), 15 km E of Río Negrito (FMNH 70181), Santa Elena (FMNH 69653), Valdivia, La Selva (FMNH 70167); Cauca, Munchique (type locality of *R. m. milleri* J. A. Allen), Río Guachicono (FMNH 90342), Río Mechengue (FMNH 90341), Valle de las Papas (Hooper 1952); Cundinamarca, San Cristóbal (FMNH 71663); Huila, Río Aguas Claras (FMNH 71701); Quindío, El Roble (Hooper 1952); Valle de Cauca, Correa, Farallones de Cali (Universidad de Cali collection), 4 km NW of San Antonio (MVZ 124064). ECUADOR: Imbabura, Intag (Hooper 1952), San Nicolás, near Pimanpiro (type locality of *R. m. eremicus* Hershkovitz); Napo, Río Oyacachi (AMNH 66808); Pichincha, Gualea (AMNH 46800), Mojanda (AMNH 46796), Quito (type locality of *R. m. soederstroemi* Thomas); Tungurahua, San Francisco (AMNH 67551).

SUBSPECIES: Three subspecies of *R. mexicanus* are reported for South America: *R. m. eremicus*, *R. m. milleri*, and *R. m. soederstroemi* (A. H. Howell 1914; Hershkovitz 1941; Hooper 1952). The molecular, morphological, and ecological analyses of D. Chávez (unpubl. data) suggest elevation of at least two of these subspecies to species status.

R. m. eremicus Hershkovitz, 1941

SYNONYM:

Reithrodontomys mexicanus eremicus Hershkovitz, 1941:4; type locality “near Pimanpiro, Imbabura Province, Ecuador; altitude, approximately 6500 feet.” Given as “Valle de la Chota, near Pimanpiro, San Nicolás” by Hooper (1952:160).

This race is restricted to light sandy soils supporting arid deciduous forest in Valle del Chota in Ecuador (Hershkovitz 1941:5). Hershkovitz (1941:5) stated that *eremicus* was distinguishable from other subspecies of *R. mexicanus* by its large ears and paler color, which he believed was “obviously correlated with the light sandy soil and open country of its habitat.” He also suggested that “although the area occupied by *R. m. eremicus* appears as an island within the range of *söderströmi* [sic], it is actually more directly connected with the range of *R. m. milleri* though the Río Chota Valley, which is the interandean trunk of the western Andean Río Mira Valley.” Even though Hershkovitz (1941) pointed to ear size as a diagnostic attribute, Hooper (1952) failed to find significant differences in ear size among races of *R. mexicanus* in South America in the samples he examined.

R. m. milleri J. A. Allen, 1912

SYNONYMS:

Reithrodontomys milleri J. A. Allen, 1912:77; type locality “Munchique (alt. 8325 ft), Cauca, Colombia.”

Reithrodontomys mexicanus milleri: Hershkovitz, 1941:2; name combination.

This race is the most widely distributed subspecies in South America, inhabiting Andean valleys and slopes at moderate to high elevations (1,800–3,150m) in Colombia and northwestern Ecuador. It occurs in both the Cordillera Occidental and Cordillera Central but is unknown from the Cordillera Oriental. Hershkovitz (1941) characterized the habitat as subtropical forest, but specimens have been collected in humid, montane evergreen forests.

Hooper (1952:159) regarded this race to be more strongly differentiated from the southern races *eremicus* and *soederstroemi* than it was from those to the north in Central America. He noted a general size increase from north to south, but specimens were too few to know whether the shift was gradual. A. H. Howell (1914) and Hershkovitz (1941) both assigned specimens from Valle de las Papas, 3,050m, Huila department, Colombia, to *soederstroemi*, but Hooper (1952) considered them most similar to topotypes of *milleri*.

R. m. soederstroemi Thomas, 1898

SYNONYMS:

Reithrodontomys söderströmi Thomas, 1898e:451; type locality “Quito,” 9,200ft, Pichincha, Ecuador (see Hooper 1952:161).

Reithrodontomys mexicanus söderströmi Hershkovitz, 1941:3; name combination.

This race is apparently restricted to the inter-Andean temperate zone of Ecuador, in the vicinity of Quito (Hooper 1952). It is larger than *milleri*, with a broader braincase

Map 26 Selected localities for *Reithrodontomys mexicanus* in South America (●). Contour line=2,000m.

and narrower zygomatic plate, but of similar color. Compared to *eremicus*, *soederstroemi* is similar in size and most cranial details but is distinct in color, with upper parts tan rather than dark reddish brown.

NATURAL HISTORY: Little has been published on the ecology or other aspects of the natural history of this species anywhere in its range in South America. Ludovic Söderström, who collected in Ecuador in the late 1890s, described individuals feeding on flowers and seeds in the gardens of Quito, emerging from climbing plants in the evening (Thomas 1898e).

Subfamily Sigmodontinae Wagner, 1843

Guillermo D'Elía and Ulyses F. J. Pardiñas

Sigmodontines constitute the most diverse South American subfamily of Cricetidae (Reig 1986), with members present in all terrestrial environments, ranging continentwide from the Cape Horn islands in the south to the Caribbean coasts of Colombia and Venezuela, and across an elevational gradient from sea level to nearly 5,000m. Outside

South America, sigmodontines today range through Central America and southern North America (to about 35°N), and historically occurred on some Caribbean islands. Most of the extant sigmodontine diversity (69 of 86 genera) is endemic to the South American continent (D'Elía 2003b), including neighboring continental islands such as Aruba, Curaçao, Trinidad, and Tobago.

The genus *Nesoryzomys* is endemic to the oceanic Galápagos Archipelago. Two genera (*Oryzomys* and *Sigmodon*) have largely North American distributions and diversities, and they enter South America only in the very northwest of the continent. One genus (*Oligoryzomys*) ranges throughout South America and reaches northward to near the Mexico-United States border. Eleven genera are distributed in Central and South America, with four of these extending barely into Panama (*Ichthyomys*, *Neacomys*, *Oecomys*, and *Rhipidomys*) while the other seven have broader ranges in Central America (*Handleyomys*, as currently delimited to include the “*alfaroi* species group,” *Melanomys*, *Nephelomys*, *Sigmodontomys*, *Tanyuromys*, *Transandinomys*, and *Zygodontomys*).

The water mouse *Rheomys* is the only mainland extant genus of sigmodontines not present in South America. Eight genera of sigmodontines became extinct in historic times or during the Pleistocene; four of these inhabited islands that are considered part of South America and thus would have been included in this book had they remained extant: *Megaoryzomys* (Galápagos Archipelago; Steadman and Ray 1982), *Noronhomys* (Fernando de Noronha; Carleton and Olson 1999), *Agathaeromys* (Bonaire; Zijlstra et al. 2010), and *Dushimys* (Curaçao; Zijlstra 2012). Some forms of *Aegialomys* and *Nesoryzomys* have become extinct in the Galápagos Archipelago in recent decades (Patton and Hafner 1983; Hutterer and Oromi 1993; Dowler et al. 2000).

Recent and continuing fieldwork has substantially expanded prior knowledge of the distributional range of many genera and species. For example, L. Luna and Patterson (2003) reported the rare genus *Rhagomys*, known for almost a century only from the Atlantic coastal Brazilian state of Rio de Janeiro, from the eastern slopes of the Peruvian Andes, and more recently Percequillo, Tirelli et al. (2011) documented its presence in central Amazonia.

Nevertheless, distributional patterns of the major sigmodontine groups are reasonably well known. The Oryzomyini, one of three tribes that occur in North, Central, and South America, has by far the largest geographical range, one nearly equivalent to that of the subfamily as a whole (Reig 1986; Weksler 2006). Members of this tribe, however, reach their greatest diversity in the tropical areas of South America. In contrast, the abrotrichine genera

are restricted to the Andean region, from the Altiplano in west-central Peru and western mountain ranges in Argentina and Bolivia to southernmost South America (including several islands) and the Patagonian steppes, reaching the Atlantic coast of Argentina (D'Elía et al. 2007).

Sigmodontines inhabit almost all habitat types found in their cumulative distributional range, including deserts, wet tropical and temperate forests, scrublands, wetlands, savannas, steppes, high elevation grasslands, and salt flats (Hershkovitz 1962). Many genera and even some species range across more than one habitat type. For example, *Abrothrix longipilis* can be found in steppe, bunchgrass prairie, Valdivian and subantarctic forests, and sparse shrubland. Many others, however, appear restricted both geographically and to specific habitat types. For instance, *Phyllotis anitae* is known only from the upper belt of the Yungas of northwestern Argentina. Tropical forested areas are roughly characterized by a predominance of oryzomyines and thomasomyines, temperate lowlands by akodontines, Andean piedmont deserts and high Andean areas by phyllotines, and cold arid lands, southern steppes, and temperate and subantarctic forests by abrotrichines (B. D. Patterson 1999).

Sigmodontines are generally small to medium in size, with the smallest species about 12 g in mass and the largest nearly 500 g. The largest living taxon, *Kunsia tomentosus*, does not surpass 300 mm in head and body length. External ears vary from nearly absent or much reduced (e.g., the aquatic rat *Anotomys* or the fossorial mouse *Notiomys*) to large (e.g., the cony rats of the genus *Reithrodon* or the leaf-eared pericotes of the genus *Phyllotis*). Most sigmodontines have a brownish or blackish upper pelage and grayish or whitish under parts. However, *Chinchillula* has a striking contrastingly colored pelage, with buffy or grayish upper parts with black lines, white under parts, and with both hips and rump white banded with black. *Abrothrix jelskii* is another species with a showy, contrastingly patterned pelage, at least for some of its multiple geographic races. Sigmodontine fur may be velvety, soft, woolly, long, thick, harsh, and/or composed of underfur and guard hairs. The genera *Abrawayaomys*, *Neacomys*, and *Scolomys* and the species *Rhagomys longilingua* have some hairs modified into stiffened spines.

In climbing and scansorial sigmodontines, the tail is usually longer than the head and body length; in more generalized terrestrial forms, it is about equal in length to the head and body; and in fossorial species, it is less than half the head and body length. The tail is typically thinly haired, but in some sigmodontines it ends in a penciled tip (e.g., in *Andalgalomys* and in many *Rhipidomys*).

The forefeet are in general relatively small, but those of fossorial forms, such as the giant rat *Kunsia*, are robust

and have extremely long claws. The hindfeet of aquatic species (e.g., those in *Holochilus*, *Lundomys*, *Nectomys*, and ichthyomyines) are large and webbed, and they may have stiffened natatory hairs along the edges, including the digits (ichthyomyines). Climbers (e.g., *Oecomys* and *Rhipidomys*) typically have shortened but broad hindfeet, elongated toes for grasping, and enlarged plantar pads. The hindfeet of the arboreal mouse *Rhagomys* are unique among sigmodontines in having an elongated digit V and a hallux with a nail instead of a claw.

Sigmodontines possess one pair of upper (rarely grooved) and lower incisors and lack canines, as do all other rodents; as with other cricetids, they lack premolars. Three cheek teeth, or molars, are present on each side, above and below, in all but two sigmodontines that exhibit reduction to two molars (*Neusticomys ferreirai* and *N. oyapocki*). As such, the total number of teeth is typically 16. Supernumerary molars have not been reported, in contrast with their presence in some North American neotomines. The molars exhibit substantial variation in size, morphology, and number of roots (from one to six) and are fairly complex structures. For an idealized sigmodontine molar, Reig (1977) named more than 30 cusps, cuspules, styles, lophes, folds, and islands (see also Hershkovitz 1993 for additional topographical details). Molar crown height is apparently related to diet. Sigmodontines that feed on animals, seeds, fruits, or fungus have low-crowned or brachydont molars. High-crowned or coronal hypsodont molars, which extend well above the gum line, are generally present in sigmodontines that feed on abrasive vegetation (e.g., grass). The hypsodont condition is often associated with simplified occlusal surfaces, with the connection of lophes on each tooth side forming lamina, planation of the crown, and an increase in the number of roots. Two main types of molars are recognized with respect to the number of lophes: tetralophodont and pentalophodont. Hershkovitz (1962; see also Hershkovitz 1993) suggested that the pentalophodont type represents the ancestral state from which a simpler, tetralophodont molar evolved. Remarkably, given the substantial influence that Hershkovitz's hypothesis has had on sigmodontine systematics, the evolution of molar traits has not been studied within a contemporary phylogenetic approach. In light of current phylogenetic hypotheses and the available fossil record, it appears more likely that, among the Sigmodontinae, tetralophodont and pentalophodont molar types represent the plesiomorphic and apomorphic character states, respectively. Nevertheless, the number of character state transformations of the molars that have occurred across the sigmodontine radiation, as well as the timing and the placement of those transformations, remains a mystery.

As is true for nearly all mammals, craniodental morphology has been the basis of sigmodontine taxonomy and

systematics, owing to the remarkable variety even among closely related lineages (e.g., genera; Voss and Marcus 1992). Different regions of the skull and mandibles have been minutely scrutinized, with features of the bony palate, supraorbital region, foraminal pattern, and mandible body expression forming the foundation for taxonomic assignment. Several anatomical traits show great variation. For example, the zygomatic plate (despite the myomorph condition of the sigmodontine skull) varies from being a narrow but robust structure in ichthyomyines to broad and high plates in granivorous and grazing members of the tribes Phyllotini and Sigmodontini. The bony palate also displays trenchant differences, including both short versus long and wide versus narrow conditions (Hershkovitz 1962). Another anatomical trait useful in separating major groups is the absence in oryzomyines of a suspensory process of the squamosal bone, which contacts the tegmen tympani (Weksler 2006). The internal carotid artery and its derivatives display three main circulatory patterns (Voss 1988) that have proven valuable in diagnosing taxa and supporting phylogenetic hypotheses. Recent phylogenetic analyses strongly suggest that several morphological state characters have evolved more than once within the sigmodontine radiation, whereas others may be symplesiomorphies.

With a few well-recognized exceptions (i.e., some species of *Abrothrix* and at least one of *Punomys*; Spotorno 1992), sigmodontines have complex penises (Hooper 1959; Hershkovitz 1962). A complex penis has two lateral horns on the cartilaginous distal baculum, making it appear trident-shaped. A simple, saclike stomach (Vorontsov 1979; Carleton 1973) also characterizes all sigmodontines, although the details of morphology vary among genera (Carleton 1973).

Over the last decades of the past century, the contents of the subfamily Sigmodontinae have been the center of much debate (reviewed by Carleton 1980; Reig, 1980; Stepan 1995; D'Elía 2000; Stepan, Adkins, and Anderson 2004; Musser and Carleton 2005). This debate primarily concerns whether to limit the Sigmodontinae, as currently understood, to those predominantly South American cricetids with the tridigitate baculum of the complex penis morphology (e.g., *Sigmodon*, *Oryzomys*, *Akodon*, *Phyllotis*) or to also include the predominantly North American forms with a single-pronged baculum, commonly referred to as the neotomine-peromyscines and currently placed in the cricetid subfamilies Neotominae (e.g., *Neotoma*, *Peromyscus*, *Reithrodontomys*) and Tylomyinae (e.g., *Tylomys*). Early studies based on the muscular system (Rinker 1954), accessory glands of the male reproductive system (Arata 1964; see also Voss and Linzey 1981), glans penis morphology (Hooper 1959; Hooper and Musser 1964), stomach morphology (Carleton 1973), and ectoparasite

distributions (Wenzel and Tipton 1966), together with considerations of geographic distribution, led Reig (1980; see also Hershkovitz 1966a, 1972) to argue strongly in favor of the phylogenetic distinction between sigmodontines and neotomine-peromyscines. Under this hypothesis, the Sigmodontinae are restricted to including only the predominantly South American complex penis cricetids. We note, however, that Hershkovitz (1966a) considered some forms (e.g., *Nyctomys*) in his concept of the Sigmodontinae, taxa that Reig (1984) later placed in the Tylomyinae, a new cricetid subfamily (see the emended diagnosis of this subfamily in Musser and Carleton 2005:1186).

The same year that Reig (1980) published his study favoring the restriction of Sigmodontinae to the predominantly South American complex penis cricetids, Carleton (1980) published a landmark and highly influential monograph on muroid morphological variation in which he favored an alternative, broader definition of Sigmodontinae. Even though Carleton's analysis (Fig. 41, p. 117) supported the monophyly of complex penis sigmodontines and their close relationship with Old World murids rather than with neotomine-peromyscines, he stated that "it is premature to taxonomically formalize a division between New World cricetines" (i.e., sigmodontines on the one hand and neotomine-peromyscines on the other).

Despite early molecular work that also supported sigmodontine monophyly (Sarich 1985; Catzefflis et al. 1993), Carleton's suggestion soon became solidified in the most important treatises of muroid rodent taxonomy (Carleton and Musser 1984; Musser and Carleton 1993; McKenna and Bell 1997), in which Sigmodontinae was defined to also include both the neotomine-peromyscines and tylomyines. However, DNA-based phylogenetic analyses published at the end of the 1990s (M. Robinson et al. 1997; Engel et al. 1998; M. F. Smith and Patton 1999; Dubois et al. 1999) strongly supported the monophyly of the Sigmodontinae (*sensu* Reig 1980) to the exclusion of the neotomine-peromyscines and tylomyines. In addition, in some of the trees recovered in these studies, the sigmodontine group was not even recovered as sister to clades of genera now placed in the Neotominae or Tylomyinae (e.g., Musser and Carleton 2005). These studies have reinforced, as presciently recognized by D'Elía (2000), the substantive distinction between sigmodontines and the rest of the New World cricetids. More recent molecular studies (Jansa and Weksler 2004; Stepan, Adkins, and Anderson 2004; Parada et al. 2013; Schenk et al. 2013; J. F. Vilela et al. 2013) have corroborated these earlier phylogenetic results and affirmed the independence of Sigmodontinae relative to both Neotominae and Tylomyinae.

Although the usage of a broadly defined Sigmodontinae has persisted in some recent literature (e.g., Álvarez-

Castañeda and Cortés-Calva 2003; Amman and Bradley 2004), Musser and Carleton's (2005) muroid catalog solidified the usage of Sigmodontinae *sensu* Reig (1980), drawing heavily on the increasing depth and breadth of molecular phylogenetic analyses. Thus, as currently defined, the subfamily Sigmodontinae includes 86 living genera and about 400 living species, of which 85 genera and 381 species inhabit South America. These numbers will continue to increase as new genera (see Weksler et al. 2006; Pardiñas, D'Elía, and Teta 2009; Percequillo, Weksler, and Costa 2011) and species (e.g., Jayat et al. 2010; R. G. Rocha, Costa, and Costa 2011; Tavares et al. 2011; C. F. Jiménez et al. 2013; Pardiñas, Teta et al. 2013; Gonçalves and Oliveira 2014) are discovered and described. Also notable, in addition to playing a key role in the discovery of new species, the increasing use of molecular data in taxonomic studies of Sigmodontinae has significantly clarified species boundaries, resulting either in the validation or synonymization of nominal forms (see, for example, D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008).

Hershkovitz (1966b) showed that the correct name to apply to the clade comprising the predominantly South American complex-penis mice and rats was based on Wagner's (1843a) "Sigmodontes," later Latinized to Sigmodontinae (Thomas 1897a), which has priority over Hesperomyinae Murray, 1866 (and such later variants as Hesperomyes Winge, 1887; Hesperomyidae Ameghino, 1889; or Hesperomyini Simpson, 1945). "Sigmodontes," and thus Sigmodontinae, is based on *Sigmodon* Say and Ord 1825, the oldest sigmodontine generic name. Reig (1980) agreed with Hershkovitz that Sigmodontinae was the correct name to use for this clade because it antedated Hesperomyinae, not because, as Hershkovitz (1966b) argued, the latter was formally unavailable. Hershkovitz (1966b) also ranked the sigmodontine group at the level of tribe (Sigmodontini) because he treated the group of mice and rats with two longitudinal rows of molar cusps as a subfamily, Cricetinae, of a broadly conceived family Muridae.

Historically, genera of Sigmodontinae have been united into various groups, beginning with Oldfield Thomas (1906c, 1916a, i, 1917d; see synopsis in Carleton and Musser 1989:53–55), only some of which have been formalized at the rank of tribe in zoological classifications. The number and content of these groups, as well as of their constituent genera, have varied from authority to authority (e.g., Hershkovitz 1966a), mostly depending on the relative weight given to different trenchant characters. The early use of genital morphology (Hooper and Musser 1964) and karyotypic data (A. L. Gardner and Patton 1976), both to advance hypotheses on the contents of sigmodontine suprageneric groups and delimit relationships, deserves special mention. By the early 1990s, the widespread adoption of phylogenetic methodology applied to morphological

character sets (Braun 1993; Steppan 1995; Pacheco 2003), DNA sequence data (M. F. Smith and Patton 1991, 1993, 1999; D'Elía 2003a; Weksler 2003, 2006; D'Elía, Luna et al. 2006; J. J. Martínez et al. 2012; Parada et al. 2013; Salazar-Bravo et al. 2013; Schenk et al. 2013), or a combination of both (e.g., Weksler 2006) has prompted a reconsideration of the distinctiveness of suprageneric groups. The major changes promoted by these studies include the recognition of a previously unnoted group (Abrotrichini), the coalescence of some groups previously recognized (i.e., scapteromyines and oxymycterines into Akodontini), and corroboration of the separation of others (e.g., Reithrodontini, Wiedomyini), as well as changes in the generic composition of most groups. Detailed historical accounts of these changes are given in the tribal accounts that follow herein.

In the most recent classification of sigmodontine rodents, D'Elía et al. (2007) recognized nine tribes plus 11 extant genera (i.e., *Abrawayaomys*, *Andinomys*, *Chinchillula*, *Delomys*, *Euneomys*, *Irenomys*, *Juliomys*, *Neotomys*, *Phaenomys*, *Punomys*, and *Wilfredomys*) they considered individually unique lineages and provisionally treated as Sigmodontinae *incertae sedis*. Since early 2013, the main elements of this classificatory scheme have not changed, and it is the one we follow here. With additional data, however, the most significant departure from this classification may be the establishment of a tribe for a strongly supported clade of mostly Andean genera that would include *Andinomys* and *Punomys* as well as *Euneomys*, *Neotomys*, and *Irenomys* (J. J. Martínez et al. 2012; Salazar-Bravo et al. 2013). Furthermore, the phyletic placement of newly described living genera (e.g., *Neomicroxus* Alvarado-Serrano and D'Elía, 2013) or those already known but yet to be described will need to be ascertained or affirmed.

Perhaps not surprisingly, genus- or species-group taxa are not evenly distributed among tribes. The Akodontini, Oryzomyini, and Phyllotini together account for more than a half of all extant genera and species in the subfamily. The Abrotrichini, Ichthyomyini, Reithrodontini, Sigmodontini, Thomasomyini, and Wiedomyini include one to five extant genera each, and only in a few cases are one or more highly speciose genera included. For example, the Thomasomyini, as currently conceived, encompasses but four living genera, one of which (*Thomasomys*) is the most diverse genus in the subfamily, with 44 species.

As will be clear from the tribal and generic accounts, the alpha taxonomic schemes advanced by Gyldenstolpe (1932), Ellerman (1941), Cabrera (1961), Carleton and Musser (1984), and Musser and Carleton (1993, 2005) have been highly influential and are mandatory sources for those interested in sigmodontine species diversity and generic allocations. Hershkovitz (1962), Reig (1987), and

Voss (1988) each played an equivalent central role for phyllotines, akodontines, and ichthyomyines, respectively. Similarly, the generic nomenclatural historical accounts assembled by Tate (1932a–i) are invaluable sources of information, particularly for tracing the often tortuous use of names and their authors. Finally, the voluminous contributions of Oldfield Thomas in describing new sigmodontine species and genera are unparalleled.

Recent and current sigmodontine taxonomic studies, in general, have been based on multiple sources of evidence. Even though it is not a universal practice (see Tavares et al. 2011), the majority of descriptions of new sigmodontine species now take advantage of the power of the genealogical analysis of DNA sequences to determine species-level lineages. The mtDNA cytochrome-*b* gene has been, by far, the sequence of choice. It is noteworthy, however, that only a handful of studies (e.g., D'Elía and Pardiñas 2004; Jayat, Ortiz et al. 2007; Jayat et al. 2010; D'Elía et al. 2011) have taken full advantage of genealogical analyses of sequence data by providing molecular synapomorphies for species newly defined. Instead, most studies relying on molecular data to delimit species have done so using the principle of monophyly and have ignored molecular characters themselves in the diagnosis of newly circumscribed species.

Although the generic composition of sigmodontine tribes may be relatively stable, phylogenetic relationships among the tribes remain uncertain. At present (mid-2013), only the coupling of the Sigmodontini and Ichthyomyini appears both well corroborated and as a sister pair falling outside of a well-supported clade that includes all other sigmodontines (Weksler 2003; Jansa and Weksler 2004; D'Elía, Luna et al. 2006; Parada et al. 2013; Salazar-Bravo et al. 2013; Schenk et al. 2013). Steppan, Adkins, and Anderson (2004) named the clade comprising all sigmodontines except Sigmodontini and Ichthyomyini the Oryzomyalia. All Sigmodontinae *incertae sedis* genera that have been included in any phylogenetic analysis fall in this oryzomyalid clade. However, within the Oryzomyalia only a few tribal relationships are relatively well corroborated. For example, the Abrotrichini and Wiedomyini are sister to each other, as are Phyllotini and the *incertae sedis* genus *Delomys* (D'Elía, Luna et al. 2006; Salazar-Bravo et al. 2013), although the latter case is based solely on the nucDNA interphotoreceptor retinoid-binding protein (IRBP) locus. As always, data from multiple other mitochondrial but especially nuclear loci will be needed to clarify clade relationships as well as to affirm the membership in each.

Since the 1970s, cytogenetic studies of Sigmodontinae have become widespread, with studies reporting new cytotypes routinely published (e.g., A. L. G. Souza, Corrêa et al. 2011). Hence, chromosomal data are available for

a large number of species in the subfamily. Available data on chromosome and autosomal arm numbers ($2n$ and FN, respectively) cover the entire or large portions of the radiation represented by living forms in the tribes Abrotrichini, Akodontini, Oryzomyini, Phyllotini, Reithrodontini, Sigmodontini, and Wiedomyini (see, for example, N. O. Bianchi et al. 1971; A. L. Gardner and Patton 1976; Pearson and Patton 1976; Kasahara and Yonenaga-Yassuda 1984). Data for species of the Thomasomyini are fewer, and those for ichthyomyine species are limited or nonexistent. Banding patterns are known for a much smaller number of sigmodontine species than those for which we have only non-differentially stained karyotypes. Cytogenetic data have been gathered mostly in the course of alpha taxonomic studies and have been used primarily to support recognition of new species (e.g., *Loxodontomys pikumche* Spotorno, Cofre et al. 1998; see comments in the account of *Loxodontomys*). Most taxonomic studies in which cytogenetic information has been used, however, have integrated those data together with morphological and/or molecular character sets (e.g., Patton et al. 2000).

Parallel to taxonomically oriented studies, several reports have focused on sigmodontine chromosomal evolution (e.g., R. J. Baker et al. 1983). In a still influential study, A. L. Gardner and Patton (1976; see also Pearson and Patton, 1976) suggested a general trend of sigmodontine chromosomal evolution toward a decrease in both chromosome and fundamental numbers from an initial complement of 70 to 80 chromosomes. Although no phylogenetically based study has been conducted to test the general applicability of this pioneering scheme of chromosomal evolution, Salazar-Bravo et al. (2001) found support for some parts in the genus *Calomys*. Nevertheless, we suggest that the pattern of sigmodontine chromosomal evolution is much more complex than that suggested by A. L. Gardner and Patton (1976). For example, the oryzomyines are not the stem stock from which all other sigmodontine lineages arose as these authors, and others at that time, envisioned. Furthermore, in a few cases (e.g., *Sigmodon*, where $2n$ ranges from 22 to 82; see Swier et al. 2009), examination of karyotypic diversity in an explicit phylogenetic context supports both an increase and a decrease in chromosome and arm number (see also R. J. Baker et al. 1983). The use of novel molecular cytogenetic techniques (e.g., reciprocal chromosome painting; K. Ventura et al. 2009) is a promising approach to determine putative chromosome homologies as well as the type of chromosome rearrangements involved in chromosome evolution for any given lineage. Such studies, however, require use of an explicit phylogenetic framework to separate homoplasy from homologies due to genealogical descent.

Although extensive, sigmodontine diversity in the fossil record of South America is not as great as at present (for a review, see Pardiñas et al. 2002). The oldest recorded South American sigmodontines come from presumed latest Miocene sediments in La Pampa (Verzi and Montalvo 2008; but see Prevosti and Pardiñas 2009) and Catamarca (Nasif et al. 2010) provinces, Argentina. By the beginning of the Pliocene, about 5 mya, genera representing at least four tribes as currently defined were present in central Buenos Aires province, Argentina. These include the Reithrodontini, Phyllotini, Akodontini, and Abrotrichini. Sigmodontines are rare in Early Pliocene beds (Montehermosan to Sanandresian ages) but become more abundant in Late Pleistocene sediments. Although more than half of the extant South American genera are represented in the fossil record (many from Holocene deposits), seven genera are known only from the fossil record, and an additional four genera have gone extinct in historic times. The assignment of some North American fossils, such as *Abelmoschomys*, *Prosigmodon*, *Bensonmysis*, and *Symmetrodontomys* (see Lindsay 2008), is questionable and deserves further scrutiny (Prevosti and Pardiñas, in press). The oldest unequivocal fossil sigmodontines in the North American fossil record are representatives of *Sigmodon* from Early Blancan deposits (Peláez-Campomanes and Martin 2005).

An understanding of sigmodontine evolutionary history has proved to be a complex task and the center of much debate. D'Elia (2000) and Pardiñas et al. (2002) provided the most comprehensive and recent reviews, and we refer the reader to these sources for details and especially for historical aspects of the debate. There is general agreement that even though most sigmodontines are endemic to South America, the immediate ancestor of the group did not originate on the continent. This consensus derives from the lack of a potential ancestor having been discovered in South America, and this implies that, at some point in their history, sigmodontines, or their immediate ancestor, invaded South America, with Central America being the most likely source area. As mentioned previously, the fossil record indicates that this invasion was as late as the latest Miocene (or Early Pliocene).

As of early 2014, two main aspects of sigmodontine historical biogeography remain unresolved: the geographic placement of the basal sigmodontine radiation, including how many sigmodontine lineages invaded South America (see, for example, B. Patterson and Pascual 1968b, 1972; Baskin 1978, 1986; Reig 1984, 1986), and the timing of the sigmodontine invasion of South America (see, for example, Baskin 1978, 1986; Marshall 1979; Simpson 1950; Reig 1984, 1986). Although these two issues have thus far eluded resolution, advances prompted by available phyloge-

netic analyses offer two hypotheses. These analyses tend to place the Sigmodontinae as sister to the Tylomyinae (Parada et al. 2013; Schenk et al. 2013; J. F. Vilela et al. 2013). Because both groups occur only in the Americas, it is most parsimonious to hypothesize that their common ancestor resided in the New World, thus resolving one of the issues of the sigmodontine historical biogeography debate, namely, a New versus Old World home for the immediate ancestor of the Sigmodontinae (see the different positions taken by B. Patterson and Pascual 1968b, 1972; Hershkovitz 1972; Slaughter and Ubelaker 1984; and L. L. Jacobs and Lindsay 1984).

As to the second issue, the most comprehensive molecular clock-based estimates of the cladogenic events underlying the sigmodontine tribes (Parada et al. 2013; Schenk et al. 2013; J. F. Vilela et al. 2013) have indicated that the split between lineages leading to the Sigmodontini + Ichthyomyini and *Oryzomyalia* was between 14.70 and 9.28 mya. Furthermore, the base of the *Oryzomyalia*, and thus the subsequent radiation of the tribal lineages in this larger clade, was between 9.64 to 6.01 mya. Because the Panamanian land bridge was completed about 3 mya (Bartoli et al. 2005), these estimates falsify those historical biogeographic scenarios that posited a sigmodontine radiation in South America only after closure of the Panamanian land bridge (see Simpson 1950).

More importantly, the presence of sigmodontines in southern South America before the origin of the Panamanian Isthmus is now firmly established (e.g., Pardiñas and Tonni 1998), despite the reinsertion of doubts in recent reviews (e.g., S. D. Webb 2006). The number of sigmodontine lines that invaded South America remains to be ascertained (but see the discussion in Steppan, Adkins, and Anderson 2004:548–549; and especially that of Parada et al. 2013), and it also remains unclear whether some North American sigmodontines (i.e., some species of *Sigmodon* and some ichthyomyines) are in situ direct descendants of the first sigmodontines or whether they represent secondary invasions of North America from lineages that initially differentiated in South America. This issue will remain unresolved until a deeper assessment and understanding of presumptive sigmodontine North American fossils are acquired through comparison with extinct and extant South American forms (Prevosti and Pardiñas, in press). Similarly, a comprehensive phylogenetic analysis that includes all living forms of *Sigmodon* and of the Ichthyomyini is required to infer the geographic distribution of the ancestor of the sigmodontine crown group (D'Elía 2003a). This latter goal seems more feasible, and perhaps also more promising, than a comprehensive review of putative sigmodontine North

American forms, a chaotic and still expanding narrative that includes several unsupported ancestor-descendent hypotheses linking enigmatic fossils to living entities (Lindsay and Czaplewski 2011).

Reig's (1984, 1986) hypothesis regarding sigmodontine historical biogeography deserves special mention. He identified different geographic areas, which he termed "Areas of Original Differentiation, or AOD," and in which sigmodontine tribes would have radiated. He defined "an AOD [as] the geographic space within which a given taxon experienced the main differentiation of its component taxa of subordinate rank" (Reig 1984:411). Thus, for a given tribe, this area may or may not be the same as that where the ancestor of the tribe would have originated. Reig (1984:344–345) identified six tribal AODs, each defined a priori on the basis of highest occurrence of species, genera, and endemic genera. All tribal AODs fell along the Andes. As a corollary, most genus-group lineages originated in the Andes and later colonized the extensive South American lowlands. As will be developed further in the Akodontini account, testing Reig's hypothesis is not straightforward, and no study to date has provided a rigorous test. However, available evidence (i.e., known distributions of extinct and living forms, and current understanding of tribal limits) suggests that the historical biogeography of Sigmodontinae in South America is much more complex than Reig envisioned. Clearly, a significant number of generic lineages originated outside the Andes, with multiple colonizations of both the Andes and the lowlands (see M. F. Smith and Patton 1999; D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008; Salazar-Bravo et al. 2013).

Despite great progress made to date, there remain important unresolved problems in sigmodontine systematics, issues involving both low and high taxonomic levels. For example, how many sigmodontine species are there? Is the polytomy found at the base of *Oryzomyalia* hard or soft? Furthermore, these questions relate to both pattern and process: Did the tribal crown groups diversify at about the same time, or did the more diverse ones radiate earlier? Have sigmodontine species and genera accumulated at a constant rate, or have there been diversification pulses? Have chromosomal changes triggered speciation events? Why are akodontines less diverse in Amazonia than in temperate open areas? Some of these questions may be clarified through phylogenetic analyses with dense taxonomic coverage, preferably exhaustive at the species level and based on multiple loci within a molecular clock-based temporal inference (such as Parada et al. 2013; Schenk et al. 2013). The answers to other questions depend on the continuation of collection-based research,

with specimens already at hand and/or the capture of additional specimens in nature, including excavation of new and better fossils. Similarly, new areas of study such as breeding experiments coupled with developmental genetics hold great promise for new insights. We are confident that the next few years will bring new understanding of the sigmodontine radiation, one that will substantively increase our comprehension of the biological processes that generated and sustain it.

KEY TO THE TRIBES OF SIGMODONTINAE (NOTE: 12 GENERA DO NOT CLEARLY FIT WITH ANY DEFINED TRIBE AND ARE TREATED SEPARATELY UNDER THE HEADING SIGMODONTINAE *INCERTAE SEDIS*):

1. Pentalophodont molars with persistent mesoloph. . . . 2
- 1'. Tetralophodont or even simplified molars 4
2. Absence of the posterior suspensory process of squamosal connected to the tegmen tympani Oryzomyini
- 2'. Presence of the posterior suspensory process of squamosal connected to the tegmen tympani 3
3. Bony palate, short and wide Thomasomyini
- 3'. Bony palate, long and wide Wiedomyini
4. Absence of pectoral mammae 5
- 4'. Presence of pectoral mammae 6
5. Stiff mystacial vibrissae ventrally recurved, absence of zygomatic notches, presence of large masseteric tubercles, absence of a pars flaccida, and nuchal ligament attached to the third thoracic vertebra Ichthyomyini
- 5'. Skull with long rostrum and rounded braincase, without frontal or lambdoid crests; interorbital region amphora-shaped; frontal sinuses moderately developed; palate long; anterior border of mesopterygoid fossa square Abrotrichini
6. m3 strongly sigmoid 7
- 6'. m3 not strongly sigmoid 8
7. Large ears and eyes; double grooved upper incisors; cuniculoid aspect; short tail; posterior suspensory process of squamosal not connected to the tegmen tympani Reithrodontini
- 7'. Moderate ears and eyes; upper incisors usually smooth; posterior suspensory process of squamosal connected to tegmen tympani Sigmodontini
8. Moderate or large ears; parapterygoid fossa relatively broader than mesopterygoid fossa; very open sphenopalatine vacuities; complete loss of mesoloph; posterior extensions of premaxillaries and nasals subequal; gall bladder present Phyllotini
- 8'. Moderate or small ears; skull with long rostrum and rounded braincase, with frontal sinuses well developed; interorbital region amphora-shaped; persistent mesoloph usually fused to paracone; gall bladder present or absent Akodontini

Sigmodontinae incertae sedis

Guillermo D'Elía

Attempts to place sigmodontine genera in suprageneric groups have revealed some genera with unclear affinities. In precladistic studies, these genera were mostly those showing otherwise trenchant characters of more than one group. One early example of this conundrum was Thomas's (1906c, 1917d) observation that pentalophodont sigmodontines were not cleanly divided into taxa with short, unpitted palates and with six mammae (e.g., *Thomasomys* and *Rhipidomys*, the basis for the tribe Thomasomyini) versus those with long, pitted palates and eight mammae (e.g., *Oryzomys* and *Oecomys*, tribe Oryzomyini). For example, the southeastern Brazilian *Delomys* and *Phaenomys* have short and unpitted palates but eight mammae, whereas *Rhagomys rufescens* has six mammae but a posterior palate similar to that of *Oryzomys* and *Oecomys*. Musser and Carleton (2005) illustrated this problem with respect to *Abrawayaomys*, another example a taxon displaying key features seen in more than one tribe: "diagnostic traits seem to combine aspects of *Neacomys*, *Oryzomys*, and *Akodon* . . . Certain cranial features of *Abrawayaomys* suggest an archaic 'thomasomyine,' perhaps distantly related to the other endemic genera of SE Brazil."

Analyzing the distribution of character states displayed by pentalophodont sigmodontines, Voss (1993) argued that thomasomyine genera (*sensu* Hershkovitz 1962, 1966a; see also Cerqueira 1982 and Eisenberg and Redford 1999) were united by sharing putative primitive character states and that, therefore, the group was not natural (see the account of the tribe Thomasomyini). Voss (p. 25) added that these genera "could simply be called 'plesiomorphic Neotropical muroids.'" Preferring not to place genera such as *Abrawayaomys*, *Aepeomys*, *Chilomys*, *Delomys*, *Juliomys* (in 1993 *pictipes* was still placed in *Wilfredomys*), *Phaenomys*, *Rhagomys*, *Rhipidomys*, *Thomasomys*, and *Wilfredomys* into monogeneric tribes, Voss (1993) implicitly regarded them as *Sigmodontinae incertae sedis*.

Subsequently, with the adoption of an explicit phylogenetic approach given by the formal construction of phylogenetic trees, several sigmodontines could not be placed into any robust monophyletic group of tribal level. A number of these genera included, as expected, some of those traditionally considered to be of uncertain phylogenetic position (e.g., *Delomys*), whereas others were genera that for most of sigmodontine taxonomic history had been placed in a tribe. This group is well illustrated by genera that, at one time or another, have been placed in the Phyllotini (e.g., *Andinomys*, *Chinchillula*, *Euneomys*, *Irenomys*, *Neotomys*, *Punomys*;

Steppan 1995; M. F. Smith and Patton 1999; D'Elía 2003a; Salazar-Bravo et al. 2013).

Realization that several sigmodontine genera do not belong in any of the groups ranked as tribes invites two classificatory alternatives: either to erect a monogeneric tribe for each, or to treat them as Sigmodontinae *incertae sedis*. In agreement with Voss (1993) and M. F. Smith and Patton (1999), D'Elía (2003a) chose the option to treat these genera as Sigmodontinae *incertae sedis*, because, in this case, the proliferation of taxa (e.g., monogeneric tribes) would not provide any additional information to systematists. Thus, those genera without clear phylogenetic relationships (e.g., *Chinchillula*) or that are sister to well-defined tribes (e.g., *Delomys*, which is sister to Phyllotini) do not have to be forced into tribes. This policy does not exclude the continuing use of existing tribes (i.e., Sigmodontini, Reithrodontini, and Wiedomyini) composed of a single extant genus. Rather, the acceptance of both *incertae sedis* genera and current monogeneric tribes is justified by the availability of existing names. Moreover, these currently recognized tribes are only monogeneric with respect to Recent genera. The Wiedomyini, for example, includes the extinct *Cholomys* in addition to the extant *Wiedomys*; the Sigmodontini also includes the extinct *Prosigmodon* (but see Peláez-Camomanes and Martin 2005); and several extinct genera (i.e., *Ichthyurodon*, *Panchomys*, and *Tafimys*) may be part of the Reithrodontini, which is otherwise composed only of the living *Reithrodon* (but not *Euneomys* or *Neotomys*; D'Elía 2003a; J. J. Martínez et al. 2012).

The list of genera treated as Sigmodontinae *incertae sedis* has varied from author to author. For example, Reig (1986) assigned this status to *Abrawayaomys*, *Punomys*, *Rhagomys*, and *Zygodontomys*, while Musser and Carleton (1993) added a fifth genus, *Pseudoryzomys*, to Reig's list. M. F. Smith and Patton (1999), in their influential molecular phylogenetic study, found that *Delomys*, *Irenomys*, *Juliomys* (as represented by *pictipes*, then placed in *Wilfredomys*), *Reithrodon*, and *Scolomys* lacked clear phylogenetic relationships and referred to them as "additional unique lines" as a way to emphasize their uncertain placement. These authors also listed *Abrawayaomys*, *Microakodontomys*, *Phaenomys*, *Punomys*, and *Rhagomys* as *incertae sedis*, following previous morphologically based assessments, as their molecular analyses did not include them. Those taxa Smith and Patton identified as "additional unique lines" are also best viewed as *incertae sedis* (except *Reithrodon*, for which the tribal name Reithrodontini was already available, and *Scolomys*, for which subsequent broader-based molecular studies have shown a clear linkage in the Oryzomyini; Weksler 2006; D'Elía et al. 2007; Parada et al. 2013). Musser and Carleton (2005) listed nine genera as Sigmodontinae *incertae sedis*: *Abrawayaomys*, *Delomys*,

Irenomys, *Juliomys*, *Phaenomys*, *Punomys*, *Rhagomys*, *Scolomys*, and *Wilfredomys*.

The genera of Sigmodontinae *incertae sedis* listed here comprise 12 Recent taxa following the classification given by D'Elía et al. (2007). Molecular-based phylogenetic analyses (e.g., D'Elía 2003a; J. J. Martínez et al. 2012; Alvarado-Serrano and D'Elía 2013; Parada et al. 2013; Salazar-Bravo et al. 2013; K. Ventura et al. 2013) indicate that *Abrawayaomys*, *Andinomys*, *Delomys*, *Chinchillula*, *Euneomys*, *Irenomys*, *Juliomys*, *Neomicroxus*, *Neotomys*, and *Punomys* fall in the large clade referred to as Oryzomyalia, which groups all Sigmodontinae except for Sigmodontini and Ichthyomyini (Steppan, Adkins, and Anderson 2004). *Abrawayaomys*, in particular, is notable for constituting "the single representative so far known of one of the main lineages of the radiation of Sigmodontinae" (K. Ventura et al. 2013:8). Pacheco (2003), in a morphologically based phylogenetic analysis, recovered *Phaenomys* and *Wilfredomys* as members of a clade otherwise composed of thomasomyine genera (see the account of Thomasomyini); neither of these two genera has been included as yet in a molecular-based phylogenetic analysis.

Andinomys and *Punomys* appear as sisters in analyses encompassing both mtDNA and nucDNA sequences (Parada et al 2013; Salazar-Bravo et al. 2013; Schenk et al. 2013) in a larger clade that somewhat more weakly also includes *Chinchillula* and *Juliomys* with *Irenomys*, *Euneomys*, and *Neotomys*. J. J. Martínez et al. (2012) also recovered *Euneomys*, *Irenomys*, and *Neotomys* as a well-supported clade, which they argued deserved tribal rank. Further studies thus may prompt the proposition of one or more new tribes to encompass some or all of these genera. Alternatively, as emphasized by D'Elía (2000), it is possible that *incertae sedis* genera truly constitute unique members of deep sigmodontine lineages and, as such, that their uncertain position is not due to the amount or quality of the data analyzed to date. If so, sigmodontine phylogenetic diversity is even greater than has been acknowledged previously.

KEY TO THE GENERA OF SIGMODONTINAE *INCERTAE SEDIS*:

1. Fur soft, without spines; upper incisors opisthodont; cheek teeth pentalophodont or tetralophodont; occlusal surfaces varied 2
- 1'. Fur with strongly developed, flat spines; upper incisors opisthodont to proodont; cheek teeth pentalophodont; occlusal surfaces crested *Abrawayaomys*
2. Pelage short, either coarse or soft; interorbital region broad, diverging posteriorly; incisive foramina short, typically not reaching anterior edges of M1s; anteromedian

- flexus of M1 prominent; palate wide; sphenopalatine vacuities absent or small, roof of mesopterygoid fossa partially or completely ossified 3
- 2'. Pelage long, soft; interorbital region narrow, laterally compressed; incisive foramina medium to long, penetrating to or beyond anterior edges of M1s; anteromedian flexus of M1 present or not; palate narrow; sphenopalatine vacuities present, either moderate or widely open, resulting in nearly completely unossified roof of mesopterygoid fossa; cheek teeth pentalophodont or tetralophodont; molar occlusal surface crested, terraced, or planed 6
3. Size small (mass ≤ 30 g); pelage soft, zygomatic notches shallow; palate short to moderate, wide; rostral tube small or indistinct. 4
- 3'. Size medium (mass ≥ 45 g); zygomatic notches medium to deep; palate short, wide, or narrow; rostral tube distinct 5
4. Pelage short and dense; tail short, approximately 50% of head and body length; zygomatic plates narrow, sloping backward from base; palate wide, moderate in length, reaching end of molar toothrow; auditory bullae inflated; carotid circulation pattern 1 (*sensu* Voss 1988); capsular projection of mandible inconspicuous. *Neomicroxus*
- 4'. Pelage long; tail longer than head and body; zygomatic plates broad; palate wide, short, not reaching end of molar toothrow; auditory bullae small; carotid circulation pattern 2 or 3 (*sensu* Voss 1988); capsular projection of mandible conspicuous *Juliomys*
5. Pelage short, coarse; tail length subequal with head and body length, scales conspicuous; nose same color as head and back; zygomatic notches moderately excavated; palate wide, short; rostral tube present; sphenopalatine vacuities absent, roof wholly ossified; auditory bullae small, uninflated; primary cusps alternating *Delomys*
- 5'. Pelage short, soft; tail long, $>120\%$ of head and body length, and hairy, but scales visible; nose conspicuously reddish; palate narrow, short; rostral tube absent; sphenopalatine vacuities moderate, elongated; auditory bullae large, inflated; primary cusps opposite *Wilfredomys*
6. Upper incisors smooth, without groove; carotid circulation pattern 1 (*sensu* Voss 1988); cheek teeth tetralophodont or pentalophodont 7
- 6'. Upper incisors with longitudinal groove; carotid circulation pattern 1 or 2 (*sensu* Voss 1988); cheek teeth tetralophodont 10
7. Body not uniformly colored, darker on midback, with conspicuous black and white thigh stripes and strongly contrasting whitish venter; body large, very stout, mass >120 g; pelage long, very thick and soft; tail short ($<70\%$ head and body length), hairy, with scales not visible; skull with long and narrow palate; sphenopalatine vacuities large, mesopterygoid roof unossified; cheek teeth tetralophodont with terraced molars; anteromedian flexus of M1 absent or very shallow *Chinchillula*
- 7'. Body color uniform, without black and white thigh stripes or contrasting ventral fur; body either stout or elongated, medium to large, mass <100 g; pelage long, not thick but soft; tail medium to short, haired, scales either visible or not; palate narrow but either long or short; sphenopalatine vacuities either large or medium, mesopterygoid roof either unossified or with elongated openings. 8
8. Body color brilliant reddish; tail long, $>120\%$ head and body length; rostrum broad, tapering anteriorly; zygomatic notch shallow; cheek teeth pentalophodont, crested *Phaenomys*
- 8'. Body color yellowish or grayish brown; tail short, $<90\%$ head and body length; rostrum broad, parallel sided; zygomatic notch deep, well developed; cheek teeth pentalophodont and crested or tetralophodont and planar . 9
9. Body elongate; dorsum streaked with dark brown; tail about 80% of head and body length, moderately haired, scales visible; zygomatic spine strongly developed; palate short, narrow; cheek teeth tetralophodont; molar cusps alternate; anteromedian flexus of M1 absent or very shallow *Andinomys*
- 9'. Body stout; dorsum without dark brown streaking; tail very short, $<50\%$ head and body length, well haired, scales not visible; zygomatic spine absent; palate long, narrow; cheek teeth pentalophodont, crested; molar cusps opposite; anteromedian flexus of M1 prominent *Punomys*
10. Tail long, $>120\%$ of head and body length, well haired but scales visible, unicolored; rostrum narrow, tapering anteriorly; zygomatic notch shallow; interorbital region somewhat laterally compressed but divergent posteriorly; upper incisors hyperopisthodont *Irenomys*
- 10'. Tail short, $<70\%$ head and body length, well haired and scales not visible, weakly to strongly bicolored; rostrum broad, parallel sided; interorbital region laterally compressed with raised edges; upper incisors weakly opisthodont 11
11. Pelage long, lax, and very thick; dorsal color gray to dark-gray brown; nose same color as head and body; tail distinctly bicolored; incisive foramina medium, reaching anterior portion of M1; compressed interorbital region very long; palate long, narrow; carotid circulation pattern 1 (*sensu* Voss 1988); occlusal surface of cheek teeth terraced; primary cusps opposite *Euneomys*
- 11'. Pelage long, lax, but not as thick; dorsal color dark reddish brown; nose distinctly orange; tail indistinctly bicol-

ored; incisive foramina short, not reaching M1s; compressed interorbital region short; palate short, narrow; carotid circulation pattern 2 (*sensu* Voss 1988); occlusal surface of cheek teeth planar; primary cusps alternate *Neotomys*

Genus *Abrawayaomys* F. Cunha and Cruz, 1979

Ulyses F. J. Pardiñas, Pablo Teta, and Guillermo D'Elía

Abrawayaomys is a sylvan genus that uniquely combines a spiny pelage with an unusual set of craniodental attributes in the sigmodontine radiation. The genus was regarded as monotypic (e.g., Musser and Carleton 2005) until the recent description of a second species (Pardiñas, Teta, and D'Elía 2009). This genus is one of four sigmodontine taxa with spiny pelage, the others being *Neacomys*, *Scolomys*, and *Rhagomys longilingua*. It is known from the Brazilian coastal forests, from Bahia to Rio de Janeiro and from the Paraná-Paraíba interior forest in northeastern Argentina. No fossils of *Abrawayaomys* are known (G. A. B. Fonseca and Kierulff 1989; Massoia 1993).

Species of this genus are medium-sized rodents (total length 200–290 mm, condylobasal length of the skull 27–29 mm) with a robust head, rounded small ears, and a tail varying from slightly shorter to longer than combined head and body length, with or without a terminal tuft of brown to white hairs. The body pelage is short and close with a moderately spiny texture. The overall appearance is strongly agouti and hispid, with weak distinction between dorsal and ventral colorations. Dorsal and ventral hairs of approximately the same length are either spiny or long and thin. The spiny hairs are flat, have a dorsal longitudinal groove, are rigid, and are broadest at their midpoint, especially on the dorsum. Spines are black-tipped and most abundant on the dorsum and rump, shorter and darker on the head, and slightly shorter, without dark tips, fewer in number, and thinner in structure on the under parts. Both mental and inguinal areas are free of spines. Mystacial and supraorbital vibrissae are short. Rigid tail hairs are arranged in sets composed of five hairs per scale. The pes is long, but the claws are short and covered with dense ungual tufts; digit V is very short; and the plantar surface has six pads, with the hypothenar overlapping the thenar. A mammary count has not been previously reported in the literature, but a specimen from São Paulo state, Brazil, has three pairs, one each in postaxial, abdominal, and inguinal positions.

The skull of *Abrawayaomys* is robust and compact, notable for its extremely short and broad rostrum. The rostrum is broader than the narrowest part of the interorbital region, and has conspicuous nasolacrimal capsules. The

premaxillaries end behind the anterior plane of the incisors. The nasals, with the anterior half considerably expanded, do not extend beyond the anterior ends of the premaxillaries. The interorbital region is smooth, hourglass in shape, weakly beaded, and has its narrowest point positioned anteriorly. The coronal suture is U-shaped, and the interparietal is transversally compressed and rhomboid in outline. Anterior borders of the zygomatic plates are straight and lack zygomatic spines; the zygomatic notches are inconspicuous. An alisphenoid strut is usually present. The tegmen tympani contacts the squamosal. The hamular process of the squamosal is long, obliquely oriented, and terminates in a spatula shape; the subsquamosal fenestra and the postglenoid foramen are subequal in size. The carotid circulation is pattern 1 (*sensu* Voss 1988), with a squamosal-alisphenoid groove and sphenofrontal foramen present.

The incisive foramina are short, not reaching the anterior face of M1s. The palate is long, extending slightly beyond the posterior margin of M3s. Posterolateral palatal pits are very small and positioned at the level of the anterior border of the mesopterygoid fossa; the anterior margin of the mesopterygoid fossa is rounded, with its roof typically lacking sphenopalatine vacuities. The middle lacerate foramen is nearly closed. Tympanic bullae are inflated; bony tubes are reduced. Maxillary tooththrows are parallel. The mandible of *Abrawayaomys* is short and robust, with an enlarged retromolar fossa; the condyloid, coronoid, and angular processes are subequal in size. The angular notch is shallow, and the capsular projection is very conspicuous. Internally, a well-developed and curved duct for the mandibular nerve is visible through the translucent bone and leads to a large mandibular foramen.

The upper incisors are narrow but noticeably deep, and they vary from slightly opisthodont to proodont. The anterior enamel is orange; the dentine fissure straight and large (*sensu* Stepan 1995:23). The lower incisors are noticeably deep but transversally thin, faced with paler enamel than the uppers. The molars are small and brachydont, slightly crested, and with an “intermediate” main cusp arrangement (*sensu* Stepan 1995:24). M1 is pentalophodont with an anteromedian flexus varyingly visible and a reduced mesoloph fused with the paracone; the procingulum of M1 is anteroposteriorly narrow and labially displaced; enterostyles are present on M1–2. M3 is notably reduced, with an occlusal morphology suggesting persistence of only the proto- and paracone areas, because the posterior portion of this tooth is greatly narrowed. The number of molar roots is M1/m1 = 3/2, M2/m2 = 3/2, and M3/m3 = 1–2/2.

Axial skeletal counts of one Argentinean specimen (*A. chebezi*) totaled 12 ribs and 15 thoracolumbar, three sacral, and 36 caudal vertebrae (Pardiñas, Teta, and D'Elía 2009).

The glans penis is short, stout, and entirely covered with spines; lateral bacular mounds are not visible in external

view; and the medial bacular mound is slightly larger than the lateral ones. The proximal baculum is short, stout, and triangular; a laterally flared base has a distinctly deep median notch. The cartilaginous distal baculum is small and tridigitate (Pardiñas, Teta, and D'Elía 2009). The stomach is hemiglandular-unilocular (Finotti et al. 2003).

SYNONYM:

Abrawayaomys F. Cunha and Cruz, 1979:2; type species *Abrawayaomys ruschii* F. Cunha and Cruz, 1979, by original designation.

REMARKS: Two species are currently recognized, one from Brazil (*A. ruschii*) and the other from Argentina (*A. chebezi*), but the few available specimens hamper any assessment of intra- or interpopulation variation (Pardiñas, Teta, and D'Elía 2009). Specimens from Rio de Janeiro may well represent *A. chebezi*. As both samples from Argentina and Rio de Janeiro depart less from the holotype of *A. ruschii* (from Espírito Santo state) than do those from Minas Gerais, the latter may represent a third, as yet undescribed species. To further complicate the existing taxonomy, five skins collected in São Paulo state, Brazil, document important morphological differences between young and adults. For example, young individuals have a proportionally shorter tail (relative to head and body length), a tail tuft is either lacking or very short, the hindfeet are brown above, and there is very limited contrast between the dorsal and ventral colors. Adults, in contrast, have proportionally longer tails that terminate in a long tuft of white hairs (ca. 20 mm), whitish hindfeet, and strikingly demarcated dorsal and ventral colors. These limited comparisons clearly indicate that *Abrawayaomys* is in need of a thorough revision aimed to define both the number of species and their respective geographic distributions.

KEY TO THE SPECIES OF *ABRAWAYAOMYS*:

1. Tail longer than head and body, with a dark brown tuft; interorbital region hourglass in shape; upper tooththrow length ≤ 4 mm; anteromedian flexus on M1 inconspicuous or absent *Abrawayaomys chebezi*
- 1'. Tail shorter than head and body and without tuft, or longer and terminating in white tuft; interorbital region with anteriorly convergent sides; upper tooththrow length ≥ 4 mm; anteromedian flexus on M1 conspicuous *Abrawayaomys ruschii*

Abrawayaomys chebezi Pardiñas, Teta, and D'Elía, 2009

Chebez's Spiny Mouse

SYNONYMS:

Thomasomys (?) *pictipes*: Massoia, 1988c:6; part; not *Thomasomys pictipes* Osgood, 1933.

Abrawayaomys ruschii: Massoia, Chebez, and Heinonen Fortabat, 1991a:39; part; not *Abrawayaomys ruschii* F. Cunha and Cruz, 1979.

Abrawayaomys chebezi Pardiñas, Teta, and D'Elía, 2009; type locality "Argentina: Province of Misiones, Department of Iguazú, conjunction Arroyo Mbocací and route 12 [25.680115°S, 54.508060°N]."

DESCRIPTION: Smaller than *A. ruschii*, especially in molar measurements (upper tooththrow length 3.30–3.96 mm), and characterized by tail longer than head and body, terminating in dark tuft; basally gray ventral hairs with cream to yellowish tips; anterior third of nasals not conspicuously expanded laterally; nasofrontal suture V-shaped, extending posteriorly past level of lacrimals; interorbital region hourglass in shape; alisphenoid strut present; inconspicuous or absent anteromedian flexus on M1, and proodont upper incisors.

DISTRIBUTION: *Abrawayaomys chebezi* is known from the western, forested portions of Misiones province in Argentina (Massoia 1993; Pardiñas, Teta, and D'Elía 2009) that drain towards the Río Paraná.

SELECTED LOCALITIES (Map 27): ARGENTINA: Misiones, Iguazú, junction Arroyo Mbocací and Rte 12 (type locality of *Abrawayaomys chebezi* Pardiñas, Teta, and D'Elía), Eldorado, Segunda Iglesia Cuadrangular, Barrio Parque Km 11 (Massoia, Chebez, and Heinonen Fortabat 1991a), Montecarlo (Massoia 1993, 1996), Oberá, Escuela Provincial 639 "Rosario Vera Peñaloza," Lote 92, Sección II de Campo Ramón (Massoia 1988c, 1996), Parque Provincial Urugua-í (CNP 3631).

SUBSPECIES: *Abrawayaomys chebezi* is monotypic.

NATURAL HISTORY: Little is known about the natural history of this species. It is certainly preyed upon by the Barn Owl, *Tyto alba*, as three of five records from Misiones are based on remains recovered from the pellets of this owl (Massoia 1993). The holotype (MACN 20253) was captured using a Sherman trap on the southern margin of Arroyo Mbocací, in secondary forest belonging to the "Rosewood and Assai Palm Forest" unit (*sensu* Martínez-Crovetto 1963), where the predominant tree species are *Matayba elaeagnoides*, *Begonia descoleana*, and *Podostemum comatum*. Some localities are in areas highly disturbed by human activities, where only small patches of the "Laurel and Guatambu Forest" survive, or in ecotonal areas between forest and the open grasslands of the "Campos and Malezales" ecoregion (Pardiñas, Teta, and D'Elía 2009).

C. Galliari collected the second specimen (CNP 3631) in late September 2012 in disturbed secondary forest in Parque Provincial Urugua-í. This animal is an adult male weighing 35 g and had scrotal testes. A large assemblage of ectoparasites collected from this individual included mites, most of the genus *Androlaelaps*, and two fleas, one identi-

Map 27 Selected localities for *Arawayaomys chebezi* (○) and *Arawayaomys ruschii* (●).

fied as *Polygenis* (*Polygenis*) sp. and the other *Adoratopsylla* (*Adoratopsylla*) *antiquorum antiquorum*. The latter may represent an accidental association because fleas of this genus are mainly associated with marsupials (M. Laretschi, pers. comm.).

REMARKS: Massoia (1988c:Figs. 3 and 4) referred to the first specimen (a mandible recovered from owl pellets) of *Arawayaomys* collected in Argentina as *Thomasomys* (?) *pictipes*. There is an unconfirmed published mention of this species from Puerto Caragatay, Misiones (Massoia 1993). Specimens from Rio de Janeiro, Brazil, are perhaps referable to this species (Pardiñas, Teta, and D'Elía 2009).

Arawayaomys ruschii F. Cunha and Cruz, 1979

Ruschi's Spiny Mouse

SYNONYM:

Arawayaomys ruschii F. Cunha and Cruz, 1979:2; type locality "Forno Grande [= Parque Estadual do Forno Grande (20.5°S, 41.6°W)], município de Castelo, ES [= Espírito Santo], Brasil."

DESCRIPTION: Larger than *A. chebezi*, especially in molar measurements (upper toothrow length of holotype, 5.41 mm); characterized by tail shorter than head and body and without terminal tuft, or longer than head and body with white tuft; yellowish to whitish ventral coloration; rostral third of nasals conspicuously expanded laterally; straight nasofrontal suture at about level of lacrimals; in-

terorbital region with anteriorly convergent sides; alisphenoid strut sometimes present; conspicuous anteromedian flexus on M1; and slightly opisthodont upper incisors.

DISTRIBUTION: *Arawayaomys ruschii* is known from few localities in the Brazilian states of Espírito Santo, Minas Gerais, Rio de Janeiro, São Paulo, and Santa Catarina.

SELECTED LOCALITIES (Map 27): BRAZIL: Espírito Santo, Castelo, Parque Estadual do Forno Grande (type locality of *Arawayaomys ruschii* F. Cunha and Cruz); Minas Gerais, Mata da Prefeitura, 6 km SW of Viçosa (USNM 552416), Ouro Branco (G. Lessa et al. 2009), Parque Estadual do Rio Doce (UFMG 2492), Parque Estadual da Serra do Cipó (Passamani et al. 2011); Rio de Janeiro, Angra dos Reis, Terra Indígena Guarani Sapukai (L. G. Pereira et al. 2008); São Paulo, Biritiba Mirim (M. J. de J. Silva et al. 2009); Santa Catarina, Caldas da Imperatriz (Cherem et al. 2005).

SUBSPECIES: *Arawayaomys ruschii* is monotypic.

NATURAL HISTORY: Little is known about the natural history of this species. Observations on diet, derived from a single individual, indicate that *Arawayaomys ruschii* feeds preferentially on fruits, seeds, and leaves (Finotti et al. 2003). Capture sites of most specimens are from the interior of forests fragments as well as along their margins; most specimens have been caught during the rainy season (G. Lessa et al. 2009). Postcranial anatomy suggests that this species is terrestrial in its mode of locomotion (Coutinho et al. 2013), an observation supported by reported captures in traps set on the ground.

REMARKS: Specimens from Minas Gerais display a long tail with a large white apical tuft, a variably present alisphenoid strut, and an interorbital region with anteriorly convergent borders, character differences from other samples that invite further exploration of their taxonomic status (Pardiñas, Teta, and D'Elía 2009).

The diploid number for specimens from Rio de Janeiro and São Paulo states, Brazil, is 58, with all autosomes predominantly acrocentric; the X is a medium-sized metacentric and the Y a medium-sized submetacentric (L. G. Pereira et al. 2008; M. J. de J. Silva et al. 2009).

Genus *Andinomys* Thomas, 1902

Jorge Salazar-Bravo and Jorge Pablo Jayat

Andinomys occurs between 14°S and 28.5°S, from southern Peru and northernmost Chile through southwestern Bolivia and northwestern Argentina. Individuals have been trapped across an elevational range from 650 to 4,500 m, with most records occurring above 1,500 m. As expected from this broad geographic distribution, the genus occupies multiple habitats, from subtropical mountain forests and semiarid Puna and pre-Puna to high elevation grasslands

(J. P. Jayat, Pacheco, and Ortiz 2009). The following account is abstracted from Osgood (1947), Hershkovitz (1962), Steppan (1995), S. Anderson and Yates (2000), and P. E. Ortiz and Jayat (2007a), which should be consulted for additional details on morphological characters, fossil record, and distribution.

Andinomys is characterized by a large and heavy body (head and body length 134–176 mm for specimens from central Bolivia and northwestern Argentina). The fur is soft and lax; the color to the dorsum and sides is drab, but the under parts are buffy white with hairs basally slate colored. Tail length ranges from about 60% to nearly equal to head and body length; the tail is sharply bicolored, densely furred, but lacks a terminal pencil. Forefeet and hindfeet are well haired on their upper surfaces, covered with white hair above, and with silvery-white unguis tufts that extend well beyond the claws. Digit V of hindfoot (not including claw) reaches at least to the base (often to the middle) of the second phalanx of digit IV; palmar pads large but not fused. The pinnae are comparatively small (24–29 mm long). Eight mammae are present, with two pairs in both pectoral and inguinal positions.

The skull is flattened, with a broad rostrum and nasals that are broader than the interorbital constriction and somewhat expanded at their anterior edges. The premaxillomaxillary suture is oriented dorsoventrally. The supra-orbital region is narrow, with squared or slightly raised edges. Infrafrontal fontanelles are often present (S. L. Gardner and Anderson 2001). Zygomatic plates are deep, with their anterior borders slightly concave and with anterodorsal corners projecting as a short spine; zygomatic notches are broad and deeply excavated. The hamular process of the squamosal is long and thin, with a flattened posterior terminus. Incisive foramina are comparatively widely open, with smoothly rounded edges. Posterolateral palatal depressions are pitted and troughlike, continuing as gutters onto the anterolateral portion of the palate. The mesopterygoid fossa is comparatively broad; the parapterygoid fossae are shallow. The carotid circulation is characterized by conspicuous sphenofrontal and stapedia foramina and a squamosal-alisphenoid groove (pattern 1 of Voss 1988). The mandible is robust, with a poorly developed capsular projection, the coronoid process is higher than the articular condyle, and the anterior margin of the masseteric crest extends to the level of the m1 protoconid.

Upper incisors are opisthodont, broad, and asulcate. The upper molar rows diverge posteriorly, and molars above and below are hypsodont, large, prismatic, and flat crowned, with primary cusps having alternating and deeply penetrating flexi and flexids (P. E. Ortiz and Jayat 2007a). A labial root of M1 is present.

Steppan (1995) provided vertebral counts of 13 thoracic, six lumbar, and 28–30 caudal (modal number of 30). The stomach is atypical for most sigmodontine rodents in that it is bilocular, with a deep incisura angularis projecting well past the esophageal opening; the size and position of the glandular epithelium is unknown (Spotorno 1976). The phallus in males is barrel shaped with a slightly ventrally placed crater. The distal process of the baculum is unique among the sigmodontines, with a short and wide central element flanked by longer (at least 60% longer) wing-shaped lateral digits (Spotorno 1986).

SYNONYM:

Andinomys Thomas, 1902g:116; type species *Andinomys edax* Thomas, 1902, by original designation.

REMARKS: The genus and its single living species are known from the Middle-Upper Pleistocene of Argentina and Lower-Middle Pleistocene of Bolivia, to the Recent (Marshall et al. 1984; Marshall and Sempere 1991; Pardiñas et al. 2002; P. E. Ortiz and Jayat 2007a). It was present at seven of nine Late Quaternary micromammal localities in Argentina but was not abundant in any (P. E. Ortiz and Jayat 2007a).

Andinomys edax Thomas, 1902

Andean Rat, Chozchorito

SYNONYMS:

Andinomys edax Thomas, 1902g:116; type locality “El Cabrado, between Potosí and Sucre, [Potosí,] Bolivia. Altitude 3700 metres.”

Andinomys edax lineicaudatus Yepes, 1935b:345; type locality “Argentina, Tucumán, Cerro San Javier 2000 m.”

Andinomys lineicaudatus: M. M. Díaz and Barquez, 2007: 500; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Andinomys edax* has been recorded from approximately 60 localities between 500 and 4,500 m in habitats ranging from subtropical mountain forests to the semiarid Puna and pre-Puna of extreme southern Peru, northernmost Chile, Bolivia, and northwestern Argentina.

SELECTED LOCALITIES (Map 28): ARGENTINA: Catamarca, Barranca Larga, Cueva Los Viscos (P. E. Ortiz, Cirignoli et al. 2000), 45 km W of Chumbicha (Thomas 1919f); Jujuy, Cerro Hermoso (MACN 19.554), Rinconada, 6 km N, road to Timón Cruz (M. M. Díaz and Barquez 2007); Salta, La Poma, 3 km E (PEO-e 201), ca. 5 km S of Los Toldos (PEO-e 271); Tucumán, Horco Molle (Capllonch et al. 1997). BOLIVIA: Chuquisaca, 9 km (by road) N of Padilla (S. Anderson 1997); Cochabamba, 16.5 km NW of Colomi (AMNH 268919); Oruro, Finca Santa Helena, approx. 10 km (by road) SW of Pazna (UMMZ 155850); Potosí, 20 mi S of Potosí (S. Anderson 1997); Tarija, Ran-

cho Tambo (AMNH 262771). CHILE: Tarapacá, Arica (FMNH 132651). PERU: Puno, Juli (MCZ 39470); Tacna, 1.5 mi N (10 km by road) of Tarata (MVZ 139480).

SUBSPECIES: Yepes (1935b) recognized two subspecies, *A. edax edax* from southern Bolivia and extreme northwestern Argentina, and *A. edax lineicaudatus* in northwestern Argentina. These two names continue to be used in the literature, both at subspecific and specific levels (see M. M. Díaz and Barques 2007 versus Jayat, Ortiz, and Miotti 2008, and Remarks).

NATURAL HISTORY: Little is known about the natural history of the species. Of 10 specimens collected by one of us (JPJ) in high-elevation grasslands of northwestern Argentina, two females caught in April had signs of reproductive activity (open vaginas). The remainder of the specimens, captured in June, July, and August, showed no signs of reproductive activity. Pearson (1951) reported one (of three collected females) as pregnant with three large embryos (crown-rump length = 34 mm), in mid-December in southern Peru. For Jujuy, M. M. Díaz and Barquez (2007) reported females with closed vaginas in February and March, one lactating female and another with three embryos in February, and females with open vaginas in March (one with two embryos). Young individuals were trapped in February, June, and July. From these observations, it appears that *Andinomys edax* is reproductively active from early December to June.

Molting was found in all individuals collected in the high-elevation grasslands of northwestern Argentina (with the exception of one female taken at the end of August). This observation agrees with M. M. Díaz and Barquez (2007), who observed molting in specimens from Jujuy and trapped in February and March. Two fleas (*Ectinorus uncinatus* and *Neotyphloceras crassispina hemisus*) and a louse (*Hoplopleura zentaensi*) parasitize *Andinomys edax* (Beaucournu and Gallardo 1991; D. Castro and Gonzalez 1997; Autino and Lareschi 1998). No other parasites are known.

Andinomys edax is never an abundant member of the sigmodontine fauna anywhere in its known range, accounting for no more than 2% of the individuals captured at sites in northwestern Argentina. The species is also not abundant in owl pellets, where it occurs in about 2% of specimens examined (JPJ, pers. obs.).

REMARKS: M. M. Díaz (1999) elevated each of the subspecies recognized by Yepes (1935b) to specific status, based on sympatry at localities of the pre-Puna of Jujuy province, Argentina. M. M. Díaz and Barquez (2007) also recognized these two taxa at the species level, stating *A. edax* was restricted to Puna and pre-Puna habitats between 2,000 and 4,800 m, while *A. lineicaudatus* occurred in the Yungas forest below 2,500 m. However,

Map 28 Selected localities for *Andinomys edax* (●). Contour line = 2,000 m.

specimens captured by one of us (JPJ) in ecotonal habitats between semiarid highlands and Yungas forests in northwestern Argentina displayed combinations of qualitative (tail coloration) and morphometric (hindfoot length) characters thought to be diagnostic for the two taxa, which suggested the possibility of gene flow between them (Jayat, Ortiz, and Miotti 2008). Given the lack of detailed study of patterns of variation, combined with the lack of differences in karyotypic characters, for the moment at least we maintain the view of Yepes (1935b) and regard *Andinomys* as comprising a single species with two subspecies.

The karyotype is uniform across localities from Argentina (Pearson and Patton 1976), Bolivia (Peurach 1994), and Chile (Spotorno et al. 1994, 2001), with $2n=56$ and $FN=56$, an autosomal complement composed of one pair of metacentric and 27 pairs of acrocentric elements and both X and Y chromosomes acrocentric. The Y is about 60% the length of the X. Comparisons of G-banded chromosomes led Spotorno et al. (2001) to suggest homology in 18 chromosomal arms between *A. edax* and *Euneomys chinchilloides*.

Genus *Chinchillula* Thomas, 1898*Jorge Salazar-Bravo*

These colorful animals are known from scattered localities between 3,500 and 4,800m in southeastern Peru, western Bolivia, and northern Chile, where they are often associated with rocky outcrops and stone walls in the highland Puna. Except as noted below, the following account is abstracted from Osgood (1947) and Hershkovitz (1962), who should be consulted for additional details. The genus is not known from the fossil record (McKenna and Bell 1997).

Chinchillula is medium to large in size, with a stout body (total length ranging from 247 to 282 mm; S. Anderson 1997). The tail is short and well-haired (between 50% and 75% of the total length, ranging between 94 and 114 mm; Pearson 1951; S. Anderson 1997), bicolored, with a mid-dorsal brown stripe, and terminating in a thin pencil. The pelage is long, very dense, silky, and distinctly colored buffy to tawny, lined with black over the back. The venter is white, and the hips and rump are white but are crossed by a conspicuous black band. The ears are long, broad, and brown with white preauricular and postauricular tufts. The limbs and feet are white, and ungual tufts almost conceal the claws. The plantar pads are smooth, bare, and have large tubercles. The mammary count is eight, with two pairs in both axillary and inguinal positions.

The skull is flattened in profile. The supraorbital region is narrow and parallel-sided, with edges squared or raised, but with temporal ridges obsolete or absent. The zygomatic arches are evenly bowed, and the zygomatic plates are broad but slant posteriorly from bottom to top, and well-developed zygomatic spines are present. The incisive foramina are long, reaching to the middle of M1s. The bony palate is also long, extending posterior to M3s. Posterolateral palatal depressions are shallow. The mesopterygoid fossa is broad. The width at the anterior base of pterygoid processes is greater than that of the parapterygoid fossa measured on same plane. The parapterygoid fossa is deep in adults. The tympanic bullae are moderately inflated but are often shorter than the length of the molar row (Hershkovitz 1962). Carotid circulation is primitive (pattern 1 of Voss 1988); both stapedial and sphenofrontal foramina and a squamosal-alisphenoid groove are present.

The upper incisors are long, orthodont to slightly opisthodont, with smooth to weakly grooved anterior surfaces. Upper molar rows are parallel or slightly divergent posteriorly. The cheek teeth are highly hypsodont, flat-crowned, and prismatic (Osgood 1947); the cusps are subtriangular or subovate in outline, and the enamel pattern is essentially 8-shaped. The high points of opposing enamel folds never touch, but extend nearly to, or rarely beyond, the midline

of each molar. M1 has a subtriangular procingulum in older specimens; a posteroloph is always absent. Both M2 and M3 have a simplified occlusal pattern, as only the metaflexus and hypoflexus are present (there is no procingulum or posteroloph). The lower first molar has a procingulum with a small anterolingual styloid, and m2–m3 have a simplified occlusal structure without a procingulum or posterolophids.

Didier (1959) described the general morphology of the phallus; Spotorno (1986) extended this description and stressed the unique nature of the structures. Axial skeletal elements consist of 13 thoracic, six lumbar, and 21 or more caudal vertebrae (Steppan 1995). Voss (1991a) noted the presence of a gall bladder, and Dorst (1973b) detailed stomach morphology.

SYNONYM:

Chinchillula Thomas, 1898c:280; type species *Chinchillula sahamae* Thomas, by monotypy.

REMARKS: Thomas (1898c) described *Chinchillula* as a genus distantly allied to *Phyllotis*, a concept followed by most subsequent authors (e.g., Ellerman 1941; Osgood 1947; Olds and Anderson 1990; Braun 1993; Steppan 1993; Steppan 1995). Analyses of mitochondrial and nuclear sequence data have indicated that *Chinchillula* is the sister taxon to a clade formed by *Irenomys*, *Punomys*, and *Andinomys* (Salazar-Bravo et al. 2013) and that these four genera, for the moment, should be considered Sigmodontinae *incertae sedis* as suggested by D'Elia et al. (2007).

Chinchillula sahamae Thomas 1898

Altiplano Chinchilla Mouse, Achallo, Chinchillón, Carpinto

SYNONYM:

Chinchillula sahamae Thomas, 1898c:280; type locality “Esperanza, a ‘tambo’ in the neighbourhood of Mount Sahama, [La Paz,] Bolivia.”

DESCRIPTION: As for the genus.

DISTRIBUTION: *Chinchillula sahamae* is known from fewer than 20 localities in western Bolivia, southern Peru, and northern Chile, all at elevations between 3,500 and 4,800m.

SELECTED LOCALITIES (Map 29): BOLIVIA: La Paz, Esperanza (type locality of *Chinchillula sahamae* Thomas 1898), 5 km E of Ulla-Ulla (S. Anderson 1997); Oruro, Quebrada Kohuiri (S. Anderson 1997). CHILE: Arica y Parinacota, Parinacota (Mann 1978). PERU: Apurimac, 25 mi SW of Chalhuanca (MVZ 116034); Arequipa, Cabrerías (Zeballos and Carrera 2010), El Rayo (Zeballos and Carrera 2010), 21 mi ENE of Puquio (MVZ 116035); Cusco, Coordillera de Sicuani (Hershkovitz 1962); Puno, 11 km W and 12 km S of Ananea (MVZ 172677), 5 km E of Lago Suche (MVZ 115939), 5 mi SSW of Limbani (MVZ

116183), 36 km SE (by road) of Macusani (MVZ 172675); Tacna, 5 km E of Lago Sucho (MVZ 115939), 2.6 mi N of Tarata (MVZ 139484).

SUBSPECIES: *Chinchillula sahamae* is monotypic.

NATURAL HISTORY: *Chinchillula sahamae* is relatively poorly known in most aspects of its ecology, behavior, and reproductive biology. All known localities are in bunchgrass-dominated Altiplano, where it is often associated with rocky outcrops or man-made stone walls (e.g., Pearson 1951). In both Parque Nacional Sajama (Bolivia) and Reserva Nacional de Salinas y Aguada Blanca (Peru), individuals were associated with *Polylepis* patches (Yensen and Tarifa 2002; Zeballos and Carrera 2010). Sympatric species in southern Peru include two species of *Abrothrix*, two species of *Akodon*, *Necomys amoenus*, two species of *Phyllotis*, three of *Auliscomys*, *Neotomys ebriosus*, and a species each of *Galea* and *Lagidium* (Pearson 1951). In west-central Bolivia, *Chinchillula* co-occurs with *Akodon albiventer*, *Abrothrix jelskii*, *Phyllotis chilensis*, and *Lagidium viscaccia* (Yensen and Tarifa 2002).

At one locality in La Paz (Bolivia), the capture rate per 100 traps was 0.9 (Yoneda 1984), but with this rate ranging from 0.3 to 2 in different study years at various sites in Arequipa and Moquegua (Peru; Zeballos and Carrera 2010). The species is herbivorous, feeding on grass or herbs (Pearson 1951; Dorst 1973b; Mann 1978). In southeastern Peru, the diet was composed of 96.57% grass and herbs and 0.01% seeds (H. Zeballos, pers. comm.). Signs of reproductive activity start at the beginning of October (Pearson 1951). Observations of the growth pattern in captive individuals have suggested an exponential growth for the first eight weeks after birth, reaching an asymptote at about week 15 (Aliaga-Rossel et al. 2009).

Ectoparasites recorded from *Chinchillula sahamae* include two species of trombiculid mites of the genus *Crotiscus* (Brennan 1957), one of the genus *Odontacarus* (J. T. Reed and Brennan 1975), one of *Euschoengastia* (misspelled by Hershkovitz 1962 as *Euschonygastia*), five species of fleas (Hershkovitz 1962; Smit 1968), and a beetle (Hershkovitz 1962).

Although thought to be threatened or even at risk in Chile and Peru (e.g., Coffre and Marquet 1999; Zeballos 2001), possibly due to overexploitation for their colorful pelts, no studies have been conducted to assess local population status. The species was deemed “data deficient” by Bolivian authorities (Aguirre et al. 2009).

REMARKS: Pine et al. (1979) and Mann (1978) made a case for the presence of morphological and chromatic differences between Bolivian and Peruvian samples, and one specimen from Chile. The record from “Sumbay, Arequipa” mapped by Hershkovitz (1962) is at odds with current maps and ornithological gazetteers (Stephens 1983),

Map 29 Selected localities for *Chinchillula sahamae* (●). Contour line = 2,000 m.

which locate Sumbay to the northeast, not the southwest, of the city of Arequipa. In addition, as mapped, Hershkovitz’s Sumbay would be at about 2,000 m, an elevation from which no records of *Chinchillula* currently exist. Eisenberg and Redford (1992) mapped two localities in Chile, but Parinacota is the only one from which a vouchered specimen exists (see Selected Localities).

Pearson and Patton (1976) described a karyotype with $2n = 60$, $FN = 64$ for Peruvian specimens.

Genus *Delomys* Thomas, 1917

Robert S. Voss

The genus *Delomys* contains two species that inhabit moist forests and perhaps other habitats from sea level to 2,700 m elevation in northeastern Argentina and southeastern Brazil. The only known fossils are from late Pleistocene cave deposits near Lagoa Santa in the Brazilian state of Minas Gerais (Winge 1887; Voss and Myers 1991; Voss 1993). Although Osgood (1933a), Ellerman (1941), and Cabrera (1961) regarded *Delomys* as a junior synonym of *Thomasomys*, subsequent analyses of karyotypic, morphological, and molecular data suggest that these taxa are not closely related (Zanchin, Sbalqueiro et al. 1992; Voss 1993; M. F. Smith and Patton 1999; D’Elía 2003a; Weksler 2003), and the genus remains unclassified at the tribal level (D’Elía et al. 2007). Recent molecular analyses (e.g., Parada et al. 2013; Salazar-Bravo et al. 2013) have

recovered *Delomys* as the sister taxon of the tribe Phyllotini, a wholly unexpected and surprising result. Except as noted below, the following account is abstracted from Voss (1993), which should be consulted for additional information about comparative morphology, taxonomy, nomenclature, and natural history.

Species of *Delomys* are small to medium-sized sigmodontines with relatively short, close, grizzled yellowish, brownish, or grayish dorsal pelage. A dark mid-dorsal stripe that extends from the nape to the base of the tail may be present or absent. The ventral pelage is distinctly paler than the dorsal fur, but the ventral pelage is always gray based (never self-colored). Mystacial, superciliary, genal, submental, interramal, and carpal vibrissae are present. The pinnae are large, thin, pliant, and sparsely covered with short hairs. The hindfoot is narrow, with six large plantar pads (thenar, hypothenar, and three interdigitals) and short outer digits; digit V is nonopposable, and its claw does not extend much beyond the first interphalangeal joint of digit IV. Conspicuous ungual tufts of long silvery hairs are present at the bases of the pedal claws. Females have either eight mammae (in inguinal, abdominal, postaxial, and pectoral pairs) or six mammae (in which case the pectoral pair is absent). The naked-appearing tail may be shorter than, equal to, or longer than the combined length of the head and body.

In dorsal view, the skull is characterized by a long tapering rostrum flanked by small but well-defined zygomatic notches; the interorbital region is hourglass in shape, neither conspicuously inflated nor strongly constricted, with smoothly rounded supraorbital margins. The braincase is rounded and smooth, without well-developed ridges or crests. In lateral view, the premaxillae and nasals are produced anteriorly beyond the small incisors to form a short bony rostral tube. Zygomatic plates are moderately broad with approximately vertical anterior margins, and lack anterodorsal spinous processes.

In ventral view, the incisive foramina are long (70–77% of diastemal length, on average), but they do not extend posteriorly between the molar rows. The bony palate is wide and short, without conspicuous ridges, grooves, or complex posterolateral pits. The mesopterygoid fossa is wide, with a square or biconcave anterior margin that extends anteriorly between the last molars; the bony roof of the fossa is complete or perforated by very small sphenopalatine vacuities. Because the alisphenoid strut is absent, the buccinator-masticatory foramen and the foramen ovale are confluent.

The carotid circulation is primitive (pattern 1 of Voss 1988), as evidenced by a large stapedia foramen (for the stapedia artery) and a prominent squamosal-alisphenoid groove and sphenofrontal foramen (for the supraorbital stapedia ramus). The postglenoid foramen is separated from

the subsquamosal fenestra by a slender hamular process of the squamosal. An anterior process of the tegmen tympani overlaps a posterior suspensory process of the squamosal above the anterodorsal lip of the bulla. The bullae are small, the tympanic membrane pars flaccida is large, and the orbicular apophysis of the malleus is well developed.

The mandible has a short, falciform coronoid process but lacks a distinct capsular process alveolus. The basihyal lacks an entoglossal process.

The upper incisors are small, narrow, ungrooved, and strongly opisthodont. The molars are brachydont, bunodont, and pentalophodont (with well-developed mesoloph and mesolophids). The principal cusps of the upper teeth are arranged in opposite labial/lingual pairs, but the labial and lingual reentrant folds interpenetrate to create an incipiently lophodont pattern. The anterocone of M1 is divided by a deep anteromedian flexus into distinct anterolabial and anterolingual conules. An ectolophid is always present on m1 and sometimes also on m2. The upper molars usually have three roots each, and the lower molars have two roots each.

The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. The entepicondylar foramen of the humerus is absent. Axial skeletal counts include 13 ribs and 19 thoracolumbar, four sacral, and 29 or more caudal vertebrae.

The stomach is unilocular and hemiglandular, without any extension of gastric glandular epithelium into the corpus. The gall bladder is present. Phallic and other male reproductive characters remain undescribed.

SYNONYMS:

Hesperomys: Hensel, 1872b:42; part (description of *dorsalis*); not *Hesperomys* Waterhouse, 1839.

Akodon: E.-L. Trouessart, 1897:537; part (listing of *dorsalis*); not *Akodon* Meyen, 1833.

Oryzomys: Thomas, 1903c:240; part (description of *sublineatus*); not *Oryzomys* Baird, 1857.

Thomasomys: Thomas, 1906c:443; part (listing of *dorsalis* and *sublineatus*); not *Thomasomys* Coues, 1884.

Delomys Thomas, 1917d:196; type species *Hesperomys dorsalis* Hensel, 1872, by original designation.

REMARKS: Species of *Delomys* have at one time or another been referred to *Hesperomys*, *Calomys*, *Akodon*, *Oryzomys*, and *Thomasomys* (none of which are, properly speaking, generic synonyms). This historical confusion reflects both the uncertain morphological diagnoses of neotropical cricetid taxa in general and the genuinely ambiguous relationships of *Delomys* in particular. Although the sister-group relationship between *Delomys* and phyllotines recovered by Parada et al. (2013) seems to be impressively

supported by their molecular data, future testing with sequence data from additional loci is much to be desired.

Hershkovitz's (1998:212) comments on morphological variation in *Delomys* imply that the two recognized species (*D. dorsalis* and *D. sublineatus*) cannot be distinguished by the phenotypic characters used in the key that follows here. However, all of the material that I examined (Voss 1993) was unambiguously identifiable by these criteria. Because Hershkovitz did not describe any other diagnostic differences, it is not clear how his species samples were identified if not by the morphological characters employed here.

Voss (1993:32–34) assigned to *Delomys* Winge's (1887) *Calomys plebjus*, described from a large cranial fossil fragment collected by P. W. Lund at Lapa da Serra das Abelhas, Lagoa Santa, Minas Gerais state, Brazil. The connection between *plebjus* to either of the extant species in the genus is problematical, and Voss (1993:34) concluded that "*plebejus* is a *nomen dubium* that should be used only in reference to Winge's hypodigm."

KEY TO THE SPECIES OF *DELOMYS*:

1. Dorsal pelage very soft and dense, usually some shade of dark brown or brownish gray, often with indistinct dark mid-dorsal stripe from nape to base of tail; no band of clear yellow or buff separating dorsal and ventral coloration along flanks; vibrissae long, extending to or beyond tips of pinnae when laid back along head; individual hairs on dorsal surface of hindfoot with indistinct melanic bands (visible only under magnification); claw of digit V extends to or slightly beyond first interphalangeal joint of digit IV; tail subequal to or longer than combined length of head and body; $2n=82$ chromosomes. *Delomys dorsalis*
- 1'. Dorsal pelage coarser, less dense, and paler (usually distinctly grizzled yellowish), the dark mid-dorsal stripe (when present) shorter, usually not extending from nape to tail base; dorsal and ventral pelage almost always separated by lateral band of clear yellow or buff along flanks; mystacial vibrissae short, not extending to tips of pinnae when laid back along head; individual hairs on dorsal surface of hindfoot usually pure white (without any melanic bands); claw of digit V does not extend to first interphalangeal joint of digit IV; tail usually shorter than combined length of head and body; $2n=72$ chromosomes *Delomys sublineatus*

Delomys dorsalis (Hensel, 1872)

Striped *Delomys*

SYNONYMS:

Hesperomys dorsalis Hensel, 1872b:42; type locality "Provinz Rio Grande do Sul," Brazil; restricted to Taquara, Rio Grande do Sul, by Avila-Pires (1994:372).

Delomys dorsalis dorsalis: Gyldenstolpe, 1932a:60; name combination.

Delomys dorsalis lechei: Gyldenstolpe, 1932a:61; name combination.

Thomasomys dorsalis dorsalis: Ellerman, 1941:368; name combination.

Thomasomys dorsalis collinus: Ellerman, 1941:369; name combination.

Thomasomys dorsalis lechei: Ellerman, 1941:369; name combination.

Thomasomys lechei: Moojen, 1952b:59; name combination.

Thomasomys collinus: Moojen, 1952b:60; name combination.

Delomys collinus: Avila-Pires, 1960b:32; name combination.

DESCRIPTION: A softer-furred and longer-tailed species than *Delomys sublineatus*, with or without distinct mid-dorsal stripe from nape to base of tail, but consistently lacking lateral line of clear yellow or buff between dorsal and ventral pelage color zones. Mystacial vibrissae long, extending to or beyond tips of adducted pinnae; hindfoot covered dorsally with dark-banded hairs; claw of digit I extending to middle of first phalanx of digit II; claw of digit V extending to or just beyond first interphalangeal joint of digit IV.

DISTRIBUTION: From Rio Grande do Sul (Brazil) and Misiones (Argentina) northward along the humid Atlantic littoral and interior mountains of southeastern Brazil to Minas Gerais. Specimens have been collected near sea level in northern Argentina and southern Brazil (between 25° and 30°S latitude), but most northern collections are from higher elevations (to 2,700m according to Hershkovitz 1998). *Delomys dorsalis* is known to occur sympatrically with *D. sublineatus* at several localities in the Brazilian states of São Paulo and Rio de Janeiro (Voss 1993).

SELECTED LOCALITIES (Map 30): ARGENTINA: Misiones, Caraguatay, Río Paraná (FMNH 26818). BRAZIL: Minas Gerais, Parque Nacional do Caparaó (Hershkovitz

1998); Paraná, Roça Nova (Voss 1993); Rio de Janeiro, Itatiaya (type locality of *Delomys dorsalis collinus* Thomas), Teresópolis (Voss 1993); Rio Grande do Sul, Taquara (type locality of *Hesperomys dorsalis obscura* Leche); São Paulo, Alto da Serra (Voss 1993), Apiaí (MZUSP 26936), Estação Biológica de Boracéia (MVZ 183055), Casa Grande (Voss 1993), Fazenda Intervalles, Base do Carmo (MVZ 183047), Piquete (Voss 1993).

SUBSPECIES: Voss (1993:30–31) reviewed geographic variation in morphology among available samples of *D. dorsalis* and remarked that “the names *collinus* and *dorsalis* could be retained for subspecies distinguished by mammary counts alone, an option that should be evaluated by future researchers with larger samples and material from additional localities in São Paulo state” (see also Remarks).

NATURAL HISTORY: Field observations summarized by Voss (1993) suggest that species of *Delomys* are nocturnal inhabitants of moist-forest habitats. Trapping studies (e.g., Olmos 1991; Cademartori et al. 2008) consistently indicate that these rodents are primarily terrestrial, although there is also some evidence that *D. dorsalis* climbs well and may seasonally occur in subcanopy vegetation (Cademartori et al. 2005). Although montane (or premontane) forests are apparently favored at tropical latitudes, some subtropical collection localities for *D. dorsalis* are closer to sea level. Several reports (e.g., Miranda-Ribeiro 1905; Davis 1945a, 1947) suggest that these rats move among and under the sheltering clutter of logs, organic debris, mossy roots, tangled bamboo, and herbaceous understory vegetation rather than frequenting open areas on the forest floor. In the moist mixed-coniferous forests of Rio Grande do Sul, *D. dorsalis* is more abundant in habitats with denser undergrowth and fewer *Araucaria* pines than in habitats with sparse undergrowth and more abundant *Araucaria* (Cademartori et al. 2004; Dalmagro and Vieira 2005). In the only dietary study published to date, *D. dorsalis* was found to eat a variety of fruits and seeds as well as invertebrates and fungi (E. M. Vieira et al. 2006). Apparently, *D. dorsalis* is reproductively active year round; the gestation period is 21 to 22 days, and the litter size ranges from two to five young (Cademartori et al. 2005).

REMARKS: Zanchin, Sbalqueiro et al. (1992) described the karyotype of *Delomys dorsalis* as $2n=82$, but fundamental numbers (FN) differ among karyotyped populations of this species.

As recognized herein, *Delomys dorsalis* is geographically variable. Available samples from southern populations (e.g., in Argentina and Rio Grande do Sul) have smaller measurement means and more mammae (eight, in four pairs) than samples from northern populations (e.g., in Rio de Janeiro), which are larger on average and have fewer mammae (six, in three pairs). However, geographically in-

termediate samples (from Paraná and southern São Paulo) are morphometrically intermediate, and adjacent eight- and six-mammate populations (in southern and northern São Paulo, respectively) are not morphometrically divergent. Therefore, although different names are available for the small eight-mammate southern form (*dorsalis*) and the large six-mammate northern form (*collinus*), these appear to represent opposite ends of two independent north-south clines rather than distinct taxa (Voss 1993).

Alternatively, Bonvicino and Geise (1995) argued that *collinus* and *dorsalis* are distinct species based on their analyses of karyotypic data. They found that specimens from the type locality of *collinus* (Itatiaya, in Rio de Janeiro state) and from Caparaó (in Minas Gerais) had a fundamental number (FN) of 86 autosomal arms, whereas the specimens karyotyped by Zanchin, Sbalqueiro et al. (1992) had FN=80. If this karyotypic difference were correlated with the morphological variation previously described, the case for taxonomic discrimination would be strong. However, the FN=80 karyotype has been reported from both small-bodied eight-mammate populations (e.g., in Rio Grande do Sul) and large-bodied six-mammate populations (in northern São Paulo), so the taxonomic picture is still unclear. Bonvicino and Geise (1995:125) implied that “morphological analyses” corroborated their recognition of *collinus* and *dorsalis* as distinct species, and they suggested that the absence of heterozygotes (with intermediate fundamental numbers) indicated reproductive isolation. However, no diagnostic morphological criteria were provided in their report, and

Map 30 Selected localities for *Delomys dorsalis* (●).

geographic variation in fundamental number is an obvious alternative explanation for the scant data at hand. In the absence of other evidence, the hypothesis that *dorsalis* and *collinus* are conspecific (Thomas 1917d; Voss 1993; Hershkovitz 1998) remains to be convincingly falsified.

Delomys sublineatus (Thomas, 1903)

Pallid Delomys

SYNONYMS:

Oryzomys sublineatus Thomas, 1903c:240; type locality “Engenheiro Reeve, Inland of Victoria, Prov. Espírito [= Espírito] Santo, Brazil. Alt. 500 m.”

Thomasomys sublineatus: Thomas, 1906c:443; name combination.

Delomys sublineatus: Thomas, 1917d:196; first use of current name combination.

Thomasomys dorsalis sublineatus: Cabrera, 1961:428; name combination.

DESCRIPTION: A coarser-furred, shorter-tailed species than *Delomys dorsalis*, usually lacking a distinct mid-dorsal stripe and almost always with a lateral line of clear yellow or buff separating dorsal and ventral pelage color zones. Mystacial vibrissae short, not extending to tips of pinnae when laid back alongside head; hindfoot covered dorsally with (usually) pure white hairs; digit I short, with claw not extending to middle of first phalanx of digit II; digit V also short, with claw not extending to second interphalangeal joint of digit IV.

DISTRIBUTION: *Delomys sublineatus* occurs from the state of Paraná northward along the Atlantic coast and interior mountains of southeastern Brazil to the state of Espírito Santo. Specimens have been collected from near sea level to about 1,200 m elevation. See the preceding account for records of sympatry with *D. dorsalis*.

SELECTED LOCALITIES (Map 31): BRAZIL: Espírito Santo, Engenheiro Reeve (type locality of *Oryzomys sublineatus* Thomas), Santa Teresa (Voss 1993); Minas Gerais, Conceição do Mato Dentro (Voss 1993); Rio de Janeiro, Teresópolis (Voss 1993); Santa Catarina, Hansa (Voss 1993); São Paulo, Estação Biológica de Boracéia (MVZ 183075), Caucaia do Alto (Püttker et al. 2008a), Iporanga (Voss 1993), Salto Grande (Voss 1993).

SUBSPECIES: *Delomys sublineatus* is monotypic.

NATURAL HISTORY: Unfortunately, the available information is not sufficient to confidently identify natural history differences between this species and *Delomys dorsalis* (see earlier). However, its shorter vibrissae, tail, and fifth pedal digits all suggest that *D. sublineatus* may be less scansorial than *D. dorsalis*, and there are anecdotal indications that the two species may differ in habitat use along moisture and/or successional gradients where they occur sympatrically (Voss 1993).

Map 31 Selected localities for *Delomys sublineatus* (●).

Delomys sublineatus is said to be sensitive to forest fragmentation, with local abundance decreasing in smaller or more isolated patches (Pardini et al. 2005; Püttker et al. 2008a; Püttker, Bueno et al. 2013). This species was restricted to native vegetation in a comparison among fragments (Umetsu and Pardini 2007) but seemed to be insensitive to variation in vegetation structure in fragments of native habitat (Püttker et al. 2008b). Püttker, Pardini et al. (2008) examined the relationship between body size, parasite load, and density as a function of vegetation fragment size, and Püttker et al. (2006) examined individual movement patterns based on a capture-recapture study.

REMARKS: No noteworthy geographic variation has been reported for this species. Zanchin, Sbalqueiro et al. (1992) described a karyotype with $2n=72$, $FN=90$.

Genus *Euneomys* Coues, 1874

Janet K. Braun and Ulyses F. J. Pardiñas

Members of the genus *Euneomys* range from about 33°S in Argentina and Chile southward to the southernmost part of Cabo de Hornos (Osgood 1943b; Pardiñas, Teta, Chebez et al. 2010; however, see comments for *E. fossor* regarding a single locality north of 35°S). Four species are currently recognized. These occur in dry, open grassland with thickets of *Nothofagus* above the tree line to bare, rocky, windswept scree with limited vegetation (Musser and Carleton 2005). Locality records span elevations from near sea level in the southern part of the distribution to more than 3,300 m in the

north. The following generic description is, except as noted, compiled from information presented by Coues (1894), Gyldenstolpe (1932), Ellerman (1941), Mann (1944), Hershkovitz (1962), and Steppan (1995), supplemented by our examination of holotypes and recently collected specimens.

All species of *Euneomys* are externally similar, vole-like animals that are rather large in size and heavy in body. The eyes are large and rimmed in black, a feature reminiscent of *Reithrodon*. The ears are moderate in size (about 20 mm in length) and covered by fine hairs. The fur is thick and soft. The tail is relatively short (<70% of head and body length), bicolored, and lacks a terminal pencil. The hindfeet are broad and unwebbed; the claws are short, and the plantar surface is naked, with six large and well-developed tubercles (thenar, hypothenar, and four interdigitals) present. Eight mammae (in four pairs) are present.

The dorsal contour of the skull is convex in lateral view, the braincase is relatively short, and the rostrum is broad and short. The interorbital region is narrow, parallel-sided, without beading, but is slightly raised dorsally. The zygomatics are expanded posteriorly. The anterior border of the zygomatic plates is nearly straight or very slightly concave; their dorsal surfaces rise above the dorsal surface of the rostrum so that the anterior roots of the zygomatics insert at the dorsal surface. The premaxillomaxillary suture below the infraorbital foramen is directed forward along a line about parallel to the longitudinal plane of the palate. The incisive foramina are narrow and extend just past the anterior plane of M1. The palate is long, ridged, and has paired and sometimes complicated posterolateral depressions. The parapterygoid fossae are broad and moderately excavated. The mesopterygoid fossa is distinctly narrower than the parapterygoid fossae. A vertical strut of the alisphenoid typically separates the buccinator-masticatory and accessory oval foramina. The hamular process is long. The bullae are not notably inflated, and the lacerate foramina are largely open. The mandible is dorsoventrally deep in proportion to its length, and there is a pronounced capsular process at the base of the coronoid process.

The upper incisors are opisthodont, broad, and possess a single anterior groove. The upper molar rows are slightly to strongly divergent posteriorly. The molars are tetralophodont (mesoloph and mesolophids are absent), hypsodont, and flat-crowned, with their principal cusps and crests forming a sigmoidal shape; folds are narrow. M3 is S-shaped with an open hypoflexus. The procingulum of m1 is typically separated (that is, an anterior murid is absent) from the protoconid and metaconid, and the anterolabial cingulum is absent. Both M1 and M3 are three-rooted.

Axial skeletal elements have counts of 13 thoracic ribs, six lumbar vertebrae, and 22 to 24 caudal vertebrae. The neural spine of the third thoracic vertebra is highly elon-

gated, and the spine of the second cervical vertebra overlaps the third cervical vertebra. The stomach is unilocular and hemiglandular, but the glandular epithelium extends past the esophageal orifice into the corpus (Carleton 1973). A gall bladder is present (Voss 1991).

Information on parasites is available in Fain (1976), Lewis and Spotorno (1984), Smit (1987), Beaucournu and Gallardo (1988), and J. P. Sánchez (2013). Fossil material is known from Holocene deposits in Argentina (Pardiñas et al. 2002; Teta et al. 2005) and Late Pleistocene deposits in Chile (Simonetti and Rau 1989; Latorre 1998).

REMARKS: The genus is in need of systematic revision; see Yáñez et al. (1987), Reise and Gallardo (1990), Pearson and Christie (1991), and Musser and Carleton (2005) for comments regarding information known to date.

SYNONYMS:

Reithrodon Waterhouse, 1839:68; part (description of *typicus* and *chinchilloides*); not *Reithrodon* Waterhouse, 1837.

Euneomys Coues, 1874:185; as a subgenus of *Reithrodon*; type species *Reithrodon chinchilloides* Waterhouse, 1839, by original designation.

Chelemyscus Thomas, 1925d:585; type species *Reithrodon fossor* Thomas, 1925, by monotypy.

KEY TO THE SPECIES OF *EUNEOMYS*:

1. Known only from the type locality in Salta province, Argentina *Euneomys fossor*
- 1'. Not known from Chile and Argentina north of 30°S . 2
2. Area from just dorsal to rhinarium to lower lips covered with short, brown hairs; upper incisors with grooves placed centrally; size larger; dorsally darker and grayer and laterally cinnamon; length of maxillary tooththrow generally >6.0 mm; interorbital breadth generally >4.2 mm; posterolateral palatal pits moderately deep
. *Euneomys mordax*
- 2'. Area from just dorsal to rhinarium to lower lips covered with short, white hairs; upper incisors with grooves placed laterally; size smaller; dorsally browner and laterally buffy; length of maxillary tooththrow generally <6.0 mm; interorbital breadth generally <4.2 mm; posterolateral palatal pits deep 3
3. Known only from Tierra del Fuego and nearby areas
. *Euneomys chinchilloides*
- 3'. Known from areas north of Tierra del Fuego in Chile and Argentina *Euneomys petersoni*

Euneomys chinchilloides (Waterhouse, 1839)

Tierra del Fuego Euneomys

SYNONYMS:

Reithrodon chinchilloides Waterhouse, 1839:72; type locality "South shore of the Strait of Magellan, near the

Eastern entrance.” The diary of Captain R. FitzRoy (1839:322–323) for the period from February 17–25, 1834, indicated that the HMS *Beagle* was anchored in San Sebastián Bay, Tierra del Fuego, where C. Darwin and others worked the northeastern portion of the island. Therefore, the holotype of *chinchilloides* Waterhouse was probably collected near Bahía San Sebastián on the Argentina side of Tierra del Fuego (see also Osgood 1943b).

Reithrodon (Euneomys) chinchilloides: Coues, 1874:185; name combination.

Euneomys chinchilloides: Thomas, 1901f:254; name combination.

Euneomys ultimus Thomas, 1916b:185; type locality “St. Martin’s Cove, Hermite Island,” Hermite Islands, Magallanes y Antártica Chilena, Chile.

Euneomys chinchilloides chinchilloides: Osgood, 1943b:214; name combination.

Euneomys chinchilloides ultimus: Osgood, 1943b:216; name combination.

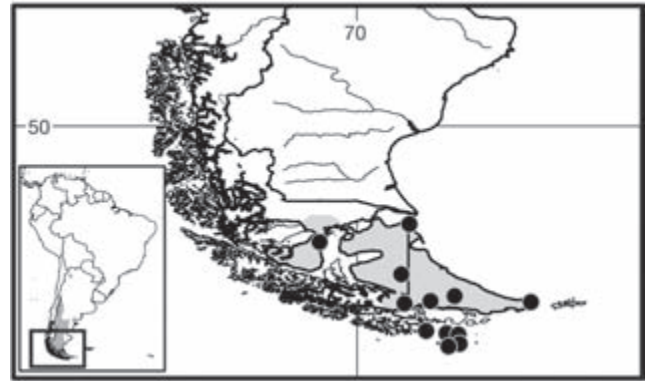

Euneomys [(Euneomys)] chinchilloides chinchilloides: Cabrera, 1961:499; name combination.

Euneomys [(Euneomys)] chinchilloides ultimus: Cabrera, 1961:499; name combination.

DESCRIPTION: Medium sized, with short tail, dense and soft pelage with rich coloration, and rather small ears for genus; slightly larger than *E. petersoni*. Skull broad and heavy; zygomatic plates with straight anterior border or nearly straight, only slightly inclined backward from bottom to top; posterior palate marked with lateral pits separated from parapterygoid fossae by high ridge; lower half of premaxillomaxillary suture extends forward to point more than halfway between cheek teeth and incisors; front of upper incisors laterally grooved; and cheek teeth hypsodont and with a markedly oblique pattern. Specimens from Tierra del Fuego and from the southern mainland in Chile tend to be darker than those elsewhere (Osgood 1943b; Pearson and Christie 1991).

DISTRIBUTION: *Euneomys chinchilloides* occurs on Isla Grande de Tierra del Fuego, neighboring islands, and southernmost mainland Chile (Magallanes y Antártica Chilena). Fossils of true *chinchilloides* are recorded in the Late Pleistocene-Late Holocene sequence of the archaeological site Tres Arroyos 1, Tierra del Fuego (Latorre 1998).

SELECTED LOCALITIES (Map 32): ARGENTINA: Tierra del Fuego, Bahía Buen Suceso (USNM 482138), Lake Fagnano [= Lago Kami] (Osgood 1943b), southeastern end Lake Fagnano [= Lago Kami] (Osgood 1943b), south shore of the Strait of Magellan, near the eastern entrance (type locality of *Reithrodon chinchilloides* Waterhouse). CHILE: Magallanes y Antártica Chilena, Cerro Cóndor, top, 5 km W of Lapataia (Reise and Venegas 1987), Estancia la Fron-

Map 32 Selected localities for *Euneomys chinchilloides* (●). Contour line = 2,000 m.

tera (Reise and Gallardo 1990), Grevy Island (Olrog 1950), Martial Bay, Herschel Island (RNP 1534), vicinity of Punta Arenas (Osgood 1943b), Orange Bay, Hoste Island (Milne-Edwards 1890), St. Martin’s Cove, Hermite Island (type locality of *Euneomys ultimus* Thomas), Wollaston Island (Olrog 1950).

SUBSPECIES: Osgood (1943b) treated *ultimus* Thomas as a subspecies of *E. chinchilloides*, based on its larger size and darker coloration.

NATURAL HISTORY: In much of the published literature, data reported for *E. chinchilloides* refers to other species of *Euneomys*, particularly *E. petersoni*. Little information is available for this species as now defined. Reproduction is reported to occur during the summer; a juvenile specimen was captured in April (Pine et al. 1978), and immatures were collected in February and March (Osgood 1943b).

REMARKS: Mitochondrial DNA cytochrome-*b* data suggest that *E. petersoni* should be treated as a synonym of *E. chinchilloides* (see E. P. Lessa et al. 2010). Although the available morphological evidence supports this hypothesis (see Reise and Gallardo 1990; Pearson and Christie 1991), additional research is needed to resolve the systematic status and relationships of the southernmost populations of *Euneomys*. The karyotype with $2n = 36$ is based on one female collected in the vicinity of Ushuaia, Tierra del Fuego, Argentina (Lizarralde et al. 1994).

Euneomys fossor (Thomas, 1899)

Salta *Euneomys*

SYNONYMS:

Reithrodon fossor Thomas, 1899c:280; type locality “Salta Province, N. Argentina.”

E[euneomys]. fossor: Thomas, 1901f:254; name combination.

[*Chelemyscus*] *fossor*: Thomas, 1925d:585; name combination.

Euneomys [(*Chelemyscus*)] *fossor*: Cabrera, 1961:500; name combination.

DESCRIPTION: Skull larger and heavier than that of *E. chinchilloides*; nasals decidedly expanded anteriorly, just surpassing premaxillae posteriorly; supraorbital edges square, not ridged, their anterior ends marked by slight projections, somewhat like rudimentary postorbital processes; coronal suture evenly curved; interparietal broad; anterior zygomatic root almost as in *E. chinchilloides*, but with slight concavity on front edge rather than deep undercutting in latter species; incisive foramina widely open anteriorly and extend posteriorly to level of M1s; palate ends just behind M3s; posterolateral palatal pits well excavated; and parapterygoid plates shallow (Thomas 1899c:281).

DISTRIBUTION: *Euneomys fossor* is known only from the type locality, the exact position of which is unknown because Salta is a large province in northern Argentina. No additional specimens of this species have been reported, and no other species of *Euneomys* has been recorded from north of about 32°S (Pardiñas, Teta, Chebez et al. 2010).

SELECTED LOCALITIES (Map 33): ARGENTINA: Salta, “Salta Province” (type locality of *Reithrodon fossor* Thomas).

SUBSPECIES: *Euneomys fossor* is monotypic.

NATURAL HISTORY: The natural history of this species is unknown.

REMARKS: The status of this species is uncertain, both because the holotype consists of a mismatched skin and skull, and because the type locality is vague. However, as Pearson and Christie (1991) clearly stated, the name is available for nomenclatorial purposes. The holotype was a fluid-preserved specimen sent to Oldfield Thomas by Francisco P. Moreno, then director of the Museo de La Plata. Although Thomas (1899c:281) wrote that “it [the skull] was extracted [from the fluid] in the Museum [Natural History] on arrival, so that any mistake seems quite impossible,” his name was, in fact, based on a *Euneomys* skull and a *Chelemys* skin (see Hershkovitz 1962; Pearson 1984; Pearson and Christie 1991). Thomas must have recognized a problem with the specimen, however, as he also noted (Thomas 1899c:281) that “the skull should be taken as the type if it were hereafter shown not to belong to the skin.” Thomas (1925d:585) erected the genus *Chelemyscus* for *fossor* based on the combination of “deeply grooved incisors and large fossorial fore-claws.” Galliari et al. (1996) considered *fossor* a *nomen dubium*, an incorrect conclusion because the type of *fossor* presumably contains sufficient character information to resolve its specific status.

Map 33 Type locality of *Euneomys fossor* (●), mapped without certainty and only to indicate “Salta province.” Contour line = 2,000 m.

Euneomys mordax Thomas, 1912

Large *Euneomys*

SYNONYMS:

Euneomys mordax Thomas, 1912b:410; type locality “Fort San Rafael, Province of Mendoza,” Argentina. Fuerte de San Rafael (= Fort San Rafael) is located 24 km WNW San Rafael, Mendoza province, Argentina; however, the geographic provenance of the holotype of *mordax* was questioned by Reise and Gallardo (1990:79), Pearson and Christie (1991:126), and Pearson and Lagiglia (1992:38). According to the last authors “nosotros sugerimos . . . que Bridges colectó los tipos de . . . *Euneomys mordax* . . . durante su cruce de Los Andes [sic] cerca del Volcán Peteroa.”

Euneomys noei Mann, 1944:95; type locality “Valle de la Junta, Cajón del Río Volcán, a 2.400 m de altura,” Metropolitana de Santiago, Chile.

Euneomys [(*Chelemyscus*)] *mordax*: Cabrera, 1961:500; name combination.

Euneomys chinchilloides noei: Mann, 1978:26; name combination.

DESCRIPTION: Larger than that *E. chinchilloides* or *E. petersoni*; fur long, thick, and woolly; hairs on back about 12–13 mm in length; general color dull gray, belly paler, not sharply defined, hairs broadly washed with cream-buff; ears of medium length, well-haired, blackish; manus and pes dull grayish white above; foreclaws not enlarged;

and tail thickly haired, grayish white with indistinct darker line above. Skull stout and heavily built; nasals considerably inflated anteriorly; posterolateral palatal depressions not well developed; supraorbital edges less sharply angular than in *E. fossor*; posterolateral palatal pits comparatively less developed and narrower than in either *E. chinchilloides* or *E. petersoni*; incisors very broad and heavy, with strong groove in more or less central position.

DISTRIBUTION: *Euneomys mordax* is currently known from isolated high Andean (usually above 1,700 m) localities in west central Argentina, Mendoza and Neuquén provinces, and adjacent parts of Chile, including Región Metropolitana in the north and Araucanía in the south (Reise and Gallardo 1990; Pearson and Christie 1991). Pearson and Christie (1991) tentatively associated a large fossil form collected in Latest Pleistocene–Early to Late Holocene strata of Trafal I cave, Neuquén, Argentina, with *E. mordax*. Pearson (1995:112) also suggested that *E. mordax* was present in Río Negro province, Argentina: “I have seen what appear to be its runways and fecal pellets in appropriate habitat at high altitude at Laguna Toncek in Nahual Huapi Park.”

SELECTED LOCALITIES (Map 34): ARGENTINA: Mendoza, Laguna de la Niña Encantada (Jayat, Ortiz, and Miotti 2006), Valle Hermoso, 28 km E of Volcán Peteroa (A. A. Ojeda et al. 2005); Neuquén, 1.5 km S of Copahue (MVZ 181568). CHILE: Araucanía, 3.5 km W of Paso Pino Hachado (MSU 7460); Biobío, Aguas Calientes, 5 km E of Termas Chillán (Reise and Venegas 1987); Santiago, La Parva (Pine et al. 1979), Valle de la Junta, Cajón del Río Volcán (Mann 1944).

SUBSPECIES: We treat *Euneomys mordax* as monotypic.

NATURAL HISTORY: Little is known of the natural history of this species, except for limited information on habitat preference. In Malleco province, Chile, individuals were captured in *ñirre* (*Nothofagus*) grassland habitat at 1,740 m (Greer 1965); in Neuquén province, Argentina, Pearson and Christie (1991:123) collected it in “a clearly defined system of runways and tunnels in deep soil in a wet ‘alpine’ meadow with 100% ground cover, including low bushes.” Specimens of *E. petersoni* have been collected at or near most localities where *E. mordax* has been collected (e.g., Pine et al. 1979; Reise and Gallardo 1990; Pearson and Christie 1991; Pearson 1995; A. A. Ojeda et al. 2005). Pearson and Christie (1991) provided information on habitat separation between these two species and suggested that *E. mordax* preferred deeper soils and *E. petersoni* was more often found on bare, windswept rocky scree. Mella (2006) found *E. mordax* to be very uncommon during a population ecology study at El Monumento Natural “El Mo-

rado,” Región Metropolitana de Santiago, Chile. Mann (1944, 1978) provided abundant information about the environments occupied by *E. noei* in the canyon of the Río Maipo, as well as adaptations displayed by this rodent in surviving the hostile high Andean conditions.

REMARKS: Resemblances between *E. fossor* and *E. mordax* have not been highlighted since Thomas (1912b); if both nominal forms belong to the same entity, *fossor* antedates *mordax* and should be replaced. For comments on the location of the type locality of *mordax*, see the detailed study by Pearson and Lagiglia (1992). Although A. A. Ojeda et al. (2005) indicated that the type locality was restricted to “cerca del Volcán Peteroa” by Pearson and Lagiglia (1992), it is unclear as to whether this was a formal redesignation of the type locality because it was not followed by Musser and Carleton (2005). Pine et al. (1979), Yáñez et al. (1987), Reise and Gallardo (1990), Pearson and Christie (1991), and A. A. Ojeda et al. (2005) compared morphology and karyology of *E. mordax* and *E. petersoni*.

The status of *noei* Mann remains problematic. Hershkovitz (1962:500) considered this form (not mentioned in Cabrera 1961) as “doubtfully separable from *Euneomys mordax*.” Furthermore, Pine et al. (1979) highlighted the composite nature of the type series of *noei* Mann, which includes a small form similar to *chinchilloides* and a large form similar to *mordax*. According to Pearson and Christie (1991:126), “the type specimens of *Euneomys mordax* Thomas and *E. noei* Mann have grooves positioned

Map 34 Selected localities for *Euneomys mordax* (●). Contour line = 2,000 m.

centrally on the upper incisors and are relatively large . . . There is no evidence that *noei* is specifically distinct from *mordax*.”

The karyotype is $2n=42$, $FN=66$ (specimens from Paso Pino Hachado, Chile, and Valle Hermoso, Argentina; Reise and Gallardo 1990; A. A. Ojeda et al. 2005).

Euneomys petersoni J. A. Allen, 1903

Peterson's Euneomys

SYNONYMS:

Euneomys petersoni J. A. Allen, 1903b:192; type locality “upper Rio Chico de Santa Cruz, near the Cordilleras, Patagonia,” Santa Cruz, Argentina. The holotype was collected by J. B. Hatcher, and our review of Hatcher’s (1903) geographical notes, coupled with fieldwork that followed his itinerary, suggests that the holotype was secured near the headwaters of the Río Chico, 4.5 km upstream from Estación El Portezuelo, at about 48.42°S, 71.78°W.

Euneomys dabbenei Thomas, 1919e:127; type locality “Lago Viedma, Santa Cruz, Patagonia,” Argentina.

Euneomys dabbbeni Ellerman, 1941:460; incorrect subsequent spelling of *dabbenei* Thomas.

Euneomys [(*Euneomys*)] *petersoni*: Cabrera, 1961:499; name combination.

Euneomys chinchilloides petersoni: Hershkovitz, 1962: 499; name combination.

DESCRIPTION: Smaller than *E. chinchilloides*. Pelage very long and soft, almost woolly, and colored dark gray-brown above variegated with blackish and fulvous streaks; sides much paler and more fulvous, especially along lower border; belly soiled white; ears dark brown on both surfaces and very thinly haired; sides of nose and lower border of cheeks whitish gray, either with faint tinge of yellow or pure white; soles naked except for posterior third; tail one-third or less of total length, well clothed, dusky brown above, with sides and ventral surface white. Skull long and narrow; bullae small and pointed; upper incisors possess lateral grooves.

DISTRIBUTION: *Euneomys petersoni* is widespread in arid lands of southern and central Patagonia, Argentina, from the Atlantic coast to the Andes and from the Straits of Magellan to northwestern Mendoza and southern San Juan provinces, Argentina (Osgood 1943b; Pardiñas, Teta et al. 2003; Pardiñas, Teta, Chebez 2010; Viana et al. 2011). In Chile, recorded localities are restricted to the Andean piedmont from Torres del Paine to Santiago (Osgood 1943b; Pine et al. 1979; Reise and Gallardo 1990). Fossils and subfossils of *E. petersoni* are known from several archaeological sites that range in age from terminal Pleistocene to Recent in southern (e.g., Cueva del Milodón; Simonetti and Rau 1989), western, and central Patagonia (e.g.,

Epullán Grande cave, Trafal I cave; Pearson and Pearson 1993; Pardiñas, Teta, D’Elía, and Lessa 2011).

SELECTED LOCALITIES (Map 35): ARGENTINA: Chubut, Cerro El Sombrero (CNP-E 294), Estancia El Guachito (Pardiñas et al. 2000), Estancia Talagapa (CNP-E 204), Pampa de los Guanacos (CNP-E 303), Sierra Apas (Pardiñas, Teta, and Udrizar Sauthier 2008); Mendoza, Laguna de la Niña Encantada (CNP-E 55), RN 40 footbridge over Río Grande (CNP-E 198), Seccional Horcones PP Aconcagua (Pardiñas, Teta, Chebez et al. 2010); Neuquén, Cañadón del Tordillo (Pardiñas, Teta et al. 2003), vicinity of Copahue (Pearson and Christie 1991), 4 km S of Pilolil (Pardiñas, Teta et al. 2003), PN Laguna Blanca, 0.58 km W and 4.20 km N of Co. Mellizo Sud (RDS 18216), Risco Alto, Auca Mahuida (PPA 147); Río Negro, Cerro Corona, Meseta de Somuncura (CNP 2426), 10 km WNW of Comallo (MVZ 165850), Laguna del Molino, Ingeniero Jacobacci (CNP-E 280); San Juan, Pampa larga (Vianna et al. 2011); Santa Cruz, Cerro Fortaleza (CNP-E 500), Cerro Ventana (CNP-E 376), Estancia La Anita (CNP-E 380), Estancia La Dorita, Cañadón Loreley (CNP-E 588), Estancia La María (CNP-E 426), 4 km W of Faro de Cabo Vírgenes (CNP-E 433), Parador Luz Divina, Río La Leona (CNP-E 93), Punta Beagle (CNP-E 434). CHILE: Aysén, Coihaique (Reise and Gallardo 1990), Puerto Ibáñez (Reise and Gallardo 1990); Araucanía, 9.4 km W of Paso Pino Hachado (Greer 1965); Biobío, Chillán (Reise and Gallardo 1990); Magallanes y Antártica Chilena, Cueva del Milodón (Reise and Gallardo 1990), Palli [= Pali] Aike (Yáñez et al. 1987) Sector Lago Toro, Parque Nacional Torres del Paine (Jaksic et al. 1978); O’Higgins, Baños del Flaco (Yáñez et al. 1987); Santiago, El Colorado (LCM 774).

SUBSPECIES: *Euneomys petersoni* is monotypic.

NATURAL HISTORY: *Euneomys petersoni* has been captured on barren, rocky, windswept slopes with little vegetation in Chile (Kelt 1994) and in Neuquén and Río Negro provinces, Argentina (Pearson and Christie 1991). In Malleco province, Chile, *E. petersoni* was captured in ñirre (*Nothofagus*) grassland at 1,555 m (Greer 1965). As noted in the *E. mordax* account, *E. petersoni* has been collected at or near most localities where *E. mordax* has been collected (e.g., Pine et al. 1979; Reise and Gallardo 1990; Pearson and Christie 1991; Pearson 1995; A. A. Ojeda et al. 2005). This species is nocturnal and herbivorous (Kelt 1994; Pearson 1995); Kelt (1994) also reported that the diet includes insects. Individuals collected during the summer (December) in Chile were reproductively active (Kelt 1994); subadults and a female that had been lactating were collected in February in Santa Cruz (J. A. Allen 1903b). Major predators include the Barn Owl (*Tyto alba*) and Burrowing Owl (*Athene cunicularia*) in Patagonia, Argentina (De Santis et al. 1997; Sahores and Trejo 2004), and the Magellanic Horned Owl

(*Bubo magellanicus*) in southern Chile (Reise and Venegas 1974). Blood samples taken from *E. petersoni* in southern Chile contained the protozoan *Trypanosoma cruzi*, which causes Chagas disease in humans (Rozas et al. 2007).

REMARKS: Osgood (1943b) regarded *petersoni* J. A. Allen as a valid species, a view resurrected by Musser and Carleton (2005:1115) based on putative morphometric differences between this taxon and *E. chinchilloides*. Nevertheless, in much of the published literature, this taxon has been included in *E. chinchilloides*. The inclusion of *petersoni*, along with *dabbeni* Thomas, as likely synonyms of *chinchilloides* Waterhouse is supported by the mtDNA cytochrome-*b* analyses of E. P. Lessa et al. (2010), which also delineated an apparently unnamed taxon (if *fossor* Thomas does not apply) of *Euneomys* in northern Patagonia, western Mendoza province, Argentina, and central Chile. The uniqueness of this latter clade is concordant with a different diploid number for animals from Mendoza (see below). Additional research, particularly a morphological restudy of available museum specimens, is needed to resolve the systematic status and relationships of these forms.

Map 35 Selected localities for *Euneomys petersoni* (●). Contour line = 2,000 m.

A karyotype with $2n=36$, $FN=66$ has been reported for specimens from San Carlos de Bariloche, Río Negro, Argentina, and Coyhaique, Chile (Reise and Gallardo 1990). Specimens from Valle Hermoso, Mendoza province, Argentina, had $2n=34$ (FN not reported; Ojeda et al. 2005; cited as *E. chinchilloides*). Animals from Farellones, Santiago, Chile, had $2n=36$, $FN=69$, with an all-biarmed complement, except the smallest autosome pair and the X-chromosome, both of which are acrocentric (Spotorno 1986; reported as *E. noei*, but we refer both specimens, LCM 631 and 774, to *E. petersoni* because they possess characters of this species, most notably a lateral position of incisive grooves).

Genus *Irenomys* Thomas, 1919

Pablo Teta and Ulyses F. J. Pardiñas

The genus *Irenomys* is primarily restricted to cold, forested areas in southern South America (Kelt 1993) and is the only sigmodontine rodent endemic to *Nothofagus* forest (Osgood 1943b). Osgood (1943b), Mann (1978), Kelt (1993, 1994), Steppan (1995), and Pardiñas, Cirignoli et al. (2004) reviewed anatomical characters, distribution, and ecology.

Irenomys is medium-sized, with a tail much longer than the head and body length (about 150%). The pelage is thick and soft. The ears are of medium length and densely haired. The eyes are large. The forefeet and hindfeet are large and broad. The heel is only sparsely furred. The dorsum is grayish cinnamon rufous, streaked with fine dusky lines. The under parts are plumbeous, heavily washed with pinkish cinnamon buff. Ears are brownish black, occasionally with an indistinct subauricular white spot. The forefeet and hindfeet are whitish; toes are white. The tail is unicolored blackish brown, conspicuously clothed with short hairs, and ends in a short (ca. 5 mm) pencil of hairs. The mean and range of external measurements of 37 adults from Chile are: total length, 280 mm (270–326 mm), length of tail, 165 mm (162–196 mm), length of hindfoot, 30 mm (28–32 mm), and length of ear, 22 mm (20–25 mm). The average adult mass of 36 Chilean specimens is 42 g (Kelt 1993, 1994). The adult weight of Argentinean specimens ranged from 30 to 67 g (Pearson 1983). Males and females are of the same weight (Pearson 1983).

The skull is relatively long and narrow. The braincase is long, the interparietal is very large, and the interorbital region is rather parallel-sided but greatly constricted. The coronal suture is V-shaped. The zygomatic plates are high and slightly projected forward. The nasals are rather flat and project beyond the anterior tips of the premaxillae. The incisive foramina are long and wide, extending posteriorly to the protocone of the M1; the posterior end of the palate lies even with the posterior end of the toothrow, defining

a short bony palate. Posterior palatal pits are absent. The parapterygoid fossa is deeply excavated, with its lateral border unusually thickened, flattened, and directly outward. The hamular process is thin along its entire length. The tegmen tympani is present and attached to the squamosal process. A thick alisphenoid strut is present. The circulatory carotid pattern is primitive (*sensu* Voss 1988). The mandible is short and robust with a prominent lower masseteric ridge and an inconspicuous capsular projection. The height of the coronoid process is subequal with the mandibular condyle. The lunar notch is well defined by a long condyloid process (Kelt 1993, 1994; Steppan 1995). Greer (1965) and Kelt (1993, 1994) provided cranial measurements.

The upper incisors are opisthodont, with a sharply defined longitudinal groove on the anterior face (Steppan 1995:Fig. 9D). The molars are hypsodont and laminated, with very deeply dissected surfaces, providing a characteristic prismatic appearance. Hershkovitz (1962:94) described this pattern, unique among sigmodontines, as “partial transverse lamination.” Opposite flexi/flexids of all molars meet at midline; there is no posterolophid on m1, nor is there a labial root for either M1/m1; three roots are present on M3, and the molar rows diverge slightly posteriorly (Steppan 1995).

Axial skeletal elements have counts of 13 ribs, 19 thoracolumbar vertebrae, and 34–39 caudal vertebrae. The first rib articulates only with the first thoracic vertebra. The deltoid tuberosity is greater than 59% of the length of the humerus as measured from the condyle (Steppan 1995).

The stomach is unilocular-hemiglandular with the glandular epithelium extending to the corpus (Carleton 1973:13–14). A gall bladder is present (Voss 1991a). The male phallus is complex but without hooks or knobs on the dorsal surface of the lateral mounds (Steppan 1995: Table 4). Preputial glands consist of a single large lateral pair and a medial pair of medium length (Voss and Linzey 1981).

Species of *Oligoryzomys* are of similar color and also have long tails, but they lack grooves on their upper incisors. The eyes of *Irenomys* are larger and are surrounded by dark fur. The tail is thicker and strikingly bicolor. *Phyllotis* have larger ears, proportionally shorter tails, and lack grooves on the upper incisors; their molars are not as highly dissected (Pearson 1995).

SYNONYMS:

Mus: Philippi, 1900:10; part (description of *tarsalis*); not *Mus* Linnaeus, 1758.

Irenomys Thomas, 1919b:201, type species *Reithrodon longicaudatus* Philippi, 1900, by original designation.

Irenomys tarsalis (Philippi, 1900)

Chilean Tree Rat

SYNONYMS:

Mus tarsalis Philippi, 1900:10, plate 1, Fig. 3; type locality “in provincia Valdivia,” stated (p. 11) to have been collected “en el pequeño conservatorio de me jardín en mi fundo San Juan,” near La Unión, Los Ríos, Chile.

Reithrodon longicaudatus Philippi, 1900:64, plate XI, Fig. 1; type locality “in litore occidental Patagoniae;” cited as “Melinka, Guaitecas Islands, 44° S, [Los Lagos,] Chile” by Osgood 1943b:219.

Irenomys longicaudatus: Thomas, 1919b:201; generic description and name combination.

Irenomys tarsalis tarsalis: Osgood, 1943b:217; name combination.

Irenomys tarsalis longicaudatus: Osgood, 1943b:219; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Irenomys tarsalis* is restricted largely to the *Nothofagus* forests of the southern Andes of Argentina and Chile. In Chile, the species is known from forested habitat from Chillán (Ñuble province, VII Region) to at least Puerto Ibáñez (General Carrera province, XI Region) along the Andes and from Nahuelbuta to Isla Grande de Chiloé and the Guaitecas Islands (Osgood 1943b; Kelt 1994) along the coastal range. Although the species is mostly absent from the valleys of south central Chile (Kelt 1993), Saavedra and Simonetti (2000) reported isolated populations in coastal patches of temperate forest and Kelt et al. (2008) captured one individual in a shrubby riparian corridor about 40 km S of and 900 m lower in elevation than the nearest forested region. In Argentina, it is found in *Nothofagus* forests and precordilleran steppes from Neuquén province south to southern Chubut province (Pearson 1983; see Pardiñas, Cirignoli et al. 2004 and G. M. Martin 2010 for records of Argentinean localities). The known fossil record is restricted to latest Pleistocene and Holocene deposits in Río Negro (El Trébol archaeological site; Hajduk et al. 2004) and Neuquén provinces (Cueva Trafal I and Estancia Nahuel Huapi; Pearson and Pearson 1993; Rebane 2002), Argentina.

SELECTED LOCALITIES (Map 36): ARGENTINA: Chubut, Lago Fontana (MLP 11.VI.96.10), Lago Futalaufquen (Monjeau et al. 1997), Lago La Plata, west side (Pardiñas, Cirignoli et al. 2004); Neuquén, 3 km NW of Confluencia (MVZ 159421), Pilolil (Pardiñas, Cirignoli et al. 2004); Río Negro, 19 km NNE of El Bolsón (MVZ 152171), Cerro Leones, 15 km ENE of Bariloche (Pearson and Pearson 1982). CHILE: Aysén, 0.25 km W of Puerto Ingeniero Ibáñez (Kelt et al. 2008), Reserva Nacional Coyhaique, 3 km N of Coyhaique (Kelt 1996), Melinka, Islas Guaitecas (Osgood 1943b); Los Lagos, mouth of Río Inio,

Isla Grande de Chiloé (Osgood 1943b), Petrohue, Lago Todos Los Santos (Osgood 1943b); Los Ríos, Fundo San Juan, near La Unión, Valdivia (type locality of *Mus tarsalis* Philippi); Biobío, Aserradero, 7 km below Termas Chillán (Reise and Venegas 1987), Reserva Nacional Los Queules (isolated northern record; Saavedra and Simonetti 2000).

SUBSPECIES: Osgood (1943b) tentatively recognized two subspecies: *tarsalis* Philippi, spread over the mainland range of the species, and *longicaudatus* Philippi, restricted to Isla Melinka, one of the small islands of the Guaiteca group off the southern end of Chiloé Island. However, as noted by Osgood (1943b:200), the series of *longicaudatus* that he examined was composed largely of juvenile specimens, which compromised the taxonomic value of his observations. Thus, the adequacy of these subspecies designations has yet to be tested by either more appropriately aged samples or any modern methodology.

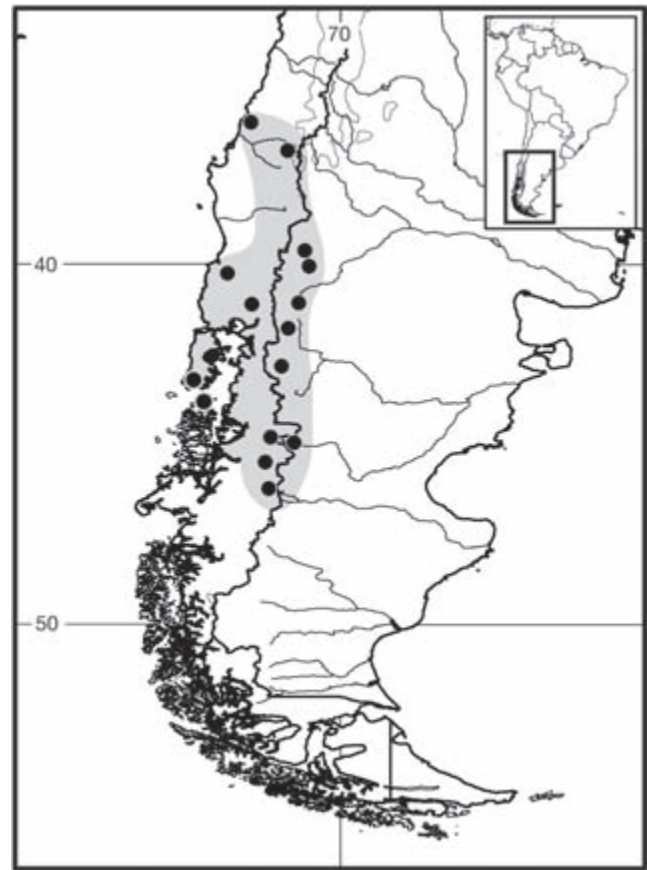

NATURAL HISTORY: *Irenomys tarsalis* is mainly found in dense *Nothofagus* forest with thick stands of *Chusquea* bamboo (Pearson 1983). Population densities in a Coihue (*Nothofagus dombeyi*) forest in southern Argentina varied from 1.4 individuals per hectare in November to 5.1 in May (Pearson and Pearson 1982). The species is nocturnal and scansorial (Pearson 1983; Kelt 1994). Individuals are frequently captured in traps placed along logs, at the base of trees, or in hollows formed by surface roots and boulders covered by lichens and mosses (Kelt 1994). It also has been collected in shrubby habitats in Chile (B. D. Patterson et al. 1990) and in the more arid fringes of cypress trees (*Austrocedrus chilensis*) at the edge of the Argentinean precordillera (Pearson 1983). *Irenomys tarsalis* has been considered a rare or uncommon species (B. D. Patterson et al. 1989, 1990; Saavedra and Simonetti 2000), a view probably resulting from low capture success due to ground placement of traps. It was the second most common mammal observed in the arboreal stratum with camera traps (Amico and Aizen 2000). It climbs well, sometimes jumping a few centimeters from one branch to another, or it may hold on with the hindfeet and reach across a gap with extended front feet (Pearson 1983). This mouse breeds in the spring, although the season may extend to late summer–early autumn (Greer 1965; Pearson 1983). Litter size ranges from three to six (Greer 1965; Pearson 1983; Kelt 1994). The species is primarily granivorous-frugivorous, but also eats green vegetation and fungi (Pearson 1983; Meserve et al. 1988). A captive specimen accepted rolled oats, apple, and tender bamboo shoots but refused carrot, bamboo blossoms, bread, and grubs (Pearson 1983).

Skeletal remains of *Irenomys* have been found in owl pellets of the Magellanic Horned Owl (*Bubo magellanicus*; Massoia, Chebez, and Heinonen Fortabat 1991a), the

Rufous-legged Owl (*Strix rufipes*; D. R. Martínez 1993), and the Barn Owl (*Tyto alba*; Trejo and Lambertucci, 2007). These are docile rodents that may be removed from live-traps by hand (Pearson 1983). When released from captivity, they climbed bamboos or trees, scampered away across the forest floor, or disappeared down a burrow (Pearson 1983).

REMARKS: *Mus mochae* Philippi, 1900, included by Gyldenstolpe (1932) in the genus *Irenomys*, is, according to Osgood (1943b), a composite of an *Irenomys tarsalis* skull and an *Abrothrix olivacea* skin. Osgood (1943b:219) noted that the type of Philippi's *tarsalis* has apparently been lost, and that no other specimen of this species has been found subsequently at the type locality or in the region surrounding it. He also stated (1943b:220) that the skull of the type of *longicaudatus* Philippi had been lost, although the skin still remained as a mount.

Irenomys tarsalis has $2n=64$ chromosomes (FN=98) and a C-banding pattern characterized by small amounts of centromeric heterochromatin. The autosomal complement consists of five pairs of metacentrics (two large, two medium-sized, and one small), 13 pairs of submetacentrics (medium- to small-sized), and 13 pairs of medium-sized acrocentrics. The X chromosome is the largest acrocentric

Map 36 Selected localities for *Irenomys tarsalis* (●). Contour line = 2,000 m.

element in the karyotype; the Y chromosome is a medium-sized metacentric (A. A. Ojeda et al. 2004).

Genus *Juliomys* E. M. González, 2000

Enrique M. González, João A. de Oliveira, and Pablo Teta

The genus *Juliomys* includes at least three living and one extinct species of mice endemic to the Atlantic Forest. E. M. González (2000) erected the genus for an odd species of uncertain affinities that was described by Osgood (1933d) as *Thomasomys pictipes*. Prior to the description of *Juliomys*, Musser and Carleton (1993) moved *pictipes* to *Wilfredomys*, mostly based on overall impressions concerning its closeness to *W. oenax* made by Osgood (1933d) and Pine (1980). The other two species were described recently (J. A. Oliveira and Bonvicino 2002; L. P. Costa et al. 2007), but even more recent analyses suggest a greater diversity in this genus than now recognized (Paresque et al. 2009; see also Pavan and Leite 2011). In addition, Cherem et al. (2004) and Cherem (2005) recognized, as *Juliomys* sp., several individuals from coastal localities in the Brazilian state of Santa Catarina, as did D. O. Lima et al. (2010) for ones from the southernmost locality for the genus at the boundary of the Atlantic Forest in Rio Grande do Sul state. It is unclear at present whether these southern Brazilian localities all hold the same entity or different ones (Pavan and Leite 2011). Finally, Pardiñas and Teta (2011a) recorded an apparently extinct species of *Juliomys*, assigning to this genus a Lagoa Santa fossil described by Winge (1887) as *Calomys anoblepas*.

Analyses of the karyotypes of *Juliomys* indicate that centric and tandem fusions plus pericentric inversions have been the most frequent rearrangements involved in the karyotypic differentiation in the genus (Paresque et al. 2009). Phylogenetic analysis using nucDNA IRBP sequences placed *Juliomys* as sister to a clade formed by *Euneomys* and *Irenomys* (D'Elía et al. 2006). Similar analysis based on the mtDNA cytochrome-*b* sequences, or on concatenated nucDNA IRBP and cytochrome-*b* sequences, failed to associate *Juliomys* with any other sigmodontine, with reasonable levels of support (M. F. Smith and Patton 1999; D'Elía 2003a). *Juliomys*, once considered a member of Thomasomyini, is currently regarded as Sigmodontinae *incertae sedis* (D'Elía et al. 2007). Divergence in cytochrome-*b* sequences among extant species is extensive, ranging from 10–14% (L. P. Costa et al. 2007; Pardiñas, Teta et al. 2008; de la Sancha et al. 2009; Pavan and Leite 2011).

Species of *Juliomys* are small sigmodontines, with a tail longer than the head and body. Despite notable differences in the intensity of color, particularly on the muzzle, and in

the length of pelage among the three species, all of them have an ochraceous dorsum, orangish top of the head and on the rump, and dusky anterior back and shoulders. The flanks are paler than the dorsum, gradually transitioning toward the venter, which varies between white and pale ochraceous in the different species, contrasting in some regional samples with dark patches resulting from the slaty hair bases. The tail varies from slightly to markedly bicolored in the different species, with the terminal part uniformly dusky. Dorsal surfaces of forefeet and hindfeet are covered with light ochraceous hairs intermixed with a few dark hairs, resulting in a general color varying from pale orange to orange-brown; the toes are covered with whitish hairs, and ungual tufts of white hairs are intermixed with a few dark hairs, giving a general color that varies from self-colored, yellow-white to gray-based. Plantar surfaces of the hindfoot have six plantar pads (thenar, hypothenar, and four interdigital). Digit I of the hindfoot is approximately half the length of digit V. Mammary count varies from eight (one pectoral, one postaxial, and two inguinal pairs), in *J. ossitemuis*, to 10 (one pair each in pectoral, postaxial, thoracic, abdominal, and inguinal positions), in *J. pictipes*. The stomach is unilocular-hemiglandular (L. P. Costa et al. 2007).

The skull is delicate, with a short rostrum (<35% occipitonasal length) and rounded braincase. The nasals become wider anteriorly. The interorbital region is narrow with somewhat squared but not ridged supraorbital edges. The anterior portion of the interfrontal suture is incompletely fused, with a slit-like fontanelle sometimes present. The coronal suture is V-shaped, the interparietal is wide, and the occipital region is reduced. The zygomatic plates are narrow, with their anterior borders nearly vertical; the zygomatic notches are shallow. The palate is short and broad; the mesopterygoid fossa is lyre-shaped and extends anteriorly between the posterior third of the last molars, and is narrower than the parapterygoid fossae. The auditory bullae are small, with the petrotic bone externally apparent in basicranial view and forming part of the carotid canal. The mandibles display a curved lateral profile and a well-developed capsular process. The incisors are robust, orthodont to opisthodont. The molars are brachydont with a crested, coronal topography and well-developed flexus/ids and mesoloph/ids; an ectolophid is usually present on m1 and m2.

Species of *Juliomys* are forest dwellers, presumably arboreal mice, although some of the few specimens available were trapped on the ground. Individuals are rather uncommonly collected using standard terrestrial live or kill traps, but may be the most common rodent of the understory or the sole taxon captured in the canopy when pitfall or canopy traps are used (Graipel 2003).

SYNONYMS:

- Calomys*: Winge, 1887:44; part (description of *anoblepas*); not *Calomys* Waterhouse, 1837.
Oryzomys: E.-L. Trouessart 1897:527; part (listing of *anoblepas*); not *Oryzomys* Baird, 1857.
Thomasomys: Osgood, 1933d:11; part (description of *pictipes*); not *Thomasomys* Coues, 1884.
Oligoryzomys: Massoia, Chebez, and Heinonen-Fortabat, 1991b:17; part (regarded *pictipes* as synonym of *Oligoryzomys flavescens antoniae* Massoia); not *Oligoryzomys* Bangs, 1900.
Wilfredomys: Musser and Carleton, 1993:752; part (listing of *pictipes*); not *Wilfredomys* Avila-Pires.
Juliomys E. M. González, 2000:3; type species *Thomasomys pictipes* Osgood, by monotypy.

KEY TO THE SPECIES OF *JULIOMYS*:

1. Size relatively large; zygomatic notch deep; interorbital region broad, convergent anteriorly; tympanic bullae small; squamosal-alisphenoid groove absent; sphenopalatine vacuities absent or minute; lateral extension of parietals small; posterior projection of condyloid process short; $2n=36$ *Juliomys pictipes*
- 1'. Size relatively small; zygomatic notch shallow; interorbital region narrow, hourglass in shape; tympanic bullae large; squamosal-alisphenoid groove present; sphenopalatine vacuities large to very large; lateral extension of parietals broad; posterior projection of condyloid process long; $2n=20$ 2
2. Nose brown; dorsal pelage long; ventral pelage pale ochraceous; tail markedly bicolored; interfrontal fontanelle present; posterolateral palatine pits large; ectolophid/ectostylid of m1–m2 small; NF=34
. *Juliomys rimofrons*
- 2'. Nose orange; dorsal pelage short; ventral pelage cream-white; tail slightly bicolored; interfrontal fontanelle usually absent; posterolateral palatine pits small; ectolophid/ectostylid of m1–m2 conspicuous; NF=36
. *Juliomys ossitenuis*

Juliomys ossitenuis L. P. Costa, Pavan, Leite, and Fagundes, 2007

Delicate Red-nosed Tree Mouse

SYNONYM:

Juliomys ossitenuis L. P. Costa, Pavan, Leite, and Fagundes, 2007; type locality “Fazenda Neblina, Parque Estadual da Serra do Brigadeiro, 20 km W Fervedouro, Minas Gerais, Brazil, 20°43'S 42°29'W, elevation 1300 m.”

DESCRIPTION: Small, with tail (89–116 mm) longer than head and body (82–97 mm); fur soft and short; dorsal coloration dark orange brown above, venter contrastingly cream white; nose, rump, and inner pinna orange brown;

tail faintly bicolored, terminating in short tuft; hands and feet short and broad, their dorsal surfaces covered with pale orange hairs. Skull slender and delicate (occipitonasal length 21.9–26.8 mm); rostrum short and narrow, less than one-third skull length; zygomatic notches very shallow; interorbital region narrow and hourglass in shape, with margins only slightly angled; posterolateral palatine pits small; tympanic bullae large; squamosal-alisphenoid groove present; sphenopalatine vacuities very large; lateral extension of parietals broad; condyloid process of mandible long; m1–m2 with conspicuous ectolophid/ectostylid (J. A. Oliveira and Bonvicino 2002; L. P. Costa et al. 2007).

DISTRIBUTION: *Juliomys ossitenuis* is endemic to the Atlantic rainforest and semideciduous forests of southeastern Brazil in the states of São Paulo, Minas Gerais, and Espírito Santo (L. P. Costa et al. 2007; Pavan and Leite 2011).

SELECTED LOCALITIES (Map 37; from L. P. Costa et al. 2007, except as noted): BRAZIL: Espírito Santo, Casa Queimada, Parque Nacional do Caparaó, Parque Estadual do Forno Grande (Pavan and Leite 2011); Minas Gerais, Fazenda do Itaguaré, 16 km SW of Passa Quatro, Fazenda Neblina, Parque Estadual da Serra do Brigadeiro, 20 km W of Fervedouro (type locality of *Juliomys ossitenuis* L. P. Costa, Pavan, Leite, and Fagundes); São Paulo, Cristo (Pavan and Leite 2011), Estação Ecológica do Bananal, Mulheres, Museros, Quilombo, Reserva Florestal do Morro Grande.

SUBESPECIES: *Juliomys ossitenuis* is monotypic.

NATURAL HISTORY: This species inhabits Atlantic rainforest and semideciduous forests above 800 m, including cloud forests at higher elevations. Apparently, populations from northern latitudes prefer higher elevations (L. P. Costa et al. 2007). Most of the known specimens are from protected areas of mature, continuous forests. The holotype and three paratypes were collected with Sherman traps placed on tree branches or vines, but other specimens were obtained with pitfall traps (L. P. Costa et al. 2007). The only reproductive data available correspond to a lactating female collected in May at the beginning of the dry season (L. P. Costa et al. 2007). This species was found in syntopy with *J. pictipes* at two localities (Mulheres and Museros) in São Paulo state (L. P. Costa et al. 2007).

REMARKS: The karyotype is $2n=20$, FN=36 (L. P. Costa et al. 2007). This chromosome complement differs from that of *J. pictipes* by at least eight Robertsonian fusions/fissions plus one pericentric inversion. Although the $2n=20$ karyotypes of *J. ossitenuis* and *J. rimofrons* appear very similar, several chromosomes are clearly different in size and morphology, which suggests that several complex rearrangements separate their autosomal complements.

Map 37 Selected localities for *Juliomys ossitenuis* (●).

The Y chromosomes are also very distinctive. Molecular phylogenetic analyses based on the mtDNA cytochrome-*b* gene sequences confirmed that *J. ossitenuis* is a well-supported monophyletic clade, highly divergent from the other two species in the genus (L. P. Costa et al. 2007; Pardiñas, Teta et al. 2008).

Juliomys pictipes (Osgood, 1933)

Small Red-nosed Tree Mouse

SYNONYMS:

Thomasomys pictipes Osgood, 1933d:11; type locality “Caraguatay, Rio Parana, 100 miles south of Rio Iguassu, Misiones, Argentina,” restricted by Pardiñas et al. (2007) to Puerto Caraguatay (26.616°S, 54.766°W), Misiones, Argentina, although the holotype was probably obtained at the nearby locality Puerto Benson (Pardiñas, Teta et al. 2008).

Wilfredomys pictipes: Musser and Carleton, 1993:752; name combination.

Juliomys pictipes: E. M. González, 2000:3; first use of current name combination.

DESCRIPTION: Largest species in genus, with tail (82–95 mm) slightly shorter than head-body length (90–110 mm); body color pale orange-brown above and white to cream-white below; tail markedly bicolored (except for dusky terminal half-inch); hindfeet clear ochraceous-tawny above, with whitish toes. Interorbital region of skull broad, with anteriorly convergent borders; lateral

expansion of frontal bones restricted; zygomatic notches deeply to moderately expressed; upper free border of zygomatic plates reduced; incisive foramina short, not reaching anterior plane of M1s; tympanic bullae relatively small; squamosal-alisphenoid groove and sphenofrontal foramen absent; sphenopalatine vacuities absent or minute; condyloid process of mandible short (L. P. Costa et al. 2007; Pardiñas, Teta et al. 2008).

DISTRIBUTION: *Juliomys pictipes* is endemic to the Atlantic rainforest of southeastern Brazil, eastern Paraguay, and northeastern Argentina. Pavan and Leite (2011) suggested that the distribution is disjunct, with those populations in southern Brazil, eastern Argentina, and eastern Paraguay separated from the remainder of the range by a broad expanse of *Araucaria* forest.

SELECTED LOCALITIES (Map 38): ARGENTINA: Misiones, Arroyo de Salamanca, Parque Provincial “Ernesto Che Guevara” (Pardiñas, Teta et al. 2008), Balneario de la Reserva Privada de Usos Múltiples de la Universidad Nacional de La Plata “Valle del Arroyo Cuña Pirú” (Pardiñas, Teta et al. 2008), Parque Nacional Iguazú, Sendero Macuco (Pardiñas, Teta et al. 2008). **BRAZIL:** Espírito Santo, Alto Alegre, Reserva Biológica Duas Bocas (Pavan and Leite 2011); Minas Gerais, Estação de Pesquisa e Desenvolvimento Ambiental de Peti (L. P. Costa et al. 2007), Reserva Particular do Patrimônio Natural do Caraça, 25 km SW of Santa Bárbara (Pavan and Leite 2011); Paraná, Fazenda Monte Alegre (Pavan and Leite 2011); Rio de Janeiro, Fazenda Boa Fé (L. P. Costa et al. 2007), Mata do Mamede (L. P. Costa et al. 2007); Rio Grande do Sul, Parque Estadual do Turvo (Pavan and Leite 2011); Santa Catarina, Barragem do Rio São Bento (Graipel 2003), Santo Amaro da Imperatriz (Graipel 2003); São Paulo, Fazenda Intervaes (Pavan and Leite 2011), Floresta Nacional de Ipanema, 20 km NW Sorocaba (L. P. Costa et al. 2007), Riacho Grande (L. P. Costa et al. 2007), São Luís do Paraitinga (Pavan and Leite 2011), Mulheres (Pavan and Leite 2011). **PARAGUAY:** Alto Paraná, Refugio Biológico Limoy, north of Río Limoy (de la Sancha et al. 2009).

SUBSPECIES: *Juliomys pictipes* is monotypic.

NATURAL HISTORY: This is a primarily arboreal rodent that typically inhabits the lower to middle strata in mature and secondary Atlantic rainforest (E. M. Vieira and Monteiro-Filho 2003; Pardini and Umetsu 2006). Three of four Argentinean specimens were captured on the ground near watercourses in areas of dense underbrush of bamboos (Pardiñas, Teta et al. 2008). One individual in Paraguay was trapped with a Sherman live-trap 1.5 m above the ground in primary forest with ferns and low lianas (de la Sancha et al. 2009). Pine (1980) reported young animals caught by hand in nests situated in bamboo and on a bro-

meliad branch, 5–8 m above the ground. This rodent has been more frequently caught with pitfall traps than with Sherman traps, in forested areas of southeastern Brazil (Pardini and Umetsu 2006; Umetsu et al. 2006). Diets of wild-caught individuals include fruit pulp and small seeds (<10 mm diameter; E. M. Vieira and Monteiro-Filho 2003). One pregnant female was caught in December in Paraguay (de la Sancha et al. 2009) and another in August in Argentina (Pardiñas, Teta et al. 2008); both contained three embryos. Ectoparasites found on specimens from Brazil include the mites *Androlaelaps fahrenheitsi*, *Eubrachylaelaps rotundus*, *Gigantolaelaps gilmorei*, *G. oudemansi*, *G. wolffsohni*, *Laelaps castroi*, *L. navasi*, *L. paulistanensis*, *L. thori*, *Mysolaelaps parvispinosus*, the tick *Ixodes lorica-tus*, and the fleas *Craneopsylla minerva*, *Polygenis (Neopolygenis) atopus*, *P. (N.) pradoi*, and *P. (P.) roberti* (Nieri-Bastos et al. 2004).

REMARKS: Massoia, Chebez, and Heinonen Fortabat (1991b) regarded “*Thomasomys pictipes*” as a synonym of *Oligoryzomys flavescens antoniae* Massoia, which was clearly in error. The observed molecular differentiation among the mtDNA cytochrome-*b* haplotypes of Argentinian, Brazilian, and Paraguayan specimens of *J. pictipes* is moderate, ranging from 0.13% to 2.3%. The pattern of divergence does not conform to an isolation-by-distance pattern, so the variation is not a simple function of geography (Pardiñas, Teta et al. 2008; de la Sancha et al. 2009). The karyotype of *J. pictipes* is $2n = 36$, FN = 34, based on speci-

mens from Fazenda Intervalles, São Paulo, Brazil (Bonvicino and Otazu 1999).

Juliomys rimofrons J. A. Oliveira and Bonvicino, 2002

Montane Red-rumped Tree Mouse

SYNONYM:

Juliomys rimofrons J. A. Oliveira and Bonvicino, 2002:310; type locality “Brejo da Lapa (22°21’S, 44°44’W, altitude approx. 2000 m), situated to the east of Pedra Furada (2589 m) in the Serra da Mantiqueira, municipality of Itamonte, state of Minas Gerais, Brazil.”

DESCRIPTION: Size intermediate among three species, with head and body length 85–93 mm, tail length 99–121 mm; fur long and soft, brownish ochraceous above, dark orangish on rump, pale brown on venter, but with slaty hair base often apparent; dark eye-ring present; hairs on neck and chin whitish with gray bases, and those around mouth totally white; tail bicolored, dark above and whitish below, with distinct longitudinal line of blackish hairs extending midventrally and entire ventral surface becoming darker toward tip, terminating in an inconspicuous pencil of dark and whitish hairs; tail also rather hirsute, covered with dark hairs up to three scales in length. Skull delicate, with a short rostrum (30–34% of occipitonasal length); braincase round and inflated; interorbital region narrow, with gently squared or angled but not ridged supraorbital edges; narrow zygomatic plates, with anterior margins straight; zygomatic notches shallow; incisive foramina long, reaching anterior part of M1s; squamosal-alisphenoid groove present; tympanic bullae larger than in other species, but not obstructing view of periotic in basicranial aspect; single pair of posterolateral palatal pits; sphenopalatine vacuities large to very large; condyloid process of mandible long; ectolophid/ectostylid of m1–m2 reduced. Persistent fontanelle along middle third of frontal suture (basis for specific epithet) present in all known specimens, and in six *J. ossitenuis* from one locality, but absent from *J. pictipes* (J. A. Oliveira and Bonvicino 2002; L. P. Costa et al. 2007).

DISTRIBUTION: This species is known from the type locality in Minas Gerais state and two closely adjacent localities to the immediate south in São Paulo and Rio de Janeiro states, Brazil.

SELECTED LOCALITIES (Map 39): BRAZIL: Minas Gerais, Itamonte, Brejo da Lapa (type locality of *Juliomys rimofrons* J. A. Oliveira and Bonvicino); Rio de Janeiro, Paraty (R. Fonseca et al. 2013); São Paulo, São José do Barreiro (R. Fonseca et al. 2013).

SUBSPECIES: *Juliomys rimofrons* is monotypic.

NATURAL HISTORY: Little is known about the ecology or other aspects of the natural history of this species. All known specimens were collected on the ground, in a trapline extending for nearly 100 m through vegetation varying

Map 38 Selected localities for *Juliomys pictipes* (●).

Map 39 Selected localities for *Juliomys rimofrons* (●).

from *Araucaria* forest to patches of grasses and bromeliads (J. A. Oliveira and Bonvicino 2002).

REMARKS: The karyotype of *J. rimofrons* has a reduced diploid number ($2n=20$) relative to specimens of *J. pictipes* ($2n=34$). However, the same number of autosomal arms ($FN=34$) in these two species suggests Robertsonian changes as the mechanism of generating karyotypic divergence (J. A. Oliveira and Bonvicino 2002).

Genus *Neomicroxus* Alvarado-Serrano and D'Elía, 2013

Diego F. Alvarado-Serrano and Guillermo D'Elía

Neomicroxus is a recently established genus for two species, *bogotensis* (Thomas) and *latebricola* (Anthony), both previously placed within *Akodon* although their distinctiveness had been recognized for many years (Reig 1987; J. Ventura et al. 2000; Voss 2003). The genus, which is currently of uncertain position in the sigmodontine radiation, is restricted to the northern Andes, from central Ecuador north to the Cordillera de Mérida of Venezuela.

The taxonomic history of species allocated to *Neomicroxus* has been unstable. Thomas (1895c) described *bogotensis* under *Akodon*, but he later grouped it together with *Akodon mimus* under a “small *Akodon*-like *Oxymycteri* group” (Thomas 1901b:183). Thomas (1909) subsequently formalized this association when he erected *Microxus* (currently a synonym of *Akodon*), placing *bo-*

gotensis in his new genus because it and *mimus* (the type species of *Microxus*) share uniquely narrow and posteriorly slanting zygomatic plates (see also Thomas 1920h). Later, Anthony (1924b) described *latebricola*, also under *Microxus*, based on its strong resemblance to *bogotensis*, although he did not compare it to *mimus*.

The validity of *Microxus* either as a genus or subgenus of *Akodon* has been debated. Gyldenstolpe (1932a) maintained *Microxus* as a distinct genus, placing both *bogotensis* and *latebricola* within it. Tate (1932h) also maintained *Microxus* as a genus but suggested that it was part of an *Akodon* complex and that *bogotensis* was undoubtedly an akodont. Furthermore, Tate (1932h:27) stated that the slope of the zygomatic plates, the principal character used to group species under *Microxus*, was “less important than it appeared to be a first light.” Following Tate’s (1932h) suggestion, Cabrera (1961), Hooper and Musser (1964), and Hinojosa et al. (1987) placed *Microxus* as a subgenus in *Akodon*; alternatively, Hershkovitz (1966a) placed it in *Abrothrix*. Reig (1987) revalidated *Microxus* as a genus, but his view was restricted to *bogotensis* and not *mimus*, the type species (Patton et al. 1989). Phylogenetic analyses of allozymes (Patton et al. 1989) and both mtDNA (M. F. Smith and Patton 1999) and nucDNA sequences (D’Elía 2003a) have consistently shown that *mimus* falls in *Akodon*, and as a result *Microxus* is currently regarded as a simple subjective synonym of *Akodon* (see that account). Furthermore, the several species that have been historically associated with *Microxus* by various authors are now allocated to other genera, including *Akodon* (*affinis*, *mimus*, and *torques*; D’Elía 2003a; M. F. Smith and Patton 2007), *Brucepattersonius* (*iheringi*; Hershkovitz 1998), and *Abrothrix* (*lanosa*; Feijoo et al. 2010). Until very recently, however, the position of both *bogotensis* and *latebricola* had remained in limbo. Alvarado-Serrano and D’Elía (2013) have now documented the uniqueness of this pair of taxa as well as their distinction from *mimus* and all other *Akodon* species, based on combined morphological, morphometric, and molecular analyses. These authors erected *Neomicroxus* to encompass *bogotensis* and *latebricola*, selecting the later as the type of their new genus.

Both species of *Neomicroxus* are small, delicate mice (total length about 90–100 mm), with a highly similar bauplan and that share a soft dorsal pelage, grizzled to dark chestnut or blackish brown in color, with a slightly paler venter without countershading. The pinnae are dark and project beyond the fur of the head but do not reach the eyes when laid forward. Mystacial vibrissae are proportionally short and do not reach the pinnae when laid back. The overall coloration of the pes, manus, and tail is dark brown. The plantar surfaces of the hindfeet are smooth and have six pads, with the hypothecar separated from the thenar by a distinct gap.

The skull is delicate, with an inflated braincase and a proportionally long, tapering rostrum. Zygomatic notches are indistinct. The interorbital region is hourglass in shape, with smoothly rounded supraorbital edges. The zygomatic arches are parallel and have a distinct jugal that separates the maxillary and squamosal zygomatic processes in lateral view. The zygomatic plates are narrow and slanted posteriorly from their bases, surrounding a wedge-shaped infraorbital foramen; the anterior root of the zygoma forms a very low anterorbital bridge. The anterior margin of the superficial masseter is evident in both species (as a scar in the skull of *latebricola* and as an indistinct tubercle in *bogotensis*). The nasals extend posteriorly past the suture between the frontals, lacrimals, and maxillaries. The incisive foramina are relatively short, extending posteriorly just to the anterior margins of the M1s. The palate is long, with very shallow palatal troughs and reduced or no posterolateral pits. The anterior border of the mesopterygoid fossa is broad, U-shaped, and does not reach the plane formed by the posterior margins of the M3s; the roof of the fossa is perforated by sphenopalatine vacuities. An alisphenoid strut is absent. The carotid circulation pattern (type 1; Voss 1988) consists of a prominent trough for the masticatory-buccinator nerve, a large stapedia foramen, a posterior opening of the alisphenoid canal present but not enlarged, and a prominent anteroposterior squamoso-alisphenoid groove. The subsquamosal fenestra and postglenoid foramen are open, with a significant dorsoventral overlap in *latebricola* but not in *bogotensis*. Auditory bullae are inflated, the stapedia process is conspicuous, and the mastoid fenestra is usually present. The mandible is well developed, with falciform coronoid processes that are subequal in height to the mandibular condyles.

The upper incisors are nearly orthodont, ungrooved on their anterior faces, and with a straight dentine fissure. The molars are hypsodont (more so in *latebricola*); their main cusps are opposite, rounded, and subequal in size. M1s have a well-developed anteromedial flexus that divides the procingulum into anterolabial and anterolingual conules of similar size. An anteroloph (more developed in *bogotensis*) is evident only in barely worn teeth. Both M1 and M2 lack a mesostyle and enterostyle; a mesoloph is visible in *bogotensis* but inconspicuous in *latebricola*; a posteroloph is also present, with a well-developed posteroflexus. M3 is reduced and cylindrical in occlusal, with a rounded interior island of enamel. An anteromedian flexid is present on m1, but only in little worn teeth; no anterolabial cingulum is evident. A mesolophid is visible in m1 and m2 of *bogotensis* but is inconspicuous in *latebricola*; a posterolophid is present in both species. A mesostylid is absent in all lower molars.

Male reproductive accessory glands include a single pair of ventral prostates (for *bogotensis*), which contrasts with

the double condition found in many akodontines (Voss and Linzey 1981).

Neomicroxus is endemic to the northern Andes, ranging from central Ecuador through the Colombian Andes to the Cordillera de Mérida in western Venezuela, at elevations above 2,400 m and reaching as high as 3,900 m.

Knowledge of the conservation status of *Neomicroxus* is limited. Currently, *bogotensis* is listed as a species of least concern (Gómez-Laverde and Rivas 2008), and *latebricola* (represented by its holotype until recently [Voss 2003]) is listed as vulnerable (Boada, Gómez-Laverde, and Anderson 2008). However, trapping efforts targeting *latebricola* suggest that the species is more common than previously thought (D. F. Alvarado-Serrano, unpubl. data).

SYNONYMS:

Acodon: Thomas, 1895c:369; part (description of *bogotensis*); not *Akodon* Meyen.

Microxus: Thomas, 1909:237; part (listing of *bogotensis*); but not *Microxus* Thomas.

Neomicroxus Alvarado-Serrano and D'Elía, 2013:1008; type species *Microxus latebricola* Anthony, by original designation.

REMARKS: Although the generic allocation of *bogotensis* and *latebricola* relative to *Akodon*, especially to *A. mimus*, were questioned previously (Patton et al. 1989; Voss 2003), no author had doubted their position in the Akodontini. However, the molecular analyses of Alvarado-Serrano and D'Elía (2013), which included samples of *latebricola*, unambiguously placed this species outside of the Akodontini and underscored *Neomicroxus* as an unexpectedly non-akodontine genus substantially convergent on an akodont morphology, a situation similar to that of *Abrothrix* (tribe Abrothrichini; see that account). Pending future phylogenetic resolution, we place *Neomicroxus* as *incertae sedis* in the Oryzomyalia (*sensu* Steppan, Adkins, and Anderson 2004), as it does not appear closely related to any other lineage.

KEY TO THE SPECIES OF *NEOMICROXUS*:

1. Origin of superficial masseter from indistinct tubercle; visible mesoloph; inflated frontal sinuses
 *Neomicroxus bogotensis*
- 1'. Origin of superficial masseter from scar; indistinguishable mesoloph; flatter frontal sinuses
 *Neomicroxus latebricola*

Neomicroxus bogotensis (Thomas, 1895)

Bogotá Grass Mouse, Bogotá Akodont

SYNONYMS:

Acodon bogotensis Thomas 1895c:369; type locality: "Plains of Bogota," Cundinamarca, Colombia.

[*Akodon* (*Akodon*)] *bogotensis*: E.-L. Trouessart, 1897: 537; name combination.

M[icroxus]. bogotensis: Thomas, 1909:237; name combination.

N[eomicroxus]. bogotensis: Alvarado-Serrano and D'Elía, 2013:1008; first use of current name combination.

DESCRIPTION: Small, head and body length 78–90 mm, tail length 62–75 mm, ear length 13–20 mm, hind-foot length (without claw) 19–21 mm, greatest skull length 21.1–24.1 mm, and upper molar series length 3.4–3.8 mm. Dorsal fur grizzled to blackish brown, slightly more grayish underneath. Forefeet and hindfeet dark brown above, with short, grayish ungual tufts not surpassing claws. Tail short, about 60–70% of head and body, and indistinctly bicolored (dark above, paler below by presence of brownish and silvery hairs). Mystacial vibrissae short, not extending beyond pinna when laid back. Skull delicate, with inflated braincase and long, tapering rostrum; interorbital region broad (about width of rostrum across nasolacrimal capsules), with narrowest point located midback; supraorbital edges smooth; zygomatic notches very shallow; masseteric tubercles indistinct; incisive foramina short and proportionately wide, extending posteriorly to anterior margins of M1s; mesopterygoid fossa broad, its roof with large sphenopalatine vacuities; auditory bullae inflated with short bony tubes. Details of teeth as for genus.

Map 40 Selected localities for *Neomicroxus bogotensis* (●). Contour line = 2,000 m.

DISTRIBUTION: This species is endemic to the northern Andes, in the Cordillera Oriental of Colombia and Cordillera de Mérida and Páramo de Tamá in Venezuela. Soriano et al. (1999) listed this species for Trujillo state, Venezuela, but without documentation. No fossils are known.

SELECTED LOCALITIES (Map 40): COLOMBIA: Cundinamarca, Choachí (AMNH 61567), El Verjón (AMNH 62754). VENEZUELA: Mérida, Mucubají (M. A. Barros and Reig 1979), 8 km SE of Tabay, near La Coromoto (USNM 374614); Táchira, Buena Vista, 41 km SW of San Cristobal, near Páramo de Tamá (USNM 442345).

SUBSPECIES: *Neomicroxus bogotensis* is monotypic.

NATURAL HISTORY: This species is apparently rare, omnivorous, and nocturnal, inhabiting high-elevation evergreen montane forests and shrubby upland meadows. It is most commonly found in *Polylepis* forests or *Espeletia* stands, and is often associated with moss-covered rocks (O. J. Linares 1998; J. Ventura et al. 2000).

REMARKS: M. A. Barros and Reig (1979) described a karyotype from specimens collected at Mucubají, Mérida state, Venezuela, with $2n = 35-37$ and $FN = 48$.

Neomicroxus latebricola (Anthony, 1924)
Ecuadorean Grass Mouse, Ecuadorean Akodont

SYNONYMS:

Microxus latebricola Anthony 1924b:3; type locality “Hacienda San Francisco, east of Ambato, on Rio Cutatagua, elevation about 8000 feet, Ecuador.”

Akodon latebricola: Musser and Carleton, 1993:690; name combination.

N[eomicroxus]. latebricola: Alvarado-Serrano and D'Elía, 2013:1008; first use of current name combination.

DESCRIPTION: Small, with head and body length 74–103 mm, tail length from 63–98 mm, hindfoot length (without claw) 19–23 mm, ear length 14–17 mm, greatest skull length 22.88–25.63 mm, and upper molar series length 3.32–3.74 mm. Dorsal pelage grizzled dark chestnut brown, somewhat paler underneath, and without visible lateral line separating dorsal and ventral color; dorsal surfaces of both fore- and hindfeet dark brown, covered by gray hairs, and with relatively reduced light gray ungual tufts covering, but not surpassing, claws. Tail about same length as head and body, slightly bicolored, and covered with dark hairs above and silvery hairs below. Vibrissae short, not extending beyond pinna when laid back. Skull delicate with long, thin, tapering rostrum and inflated braincase; interorbital region hourglass in shape, about same width as rostrum at nasolacrimal level, with smooth supraorbital edges; origin of superficial masseter from scar on anterior margin of zygomatic plates; zygomatic notches absent to barely perceptible; alisphenoid struts absent; incisive foramina short and proportionately wide, barely extending posteriorly to anterior

Map 41 Selected localities for *Neomicroxus latebricola* (●). Contour line=2,000 m.

margins of M1s; auditory bullae inflated; masseteric tubercles of mandible indistinct. See generic description for molar details.

DISTRIBUTION: This species is endemic to high elevations of the eastern Andes in Ecuador, from Tungurahua province in the middle of the country (C. Boada, pers. comm.) to Carchi province near the frontier with Colombia. It is not known from the fossil record.

SELECTED LOCALITIES (Map 41): ECUADOR: Carchi, La Buitrera ravine, Reserva Ecológica el Ángel (EPN 9803), ravine near “Potrerillos,” Ipuerán (EPN 9641); Napo, 10.6 km (by road) W of Papallacta (UMMZ 155616); Tungurahua, 2 km SW of Laguna Pisayambo, Pisayambo, Parque Nacional Llanganates (MECN 1739).

SUBSPECIES: *Neomicroxus latebricola* is monotypic.

NATURAL HISTORY: Few data are available on the ecology of this species. It is known only from high Andean environments, including subalpine forests and páramo above 3,000 m. The reproductive biology and other aspects of the behavior or population attributes remain unknown beyond the fact that it is not strictly nocturnal (Voss 2003).

REMARKS: The karyotype of *N. latebricola* is unknown.

Genus *Neotomys* Thomas, 1894

Pablo E. Ortiz and Jorge Pablo Jayat

Neotomys is one of the more distinctive genera of sigmodontine rodents and is restricted to the Central Andes. The single species of *Neotomys* is commonly known as the

Andean swamp mouse (M. M. Díaz and Barquez 2007), “ratón de hocico rojo” (D’Elía et al. 2006), or Red-nosed *Neotomys* (Musser and Carleton 2005), with the latter two names derived from its distinctly rufous muzzle. The genus ranges from about 10°S in central Peru southward throughout most of southern and western Bolivia and northernmost Chile to northwestern Argentina at about 29°S (S. Anderson 1997; Pardiñas and Ortiz 2001; Jayat, Ortiz, and Miotti 2008). Individuals occur in high-elevation grasslands of the Puna environment above 2,700 m elevation as well as in humid grasslands below that elevation and below the limits of the Puna in the southern part of its range. Because *Neotomys* is known from only a few specimens and localities, much remains to be understood about its distribution, natural history, and patterns of geographic variation.

The following account is abstracted mainly from Thomas (1894b), Sanborn (1947a), Pine et al. (1979), Steppan (1995), S. Anderson (1997), and Pardiñas and Ortiz (2001). These sources should be consulted for additional details concerning taxonomy, morphology, distribution, fossil record, and ecology.

Externally, *Neotomys* is characterized by its medium size (total length 176–225 mm), a tail shorter than the body (tail length 72–88 mm), small hindfeet with the plantar surface entirely naked (hindfoot length 22–26 mm), and moderate-sized ears nearly circular in outline (ear length 18–19 mm). The dorsal pelage is dense, soft, long, and colored grizzled grayish brown; long gray hairs with white tips project above the dorsum. A rufous muzzle contrasts with the duller face and head coloration. The venter is grayish white to gray and the tail is bicolored, brownish gray on the dorsum and whitish on the lower surface; an ochraceous patch is present at the tail base. The upper surfaces of both forefeet and hindfeet are white, with a tinge of cinnamon, and the ears are brownish.

The skull is distinctively short and robust, with the nasals greatly expanded anteriorly. The interorbital region is very narrow, narrower than the muzzle, hourglass in shape, and angled in cross-section but not overhanging. The frontals are typically not completely fused along the midline, and a small fontanelle is often present. The zygomatic plates have a pronounced concavity at their anterior margins and prominent spinous anterodorsal processes. Premaxillaries end well anterior of the upper incisive plane. The premaxillomaxillary suture has an acutely angled bend in the middle of the rostrum (Steppan 1995; Pardiñas 1997; Steppan and Pardiñas 1998). The incisive foramina are short and wide, not reaching the anterior plane of M1. The posterior part of the palate has two deep excavations between M2 and M3, and is divided by a posterior palatine ridge. The mesopterygoid fossa reaches the posterior plane of M3 and the parapterygoid fossae are deeply excavated above the level of the bony palate.

The mandible is very deep and robust with an indistinct capsular projection. The coronoid process is small and does not extend to the level of the mandibular condyle. The mandibular ramus has a distinct ventromedial process at the posterior terminus of the symphysis (Steppan 1995).

The upper incisors are extremely broad, and have a smooth anterior surface with a groove on their labial margin. The lower incisors are robust; their anterior surface is broad and flat. The molars are hypsodont and strongly laminated, with numerous roots and planar occlusal crowns. The primary cusps are alternate. M3 is very large, much larger than M2. In young specimens, the procingulum of m1 is slightly separated from the rest of the molar by fusion of the meta- and protoflexids. An anteromedian flexid may also be visible in young individuals. This flexid dissects the procingulum on the lingual side but disappears with very little wear as individuals age (Pardiñas and Ortiz 2001).

SYNONYM:

Neotomys Thomas, 1894b:346; type species *Neotomys ebriosus* Thomas, by monotypy.

REMARKS: The tribal position of *Neotomys* has been strongly debated. Sanborn (1947a) pointed out several similarities between *Neotomys*, *Reithrodon*, and *Euneomys*. Hershkovitz (1955b), on the basis of molar occlusal morphology and palate pattern, placed *Neotomys* and *Reithrodon* together with *Sigmodon* and *Holochilus* in his “Sigmodont” group. However, Reig (1986) considered *Neotomys* to be a transitional form between the Sigmodontini and the Phyllotini. Subsequent research, including phylogenetic analyses of morphological data, placed *Neotomys* in the Phyllotini as part of a restricted generic group (the *Reithrodon* group) together with *Reithrodon*, *Euneomys*, and a few extinct genera (Olds and Anderson 1990; Steppan 1995; Steppan and Pardiñas 1998; P. E. Ortiz, Pardiñas, and Steppan 2000). Currently considered Sigmodontinae *incertae sedis*, *Neotomys* has recently been linked in molecular sequence analyses as sister to *Euneomys*, another *incertae sedis* genus (Parada et al. 2013; Salazar-Bravo et al. 2013; Schenk et al. 2013); these and earlier molecular studies (M. F. Smith and Patton 1999; D’Elía 2003, see also Pardiñas et al. 2002) failed to support any connection between *Neotomys* and phyllotines.

Neotomys ebriosus Thomas, 1894

Andean Swamp Rat

SYNONYMS:

Neotomys ebriosus Thomas, 1894b:346; type locality “Valley of Vitoc, [Junín,] East Central Peru.”

Neotomys vulturinus Thomas, 1921k:612; type locality “Sierra de Zenta, 4500 m,” Jujuy, Argentina; corrected to Sierra de Tilcara (M. M. Díaz and Barquez 2007).

Neotomys ebriosus ebriosus: Sanborn, 1947a:52; name combination.

Neotomys ebriosus vulturinus: Sanborn, 1947a:54; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Neotomys ebriosus* is found in the central Andes from central and southern Peru (Ancash, Pasco, Junín, Cusco, and Puno regions) and south through the highlands of Bolivia (La Paz, Cochabamba, Potosí, and Tarija departments) to northernmost Chile (Tarapacá region) and northwestern Argentina (Jujuy, Salta, Catamarca, and San Juan provinces; Sanborn 1947a; Pine et al. 1979; Redford and Eisenberg 1992; Musser and Carleton 1993; S. Anderson 1997; M. M. Díaz et al. 2000; Pardiñas and Ortiz 2001; Jayat, Ortiz, and Miotti 2008). Although *N. ebriosus* has been treated historically as a mammal of the Altiplano, inhabiting elevations above 3,000 m (Pearson 1951), in the southern part of its range it occurs in places outside the limits of Puna and related highland systems down to elevations as low as 2,700 m.

P. E. Ortiz and Pardiñas (2001) and Pardiñas and Ortiz (2001) reported Pleistocene fossils from the province of Tucumán, Argentina, at 1,900 m elevation, where *N. ebriosus* is not known to be part of the Recent fauna. Remains of this species from several Holocene archaeological sites have also been reported in highlands of northwestern Argentina (P. E. Ortiz 2001; Pardiñas and Ortiz 2001; Teta and Ortiz 2002).

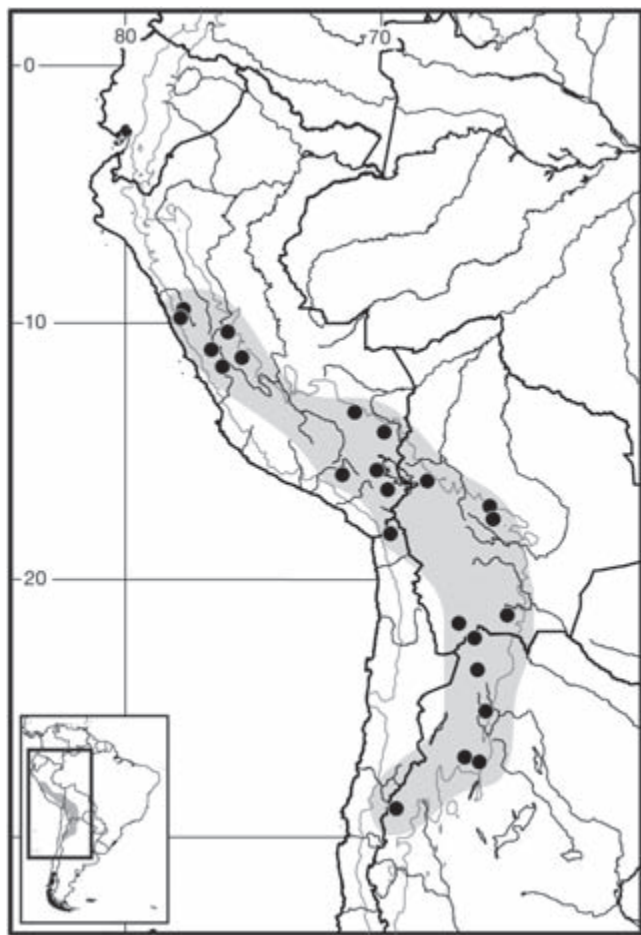

SELECTED LOCALITIES (Map 42): ARGENTINA: Catamarca, Alero Los Viscos, Barranca Larga (Pardiñas and Ortiz 2001), Sierra de Aconquija (Thomas 1926h); Jujuy, Sierra de Venta (= Sierra de Tilcara; type locality of *Neotomys vulturinus* Thomas), Yavi, near La Quiaca (Pardiñas and Ortiz 2001); Salta, Valle Encantado (P. E. Ortiz, Pardiñas, and Steppan 2000); San Juan, Vega Agua del Godo (Barquez 1983). BOLIVIA: Cochabamba, Incachaca (S. Anderson 1997), 7.5 mi SE of Rodeo (S. Anderson 1997); La Paz, Lago Viscachani (S. Anderson 1997); Potosí, Lipez (S. Anderson 1997); Tarija, Sama (S. Anderson 1997). CHILE: Arica y Parinacota, 1 km W of Putre (Pine et al. 1979). PERU: Ancash, 12 km W of Huaras (MVZ 150167), Ticapampa (Steppan 1995); Arequipa, 2 km W of Sumbay (MVZ 174043); Cusco, Ccolini, near Marcapata (Pine et al. 1979); Junín, Yauli Valley, Pomacocha (MVZ 138144), Vitoc Valley, Marainiyoc (Sanborn 1947a); Lima, 1 mi E of Casapalca (MVZ 120212); Pasco, Chiquirín (Sanborn 1947a); Puno, Abra Aricoma, 13 mi ENE of Crucero (MVZ 139590), Hacienda Collacachi (Sanborn 1947a), Hacienda Ontave (MVZ 141616).

SUBSPECIES: Both Sanborn (1947a) and Cabrera (1961) recognized two subspecies: *N. e. ebriosus*, occurring from Peru south to central Bolivia, and *N. e. vulturinus*,

from southern Bolivia and northern Argentina. A lack of suitable series of specimens from sufficient localities precludes our ability to evaluate this hypothesis.

NATURAL HISTORY: The limited knowledge of the natural history of *N. ebriosus* comes from Thomas (1921k, citing field observations of Emilio Budin), Sanborn (1947a), Pine et al. (1979), and Barquez (1983). Individuals are predominantly herbivorous and have been trapped most commonly in grasslands along streams with dense cover, among reeds on lake margins, and in marshes. The diel activity pattern may be either diurnal or nocturnal, with individuals at higher elevations more active during the warmth of the day and those at lower elevations more nocturnal. Individuals apparently avoid rocky areas, although they may shelter under isolated rocks on level ground. The species is not common at any recorded locality, and local populations are scattered and isolated.

REMARKS: The “Sierra de Zenta” given by Thomas (1921k) as the type locality of his *vulturinus* is actually the Sierra de Tilcara (see M. M. Díaz and Barquez 2007:423–424), some 50 km to the south (see also Pardiñas and Ortiz 2001).

Map 42 Selected localities for *Neotomys ebriosus* (●). Contour line = 2,000 m.

The karyotype is $2n=70$ and $FN=72$, with an autosomal complement of 68 acrocentric pairs ranging in size from large to small and sex chromosomes consisting of a large subtelocentric X and a small metacentric Y (Pearson and Patton 1976).

Genus *Phaenomys* Thomas, 1917

Alexandre R. Percequillo

The monotypic *Phaenomys* is among the rarest of the endemic genera of the Brazilian Atlantic Forest. Currently known from only a few specimens and localities, much remains to be known about its morphology, distribution, ecology, and consequently, phylogenetic relationships. Vaz (2000), Bonvicino, Oliveira et al. (2001), and Passamani et al. (2011) have provided important recent information about some of these matters.

Phaenomys is medium sized (head and body length 143–170 mm), with the tail longer than the head and body (tail length 187–199 mm), short and wide hindfeet (length 31–32 mm), and short and rounded ears (length 17–20 mm). The dorsal pelage is dense, lax, and long (wool hairs 9–10 mm; cover hairs 12–13 mm; guard hairs 14–16 mm). The dorsal color varies from rufous to rust-orange; the ventral color varies from nearly white to pure white, sometimes slightly washed with buff or rufous. The tail is uniformly colored dorsoventrally, gray to dark brown. The hindfeet have a distinctive yellowish to pale rust-colored patch in the medial metatarsal region; the proximal part of the hindfeet is rust, but the distal part and digits are white or dirty white. The ears are brownish, covered externally with short rusty hairs and internally with faded rusty hairs. The mystacial vibrissae are dense, thick, and long, extending backward beyond the ears. Females possess four pairs of mammae, one pair each in the thoracic, pectoral, abdominal, and inguinal positions.

The skull is distinctive, with a long and narrow rostrum and small nasolacrimal capsules flanked by very shallow and narrow zygomatic notches. The interorbital region is narrow, hourglass in shape, and may diverge slightly posteriorly. Its dorsolateral margins have a small but well-defined crest that extends dorsolaterally to the middle part of the braincase; the development of this crest is defined by a shallow depression along the frontal bones. The braincase itself is long and rounded. The interparietal is long and wide. The lambdoidal crest is weakly developed. The zygomatic arches are heavily built and divergent posteriorly, and zygomatic plates are narrow with straight anterior margins. An alisphenoid strut is absent. The incisive foramina are long and wide, occasionally reaching the plane of M1, and they occupy about 79% of the diastema; the paired foramina are widest medially. The palate is short

and narrow, with the rounded anterior margin of the mesopterygoid fossa reaching the paracone of M3; the posterolateral palatal pits are small and simple. The mesopterygoid fossa is wide; its roof is not completely ossified, as narrow and long sphenopalatine vacuities are present at the presphenoid-basisphenoid suture. The parapterygoid fossae are wide and flat, with small posterior openings for the alisphenoid channel. The carotid circulatory pattern is pattern 1 (*sensu* Voss 1988). The foramen lacerum medium is very narrow; the bullae are in contact with the squamosal along almost its entire length. The tegmen tympani overlaps the suspensory process of the squamosal, configuring a small postglenoid foramen. The hamular process of the squamosal is long and wide, resulting in a narrow or sometimes absent subsquamosal fenestra. The tympanic bullae are small, flask shaped, and have short bony tubes. The mandible has a strong falciform coronoid process that surpasses the condyloid process in height and defines a deep superior notch; the angular process is weakly projected posteriorly, extends to the level of the condyloid process, and forms a shallow inferior notch. A capsular process is absent.

The upper incisors are asulcate, strongly opisthodont, with a yellow anterior enamel band. The molars are pentalophodont, brachydont, and bunodont, with well-defined cusps arranged in opposite pairs. The main cusps are connected by a flexus(-id) and mure(-id). The molar toothrow is large and wide (M1–M3 length averages 6.36 mm, range: 6.05–6.55 mm; M1 breadth averages 1.85 mm, range: 1.8–1.95 mm). The procingulum of M1 is divided by a deep and well-defined anteromedian flexus; the labial anteroconule is larger and more mesially situated than the lingual one. The anteroloph, paraloph, mesoloph, metaloph, and posteroloph are quite visible in unworn M1 and M2. A distinct enamel island, the mesofossetus, is visible on M1 and M2. The M3 is smaller than M1 and M2, with the posterior cusps, flexi, and lophs coalesced. The anteroconid of m1 is divided by the anteromedian flexid.

Phaenomys ferrugineus (Thomas, 1917)

Rusty *Phaenomys*

SYNONYMS:

Oryzomys ferrugineus Thomas, 1894b:352; type locality “Rio Janeiro [= Rio de Janeiro],” Brazil.

[*Oryzomys* (*Oryzomys*)] *ferrugineus*: E.-L. Trouessart, 1904:419; name combination.

[*Thomasomys*] *ferrugineus*: Thomas, 1906c:443; name combination.

Phaenomys ferrugineus: Thomas, 1917d:196; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Phaenomys ferrugineus* is endemic to the Atlantic Forest of southeastern Brazil, unambiguously known from a few localities in Minas Gerais, Rio de Janeiro, and São Paulo states, and that range in elevation from about 900 to 1,600 m (see Remarks).

SELECTED LOCALITIES (Map 43): BRAZIL: Minas Gerais, Casa Alpina Hotel (Passamani et al. 2011); Rio de Janeiro, Rio de Janeiro (type locality of *Oryzomys ferrugineus* Thomas), Nova Friburgo, Córrego Grande, 26 km NE of Socavão (Vaz 2000; misspelled as Sacavão by Passamani et al. 2011), Socavão, near Teresópolis (Vaz 2000); São Paulo, Fazenda Califórnia, Serra do Bananal (MZUSP 6004).

SUBSPECIES: *Phaenomys ferrugineus* is monotypic.

NATURAL HISTORY: There is virtually no information on ecology, life history, or behavior for *P. ferrugineus*. Bonvicino, Oliveira et al. (2001) trapped one specimen on the ground in herbaceous vegetation in an agricultural area, part of which was pasture. Humid and dense forests, with abundant ferns and trees festooned with orchids and bromeliads, cover the unaltered areas where this species presumably occurs (Vaz 2000). In Minas Gerais, this species was captured in montane Atlantic Forest, at a site “with abundant leaf litter” and a “continuous and dense canopy formed by young trees” (Passamani et al. 2011:827). Based on the few known localities, *P. ferrugineus* occurs in the higher elevations (between about 900 [Socavão] and 1,550 m [Casa Alpina Hotel, Itamonte]) of the Serra do Mar, Serra do Bocaina, and Serra da Mantiqueira. If the record from the city of Rio de Janeiro were valid (see Remarks), the species would thus range from sea level to 1,550 m.

REMARKS: Thomas (1894b) originally described *P. ferrugineus* as a member of the genus *Oryzomys*, distinguishing his new species from other taxa described earlier, namely, *Mus vulpinus* Brants (= *Holochilus vulpinus*), *Mus leucogaster* Brandt (= *Trinomys* sp.), *Mus cinnamomeus* Pictet (= *Oecomys catherinae*), *Mus phytodes* (also = *Euryoryzomys russatus*), and *Mus vulpinus* Lund (= *Cerradomys subflavus*). In 1906, Thomas placed *ferrugineus* in the genus *Thomasomys* based on palatal morphology, especially extension of mesopterygoid fossa between the last molars and the absence of posterior palatal pits. Nevertheless, he noted

that *T. ferrugineus* and *T. dorsalis* [= *Delomys dorsalis*] were exceptional among the group of species he placed in *Thomasomys* in possessing “2–2 = 8 mammae” (1906:444). Finally, Thomas (1917d) erected a new genus to accommodate this intriguing species, an action accepted unequivocally by all subsequent authorities (Gyldenstolpe 1932; Ellerman 1941; Cabrera 1961; Musser and Carleton 1993, 2005). However, although the unanimous recognition of *P. ferrugineus* as a monotypic genus has brought nomenclatural stability, this stability has not clarified the phylogenetic position of this apparently unique taxon.

Phaenomys ferrugineus has never been included in any of the morphological phylogenetic analyses of sigmodontine relationships (e.g., Stepan 1995), probably due to the scarcity of specimens in collections. This lack of specimens has also prevented the inclusion of this species in molecular-based phylogenetic studies, which are being widely and wisely employed for phyletic assessment. At present, only 14 specimens are known in museums (CMUFL, MNRJ, MZUSP, BM, ZMB). Only skins were preserved for about half of these (Vaz 2000); when skulls were preserved, most are damaged (all BM specimens, including the holotype). Only recently, in 2001, more than a century after the original description by Thomas (1894b), have new specimens been reported, each providing important data on geographic distribution, morphology, and cytogenetics (Vaz 2000; Bonvicino, Oliveira et al. 2001; Passamani et al. 2011). Passamani et al. (2011) provided the first color photograph of a living animal as well as views of a complete skull and mandible.

The specimen from Itamonte, Minas Gerais state, represents an important extension to the distribution of *P. ferrugineus*; it is the first record of the species from the inland Serra da Mantiqueira, a complex of hills and high mountains (some reaching more than 2,000m) oriented parallel to the Serra do Mar, where most other known localities are found. The reported locality of *P. ferrugineus* in Bahia (see Thomas 1917d) and, especially, the purported type locality in Rio de Janeiro (Thomas 1894b) cannot be confidently regarded as valid records. The specimens bearing these provenances on skin tags (BM 63.11.16.2 and 76.12.8.3) were bought by the BM from dealers such as “Maison Verreaux, Magazin de Zoologie” in Paris. Therefore, the putative collecting localities of both specimens are problematic (Percequillo et al. 2004).

The karyotype consists of $2n=78$ and $FN=114$, with an autosomal complement of 19 biarmed and 19 acrocentric pairs that grade in size from large to small and sex chromosomes that include a large submetacentric X and small Y (Bonvicino, Oliveira et al. 2001).

Map 43 Selected localities for *Phaenomys ferrugineus* (●).

Genus *Punomys* Osgood, 1943

James L. Patton

Known only from seven localities in southern Peru (Pacheco and Patton 1995), *Punomys* has the highest elevational range of any species of mammals in the neotropics. This is a medium-sized, stoutly built, vole-like mouse with long and lax fur, a short tail, and relatively small ears. The soles of the hindfeet are hairy for the proximal one quarter of their length, the toes are of medium length, and the claws are uniformly small. Females have eight mammae, paired in pectoral, axillary, abdominal, and inguinal positions. The skull is rather heavy, with a broad and short rostrum, well-developed nasals expanded anteriorly, a squared braincase, a narrow interorbital region with rounded edges, and robust zygomatic arches. The incisive foramina are long and narrow; the palate is complex and dissected by two long and deep sulci; the mesopterygoid fossa extends nearly to the posterior margin of M3; and tympanic bullae are large and inflated. The carotid circulation is pattern 1 (of Voss 1988), characterized by an enlarged carotid canal and stapedia foramen, a squamosal-alisphenoid groove, sphenofrontal foramen, and a groove on the posterolateral margin of the parapterygoid plates. An alisphenoid strut is absent. The tegmen tympani is well developed and overlaps the squamosal, and the mastoid is large with a small to medium-sized fenestra.

The upper incisors are strong and orthodont. The molars combine coronal hypsodonty with high, sharp-angled individual cusps in the unworn condition; molar tooththrows diverge posteriorly. The occlusal surface of the molars is complex due to the presence of both labial and lingual styles, with the latter better developed. M1 is strongly curved with the procingulum divergent anteriorly, and with anterolabial and anterolingual conules of subequal size. Four main, distinct cusps are present on M3.

SYNONYM:

Punomys Osgood, 1943a:369; type species *Punomys lemminus* Osgood, by original designation.

REMARKS: *Punomys* is a poorly known and enigmatic taxon of incompletely understood phylogenetic and biogeographic affinities. Vorontsov (1959) placed the genus in the tribe Phyllotini, an action adhered to by Olds and Anderson (1990) and Braun (1993). Reig (1986) suggested that *Punomys* may represent an early descendant of a protophyllotine stock. Alternatively, Hershkovitz (1962) and Reig (1980, 1984) suggested that the genus be maintained as *incertae sedis* in the sigmodontines to emphasize its unique combination of morphological attributes. Steppan (1993, 1995), in a cladistic analysis of craniodental, postcranial skeletal, external, and soft organ characters, supported this latter position and removed *Punomys* from the Phyllotini. His analyses suggested that *Punomys* lies outside the phyllotines, near the base of a phyllotine-akodontine-scapteromyine radiation. Recent mtDNA and nucDNA sequence analyses, however, have supported a sister relationship between *Punomys* and *Andinomys*, in a larger clade that contained *Chinchillula*, *Euneomys*, *Juliomys*, *Irenomys*, and *Neotomys* (Parada et al. 2013; Salazar-Bravo et al. 2013; Schenk et al. 2013).

KEY TO THE SPECIES OF *PUNOMYS*:

1. Pelage of upper parts pale yellow-gray, strongly contrasting with that of under parts; tail <30% of head and body length. *Punomys lemminus*
- 1'. Pelage of upper parts overall darker, not contrasting in color with under parts; tail >30% of head and body length *Punomys kofordi*

Punomys kofordi Pacheco and Patton, 1995

Koford's Puna Mouse

SYNONYM:

Punomys kofordi Pacheco and Patton, 1995:86; type locality "13 mi (20.8 km) ENE Crucero, Lago Aricoma, Department of Puno, Perú, 15,000 ft (4,550 m), approximately 14°17'S, 69°47'W."

DESCRIPTION: Pelage similar to that of *P. lemminus*, but overall darker with under parts and not contrasting

with dorsum; tail short (range: 65–77 mm), but averaging 34% of total length rather than 27%; hindfoot absolutely shorter (mean 27.2 mm versus 28.7 mm). Skull distinguished by parallel as opposed to more anteriorly convergent zygomatic arches; squared anterior root of zygoma; narrower zygomatic plates with straight frontal edges as opposed to broad plates, and more posteriorly an upward slanting edge; spine of zygomatic notches angled laterally rather than directed anteriorly, particularly in ventral view; zygomatic notches broad rather than shallow; nasals not abruptly expanded anteriorly, terminating in deep, posterior V-shaped notch; palatal bridge short (mean 6.6 mm versus 7.4 mm); anterior opening of alisphenoid canal small; and postcingular conules of M1 subequal in size.

DISTRIBUTION: *Punomys kofordi* is known from only three localities in the vicinity of Abra Aricoma and the head of the Limbani Valley, all above 15,000 ft [4,500 m] in the Cordillera Carabaya (of the Cordillera Oriental) in southern Peru, and one locality at 4,770 m in eastern La Paz department, Bolivia.

SELECTED LOCALITIES (Map 44): BOLIVIA: La Paz, cumbre del camino a Yungas (Salazar-Bravo et al. 2011). PERU: Puno, Abra Aricoma, 13 mi ENE of Crucero, Lago Aricoma (type locality of *Punomys kofordi* Pacheco and Patton), 8 mi SSW of Limbani, 15,000 ft (Pacheco and Patton 1995).

SUBSPECIES: *Punomys kofordi* is monotypic.

Map 44 Selected localities for *Punomys kofordi* (●) and *Punomys lemminus* (○). Contour line = 2,000 m.

NATURAL HISTORY: This species is known only from the more humid eastern Cordillera bordering the Altiplano. Pregnant or lactating females were taken from June to September (field notes of C. B. Koford, MVZ archives), suggesting that reproduction is timed differently for *P. kofordi* than for *P. lemminus*. Litter size ranged from two to three (summarized by Pacheco and Patton 1995). Specimens from 8 mi SSW Limbani were captured “in barren, broken rock areas and . . . were near fleshy-leaved, pungent *Senecio* plants or piles of *Senecio* cuttings” (Pearson 1957:4). The recent specimen from Bolivia (Salazar-Bravo et al. 2011) was trapped at the entrance of a small, shallow cave fronted by the perennial shrub *Cajophora horrida* (Loasaceae).

REMARKS: Although very similar to and clearly closely related to *P. lemminus*, *P. kofordi* has most likely been geographically separated from its congener for much of the Pleistocene by the expanded glacier of the Quelccaya Ice Cap of the Cordillera Vilcanota, which lies at the northern nexus of the Cordillera Occidental and Cordillera Oriental.

Punomys lemminus Osgood, 1943

Western Puna Mouse

SYNONYM:

Punomys lemminus Osgood, 1943a:369; type locality “San Antonio de Esquilache, Department of Puno, Peru; altitude 15,000 feet.”

DESCRIPTION: As for genus. Differences between *P. lemminus* and *P. kofordi* noted under description of latter.

DISTRIBUTION: *Punomys lemminus* is known from only four widely scattered localities, all above 14,600 ft [4,400 m] in the Cordillera Occidental of southern Peru (see map, Pacheco and Patton 1995).

SELECTED LOCALITIES (Map 44): PERU: Arequipa, Huaylarco, 55 mi ENE of Arequipa (Pearson 1957); Puno, Caccachara (Pearson 1951), San Antonio de Esquilache (type locality of *Punomys lemminus* Osgood); Tacna, 12 mi NE of Tarata (Pearson 1957).

SUBSPECIES: *Punomys lemminus* is monotypic.

NATURAL HISTORY: Pearson (1951) noted that *P. lemminus* was neither scarce nor shy at Caccachara, where he observed it during the day feeding or scurrying from the shelter of one rock to another. Here, they fed mostly or entirely on a dwarf, fleshy-leaved tola shrub (*Senecio adenophylloides*) or a low, ground-pine-like herb (*Werneria digitata*) growing in most places. They cut twigs of both plants into lengths as great as 12 inches and stored them under rocks in caches of several dozen twigs. These materials were chewed only slightly when eaten so that stomach contents were a mass of coarsely chopped plant material, and feces were large and irregularly shaped pellets consisting of fragments of undigested

vegetation. The species was always encountered among rocks near yareta (*Azorella yarita*) and the other two food plants mentioned and near surface water. Other species of small mammals in the same local community included *Lagidium peruanum*, *Auliscomys boliviensis*, *Phyllotis xanthopygus*, *Chinchillula sahamae*, and *Abrothrix jelskii*.

Genus *Wilfredomys* Avila-Pires, 1960

Enrique M. González, João A. de Oliveira and Ulyses F. J. Pardiñas

Wilfredomys is a monotypic genus endemic to the southern portion of the Atlantic Forest in Brazil and the gallery and canyon forests of Uruguay (E. M. González and Oliveira 1997). The single species is medium-sized and long-tailed (head and body 110–115 mm; tail 170–220 mm; mass 50–75 g) with striking coloration, including ears covered by very short ochraceous hairs on both sides and a bright ochraceous-rufous area around the nose. The dorsal surface of the head and body is usually pale orange-brown lined with gray due to a mixture of light yellow to orange distal parts of the shorter hairs, and dark brown to black tips of the longer hairs, with gray bases of both types of hair. The rump of some specimens can attain an ochraceous-orange tone due to the prevalence of distally orange hairs. The venter lacks dark hairs and is thus lighter than the dorsum without a clear line of demarcation from it. The distal light-yellow portions of the ventral hairs often obscure their slaty basal halves. Hairs are whitish to their bases only in the throat and inguinal regions. Mixed whitish and ochraceous short hairs cover the upper surfaces of the manus and pes. The tail is very long, brown, slightly paler below, covered by very short ochraceous hairs, and terminates in a short pencil of hairs of 2–3 mm long. The mystacial vibrissae are dark and long, extending to the posterior limit of the pinnae when laid back beside the head. Plantar surfaces of the hindfeet have six tubercles, the thenar, hypothenar, and four interdigitals.

The skull has a relatively short rostrum, wide zygomatic arches, a shallow and narrow zygomatic notch, and a round braincase. The incisive foramina are very long and wide, reaching the anterior face of the protocone of M1, and the interorbital region is narrow, hourglass in shape, with squared (but not ridged) supraorbital margins, and a shallow depression along the frontal suture. Bullae are rather large. The palate is short, as the mesopterygoid fossa reaches to the last upper molar. Large posterolateral palatal pits are located along side the mesopterygoid fossa behind M3. The parapterygoid fossae are wider than the mesopterygoid fossa. An alisphenoid strut is lacking, and the carotid

circulation pattern is the generalized pattern 1 (*sensu* Voss 1988). Incisors are orthodont, and molars are moderately lophodont, the main cusps high and well defined. The anterocone bears a deep and obliquely oriented anteromedian flexus defining a lingual anteroconule much smaller than the labial one. An ectolophid is lacking. Mesolophs and mesostyles are well developed. Vaz Ferreira (1960), E. M. González (2000), and Pardiñas and Teta (2011a) have each illustrated several cranial and dental traits.

SYNONYMS:

Thomasomys: Thomas, 1928a:154; part (description of *oenax*); not *Thomasomys* Coues, 1884.

Wilfredomys Avila-Pires, 1960c:4; type species *Thomasomys oenax* Thomas, by original designation.

REMARKS: The name *Wilfredomys* was coined by Avila-Pires (1960c) in the course of clarifying the relationships of several taxa traditionally included in *Thomasomys*. Although ranked as a full genus in most recent treatises (e.g., Musser and Carleton 2005), in prior decades the name *Wilfredomys* was either not mentioned at all or treated as a subgenus (e.g., Pine 1980; Carleton and Musser 1984). The external similarity between *Wilfredomys* and *Wiedomys* often resulted in misidentifications (e.g., Ximénez 1965). These similarities were attributed to convergence by Pine (1980); however, Pacheco's (2003) character analysis added several traits of internal morphology to the known, shared features of the two genera.

Wilfredomys oenax (Thomas, 1928)

Red-nosed Tree Mouse

SYNONYMS:

Hesperomys pyrrhorhinus: Thomas, 1886a:421; part; not *Mus pyrrhorhinos* Wied Neuwied.

Thomasomys oenax Thomas, 1928a:154; type locality "Rio Grande do Sul. Type from San Lorenzo" (Thomas 1928a:155); São Lourenço do Sul, Rio Grande do Sul, Brazil (see Pine 1980:196).

Wilfredomys oenax: Avila-Pires, 1960c:4; first use of current name combination.

Wiedomys pyrrhorhinos: Ximénez, 1965:135; part; not *Mus pyrrhorhinos* Wied Neuwied.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Wilfredomys oenax* is known from a few scattered localities in the Atlantic Forest, in the Brazilian states of São Paulo, Santa Catarina, Paraná, and Rio Grande do Sul and in riparian forest of Uruguay, in the departments of Artigas, Cerro Largo, Durazno, Rivera, Tacuarembó, Treinta y Tres, and Florida (Bonvicino, Oliveira, and D'Andrea 2008; E. M. González and Martínez Lanfranco 2010). Hershkovitz (1998:201, citing K. Blair) reported an unconfirmed record for Caparaó National Park, Minas Gerais, Brasil, from nonvouchered owl pellet remains.

SELECTED LOCALITIES (Map 45): BRAZIL: Paraná: Curitiba (Avila-Pires 1960); Rio Grande do Sul, Itaquí (MZUSP 3181), Uruguaiana (MNRJ 2010); Rio Grande do Sul, São Lourenço do Sul (type locality of *Thomasomys oenax* Thomas); São Paulo, Ubatuba (E. M. González and Oliveira 1997). URUGUAY: Artigas, Rincón de Franquía (E. M. González and Oliveira 1997); Florida, Arteaga, Cerro Colorado (E. M. González and Martínez Lanfranco 2010); Rivera, Minas de Corrales (E. M. González and Martínez Lanfranco 2010); Treinta y Tres: Paso Ancho, Cañada de las Piedras and Rte 8 (E. M. González and Martínez Lanfranco 2010).

SUBSPECIES: We consider *Wilfredomys oenax* to be monotypic. Pine (1980), however, suggested the existence of two subspecies, and Vaz Ferreira (1960) highlighted differences between the type and one specimen from Uruguay. Examination of most of the known material reveals variability in some cranial and pelage features, of which the length of the nasals, the shape of the mesopterygoid fossa, and the extent of an ochraceous-orange tone on the dorsum are the most remarkable. Nevertheless, among the few specimens available in collections, specimens with various degrees of development of the conditions of these characters can be found. In addition, label information (e.g., sex, locality) is often lacking, hampering an evaluation of possible geographic trends as opposed to simple sexual dimorphism.

NATURAL HISTORY: The scarce field data available for this rare arboreal rat, mostly gathered in Uruguay, indicate that it occurs in gallery and montane forests with considerable epiphytic vegetation, particularly bromeliads (*Tillandsia* spp.). A specimen from Imboá, Uruguaiana (Rio Grande do Sul, Brazil), obtained by Emilie Snethlage was taken from a nest in the low forest bordering a river. In Uruguay, *W. oenax* was found nesting in the abandoned globular nests of the furnariid *Anumbius annumbi* on several occasions (R. Vaz Ferreira and F. Achaval, pers. comm.; E. M. González, unpubl. data; G. D'Elía, pers. comm.) and in nests made from *Tillandsia* (Cravino, pers. comm.; Prigioni and Sappa, pers. comm.). It is not clear whether the rats made the second type of nest or they were abandoned bird nests. Four specimens trapped by the American Museum of Natural History expedition to Uruguay in 1962–1963 were obtained in a canyon with mesic subtropical woodland and with a sampling effort of 4,400 trap-nights (Barlow 1969). One specimen (AMNH 206018) was trapped among large rocks in the forest on the north-facing slope of the canyon and was the only rat caught in a line of 50 traps. The remaining three specimens were trapped 20 m or less from the first, in branches from 1.5 to 2 m above the ground. Two of these specimens were males in breeding condition, with testes measuring 10 × 6 mm and that contained abundant mature sperm in the epididymides and the semi-

Map 45 Selected localities for *Wilfredomys oenax* (●). Contour line=2,000 m.

niferous tubules. Stomachs of three of the mice contained about 6 cc of greenish plant material, bait, and purplish berries from the *aruera* (*Lithraea molleoides* [Anacardiaceae]). Vaz Ferreira (1960) captured his specimen during the night while it was walking on a branch. This species has been found in Barn Owl (*Tyto alba*) pellets (Langguth 1965); a semidigested specimen was found in the gut of the Pampas Lancehead (*Bothrops pubescens*; E. M. González and Martínez Lanfranco 2010).

REMARKS: Pine (1980) detailed the history of the joint confusion of synonyms of *Wilfredomys oenax* and *Wiedomys pyrrhorhinos* (see also Hershkovitz 1959a:8).

Tribe Abrotrichini D'Elía, Pardiñas, Teta, and Patton, 2007
Guillermo D'Elía, Ulyses F. J. Pardiñas, and Pablo Teta

One of the most remarkable results of the DNA sequence-based phylogenetic analyses assessing sigmodontine relationships (M. F. Smith and Patton 1999; D'Elía 2003a) was the discovery of a clade formed by five taxa of generic rank (*Abrothrix* [including *Chroeomys*], *Chelemys*, *Geoxus*, *Notiomys*, and *Pearsonomy*) and that was independent of the Akodontini, the assemblage of sigmodontines among which these taxa had been traditionally placed (e.g., Ellerman 1941; Cabrera 1961; Reig 1987; Musser and Carleton 1993). This finding was particularly surprising because some of these taxa (e.g., the genus *Abrothrix* as well as forms currently allocated to it such as *andina*, *olivacea*,

and *xanthorbina*) had been placed in the genus *Akodon* (Musser and Carleton 1993). However, Hershkovitz (1966a) posited that *Abrothrix* (which, at that time was restricted to *A. longipilis* and closely related forms) was part an “oxymycterine” group that he erected, an assemblage of taxa, including the nominotypical genus *Oxymycterus*, now phylogenetically firmly embedded in the Akodontini (see that account). Massoia (1983) followed Hershkovitz's suggestion and gave the Oxymycterini tribal status.

In his classic review of the Akodontini, Reig (1987) provided morphological diagnoses for *Abrothrix* (as a subgenus of *Akodon*), *Chroeomys* (as a valid genus, but now considered a synonym of *Abrothrix*; D'Elía 2003a), *Chelemys*, *Geoxus*, and *Notiomys*, and included a discussion of chromosomal and ecological similarities of these taxa. His treatment of *Chelemys* and *Geoxus* as genera separate from *Notiomys* followed Pearson (1983, 1984).

The first indication that abrotrichines constituted a distinct group came from allozyme studies (Patton et al. 1989; Spotorno et al. 1990; Dickerman 1992; Barrantes et al. 1993) as well as from the initial mtDNA gene sequence analysis (M. F. Smith and Patton 1991). However, the limited taxonomic coverage of these studies precluded a clear picture of the phyletic relationships between abrotrichines and akodontines until the expanded sequence analysis by M. F. Smith and Patton (1999; see also M. F. Smith and Patton 1993). M. F. Smith and Patton (1993, 1999) listed some character states, including anatomical, chromosomal, and allozyme characters, along with distributional and ecological features, that supported the distinctiveness of the abrotrichine group. Furthermore, they recommended (M. F. Smith and Patton 1999:106–107) ranking this group of genera as a tribe, suggesting that an appropriate name for it would be Abrotrichini, although they referred to the group informally as “the Andean Clade” (see also M. F. Smith and Patton 1993:170). References to the group by subsequent authors used this informal name, the incorrect spelling Abrotrichini (e.g., Weksler 2003; Rodríguez-Serrano, Palma, and Hernández 2008), or the informal derivative “abrotrichines” (e.g., D'Elía 2003a). Further phylogenetic studies, which combined mtDNA and nucDNA sequences, corroborated the distinctiveness of the group in the radiation of Sigmodontinae (D'Elía 2003a; D'Elía et al. 2003; D'Elía, Luna et al. 2006; D'Elía, Ojeda et al. 2006). Given the body of molecular evidence, D'Elía et al. (2007) formally described the tribe Abrotrichini, provided a diagnosis based on morphological characters, and established its current contents. The Abrotrichini constitutes the most recently proposed sigmodontine tribe.

The phylogenetic position of Abrotrichini in the sigmodontine radiation remains unresolved. Molecular sequences place the tribe in *Oryzomyia* (see Stepan, Adkins, and

Anderson 2004), where the Abrotrichini appear either as sister to Wiedomyini (D'Elía, Luna et al. 2006; D'Elía, Ojeda et al. 2006; Parada et al. 2013; Salazar-Bravo et al. 2013) or in a broader clade containing the Phyllotini, Oryzomyini, and Wiedomyini (D'Elía 2003a). Reig (1986, 1987), who considered abrotrichines to be typical akodonts, also suggested, on morphological grounds, a phylogenetic relationship between the oryzomyines, akodontines, and phyllotines. The analyses of Parada et al. (2013) provided strong support for a phylogenetic linkage between the Abrotrichini and Wiedomyini.

M. F. Smith and Patton (1993, 1999), D'Elía (2003a), D'Elía, Ojeda et al. (2006), Rodríguez-Serrano, Palma, and Hernández (2008), Feijoo et al. (2010), Teta, D'Elía et al. (2011), and Cañón-Valenzuela (2012) have addressed phylogenetic relationships in the Abrotrichini with DNA sequences. Even without the few species of *Abrothrix* that have yet to be included in any study, results are robust in documenting two main clades in the tribe. One of these includes the terrestrial forms currently referred to *Abrothrix*, while the other encompasses the mainly fossorial, long-clawed genera *Chelemys*, *Geoxus*, *Notiomys*, and *Pearsonomys*. Relationships within both of these clades remain less resolved.

Continued molecular phylogenetic analyses suggest that adjustments of the current genus-group classification of Abrotrichini may be required because neither *Chelemys* nor *Geoxus* appear to be monophyletic (Rodríguez-Serrano, Palma, and Hernández 2008; E. P. Lessa et al. 2010). Alternative classificatory choices might include but are not limited to: erect a new genus for *Chelemys macronyx* and another for southern populations currently referred to as *Geoxus valdivianus*, or return to Osgood's (1925) view of *Notiomys (sensu lato)*, one that included both *Chelemys* and *Geoxus* (see Pearson 1984 for review). Given current knowledge, which is much more exhaustive than that available to Osgood (see, for example, Pardiñas, Udrizar Sauthier et al. 2008), a scheme that would unite into a single genus such morphologically divergent taxa as *Geoxus valdivianus* and *Notiomys edwardsii* is difficult to support.

Pending publication of a revision of Abrotrichini currently in progress (P. Teta, unpubl. data), we recognize the traditional five abrotrichine genera, with a total of 14 species. This assemblage is distributed from the Altiplano in west-central Peru south through the western mountains of Bolivia to southernmost Argentina and Chile (including Cape Horn and other islands), and the Patagonian steppes to the Atlantic coast of Argentina (Osgood 1943b; Teta, Pardiñas, and D'Elía 2006).

Abrotrichines are small to medium sized (from approximately 20 g in *Notiomys edwardsii* to 75 g in *Chelemys macronyx*) sigmodontine rodents, diagnosed by the following combination of characters (from D'Elía et al. 2007).

Pelage long and soft, generally slate gray or brownish, although some are blackish (*A. sanborni*, *Chelemys*, *Geoxus*) or with bright colors (*A. jelskii*); tail typically short and well haired; feet large and strongly built, with naked plantar surfaces; claws equally robust on forefeet and hindfeet (Gyldenstolpe 1932; Osgood 1943b); skull with long muzzle and rounded braincase, without frontal or lambdoid crests; interorbital region amphora-shaped; nasals and premaxillae slightly projected anterior to the incisors to somewhat trumpet-like; nasals longer than frontals; zygomatic plates typically narrow, with the upper free border reduced or absent; infraorbital foramina wide; frontal sinuses moderately developed; palate long; anterior border of mesopterygoid fossa squared; mandibular ramus generally gracile and elongate, except in *Chelemys* (Gyldenstolpe 1932; Osgood 1943b; Reig 1987).

Upper incisors broad and ungrooved; teeth brachydont to mesodont; upper and lower molars with labial and lingual cusps arranged in opposite or slightly alternate pairs; M1/m1 reduced, fan-shaped, procingulum and shallow or absent anteroflexus(-id); M1 with very shallow to obsolete anteromedian flexus; paraflexus and metaflexus strongly oriented backward to transversely oriented; paracone globose and oriented forward, mesoloph(id) poorly to moderately developed, usually fused to the paracone; M3 reduced and subcylindrical, except in *Chelemys*, with an internal ring-like enamel fossette (Gyldenstolpe 1932; Reig 1987; D'Elía, Ojeda et al. 2006).

The axial skeleton includes 13 ribs, 13 thoracic vertebrae, six lumbar vertebrae, and 18–29 caudal vertebrae (Steppan 1995). Both types of unilocular-hemiglandular stomachs described by Carleton (1973) are present in the Abrotrichini (Carleton 1973; D'Elía, Ojeda et al. 2006; Pardiñas, Udrizar Sauthier et al. 2008). Species of *Abrothrix* have elongated phalli with a much reduced or no distal baculum; the genera *Chelemys*, *Geoxus*, and *Pearsonomys* have a tridigitate distal baculum (the phallus of *Notiomys* is unknown); the phalli of *Pearsonomys* and *Geoxus* have a prominent dorsal hood that extends beyond the terminal crater (Hooper and Musser 1964; Spotorno 1986; D'Elía, Ojeda et al. 2006). *Abrothrix longipilis*, *A. jelskii*, *A. olivacea*, and *Geoxus valdivianus* have two pairs of preputial glands (Voss and Linzey 1981). The number of preputial glands in other genera is unknown.

The karyotype among the Abrotrichini is quite uniform. A diploid complement of 52 chromosomes is present in several species of *Abrothrix*, *Chelemys macronyx*, and *Geoxus valdivianus* (N. O. Bianchi et al. 1971; M. H. Gallardo 1982; Pearson 1984; Liascovich et al. 1989; Spotorno et al. 1990), prompting M. F. Smith and Patton (1999) to suggest that $2n=52$ was a synapomorphy for the tribe. Later studies have shown that *Pearsonomys* has $2n=56$ (D'Elía,

Ojeda et al. 2006), that typical *Chelemys macronyx* has $2n=54$ (A. A. Ojeda et al. 2005), and that some populations of *Abrothrix olivacea* from eastern Patagonia have $2n=44$ (V. A. Rodríguez and Theiler 2007). The karyotype of *Notiomys edwardsii* and other nominal forms remains unknown. Further studies are needed to assess the directions and modes of abrotrichine chromosomal evolution, including the ancestral condition for the tribe (i.e., whether the common ancestor had $2n=52$).

The earliest known fossils considered to be abrotrichines are *Abrothrix kermacki* Reig, 1978, and *A. magnus* Reig, 1987, both from the Pliocene of Argentina (Reig 1978, 1987). Pardiñas (1995b) tentatively questioned the generic allocation of *magnus*. Our most recent and unpublished assessment suggests that both taxa are more likely to belong to two different and as yet undescribed Akodontini genera. A third form, referred in the literature as aff. *Abrothrix* and from Pliocene deposits in Jujuy province of northwestern Argentina, represents an extinct, undescribed species of this genus (P. E. Ortiz, García López et al. 2012). No extinct genus has been assigned to the tribe Abrotrichini. The oldest fossils of living abrotrichines are known from the Lujanian and Platan South American Land Mammal Ages (Late Pleistocene–Early Holocene; Pardiñas et al. 2002). Molecular clock dating based on both mtDNA and nucDNA sequences has suggested that the abrotrichine crown group originated approximately 4.9 mya (3.66–6.33), with differentiation of the two main clades beginning about 3.5–4.0 mya (Parada et al. 2013). Rodríguez-Serrano, Palma, and Hernández (2008) found statistical support that the common ancestor of Abrotrichini was fossorial, which would necessitate that fossoriality was lost in the lineage leading to *Abrothrix*. This nonparsimonious directionality of character change presents us with an open question.

KEY TO THE GENERA OF ABROTRICHINI:

1. Tail proportionally long, $\geq 60\%$ of the combined head and body length; anterior claws < 3 mm *Abrothrix*
- 1'. Tail proportionally short, $\leq 60\%$ of the combined head and body length; anterior claws > 4 mm 2
2. Pinnae concealed in pelage; dorsal (agouti) and ventral (whitish) coloration sharply demarcated; sides of muzzle brightly colored with orange; rhinarium leathery *Notiomys*
- 2'. Pinnae protruding from pelage; dorsal and ventral coloration usually darker, but sometimes slightly differentiated, brown to blackish, paler on the venter; sides of the muzzle without orange color; rhinarium not leathery . . 3
3. Manual claws not flattened at tips; skull robust; toothrow long (> 4.5 mm); upper molars with well-developed anteroloph and mesoloph; zygomata heavy and widely flaring *Chelemys*
- 3'. Manual claws flattened at tips; skull more delicate; toothrow short (< 4.5 mm); upper molars lacking mesoloph; zygomata not widely flaring 4
4. Size small (greatest length of skull usually < 29 mm); ears short; pes short (< 24 mm); pelage smooth and dense *Geoxus*
- 4'. Size large (greatest length of skull usually > 30 mm); ears long; pes long (> 25 mm); pelage coarse . . . *Pearsonomys*

Genus *Abrothrix* Waterhouse, 1837

Bruce D. Patterson, Margaret F. Smith, and Pablo Teta

The genus *Abrothrix* comprises species of mice that have variously been allocated to *Mus*, *Hesperomys*, *Akodon*, *Oxymycterus*, *Microxus*, *Bolomys*, and *Chroeomys*. Its current contents stem from several DNA sequence analyses, beginning with M. F. Smith and Patton (1991) and followed sequentially by M. F. Smith and Patton (1993, 1999), D'Elía (2003a), Pearson and Smith (1999), M. F. Smith et al. (2001), and Teta, D'Elía, et al. (2011). Those species not yet included in any published molecular analysis are placed in *Abrothrix* by morphological and/or karyotypic characters (see, for example, Spotorno, Zuleta, and Cortes 1990; Spotorno 1992). The genus ranges from the Altiplano of southern Peru through the highlands of Bolivia, northern Chile, and Argentina south through Tierra del Fuego; its range reaches the Pacific at 30°S and the Atlantic at about 40°S , and includes numerous islands where an endemic species occurs.

Abrothrix was named for its long, soft fur, which fairly characterizes all members of the genus. Most species are colored slate gray, although the range includes blackish (*sanborni*) to brightly bicolored (*jelskii*). The tail is short and well haired; Osgood (1943b:195) noted that in at least some *Abrothrix* (i.e., *longipilis* and *sanborni*) the skin of the tail clings tightly to the caudal vertebrae, preventing the preparator from easily removing it without making ventral incisions on the tail. Feet are large and strongly built, with naked palms and soles, and claws equally strong on forefeet and hindfeet.

The skull has a relatively long rostrum and rounded braincase. The nasals and premaxillae usually project anterior to the incisors into a somewhat trumpet-shape, and are longer than the frontals. The zygomatic plates are relatively deep and short, sometimes slanting posteriorly upward; the incisive foramina reach the protocone of M1, and the palate extends well posterior to M3 (except in *A. illutea* and *A. jelskii*). The frontal sinuses are moderately inflated and the bullae are not enlarged (except in *A. jelskii*). The upper incisors are broad and ungrooved, and the molars above and below are broad, rooted, and with hypsodont crowns.

Abrothrix was originally diagnosed by the lack of an antero-medial sulcus on M1; although this characterizes the type species *A. longipilis*, other species now allocated to the genus have this trait (especially *olivacea*, *hershkovitzi*, and *andina*; see also Osgood 1943b:196). *Abrothrix* has a shallow anteroflexus, poorly developed mesoloph(-id), strong mesoflexid, and weaker posteroflexid oriented transversely, and entoconids bulging into the buccal cavity; m3 is elongate but smaller than m2 (see Gyldenstolpe 1932; Reig 1987).

A combination of these characters can be used to separate *Abrothrix* from other abrotrichine and akodontine rodents, but members of the genus can be recognized at a glance by their bacula and/or glandes penes. *Abrothrix longipilis* and *A. sanborni* have a simplified baculum that lacks the characteristic (and primitive) tridigitate distal elements of most other muroid lineages, including other sigmodontines (see Musser and Hooper 1964; Spotorno 1992). In contrast, other taxa here allocated to *Abrothrix* have bacula that retain the tridigitate arrangement, albeit greatly reduced so that the apical digits are scarcely visible, little more than vestigial remnants (M. H. Gallardo et al. 1988; Spotorno 1992; Feijoo et al. 2010).

Abrothrix longipilis and *A. jelskii* have two pairs of preputial glands (Voss and Linzey 1981). The ampullary glands of *A. longipilis* are especially large in relation to the male tract as a whole. Dorsal prostates are also unusually large, and are partly covered by extensive lateral prostatic tissue. Vesicular glands are lobed medially and along their greater curvatures, but in some individuals papilla-like processes rather than rounded lobes are found on the medial surfaces (Voss and Linzey 1981). In *A. jelskii*, the lateral preputial glands extend beyond the ventral flexure of the penis, and the vesicular glands are lobed medially and along their curvatures; the subterminal flexures are rough and irregular in appearance. The stomachs of *A. longipilis*, *A. jelskii*, and *A. olivacea* are unilocular-hemiglandular (Carleton 1973).

Axial skeletal elements have counts of 13 ribs, 13 thoracic vertebrae, six lumbar vertebrae, and 26–29 (*Abrothrix longipilis*), 23–26 (*A. jelskii*), 2–23 (*A. olivacea*, *A. andina*), or 24–27 (*A. sanborni*) caudal vertebrae (Steppan 1995).

Almost all species of *Abrothrix* that have been karyotyped to date (*andina*, *olivacea* [including *xanthorhina*], *lanosa*, *longipilis*, and *illutea*) share a diploid number of 52, and where details of individual chromosomes are available, an autosomal fundamental number of 56 (Spotorno and Fernandez 1976; M. H. Gallardo 1982; M. Rodríguez et al. 1983; B. D. Patterson et al. 1984; Liascovich et al. 1989; Espinosa et al. 1991). Recently, however, V. A. Rodríguez and Theiler (2007) described a $2n=44$ karyotype for 12 *A. olivacea* specimens from Comodoro Rivadavia, in coastal Chubut province, Argentina. The significance of this chromosomal difference is unclear.

The earliest fossils assigned to *Abrothrix* are those of *A. kermacki* from the Chapadmalal Formation, upper Pliocene–lowermost Pleistocene, near the present city of Mar del Plata, Buenos Aires province, Argentina (Reig 1987). *Abrothrix magna* is known from early Pleistocene (Vorohuean) deposits, also from near Mar del Plata (Reig 1987). These locality records are from almost 1,000 km east of the present distributional limits of the genus (Reig 1987). As noted above, however, Pardiñas (1995b) questioned the generic placement of *magna* and Teta et al. (2012), through inspection of their type series and additional materials, suggested that *kermacki* and *magna* probably belong to the Akodontini. P. E. Ortiz, García López et al. (2012) described other fossils, including some Pliocene remains referred as aff. *Abrothrix*, from sites in northwestern Argentina; these perhaps represent the earliest true Abrotrichini.

SYNONYMS:

Mus (Abrothrix) Waterhouse, 1837:21; type species *Mus (Abrothrix) longipilis* Waterhouse, by original designation.

Abrothrix: Gray, 1843b:xxiv, 114; first use as genus.

Habrothrix Wagner, 1843a:519; unjustified emendation of *Abrothrix* Waterhouse.

Acodon Thomas, 1895c:369; part (description of *hirtus*); incorrect subsequent spelling of *Akodon* Meyen.

Akodon: E.-L. Trouessart, 1897:535; part (listing of *longipilis*, *andinus*, *hirtus*, *xanthorhinus*, *brachyotis*, *olivaceus*, and *jelskii*); not *Akodon* Meyen, 1833.

Chroeomys Thomas, 1916i:340; type species *Akodon pulcherrimus* Thomas, by original designation.

Chraeomys Gyldenstolpe, 1932a:122; incorrect subsequent spelling of *Chroeomys* Thomas.

Microxus: Gyldenstolpe, 1932a:133; part (listing of *pulcherrimus*, *cayllomae*, *inambarii*, *cruceri*, *inornatus*, *bacchante*, *sodalis*, *scalops*, *jelskii*, *pyrrhotis*); not *Microxus* Thomas.

Bolomys: Tate, 1932h:23; part (listing of *andinus*, *jucundus*, *gossei*); not *Bolomys* Thomas.

REMARKS: We note that *Abrothrix* is based on a feminine Greek name (-*trichos*, hair), but *Akodon* is based on a masculine Greek name (-*odon*, tooth). As a consequence of taxonomic history, there has been chaotic variation in the genders of specific epithets as taxa have been transferred between these two genus-groups.

KEY TO THE SPECIES OF ABROTHRIX:

1. Coloration generally striking, often with fulvous on nose (sometimes also on feet and tail) and white postauricular patches, white (or grayish) venter contrasts with darker dorsum; palate ending at about back edges of last molars; incisors very slender and yellow; bullae enlarged *Abrothrix jelskii*

- 1'. Coloration not so striking, some forms with fulvous wash on nose and face; palate ending at about or at some distance behind back edges of last molars; incisors broader and darker; bullae not enlarged. 2
2. Length of tail usually >75 mm; condyloincisive length >27 mm. 3
- 2'. Length of tail usually <75 mm; condyloincisive length <27 mm. 4
3. Dorsal color uniform dark olive gray; ventral surface ashy gray, with small patches of white under chin and in inguinal area; nasals and premaxillae slightly projected anterior to incisors; nasofrontal sutures not forming acute angle, not reaching line connecting lacrimals; palate ending near back edge of last molars; cartilaginous distal baculum reduced, composed of two apical digits *Abrothrix illutea*
- 3'. Dorsal color ranges from gray to brown, sometimes washed with chestnut or reddish brown along back; venter silvery; nasals extend anteriorly into slight trumpet; nasofrontal sutures form acute angle, reaching line connecting lacrimals; palate ending some distance behind back edges of last molars; baculum long and sharply curved near tip, completely lacking apical digits. *Abrothrix longipilis*
4. Dorsal profile of the skull flat, convex; nasals and premaxillae strongly projected anterior to the incisors into a trumpet shape; baculum long and sharply curved near the tip, without apical digits 5
- 4'. Dorsal profile of the skull flat to slightly bowed; nasals and premaxillae not strongly projected anterior to the incisors; baculum consists proximally of a straight, blunt rod bearing three apical digits much reduced in size 6
5. Coloration uniformly blackish brown, including hairs of tail and feet, without indication of counter coloration; ears normal length; tail long (70–80% head and body length); nasofrontal sutures form acute angle, surpassing line connecting lacrimals; mandible slender, ramus hardly constricted behind m3; lunar notch shallow *Abrothrix sanborni*
- 5'. Dorsal coloration olivaceous, slightly demarcated from venter; dorsal surface of manus and pes covered by short buffy hairs; ears short; tail short (60% to 70% head and body length); nasofrontal suture acute, reaching line connecting lacrimals; mandible slender, with marked constriction of ramus below m3; lunar notch well excavated anteriorly. *Abrothrix lanosa*
6. Pelage long and dense; color pale, ochraceous; venter gray with strong buffy wash; small white postauricular spots; tail length 47–67 mm; hindfoot length 19–23 mm; ear length 13–16 mm *Abrothrix andina*
- 6'. Pelage shorter and sparser; color more saturate, ranging from dark brown or olive brown to ochraceous gray; some populations exhibit a wash of yellow or orange on nose, feet, and tail; length of tail 60–84 mm; length of hindfoot 22–25 mm; length of ear 15–18 mm. 7
7. Size large (adult mass >30g); tail about two-thirds length of head and body; condylobasal length >23.5 mm; maxillary diastema >6.5 mm. *Abrothrix herskovitzi*
- 7'. Size small (adult mass usually <30g); tail shorter than 65%; condylobasal length <23.5 mm; maxillary diastema <6.5 mm *Abrothrix olivacea*
- Abrothrix andina* (Philippi, 1858)
Andean Soft-haired Mouse

Bolomys gossei: Tate, 1932h:23; name combination.
Akodon [(Akodon)] gossei: Ellerman, 1941:411; name combination.
Akodon [(Akodon)] jucundus: Ellerman, 1941:411; name combination.
Akodon andinus andinus: Osgood, 1943b:177; name combination.
Akodon andinus dolichonyx: Osgood, 1943b:179; name combination.
Akodon andinus polius Osgood, 1944:196; type locality “Salinas, Arequipa, Peru. Altitude 14,000 feet.”

Akodon [(*Akodon*)] *andinus*: Honacki, Kinman, and Koppel, 1982:394; name combination.

“*Akodon*” *andinus*: Patton and Smith, 1992b:93; name combination.

Chroeomys andinus: S. Anderson, 1997:433; name combination.

Abrothrix andinus: Tamayo et al., 1987:5; first use of current name combination but incorrect gender agreement.

Chroeomys andinus dolichonyx: S. Anderson, 1997:434; name combination.

[*Abrothrix andinus*] *cinnamomea*: Musser and Carleton, 2005:1089; name combination and incorrect gender agreement.

[*Abrothrix andinus*] *dolichonyx*: Musser and Carleton, 2005:1089; name combination.

[*Abrothrix andinus*] *cinnamomea*: Musser and Carleton, 2005:1089; name combination and incorrect gender agreement.

[*Abrothrix andinus*] *gossei*: Musser and Carleton, 2005:1089; name combination.

[*Abrothrix andinus*] *jucundus*: Musser and Carleton, 2005:1089; name combination and incorrect gender agreement.

[*Abrothrix andinus*] *polius*: Musser and Carleton, 2005:1089; name combination and incorrect gender agreement.

DESCRIPTION: Smallest species (average head and body length 90 mm; average tail length 65 mm); pelage mainly light buffy and without countershading, with distinct whitish postauricular patches and whitish lips and chin. Skull delicate, with a short and narrow rostrum, rounded braincase, and moderately extended nasals and premaxillae; borders of the mesopterygoid fossa slightly divergent posteriorly; tympanic bullae relatively large and rounded (Osgood 1943b; Mann 1978). Baculum with minute, vestigial apical digits (Spotorno 1992).

DISTRIBUTION: High-elevation grasslands, generally between 2,000 and 3,000 m, from south-central Peru through western Bolivia to northwestern Argentina and northern Chile (to 34°S; Muñoz-Pedreros 2000). In places, *A. andina* ranges to 5,000 m elevation (Mann 1978) and may be found at lower elevations (950 m) in central Chile during extremely cool winters (Iriarte and Simonetti 1986).

SELECTED LOCALITIES (Map 46): ARGENTINA: Catamarca, Minas Capillitas (Mares, Ojeda, Braun et al. 1997); Jujuy, Cerro Lagunita, near Maimara (type locality of *Akodon jucundus* Thomas), Tres Cruces (Osgood 1943b); La Rioja, Pastillos, Reserva Provincial “Laguna Brava” (OMNH 23218); Mendoza, 3 km W of Refugio Militar General Alvarado (OMNH 23623), ca. 3 km SSE of Vallecitos (OMNH 30208); Salta, Cauchari (MSB 75243); San Juan, Tudcum (OMNH 23627); Tucumán, Paso El Infiernillo (MSU 19221). BOLIVIA: Oruro, 1 km SW of Sajama (S. Anderson 1997); Potosí, Lipez (S. Anderson

1997). CHILE: Antofagasta, Ojos San Pedro, 55 km NE of Calama (MVZ 116766), San Pedro de Atacama (type locality of *Hesperomys dolichonyx* Philippi); Arica y Parinacota, Chungará (Rodríguez-Serrano, Hernández, and Palma 2008); Atacama, Leoncitos (Osgood 1943b); Valparaíso, Farellones, 51 km E of Santiago (Spotorno 1992). PERU: Arequipa, Huaylarco, 55 mi ENE of Arequipa (MVZ 116009), Laguna Salinas (Spotorno 1992), 2 km W of Sumbay (M. F. Smith and Patton 1999); Tacna, 2 km NW of Nevado Livine (Spotorno 1992).

SUBSPECIES: Two subspecies have been traditionally recognized in *Abrothrix andina*. The nominotypical race is larger, exceeding 150 mm in total length, is colored reddish brown, and is found in Chile from Santiago to Coquimbo. It is replaced to the north by *A. a. dolichonyx*, which is smaller and paler, and ranges into Peru (Mann 1978) and Bolivia (S. Anderson 1997). However, this species has not been subjected to rangewide analyses of geographic variation, so the validity of these subspecies remains to be substantiated.

NATURAL HISTORY: *Abrothrix andina* is mostly nocturnal, although it is diurnal during autumn to winter (J. R.

Map 46 Selected localities for *Abrothrix andina* (●). Contour line = 2,000 m.

Contreras and Rosi 1981; Mares, Ojeda, and Kosco 1981). It is a good digger that constructs a system of galleries about 5 cm deep in the soil, winding among the rocks (Mann 1978; J. R. Contreras and Rosi 1981). Its preferred habitat is dense patches of *Lepidophyllum* (Asteraceae), with suitable numbers of refuges. The sparse and low-stature bunchgrass and small shrub community on hard soil pavements contrast with the lush, denser vegetation occupied by sympatric *Akodon* (Pearson 1951). In Chile, its diet includes arthropods, seeds, and other plant material (Mann 1978; S. I. Silva 2005). In Argentina, males with scrotal testes were trapped in January (Mares, Ojeda, Braun et al. 1997) and lactating females in March (R. A. Ojeda and Mares 1989). *Abrothrix andina* is an important prey item in the diet of the Barn Owl (*Tyto alba*) and foxes (*Lycalopex* spp.) in the Atacama Desert (Jaksic et al. 1999).

REMARKS: Palma, Marquet, and Boric-Bargetto (2005) examined the phylogeography of pre-Puna and Puna populations from northern Chile. *Abrothrix andina* is known from late Holocene remains at the archaeological site Tebenquiche Chico 1, Catamarca, Argentina (P. E. Ortiz 2001; P. E. Ortiz, Jayat, Nasif et al. 2012).

Abrothrix hershkovitzi (B. D. Patterson, Gallardo, and Freas, 1984)

Hershkovitz's Soft-haired Mouse

SYNONYMS:

Akodon (Akodon) hershkovitzi B. D. Patterson, Gallardo, and Freas 1984:8; type locality "Chile, [Magallanes y Antártica Chilena,] Magallanes Prov., Isla Capitán Aracena, head of Bahía Morris, elev. ca. 60 m; 54°14'S, 71°30'W."

Akodon hershkovitzi: Tamayo et al., 1987:5; name combination.

Akodon (Abrothrix) hershkovitzi: Reig, 1987:366; name combination.

Abrothrix hershkovitzi: Musser and Carleton, 2005; first use of current name combination.

DESCRIPTION: Medium sized, larger than adjacent races of *A. olivacea* (*xanthorhina*, *canescens*), with an absolutely and relatively longer tail (71 mm, 65% versus 55% head and body length) and greater condylobasal length (>23 mm). Pelage pattern similar to other Cape forms, with head, back, and sides agouti, a buffy white chin and venter, rufescent dorsum of feet, tricolored tail, and ochraceous (yellowish-brown) on the sides of nose. Pelage generally coarsely grizzled, forefeet and hindfeet more tan than rufescent, and tail heavily pigmented dorsally, with rufous on lateral margins and whitish below. Rostrum long, with somewhat trumpeted nasals and premaxillae. Baculum with minute, vestigial apical digits (*sensu* Spotorno 1992; authors unpubl. data).

DISTRIBUTION: This species occurs in the Magellanic steppe and coastal forests of outer islands in the Chilean

Archipelago (B. D. Patterson et al. 1984). The type locality is on Isla Capitán Aracena, on the Magdalena Channel, south of the Magellanic Straits, and the species also occurs on four islands in the Cabo de Hornos group.

SELECTED LOCALITIES (Map 47; from B. D. Patterson et al. 1984): CHILE: Magallanes y Antártica Chilena, Caleta Lientur, Isla Wollaston, Caleta Toledo, Isla Deceit, Isla Capitán Aracena (type locality of *Akodon (Akodon) hershkovitzi* B. D. Patterson, Gallardo, and Freas), Isla Grevy, Isla Hornos.

SUBSPECIES: *Abrothrix hershkovitzi* is monotypic.

NATURAL HISTORY: This species has not been studied in the field since its initial discovery.

REMARKS: This species was originally described in the subgenus *Akodon* to emphasize its evident affinities with *A. markhami*, *A. olivacea*, and *A. xanthorhina*, which are all now included in *A. olivacea* (B. D. Patterson et al. 1984; Muñoz-Pederos 2000). However, despite phallic differences, this group shows affinity with typical *Abrothrix* in cranial and dental characters, and no consistent or qualitative differences between these two groups have been demonstrated. On the basis of cranial characters, especially of the rostrum, Reig (1987) placed *hershkovitzi* in the subgenus *Abrothrix*, which subsequently was accorded generic rank after its distinctive bacular and other penial characters came to be appreciated (Spotorno et al. 1990). To date, the molecular analyses that confirm the membership of *olivacea* and *xanthorhina* in *Abrothrix* (Pearson and Smith 1999; M. F. Smith and Patton 1999) have not included *A. hershkovitzi*.

Abrothrix hershkovitzi occurs on outer islands in the Chilean coastal archipelago, a broad swath of about 3,000 islands that fringe the Pacific coast of southern Chile, from Chiloé Island at 40°S latitude to Isla Hornos at 56°S. Many of these islands were likely buried under glacial ice as recently as 12,000 ybp (Heusser 2003). Thus, like *A. o. markhami*, *A. hershkovitzi* was probably derived via colonization from adjacent mainland populations now represented by *A. o. xanthorhina*. Because both *xanthorhina* and *markhami* are now regarded as subspecies of *A. olivacea* (Pearson and Smith 1999; Rodríguez-Serrano, Hernández, and Palma 2008), *A. hershkovitzi* cannot logically be considered a distinct species without rendering this enlarged *olivacea* paraphyletic. However, founder effect and genetic drift promote rapid evolutionary divergence, especially in insular forms (Mayr 1963; Wright 1969), and cladistic classifications inevitably break down if biological species concepts are employed. Patton and Smith (1994) presented a particularly well-documented example of this involving the pocket gophers *Thomomys bottae* and *Thomomys townsendii* (Geomysidae). The genetic and morphological differentiation of island forms of *Abrothrix* deserves closer scrutiny.

Map 47 Selected localities for *Abrothrix herskovitzi* (●).

Abrothrix illutea Thomas, 1925

Gray Soft-haired Mouse

SYNONYMS:

Abrothrix illutea Thomas, 1925c:582; type locality originally given as “Concepción, 400 m,” Tucumán, Argentina, later modified to “Sierra de Aconquija, 3000–4000 m” in the same province (Thomas 1929:41). Teta, D’Elía et al. (2011), however, reviewed this history and reaffirmed Concepción as the correct type locality.

[*Abrothrix*] *illutea*: Tate, 1932h:24; name combination.

Akodon [(*Abrothrix*)] *illutea*: Ellerman, 1941:416; name combination.

Akodon (*Akodon*) *illutea*: A. L. Gardner and Patton 1976: 30; name combination.

Akodon illuteus: Mares, Ojeda, Braun, and Barquez 1997: 114; name combination.

Abrothrix illuteus: Capplonch, Autino, Díaz, Barquez, and Goytia, 1997:54, 61; incorrect gender agreement.

DESCRIPTION: Dorsal color uniform dark olive-gray, with whitish patches of hairs on chin and hairs white to base in inguinal area (Liascovich et al. 1989); skull robust, with interorbital constriction hourglass in shape and smoothly rounded; muzzle elongated; nasals and premaxillae not strongly flared and project only slightly anterior to incisors (M. M. Díaz 2000); palate ends at about posterior margins of M3s; upper incisors broad and orthodont; molar crowns hypsodont, M1 with well-developed anteroloph and mesoloph. Stomach unilocular-hemiglandular. Terminal crater of phallus ventrally directed; cartilaginous distal baculum reduced, composed of two lateral digits. See Teta, D’Elía, Pardiñas et al. 2011 for emended diagnosis.

DISTRIBUTION: Confirmed records of *A. illutea* are limited to the Catamarca and Tucumán provinces in northwestern Argentina, between 700 and 2,500 m (Teta, D’Elía, Pardiñas et al. 2011). The presence of *A. illutea* at elevations of 3,000 to 4,000 m in the Nevados de Aconquija on the border between Catamarca and Tucumán

(Thomas 1929) is doubtful, and the presence of the species in Jujuy (Olrog 1979) remains to be confirmed (see M. M. Díaz 1999b; Teta, D’Elía, Pardiñas et al. 2011).

SELECTED LOCALITIES (Map 48): ARGENTINA: Catamarca, Andalgala (MACN 50.434), 5 km S of Las Higuierillas on Hwy 9 (Teta, D’Elía, Pardiñas et al. 2011); Tucumán, Concepción (type locality of *Abrothrix illutea* Thomas), El Naranjal (TTU 32830), 10 km S of Hualinchay (Jayat et al. 2006), Zanjón de Tafí, 2 km SW of Tafí del Valle (Teta, D’Elía, Pardiñas et al. 2011).

SUBSPECIES: *Abrothrix illutea* is monotypic.

NATURAL HISTORY: This species inhabits moist southern pine (*Podocarpus parlatorei* [Podocarpaceae]) and *aliso* (*Alnus acuminata* [Betulaceae]) forests on steep slopes at intermediate elevations, about 1,700 m (Capplonch et al. 1997; Barquez et al. 1991). It is also known from a few records for the “Selva Montana” between 700 and 2,200 m. At its upper elevational limit, it inhabits tall grass and brushy habitats along streams (Fonollat 1984). *Abrothrix illutea* was the second most common item in the diet of Barn Owls (*Tyto alba*) in Tucumán province (P. E. Ortiz and Pardiñas 2001). It is known from late Pleistocene remains from the Tafí Valley, Tucumán, Argentina (P. E. Ortiz and Pardiñas 2001).

REMARKS: Thomas (1929) changed the type locality from Concepción to the Aconquija Mountains, 3,000 to 4,000 m, believing that a temperate-zone taxon like *Abrothrix* could not occur in the subtropical lowlands, where it has been subsequently confirmed to occur (Liascovich et al. 1989;

Map 48 Selected localities for *Abrothrix illutea* (●). Contour line = 2,000 m.

Teta, D'Elía, Pardiñas et al. 2011). Osgood (1943b) never examined this species and suspected, from its widely disjunct distribution, that the species was wrongly allocated to *Abrothrix* and might possibly belong in *Hypsimys*. However, both morphology and karyology ally it with *Abrothrix* (Liascovich et al. 1989). Cranially and dentally, it fits revised diagnoses of *Abrothrix*, and its karyotype ($2n=52$, FN=56) is practically identical to that of *Abrothrix longipilis* and other species in the genus. The report of a $2n=39-42$ karyotype that N. O. Bianchi et al. (1971) and Dulout et al. (1976) ascribed to *A. illutea* was based on incorrectly identified specimens of *Akodon varius* (see Liascovich et al. 1989). Phylogenetic analyses of nuclear DNA sequences support a clade composed of *A. illutea*, *A. andina*, *A. jelskii*, and *A. olivacea* (Teta, D'Elía, Pardiñas et al. 2011).

Abrothrix jelskii (Thomas, 1894)

Ornate Soft-haired Mouse

SYNONYMS:

- Hesperomys (Habrothrix) scalops*: Thomas, 1884; part; not *Oxymycterus scalops* Gay [= *Chelemys megalonyx*].
Akodon Jelskii Thomas, 1894b:360; type locality "Junin, Central Peru."

[*Abrothrix jelskii*] *scalops*: Musser and Carleton, 2005: 1089; name combination.

[*Abrothrix jelskii*] *sodalis*: Musser and Carleton, 2005:1089; name combination.

DESCRIPTION: Color pattern striking and variable over range, generally strongly countershaded, with venter whitish or grayish; contrasting patches of white or buff hair behind ears and fulvous or ochraceous hairs on muzzle, feet, tail dorsum, flanks, or back. Skull with enlarged tympanic bullae, short rostrum, and nasals and premaxillae that do not form trumpet-like tube; incisors unusually slender, with pale yellow anterior surfaces. Baculum minute, with vestigial apical digits (Spotorno 1992).

DISTRIBUTION: High-elevation grasslands above about 3,400m, from Ancash and Pasco regions in central Peru (Arana-Cardó and Ascorra 1994) south to western Bolivia and northwestern Argentina.

SELECTED LOCALITIES (Map 49): ARGENTINA: Jujuy, Cerro de la Lagunita, east of Maimará (type locality of *Akodon bacchante sodalis* Thomas); Salta, Santa Victoria range, 13 km NW of Lizoite (Jayat et al. 2013). BOLIVIA: Cochabamba, Choro (type locality of *Akodon bacchante* Thomas); La Paz, Laguna Viscachani (S. Anderson 1997), Pelechuco (S. Anderson 1997); Oruro, Quebrada Kohuiri (S. Anderson 1997); Potosí, Kirkari Mountains (S. Anderson 1997), Lipez (S. Anderson 1997). PERU: Ancash, 3 km S and 12 km W of Huaras (MVZ 135680); Arequipa, 5 km W of Cailloma (MVZ 174286), Salinas, 22 mi E of Arequipa (Spotorno 1992); Ayacucho, 4 km W (by road) of Pampamarca (MVZ 174290), 15 km WNW of Puquio (MVZ 137986), 6 mi. NNE of Tambo (AMNH 208088); Cusco, Ollantaytambo (type locality of *Chroeomys inornatus* Thomas); Huancavelica, Huancavelica (Sanborn 1947b); Junín, 7 km E of Concepción (LSUMZ 14405); Lima, 1.5 km W of Casapalca (MVZ 119941); Pasco, 10 mi NE of Cerro de Pasco (MVZ 119942); Puno, Limbani (type locality of *Akodon pulcherrimus inambarii* Thomas), 6.5 km SW of Ollachea (MVZ 173080); Tacna, 1 mi NE of Challapalca (MVZ 141357).

SUBSPECIES: *Abrothrix jelskii* varies remarkably over its range. Subspecific variation was reviewed by Sanborn (1947b) and has not been analyzed since; gene flow among

Map 49 Selected localities for *Abrothrix jelskii* (●). Contour line = 2,000 m.

the geographic races has not been studied or demonstrated in this species. Patton and Smith (1992b) noted that the sharp chromatic differences between northern and southern populations might indicate that they belong to different species. Pearson (1982) noted sharp discontinuities in morphology that coincided with the Río Acarí (southeast of Nazca, Peru, a western drainage) and the Río Tambo (formed by the confluence of the Ene and Perené, draining to the Urubamba in the east).

NATURAL HISTORY: Pearson (1982) considered *Abrothrix jelskii* to be a species of broad distribution found throughout the entirety of the Altiplano. It occupies a variety of habitats “such as grassy places, rocks, vacant huts, and even occupied houses” (Pearson 1951:140), and therefore is possibly sympatric with every other mammal of the Altiplano. It may be active day and night (Dorst 1971). In Peru, stomachs were found to contain forbs, insects, grass, and seeds (Pizzimenti and DeSalle 1980). Fleas, lice (*Hoplopleura affinis*), and mites (*Atricholaelaps glasgowi*) were collected from *Abrothrix jelskii* at Caccachara (Pearson 1951).

Abrothrix lanosa (Thomas, 1897)

Woolly Soft-haired Mouse

SYNONYMS:

Oxymycterus lanosus Thomas, 1897d:218; type locality “Monteith Bay, Straits of Magellan,” equated to Seno Monteith, in the Madre de Dios Archipelago, Magallanes y Antártica Chilena, Chile by Teta, Pardiñas, and D’Elía (2006).

Microxus lanosus: Thomas, 1909:237; name combination.

Akodon (Abrothrix) lanosus: Osgood, 1943b:197; name combination.

Akodon longipilis lanosus: Mann, 1978:157; name combination.

Akodon lanosus: Tamayo, Núñez, and Yáñez, 1987:5; name combination.

Abrothrix lanosus: Lozada, Monjeau, Heinemann, Guthmann, and Birney, 1996:1; first use of name combination but incorrect gender agreement.

DESCRIPTION: One of smaller members of genus; reduced eyes and ears barely visible through dense, woolly pelage; reduced countershading of venter (especially as compared to sympatric *A. olivacea xanthorhina*); and tail length about 65% head and body length (Feijoo et al. 2010). Dorsal pelage brown to cinnamon brown; under parts usually heavily washed with fulvous; feet white, and tail bicolored (Osgood 1943b). Skull delicate, with enlarged and pointed rostrum, gracile zygomatic arches, and rounded braincase; nasals project beyond anterior plane of incisors and together with premaxillae form well-defined trumpet-like tube; nasofrontal suture acuminate (reaching level of small lac-

rimal bones); masseteric tubercle present; palate long, with anterior border of mesopterygoid fossa posterior to plane of M3s (Feijoo et al. 2010). Baculum “simple” (*sensu* Spotorno 1992); glans penis described and figured by Feijoo et al. (2010).

DISTRIBUTION: *Abrothrix lanosa* is known along a narrow strip extending from 48° to 55°S in northwestern Santa Cruz province of Argentina, south through Última Esperanza and Magallanes in southern Chile to Tierra del Fuego, Argentina (see Galliari and Pardiñas 1999; Feijoo et al. 2010). Osgood (1943b) suspected that either *A. sanborni* or *A. lanosa* would be found living in the coastal archipelago between Chiloé and Tierra del Fuego, where *A. hershkovitzi* and *A. olivacea (markhami)* were later discovered. Late Pleistocene to Late Holocene fossils have been recorded from three archaeological deposits, two within the current range of *A. lanosa* on Isla Grande de Tierra del Fuego about 150 km north of the nearest known extant population (summarized by Feijoo et al. 2010). The species is known from Late Pleistocene and Late Holocene remains collected at Cueva del Milodón, Magallanes y Antártica Chilena, Chile (Simonetti and Rau 1989); Rockshelter 1, Tres Arroyos, Tierra del Fuego, Chile; and Cerro Casa de Piedra 5, Santa Cruz, Argentina (Feijoo et al. 2010).

SELECTED LOCALITIES (Map 50): ARGENTINA: Santa Cruz, Cerro Casa de Piedra (Galliari and Pardiñas 1999), Valle del Río Tucu-Tuco (J. A. Allen 1905); Tierra del Fuego, Bahía Buen Suceso (Pine et al. 1978), Lapataia (Reis and Venegas 1987), Lago Fagnano (Osgood 1943b). **CHILE:** Magallanes y Antártica Chilena, Bahía Parry (Feijoo et al. 2010), Parque Nacional Torres del Paine (Jaksic et al. 1978), vicinity of Punta Arenas (Osgood 1943b), Seno Monteith, Isla Madre de Dios (type locality of *Oxymycterus lanosus* Thomas).

SUBSPECIES: *Abrothrix lanosa* is monotypic.

NATURAL HISTORY: Osgood (1943b:197) encountered *A. lanosa* “in or near deep forest on Tierra del Fuego and in the vicinity of Punta Arenas where it shows preference for cool, damp habitat.” Pine et al. (1978) recorded this species from dense, humid forest dominated by *Nothofagus betuloides* [Nothofagaceae] and *Drimys winteri* [Winteraceae] (see Massoia and Chebez 1993). Feijoo et al. (2010) found this mouse in coastal localities with well-developed soils and dense vegetation cover of *matanegra (Junelia tridens)* [Verbenaceae], although very close to the edge of nearby Fuegian forest. *Abrothrix lanosa* has been found in low numbers in Magellanic Horned Owl (*Bubo magellanicus*) pellets from Magallanes y Antártica Chilena, Chile (Jaksic et al. 1978). Captive individuals are docile and easy to manage with bare hands. Times of capture during the summer reveal that the species is basically

nocturnal but also exhibits some diurnal activity (Feijoo et al. 2010).

REMARKS: The affinities of *A. lanosa* with *Abrothrix* are now clear. Although initially allied with *Oxymycterus* and *Microxus* (Gyldenstolpe 1932), this species was later linked to the subgenus *Abrothrix* of *Akodon* by Osgood (1943b; see also Reig 1987). Mann (1978) considered *lanosa* a subspecies of *A. longipilis*, but Osgood (1943b) and Yáñez et al. (1978) affirmed its specific rank. The lack of recently collected material for comparative studies of non-traditional characters have shielded this species from the most recent cytogenetic and molecular analyses of group relationships. However, Feijoo et al. (2010) reported new records as well as phylogenetic analyses of mtDNA cytochrome-*b* sequences that indicate relationships with *A. jelskii*, and of nucDNA IRBP sequences showing its affinities with *A. longipilis*, the latter seeming more reasonable on geographic grounds. Future analyses with expanded data sets can be expected to clarify the phylogenetic position of *A. lanosa*.

Musser and Carleton (1993) erroneously gave the type locality as “Argentina, Tierra del Fuego Prov., Bahía Mon-

Map 50 Selected localities for *Abrothrix lanosa* (○) and *Abrothrix sanborni* (●). Contour line = 2,000 m.

teith, Straits of Magellan.” Osgood (1943b) was apparently unable to locate this locality. However, Teta, Pardiñas, and D’Elía (2006), based on historical research, equated the type locality to Seno Monteith, in the Madre de Dios Archipelago, Magallanes y Antártica Chilena region, Chile (see also Feijoo et al. 2010).

Abrothrix longipilis (Waterhouse, 1837)

Long-haired Soft-haired Mouse

SYNONYMS:

Mus longipilis Waterhouse, 1837:16; type locality “Coquimbo,” Coquimbo, Chile.

Hesperomys longipilis: Wagner, 1843a:466; name combination.

Mus porcinus Philippi, 1858:78; type locality “in planitie prov. Santiago prope locum Angostura,” Metropolitana de Santiago, Chile.

Hesperomys (Habrothrix) longipilis: Thomas, in Milne-Edwards, 1890:28; name combination.

Acodon hirtus Thomas, 1895c:370; type locality “Fort San Rafael, Mendoza,” Argentina; but see Pearson and Lagiglia (1992) for doubts about this locality.

Mus brachytarsus Philippi, 1900:37, plate XV, Fig. 2; type locality “Prope Santiago loco dicto Quinta Normal,” Metropolitan de Santiago, Chile.

Mus fusco-ater Philippi, 1900:45, plate XIX, Fig. 1; type locality not specified.

Mus melampus Philippi, 1900:49, plate XX, Fig. 4; type locality “Ad vicum Cartajena ad austrum urbis Valparaiso,” vicinity of Cartagena, Valparaiso, Chile.

Akodon suffusus Thomas, 1903c:241; type locality “Valle del Lago Blanco, Southern Chubut (Cordillera Region),” Argentina.

Akodon francei Thomas, 1908:496; type locality “Santa Maria [= Estancia Santa María], Tierra del Fuego,” Magallanes y Antártica Chilena, Chile.

Abrothrix francei: Thomas, 1916i:340; name combination.

Abrothrix hirtus: Thomas, 1916i:340; name combination but incorrect gender agreement.

Abrothrix longipilis: Thomas, 1916i:340; first use of current name combination.

Abrothrix suffusus modestior Thomas, 1919b:202; type locality “Maiten [= El Maitén],” Chubut, Argentina.

Abrothrix suffusus moerens Thomas, 1919b:203; type locality “Beatriz, [Península Quetrihué,] Nahuel Huapi. 800 m,” Río Negro, Argentina.

Chelemys angustus Thomas, 1927d:654; type locality “Bariloche, E. of Lake Nahuel Huapi. Alt. 800 m,” Río Negro, Argentina (see Pearson 1984).

Abrothrix hirta nubila Thomas, 1929:40; type locality “Estancia, Alta Vista, Lago Argentino, 600 m,” Santa Cruz, Argentina.

- Abrothrix hirta hirta*: Thomas, 1929:40; name combination.

- [*Abrothrix longipilis*] *nubila*: Musser and Carleton, 2005:1090; name combination.
- [*Abrothrix longipilis*] *porcinus*: Musser and Carleton, 2005:1090; name combination and incorrect gender agreement.
- [*Abrothrix longipilis*] *suffusus*: Musser and Carleton, 2005:1090; name combination and incorrect gender agreement.
- DESCRIPTION: Large and robust (head and body length up to 130 mm); tail bicolored; pelage with long guard hairs. Color varies greatly geographically but most races retain reddish-brown markings on back bordered by more uniformly grayish flanks and venter. Skull robust, with sharply trumpeted nasals; nasofrontal suture markedly acuminate (extending posteriad beyond line drawn between lacrimal bones); masseteric tubercle absent; palate long, extending past posterior borders of M3s. Baculum "simple" (*sensu* Spotorno 1992); strongly curved at the tip, lacking discrete apical elements.
- DISTRIBUTION: *Abrothrix longipilis* ranges from Coquimbo, Chile, and Mendoza, Argentina, in the north to Tierra del Fuego in the south (Osgood 1943b; Mann 1978; Pardiñas, Teta et al. 2003). The species is known from Late Pleistocene and Holocene deposits in Chile (Simonetti and Rau 1989; Simonetti and Saavedra 1998; Saavedra et al. 2003) and from several Holocene archaeological sites in extra-Andean Patagonia of Argentina (Pearson 1987; Pearson and Pearson 1993; Pardiñas 1998, 1999b; Teta et al. 2005).
- SELECTED LOCALITIES (Map 51): ARGENTINA: Chubut, Estancia San Pedro (Pardiñas, Teta et al. 2003),

Paso del Sapo (Pardiñas, Teta et al. 2003), Río Arrayanes, Parque Nacional Los Alerces (MVZ 188127); Mendoza, Fort San Rafael (type locality of *Acodon hirtus* Thomas), Laguna de la Niña Encantada, Los Molles (Massoia et al. 1994b); Neuquén, Cañadón del Tordillo (Pardiñas, Teta et al. 2003), Parque Nacional Laguna Blanca (Pardiñas, Teta et al. 2003); Río Negro, Cerro Somuncurá Chico (Pardiñas, Teta et al. 2003), Estancia Maquinchao (Pardiñas, Teta et al. 2003); Santa Cruz, Lago Cardiel (Osgood 1943b), Seccional Glacier Moreno (MVZ 160117), mouth of Río Coig (Osgood 1943b); Tierra del Fuego, Bahía San Sebastián (Marconi 1988). CHILE: Aysén, Río Coihuique [*sic*] Station (Osgood 1943b); Araucanía, Parque Nacional Nahuelbuta (MVZ 140000); Coquimbo, Coquimbo (type locality of *Mus longipilis* Waterhouse), Parque Nacional Fray Jorge (FMNH 130902); Los Lagos, Maicolpue, 2 km S of Bahía Mansa (FMNH 130584), Petrohué, Lago Todos Santos (Osgood 1943b); Los Ríos, 6 km S of Puerto Fuy (MVZ 173700); Magallanes y Antártica Chilena, El Torcido (TTU 30136), Lago Pehoe, Torres del Paine (MVZ 175129), Santa Maria, near Porvenir (type locality of *Akodon francei* Thomas); Santiago, Angostura (type locality of *Mus porcinus* Philippi); Valparaíso, Los Molles, 30 km N of La Ligua (MVZ 150038).

SUBSPECIES: Osgood (1943b), Cabrera (1961), and Mann (1978) regarded *A. longipilis* as polytypic with eight subspecies, four limited to Chile (from north to south *longipilis*, *apta*, *castanea*, and *francei*) and four either restricted to or largely restricted to Argentina (*hirta*, *moerens*, *suffusa*, and *nubila*). Palma et al. (2010) analyzed variation in the mtDNA cytochrome-*b* and nucDNA beta-fibrinogen sequences across the species' full latitudinal range in Chile. They found reasonable concordance between clades and subspecific taxonomy, and they recovered the northernmost subspecies (*longipilis*) as the basal split in *A. longipilis*. In a broader study, including 41 Argentinean and Chilean populations, Sierra-Cisternas (2010) tested the agreement between classical taxonomy and the recovered molecular phylogeographic pattern. This author found eight major clades strongly supported, structured geographically, and with significant genetic differentiation. In contrast with Palma et al. (2010), Sierra-Cisternas (2010) found little correspondence between clades and traditional subspecific classification. Both morphological (M. H. Gallardo et al. 1988) and molecular (Palma et al. 2010; Sierra-Cisternas 2010) data strongly suggest that, in its current meaning, *A. longipilis* includes two or more species. This complex is ripe for a comprehensive analysis of the geographic variation in both morphological and molecular characters, both to validate the existing infraspecific taxonomy

and to delineate the processes underlying the impressive diversification observed.

NATURAL HISTORY: Pearson (1983) and Kelt (1994) have provided notes on the natural history of *Abrothrix longipilis* in Argentina and southern Chile, respectively. This species is abundant in dense forests of *Nothofagus* (Meserve, Lang et al. 1991), but also occurs in most other habitats, such as marshes, shrubby steppes, tussock grass, or rocky areas (Kelt 1994; Pearson 1995). Although these animals burrow well, they can also climb trees (Pearson 1983). They may be active in the morning, afternoon, and at night (Pearson 1983). In Argentina, the diet included berries, seeds, fern spores, insects, fungi, worms, and slugs (Pearson 1983). In Chile, the species has been alternately characterized as either herbivorous-insectivorous or highly insectivorous, and fungivorous-insectivorous or strongly fungivorous (Meserve et al. 1988; S. I. Silva 2005).

Abrothrix longipilis breeds in spring and summer months in Río Negro province, Argentina, and in southern Chile (Pearson 1983; L. A. González and Murúa 1985; Kelt 1994; Guthmann et al. 1997). Pearson (1992) provided details of the reproductive cycle of both sexes in Río Negro and Neuquén provinces, Argentina. He found that males were equal in length to but 8% heavier than females and that sexually active males were longer and heavier than inexperienced males. Few wild mice survived two winters, and most females underwent several infertile ovulation cycles before becoming pregnant, shedding 4.66 ova and giving birth to litters averaging 3.85 young. According to Pearson (1983) and Kelt (1994), by late October most overwintering males had entered breeding condition, and by November and December essentially all adult males were breeding. Testes and vesicular glands of breeding individuals each exceeded 9 mm in length (Pearson 1983). Pregnant and lactating females were caught in late October, November, December, and February (Pearson 1983; Kelt 1994), and reproduction ceased before April (Pearson 1983). In northern Chile, reproductive activity peaked much earlier than in Argentina (Meserve and Glanz 1978). Embryo counts averaged 3.78 (range: 2–5) in Río Negro (Pearson 1983), and 3.7 (range: 2 to 5) in Malleco, Chile (Greer 1965). In the northern Chilean scrub, females had embryo counts of four and six (Meserve and Le Boulengé 1987).

The age structure in Río Negro and southern Chile remains relatively constant over the year, although populations include more juveniles in the fall (Pearson 1983; Kelt 1994). High numbers of old individuals, especially in spring samples, suggested that populations contain significant numbers of individuals that have survived two winters (Pearson 1983; Guthmann et al. 1997). Longi-

tudinal studies suggest that *A. longipilis* populations are less eruptive than sympatric *A. olivacea* or *Oligoryzomys longicaudatus* (Meserve et al. 1999). Population peaks of *A. longipilis* occurred at the end of summer and beginning of autumn (Guthmann et al. 1997). Home-range size in forest agroecosystems of central Chile varied between 1,636 m² in winter to 2,758 m² in spring (Muñoz-Pedrerros et al. 1990). Recaptures of this species at Mallico were in areas no greater than 40 to 241 m² (Greer 1965). Densities in the *Nothofagus* forest of Río Negro, Argentina, ranged from 0.4 to 4.8 individuals per hectare in the spring to 2.8 to 10.8 in the autumn (Pearson and Pearson 1982). In southern Chile, *Abrothrix longipilis* was found to be one of the most abundant rodents in pristine temperate rainforests, and occurred across all sampled elevations (B. D. Patterson et al. 1989, 1990). Pearson (2002) and Sage et al. (2007) described a population outbreak of this species in northwestern Argentinean Patagonia.

Abrothrix longipilis is a main prey item of both Barn (Tyto alba) and Magellanic Horned Owls (*Bubo magellanicus*) in Argentina and Chile (Jaksic et al. 1981; Trejo and Grigera 1998; Pillado and Trejo 2000; Teta et al. 2001; Trejo and Ojeda 2004; Nabte et al. 2006). Other important predators are the Rufous-legged Owl (*Strix rufipes*) in forests of Chile and Argentina (I. Díaz 1999; D. R. Martínez and Jaksic 1997; Udrizar Sauthier et al. 2005), the White-tailed Kite (*Elanus leucurus*) in central and southern Chile (Jaksic et al. 1981; González-Acuna et al. 2009), and the South American Gray Fox (*Lycalopex griseus*) in the forests of Valdivia, Chile (Rau et al. 1995). In the Mediterranean region of Chile, *A. longipilis* is an important reservoir of Andes Virus, which is the predominant etiological agent of hantavirus cardiopulmonary syndrome, in which it is second only to *Oligoryzomys longicaudatus* (R. A. Medina et al. 2009).

REMARKS: This species was long thought to be closely related to and perhaps conspecific with *A. sanborni* (see Osgood 1943b; Pine et al. 1979) and *A. lanosus* (Mann 1978). Based on both mtDNA and nucDNA sequence analyses, Palma et al. (2010) suggested a sister relationship between *A. longipilis* and *A. jelskii* rather than with *A. sanborni*, whereas Teta, D'Elía, Pardiñas et al. (2011) recovered *A. longipilis* as sister to *A. lanosa*. Pearson (1984) assigned *Chelemys angustus* to the synonymy of *A. longipilis*; other synonyms follow Osgood (1943b) and Reig (1987). Osgood (1943b) and Muñoz-Pedrerros (2000) delineated and mapped subspecies boundaries in Chile. As yet, the patterns of character variation that might support subspecies recognition across the broad species range to the east in Río Negro and Chubut provinces, Argentina (Teta et al. 2002), have yet to be evaluated.

Map 51 Selected localities for *Abrothrix longipilis* (●). Contour line = 2,000 m.

Abrothrix olivacea (Waterhouse, 1837)

Olive Soft-haired Mouse

SYNONYMS:

Mus olivaceus Waterhouse, 1837:16; type locality "Valparaíso," Valparaíso, Chile.

Mus brachiotis Waterhouse, 1837:17; type locality "in insula parvulâ apud Midship Bay, Chonos Archipelago" subsequently fixed to "Islet off E. coast of [Isla] Chiloé," Los Lagos, Chile, by Thomas (1927b:551).

Mus xanthorhinus Waterhouse, 1837:17; type locality "Santa Cruz," Santa Cruz, Argentina, subsequently fixed to "Hardy Peninsula, Tierra del Fuego [= Isla Hoste, Magallanes, Chile]," by Thomas (1927b:551).

Mus canescens Waterhouse, 1837:17; type locality "Port Desire" [= Puerto Deseado], Santa Cruz, Argentina.

- Mus Renggeri* Waterhouse, 1839:51; type locality “Valparaíso and Coquimbo,” subsequently fixed to “Valparaíso,” Valparaíso, Chile, by Thomas (1927b:550).
- Mus brevicaudatus* Philippi, 1872:446; type locality “Puerto Montt,” Los Lagos, Chile.
- Hesperomys* [*Calomys*] *canescens*: Burmeister, 1879:227; name combination.
- Hesperomys* (*Habrothrix*) *xanthorhinus*: Thomas, 1881b:5; name combination.
- Hesperomys* (*Habrothrix*) *olivaceus*: Thomas, 1882:110; name combination.
- A*[*codon*]. *olivaceus*: Thomas, 1894b:364; name combination.
- Akodon olivaceus*: J. A. Allen, 1897c:117; name combination.
- Hesperomys* (*Acodon*) *xanthorhinus*: Matschie, 1898:7; name combination.
- Mus brachyotis* Philippi, 1900:12; incorrect subsequent spelling of *Mus brachiotis* Waterhouse.
- Mus lepturus* Philippi, 1900:17, plate IV, Fig. 2; type locality “provincia Santiago ad Peine,” Antofagasta, Chile.
- Mus psilurus* Philippi, 1900:17, plate IV, Fig. 3; type locality “provincia Colchagua,” O’Higgins, Chile.
- Mus trichotis* Philippi, 1900:18, plate V, Fig. 1; type locality “Andibus provinciae Santiago,” Andes, Metropolitana de Santiago, Chile.
- Mus Foncki* Philippi, 1900:20, plate V, Fig. 4; type locality “prope Puerto Montt in provincia Llanquihue,” Los Lagos, Chile.
- Mus chonoticus* Philippi, 1900:24, plate VII, Fig. 2; type locality “in insulis ‘Chonos’,” Chonos Archipelago, Los Lagos, Chile.
- Mus vinealis* Philippi, 1900:24, plate VII, Fig. 3; type locality “provincia Santiago in vineis sarmenta adscendens, uvas consumens,” Metropolitana de Santiago, Chile.
- Mus* (*Oxymycterus*) *Landbecki* Philippi, 1900:26, plate VIII, Fig. 2; type locality “prope Illapel et Choapa,” Coquimbo, Chile.

- [*Abrothrix olivaceus*] *xanthopus*: Musser and Carleton, 2005:1000; name combination and incorrect gender agreement.
- Abrothrix olivaceus tarapacensis* Rodríguez-Serrano, Cancino, and Palma, 2006:977; type locality “Quebrada de Tarapacá, región I Tarapacá, Chile.”
- DESCRIPTION:** Small; pelage color varies greatly geographically, ranging from dark brown or olive brown to gray or pale ochraceous; some forms with yellow or orange patches on nose, feet, and tail. Skull small (condyloincisive length <27 mm) and delicate, with short and narrow rostrum, bowed dorsal profile, and moderately extended nasals and premaxillae; palate long, extending past posterior borders of M3s. Distal baculum minute, with vestigial apical digits (Spotorno 1992).
- DISTRIBUTION:** *Abrothrix olivacea* ranges from northernmost Chile through southernmost Chile and Argentina. A disjunct low-elevation population lives in lomas of the Atacama Desert, and the species ranges exclusively west of the Andes until the latitude of Concepción, where it extends onto the eastern slopes of the Andes, reaching the Atlantic near Península Valdés at about 43°S and spreading across much of Patagonia. Its northern range in Argentina corresponds to that of the Patagonian Botanical Province (Osgood 1943b; Lozada et al. 1996; Pardiñas, Teta et al. 2003). Isolated historical records, perhaps reflecting a past wider distribution, are known from Monte Desert localities in northern Patagonia (i.e., Choele Choei [MACN 28.111], Laguna del Barro [Thomas 1929], Puerto Madryn [Mahnert 1982], and Rawson [Thomas 1929]). *Abrothrix olivacea* also occurs on many of the larger islands in the coastal archipelago, including Isla

Grande de Tierra del Fuego and Isla Wellington (represented by the taxon *markhami*), but appears to be contiguously allopatric with the insular endemic *Abrothrix hershkovitzi* on Isla Capitán Aracena and the Cape Horn island group.

SELECTED LOCALITIES (Map 52): ARGENTINA: Chubut, 4 km N of El Maitén (MVZ 151006), 30 km W of José de San Martín (MVZ 206338), Rawson (Pardiñas, Teta et al. 2003); Mendoza, Laguna de la Niña Encantada, Los Molles (Massoia et al. 1994b); Neuquén, Parque Nacional Laguna Blanca (Pardiñas, Teta et al. 2003); Río Negro, Cerro Somuncurá Chico (Pardiñas, Teta et al. 2003); Santa Cruz, Cape Fairweather (Osgood 1943b), 52 km WSW of El Calafate (MVZ 151011), 4.4 km E of Los Antiguos, Estancia La Aurora (MVZ 206341), Puerto Deseado (type locality of *Mus canescens* Waterhouse); Tierra del Fuego, Estancia Cullen (Osgood 1943b), Estancia Via Monte (Osgood 1943b), head of Bahía Capitán Canepa, Isla de los Estados (type locality of *Akodon (Akodon) llanoi* Pine), Lake Yerwin (Osgood 1943b). CHILE: Aysén, Archipiélago de los Chonos (type locality of *Mus chonoticus* Philippi), Puerto Aysén (Osgood 1943b); Antofagasta, Paposo (MVZ 119157); Araucanía, Parque Nacional Nabuelbuta (MVZ 137886); Arica y Parinacota, Quebrada de Camarones (Rodríguez-Serrano, Hernández, and Palma 2008); Atacama, Caldera (Osgood 1943b); Biobío, Isla Mocha (type locality of *Mus Mochae* Philippi); Coquimbo, Romero (Osgood 1943b); Los Lagos, Puerto Montt (type locality of *Mus Foncki* Philippi), mouth of Río Inio, Isla Grande de Chiloé (Osgood 1943b); Magallanes y Antártica Chilena, Hardy Peninsula, Isla Hoste (type locality of *Mus xanthorhinus* Waterhouse), Isla Wellington, Puerto Eden (type locality of *Akodon (Akodon) markhami* Pine), Lake Sarmiento (Osgood 1943b), Puerto Natales, Última Esperanza (Osgood 1943), Punta Arenas (Osgood 1943b), east end of Riesco Island (Osgood 1943b); Tarapacá, mouth of Río Loa (Rodríguez-Serrano, Hernández, and Palma 2008); Valparaíso, Valparaíso (type locality *Mus olivaceus* Waterhouse), San Carlos de Apoquindo (Osgood 1943b).

SUBSPECIES: Multiple subspecies had been recognized for both *olivacea* and *xanthorhina* before their amalgamation into a single species (see Remarks). For example, Cabrera (1961) listed five geographic races for *olivacea*, four in Chile (from north to south along the coast, the nominotypical form, *pencana*, and *brachiotis*, with *mochae* from Isla Mocha) and *beata* in Argentina (see also Osgood 1943b; Mann 1978). Cabrera (1961) included two subspecies in his concept of *xanthorhina*, the nominotypical form from forests of extreme southern Chile and *canescens* from the steppes of Patagonian Argentina. Since then, two insular taxa described as species

have been synonymized with *A. olivacea*, namely, *llanoi* and *markhami* (B. D. Patterson et al. 1984; Rodríguez-Serrano, Hernández, and Palma 2008). Rodríguez-Serrano, Hernández, and Palma (2008) described *tarapacensis* as a subspecies from northern Chile. A thorough understanding of patterns of morphological variation as well as comprehensive phylogeographic analyses are needed to gauge the validity of each of these geographic forms and their relationships to the insular endemic *A. hershkovitzi*.

NATURAL HISTORY: In central Chile, *A. olivacea* lives in semiarid scrub habitat; in Patagonia, it occupies semiarid bushy steppes and bunchgrass habitats (Kelt 1994; Pearson 1995); and in the Andes, it is found in moister habitats such as meadows, thick grasses, and dense *Nothofagus* forests from western Neuquén, western Río Negro, and northwestern Chubut, Argentina, to southern Chile and Tierra del Fuego (B. D. Patterson et al. 1984; Pearson 1995; Lozada et al. 1996). In the Chilean archipelago, the species occurs in dense coastal forest of *Nothofagus betuloides* [Nothofagaceae], *Drimys winteri* [Verbenaceae], and *Lomatia ferruginea* [Proteaceae] and in grassy meadows with sparse shrub cover (the type series of *markhami* Pine).

Pearson (1983), Kelt (1994), and Lozada et al. (1996) summarized the natural history of *Abrothrix olivacea*. It is partly diurnal and climbs well (Pearson 1983; Tapia 1995). It builds simple nests of grass, underground or sheltered in roots or rocks (Mann 1978), and, when living in dense grass, creates runways (Pearson 1983). It can also dig, and in Chile has been found living in burrows of other rodents such as *Spalacopus*. The diet includes berries, seeds, arthropods, green vegetation, fungi (Pearson 1983; Lozada et al. 1996), and invertebrates (see S. I. Silva 2005). These mice reproduce from early spring through summer (Meserve and Glanz 1978; Pearson 1983; Murúa et al. 1987; Kelt 1994; Guthmann et al. 1997), but the length of the reproductive season may vary (Kelt 1994). Pregnant and lactating females have been caught in late October, November, December, February, March, and April (Pearson 1983; Kelt 1994). The average litter size ranged from 5.0 (in steppe habitat) to 5.1 (in forest habitat) in Río Negro (Pearson 1983; Lozada et al. 1996), and 5.5 in Malleco, Chile (Greer 1965), and Tierra del Fuego (Marconi 1988). Females produced two or three litters per season (Lozada et al. 1996; Muñoz-Pedreros 2000). Older females tended to have large litters (Pearson 1983). Reproductively active males had testes 10–13 mm long and vesicular glands 10 mm in length (Pearson 1983).

The population structure clearly reflects summer recruitment to the autumn population (Pearson 1983; Kelt 1994). Adult males weighed a significant 9.2% more than adult females (Pearson 1983). Murúa and González (1985)

documented seasonal fluctuations in numbers and body mass, and described multiannual cycles with temporally different cohorts characterized by different age structures and survival rates. These multiannual fluctuations are variable both in space and time, and local populations may remain stable for long periods (Meserve, Kelt, and Martínez 1991; Meserve et al. 1999). El Niño events can result in increased densities by an order of magnitude or more (Meserve et al. 1995).

Factors involved in regulating numbers may include age composition of the breeding stock, differential survival of cohorts, and presaturation dispersal (Murúa and González 1985). Maximum density can vary both seasonally and geographically. In Chilean shrubland-grassland, maximum density was attained in the fall, with 37.7 individuals per hectare; in temperate Chilean woodlands, density peaked in winter at 37.9 individuals per hectare (L. C. González et al. 1982). At a semiarid site in northern Chile, Fulk (1975) estimated density at 30.3 individuals per hectare in August and 97.0 individuals per hectare in November, with an average home range diameter of 54.0 m. Densities in *Nothofagus* forest of Río Negro province, Argentina, ranged from 0 to 1.9 individuals per hectare in spring and increased to 4.2 to 17.9 in autumn (Pearson and Pearson 1982). Lozada et al. (1996) reported a maximum of 40 individuals per hectare in steppe habitat in Río Negro province, and Marconi (1988) recorded an even higher density (63 individuals per hectare) in southern Tierra del Fuego province, Argentina. Over four consecutive years, densities in steppe habitat in Río Negro, Argentina, peaked consistently in March, with lows in September (Lozada et al. 1996). Jaksic and Lima (2003) reviewed this history of population outbreaks.

In forest agroecosystems of central Chile, the home range varied between 1,779 m² in winter to 2,776 m² in spring (Muñoz-Pedreras et al. 1990). In Chilean temperate rainforest and shrubland-grassland, males increased their home range at the onset of the reproductive period while females maintained the same home range size throughout the year (L. C. González et al. 1982). The average home range in steppe areas of Río Negro varied from 548 m² for females and 598 m² for males during the nonreproductive season, and increased to 610 m² and 1,307 m² in reproductively active females and males, respectively (K. M. Heinemann et al. 1995). Home range was reduced substantially during outbreaks in southern Chile (L. A. González et al. 2000). B. D. Patterson et al. (1989, 1990) examined the distribution, abundance, and habitat association along an elevational transect in a temperate rainforest in Chile; *A. olivacea* was the most frequently captured of the 10 small mammals sampled and occurred at all elevations as well as exhibited modal habitat preferences.

Barn Owls (*Tyto alba*) and Magellanic Horned Owls (*Bubo magellanicus*) prey upon *A. olivacea* throughout its range (Jaksic et al. 1981; Torres-Mura and Contreras 1989; Trejo and Grigera 1998; Pillado and Trejo 2000; Teta et al. 2001; Trejo and Ojeda 2004; Nabte et al. 2006). Additional predators include by the Burrowing Owl (*Athene cunicularia*) in the Mediterranean ecosystems of Chile (Fulk 1977; Meserve et al. 1987) and in northern Patagonia, Argentina (A. Andrade, Udrizar Sauthier et al. 2004), the Short-eared Owl (*Asio flammeus*) in Chile's Lake District (Figueroa-R. et al. 2009) and in the agricultural landscapes of southern Chile (D. R. Martínez et al. 1998), the Rufous-legged Owl (*Strix rufipes*) in forests of Chile and Argentina (I. Díaz 1999; Udrizar Sauthier, Andrade et al. 2005), the White-tailed Kite (*Elanus leucurus*) in central and southern Chile (Jaksic et al. 1981; González-Acuna et al. 2009), and the South American Gray Fox (*Lycalopex griseus*) in the Valdivian forests of Chile (Rau et al. 1995).

This species is known from Holocene remains in Chile (Simonetti and Saavedra 1998; Saavedra, Quiroz, and Iriarte 2003) and from several Holocene archaeological sites in the extra-Andean Argentinean Patagonia (Pearson 1987; Pearson and Pearson 1993; Pardiñas 1998, 1999b; Teta et al. 2005).

REMARKS: For most of the twentieth century, *olivacea* Waterhouse and *xanthorhina* Waterhouse were regarded as separate species, and locally they can appear and behave quite differently (see Osgood 1943b; B. D. Patterson et al. 1984; Pearson 1995). Yet the two merge clinally in cranial and body measurements and in molar characters, which caused Yáñez et al. (1978) to consider them conspecific. More recently, genetic studies of contact zones between the two indicate that they are reproductively confluent. Pearson and Smith (1999) studied what were then regarded as *A. olivacea brachiotis* and *A. xanthorhina canescens* where their ranges are contiguous in northern Patagonia. Morphological analyses demonstrated that intermediates predominated across a 30-km zone near Bariloche, and DNA analyses confirmed their genetic similarity. Similar results were obtained in studies of contact between these same nominal taxa east of Aisen, 500 km south of Bariloche (M. F. Smith et al. 2001). Haplotypes of "*canescens*" had not yet achieved reciprocal monophyly relative to those of "*brachiotis*," thus supporting *olivacea* and *xanthorhina* as conspecific, in keeping with morphometric appraisals (Yáñez et al. 1979). Studies of additional contact zones are needed to resolve the specific or subspecific rank of other *Abrothrix* taxa, especially *canescens-xanthorhina* and *xanthorhina-hershkovitzi* (see also Musser and Carleton 2005).

Both Rodríguez-Serrano, Hernández, and Palma (2008) and Abud (2011) used comparable molecular analyses to show that the insular endemics *markhami* Pine and

Map 52 Selected localities for *Abrothrix olivacea* (●). Contour line=2,000 m.

hershkovitzi B. D. Patterson, Gallardo, and Freas, respectively, were independent and recent derivatives of *A. olivacea*. The southern Andes and outlying islands were extensively glaciated until the end of the Pleistocene (Hessner 2003). Thus, territory currently occupied by *A. olivacea* and these two insular derivatives would only have been available for colonization after glacial retreat, either by expanding low-latitude populations or by high-latitude relicts that managed to persist in refugia (Rodríguez-Serrano, Hernández, and Palma 2008; E. P. Lessa et al. 2010). The apparent paraphyly of *A. olivacea* with respect to both *markhami* and *hershkovitzi* is to be expected, given their recent, post-Pleistocene origin. Although we regard *hershkovitzi* as a species, this phylogenetic placement could support its potential synonymy with *A. olivacea*, as we treat *markhami* Pine.

Abrothrix sanborni Osgood, 1943

Sanborn's Soft-haired Mouse

SYNONYMS:

Akodon (Abrothrix) sanborni Osgood, 1943b:194; type locality "mouth of Río Inio, south end of Chiloé Island [= Isla Grande de Chiloé]," Los Lagos, Chile.

Akodon sanborni: Cabrera, 1961:457; name combination.

Akodon longipilis sanborni: Mann, 1978:157; name combination.

Abrothrix sanborni: Tamayo, Núñez, and Yáñez, 1987:5; first use of current name combination.

DESCRIPTION: Small; coloration uniformly blackish-brown, including tail and feet, without indication of countershading; small, scantily haired ears; head and body length averaging 105 mm, tail about 76 mm (Osgood 1943b). Skull delicate with narrow and elongate rostrum, trumpeted nasals, acuminate nasofrontal suture extending posteriad beyond line drawn between lacrimals, gracile zygomatic arches, and rounded braincase; infraorbital plates narrow and sloping, with conspicuous masseteric tubercles at base. Baculum "simple" (*sensu* Spotorno 1992) and strongly curved at tip, lacking discrete apical elements.

DISTRIBUTION: *Abrothrix sanborni* inhabits the coastal rainforests of southern Chile, including Isla Grande de Chiloé but not, insofar as known, the Guaitecas Archipelago (Osgood 1943b; B. D. Patterson, unpubl. data). Pearson (1995) recorded this species at Lago Quillén, Neuquén, Argentina. At La Picada, Chile, it was significantly more common at low elevations, and was not recorded at elevations above 820 m (B. D. Patterson et al. 1989).

SELECTED LOCALITIES (Map 49): ARGENTINA: Neuquén, NW shore of Lago Quillén (Pearson 1995). CHILE: Aysén, Lago Atravesado (Figueroa et al. 2001), 4 km NW of Puerto Ibáñez (FMNH 130197); Los Lagos, Anticura, Parque Nacional Puyehue (MVZ 173501), 15 km E of Chepu, Isla Grande de Chiloé (Reis and Venegas 1987), Peulla, Parque Nacional Vicente Pérez Rosales (FMNH 124050), mouth of Río Inio, Isla Grande de Chiloé (Osgood 1943b), Valle de la Picada (B. D. Patterson 1989).

SUBSPECIES: *Abrothrix sanborni* is monotypic.

NATURAL HISTORY: *Abrothrix sanborni* is active both day and night (Meserve et al. 1982). Its diet includes high proportions of fungi, moderate amounts of larval and adult arthropods, plant foliage, seeds, and fruits (Meserve et al. 1988). This species breeds in spring and summer (Figueroa et al. 2001). B. D. Patterson (1989, 1990) studied distribution, abundance, and habitat associations along an elevational transect in a temperate rainforest of Chile. *Abrothrix sanborni* was caught at sites with dense canopy cover, tall trees, sparse shrub cover, deep litter, ground cover of bryophytes and bamboo, and gentle slopes (B. D. Patterson et al. 1990).

REMARKS: The species is dark, almost blackish in color and has smaller, more sparsely haired ears than *Abrothrix longipilis*. However, there are persistent reports of putative hybrids between them (see Pine et al. 1979; M. H. Gallardo et al. 1988; Pearson 1995). Morphometric analyses by Yáñez et al. (1978) showed greater quantitative differences between *sanborni* and *longipilis* than among geographic samples of the latter. M. H. Gallardo et al. (1988), citing gross similarities in phenetic and immunodiffusion characters, suggested that *sanborni* was merely another geographic race of *Abrothrix longipilis*. However, Palma et al. (2010) documented that *A. sanborni* and *A. longipilis* were nonsister species, based on phylogenetic analyses of mtDNA and nucDNA sequences. More recently, G. D'Elía, P. Teta, N. S. Upham, and B. D. Patterson (pers. obs.) have each uncovered morphometric and mtDNA sequence evidence for two distinct groupings in *A. sanborni* as treated in this account.

Genus *Chelemys* Thomas, 1903

Pablo Teta, Ulyses F. J. Pardiñas, and Guillermo D'Elía

The genus *Chelemys* includes two species of medium-sized sigmodontine rodents of fossorial habits. It ranges from central Chile and west-central Argentina through the Andes south to the vicinity of the Straits of Magellan. Originally described as a subgenus of *Akodon*, *Chelemys* was later considered to be a distinct genus (J. A. Allen 1905; Thomas 1919b, 1927d; Gyldenstolpe 1932) or was subsumed under *Notiomys* (Osgood 1925, 1943b; Ellerman 1941; Cabrera 1961). Pearson (1984) and Reig (1972, 1987) established the basis for the current classification, treating *Chelemys* as a distinct genus while also according generic rank to *Geoxus* and *Notiomys*. B. D. Patterson (1992a) made additional morphological and morphometric comparisons among *Chelemys* and the other long-clawed Abrotrichini.

Chelemys is a medium-sized, stout, short-tailed mouse. The fur is short, soft, and dense. Ears are small and project above the fur only slightly, and the tail is short and very thickly clothed with hairs that completely cover the scales. The pollex possesses a distinct claw; forefeet are strong and digits II through V possess long and sharply pointed claws. Hindfeet are short and broad, also furnished with strong claws and possess a fringe of hairs along their lateral margins, although these are less developed than in *Notiomys*. The palms and soles are naked; the plantar skin of the hindfeet is squamate, and six large, rounded, and prominent pads are present; pedal digit V has a well-developed claw that reaches the second phalanx of dIV (Gyldenstolpe 1932).

The skull is robust, with a relatively short and broad rostrum, nearly quadrangular braincase, noninflated frontals, an arcuately biconcave interorbital region with non-

squared supraorbital edges, a comparatively well-developed although narrow interparietal, broad and nearly vertical to slightly inclined forward zygomatic plates, a palate that extends to (*C. macronyx*) or slightly posteriorly past the molars (*C. megalonyx*), small or indistinct posterolateral palatal pits, a deep and broad mesopterygoid fossa with a rounded to square anterior border, and comparatively deep parapterygoid fossae (Gyldenstolpe 1932; Reig 1987). The carotid circulation pattern is type 1 (*sensu* Voss 1988), characterized by an enlarged carotid canal and stapedia foramen and the supraorbital branch of the stapedia artery visible as a groove along the inferior surface of the squamosal and alisphenoid bones and exiting through a sphenofrontal foramen or anterior alar canal. An alisphenoid strut is absent. The mandible is strongly built, with the ramus much deeper than in *Geoxus*, *Notiomys*, or *Pearsonomys*. The coronoid process is long and strong, and the capsular projection is of medium size (Reig 1987).

The upper incisors are fairly thick and robust, ungrooved, and proodont (*C. megalonyx*) or orthodont (*C. macronyx*). Molars are moderately high, with a greater degree of hypsodonty than in other members of the tribe, rather large and broad in *C. macronyx* and smaller in *C. megalonyx*. M1 has a moderately reduced procingulum without an anteromedian flexus; a parastyle is well developed. Upper molars have the para- and metaflexus strongly oriented backward; there is no mesoflexus on any teeth, as the para- and mesoloph are completely fused; a mesostyle is normally absent, and an enterostyle is totally missing. M3 is relatively well developed, about two-thirds the length of M2. The lower first molar (m1) has an anterior-posteriorly compressed procingulum without an anteromedian flexid in adult individuals and a well-developed prostylid. All lower molars have oblique ento- and postero-flexids, a more transverse metaflexid, coalesced mesoloph and paraloph, and lack both a mesostylid and ectostylid. The third lower molar is sigmoid-shaped, not reduced, more than three-quarters the length of m2 (Reig 1987).

Vertebral counts in nine individuals were 13 thoracic, six lumbar, and 20–22 caudal; the rib count was 13 (Stepan 1995).

Unlike *Notiomys* and *Geoxus*, *Chelemys* has a very large cecum (Pearson 1984). The stomach is unilocular-hemiglandular (Pardiñas, Udrizar Sauthier et al. 2008). *Chelemys macronyx* has a gall bladder (Voss 1991a); its presence is unknown for *C. megalonyx*.

SYNONYMS:

Hesperomys: Waterhouse, 1845:154; part (description of *megalonyx*).

Oxymycterus Gay, 1847:108; part (description of *sca-lops*); incorrect subsequent spelling of *Oxymycterus* Waterhouse.

Oxymycterus: Philippi, 1872:445; part (inclusion of *megalonyx* and *scalops*).

Acodon Thomas, 1894b:362; part (description of *macronyx*).

Akodon: E.-L. Trouessart, 1897:538; part (listing of *megalonyx* and *macronyx*).

Mus: Philippi, 1900:57; part (description of *microtis*).

Akodon (*Chelemys*) Thomas, 1903c:242; type species *Hesperomys megalonyx* Waterhouse, as subgenus.

Chroemys: Thomas, 1916i:340; part (described as subgenus, included *scalops* Gay).

Chelemys: Thomas, 1919b:207; first use intended to represent a valid genus.

Notiomys: Osgood, 1925:121; part (listed *megalonyx*, *macronyx*, and *vestitus* as species; described *connectens* as species and *alleni* as subspecies of *vestitus*).

REMARKS: *Oxymycterus delfini* Cabrera 1905 (type locality: "Punta Arenas") is known only by the type specimen, which is lost (Osgood 1943b:166; Cabrera 1961:471). This form was treated as allied to *Notiomys vestitus alleni* (= *Chelemys macronyx*) (Osgood 1925), *C. megalonyx* (Mann 1978; Tamayo and Frassinetti 1980), or as a distinct species under the genera *Microxus* (Tate 1932h) or *Chelemys* (W. E. Johnson et al. 1990; Musser and Carleton 2005). Our evaluation of the original description casts doubt on the generic allocation of *delfini*. First, even though the external measurements of *delfini* are broadly consistent with those reported for large series of *Chelemys*, their combination seems unlikely in the same individual, as first noted by Osgood (1943b:166). Second, the greatest length of the skull and upper molar length are much less than those of typical *C. macronyx* (e.g., upper toothrow length=4.5 mm in *delfini* vs. 5.4–5.9 in *C. macronyx* [B. D. Patterson 1992a]). According to the original description, *delfini* has a nearly uniform coloration, and its tail annulations are clearly visible (Cabrera 1905:15). By contrast, both known *Chelemys* species generally show countershading and have very thickly haired tails in which the hairs hide the scale annulations (B. D. Patterson 1992a). Finally, as Cabrera (1905:16) stated, "El tercer molar inferior es casi como una tercera parte del que le precede" [the third lower molar is almost a third of the preceding one (translation ours)]. This dental feature is especially different from the condition in *Chelemys*, where m3 is almost equal in size to m2. Thus, the inclusion of *delfini* Cabrera in *Chelemys* lacks convincing support.

Our comparisons with other southern abrotrichines, including *Abrothrix lanosa*, *A. olivacea*, and *Geoxus valdivianus*, suggest to us a connection between *delfini* and *Geoxus*, especially southern populations usually included in the subspecies *G. v. michaelsoni*. Both *delfini* and *michaelsoni* have a uniformly dark color and, most importantly, small third lower molars. We thus consider *Oxymycterus delfini* Ca-

brera a junior synonym of *G. v. michaelsoni*, a decision that has two major taxonomic consequences. First, *Chelemys* has only two living species, not three as has been listed in recent compendia (e.g., Musser and Carleton 2005). Second, the southernmost limits of *Chelemys* are at about 50°30'S, not at a point farther to the south.

As currently understood, *Chelemys* is not monophyletic, based on phylogenetic analysis of both mitochondrial and nuclear DNA sequences, with *C. megalonyx* the sister to *Notiomys edwardsi* rather than to its present congener *C. macronyx* (Rodríguez-Serrano, Palma, and Hernández 2008; Feijoo et al. 2010; Teta, D'Elía, Pardiñas et al. 2011). If the current abrotrichine generic classification is to be maintained (i.e., *Chelemys* to be considered a genus separate from *Notiomys*), a new generic name to contain *C. macronyx* is needed.

KEY TO THE SPECIES OF CHELEMYS:

1. Skull robust; incisors orthodont; anterior borders of zygomatic plates nearly vertical; anterior border of mesopterygoid fossa even with posterior face of M3; bullae small; width of manus about 5 mm *Chelemys macronyx*
- 1'. Skull more delicate; incisors proodont; anterior borders of zygomatic plates moderately slanted posteriorly upward; anterior border of mesopterygoid fossa posterior to the M3; bullae larger; width of manus about 7 mm *Chelemys megalonyx*

Chelemys macronyx (Thomas, 1894)

Andean Long-clawed Mouse

SYNONYMS:

Acodon macronyx Thomas, 1894b:362; type locality "East side of the Andes, near Fort San Rafael, Province of Mendoza," Argentina. Pearson and Lagiglia (1992; see also Reise and Gallardo 1990:79; Pearson and Christie 1991:126) questioned the designated type locality, arguing that the actual provenance was probably near Volcán Peteroa, on the Argentinean-Chilean border.

Akodon (*Chelemys*) *vestitus* Thomas, 1903c:242; type locality "Valle del Lago Blanco, Cordillera region of Southern Chubut Territory, Patagonia," Argentina; further restricted to "Estancia Valle Huemules (45.94°S, 71.91°W, 593 m, Río Senguerr, Chubut)" by Pardiñas et al. (2007:406).

Chelemys vestitus: Thomas, 1919b:207; name combination.

Notiomys connectens Osgood, 1925:120; type locality "Villa Portales [38.45°S, 71.37°W], Province of Cautin [Araucanía], Chile. Altitude 3,300 ft."

Notiomys macronyx: Osgood, 1925:122; name combination.

Notiomys vestitus: Osgood, 1925:123; name combination.

Notiomys vestitus alleni Osgood, 1925:124; type locality “upper Rio Chico, Santa Cruz, southern Argentina.” Our reconstruction of the itinerary followed by J. B. Hatcher (1903), the collector of the type specimen, indicates that this locality is Estancia Tucu Tucu (ca. 48.42°S, 71.78°W), Río Chico, Santa Cruz, Argentina.

Chelemys vestitus fumosus Thomas, 1927d:654; type locality “Sierra de Pilpil, 2000m,” about 15 km S San Martín de Los Andes (40.20°S, 71.25°W), Lácar, Neuquén, Argentina.

Chelemys macronyx: Gyldenstolpe, 1932a:126; first use of current name combination.

Chelemys vestitus vestitus: Gyldenstolpe, 1932a:126; name combination.

Chelemys connectens: Gyldenstolpe, 1932a:127; name combination.

Chelemys vestitus alleni: Gyldenstolpe, 1932a:127; name combination.

Notiomys macronyx macronyx: Osgood, 1943b:159; name combination.

Notiomys macronyx vestitus: Osgood, 1943b:162; name combination.

Notiomys macronyx alleni: Osgood, 1943b:165; name combination.

Notiomys vestitus fumosus: Ellerman, 1941:425; name combination.

DESCRIPTION: Large and robust, with relatively short ears and tail (total length 182–209 mm; tail length 52–63 mm); claws on forefeet long (ca. 6–7 mm); fur thick and short, dark olive brown to dark coffee dorsally and buffy brown to grayish or whitish on venter. Ventral color often extends onto sides, sharply demarcated from dorsum in most individuals. Average mass 66.7 g (range 43–86 g; Pearson 1983). Skull characterized overall by robustness (greatest length 30.4–32.2 mm), squared outline, and broad rostrum; zygomatic plates high, with anterior borders nearly vertical and without upper free borders; incisive foramina long, reaching protocones of M1s; anterior border of mesopterygoid fossa even with posterior faces of M3s; bullae small; upper incisors orthodont, faced with pale orange enamel; molars large and heavy (upper toothrow 5.4–5.9 mm) with developed mesoloph usually fused to paracones. Both B. D. Patterson (1992a) and Kelt (1994) provided external and cranial measurements.

DISTRIBUTION: *Chelemys macronyx* occurs in the southern Andean portions of Argentina and Chile, from about 33.5°S south to 52°S. Most of its range is in Argentina, where the species is mainly found in a narrow band of high-elevation open areas and forested environments, from southwestern Mendoza to southwestern Santa Cruz provinces (Osgood 1943b; Pardiñas, Teta et al. 2003; Pardiñas,

Udrizar Sauthier et al. 2008; V. L. Roldán 2010). Scattered, isolated populations occur through central Patagonia in suitable environments (Teta et al. 2002; Pardiñas, Teta et al. 2003). In Chile, *C. macronyx* is known from mainly along the Andes, but in the southernmost portion of its distribution it reaches lowlands close to the Pacific Ocean. The northernmost record for Chile is based on a specimen (LCM 1761) collected with the type series of *Loxodontomys pikumche* (Spotorno, Cofre et al. 1998; Teta, Pardiñas, and D’Elía 2011). Remarkably, *C. macronyx* is absent from several well-studied communities in the Valdivian forest, such as those at La Picada, Osorno (B. D. Patterson et al. 1989), and Fundo San Martín (Murúa et al. 1987, in which article the name “*Chelemys* spp.” [pg. 730] refers to *Pearsonomys*).

The known fossil record of *C. macronyx* is restricted to the Holocene of Argentinean Patagonia (Pearson and Pearson 1993, Pardiñas 1998, 1999a; Teta, Andrade, and Pardiñas 2005; Udrizar Sauthier 2009). This rodent has been extralimitally recorded in Late Holocene assemblages both in northwestern Patagonia (Pilcaniyeu; Teta, Andrade, and Pardiñas 2005) and the southernmost mainland (Pali Aike; Pardiñas, Teta, Formoso, and Barberena 2011). However, the species is absent in the Late Pleistocene-Holocene sequence of Cueva del Milodón (Simonetti and Rau 1989; U. F. J. Pardiñas, unpubl. data), an area where it is present today. Both situations suggest that this species experienced one or more expansion-retraction events, involving hundreds of kilometers (Teta, Andrade, and Pardiñas 2005; Pardiñas, Teta, Formoso, and Barberena 2011). This dynamic is supported by phylogeographic analyses of mtDNA cytochrome-*b* gene sequences (Alarcón et al. 2011).

SELECTED LOCALITIES (Map 53): ARGENTINA: Chubut, 41 km W of Alto Río Senguerr (CNP-E 473), Cabaña Arroyo Pescado (CNP-E 327), Cholila (CNP-E 135), Establecimiento La Ollada (CNP-E 291), Estancia San Pedro (Teta et al. 2002), Estancia Santa María, Puesto El Chango (CNP-E 328), Paso del Sapo (Pardiñas, Teta et al. 2003), Sierra de Tepuel, Cañadón de la Madera (CNP 2374), 4 km S of Tres Banderas (CNP-E 75); Mendoza, Cerro Colorado (Alarcón et al. 2011), Laguna del Diamante (OMNH 23520), Laguna de la Niña Encantada (Massoia et al. 1994a; CNP-E 55); Neuquén, Arroyo Covunco and RNN°40 (CNP-E 87), Cueva Trafal I (CNP-E 595), 12 km NE of Refugio Parque Provincial Tromen (CNP-E 529); Río Negro, Cañadón Quetrequile (CNP-E 284), Puesto de Hornos, Estancia Maquinchao (Teta et al. 2002); Santa Cruz, Alero Destacamento Guardaparque (CNP-E 103), 8 km N of El Chaltén (CNP-E 418), Cerro Comisión (CNP-E 413), Cueva de las Manos (CNP-E 47). CHILE: Aysén, 3 km N of Coyhaique, Reserva Nacional

Coyhaique, Laguna Venus (Kelt 1996), Osorno, Paso Puyehue (Reise and Venegas 1987), Sector el Manzano (Alarcón et al. 2011); Araucanía, Paso de Las Raíces, 58 km W of Curacautín (Reise and Venegas 1987); Biobío, 7 km below Termas Chillán (Reise and Venegas 1987); Magallanes y Antártica Chilena, Cueva del Milodón (U. F. J. Pardiñas, unpubl. data), Laguna Lazo, Lake Sarmiento, Última Esperanza (Osgood 1943b); Maule, Baño San Pedro, Romeral (MNHNC 298 JCT); Santiago, Las Melosas (Pardiñas, Teta, Formoso, and Barberena 2011).

SUBSPECIES: Although four trinomials have been used for *C. macronyx*, the reality of these supposed taxa has never been evaluated by a rigorous assessment of morphological variation. A phylogeographic analysis based on mtDNA sequences retrieved a shallow genealogy for *C. macronyx* that is geographically structured into two well-supported and allopatric clades. One of these is distributed at high-Andean localities in the Argentinean provinces of Mendoza and northern Neuquén, and the other clade occupies most of the distributional range of the species at medium- to low-elevation localities in northwestern Neuquén, Chubut, and Santa Cruz provinces in Argentina as well as Aysén and Magallanes y Antártica Chilena regions in Chile. The northern clade appears to have been demographically stable, while the southern clade shows a signal of recent demographic expansion. Divergence between the two main clades found is limited (i.e., 2.3% at the mtDNA cytochrome-*b* gene), supporting a relatively recent origin, with expansion from late Pleistocene refugia. A study in progress, based on cranial anatomy and metrics, indicates two distinct morphotypes in *C. macronyx* that are congruent with the phylogroups uncovered by Alarcón et al. (2011). Northern samples are characterized by a mesopterygoid fossa with a rounded anterior border and both large and nearly circular foramina ovale; central and southern samples have a squared anterior border to the mesopterygoid fossa and ovate to piriform foramina ovale. One of us (PT) believes that two subspecies are recognizable, the nominotypical *C. m. macronyx* for northern samples and *C. m. vestitus* for central and southern ones. Under this treatment, *alleni* Osgood, for which a haplotype from a topotypic specimen was included in the Alarcón et al. (2011) study, is a junior synonym of *vestitus* Thomas. The same would likely apply to *fumosus* Thomas, for which haplotypes recovered from specimens collected near its type locality belong to the central-southern clade. Further analyses incorporating larger geographic coverage, especially in Chile, combined with variation at nuclear loci are needed to test this hypothesis.

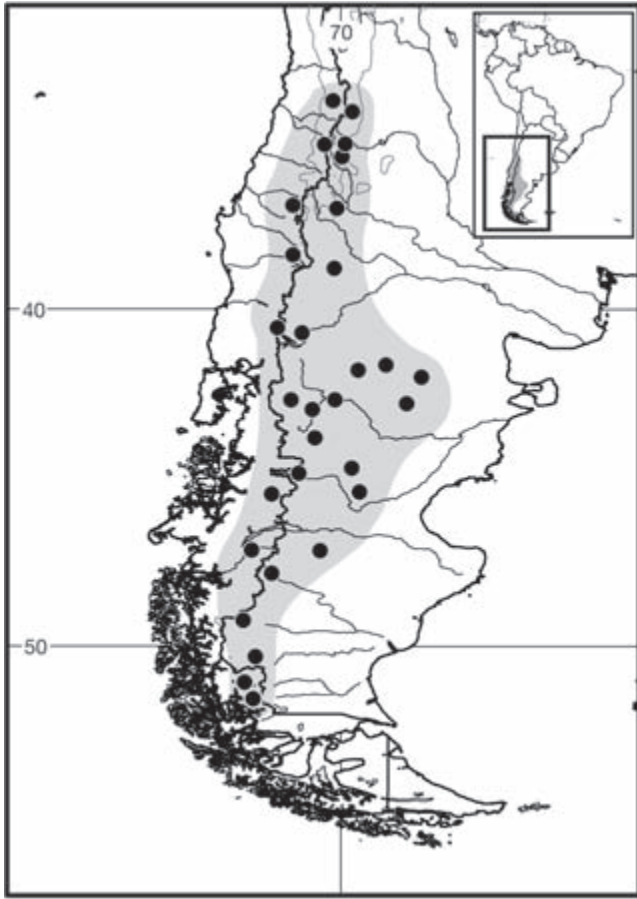

NATURAL HISTORY: *Chelemys macronyx* lives primarily in *Nothofagus pumilio* forest, from timberline to the edge of the precordilleran steppe (Pearson 1983). It

also occurs in moist habitats or under shrubs in semiarid steppes or in areas of lush grasses and loose soils with scattered canopy of *N. pumilio* or *N. antarctica* (Pearson 1983; Kelt 1994). In Malleco, Chile, it prefers deep soils in forested to shrubby areas (Greer 1966). This mouse is primarily subterranean, and can be both diurnal and nocturnal. During winter, *Chelemys* constructs networks under the snow, especially in areas with a dense cover of amancay lilies (*Alstroemeria aurantiaca*) in *Nothofagus* forests. Such networks may cover almost one-third of the surface over an area of 10–30 m² (Pearson 1984). Stomach contents have included arthropods, green vegetable matter, and fungi (Pearson 1983).

Population densities in mixed *Nothofagus betuloides*–*N. pumilio* forest and in pure stands of *N. antarctica* in Río Negro province, Argentina, varied between 1.1 (November) and 14.7 (May) and 0 (November) and 1.3 (May) individuals per hectare, respectively (Pearson and Pearson 1982). In a high elevation shrubby area (>2,000 m) in central Chile, Mella (2006) found densities that varied between 1.6 (spring) and 17.2 (summer). Testes in reproductively active males ranged from 11 to 14 mm long, and vesicular glands were 10 mm or longer (Pearson 1983). Both Pearson (1983) and Kelt (1994) described the age structure and reproductive cycles. The breeding season seems to begin abruptly when the ground is still covered by snow and continues for a considerable period during spring and summer. Individuals of both sexes may begin breeding before reaching full adult size (Pearson 1983). One pregnant female carried four embryos, another five (Pearson 1983). The autumn population included two age groups, one composed of young of the year and the other of adults >1 year in age; the spring population was composed almost entirely of adults born the preceding spring or summer (Pearson 1983). Individuals born at the beginning of the reproductive season do not venture from their burrows until late spring (Kelt 1994).

REMARKS: Both Mann (1978) and Tamayo Frassinetti (1980) considered *Chelemys macronyx* to be a subspecies of *C. megalonyx*. According to Osgood (1943b), *Notiomys connectens* Osgood (1923) is a composite of a *Chelemys* skin and an *Abrothrix* skull; to fix the name, Osgood (1943b) selected the skin as the holotype of *connectens* and placed the name in his synonymy of *Notiomys macronyx vestitus*. *Chelemys angustus* Thomas, 1927, was based on a specimen of *Abrothrix longipilis* (see Pearson 1984).

Specimens from southwestern Mendoza and considered to be topotypes have $2n=54$, $FN=62$, and four microchromosomes (A. A. Ojeda et al. 2005). Specimens from Bariloche (Argentina), Paso de Pino Hachado, and Coyhaique

Map 53 Selected localities for *Chelemys macronyx* (●). Contour line = 2,000 m.

(Chile) show the same autosomal complement but differ in the number of microchromosomes (unpubl. data cited by A. A. Ojeda et al. 2005). It is noteworthy that Pearson (1984) reported a $2n = 52$ complement for individuals from Bariloche and Castaño Overo, northwestern Patagonia. The biological and taxonomic significance of these differences remain unclear.

Chelemys megalonyx (Waterhouse, 1845)

Chilean Long-clawed Mouse

SYNONYMS:

Hesperomys megalonyx Waterhouse, 1845:154–155; type locality “Chile . . . Lake of Quintero,” Valparaíso, Chile.

Oxymycterus scalops Gay, 1847:108; type locality “campos de las provincias centrales,” Chile.

A[codon] megalonyx: Thomas, 1894b:362; name combination.

Akodon megalonyx: E.-L. Trouessart, 1897:538; name combination.

Mus microtis Philippi, 1900:57; type locality “E provincia Maule,” Chile.

Akodon (Chelemys) megalonyx: Thomas, 1903c:242; name combination.

Notiomys megalonyx: Osgood, 1925:12; name combination.

Chraeomys scalops: Gyldenstolpe, 1932a:123; name combination.

Chelemys megalonyx: Gyldenstolpe 1932a:126; first use of current name combination.

Notiomys megalonyx megalonyx: Osgood, 1943b:157; name combination.

Notiomys megalonyx microtis: Osgood, 1943b:158; name combination.

DESCRIPTION: Medium-sized, mole-like mouse, with elongated front claws (<6 mm), thick pelage, and short tail (total length <180 mm; tail <60 mm); fur long, soft, nearly uniform grayish brown above and grayish white below; chest with brown mark; tail uniformly brown. Skull more elongated and gracile than that of *C. macronyx*; frontal sinuses well inflated; nasals narrow with parallel borders; nasofrontal suture U-shaped and extends posteriad to level of lacrimals; braincase globose; zygomatic plates without upper free border, with anterior margins convex and inclined backward with noticeable masseteric-like tubercle; incisive foramina do not reach beyond anterior faces of M1s; palate long and flat; mesopterygoid roof fully ossified or with vacuities reduced to narrow slits; bullae well inflated; incisors proodont, with pale orange to whitish enamel; upper molar series slightly divergent anteriorly; molars comparatively small and narrow (upper toothrow <5 mm); M3 more reduced than in *C. macronyx*.

DISTRIBUTION: This species is known from only a few scattered localities in an apparently disjunct distribution in coastal central Chile (Osgood 1943b; Mann, 1978). In the north, it is limited to the Coquimbo to Santiago regions and in the south to Araucanía, and presumably Maule regions, with no records from intervening regions.

SELECTED LOCALITIES (Map 54): CHILE: Araucanía, Comuna de Victoria, cuenca del Río Quino, near Curacautín (V. Quintana 2009), Temuco (Osgood, 1943b); Coquimbo, Parque Nacional Fray Jorge (UACH 1462, 2732); Santiago, Rinconada de Maipú (MNHN 1545, 1546; J. Yáñez, pers. comm.); Valparaíso, La Ligua (USNM 391799), Lake of Quintero (Waterhouse 1845), Olmué (Osgood 1925), Valparaíso (Osgood 1943b).

SUBSPECIES: Osgood (1943b) recognized two subspecies, the nominotypical *C. m. megalonyx* (Waterhouse), found around Valparaíso in the north, and *C. m. microtis* (Philippi), with type locality unspecified but somewhere in Maule province, in the southern portion of the distribution. As noted by Osgood (1943b), the inclusion of *microtis*

Philippi in *C. megalonyx* is questionable, as some measurements of the holotype (tail length, hindfoot length) are much smaller than typical of *megalonyx*. Apparently, the only known specimen collected at a precisely known locality, and referable without question to Philippi's *microtis*, is BM 8.3.1.15 from Temuco (identified by Osgood 1943b:159). We provisionally assign specimens reported by V. Quintana (2009) from a forest fragment near Curacautín to Philippi's *microtis*, although no voucher was preserved and both an available photograph and measurements taken in the field are equivocal. It is possible that this record is of *C. macronyx*, not *C. megalonyx*. The presence of *C. megalonyx* in the lowlands of south-central Chile requires adequate documentation. No recent study has assessed the distinction between the two subspecies recognized by Osgood (1943b).

NATURAL HISTORY: Almost nothing is known about the ecology of this rodent. It is semifossorial and digs tunnels, preferably in humid soils, with burrow openings usually protected by rocks, shrubs, or fallen logs (Mann 1978). Koford (1955) mentioned the capture of one individual between shrub and cactus at the foot of a long steep slope. Mann (1978) reported this rodent in dense mesophytic forest and shrubby coastal areas. *Chelemys megalonyx* appears to be rare, or at least very difficult to trap. Recently collected specimens come from Parque Nacional Fray Jorge, a protected

area of arid Mediterranean thorn-scrub with remnants of fog forests at higher elevation near the city of Coquimbo, and from disturbed forest along the Río Quino in the municipality of Victoria, Malleco province (V. Quintana 2009).

REMARKS: Mann (1978) and Tamayo and Frassinetti (1980) listed *delfini* Cabrera (see Remarks under genus), along with *macronyx* Thomas, as subspecies of *C. megalonyx*. *?Oxymycterus niger* Philippi, 1872:445 has been considered a synonym of this species by some authors (e.g., Gyldenstolpe 1932:126), presumably following the tentative remarks made by Osgood (1925:122). However, the holotype of *niger* is lost, and, as recognized by Osgood (1925, 1943b), the allocation of *niger* to *megalonyx* is uncertain.

Genus *Geoxus* Thomas, 1919

Pablo Teta, Ulyses F. J. Pardiñas, and Guillermo D'Elía

The monotypic genus *Geoxus* is mostly restricted to humid habitats, such as forest, shrublands, and wetlands; in Chile from about 36°S south to Fuerte Bulnes (53°40'S) and in Argentina from 39°S to Santa Cruz province (47°S; Osgood 1943b; Pearson 1995). Osgood (1925, 1943b) reviewed the genus as part of his broad concept of *Notiomys*. Thomas (1927d) was the first to defend generic status, a position later promoted by Pearson (1984; see Reig 1987). Maximum parsimony and likelihood analyses of mtDNA cytochrome-*b* and nucDNA sequences suggested that *Geoxus* is closely related to *Pearsonomys* (M. F. Smith and Patton 1999; D'Elía, Ojeda et al. 2006). However, as currently conceived, the genus is non-monophyletic because northern populations form a clade sister to *Pearsonomys* with southern populations sister to that clade (E. P. Lessa et al. 2010; see further discussion in the tribal account). Except as noted, the following account is based on Osgood (1943b) and Pearson (1983, 1984), each of whom should be consulted for further details (see also B. D. Patterson 1992a). Our descriptions of the skull and molars are taken from Reig (1987).

The body shape is highly modified for fossorial life. The size is small (head and body length about 96 mm, tail length 45 mm, and mass 25 g). The fur is velvety and mole-like; the upper parts vary from blackish brown to olive brown, and the under parts are only slightly paler than the upper parts, slaty gray to brown. The ears are small but pinnae are visible externally; the tail is shorter than half the length of head and body, may be unicolored or indistinctly bicolored, and is very thickly clothed with hairs that conceal the scales. The pollex and other digits of the forefeet have long and strong claws; those of the hindfeet are much shorter, without a fringe of hairs along their lateral margins. Both palms and soles are naked, with pads smooth and rounded (Gyldenstolpe 1932; Reig 1987).

Map 54 Selected localities for *Chelemys megalonyx* (●); distribution is mapped as disjunct (see Subspecies). Contour line = 2,000 m.

The skull is slender and rather delicately built, with a long and narrow rostrum. The premaxillary bones extend to or end slightly anterior to the nasals; the frontal region is inflated; the interorbital region has smooth and rounded sides so that supraorbital edges are not square shaped; and the interparietal is narrow and short. In lateral view, the zygomatic plates are reduced, narrow, and slanted posteriorly from bottom to top; the alisphenoid is anteriorly expressed to hide the (sometimes incomplete) sphenofrontal foramen and the anterior lacerate foramen. The incisive foramina are long, extending to or between the anterior borders of M1; the palate is long, extending slightly behind the level of the third molars, and lacks posterior palatal pits. The pterygoid region is long; the mesopterygoid fossa has nearly parallel sides and a squared anterior border. The stapedial process of the bulla is fused to the parapterygoid. The mandible is particularly slender, with a smooth diastema, short coronoid process, and small capsular projection; the condyloid process not inclined inward (Reig 1987).

The incisors are rather slender, and the upper ones orthodont. The molars are small, narrow, simple, and brachyodont. The upper molars have transversely oriented para- and metaflexi, a mesoflexus is absent, and the para- and mesoloph are coalesced; both mesostyle and anterostyle are missing. M1 has a reduced procingulum, shallow anteroflexus, and no anteromedian flexus. [M3 is greatly reduced, less than two-thirds the length of M2, without a metacone and round in occlusal view. The lower molars have transverse lophids and flexids with little infolding. The procingulum of m1 is narrow and lacks an anteromedian flexid, and a protostylid is present; m3 is also reduced, less than three-fourths the length of M2, and with a simplified enamel pattern (Reig 1987).

The axial skeletal elements in *Geoxus* have modal counts of 13 ribs and 13 thoracic, six lumbar, and 20–23 caudal vertebrae (Steppan 1995).

The stomach is unilocular hemiglandular. The antrum, which is covered by glandular epithelium, is larger than the corpus, which in turn is mostly covered by cornified epithelium; glandular epithelium from the antrum extends to the corpus and surpasses to the left of the esophageal orifice (Carleton 1973). A caecum is absent (Reig 1987), but a gall bladder is present (Voss 1991a).

The penis of *Geoxus* has a prominent dorsal hood extending beyond the terminal crater; there are large urethral flaps, with each bearing at its distal end a medially directed spine, and three cartilaginous digits, with the central one larger than both laterals and with its tip protruding from the crater. The baculum is ventrally keeled and has a rounded and prominent head. Its base resembles an equilateral triangle with a notch on its proximal face (Hooper and Musser 1964). *Geoxus* has two pairs of preputial glands, a large

pair lying lateral to the glans penis and a much smaller pair near the midventral margin of the prepuce; these glands do not exceed the prepuce in length. The bulbourethral, dorsal and anterior prostates, and ampullary glands are unusually large and well developed (Voss and Linzey 1981).

SYNONYMS:

Oxymycterus: Philippi, 1858:303; part (description of *valdivianus*).

[*Acodon*]: Thomas, 1894b:362; part (description of *macronyx*).

Acodon (Chelemys): J. A. Allen, 1905:80; part (listing of *michaelseni*).

Geoxus Thomas, 1919b:208; type species *Geoxus fossor* Thomas, by original designation.

Notoxus Thomas, 1919b:209; *lapsus calami* for *Geoxus* Thomas.

Notiomys: Osgood, 1925:115; part (listing of *valdivianus*, *fossor*, and *michaelseni*; description of *auraucanus* and *chiloensis*).

Geoxus valdivianus (Philippi, 1858)

Valdivian Long-clawed Mouse

SYNONYMS:

Oxymycterus valdivianus Philippi, 1858:303; type locality "Valdivia," Los Ríos, Chile.

[*Acodon*] *valdivianus*: Thomas, 1894b:363; name combination.

Hesperomys (Acodon) michaelseni Matschie, 1898:5; type locality "Süd-Patagonien, Punta Arenas," Magallanes y Antártica Chilena, Chile.

Mus (Oxymycterus) valdivianus: Philippi, 1900:21; name combination.

Oxymycterus microtis J. A. Allen, 1903b:189; type locality "Pacific slope of the Cordilleras, near the head of the Río Chico de Santa Cruz," Argentina. Our reconstruction of the itinerary followed by J. B. Hatcher and O. A. Peterson, the collectors of the type specimen, indicates that this locality corresponds to a point in front of Estancia Tucu Tucu (ca. 48.46°S, 71.98°W), Río Chico, Santa Cruz, Argentina.

Akodon (Chelemys) michaelseni: J. A. Allen, 1905:80; name combination.

Notiomys michaelseni: E.-L. Trouessart, 1904:436; name combination.

Notiomys microtis: E.-L. Trouessart, 1904:436; name combination.

Geoxus fossor Thomas, 1919b:208; type locality "Maiten [= El Maitén, Cushamen], W. Chubut. 700m," Argentina.

- Notoxus fossor*: Thomas, 1919b:209; *lapsus calami*.
N[otoxus?]. microtis: Thomas, 1919b:209; name combination.
[Geoxus] michaelsoni: Thomas, 1919b:209; name combination.
N[otoxus?]. michaelsoni: Thomas, 1919b:209; name combination.
[Geoxus] valdivianus: Thomas, 1919b:209; first use of current name combination.
Notiomys valdivianus: Osgood, 1925:115; name combination.
Notiomys valdivianus araucanus Osgood, 1925: 117; type locality “Tolhuaca, Province of Malleco, [Araucanía,] Chile.”
Notiomys valdivianus chiloensis Osgood, 1925:117; type locality “Quellon [= Quellón], Chiloe Island [Isla Grande de Chiloé, Los Lagos,] Chile.”
Notiomys fossor: Osgood, 1925:118; name combination.
Geoxus valdivianus valdivianus: Gyldenstolpe, 1932a:124; name combination.
Geoxus valdivianus araucanus: Gyldenstolpe, 1932a:125; name combination.
Geoxus valdivianus chiloensis: Gyldenstolpe, 1932a:125; name combination.
Notiomys valdivianus bullocki Osgood, 1943b:154; type locality “Mocha Island, coast of southern Chile, Province of Arauco [Biobío].”
Notiomys valdivianus valdivianus: Osgood, 1943b:151; name combination.
Notiomys valdivianus bicolor Osgood, 1943b:155; type locality “Casa Richards, Rio Nirehuao [= Río Ñirehuao], [Aysén,] Chile. Lat. 45°3'S [45.260°S, 71.705°W].”
Notiomys valdivianus michaelsoni: Osgood, 1943b:156; name combination.
Notiomys valdivianus fossor: Cabrera, 1961:473; name combination.
G[eo]xus. v[aldivianus]. fossor: Pearson, 1984:232; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: Chile from about 36°S, including Mocha and Chiloé islands, to the Straits of Magellan; and southwestern Argentina, in *Nothofagus* forests and precordilleran steppes, from central Neuquén province south to Santa Cruz province (Osgood 1943b; Pearson 1983, Pardiñas, Teta et al. 2003). Saavedra and Simonetti (2001) reported isolated populations in coastal patches of temperate forest in central Chile. The fossil record is restricted to Holocene deposits in the Argentinean Patagonia (Pearson and Pearson 1993; Pardiñas 1998, 1999a).

SELECTED LOCALITIES (Map 55): ARGENTINA: Chubut, El Maitén (type locality of *Geoxus fossor* Thomas), 6.5 km W of bridge over Río Tecka, on RPN°17

(CNP-E 323), Capilla El Triana (CNP-E 449); Neuquén, Cueva Trafal I (Pearson and Pearson 1993), south margin of Lago Caviahue (CNP 812), bridge on RPN°13 over Río Carreri (Pardiñas, Teta et al. 2003); Río Negro, Cerro Leones (Pearson and Pearson 1993), Cabaña Cacique Foyel (Udrizar Sauthier, Andrade, and Pardiñas 2005); Santa Cruz, near Estancia Tucu Tucu (type locality of *Oxymycterus microtis* J. A. Allen). CHILE: Aysén, ca. 15 km E of Puerto Chacabuco, 15 km S of Aysén, NW end of Lago Riesco (Kelt 1996), El Manzano (E. P. Lessa et al. 2010); Araucanía, Reserva Nacional Malalcahuello (E. P. Lessa et al. 2010), Villarica (UACH 2450); Biobío, Isla Mocha (Osgood 1943b), vicinity refugio Club Andino Alemán on W side of Chillán Volcano (Reise and Venegas 1987); Los Lagos, Isla Grande de Chiloé, Río Inio (Osgood 1943b), La Picada (UACH 3488), Puyehue (UACH 5428); Los Ríos, Costa Río Caunahue (E. P. Lessa et al. 2010), Fundo San Martín, San José, Valdivia (UACH 700); Magallanes y Antártica Chilena, Cueva del Milodón (U. F. J. Pardiñas, unpubl. data), Fuerte Bulnes (<http://www.flickr.com/photos/martinezpina/5331904118/in/photostream/>), Punta Arenas (type locality of *Hesperomys (Acodon) michaelsoni* Matschie); Maule, Reserva Nacional Los Queules (Saavedra and Simonetti 2001).

SUBSPECIES: Osgood (1943b), Cabrera (1961), and Mann (1978) each recognized six subspecies in *G. valdivianus* (*G. v. bicolor*, *G. v. bullocki*, *G. v. chiloensis*, *G. v. fossor*, *G. v. michaelsoni*, and *G. v. valdivianus*). This hypothesis has yet to be tested using modern morphological and/or molecular methodologies (also see comment under Remarks).

NATURAL HISTORY: *Geoxus valdivianus* is a forest dweller that occurs in pure and mixed stands of *Nothofagus*, although it may be caught occasionally in lush meadows or in marshes bordering forests, in areas with heavy undergrowth of cane and *Berberis* shrubs, in small clumps of *Nothofagus pumilio* surrounded by pasture, or at timberline in tussock grass with patches of *Araucaria araucana* or low bushes of *Nothofagus* (Greer 1965; Reise and Venegas 1974; Pine et al. 1979; Pearson 1983, 1984). More recently, K. García et al. (2011) caught one individual in an exotic plantation of *Pinus contorta*. Population densities in *Nothofagus* forests of Río Negro, Argentina, varied between 0.4 and 0.5 animals per hectare (Pearson and Pearson 1982). This species is active both during the day and night, and eats small invertebrates (e.g., adult and larval arthropods and annelids), vegetation, and fungi (Pearson 1983; Meserve et al. 1988). It is partially subterranean but often is found in dense litter or herbaceous vegetation in runaways alongside logs (Pearson 1983, 1984; Kelt 1994). It may use tunnels made by other rodents (e.g., *Aconaeomys*), or it may make its own burrows in soft soil rich in humus (Pearson 1983, 1984; see also Greer 1965).

Males with descended testes were caught in October, November, and December in northwestern Patagonia, Argentina (Pearson 1983); and in March and November in the Aysén region, Chile. Females in breeding condition were caught in October, November, and December in northwestern Patagonia (Pearson 1983), with an average of 3.5 embryos. Pearson (1983) documented reproduction, age structure, sex ratio, and body size in Patagonian Argentina. B. D. Patterson et al. (1989, 1990) examined the distribution, abundance, and habitat selection along an elevational gradient in a temperate rainforest of southern Chile.

REMARKS: Pearson (1984) noted the uncertainty of the generic association and specific status of *Hesperomys* (*Acodon*) *michaelseni*, and considered it perhaps allied to *Notiomys* or *Geoxus*. Pardiñas, Udrizar Sauthier et al. (2008), however, rejected the link of Matschie's *michaelseni* with *Notiomys*. Reig (1987) considered *michaelseni* as a probably valid species of *Geoxus*. Although the genus is currently viewed as monotypic, the available, although limited, molecular data indicate that samples of *G. valdivianus* are paraphyletic with respect to *Pearsonomys* (E. P.

Lessa et al. 2010), suggesting that at least two species are contained in our current concept. If so, names are available from the current list of subspecies epithets.

The diploid number of a specimen of *Geoxus* from Río Negro, Argentina, was $2n=52$, with one pair of large subtelocentric autosomes, two pairs of very small metacentrics, remaining autosomes acrocentric, a large submetacentric X chromosome, and a very small metacentric Y chromosome (Pearson 1984). Chilean specimens apparently have a $2n=56$ karyotype (M. H. Gallardo, unpubl. data, cited in D'Elía, Ojeda et al. 2006).

Genus *Notiomys* Thomas, 1890

Pablo Teta and Ulyses F. J. Pardiñas

Notiomys is the only endemic sigmodontine genus of the Patagonian steppes and tablelands of southern Argentina. Currently considered to be monotypic, containing the single species *N. edwardsii*, several other taxa were placed in *Notiomys* during the last century (see Osgood 1925, 1943b; Cabrera 1961). Pearson's (1984) revision established the current contents of the genus, clarifying the status of *angustus* Thomas (1927d; a synonym of *Abrothrix longipilis*) while placing *macronyx* Thomas (1894b; including *delfini* Cabrera [but see Remarks for *Chelemys*]), and *megalonyx* Waterhouse (1845) in *Chelemys*, and *valdivianus* Philippi (1858) in *Geoxus*. Keystone contributions that document the taxonomic history and changing contents of *Notiomys* are those of Osgood (1925), Pearson (1984), Reig (1987), and B. D. Patterson (1992a). Phylogenetic analyses based on nucDNA sequences have placed *Notiomys* as sister to *Geoxus* + *Pearsonomys* (D'Elía, Ojeda et al. 2006). However, Rodríguez-Serrano, Hernández, and Palma (2008) recovered, with low support, a sister relationship between *Notiomys* and *Chelemys macronyx*. This account is based mostly on Pardiñas, Udrizar Sauthier et al. (2008), who included detailed anatomical descriptions as well as data on distribution, natural history, and both genetic and morphological variation.

Notiomys is a small mouse with a short tail (head and both length about 86 mm, tail length about 40 mm, mass about 20 g). Its fur is not mole-like, as has sometimes been reported, but has bright colors. The dorsal pelage is dense, soft, but not long (mid-dorsal hairs about 7–8 mm in length). The dorsal head and body coloration shows an agouti effect, produced by almost entirely gray hairs with ochraceous tips; the ventral color is gray cream to white, with individual hairs basally gray and distally white. A line of hairs with their distal half orange separates the dorsal and ventral colors. The muzzle has bright orange spots laterally; the rhinarium is tipped with a pinkish, leathery button. The eyes are reduced in size (about 4 mm in diameter).

Map 55 Selected localities for *Geoxus valdivianus* (●). Contour line = 2,000 m.

The longest mystacial vibrissae (about 30 mm) are white in color and surpass the pinnae margin when appressed against the side of the head. Pinnae are small and extremely thin, edged with long and silky white hairs that make it difficult to detect their margins. The tail is whitish, slightly brownish above, and well haired. The hindfeet are short and broad, with a lateral fringe of stiff hairs extending well beyond the plantar surfaces. The fore claws are long (about 4 mm) but more weakly developed than those of *Geoxus*; the claws of the hindfeet are shorter (about 3 mm) than in *Geoxus*. Palms and soles are naked, except for the heel.

The skull is heavily built (greatest length 23.5–24.1 mm; zygomatic breadth 11.8–13.5 mm). The rostrum is short, wide, and conical. The interorbital region is especially broad (4.7–5.1 mm), amphoral or hourglass in shape, with inflated frontal sinuses and sharply squared supraorbital ridges. The interparietal is small and narrow. The braincase is short and round. The nasals and premaxillae extend anteriorly beyond the incisors, giving the rostrum a trumpet-like appearance. The zygomatic plates are tall and narrow, moderately slanting posteriorly from bottom to top to almost vertical and almost without upper free borders. The infraorbital foramina are strikingly large and flared. Incisive foramina are short, typically not reaching the level of M1; the palate is broad and long, extends well past the last molars, and has minute to large posterior palatal pits. The pterygoid region is short, with the anterior border of the mesopterygoid fossa rounded. An alisphenoid strut is absent, and the foramen ovale is confluent with the alisphenoid canal. A tunnel for a secondary arterial connection between the internal carotid and orbital-maxillary circulation is present in some individuals (e.g., MVZ 163067). A trough for the masticatory-buccinator nerve is broad but very shallow, and the squamosal-alisphenoid groove is clearly visible with a medial perforation, leading anteriorly to a medium-sized sphenofrontal foramen.

The mandible is gracile, although not as slender as in *Geoxus*, with a large and lateralized mental foramen, long and robust coronoid process, small capsular projection, and short angular process (Pearson 1984; Reig 1987). The masseteric crest is moderately developed; its inferior ridge meets the upper ridge, forming a unique crest at the level of the mental foramen.

The upper incisors are robust and orthodont, and the molars are brachyodont, with some tendency to mesodonty, and small, fairly narrow, and elongated (toothrow 3.15–3.40 mm). Coronal topography is crested (in juvenile specimens) to planate (in adults); the main cusps are arranged in an opposite pattern. M1 is trilophodont; the procingulum is fan-shaped and slightly compressed transversely with a shallow but consistently present anteromedian flexus and a mesoflexus. M2 is bilophodont with a short anteroloph

directed forward, with the paraflexus, hypoflexus, and mesoflexus each almost obsolete; a short posteroloph is directed posteriorly. M3 is simple and greatly reduced, round in outline, and less than one-half the length of M2. On the lower molars, the meso- and posteroflexids are not deeply infolded, and the lophids are oriented rather transversely; the procingulum of m1 is narrow, with a shallow anteromedian flexid, and mesolophid remnants are visible on m1; m3 is greatly reduced, rounded, and simple, less than one-half the length of M2, with a shallow hypoflexid. Both mesostyle/mesostylid and enterostyle/ectostylid are missing (Reig 1987). M1 has two large and circular roots (one anterior, one posterior); a small accessory labial root may be present under the paracone. M2 has three roots, one lingual and elliptical in outline, and two labials that are subequal and circular. M3 has a single circular root. The m1 has two large roots located along the midline of the tooth, and one reduced root on the labial side; m2 has two roots; m3 has a single circular root.

Vertebral counts of two specimens (CNP 1, MVZ 163065) are 13 thoracic, six lumbar, and 18 caudal; there are 13 ribs (three free) (Steppan 1995; Pardiñas, Udrizar Sauthier et al. 2008).

The stomach is unilocular hemiglandular (Carleton 1973). The antrum, which is covered by glandular epithelium, is larger than the corpus, which in turn is mostly covered by cornified epithelium. The glandular epithelium of the antrum extends to the corpus, surpassing the esophageal orifice (Pardiñas, Udrizar Sauthier et al. 2008). A gall bladder is present. Spotorno (1986) described the male phallus as short and barrel shaped, with tips of the distal baculum clearly protruding from the crater. The distal processes of the baculum are small with three very similar digits, tips somewhat hooked, and laterals with faint hooks. The proximal baculum has a short tip with a very well-developed base. The rounded urethral processes are proportionally large for a penis of this size.

Chelemys and *Geoxus* are larger than *Notiomys* and have mole-like fur. The claws of *Geoxus* are stouter than those of *Notiomys* and much longer than those on the hindfeet. Both *Notiomys* and *Geoxus* have tiny, almost cusplike teeth, but the skull of *Notiomys* is much shorter and wider than that of *Geoxus*. The skull of *Chelemys* is much larger than that of *Notiomys*, and its teeth are much larger and heavier (Pearson 1995). *Notiomys* also lacks a well-developed cecum like that of *Chelemys* (Pearson 1984).

SYNONYMS:

Hesperomys (*Notiomys*) Thomas, 1890:24; as a subgenus of *Hesperomys* Waterhouse; type species *Hesperomys* (*Notiomys*) *edwardsii*, by original designation.

Notiomys: Thomas, 1897a:1020; elevation to genus.

Notiomys edwardsii (Thomas, 1890)

Edwards's Long-clawed Mouse

SYNONYM:

Hesperomys (*Notiomys*) *edwardsii* Thomas, 1890:24; type locality "la Patagonia, au sud de Santa Cruz, vers 50° degré de latitude Sud" (Thomas in Milne-Edwards 1890:A.25); restricted to Puerto Santa Cruz (province of Santa Cruz, Argentina) by Pardiñas, Udrizar Sauthier et al. (2008).

DESCRIPTION: As for the genus.

DISTRIBUTION: This species occurs in shrub and herbaceous steppes and basaltic plateaus in the Argentinean provinces of Santa Cruz, Chubut, and Río Negro. The fossil record is restricted to four Holocene deposits in northern Patagonia (Pardiñas 1999a; Pardiñas, Udrizar Sauthier et al. 2008). Two of these records fall in areas where this species is not currently found, suggesting at least a wider distribution during part of the last 10 kya (Pardiñas, Udrizar Sauthier et al. 2008).

SELECTED LOCALITIES (Map 56): ARGENTINA: Chubut, Campo de Pichiñán (Pardiñas, Udrizar Sauthier et al. 2008), Colonia Nahuel Pan (G. M. Martin and Archangelsky 2004), Establecimiento La Ollada (Pardiñas, Udrizar Sauthier et al. 2008), Estancia Talagapa (Pardiñas, Udrizar Sauthier et al. 2008), Estancia Valle Huemules (Thomas 1919b), 30 km W of José de San Martín (Pardiñas and Galliari 1998a), Paso del Sapo (Pardiñas and Galliari 1998a), near Salina Grande (Pardiñas, Udrizar Sauthier et al. 2008), Subida del Naciente (CNP-E 27), 4 km S of Tres Banderas on RP 11 (Pardiñas, Udrizar Sauthier et al. 2008); Río Negro, Arroyo Pinturas (A. Andrade 2008), Campo Anexo Pilcaniyeu (Pearson 1984), Cerro Puntudo (A. Andrade 2008), Estancia Calcatreo (A. Andrade et al. 2002); Santa Cruz, Cueva de la Manos (Pardiñas, Udrizar Sauthier et al. 2008), Estancia La Ascención (G. R. Cueto et al. 2008), Estancia Laguna Manantiales (Pardiñas, Udrizar Sauthier et al. 2008), Estancia La María (CNP-E 442), Meseta del Lago Buenos Aires, nacimiento Río Ecker (CNP, not cataloged), N end of Lago Cardiel and RN 40 (Pardiñas, Udrizar Sauthier et al. 2008), Laguna del Diez (Jayat et al. 2006), Piedra Clavada (Thomas 1929), Puerto Santa Cruz (type locality of *Hesperomys* (*Notiomys*) *edwardsii* Thomas), Puesto El Cuero (CNP-E 426).

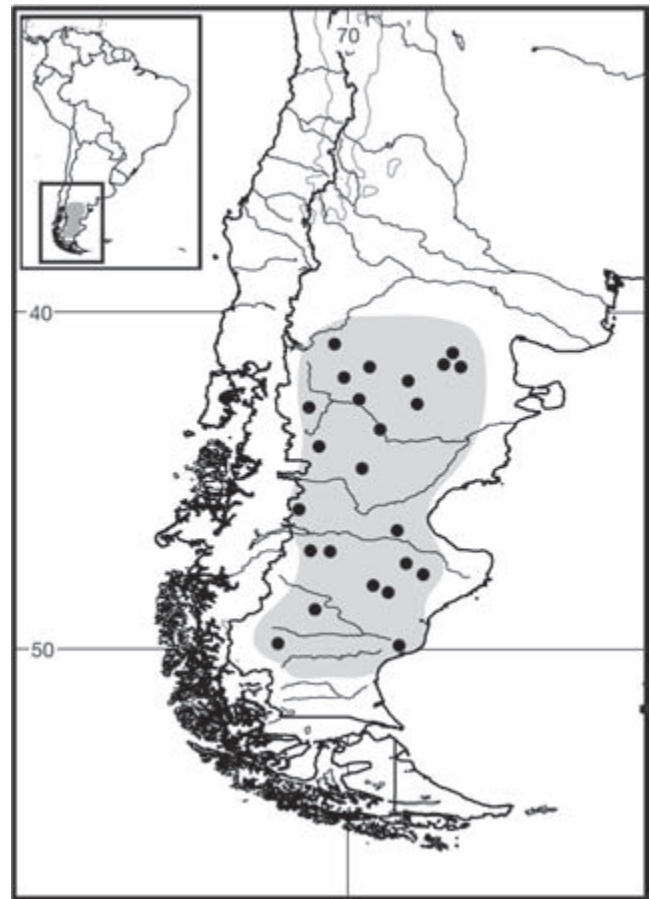

SUBSPECIES: As currently understood, *N. edwardsii* is monotypic, but see Remarks for comments on geographic variation.

NATURAL HISTORY: Little is known about this fossorial Patagonian rodent. The low trapping success in areas where owls are apparently successful at catching them suggests trap avoidance may be related to the use of traditional baits and traps. Pearson (1984) stated that *Notiomys* is found on arid steppes with sandy soil and a mixture of low

shrubs and bunchgrasses. He reported a single individual obtained in a *Ctenomys haigi* burrow (Pearson 1984). It is insectivorous, but also may eat some seeds (Pearson 1984; G. M. Martin and Archangelsky 2004). In least at some localities on the Somuncurá Plateau, it is a moderately abundant species in open grassy steppes of *Poa ligularis* and *Festuca pallescens* above 1,000m. Two young females (CNP collection) with imperforate vaginas were recorded during the summer (February and March).

REMARKS: The publication year of Thomas's description of this genus and species is sometimes cited as 1891 (e.g., Tate 1932h) or 1892 (Thomas 1929), but see Pardiñas, Udrizar Sauthier et al. (2008) who gave 1890 as the correct year of publication.

Some geographic variation in both molecular sequences and morphometric characters is known. For example, partial mtDNA cytochrome-*b* gene sequences are available for three specimens of *N. edwardsii* captured at three different localities, each with a different haplotype. Haplotypes from Campo Anexo Pilcaniyeu (41°S) and Estancia Laguna Manantiales (47.5°S), some 760 km apart, are 0.64% divergent.

Map 56 Selected localities for *Notiomys edwardsii* (●). Contour line = 2,000m.

A third haplotype, found at Laguna Blanca (41.4°S) diverges 0.75% from that of Pilcaniyeu (300 km) and 0.74% from the specimen from Manantiales (700 km) (Pardiñas, Udrizar Sauthier et al. 2008). Specimens from south of 46°S have large to very large posterolateral palatal pits, in some cases with internal subdivisions, whereas in samples from north of this latitude those pits are small to absent. There are also significant differences in some cranial measurements (zygomatic plate length, and both maxillary and mandibular molar alveolar lengths) between northern (Somuncurá) and southern (Santa Cruz) samples. Externally, specimens from southern populations are more distinctly bicolored, with more pure white on the belly and dorsal surface of the manus and pes, than those from northern populations, which generally have grayish cream venters. The systematic implications of the genetic and morphological variation, if any, remain to be explored in detail with larger and more densely distributed samples.

Until the end of the 1990s, this rodent was known from only eight localities widely dispersed across Patagonia (Pardiñas and Galliari 1998a). Today, as a result of intensified mammal surveys in the arid lands of southern Argentina, more than 50 localities are now known, based on trapped specimens or on remains recovered from owl pellets (Pardiñas and Galliari 1998a; Teta et al. 2002; Pardiñas, Teta et al. 2003; Pardiñas, Udrizar Sauthier et al. 2008).

Genus *Pearsonomys* B. D. Patterson, 1992

Guillermo D'Elía

Pearsonomys is the most recent abrotrichine genus described, but it remains poorly known. Only two reports (D'Elía, Ojeda et al. 2006; Figueroa et al. 2012) have been published since the genus was described two decades ago.

Pearsonomys comprises the single living species *P. annectens*, which was described on the basis of one specimen from the vicinity of Mehuín in the southern Chilean province of Valdivia. *Pearsonomys* has the smallest distributional range of any abrotrichine genus, being known from only five localities in a small portion of the Cordillera de la Costa, primarily in southern Chilean Valdivian temperate forest. This forest type is characterized by evergreen trees mixed with a few deciduous species that grow under conditions of high annual rainfall (1,500–3,000 mm), wet and frost-free winters, and short dry summers (see details in Murúa et al. 1987).

The description of external features that follows is mostly taken from B. D. Patterson (1992a). *Pearsonomys annectens* is of moderate size, with measurements of the holotype including total length 201 mm; tail length

77 mm; hindfoot length 27 mm; ear length 19 mm; and mass 58.5 g. D'Elía, Ojeda et al. (2006) provided external dimensions and weights of additional specimens. Males are larger than females (Figueroa et al. 2012). The tail is densely furred, unicolored, and about 60% of the head and body length. The pinnae are much larger than those of all other fossorial abrotrichines. The fur is short. Specimens housed at the Mammal Collection of the Universidad Austral de Chile display substantial variation of pelage color. Some of these, as noted by B. D. Patterson (1992a), are blackish on the dorsum and buffy on the venter; others are uniformly blackish or brown.

B. D. Patterson (1992a) described the skull of *Pearsonomys* as delicate and elongate, with nasals and premaxillae forming a trumpet. The frontal sinuses are inflated; the interorbital constriction is smoothly concave; the zygomatic plates are narrow and strongly inclined backward; the zygomatic arches are weakly developed, with the breadth across them scarcely greater than that of the braincase; and the hamular processes are well developed and separate large subsquamosal and postglenoid fenestrae. The incisive foramina are long, reaching the level of the M1s; the palate is long, extending past the posterior border of the M3s; and the bullae are longer than wide. The mandible is elongate, with the coronoid process parallel to the condyloid process and the angular process directed posteriorly.

The original description (B. D. Patterson 1992a) included few details of dental morphology, because the holotype is an old adult male with advanced tooth wear. D'Elía, Ojeda et al. (2006) subsequently described dental characteristics based on multiple specimens, noting that the teeth of *Pearsonomys* resembled those of *Geoxus*. The incisors are delicate; the upper ones orthodont, pale orange, and without grooves on the anterior surface; the lower incisors are much paler. The molar toothrows are long, narrow, and with simple occlusal surfaces that become even more simplified with wear. The upper molars are crested, with labial cusps slightly taller than lingual cusps. The principal cusps are arranged opposite one another. Flexi from opposite sides do not reach each other and are perpendicular to the main molar axis. M1 is particularly large, with a distinct and large procingulum attached to the primary cusps by a wide connecting mure, but lacking an anteroflexus; it has a shallow anteromedian flexus that disappears as tooth wear advances. The anteromedian flexus divides the procingulum into two conules; the anterolabial conule is slightly smaller than the anterolingual one. The protocone and paracone are equal in size, as the hypocone and the metacone are to each other as well. In young individuals, a small mesoloph fused to the paracone can be distinguished. Both mesostyle and enterostyle are missing. The posteroloph is

short and fused with the metacone; there is no postero-flexus. M2 has two pairs of main cusps, with the protocone and paracone slightly larger than the hypocone and metacone. M3 is reduced (less than two-thirds the length of M2), simple, and round in outline; the mesoflexus persists as a small fossette. The lower molars are crested and transversally compressed, with flexids oriented slightly posteriad. A shallow anteromedian flexid is present on m1; the anterolabial and anterolingual conulids are subequal and define a well-developed and quadrate procingulum; an anterolabial cingulum is present; the metaconid is anterior to the protoconid; the hypoflexid is wide; the entoflexid is large; a mesolophid is absent; the entoconid is anterior to the hypoconid; and the posterolophid is well developed and slightly transverse. In m2, the protoconid is clearly larger than the hypoconid; the posterolophid is well developed; and there is no mesolophid. The m3 is shorter than m2, with a large protoconid and wide hypoflexid (D'Elía, Ojeda et al. 2006).

D'Elía, Ojeda et al. (2006) described the penile morphology. A prominent dorsal hood extends beyond the terminal crater, and the urethral flaps are relatively large, each bearing at their distal end a medially directed spine. The baculum has three distal, cartilaginous digits; the central one is larger than both laterals, and its tip protrudes from the crater. The bony baculum is ventrally keeled and has a rounded and prominent head, the base of which resembles an equilateral triangle with a notch on its proximal face. Overall, the penis of *Pearsonomys* resembles that of *Geoxus* (reported on as *Notiomys valdivianus* by Hooper and Musser 1964). The presence of a dorsal hood is especially noteworthy; this structure was previously known only from *Geoxus* (but see Spotorno 1986:116), and as such Hooper and Musser (1964:27) considered it to be a diagnostic feature the later species. Spotorno (1986) studied the glans penis of several abrotrichine taxa and, in regard to *Notiomys*, made no mention of the presence of a dorsal hood. Therefore, the presence of a dorsal hood may be considered a synapomorphy of the *Pearsonomys-Geoxus* clade (D'Elía, Ojeda et al. 2006). Among abrotrichines for which male phalli have been described, that of *Pearsonomys* is tridigitate (or of the complex type described by Hooper and Musser 1964), as are those of *Chelemys*, *Geoxus*, and *Notiomys* (Spotorno 1986).

D'Elía, Ojeda et al. (2006) also described the stomach of *Pearsonomys*. It is of the unilocular-hemiglandular type (*sensu* Carleton 1973), with a single chamber and the incisura angularis barely extending beyond the opening of the esophagus. The corpus is slightly larger than the antrum. Glandular and cornified epithelia coincide almost in distribution with the antrum and the corpus, respectively. However, the glandular epithelium does cover a small area of

the corpus, because the bordering fold recurves sharply and passes to the left of the esophageal orifice. *Pearsonomys* shares the same type of unilocular-hemiglandular stomach with *Geoxus* and *Notiomys*.

SYNONYM:

Pearsonomys B. D. Patterson (1992a:132); type species *Pearsonomys annectens*, by original designation.

REMARKS: *Pearsonomys* and *Geoxus* share many morphological attributes, including a dorsal hood in the glans penis as well as details of the skull, molars, and stomach, and $2n=56$ chromosome complement (B. D. Patterson 1992a; D'Elía, Ojeda et al. 2006; M. H. Gallardo, unpubl. data, cited in D'Elía, Ojeda et al. 2006; but see also Pearson 1984). They are also sister genera in phylogenetic analyses based on molecular sequences (M. F. Smith and Patton 1999; D'Elía, Ojeda et al. 2006). D'Elía, Ojeda et al. (2006) thus questioned the placing of *annectens* in its own genus, suggesting that *annectens* may merely represent a large-sized species of *Geoxus*. Lessa et al. (2010) supported this hypothesis in a study with a larger geographic sampling, as they found *Geoxus* paraphyletic with respect to *Pearsonomys*. However, none of these authors made a formal taxonomic change, pending revision of the tribe Abrotrichini.

Pearsonomys annectens B. D. Patterson, 1992

Pearson's Long-clawed Mouse

SYNONYM:

Pearsonomys annectens B. D. Patterson, 1992a:137; type locality "Near Mehuín, 42 km N and slightly E of Valdivia, in the Provincia de Valdivia, Región de Los Lagos [now Región de Los Ríos], Chile (39°26'S, 73°10'W; Paynter, 1988), at 100 m elevation."

DESCRIPTION: As for the genus.

DISTRIBUTION: As for the genus, known from only five localities in a small fraction of the Coastal Cordillera of southern Chile. For a decade and a half following its description, *P. annectens* was known only from its type locality. Subsequently, D'Elía, Ojeda et al. (2006) reported four additional localities. No fossils are known.

SELECTED LOCALITIES (Map 57; from D'Elía, Ojeda et al. 2006, except as noted): CHILE: Araucanía, Comuy; Los Lagos, Bahía San Pedro; Los Ríos, Fundo San Martín, Fundo Santa Rosa, near Mehuín (type locality of *Pearsonomys annectens* B. D. Patterson).

SUBSPECIES: *Pearsonomys annectens* is monotypic.

NATURAL HISTORY: All known specimens were trapped in Valdivian temperate forest or in forest plantations with native vegetation under the canopy and deep soils (Figueroa et al. 2012). The species has been recorded in syntopy with the sigmodontines *Abrothrix longipilis*, *A. olivacea*, *Geoxus valdivianus*, and *Oligoryzomys*

longicaudatus, and the microbiotheriid *Dromiciops gliroides*. A male collected in April 2011 at Fundo San Martín had scrotal testes, but another secured at the same place in June 2011 had undescended testes. *Pearsonomys annectens* is apparently scarce, as Murúa et al. (2005) reported that they collected only seven specimens over more than 20 years and nearly 213,000 trap-nights of effort at Fundo San Martín, where most specimens have been taken.

REMARKS: No etymology for *annectens* is given in the original description of the species. However, Bruce Patterson (pers. comm.) explained that *annectens* (meaning joined to, connected to, annectent) refers to the intermediate morphology of this species, which combines the longer tail and large pinnae of scansorial abrotrichines of the genus *Abrothrix* with the large claws and other synapomorphies of the semifossorial *Geoxus*, *Chelemys*, and *Notiomys*.

As a result of geopolitical redistricting of the higher administrative units of Chile in 2007, the type locality is now in the Región de Los Ríos, which was split from the Región de Los Lagos.

The karyotype of *P. annectensis* $2n=56$, FN=62, with an autosomal complement composed of one pair of large subtelocentrics, 23 pairs of medium to small-sized acrocentrics, and three pairs of small metacentrics; the X is sub-

metacentric, and the largest element of the complement; the Y is a small subtelocentric (D'Elía, Ojeda et al. 2006).

Tribe Akodontini Vorontsov 1959

Guillermo D'Elía and Ulyses F. J. Pardiñas

The Akodontini ranks behind the Oryzomyini as the second most diverse sigmodontine tribe in numbers of both genera and species. Members of the Akodontini range over most of South America, being absent only from southern Patagonia and most of Chile and with low diversity in Amazonia. Akodontines also constitute a diverse ecomorphological group, encompassing typical vole-like cursorial forms such as those of the genera *Akodon* and *Necromys*, the shrew-like fossorial *Blarinomys*, large semiaquatic rats of the genus *Scapteromys*, and the largest known living sigmodontine, the fossorial genus *Kunsia*. Remarkably, no akodontines have adapted to the scansorial or arboreal niches.

The concept of an akodontine group can be traced to Thomas (1916i, 1918b) and Tate (1932h), both of whom recognized the morphologic resemblances between *Akodon* and some other taxa ranked as genera (e.g., *Abrothrix*, *Chroemys*, *Deltamys*, *Hypsimys*, *Necromys* [= *Bolomys*], *Thalpomys*, *Thaptomys*). Four decades later, Vorontsov (1959) coined the term Akodontini for this assemblage. In turn, Reig (1972, 1978, 1984, 1987) made some of the most important contributions toward delimiting the group and clarifying its evolutionary history. During this period, much of the debate on akodontine systematics centered on issues at low taxonomic levels, including species boundaries in almost all genera, the generic allocation of some species, and the distinction of several genus-level taxa, mostly those related to *Akodon*. At the peak of typological taxonomy, several taxa were named to encompass species that were morphologically similar to *Akodon* but distinguishable from it only by one or two trenchant characters. For example, Thomas (1918b) erected *Hypsimys* to contain a species characterized by its high-crowned molars, separated *Microxus* from *Akodon* based on its narrow and posteriorly sloped (from base to top) zygomatic plates (Thomas 1909), and separated *Thalpomys* from *Akodon* by its ridged interorbital region (Thomas 1916i). These taxa, together with *Deltamys*, *Necromys*, and *Thaptomys* have been considered to be either synonyms of *Akodon*, subgenera of *Akodon*, or genera depending on the weight given to these and other characters (see Gyldenstolpe 1932; Tate 1932h; Ellerman 1941; Cabrera 1961; Reig 1987; Hershkovitz 1990a, 1998). *Podoxymys* has been aligned morphologically with either or both *Oxymycterus* and *Microxus* (Anthony 1929; Ellerman 1941; Reig 1987; Pérez-

Map 57 Selected localities for *Pearsonomys annectens* (●). Contour line = 2,000 m.

Zapata et al. 1992) or has been placed in an “oxymycterine” assemblage of genera (Hershkovitz 1966a:86–87, footnote). The position of *Podoxymys* in the Akodontini, however, has not been challenged.

Aside from these examples, contents of the Akodontini remained more or less stable until molecular-based phylogenetic studies prompted substantive changes in generic membership. The most radical of these was the allocation of *Abrothrix*, *Chelemys*, *Geoxus*, *Notiomys*, and *Pearsonomys* to the newly diagnosed tribe Abrotrichini (D’Elía et al. 2007; see that account earlier). Molecular data also challenged the grouping of the “oxymycterine” genera delineated by Hooper and Musser (1964) and Hershkovitz (1966a) into the Oxymycterini (Massoia 1981a, 1983), genera that Reig (1980, 1987) placed in the Akodontini. Massoia (1979b, 1980c), Reig (1980), and Pardiñas (1996) also placed *Bibimys*, *Kunsia*, and *Scapteromys* in a separate tribe, the Scapteromyini, based on craniodental traits and ecological attributes. Molecular sequences (both mtDNA [M. F. Smith and Patton 1999; D’Elía et al. 2005] and nucDNA [D’Elía 2003a]), however, while confirming a sister relationship between *Kunsia* and *Scapteromys*, aligned these two genera in a subclade of the Akodontini that otherwise included *Blarinomys*, *Lenoxus*, and *Brucepattersonius*. Furthermore, D’Elía (2003a) and D’Elía et al. (2005) found that *Bibimys* was also an akodont, although its relationship to either *Scapteromys* or *Kunsia* was unclear (our unpublished studies do support the phyletic connection between *Bibimys* and/or *Scapteromys* and *Kunsia*). None of these analyses supported the monophyly of the Scapteromyini with respect to other akodonts, as originally envisioned.

The last important formal change at the genus level within the Akodontini was the erection of two new genera for species previously allocated to known groups. *Brucepattersonius* was proposed by Hershkovitz (1998) to include *Oxymycterus iheringi* (together with several new species), and Pardiñas, D’Elía, and Teta (2009) coined *Gyldenstolpia* for *Kunsia fronto*. Furthermore, D’Elía (2003a) and D’Elía et al. (2003) have shown that “*Akodon*” *serrensis* traditionally placed in the genus *Akodon*, does not belong to that radiation but is sister to *Thaptomys*. An ongoing morphological assessment of this taxon supports the placement of *serrensis* in its own genus. As no name is available, a new one should be erected. Similarly, Alvarado-Serrano and D’Elía (2013) have shown recently that a pair of northern Andean species, *bogotensis* and *latebricola*, that were also previously considered part of *Akodon* fall outside the akodontine radiation. These authors erected a new genus, *Neomicroxus*, to encompass these species, and excluded their new genus-group taxon from the Akodontini, placing it in the *incertae sedis* group of sigmodontines.

We treat the Akodontini as delineated by M. F. Smith and Patton (1999). The tribe is composed of 15 living genera: *Akodon*, *Bibimys*, *Blarinomys*, *Brucepattersonius*, *Deltamys*, *Gyldenstolpia*, *Juscelinomys*, *Kunsia*, *Lenoxus*, *Necromys*, *Oxymycterus*, *Podoxymys*, *Scapteromys*, *Thalpomys*, and *Thaptomys*. As noted previously, a new genus for “*Akodon*” *serrensis* should be added. The fossil genus *Dankomys* Reig has also been considered a member of the tribe (Reig 1978; but see discussion). Until now, no published phylogenetic analysis has included all akodontine genera, as all such studies have lacked representatives of *Gyldenstolpia* and *Podoxymys*. Of these two, the phylogenetic position of *Podoxymys* appears more uncertain, as *Gyldenstolpia* is closely related to *Kunsia* and *Scapteromys* (Pardiñas, D’Elía, and Teta 2009). What follows is a discussion of akodontine phylogenetic relationships at the generic level, based mostly on D’Elía (2003a). M. C. Barros et al. (2009) posited some different relationships, but limited taxon sampling precludes confidence in their results.

Akodontine genera group into five strongly supported major clades, referred to as divisions by D’Elía (2003a). Relationships among these, however, are poorly resolved (i.e., it is not possible to confidently delimit larger clades than these divisions in the Akodontini). The five divisions are an *Akodon* Division (including *Akodon*, *Deltamys*, *Necromys*, *Thalpomys*, *Thaptomys*, and “A.” *serrensis*), which is equivalent to the akodontine tribe *sensu stricto*; the *Blarinomys* Division (*Blarinomys*, *Brucepattersonius*, and *Lenoxus*); the *Oxymycterus* Division (*Oxymycterus* and *Juscelinomys*); the *Scapteromys* Division (*Scapteromys* and *Kunsia*, and probably *Gyldenstolpia* on morphological grounds); and a monotypic *Bibimys* Division (*Bibimys*). Conclusions as to the number and contents of each division seem robust but may need adjustment once multiloci sequence analyses become available that include all genera. In particular, the distinction of the *Bibimys* Division from the *Scapteromys* Division, mostly found in analyses of mtDNA cytochrome-*b* sequences, requires further testing.

Reig (1972), in his doctoral thesis and published later in separate papers (Reig 1978, 1987, 1994), covered most of the fossil record of the tribe. These fossils were recovered from strata exposed on the coast of southern Buenos Aires province, Argentina, between Mar del Plata and Bahía Blanca, but their assignment to the Akodontini is questionable. The oldest known akodontine is argued to be *Necromys bonapartei*, based on a single mandible from the classic fossiliferous locality of Farola de Monte Hermoso (Reig 1978). The exact stratigraphic provenance of this fossil has been debated (Tonni et al. 1992; Marshall and Sempere 1993). Pardiñas and Tonni (1998) stated that the holotype of *N. bonapartei* was found in rocks of the upper part of the Monte Hermoso formation, lower Chapadmalalan in

age (about 4–3.5 mya), a fact regrettably overlooked in recent accounts (e.g., S. D. Webb 2006). However, studies in progress regarding the generic affiliation of *bonapartei* suggest that it is neither a *Necromys* nor even an akodontine (see also Pardiñas 2010). *Dankomys* is an extinct genus described by Reig (1978) and based on a combined fragment of the skull and mandible exhumed from the Atlantic cliffs between Mar del Plata and Miramar, south-eastern Buenos Aires province. Reig (1994), in a posthumous publication, described a second species of *Dankomys* from younger beds in the same area. *Dankomys* has not been adequately revised; Reig (1978) stated it was close to *Necromys*. Morphological differences between the two species of *Dankomys* (the type species, *D. simpsoni*, and *D. vorohuensis*) are so marked that it is hard to allocate both to the same genus. For example, the former has the anterior border of the zygomatic plate rounded, but the latter shows a conspicuous spine projected forward and a sharply bent premaxillomaxillary suture, both conditions that strongly resemble those in phyllotines and reithrodontines rather than those in akodontines.

We believe that the oldest fossil unambiguously assignable to the Akodontini is *Akodon lorenzinii* Reig, found in exposures of the Vorohué and San Andrés formations, Late Pliocene in age. Reig (1987) believed this species was related to the living *Akodon iniscatus*. In this paper Reig also described *Akodon johannis*, from Ensenadan beds (Late Pliocene–Middle Pleistocene), and considered it close to *Thaptomys*. The oldest scapteromyine is *Scapteromys hershkovitzi* Reig from the Vorohué Formation (Late Pliocene). However, as with some of the fossil taxa already mentioned, the generic affiliation of this species needs to be reevaluated (see Pardiñas, D'Elía, and Teta 2009). The type series of Reig's (1994) *S. hershkovitzi*, in addition to the holotype, includes an additional specimen that belongs to *Abrothrix magnus*. In fact, *hershkovitzi* seems to belong to an undescribed akodontine fossil genus more closely related to *Gyldenstolpia* and *Kunsia*. The remaining genera of the tribe have their fossil records restricted to strata no older than the Ensenadan or Lujanian. Fossil *Bibimys*, *Oxymycterus*, and *Scapteromys* belong to species that are the same, or at least ones morphologically very close to living ones (Pardiñas et al. 2002). Finally, several genera, such as *Deltamys*, *Lenoxus*, and *Podoxymys*, have no known fossil record. This may be because of the particular environments inhabited by these taxa not favoring fossilization or the limited amount of paleontological prospecting in areas that are currently forested.

Reig (1984, 1986), in his general scenario of sigmodontine historical biogeography, suggested that most akodontine genera originated in the central Andes in the Late Miocene or Early Pliocene, an area that includes present-day

southwestern Bolivia, northern Chile, and northwestern Argentina. Subsequent to the origin of the basal akodontine, new genera then spread into the eastern lowlands as well as into both the northern and southern Andes to reach the current tribal range. As noted above, Reig's concept of the Akodontini differs from the one employed here; in fact, Reig (1986) envisioned an akodontine secondary *Area of Original Diversification* in the southern Andes to accommodate those taxa now placed in the Abrotrichini. As such, testing Reig's hypothesis is not straightforward, and no study has been designed to do so yet. For instance, the geographic distribution of the common ancestor of the akodontine crown group has not been inferred in any study. However, available evidence (i.e., known distributions of extinct and living forms and results of phylogenetic analyses) has indicated that the historical biogeography of Akodontini is more complex than envisioned by Reig. First, as previously reviewed, the oldest known akodontine comes from the Atlantic coast of central Argentina, a fact consistently ignored in discussions of historical biogeography because it is difficult to reconcile with the generally accepted scenario—that sigmodontines entered South America from the north and, as such, that the oldest members would have been Andean—while appealing to the incompleteness of the fossil record. Second, most genera of Akodontini are non-Andean (M. F. Smith and Patton 1999), with only one, *Lenoxus*, exclusively limited to the Andes. It is also noteworthy that *Lenoxus* is closely related to *Blarinomys* and *Brucepattersonius*, two genera distributed in eastern South America, rather than to genera with Andean species (i.e., *Akodon*, *Necromys*, and *Oxymycterus*). This suggests that akodontines reached and/or dispersed from the Andes multiple times. Relationships among species of *Akodon*, *Necromys*, and *Oxymycterus* suggest similar scenarios. In summary, we are still far from understanding akodontine biogeographic history, and no study has as yet dated most important cladogenic events, but an emerging complex picture points to the South American lowlands as an important, if not the most important, area for akodontine diversification (M. F. Smith and Patton 1999; see also Parada et al. 2013).

The extreme diversity of its members makes diagnosing the Akodontini a substantial challenge, one that, until now, has not been undertaken. Overall, the akodontine bauplan seems to be simply that of a generalized sigmodontine. Akodontines are small to medium sized, averaging 40 g in weight, although some forms are much larger (e.g., *Kunsia* reaches 500 g). The typical condition is an unspecialized, fusiform body with small, rounded ears; short legs; dark coloration with noncontrasting under parts; and a tail shorter than the combined head and body lengths (with the exception of *Lenoxus*). Eyes tend to be small or of medium size (*Blarinomys*, *Podoxymys*, *Deltamys*), and claws

are moderately to well developed (*Gyldenstolpia*, *Kunsia*). The digestive system is usually without specializations for herbivory; rather, most species are omnivorous to insectivorous and have a unilocular-hemiglandular stomach. *Blarinomys*, *Brucepattersonius*, *Kunsia*, *Lenoxus*, *Oxymycterus*, and *Scapteromys* have the unilocular-discoglandular condition (the same may be also the case in *Juscelinomys* and *Gyldenstolpia*, but stomach morphology for these genera has not been described). Large intestines are short, usually less than 15% the length of small intestines; the caecum is small or absent.

Upper incisors are never grooved. Akodontine molars are mesodont to subhypsodont; the coronal surfaces are crested or terraced with main cusps in an alternate pattern, or exceptionally planate (*Gyldenstolpia*, *Kunsia*). Mesolophs and mesolophids are moderate sized (*Bibimys*, *Scapteromys*, *Gyldenstolpia*) to reduced or, more typically, are vestigial (e.g., *Akodon*, *Necromys*, *Thaptomys*), often fully or partially coalesced with paralophs or entolophids and present only as terminal remnants; posterolophs are coalesced with metalophs and a posteroflexus is usually obsolete; the upper third molar is reduced and circular in outline. Interorbital regions are typically hourglass in shape, exceptionally with sharply divergent borders (*Thalpomys*, some species of *Necromys*); frontal sinuses are inflated; zygomatic plates are little to moderately developed, rarely high or projecting before the antorbital bridge (e.g., *Scapteromys*, *Necromys*), and never with a developed spinous process. Incisive foramina usually reach posteriorly beyond the anterior edges of the first upper molars; the palate is broad and flat. Preputial glands are usually single; a medial ventral prostate usually is reduced or absent. Diploid complements vary widely, from 10 and 70 chromosomes (after Reig 1987, with modifications).

REMARKS: Vorontsov (1959) diagnosed the Akodontini in his review of cricetid rodents, along with most other tribes currently recognized in the subfamily Sigmodontinae. Cockerell et al. (1914:359), however, were apparently the first to coin the term Akodontini, as well as Ichthyomyini and Sigmodontini, as tribes of the Sigmodontinae. Although these authors neither defined nor diagnosed these family-groups, their use of the names probably emerged from a more substantive work then in progress but apparently never published, as suggested when they wrote “in the course of some work on the classification and relationships of rodents” (Cockerell et al. 1914:347).

As mentioned previously, the current concept of the tribe Akodontini encompasses the type genus and other genera earlier placed in the tribe Oxymycterini as well as all members of the tribe Scapteromyini. As such, both family-group names, Oxymycterini and Scapteromyini, are synonymns of Akodontini.

The taxonomic history of the oxymycterine group is more complex than that of the scapteromyines, given that more genera were included in it and that some of these genera are relatively diverse. Hershkovitz (1966a), in a footnote, recognized the group; listed as members the genera *Oxymycterus*, *Podoxymys*, *Lenoxus*, and *Abrothrix* (in which he subsumed *Microxus*, now included in the synonymy of *Akodon*; M. F. Smith and Patton 1993); and provided a set of cranial and dental character states that characterize it. Two decades later, Reig (1987) reinforced the hypothesis that the oxymycterines belong to the akodontine radiation and explicitly questioned the unity of Hershkovitz’s grouping, in part because Reig considered *Abrothrix* a subgenus of *Akodon*. The same year, Hinojosa et al. (1987) added to the group the genera *Blarinomys* and *Geoxus* and reevaluated the supposedly diagnostic character states provided by Hershkovitz, demonstrating that several, if not most, of these were also present in other akodontines or not present in all oxymycterines. More significantly, given these results and a preliminary assessment of electrophoretic data, Hinojosa et al. (1987:9) cast doubts on the monophyly of the oxymycterine group. Hershkovitz (1994:14–15) accepted their conclusions and, in addition to arguing against the oxymycterine affinities of *Blarinomys* and *Geoxus*, agreed that what once seemed to be a natural group actually comprised a set of unrelated akodontine lineages united by morphological convergences. As noted previously, phylogenetic analyses based on DNA sequences strongly corroborated the presumption of Hinojosa et al. (1987) as to the polyphyly of the oxymycterine group. Core “oxymycterine” genera fall in two divisions of Akodontini (the *Oxymycterus* and *Blarinomys* divisions, *sensu* D’Elía 2003a) as well as in the tribe Abrotrichini (M. F. Smith and Patton 1999; D’Elía 2003a).

The taxonomic history of the scapteromyine group is relatively simple. A scapteromyine concept began with Peters (1861), who placed *Mus tomentosus* Lichtenstein together with *Hesperomys tumidus* Waterhouse under *Scapteromys* as a subgenus of *Hesperomys*. Later, Fitzinger (1867b) elevated *Scapteromys* to the genus level, although the usage of *Scapteromys* as a subgenus of *Hesperomys* continued (e.g., Thomas 1884). In the following years, new fossil and living species were added to *Scapteromys* (Gyldenstolpe 1932; Miranda-Ribeiro 1914; Winge 1887). In a key contribution, Hershkovitz (1966a) removed several taxa previously assigned to *Scapteromys* (e.g., *S. tomentosus*) and placed them in the newly created genus *Kunsia*. Hershkovitz also suggested that both genera be combined into an informal group he referred to as the scapteromyine group, which he diagnosed by a set of external, cranial, dental, and phallic characters. Hershkovitz also doubted that some

other taxa belonged to his scapteromyine group, including *Scapteromys labiosus* Winge, which up to that time had been placed in *Scapteromys*. Finally, he suggested that the scapteromyines were part of the akodont radiation. Avila-Pires (1972) expanded the contents of the group by describing a new subspecies of *Kunsia fronto* (see the account of *Gyldenstolpia*). The same year Reig (1972) used the name Scapteromyini and fully diagnosed the tribe. Massoia (1979b) was the first author to make the name Scapteromyini available by actual publication. He also expanded the group with the description of a new genus and species, *Bibimys torresi*. The following year, Massoia (1980c) allocated both *Akodon chacoensis* Shamel and *Scapteromys labiosus* Winge to *Bibimys*, species that Hershkovitz (1966a) had explicitly excluded from the group. As stated earlier, phylogenetic analyses of molecular sequences (M. F. Smith and Patton 1999; D'Elía 2003a; D'Elía et al. (2005) firmly place all "scapteromyine" genera in the Akodontini and fail even to support them as a monophyletic unit in the tribe.

KEY TO THE GENERA OF AKODONTINI:

1. Tail length equal to or greater than head and body length and with a white tip that strongly contrasts in color with the basal portion *Lenoxus*
- 1'. Tail length equal to or shorter than head and body length and without distal white tip 2
2. Size very large, reaching 500 g in adults; pes bicolored *Kunsia*
- 2'. Size small to large, not exceeding 250 g in adults; pes unicolored 3
3. Size small, reduced eyes, dark colored above and below 4
- 3'. Size small to large, eyes moderately reduced, underparts contrastingly colored 6
4. Pelage smooth, dense, and blackish; very short tail; ears totally obscured by fur *Blarinomys*
- 4'. Pelage velvety and dark; tail moderately long; ears quite visible 5
5. Snout elongated. *Brucepattersonius*
- 5'. Snout not elongated *Deltamys*
6. Snout elongated. 7
- 6'. Snout not elongated 8
7. Tail hairless and short. *Oxymycterus*
- 7'. Tail sparsely haired and long *Podoxymys*
- 7". Tail well-haired and conical. *Juscelinomys*
8. Conspicuously pink and enlarged upper lip. *Bibimys*
- 8'. Upper lips normal in size, not pink. 9
9. Large size >100 g, powerful claws on forefeet 10
- 9'. Small to medium sized, <100 g 11
10. Tail length >80% of head and body length *Scapteromys*
- 10'. Tail length <80% of head and body length. *Gyldenstolpia*
11. Ears rounded and well haired, color dark 12
- 11'. Ears moderately large, color not dark *Thalpomys*
12. Tail length >50% of head and body length 13
- 12'. Tail length >50% of head and body length. *Thaptomys*
13. Length of fifth digit not extending beyond base of fourth digit *Necromys*
- 13'. Length of fifth digit extending beyond base of fourth digit *Akodon*

Genus *Akodon* Meyen, 1833

Ulyses F. J. Pardiñas, Pablo Teta, Diego Alvarado-Serrano, Lena Geise, Jorge Pablo Jayat, Pablo E. Ortiz, Pablo R. Gonçalves, and Guillermo D'Elía

The contents of *Akodon* have fluctuated greatly since Meyen first designated the genus in 1833. J. A. Allen (1905:70–71) was the first to highlight the necessity of dividing the genus, by that time composed of more than 100 species, although he pointed out that "in cranial and dental characters there is great uniformity of structure, and no very evident lines of division." Thomas (1916i) attempted that task by recognizing seven genera: *Zygodontomys*, *Akodon* (with two subgenera, *Akodon* and *Chalcomys*), *Thalpomys*, *Thaptomys*, *Bolomys*, *Chroeomys*, and *Abrothrix*. It is interesting to note the importance of molar morphology in Thomas's arrangement; for example, when erecting *Zygodontomys*, he remarked, "The recognition of *Zygodontomys* as a genus distinct from *Akodon* is somewhat provisional, and can only be finally settled when specimens with unworn molars of many more species are available for examination . . . species as *Akodon lenguarum* undoubtedly tend to connect the two groups" (1916i:338).

Reworking Thomas's diagnosis of *Akodon*, Gyldenstolpe (1932) was the first to view the genus in a way similar to its current concept. He included 36 species divided into two subgenera and employed 23 trinomials to cover *Akodon* diversity. Gyldenstolpe's (1932) understanding of *Akodon*, however, included both many species now placed in this genus as well as taxa now in *Abrothrix* (*beatu*, *olivaceus*, and *gossei*), in *Bibimys* (*chacoensis*), or even in the phyllotine genus *Calomys* (*pusillus*, a putative although improbable placement).

Ellerman's (1941) comprehensive study of living rodents represented for sigmodontines the beginning of the systematics school that favored a polytypic species concept and taxonomic organization into species-groups and subgenera instead of genera. Ellerman (1941:410ff.) thus subsumed several previously proposed genera as subgenera under

Akodon, and recognized about 85 species divided among eight subgenera (*Abrothrix*, *Akodon*, *Bolomys*, *Chroeomys*, *Deltamys*, *Hypsimys*, *Thalpomys*, and *Thaptomys*). Within the subgenus *Akodon* he created the *boliviensis* and *urichi* species groups that were basically equivalent to the contents of subgenera *Akodon* and *Chalcomys*, respectively, as proposed by Gyldenstolpe (1932). This “lumping” trend reached a peak with Cabrera (1961:437), who explained his rationale “sigo la opinión de Ellerman al incluir en este género [*Akodon*], como subgéneros, los diversos géneros en que fue disgregado por Thomas, así como *Abrothrix*; pero no veo motivo para conservar separado a *Microxus*” (freely translated: “I follow the opinion of Ellerman to include in this genus [*Akodon*], as subgenera, the several genera as was partitioned by Thomas, and also *Abrothrix*; but I see no reason to keep separate *Microxus*”). Cabrera (1961) partitioned *Akodon* into nine subgenera, with the nominotypical subgenus the most diverse with 21 species, many of which are now allocated to three other genera (*Abrothrix*, *Bibimys*, and *Necromys*). Cabrera also used trinomials extensively in several complex taxa, such as *A. boliviensis*, *A. mollis*, *A. orophilus*, *A. urichi*, and *A. varius*.

As he did for *Necromys* (see that account), Osvaldo Reig (1972) established the roughly current concept of *Akodon*. This is not surprising because the dissociation of *Necromys* from *Akodon* was the first fundamentally historical point in establishing the modern concept of *Akodon* (see also Reig 1978, 1987). Reig’s (1987:358) concept of *Akodon* included “a central genus *Akodon* subdivided into five subgenera, namely *Abrothrix*, *Akodon s.s.*, *Chroeomys*, *Deltamys*, and *Hypsimys*.” However, the second fundamental departure in the taxonomic history of *Akodon* was the segregation of *Abrothrix* as not only a valid genus but one unrelated to *Akodon s.s.*, a phyletic understanding only possible with the application of molecular data (e.g., Patton et al. 1989; Barrantes et al. 1993; M. F. Smith and Patton 1991, 1993, 1999; see the *Abrotrichini* account). The confused placement of *Akodon* and *Abrothrix* is perhaps unique among sigmodontines because it involved two genera from separate tribes that are so similar in external and craniodental morphology that misidentification of both specimens and species was commonplace. Although some *Abrothrix* such as *A. longipilis* were early recognized as distinct from *Akodon s.s.* (*longipilis* is the type species of *Abrothrix*), others such as *A. andinus* and *A. olivaceus* were regarded as typical *Akodon* until molecular phylogenetic studies firmly established their correct allocation to *Abrothrix* (see the historical summary by Musser and Carleton 2005).

We include 38 species in *Akodon*, plus one still undescribed (“*Akodon* sp. 2n=10” of several authors), totaling 39 extant species. Some authors have claimed an additional undescribed species, based on a karyotype of 2n=34,

from grassland-Araucaria forest ecotones in southern Brazil (e.g., Pedó, Freitas, and Hartz 2010). Our concept of *Akodon* largely agrees with Musser and Carleton’s (2005) treatment of the genus but incorporates recent taxonomic hypotheses as well as newly described species (*philipmyersi* and *polopi*; Pardiñas, D’Elía et al. 2005; Jayat et al. 2010; C. F. Jiménez et al. 2013), synonyms (e.g., *oenos* as junior synonym of *A. spegazzinii*, *viridescens* as junior synonym of *A. polopi*, and *aliquantulus* as a junior synonym of *A. caenosus*; Jayat et al. 2010; D’Elía et al. 2011; Pardiñas, Teta, D’Elía, and Díaz 2011), and resurrections (*caenosus* as a species different from *A. lutescens*; Jayat et al. 2010). There are also three described extinct species of *Akodon*, *A. clivigenis* (Winge, 1887), *A. johannis* Reig, 1987, and *A. lorenzini* Reig, 1987 (see below).

The most recent change in *Akodon* alpha diversity involved the species *bogotensis* Thomas and *latebricola* Anthony. The non-*Akodon* condition of both was briefly highlighted by Voss (2003:21–22) on morphological grounds. Alvarado-Serrano and D’Elía (2013) have now coined *Neomicroxus* as a new genus to allocate these forms and demonstrated by phylogenetic analyses of DNA sequences that their lineage is not even part of Akodontini (see that account under Sigmodontinae *incertae sedis*). We are also confident that *serrensis* Thomas does not belong to *Akodon*, as D’Elía (2003a; see also M. F. Smith and Patton 2007; Jayat et al. 2010; Coyner et al. 2013) recovered this species outside of *Akodon* based on molecular markers. This taxon represents an undescribed genus, one in the Akodontini. The remaining 38 extant species of *Akodon* we treat herein position the genus as one the few muroids with an alpha diversity greater than 30 recognized species (Musser and Carleton 2005), and second in diversity only to the 44 species of *Thomasomys* within the Sigmodontinae.

Several of the recognized species of *Akodon* are very poorly known, and their status remains uncertain. For example, *A. pervalens*, described from the Yungas of Tarija, Bolivia, has never been reviewed although its validity has been questioned (Myers 1990; Jayat, Ortiz et al. 2007). A similar lack of data characterizes *A. affinis*, *A. dayi*, *A. sanctipaulensis*, and *A. surdus*, so the status of these as valid species should be considered provisional. In contrast, *Akodon* also includes many forms that have been thoroughly studied by multiple character sets; some of these are among the most reviewed of sigmodontine taxa. For example, detailed field and laboratory analyses of *A. azarae* or *A. cursor* have detailed diet, ecophysiology, behavior, reproduction, sex determination, habitat selection, parasites, and predation, among other attributes (e.g., Pearson 1967; Dalby 1975; Zuleta and Bilenca 1992; Gentile et al. 1997; Kittlein 1997; O. Suárez and Kravetz 1998a,b; Bergallo and Magnusson 1999; Macdonald 2001; O. Suárez

and Bonaventura 2001; C. Busch and Del Valle 2003; Cerqueira et al. 2003; Moraes et al. 2003; Olifiers et al. 2004; De Conto 2007, and the references therein). Furthermore, general knowledge of the genus has increased significantly, especially within the past two to three decades, thanks to the revision of several species or group of species. Starting with Myers' (1990) seminal study of the species related to *Akodon varius*, additional contributions focused on Andean species distributed in Peru, Bolivia, and Argentina, including the description of new entities (*siberiae*, Myers and Patton 1989a; *kofordi*, Myers and Patton 1989b; *juni-nensis* and *arequipae*, Myers et al. 1990) and a general revision of the *boliviensis* group (Myers et al. 1990). These contributions promoted similar efforts in non-Andean regions, and many species widespread in the Atlantic Forest and neighboring grasslands were studied, including a definition of the *Akodon cursor* species group (Rieger et al. 1995), phylogenetic hypotheses based on molecular and chromosomal data (e.g., Geise et al. 1998, 2001; Pardiñas, D'Elía et al. 2005; P. R. Gonçalves et al. 2007; Hass et al. 2008), descriptions of additional new species (*lindberghi* and *sanctipaulensis*, Hershkovitz 1990b; *mystax*, Hershkovitz 1998; *reigi*, L. A. González et al. 2000; *paranaensis*, Christoff et al. 2000; *philipmyersi*, Pardiñas, D'Elía et al. 2005), and karyological and morphological studies (e.g., Christoff 1997; Fagundes et al. 1998; Pardiñas, D'Elía et al. 2003; Geise et al. 2005; P. R. Gonçalves et al. 2007). More recently, and mostly associated with an important effort to collect fresh materials, revisionary studies reached west central and northwestern Argentina where several new nominal forms have been described (*aliquantulus*, M. M. Díaz et al. 1999; *oenos*, Braun et al. 2000; *polopi*, Jayat et al. 2010; *viridescens*, Braun et al. 2010; see also D'Elía et al. 2011) or restudied (*sylvanus*, Jayat, Ortiz et al. 2007; *oenos*, Pardiñas, Teta, D'Elía 2011), and the *boliviensis* group fully addressed (Jayat et al. 2010). A few additional contributions focused on species that inhabit geographic regions previously poorly known (e.g., Ecuador, Alvarado-Serrano 2005; Patagonia, Pardiñas 2009).

Reig (1978, 1980, 1981, 1984, 1986, 1987), based on both the analysis of geographic occurrences of the species of *Akodon* as well as fossil and karyological evidence, favored an "original differentiation" of the genus in the "area of the present altiplano" (Reig 1987:393). According to Reig, "The frequency of localities from which species of *Akodon* are reported shows that 82% of the occurrences belong to Andean environment . . . The ancestral akodontine may have been a generalized *Akodon*-like form . . . This ancestral form may have encountered adequate conditions in the southern proto-puna, and from here local differentiation may have developed" (1987:393). Excluding "A." *serrensis*, 21 of the remaining 37 living species are

Andean in distribution, eight occur in middle elevation and central semiarid lowlands, and the remaining eight characterize the forested or grassy eastern, mainly lowland, portions of the subcontinent. Of the Andean taxa, over 70% inhabit the eastern versant of the Andes and contiguous arid lands, with a latitudinal concentration between 8°S to 25°S. Only one species, *A. affinis*, has its entire distribution north of the Equator in the Cordillera Oriental. As Voss and Emmons (1996:12) highlighted, *Akodon* is definitively a non-Amazonian genus. The few records of *Akodon* sp. $2n=10$ in the Brazilian states of Mato Grosso (M. J. de J. Silva and Yonenaga-Yassuda 1998) and Pará (T. D. Lambert et al. 2005) are restricted to enclaves of heterogeneous or nonforested habitats. Members of the genus are absent from the Guiana shield (e.g., Tate 1939; Voss 1991) and Patagonia, with the exception of *A. iniscatus*, the southernmost representative of the genus, which reaches about 47.5°S (Pardiñas 2009). Neither *Akodon* nor any akodontine occupies the western southern slope of the Andes to the Pacific coast in Chile; rather, this region is the domain of *Abrothrix* and other abrotrichines. The roughly "dumb-bell" distributional pattern of species alpha diversity concentrated in the central Andes and Atlantic Forest is shared by *Oxymycterus*, another diverse akodontine genus (e.g., Hershkovitz 1994).

The oldest *Akodon* is *A. lorenzini* Reig, 1987, whose remains were found in the strata of Vorohué and San Andrés formations (Upper Pliocene) in the coastal cliffs exposed south of Mar del Plata, Buenos Aires province, Argentina. This small *Akodon* was stated as similar to *A. iniscatus* and *A. caenosus* (the later referred to as *puer*; Reig 1987). Another extinct species from Buenos Aires province is *A. johannis*, described by Reig (1987) from several cranial fragments of a single individual excavated from the outcrops of Miramar Formation (Middle Pleistocene). According to Reig, *A. johannis* "seems to be more closely related to *A. [=Thaptomys] nigrita* . . . Doubtless it should be allocated in the subgenus *Akodon s.s.*" (1987:380). Reig (1987) also mentioned two other living species, *Akodon* cf. *A. iniscatus* from the Vorohué Formation and *A. cf. A. montensis* (cited as *cursor*) from the Miramar Formation. The fragmentary nature of the available material of the former, however, does not allow a confident specific assignment (Pardiñas 1995b). The later probably represents the oldest record of *A. montensis* or a morphologically related species in the *cursor* group. These were also recovered in association with a complex molar sigmodontine that Reig (1972, 1987) referred to *Nectomys*, which suggests a very different sigmodontine assemblage by that time than the one currently observed in the Pampean region of Argentina. Remains referred to *A. azarae* have been described from Middle Pleistocene (about 0.7 mya) deposits in

northeastern and southeastern Buenos Aires province, Argentina (Pardiñas 1993; Voglino and Pardiñas 2005). A Middle Pleistocene owl pellet fossil assemblage from north of Mar del Plata contained an indeterminate *Akodon*, one similar in size to *A. iniscatus* or *A. azarae* (Pardiñas 2004). During the Late Pleistocene, an assemblage also produced by owls in the Andean ranges of Catamarca province, Argentina, shows a dominance of *A. spegazzinii* and a single record of *A. simulator*; in contrast, *A. caenosus*, abundant in this region today, was absent (P. E. Ortiz et al. 2011a). *Akodon spegazzinii* has a rich fossil record in northwestern Argentina (P. E. Ortiz et al. 2011b). Late Quaternary Brazilian deposits at Lagoa Santa, Minas Gerais (Winge 1887), are also rich in *Akodon* representatives, including *A. cursor*, *A. angustidens* (= *A. serrensis*; see that account), and the extinct *A. clivigenis*. The taxonomic status of the later has not been reviewed, however, and plausible synonymies with extant Brazilian forms described during recent decades are likely. *Akodon* is also registered as fossil in the Late Pleistocene of Uruguay (Ubilla 1996) and Ecuador (Fejfar et al. 1993).

Species of *Akodon* live in wide range of habitats, including the Puna, Páramo, montane tropical and subtropical forests, grassy pampas, dry montane Andean valleys, semi-desert Patagonian tablelands, and Cerrado shrubby areas. However, all species are characterized by a single external morphological bauplan, small to medium in size with short legs, claws, and ears, nonreduced eyes, inconspicuous vibrissae, brownish to grayish coloration, poorly contrasting back and ventral colors, and tail moderate in length but always shorter than the combined head-body length. Not surprisingly, there are exceptions to this general pattern, but these are few. For example, *A. albiventer* has a snowy white venter that, combined with bullar enlargement and other cranial features, supported its earlier placement in *Bolomys* (= *Necromys*), and *A. montensis* has moderately large foreclaws.

Craniodontal morphology in *Akodon* follows the same pattern of interspecific similarity (Reig 1987). The skull is normally built and usually somewhat elongated behind. The nasals are either longer or slightly shorter than the frontals. Anterior borders of the zygomatic plates are usually vertical and are never projected to form dorsal processes or points. The braincase is moderately long, usually not broadened, and either as wide as it is long or slightly shorter than half of the condylobasal length. The interorbital region is typically fairly narrow, without supraorbital ridges. Anterodorsal frontal sinuses are evident although not specially inflated. Bullae are usually not enlarged. Incisive foramina are long, typically reaching the protocone of M1. The anterior border of the mesopterygoid fossa is usually even with or slightly behind the posterior face of M3.

Zygomatic arches are delicate. The squamosal-alisphenoid region is characterized by a foramen ovale divided by a consistently present alisphenoid strut and a reduced anterior opening of the alisphenoid canal. A well-developed trough for the masticatory-buccinator nerve is present, partly configuring the primitive, pattern 1 carotid circulatory system described by Voss (1988), the widespread condition in the genus (Myers et al. 1990). The mandible is relatively low and stout, more slender in the smaller species, with the masseteric crest normally developed and reaching the middle of m1. The capsular projection is usually not defined as a distinct tubercle. Deviations from this standard in cranial morphology are infrequent. Thomas (1920h) remarked that the narrowed and slanted zygomatic plate of *A. mimus* (and to a lesser extent, *A. torques*), which he termed “microxine,” was more similar to that of *Oxymycterus* than to typical *Akodon*. The very shallow zygomatic notches, partially related to the zygomatic plate expression, also distinguished the skulls of *A. mimus* from those of most *Akodon* species, all of which have typically deeper zygomatic notches.

Myers et al. (1990:22) vividly wrote that “*Akodon* teeth are frustrating to study because they wear rapidly, and as they wear they lose much of their occlusal topology.” The upper incisors are frequently opisthodont, more rarely orthodont, always smooth and well pigmented. The molars are neither markedly elongated nor narrowed, and have a moderately developed tubercular hypsodonty; as an exception, crowns are noticeably higher in *A. budini* and *A. siberiae*. The molar crowns are usually bilevel or terraced, and the main cusps alternate in position. M1 always has an anteromedian flexus (except in “*A.*” *serrensis*), but in several members this structure disappears with wear in adult individuals (e.g., the *varius* group, *sensu* Myers 1990). Remnants of the mesoloph are usually united to the mesostyle, typically on both M1 and M2. M3 tends to be a simple cylinder (Reig 1987).

Studies of soft anatomy show that all species of *Akodon* studied to date share the widespread unilocular-hemiglandular condition, with the bordering fold bisecting the stomach on a line from the incisura angularis to a point opposite it on the greater curvature (Carleton 1973). The presence of a gall bladder is another common trait in the genus (Voss 1991; Geise, Weksler, and Bonvicino 2004); however, at least one species, *A. montensis*, lacks this structure. A single pair of large preputial glands is present that typically extends well beyond the ventral flexure of the penis (Voss and Linzey 1981).

Montes (2007) summarized the major trends across the extensive karyological literature of *Akodon*. Karyotypes have been commonly used to distinguish many species of *Akodon*, especially those that inhabit eastern and central

South America (e.g., *cursor* group taxa). Even more, several changes of taxonomic status of different nominal forms have been made on the basis of karyotypic information, either to establish them at the species level (e.g., *montensis*) or regard them as synonyms (e.g., *arviculoides*). N. O. Bianchi and Contreras (1967), in describing polymorphism of sex chromosomes in *A. azarae*, published the first cytogenetic work on *Akodon*. Later, N. O. Bianchi et al. (1971) recognized at least three karyological assemblages in *Akodon*, one of which included the species currently referred to *Abrothrix*. G and C-banding techniques were also used in early papers, starting with the analysis of N. O. Bianchi et al. (1973, 1976) and followed by many others (e.g., Yonenaga-Yasuda 1979; M. A. Barros et al. 1990; Fagundes and Yonenaga-Yasuda 1998; Geise et al. 1998). Fagundes et al. (1997) published the initial work on fluorescent hybridization in *Akodon* species. During the period from 1970 to 1990, most of the currently recognized species in the genus were karyotyped; these included individual studies that often combined cytogenetic and morphological data (see review by Montes 2007) that supported species-groups in *Akodon* (e.g., the *varius* group, *sensu* Myers 1990; *boliviensis* group of Myers et al. 1990; *fumeus* group of Myers and Patton 1989b; and *cursor* group of Rieger et al. 1995).

Outstanding contributions on karyological patterns in *Akodon*, and by extension of the Akodontini as a whole, were made by N. O. Bianchi, O. A. Reig, and their collaborators, in a series of 10 papers published between 1971 and 1984, all under the general title of “Cytogenetics of South American Akodont Rodents (Cricetidae),” as well as by Y. Yonenaga-Yasuda and her collaborators (e.g., Yonenaga 1972b; Yonenaga-Yasuda et al. 1976; Yonenaga-Yasuda 1979). In both cases, these authors dealt almost exclusively with species living in open lowland to forested areas of South America, primarily in Argentina and Brazil. Some of these works included laboratory cross-breeding experiments of putative species, such as between *A. dolores* and *A. molinae* (e.g., Merani et al. 1978). Andean forms were also the subject of several studies, most of them focused on Argentinean, Bolivian, and Peruvian forms (Barquez et al. 1980; Myers and Patton 1989a,b; Myers et al. 1990; Patton et al. 1990; Patton and Smith 1992b; Blaunstein et al. 1992). With respect to the most recent phylogenetic analyses (see below), *Akodon* species groups can be karyologically characterized as follows (Montes 2007): the *aerosus* group (*sensu* M. F. Smith and Patton 2007), plus *A. albiventer* either have $2n=22-26$ (*A. mollis*, *A. torques*, *A. orophilus*, some *A. aerosus*) or $2n=38-40$ (other *A. aerosus*, *A. albiventer*, *A. budini*, *A. mimus*, *A. siberiae*), although are all characterized by $FN=40$. Members of the

varius and *dolores* groups (*sensu* Jayat et al. 2010) have $2n=33-44$, sharing a high FN (42–44). Those of the *boliviensis* group (*A. boliviensis*, *A. spegazzinii*, *A. lutescens*, *A. subfuscus*, *A. juninensis*, *A. kofordi*, *A. fumeus*, *A. polopi*) all have the same $2n=40$, $FN=40$ karyotype. Finally, a fourth group of species that occupies open to forested areas in lowland terrains from east-central Argentina to central and eastern Brazil, some of uncertain affinities (e.g., *A. azarae*) but others closely related (e.g., *A. montensis*, *A. reigi*, *A. paranaensis*; see M. F. Smith and Patton 2007), are characterized by substantial variation, with $2n$ ranging from 14–16 (*A. cursor*), 24–26 (*A. montensis*), 36 (*A. philipmyersi*), 37–38 (*A. azarae*), 42 (*A. lindbergi*), to 44 (*A. paranaensis*, *A. reigi*).

Remarkably, besides normal XX females, in several species of *Akodon* females possess karyotypes indistinguishable from those of males, with XY females known for eight different species with at least six independent origins (Hoekstra and Edwards 2000). The XY females, known since the 1960s (N. O. Bianchi and Contreras 1967), are fertile. Cytogenetic and molecular studies have shown that these females are not Xx, with one X resulting from an arm deletion (i.e., an extreme case of dosage compensation), but XY*, where the *Sry* gene differentially expressed (see review in N. O. Bianchi 2002). Recently, A. Sánchez et al. (2010) showed that, at least for *A. azarae* and *A. boliviensis*, *Sry* mutations are not the basis of sex reversal XY* given that the *Sry* gene sequences of XY* do not significantly differ from those of males. Thus, the basis of the inactivation of the *Sry* gene in XY* remains unclear.

Beginning in the early 1990s with M. F. Smith and Patton's (1991, 1993) pioneering studies, DNA sequence data began to be extensively used in phylogenetic studies of *Akodon*. Most of these studies are based on mtDNA cytochrome-*b* gene sequences, with sequential papers offering an increasingly broader taxonomic coverage. Jayat et al. (2010) and Coyner et al. (2013) are the most recent approaches with broad taxonomic coverage of *Akodon*.

Phylogenetic studies of *Akodon* have had their major impact in two critical systematic areas: membership in the genus and delineation of species group relationships. By assessing the phylogenetic position of the type species of genus-group taxa related to *Akodon*, these molecular studies (M. F. Smith and Patton 1999; D'Elía 2003a; D'Elía et al. 2003) have both set the limits of *Akodon* and demonstrated that taxa such as *Deltamys*, *Thalpomys*, and *Thaptomys* deserved generic status, given that their respective type species, *kempi*, *lasiotis*, and *nigrita*, fell outside the crown-group clade of *Akodon* s.s. (i.e., the least inclusive clade containing “non-problematic” *Akodon* taxa and

A. boliviensis, which is the type species of *Akodon*). It is relevant to note here, however, that most of the topologies supporting the distinction of *Deltamys* are either weakly supported or, in several topologies gathered by M. F. Smith and Patton (2007) and Jayat et al. (2010), *Akodon s.s.* is paraphyletic with respect to *Deltamys*. Clearly, the generic distinction of *Deltamys* needs further scrutiny. In addition, these phylogenetic analyses have shown that *serrensis* Thomas, whose placement in *Akodon* had never been questioned, falls outside the *Akodon s.s.* clade and that, as result, this species should be given generic status. On the other hand, these phylogenetic studies have also shown that *mimus* and *budini*, type species of *Microxus* and *Hypsimys*, respectively, fall in the clade of *Akodon s.s.*, rendering these two genus-group taxa synonyms of *Akodon*. As is the case of relationships among *Akodon* species groups (see below), the phylogenetic position of some of these taxa (notably *mimus* and *kempi*) varies with the taxonomic coverage, gene(s) sequenced, and analytical method employed (M. F. Smith and Patton 2007; Jayat et al. 2010; Coyner et al. 2013). Therefore, to obtain a stable delimitation of *Akodon*, analysis of a taxonomically dense matrix using multiple mtDNA and nucDNA sequences of different loci remains a necessity.

Traditionally, species of *Akodon* have been divided into a number of species groups. Some of these groupings (e.g., the *boliviensis* versus *mollis* groups of Hershkovitz 1990b) simply define size-based associations. Others, however, were assumed to represent taxa that were part of a common evolutionary lineage “explicitly based on the overall similarity of the taxa and their apparently contiguous geographic distributions” (Myers 1990:35, in his definition of the *varius* group). Myers (1990) defined the *varius* group on morphological grounds alone; Myers et al. (1990) based their *boliviensis* group both on morphology and allozymes; and Rieger et al. (1995) delineated the *cursor* group mostly on karyotypic data. More recent studies, built primarily around a phylogenetic rather than a phenetic framework, have reviewed the contents of these earlier groups while defining new ones. In particular, M. F. Smith and Patton (2007) and Jayat et al. (2010) deserve special mention (see also Pardiñas, D’Elía et al. 2005; Jayat, Ortiz et al. 2007; Montes 2007; Coyner et al. 2013), given their dense taxonomic sampling and the overall relevance of their findings. What follows in this account is mostly based on M. F. Smith and Patton (2007) and Jayat et al. (2010); we also make some comments about the results recently published by Coyner et al. (2013), based on Coyner (2010), although these two studies have more limited taxonomic coverage and do not include several major changes proposed in recent years. However, and importantly, Coyner et al. (2013) presented

a phylogenetic hypothesis derived from concatenated mtDNA and nucDNA sequences, expanding the available molecular data for *Akodon*.

Currently, five species groups are recognized in *Akodon*. (1) The *Akodon aerosus* group is minimally composed of *A. aerosus*, *A. albiventer*, *A. affinis*, *A. mollis*, *A. orophilus*, *A. surdus* (varyingly regarded as a synonym of *aerosus* [Patton and Smith 1992a,b] or as a species, such as herein [see also Coyner et al. 2013]), and *A. torques*. M. F. Smith and Patton (2007) recovered *A. budini* and *A. siberiae* as part of their *A. aerosus* species group, but Jayat et al. (2010), in a more taxon dense study, found that both species fell outside of a core *aerosus* clade. (2) The *Akodon boliviensis* group contains *A. boliviensis*, type species of the genus, plus *A. caenosus*, *A. fumeus*, *A. juminensis*, *A. kofordi*, *A. lutescens*, *A. polopi*, *A. spegazzinii*, *A. subfuscus*, and *A. sylvanus*. (3) The *Akodon cursor* species group includes *A. cursor*, *A. montensis*, *A. reigi*, and *A. paranaensis* as well as the forms referred in the literature as *A. aff. cursor* and *Akodon sp. 2n=10* (see M. J. de J. Silva et al. 2006). M. F. Smith and Patton (2007) posited that *A. sanctipaulensis* was a member of this group, although to date it has not been included in any molecular analysis. Preliminary assessments also place *A. mystax* and *A. lindberghi* together as a small body-size subgroup in the *cursor* group, one from eastern Brazil that shares a $2n=42$ karyotype (P. R. Gonçalves et al. 2007; Jayat et al. 2010; Coyner et al. 2013). (4) The recently delimited *Akodon dolores* group (Jayat et al. 2010; see also Coyner et al. 2013), which includes *A. dayi*, *A. dolores* (including *molinae*), *A. iniscatus*, and *A. toba*. (5) An *Akodon varius* group that is now restricted to *A. simulator* and *A. varius* (see Jayat et al. 2010). Coyner et al. (2013) proposed to transfer these species to the *aerosus* group, given they appear as sister to that clade. We do not favor this proposition, given the large morphological gap between members of the two groups. *Akodon pervalens*, for which no DNA sequence data are yet available, likely belongs to the *varius* species group. Finally, there is a set of *Akodon* species whose phylogenetic position is currently unresolved, including *A. azarae*, *A. budini*, *A. mimus*, *A. philipmyersi*, and *A. siberiae*. Relationships among species groups as well as sister-pair relationships within the groups also vary greatly among analyses. More robust analyses using nuclear in addition to mitochondrial gene sequences are required to clarify further the contents of each species group as well as the relationships both among and within them.

Phylogenetic analyses of *Akodon* species have been also used in recent new species descriptions with the aim of correctly placing the new forms in the *Akodon* radiation and then to guide species comparisons (e.g.,

philipmyersi, Pardiñas, D'Elía et al. 2005; *polopi*, Jayat et al. 2010). Similarly, phylogenetic analyses have been used in taxonomic studies designed to assess the distinction of different nominal forms as, for example, cases where either recognition at the species level was supported (e.g., *sylvanus*, Jayat, Ortiz et al. 2007) or was falsified, resulting in names becoming junior synonyms (e.g., *oenos*, Pardiñas, Teta, D'Elía, and Diaz 2011; *viridescens*, D'Elía et al. 2011, see also Coyner et al. 2013:9). Finally, phylogenetic analyses have recently begun to tackle aspects of *Akodon* evolutionary history in addition to traditional questions of systematics and taxonomy, notably the independent origin of XY* females (Hoekstra and Edwards 2000), the direction of chromosomal evolution (M. C. Barros et al. 2009), or more general historical biogeography (M. F. Smith and Patton 2007; M. C. Barros et al. 2009).

SYNONYMS:

Mus: J. B. Fischer, 1829:313; part (description of *azarae*); not *Mus* Linnaeus.
Akodon Meyen, 1833:599; type species *Akodon boliviense* Meyen, by original designation.
Hesperomys: Wagner, 1843a:519; part (listing of *arenicola*); not *Hesperomys* Waterhouse.
Acodon Tschudi, 1844:177; incorrect subsequent spelling of *Akodon* Meyen.
Axodon Giebel, 1855:48; incorrect subsequent spelling of *Akodon* Meyen.

[*Akodon (Bolomys)*]: Ellerman, 1941:415; part (listing of *albiventer*, *berlepschii*, and *leucolimnaeus*); not *Bolomys* Thomas.
Akodon (Bolomys): Sanborn, 1950:13; name combination.
Plectomys Borchert and Hansen, 1983:237; *nomen nudum* (see Hershkovitz 1990b:21–23).

KEY TO THE SPECIES OF AKODON: [NOTE THAT MANY SPECIES ARE SO SIMILAR MORPHOLOGICALLY, AND SPECIES BOUNDARIES ARE SO POORLY UNDERSTOOD, THAT IT IS DIFFICULT TO PRODUCE A DEFINITIVE KEY. THE ONE PROVIDED HERE IS UNCONVENTIONAL IN THAT IT IS NOT STRICTLY DICHOTOMOUS. SUBSTANTIAL WORK IS REQUIRED TO IMPROVE ON THIS ATTEMPT.]

1. Anteromedian flexus absent *Akodon serrensis*
- 1'. Anteromedian flexus present 2
2. Found in Andes, Bolivian lowlands, dry Chaco, Monte, and Patagonia 3
- 2'. Found in Atlantic forest, Cerrado, humid Chaco, and temperate eastern grasslands 15
3. Molars strongly hypsodont; braincase rounded; rostrum narrow and pointed 4
- 3'. Molars slightly to moderately hypsodont; braincase squared; rostrum broad and moderately short 5
4. Found in eastern Andes of Cochabamba department, Bolivia; zygomatic plate narrow; tail length >45% of total length *Akodon siberiae*
- 4'. Found in eastern Andes of northwestern Argentina and southernmost Bolivia; zygomatic plate moderately broad; tail length <45% of total length *Akodon budini*
5. Size large (maxillary tooth-row length >4.5 mm); supraorbital region squared or beaded, often with edges divergent posteriorly; rostrum short and broad; interorbital region broad; $2n=34-42$, FN=40–44 6
- 5'. Size small to medium (maxillary tooth-row length <4.5 mm); supraorbital region smooth, without edges divergent posteriorly; rostrum moderately long and narrow; interorbital region narrow 7
6. Found in northern and central Bolivia; tail unicolorous dark; foot dark *Akodon dayi*
- 6'. Found in central and southern Bolivia; zygomatic plate narrower *Akodon varius*
- 6''. Found in Yungas of southern Bolivia; rostrum especially broad *Akodon pervalens*
- 6'''. Found in Yungas of southern Bolivia and northwestern Argentina; dorsally gray or brown; conspicuous buffy eye rings *Akodon simulator*
- 6'''. Found in dry Chaco; skull proportionately broader; shorter nasals *Akodon toba*
- 6'''. Found in montane Chaco and Monte; colour uniform pale brown; skull strongly bowed *Akodon dolores*
7. Found in Patagonia; $2n=33-34$ *Akodon iniscatus*
- 7'. Found in Andes and Andean ranges, $2n=40$, FN=40 8
8. Zygomatic plate of “microxine” type, inclined backward and narrow; zygomatic notches very shallow *Akodon mimus*

- 8'. Zygomatic plate of "akodont" type, straight and moderately broad; zygomatic notches distinct 9
9. Body pelage pattern distinctly countershaded; bullae especially enlarged; upper incisors slightly proodont *Akodon albiventer*
- 9'. Body pelage pattern indistinctly or not countershaded; bullae normal sized; upper incisors opisthodont to slightly orthodont 10
10. Size small to medium; interorbit narrow; $2n=34$ or 40 , $FN=40$ 11
- 10'. Size medium; interorbit broad; $2n$ variable in number 14
11. Size small; tail length <70 mm 12
- 11'. Size medium; tail length >70 mm 15
12. Zygomatic notches and plates broad; braincase moderately broad; strongly bilophodont third molars *Akodon boliviensis*
- 12'. Zygomatic notches shallow; zygomatic plates narrow; $2n=34$ *Akodon caenosus*
- 12". Zygomatic notches narrow; teeth relatively large; M3 usually oval *Akodon subfuscus*
- 12"". Zygomatic notches small and shallow; zygomatic plates narrow; M3 with a distinct metaflexus *Akodon juninensis*
- 12'''. Hindfoot <21 mm; length of maxillary tooththrow <3.8 mm *Akodon lutescens*
- 12'''. Found on eastern Andean slopes of northwestern and central Argentina; coloration variable; rostrum well developed *Akodon spegazzinii*
13. Found isolated in central Argentina in elevations $>1,500$ m *Akodon polopi*
- 13'. Found isolated in Sierra de Santa Bárbara, Jujuy province, Argentina *Akodon sylvanus*
- 13". Tail bicolored; mesopterygoid fossa broad. *Akodon fumeus*
- 13'''. Tail unicolored; mesopterygoid fossa lyre shaped *Akodon kofordi*
14. Found in the Cordillera Occidental, western Colombia *Akodon affinis*
- 14'. Found in upper eastern Andean slopes, central Peru; $2n=26$, $FN=40$ *Akodon orophilus*
- 14". Found from northwestern Peru to northern Ecuador; $2n=22-23$, $FN=40$ *Akodon mollis*
- 14'''. Found in upper montane forests of eastern Andean slopes, $1,000-2,000$ m, in Ecuador, Peru, and Bolivia; $2n=22, 38$, or 40 , $FN=40$ *Akodon aerosus*
- 14'''. Found in eastern Andean forests, $2,900-3,800$ m, of Huánuco department, central Peru; $2n=22$, $FN=40$ *Akodon josemariarguedasi*
- 14'''. Found on eastern Andean slopes of Ayacucho and Cusco departments, Peru; tail nearly naked and very long; zygomatic plate resembling "microxine" type *Akodon torques*
- 14'''. Found in cloud forests, eastern flank of southeastern Andes in Peru; fur short, crisp, and dark; cranial profile relatively flat. *Akodon surdus*
15. Size large; tail length >70 mm; maxillary tooththrow length >4.5 mm. 16
- 15'. Size small to medium; tail length <70 mm; maxillary tooththrow length <4.3 mm 17
16. $2n=10$ *Akodon* sp. $2n=10$
- 16'. $2n=14-16$; gall bladder present. *Akodon cursor*
- 16''. $2n=44$, $FN=42$ *Akodon reigi*
- 16'''. $2n=44$, $FN=44$ *Akodon paranaensis*
- 16'''. $2n=24-25$; gall bladder absent *Akodon montensis*
17. Zygomatic plates narrow 18
- 17'. Zygomatic plates broad; found in nonforested habitats of southern Brazil, eastern Paraguay, south to Uruguay and central Argentina *Akodon azarae*
18. Isolated distribution in southern Misiones province, Argentina; $2n=36$ *Akodon philipmyersi*
- 18'. Isolated on Mt. Caparaó, Brazil; $2n=42-44$; masseteric scar distinct. *Akodon mystax*
- 18''. Found in Cerrado and Atlantic forest of Brazil; $2n=42$; masseteric scar indistinct *Akodon lindberghi*
- 18'''. Isolated in São Paulo state, Brazil; interorbit broad *Akodon sanctipaulensis*
- Akodon aerosus* Thomas, 1913
Yungas Grass Mouse, Yungas Akodon
 SYNONYMS:
Hesperomys (Habrothrix) caliginosus: J. A. Allen, 1891b: 210; part; not *Hesperomys caliginosus* Tomes.
 [Acodon] *caliginosus*: Thomas, 1894b:356; part; not *Hesperomys caliginosus* Tomes.
Akodon aerosus Thomas, 1913b:406; type locality "Miraador, Baños, Ecuador. Alt. 1500 m.," Baños (ca. 2.924° S, 79.066° W), Azuay, Ecuador.
Akodon aerosus baliolus Osgood, 1915:192; type locality "Inca Mines, Inambari River, Peru," Santo Domingo (ca. 13.85° S, 69.683° W), Puno, 1,689 m, on the Río Inambari, general area of gold mines near town called Inca Mine belonging to the Inca Mining Co. (see Stephens and Traylor 1983).
Akodon (Chalcomys) aerosus: Thomas, 1916i:338; name combination.
Akodon (Chalcomys) aerosus aerosus: Gyldenstolpe, 1932a: 110; name combination.
Akodon (Chalcomys) aerosus baliolus: Gyldenstolpe, 1932a: 110; name combination.
Akodon urichi aerosus: Cabrera, 1961:448; name combination.

Oryzomys (Melanomys) caliginosus caliginosus: S. Anderson, 1985:12; part; not *Hesperomys caliginosus* Tomes.

DESCRIPTION: Described originally as large dark species almost indistinguishable externally from *Melanomys caliginosus*. Pelage dark brown above and slightly paler below, with ears, forefeet, hindfeet, and tail blackish brown. Patton and Smith (1992b) characterized species by its large body size (total length ca. 190 mm), dense but short fur, moderately long and nearly naked tail, and nearly uniform coloration (deep blackish or reddish brown dorsally and paler on the venter). Skull strongly built (condyloincisive length ca. 25.6 mm), with broad interorbital region; rostrum short and broad; smooth and nonbeaded supraorbital ridges; evenly convex dorsal profile; anterior edges of zygomatic plates straight to slightly concave; incisive foramina long, widely open, and with smoothly rounded edges; broad mesopterygoid fossa; and long maxillary toothrow (ca. 4.6 mm). S. Anderson (1997) provided external and cranial measurements for Bolivian specimens.

DISTRIBUTION: *Akodon aerosus* occurs in lower montane forests along the eastern Andean slopes, between 1,200–2,400 m, from southern Ecuador, through Peru, to central Bolivia (Patton and Smith 1992a,b; S. Anderson 1997). In Peru (Patton and Smith 1992a,b), this species is found in a series of disjunct populations in Amazonas, San Martín, Huánuco, Junín, Ayacucho, Cusco, and Puno departments. It is apparently absent from the Urubamba drainage in Cusco department, Peru, where it is replaced by *A. surdus* (see Remarks for that species). In Bolivia, it is found along a narrow band of Yungas forest between Cochabamba and La Paz departments (S. Anderson 1997). No fossils are known for *A. aerosus*.

SELECTED LOCALITIES (Map 58): **BOLIVIA:** Cochabamba, Alto Palmar, Chapare (S. Anderson 1997); La Paz, 17 km N of Apolo (Anderson 1997), base of Mt. Sorata (S. Anderson 1997). **ECUADOR:** Azuay, Baños (type locality of *Akodon aerosus* Thomas). **PERU:** Amazonas, Cordillera del Cóndor, Valle Río Comaina, Puesta Vigilancia 3, Alfonso Ugarte (USNM 581938); Ayacucho, Hacienda Luisiana [= Luisiana], Río Apurímac (Patton and Smith 1992a,b); Cusco, 72 km NE of Paucartambo (Patton and Smith 1992a), Hacienda Cadena [= Cadena], Marcapata (Patton and Smith 1992a,b), 2 km SW of Tangoshiari (USNM 588097); Huánuco, 35 km NE of Tingo Maria on Carretera Central (LSUMZ 12600); Junín, 10 km WSW (by road) of San Ramón (MVZ 172873); Puno, 14 km W of Yanahuaya (Patton and Smith 1992a,b), Inca Mines, Río Inambari (= Santo Domingo) (type locality of *Akodon aerosus baliolus* Osgood), Ocanaque, 10 mi N of Limbani (MVZ 116110), 11 km NNE of Ollachea (Patton and Smith 1992a,b).

SUBSPECIES: S. Anderson (1997) recognized *baliolus* as a subspecies for Bolivian populations, and Pacheco et al. (2012) treated *baliolus* as a species. As yet comparisons of available samples have not substantiated either hypothesis of this latitudinally widely distributed and karyotypically variable species.

NATURAL HISTORY: There is no published information of the natural history of this species. Known records are restricted to forested environments of the Yungas along the eastern versant of the Andes, between 1,200–2,400 m. Pacheco et al. (2011; referred to as *A. baliolus*) found high frequencies of *A. aerosus* in premontane forests between 1,200 and 1,985 m in the Río Tambopata drainage of Puno department, Peru. Limited reproductive data from labels of specimens in the MVZ document pregnant and lactating females in the months of July and August in southern Peru, with litter size (based on embryo counts or placental scars) ranging from two to seven.

REMARKS: A member of the *Akodon aerosus* group, as defined by M. F. Smith and Patton (2007), which includes the nominal taxa *aerosus*, *affinis*, *baliolus*, *budini*, *mollis*, *orophilus*, *siberiae*, *torques*, and putatively *albi-venter*. Thomas (1916i), mostly based on the dark-colored appearance and velvety fur of this rodent, established the subgenus *Akodon (Chalcomys)*, in which he also included *urichi*, *venezuelensis*, and *meridensis* (all three names now allocated to *Necromys*; see that account). Cabrera (1961) considered *aerosus* a synonym of *urichi*, but A. L. Gardner and Patton (1976) listed the two as separate species based on a pronounced difference in diploid number. Phylogenetic analysis of mtDNA sequences failed to recover a monophyletic *aerosus*, suggesting that more than one species is encompassed within the current concept of this taxon (see Patton et al. 1990; Patton and Smith 1992a,b; M. F. Smith and Patton 2007). Patton and Smith (1992b) included *surdus* under *aerosus*, based on their examination of mtDNA sequences of a single specimen from Machu Picchu, which is within the range of *surdus* as defined by Thomas (1917g, 1920h). Pacheco et al. (2012) treated *baliolus* as a species, based on karyotype differences noted by Patton and Smith (1992a,b) and shorter nasals of Puno samples relative to those from central Peru north to Ecuador. A thorough revision of *A. aerosus*, as delineated herein, is badly needed, both to define the number of taxa included and delimit their respective geographic ranges. Myers (1990) documented the morphological distinctiveness of *A. aerosus* as compared with *A. varius* and related forms.

Patton et al. (1990) and Patton and Smith (1992a,b) reported considerable variation in karyotype among populations in southern Peru that shared identical morphology, with $2n=40$ for specimens from Ayacucho department,

Map 58 Selected localities for *Akodon aerosus* (●). Contour line = 2,000 m.

$2n=38$ for specimens from Puno department, and $2n=22$ for those from Cusco department.

Akodon affinis (J. A. Allen, 1912)

Colombian Grass Mouse, Colombian Akodon

SYNONYMS:

Microxus affinis J. A. Allen, 1912:89; type locality "San Antonio (near Cali, alt. 8000 ft.), Cauca, Colombia"; San Antonio (3.2993°N, 76.5192°W), Santiago de Cali, Colombia.

Akodon tolimae J. A. Allen, 1913a:480; type locality "Río Toché, Quindío Andes, Tolima, Colombia; altitude, 7000 feet."

Microxus (?) *affinis*: Gyldenstolpe, 1932a:134; name combination.

Akodon affinis: Goodwin, 1953:320; first use of current name combination.

DESCRIPTION: Medium sized (total length = 160 mm; tail = 70 mm; greatest length of skull = 25.8 mm; upper toothrow = 5 mm [measurements of holotype, from J. A. Allen 1912]), characterized by uniform dusky brown upper parts, with tips of hairs yellowish, giving general olivaceous effect; venter dark grayish brown, with tips of the hairs olivaceous, giving the general effect of dark grayish brown with faint olive tinge; ears dull brown, nearly naked, rather short and broad; feet grayish brown, hairs dark with lighter tips; tail brown, not appreciably bicolored, nearly naked, shorter than head and body.

DISTRIBUTION: *Akodon affinis* is known from the Cordillera Occidental of western Colombia (Musser and Carleton 2005). No fossils are known.

SELECTED LOCALITIES (Map 59): COLOMBIA: Antioquia, Vereda Puente Peláez, Finca Cañaverl (Voss et al. 2002); Nariño, Galera (J. A. Allen 1913a), La Florida (J. A. Allen 1913a); Risaralda, La Pastora, Reserva Ucumarí (Quiceno 1993), Vereda Siató (Voss et al. 2002); Santander, 10 km W of Santander (MVZ 124065); Valle del Cauca, Bosque San Antonio, Cordillera Occidental (Quiceno 1993), Corregimiento Baragán, Hacienda La Esperanza (Quiceno 1993), Hacienda La Sirena, carretera Palmira-La Nevera (Quiceno 1993), Hacienda Los Alpes (Quiceno 1993), Laguna Sonso (Quiceno 1993), Municipio de Roldanillo (Quiceno 1993), 4 km NW of San Antonio (MVZ 124066).

NATURAL HISTORY: Few ecological data are available for this species. It is apparently common, especially in secondary and altered habitats (R. P. Anderson and M. Gómez-Laverde, pers. comm.). Voss et al. (2002) captured 10 specimens in the valley of the Río Siató, Risaralda department, at 1,520–1,620 m in 405 trap-nights. It has been found in both primary cloud forests and adjacent anthropogenically modified vegetation in relatively cool and very humid environments (Voss et al. 2002). This mouse is terrestrial, mostly diurnal and crepuscular, and probably feeds on insects, seeds, and vegetation (Quiceno 1993).

REMARKS: J. A. Allen originally allocated this species to *Microxus*, possibly influenced by its external resemblance to *A. bogotensis*. Anthony (1924:4), in his description of *A. latebricola*, suggested that *affinis* was unlike other *Microxus* and perhaps was more appropriately placed in *Akodon*. Goodwin (1953:320) later formalized Anthony's opinion, a treatment followed by Cabrera (1961:440). One individual sequenced by M. F. Smith and Patton (2007), putatively referred to this species and collected about 180 km NNE of the type locality, was found to be part of the *Akodon aerosus* group (see Remarks under *A. aerosus*). *Akodon tolimae* was treated as a full species by several authors (e.g., Reig 1987) but later was subsumed under *affinis* (Musser and Carleton 1993:688; see also Reig, Kiblicky, and Linares 1971:162). *Akodon tolimae* was briefly diagnosed as a taxon similar to *aerosus* but much smaller and darker. Although the conspecificity of *affinis* and *tolimae* is plausible, given their geographic proximity and similar morphology, their actual relationship needs clarification. Quiceno (1993) found two different cytotypes, $2n=24$ and $2n=26$, both with FN=40 in a survey of *Akodon* populations in Valle del Cauca and Risaralda departments, Colombia. He associated the former karyotype with the name *affinis* and the latter with *tolimae*, but regardless of these assignments, the chromosomal data suggest systematic complexity among *Akodon* populations in the northern Andes of Colombia.

Map 59 Selected localities for *Akodon affinis* (●). Contour line = 2,000 m.

Akodon albiventer Thomas, 1897

White-bellied Grass Mouse, White-bellied Akodon

SYNONYMS:

Akodon albiventer Thomas, 1897d:217; type locality “Lower Cachi,” Salta, Argentina; it is likely that Thomas referred to the lower course of the Río Cachi, which passes through the town of Cachi (25°07′11.93″S, 66°09′47.00″W, 2,341 m, Salta province), close to the junction with the Río Calchaquí (see Jayat et al. 2010).

Akodon Berlepschii Thomas, 1898c:281; type locality “Esperanza, a ‘tambo’ in the neighbourhood of Mount Sahama, [La Paz,] Bolivia.”

B[olomys]. albiventer: Thomas, 1916i:339; name combination.

B[olomys]. berlepschi: Thomas, 1916i:340; name combination and incorrect subsequent spelling of *Akodon berlepschii* Thomas.

Akodon [(Bolomys)] albiventer: Ellerman, 1941:415; name combination.

Akodon [(Bolomys)] berlepschii: Ellerman, 1941:415; name combination.

Akodon albiventer berlepschii: Pine et al., 1979:347; name combination.

DESCRIPTION: Small to moderate sized with total body length from 162–179 mm, tail length 69–77 mm, ear length 13–13.5 mm, and hindfoot length (with claw) 20–22 mm; fur short and coarse, slightly woolly in texture; general color pale grizzled grayish, tips of darker hairs brown and of paler ones whitish buff, all slate gray at their base; venter snowy white, contrasting strongly with the dorsum; eyes with whitish eye ring; ears short, with a few whitish hairs that form an indistinct postauricular spot; dorsal surfaces of both forefeet and hindfeet pure white; tail short, well haired, brown above and white on sides and below. Skull with short rostrum, shallow and narrow zygomatic notches, zygomatic arches not flared laterally, and broad interorbital region with rounded edges; zygomatic plates broad, with anterior margins straight; incisive foramina extend to hypoflexus of M1; mesopterygoid fossa broad, with rounded anterior margin and parallel sides; auditory bullae very large for the genus, with short and broad bony tubes. Mandibular ramus low, with short symphysis. Upper incisors orthodont. M1 with well-developed anteromedian flexus and conspicuous anteroloph; major cups nearly parallel; mesoloph present but reduced. M2 similar to M1 but with reduced procingulum. M3 even more reduced and oval in occlusal view. Lower m1 with well-developed anteromedian flexid and anterolabial cingulum; both ectostylid and ectolophid present but reduced; m2 with very shallow protoflexid visible only in young individuals; m3 bilophodont and sigmoid in shape. Condylolincisive length averages 23.7 mm and upper molar series 4.1 mm.

DISTRIBUTION: *Akodon albiventer* is widely distributed in the Andean Altiplano and other highlands, from southern Peru in Arequipa and Puno departments, through southwestern Bolivia and northern Chile, to northwestern Argentina in Jujuy and Salta provinces. Most localities are between 3,000 to 4,500 m, but a few are from as low as 2,350 m (Thomas 1897d; Pearson 1951; Pine et al. 1979; S. Anderson 1997; M. M. Díaz and Barquez 2007). The species is known from a late Holocene archaeological site at Inca Cueva, Jujuy, Argentina (Teta and Ortiz 2002; P. E. Ortiz et al. 2011b).

SELECTED LOCALITIES (Map 60): ARGENTINA: Jujuy, El Toro, 55 km W of Susques (IADIZA 3336), 0.5 mi E of Tilcara (MVZ 119934); Salta, Cauchari (MSB 75252), Lower Cachi (type locality of *Akodon albiventer* Thomas). BOLIVIA: La Paz, Salla (S. Anderson 1997); Oruro, 7 km S and 4 km E of Cruce Ventilla (S. Anderson 1997), Luca (S. Anderson 1997), 40 km S of Oruro (MVZ 119935); Potosí, Quetena Chica on Río Quetena (S. Anderson 1997), 4 mi E of Uyuni (MVZ 119936), 5 mi [= 8 km] E of Uyuni (S. Anderson 1997), 5 mi N of Villazon

(MVZ 119938); Tarija, 4.5 km E of Iscayachi (S. Anderson 1997). CHILE: Arica y Parinacota, Caritaya, 75 mi SE of Arica (MVZ 116770). PERU: Arequipa, 15 km S of Cailloma (Pearson 1951); Moquegua, 5 mi NW of Toquepala (MVZ 145543); Puno, Hacienda Calacala, 7 mi SW of Putina (MVZ 116650); Puno, 1 mi SW of Ancomarca (MVZ 141330), Hacienda Calacala, 7 mi SW of Putina (MVZ 116650), Hacienda Pairumani, 24 mi S of Ilave (MVZ 114651), 5 mi N of Mazocruz (MVZ 139552); Tacna, 0.5 mi W of Challapalca (MVZ 141335), Río Tarata (MVZ 115700).

SUBSPECIES: Thomas (1902c) noted that *albiventer* and *berlepschii* might be conspecific and that color differences between the two probably intergraded. Pine et al. (1979) unequivocally stated that the two were conspecific but that fresh pelage of individuals from within the range of *albiventer* may turn out to be more buffy-brown and less gray than in individuals from within the range of what has been called *berlepschii*. Considering the geographical distance between the two forms as currently known and keeping in mind that supposed pelage differences could have some validity, these authors provisionally recognized the two as subspecies. However, this hypothesis has not as yet been tested through geographic analysis of any character set.

NATURAL HISTORY: *Akodon albiventer* primarily occupies semiarid Puna and high Andean environments, but at their southern distributional limit the species also extends into the Monte desert. Although it has been trapped in open grassy places, *A. albiventer* seems to prefer more sheltered habitats such as dense tola shrubland and man-made rock walls that provide protection (Pearson 1951). In both Bolivia and Peru, *A. albiventer* lives together with *A. boliviensis* (Pearson 1951; S. Anderson 1997). In northern Chile, this species inhabits meadows with dense grass and rock walls, especially near watercourses (Pine et al. 1979). Here it was found in association with *Abrothrix andina*. In Argentina, *A. albiventer* occurs sympatrically with *A. spegazzinii* (M. M. Díaz and Barquez 2007). This species has been reported as mostly or entirely diurnal by several authors (Pearson 1951; Mann 1978, Pine et al. 1979). M. M. Díaz and Barquez (2007) commented on an individual feeding on grass in Jujuy province, Argentina.

There are few published observations on reproduction and molting for this species. S. Anderson (1997) reported two males with enlarged testes (8 and 9 mm long) caught in July, but 10 other large specimens caught at the same time were still sexually undeveloped. A female caught in July had an open vagina, but no females contained embryos, so the breeding season

must not begin until after July. M. M. Díaz and Barquez (2007) observed young individuals in Jujuy province between January and June. Males with nonscrotal testes were captured from February to June and in November, and males with scrotal testes in February, March, and December. These authors also mentioned females with closed vaginas in February, March, and June, and females with open vaginas in February, March, and December. Lactating and pregnant females were trapped in February, March, and December. Molting animals were collected in February, March, June, and December. Beaucournu et al. (2011) described a new species of flea in the genus *Agastyopsylla* from specimens collected from in Tarapacá, Chile.

REMARKS: *Akodon albiventer* was once considered a member of the genus *Bolomys* [= *Necromys*] (Thomas 1916; Gyldenstolpe 1932; N. O. Bianchi et al. 1971; A. L. Gardner and Patton 1976; E. Massoia, in Massoia and Pardiñas 1993). However, the inclusion of *albiventer* in *Akodon* is supported on molecular and, to a more limited extent, morphological grounds (Pine et al. 1979; Reig 1987; D'Elía et al. 2003; M. F. Smith and Patton 2007). Phylogenetic analyses based on mtDNA cytochrome-*b* gene sequences supported a sister relationship of *A. albiventer* and several Andean species of *Akodon*, including *A. aerosus*, *A. affinis*, *A. orophilus*, and *A. torques* (Jayat et al. 2010).

N. O. Bianchi et al. (1971) reported a $2n=40$ chromosomal complement, represented by 38 acrocentric and two small metacentric elements.

Map 60 Selected localities for *Akodon albiventer* (●). Contour line = 2,000 m.

Akodon azarae (J. B. Fischer, 1829)

Azara's Grass Mouse, Azara's Akodon

SYNONYMS:

Ratton agreste Brants, 1827:184; based on Azara's (1802:94) "el agreste"; ruled by the International Commission (ICZN 1982:Opinion 1232) to be a vernacular name and unavailable for use in zoological nomenclature.

M[us]? *Azarae* J. B. Fischer, 1829:325; based on Azara's (1802:94) "el agreste" with type locality given as "In Paraguaya" although Azara wrote (1802:94) "en los 30 ½ grados de latitude," erroneously interpreted as "30½° (= latitude of Entre Ríos Argentina)" by Tate (1932:26; see also Cabrera 1961:440); Pardiñas et al. (2007:401) reviewed the available evidence and corrected the type locality to "São Gabriel (30°19'S, 54°19'W, 118m) . . . in the Brazilian State of Rio Grande do Sul."

Mus arenicola Waterhouse, 1837:18; type locality "Maldonado," Maldonado, Uruguay.

Hesperomys arenicola: Wagner, 1843a:466; name combination.

[*Akodon (Akodon)*] *arenicola*: E.-L. Trouessart, 1897:536; name combination.

Akodon arenicola hunteri Thomas, 1917c:97; type locality "Isla Ella, in the delta of the Rio Parana, at the top of the La Plata Estuary"; restricted by Pardiñas et al. (2007:402) to a "small island (ca. 1 km²) surrounded by the streams Espera and Esperita (34°22'S, 58°38' W, Primera Sección Delta del Paraná, Tigre, Buenos Aires . . .)."

[*Akodon arenicola*] *arenicola*: Thomas, 1917c:97; name combination.

Akodon azarae: Tate, 1932:5; first use of current name combination.

Akodon azarae azarae: Cabrera, 1961:440; name combination.

Akodon azarae hunteri: Cabrera, 1961:440; name combination.

Akodon azarae bibianae Massoia, 1971b:131; type locality "Estación Experimental El Colorado (INTA), Departamento de Pirané, Provincia de Formosa, República Argentina."

DESCRIPTION: Medium-sized akodont, with head and body length 90–114 mm and tail length 69–90 mm; fur moderately soft and long (9–13 mm); dorsal color olive brown to deep brown, usually tinged buffy on sides and cheeks; ventral hairs gray based and buffy tipped, and thus moderately demarcated from dorsum; ears clothed in short brown hairs; hindfeet tan above; bicolored tail shorter than head and body. Skull delicate; rostrum narrow and pointed; interorbital region hourglass shaped with rounded edged; temporal and mastoid ridges weak; interparietal small; zygomatic arches weak, not flaring laterally; zygo-

matic plates narrow; palate short; incisors delicate (Myers 1990). Massoia and Fornes (1964a) and Hershkovitz (1990b) provided external and cranial measurements. Sierra de Soriano (1969) detailed the external morphology of Uruguayan specimens.

DISTRIBUTION: *Akodon azarae* ranges from Rio Grande do Sul in southern Brazil, and eastern Paraguay south through Uruguay to central Argentina (Reig 1964; Barlow 1969; Massoia 1971b; Dalby 1975; Myers and Wetzel 1979; Gamarra de Fox and Martin 1996). Known populations in Argentina are mostly restricted to the eastern part of the country (Buenos Aires, Chaco, Corrientes, Entre Ríos, Formosa, and Santa Fe provinces), extending to the southern tip of Buenos Aires province and westward to La Pampa and Córdoba provinces. There is an unconfirmed record for the Parque Nacional Teniente Enciso, in the western Chaco of Paraguay (Gamarra de Fox and Martin 1996:537). Several fossils collected from Pleistocene deposits of Buenos Aires province, Argentina, have been referred to *A. azarae* (Ameghino 1889; Pardiñas 1999a). The oldest records for the species are Middle Pleistocene (Ensenadan), from Ramallo, Mar del Plata, and the vicinity of Bahía Blanca (see Pardiñas 1993, Pardiñas and Deschamps 1996, Voglino and Pardiñas 2005).

SELECTED LOCALITIES (Map 61): ARGENTINA: Buenos Aires, Bahía Blanca (Pardiñas, Abba, and Merino 2004), Balneario San Antonio (Pardiñas, Abba, and Merino 2004), Bañado de Flores, Buenos Aires (Massoia and Fornes 1967b), Cabaña San José (Pardiñas, Abba, and Merino 2004), Estancia El Abra (Pardiñas, Abba, and Merino 2004), Monte Hermoso (Pardiñas, Abba, and Merino 2004), Santa Clara del Mar (Reig 1964); Chaco, Capitán Solari (Massoia et al. 1995b); Córdoba, La Nacional (CNP-E 653-1), Marull (CNP-E 59-2), Río Cuarto (E. Castillo et al. 2003); Corrientes, Santo Tomé (CNP-E 650-1); Formosa, Cooperativa de Villa Dos Trece [= Kilómetro 213] (Pardiñas and Teta 2005); La Pampa, Estancia Los Guadales (Siegenthaler et al. 1993), Laguna El Chañar, Puesto El Chato (Siegenthaler et al. 1993); Santa Fe, Estación Santa Margarita (Massoia et al. 1995a), Jacinto L. Arauz (Teta and Pardiñas 2010). BRAZIL: Rio Grande do Sul, Alegrete (G. Gonçalves, pers. comm.), Esmeralda (Sbalqueiro, Mattevi, Oliveira, and Freitas 1982), Guaíba (G. Gonçalves, pers. comm.), Reserva Ecológica do Taim (Sbalqueiro, Mattevi, Oliveira, and Freitas 1982). PARAGUAY: Canindeyú, Reserva Natural Privada Morombí (J. Torres, pers. comm.); Presidente Hayes, 15.5 km by road NNW of Chaco-i (Myers and Wetzel 1979), 83 km NW of Puerto Falcón (Gamarra de Fox and Martin 1996). URUGUAY: Maldonado, Maldonado (type locality of *Mus arenicola* Waterhouse); San José, Kiyú (GD 327).

SUBSPECIES: Molecular and morphological data support three subspecies in our current concept of *A. azarae*:

A. a. azarae, *A. a. bibiana*, and *A. a. hunter*. The nominate race is restricted to southern Brazil and Uruguay; the other two are in central-eastern Argentina and northeastern Argentina and eastern Paraguay, respectively.

NATURAL HISTORY: *Akodon azarae* inhabits open grasslands, wet grasslands along rivers and marshes, open thorn woodlands, and borders of cultivated fields (Crespo 1966; Pearson 1967; Dalby 1975; Teta, González-Fischer et al. 2010). It utilizes shallow holes and will occasionally burrow; Massoia and Fornes (1965b) and K. Hodara et al. (1997) described the structure of the burrow systems. This animal may be either nocturnal or diurnal (J. R. Contreras 1979b).

Akodon azarae has a polygynous mating system (Bilenca and Kravetz 1998; O. Suárez and Kravetz 1998a; Zuleta and Bilenca 1992); the breeding season lasts about eight months, a period that roughly coincides with spring through autumn (Crespo 1966; Pearson 1967; Dalby 1975; Teta, González-Fischer et al. 2010). Although delayed implantation may occur, gestation in the laboratory usually lasts 22.7 to 24.5 days; the average litter size varies between 4.7 and 5.7 (range: 3–7 in Uruguay; 3–10 in Argentina); and neonates are altricial with an average birth weight of 2.2g (De Villafañe 1981; Mills, Ellis, McKee et al. 1992; C. Busch and Del Valle 2003). Mothers can control the sex ratio of their litters (Zuleta and Bilenca 1992). O. Suárez and Kravetz (1998a,b) described copulatory behavior, mating system, and transmission of food selectivity from mothers to offspring. De Villafañe (1981) examined development under laboratory conditions. Pearson (1967) and Zuleta et al. (1988) documented age structure and population dynamics of Argentinean populations. Life span varied between 7 and 8 months in individuals born in the spring, and from 10 and 12 months for those born in the autumn (K. Hodara et al. 2000).

Diet varied geographically and seasonally, but includes variable proportions of invertebrates and plant material, such as green vegetation, leaves, fruits, and seeds (Barlow 1969; Bilenca and Kravetz 1998; C. Busch and Del Valle 2003; Macdonald 2001; O. Suárez and Bonaventura 2001; O. Suárez and Kravetz 1998b). Dalby (1975), Zuleta and Bilenca (1992), and Priotto and Steinmann (1999) reported on home range use and size. Owls are common predators of this mouse (e.g., Kittlein 1997; Pardiñas 1999a; González-Fischer 2011). Navone et al. (2009) reported on parasites. This species is known to carry the Maciel and Pergamino hantavirus strains (O Suárez et al. 2003).

REMARKS: J. B. Fischer (1829) based his *M? Azarae* on “*el agreste*” of Azara (1802:94), but his name was generally ignored in favor of *A. arenicola* Waterhouse for much of the early nomenclatural history of this species. Tate

(1932c) and Cabrera (1961) established the current concept of *A. azarae*, including *arenicola* as a subjective junior synonym, and restricted the type locality to northern Entre Ríos province, Argentina. However, as detailed by Pardiñas et al. (2007) in their study of Felix de Azara’s voyages, the Spanish naturalist apparently captured this mouse in Brazil, in the vicinity of the city of São Gabriel, Rio Grande do Sul.

Ratton agreste Brants is a senior synonym of *Mus azarae* J. B. Fisher, but had not been used in the literature since its publication, including major taxonomic synopses (e.g., E.-L. Trouessart 1897, 1904; Tate 1932c; Cabrera 1961; Musser and Carleton 2005), except for a single mention by Hershkovitz (1966a:106; see also Hershkovitz 1990b:5). To stabilize the use of *azarae* J. B. Fisher for this species, Langguth (1966a, 1978) twice petitioned the International Commission on Zoological Nomenclature that Brants’s name be rejected. In 1982 (Opinion 1232), the Commission ruled that *Ratton* Brants was suppressed for the purpose of the Principle of Priority (but not for Homonymy) and placed it on the Official Index of Rejected and Invalid Generic Names in Zoology with the Name Number 2131. The Commission further ruled that *agrestes* Brants, as published in combination with *Ratton*, was a vernacular name and unavailable for use in zoological nomenclature (see ICZN 1987).

Karyotypes with $2n=37-38$, FN=40–44, are known for specimens from central Argentina (*hunteri* from Buenos Aires and La Pampa provinces, *bibiana* from Chaco province), Uruguay, and Brazil (*arenicola* from Maldonado and *azarae* from Rio Grande do Sul; e.g., N. O. Bianchi and Contreras 1967; Vitullo et al. 1984; Kasahara and

Map 61 Selected localities for *Akodon azarae* (●). Contour line=2,000m.

Yonenaga-Yassuda 1984; Tiranti 1999a). Two types of Y chromosomes have been reported from Brazilian specimens: acrocentric in populations in the northern part of Rio Grande do Sul, and submetacentric in the southern part of that state (Mattevi et al. 1981; Sbalqueiro, Mattevi, Oliveira, and Freitas 1982).

Akodon boliviensis Meyen, 1833

Bolivian Grass Mouse, Bolivian Akodon

SYNONYMS:

Akodon boliviense Meyen, 1833:600; type locality "Auf der Hochebene von Hochperu, in dem Indianer-dorfe Pichu-pichun, auf einer Höhe von 14000 Fuss gefangen"; Pichu-Pichún, 14,000 ft., Chucuito Province, Puno Department, Peru (as clarified by Myers et al. 1990:49–50).

Acodon boliviense: Tschudi, 1844:177; name combination. [*Akodon* (*Akodon*)] *boliviensis*: E.-L. Trouessart, 1897: 535; name combination.

Akodon pacificus Thomas, 1902b:135; type locality "La Paz, [La Paz,] 4000 m," Bolivia.

DESCRIPTION: Small, with total body length averaging 155.7 mm, tail length 64.6 mm, ear length 13.7 mm, and hindfoot length 21.1 mm; dorsal fur pale, brown-tinged olivaceous, uniformly colored across back and crown, lightly streaked with black; flanks similar to dorsum in color and pattern; narrow but conspicuous yellowish eye-ring present; venter paler, with hairs buffy tipped; inguinal area especially dark, almost rufous, in some individuals; small patch of white fur often occurs at apex of chin; tail sharply bicolored and heavily clothed with hairs. Skull with comparative broad zygomatic notches, with zygomatic arches tending to flare laterally more than other members of group; interorbital region narrow, with posterior margins tending to be squared; temporal and mastoid ridges unusually strongly developed; zygomatic plates relatively broad, with anterior faces vertically oriented; posterior ascending process of alisphenoid projects at least to squamosoalisphenoid groove; tympanic hook relatively stout; mesopterygoid fossa narrow, with anterior margin usually squared and often with a small median spine; M1 with well-formed parastyle, mesostyle present but tiny, and metalophule occasionally present; M2 with anterior cingulum and mesostyle always present; M3 relatively large and complex for *boliviensis* group species, averaging about half length of M2; metaflexus and hypoflexus of M3 partly divide tooth, giving occlusal surface a distinctive figure-8 shape. Lower m1 with distinguishable, but sometimes small, protostylid; both m1 and m2 usually with ectostylid and mesostylid present but always tiny; m3 long and conspicuously S-shaped. Condylolincisive length averages 22.4 mm, upper molar series length 4.0 mm.

DISTRIBUTION: *Akodon boliviensis* is widely distributed in highland grasslands of the Puna and western Andean slopes from southern Peru through central Bolivia to northwestern Argentina in Salta province. Most specimen records are from elevations above 3,500 m, but it has been found as low as 2,400 m (Myers and Patton 1989a; Myers et al. 1990; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007; Jayat, Ortriz et al. 2008, 2010). No fossils are known.

SELECTED LOCALITIES (Map 62): ARGENTINA: Salta, ca. 3 km SE of Abra de Ciénaga Negra (MACN 23499), Azul Cuesta, ca. 9 km S of Nazareno (MACN 23503). BOLIVIA: Chuquisaca, Río Limón (S. Anderson 1997); Cochabamba, 4.4 km (by road) N of Tablas Monte (S. Anderson 1997); La Paz, Pelechuco (Tarifa et al. 2007), Río Aceramarca (S. Anderson 1997); Oruro, 10 km by road SW of Pazña, Finca Santa Helena (Myers and Patton 1989a), 1.5 km SW of Sajama (S. Anderson 1997); Potosí, 20 km S of Potosí (Myers et al. 1990), Serranía Siberia, 11 km (by road) NW of Torrecillas (S. Anderson 1997); Tarija, Sama (S. Anderson 1997). PERU: Moquegua, 19 km NE of Torata (Myers et al. 1990); Puno, 11 km W and 12 km S of Ananea (MVZ 173033), 13 mi W and 2 mi N of Crucero (Myers et al. 1990), Hacienda Calacala, 7 mi SW of Putina (MVZ 116653), 4 km E Juli (MVZ 115670), Mazocruz (MVZ 115671), 5 km W of Puno (MVZ 115673), Río Huanque (MVZ 136259), 12 km S of Santa Rosa [de Ayaviri] (Myers et al. 1990), Tincopalca, 50 mi W of Puno (MVZ 114649); Tacna, Tarata (MVZ 141313).

SUBSPECIES: Cabrera (1961) considered *A. spegazzinii* and *A. tucumanensis* as subspecies of *A. boliviensis*, and *A. alterus* as a synonym of *A. boliviensis tucumanensis*. Myers et al. (1990), in their review of geographic variation in several craniodental, soft anatomical, and other traits, concluded that *spegazzinii*, *tucumanensis*, and *alterus* were best excluded from *A. boliviensis*. These authors, however, noted differences between specimens of *A. boliviensis* from the extreme northwestern (Moquegua department, Peru) and southeastern (Tarija, Bolivia) segments of the species' range, relative to a rather homogeneous set of geographically intermediate samples, but did not recommend any formal recognition of these end points.

NATURAL HISTORY: *Akodon boliviensis* is found in the drier environments of the Puna in southern Peru but extends into humid grasslands adjacent to the eastern Andes in central Bolivia. It is common in dense bunch grasses dominated by *Stipa* and *Festuca*, and in *Polylepis* woodlands fragments, and is readily trapped where rocks or shrubs are interspersed with grasses, and along rock walls of corrals or houses where there are clumps of grasses (Myers et al. 1990; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007). In Argentina, most

records come from relatively humid areas of the eastern Andean slopes, in the transition between uppermost Yungas and high Andean grasslands (Jayat et al. 2010). Along this broad distributional range, *A. boliviensis* maybe syntopic or contiguously allopatric with several other congeneric species, including *A. aerosus*, *A. albiventer*, *A. budini*, *A. lutescens*, *A. fumeus*, *A. caenosus*, *A. mimus*, *A. pervalens*, *A. siberiae*, *A. simulator*, *A. subfuscus*, *A. toba*, and *A. varius* (Myers et al. 1990; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). S. Anderson (1997) reported pregnant females between the months of January and September, with a mean of 4.5 embryos. In northwestern Argentina, Jayat et al. (2010) reported molting individuals in winter (July and August), but only a single individual was reproductively active; some specimens caught in spring (November) were both molting and reproductively active.

REMARKS: In the first revision of the small *Akodon* from the central Andes, Myers et al. (1990) defined a *boliviensis* group, characterized the morphological and distributional limits of *A. boliviensis*, and considered *A. spegazzinii* a valid species. Jayat et al. (2010) reidentified specimens previously referred to *A. boliviensis* from Salta province, Argentina, as *A. spegazzinii*, and noted plausible occurrence of *A. boliviensis* in Jujuy province, based on animals cited as *A. alterus* by M. M. Díaz and Barquez (2007).

Karyotyped individuals of *A. boliviensis* have a $2n=40$ karyotype, with slight geographic variation in autosomal arm number and/or sex chromosome morphology. In Puno

department, Peru, individuals are $FN=40$, with 18 pairs of unarmed autosomes (one distinctly larger than the remainder, which grade in size evenly from medium to small) and one very small pair of biarmed elements. The X chromosome is a medium-sized subtelocentric, and the Y is a small submetacentric, but larger than the smallest unarmed autosome (Myers et al. 1990). Specimens from Tacna department, Peru, have a $FN=42$, with 17 pairs of unarmed autosomes, one pair of large subtelocentrics, and one very small pair of biarmed elements. The X chromosome in this karyotype is a large subtelocentric, and the Y is a small submetacentric (A. L. Gardner and Patton 1976).

Akodon budini (Thomas, 1918)

Budin's Grass Mouse, Budin's Akodon

SYNONYMS:

Hypsimys budini Thomas, 1918b:190; type locality "Leon [= León], Jujuy, 1500 m"; Argentina.

Hypsimys deceptor Thomas, 1921k:613; type locality "Higuerilla, 2000 m"; Higuerilla = Pampichuela (23°32'S, 65°02'W, 1,735 m, Valle Grande, Jujuy, Argentina; see Pardiñas et al. 2007).

Akodon [(*Hypsimys*)] *budini*: Ellerman, 1941:414; name combination.

Akodon [(*Hypsimys*)] *deceptor*: Ellerman, 1941:414; name combination.

Akodon budini: Musser and Carleton, 1993:689; name combination.

DESCRIPTION: Large, with total body length 197–221 mm, tail length 52–99 mm, ear length 12–22 mm, and hindfoot length (with claw) 22–29 mm; general coloration olivaceous brown, finely sprinkled with black hairs; dorsal color uniform from head to rump, and onto flanks; ventral color paler, but contrasts only slightly with dorsum; conspicuous patch of white hairs covers chin and, in some specimens, throat; tail bicolored, dorsally brown or blackish brown and ventrally whitish or buffy, but not densely furred. Skull large; rostrum elongated; zygomatic notches narrow and deep; and frontal sinuses slightly swollen. Interorbital region hourglass in shape, with rounded margins and without overhanging borders; braincase broad and inflated, with poorly developed mastoid and temporal ridges; zygomatic plates relatively narrow and sharply slanted backward from bottom to top; incisive foramina long, generally extending to protocone of M1 or slightly beyond; mesopterygoid fossa broad, straight or lyre shaped, and anterior margin with median spine. Mandibular ramus relatively deep; anterior end of masseteric crest situated well behind level of anterior border of m1, generally reaching protoconid; capsular projection weakly developed and placed posterior to coronoid process. Upper incisors orthodont

Map 62 Selected localities for *Akodon boliviensis* (●). Contour line = 2,000 m.

or slightly proodont; molars strongly hypsodont for an *Akodon*; M1 with well developed procingulum but with only inconspicuous anteromedian flexus; both anteroloph and mesoloph present; M2 with remnant anteroloph and mesoloph; M3 large and complex, with well-developed paraflexus and metaflexus in most specimens and with anteroloph and mesoloph small but clearly visible. Lower m1 with well-developed anteromedian flexid and anterolabial cingulum, tiny ectostylid, and vestigial mesolophid; m2 also with ectostylid and mesolophid, but less developed than in m1; m3 very large, about 50% size of m2. Greatest skull length 26.8–29.8 mm; upper molar series length 4.7–5.4 mm.

DISTRIBUTION: All the records of *A. budini* are along eastern Andean slopes from south-central Bolivia in Chuquisaca department to northernmost Argentina, in Jujuy and Salta provinces, with most at elevations between 1,000 and 3,000 m (Emmons and Feer 1997; Pardiñas, D'Elía et al. 2006; M. M. Díaz and Barquez 2007; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). Because the distribution of *A. budini* in northwestern Argentina is limited to the eastern slopes of mountain ranges (the Santa Victoria, Zenta, Calilegua, and Chañi ranges), uniformly above 1,200 m, records from Jujuy well below this elevation (see M. M. Díaz and Barquez 2007) are questionable and need to be corroborated. In this regard, restudy of a specimen from Caimancito (MACN 20282), elevation 600 m, confirms it is an *Akodon simulator*, not *A. budini*. M. M. Díaz and Barquez (2007) listed *A. budini* as occurring at several localities around the Santa Bárbara range, eastern Jujuy province, but their specimens may actually be *A. sylvanus*, a species with similar external traits. No fossils are known.

SELECTED LOCALITIES (Map 63): ARGENTINA: Jujuy, Cerro Morado, sobre Río Morado, 11 km NW of San Antonio (CML 4604), Mesada de las Colmenas (Heinonen and Bosso 1994); Salta, Pampa Verde, ca. 8 km WSW of Los Toldos and S Cerro Bravo (MACN 23505), Parque Nacional Baritú, Finca Jakulica, Los Helechos (MACN 20666). **BOLIVIA:** Chuquisaca, Cerro Bufete (Emmons 1997b; this record needs confirmation), Horcas, 80 km SE of Sucas [= Sucre?] (MVZ 134648).

SUBSPECIES: We treat *Akodon budini* as monotypic.

NATURAL HISTORY: *Akodon budini* is mainly an inhabitant of the upper elevational belts of the Yungas forest. There are few published observations on reproduction and molting. In Jujuy province, Argentina, M. M. Díaz and Barquez (2007) reported young individuals between February and July, subadults in June, males with nonscrotal testes between June and September, males with scrotal testes in February and July, and females with closed and open vaginas in June and August. Individuals in active molt were found in June. No specimen caught in northernmost

Salta province in July ($N=3$) or May ($N=43$) was reproductively active (P. Jayat and P. E. Ortiz, unpubl. data). At least four other *Akodon* species may be found in sympatry, including *A. boliviensis*, *A. caenosus*, *A. fumeus*, and *A. simulator* (Barquez, Díaz, and Ojeda 2006; M. M. Díaz and Barquez 2007; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010).

REMARKS: *Akodon budini* is the type species of the genus *Hypsimsys*, which was diagnosed from *Akodon* by the very hypsodont molars, as emphasized by Thomas: “molars [are] quite unique in this group, highly hypsodont, almost as much so as in *Chinchillula*, though of so different a type to that as to make comparison difficult. They are just what *Akodon* teeth might be expected to become if made very hypsodont, high, narrow, with the vertical grooves extending far down towards the roots, of simple sectional pattern” (1918b:190). Three years later, Thomas (1921k) described *Hypsimsys deceptor*, based on its larger size in comparison with *H. budini*. Dismissing the metric differences reported by Thomas, Cabrera (1961:451) placed *deceptor* Thomas in the synonymy of *budini* Thomas, an action followed by subsequent students of sigmodontines (e.g., Reig 1987; M. M. Díaz and Barquez 2007). Cabrera (1961), Reig (1987), and M. F. Smith and Patton (1999) recognized *Hypsimsys* as a subgenus of *Akodon*, but Galliari et al. (1996) considered it a valid genus. The allocation of *budini* to *Akodon* has been reinforced by the similarity of its karyotype to those of other species of *Akodon* (Apfelbaum et al. 1993; Vitullo et al. 1986), its close re-

Map 63 Selected localities for *Akodon budini* (●). Contour line = 2,000 m.

semblance in morphology and molecular characters to *A. siberiae* (Myers and Patton 1989a), and its phylogenetic position nested in the *Akodon* radiation (D'Elía 2003a; D'Elía et al. 2003; M. F. Smith and Patton 2007).

The karyotype of *A. budini* is $2n=38$, FN=40 (Vitullo et al. 1986; Myers and Patton 1989a). The autosomal complement consists of 18 pairs, including a single pair of large submetacentrics and two pairs of medium-sized metacentrics. The remaining autosomes are acrocentrics that decrease evenly in size from medium to small. The X chromosome is telocentric and intermediate in size between those of autosome pairs 4 and 5; the Y is telocentric and the smallest chromosome of the complement (Vitullo et al. 1986).

Akodon caenosus Thomas, 1918

Unicolored Grass Mouse, Unicolored Akodon

SYNONYMS:

Akodon puer caenosus Thomas, 1918b:189; type locality "León, Jujuy, 1500 m," Argentina.

Akodon caenosus: Thomas, 1920a:192; name combination.

Akodon puer: Vitullo et al., 1986:70; part; not *Akodon puer* Thomas.

Akodon (Akodon) puer: Apfelbaum and Reig, 1989:260; part; not *Akodon puer* Thomas.

Akodon diminutus Barquez, Díaz, and Goytia, 1994; *nomen nudum*.

Akodon lutescens caenosus: S. Anderson, 1997:421; name combination.

Akodon aliquantulus M. M. Díaz, Barquez, Braun, and Mares, 1999:788; type locality "Argentina: Tucumán Province: Departamento Tafi Viejo: Las Aguitas, Cumbres del Taficillo, 1,700 m, 26°42'S, 65°22'W."

Akodon lutescens: Pardiñas, D'Elía, Teta, Ortiz, Jayat, and Cirignoli, 2006:151; part; not *Akodon lutescens* J. A. Allen.

Akodon lutescens puer: M. M. Díaz and Barquez, 2007:488 part; neither *Akodon lutescens* J. A. Allen nor *Akodon puer* Thomas.

DESCRIPTION: Small, with total body length 124–169 mm, tail length 46–75 mm, ear length 12–15 mm, and hindfoot length (with claw) 20–6 mm; dorsal color uniform along body but may be highly variable within and among populations, typically ochraceous brown but with yellowish, rufous, or olivaceous casts, and almost always dark; venter whitish gray, buffy gray, yellowish or even ruddy, clearly contrasting with dorsum; few white hairs may be present on chin but do not form conspicuous patch; tail strongly bicolored, dorsally blackish-brown and ventrally whitish or buffy. Skull with short rostrum, very narrow and shallow zygomatic notches, and weakly developed frontal sinuses; interorbital region comparatively broad, hourglass in shape, and with rounded or slightly squared margins;

zygomatic arches not flared; braincase small and inflated, with undeveloped temporal and lambdoid crests; zygomatic plates narrow, with anterior border straight or slightly concave and generally sloping gently backward from bottom to top; incisive foramina typically extend to protocone of M1; mesopterygoid fossa very narrow, its anterior margin rounded or slightly squared and lateral margins straight to slightly divergent posteriorly; parapterygoid fossae generally broader than mesopterygoid, with convex border and slight backward divergence. Mandibular ramus very delicate; masseteric crest extends slightly behind anterior margins of m1; and angular process terminates anterior to condyle. Upper incisors orthodont to slightly opisthodont. M1 with well-developed anteromedian flexus, both anteroloph and mesoloph always present; M2 with conspicuous mesoloph; M3 variable, from completely oval without distinct features or with well-developed anteroflexus, metaflexus, and hypoflexus. Lower m1 with well-developed anteromedian flexid and both protostylid and ectostylid; m2 usually retains only labial stylid although some specimens have very small ectostylid; m3 with deep labial and lingual flexids. Greatest skull length 21.3–24.2 mm; upper molar series length 3.5–3.8 mm.

DISTRIBUTION: *Akodon caenosus* has a wide distribution, with records from Chuquisaca and Tarija departments in southern Bolivia south to Catamarca province in northwestern Argentina. Elevational range is from 400 to 3,100 m, but most records are from below 2,500 m (Myers et al. 1990; S. Anderson 1997; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). No fossils are known.

SELECTED LOCALITIES (Map 64): ARGENTINA: Catamarca: ca. 2 km SE of Huaico Hondo, on highway 42, E of Portezuelo (Jayat et al. 2010), Las Chacritas, ca. 28 km NNW of Singuil (Jayat et al. 2010); Jujuy, El Duraznillo, Cerro Calilegua (CML 1734), La Herradura, 12 km SW of El Fuerte on Rte 6 (Jayat et al. 2010), Termas de Reyes, Mirador, on Rte 4 (Jayat et al. 2010); Salta, ca. 5 km NW of Campo Quijano, Km 30 on Rte 51 [Quebrada del Toro] (Jayat et al. 2010), Cañadón Ojo de Agua, 10 km S of Rosario de la Frontera (Jayat et al. 2010), Pampa Verde, ca. 8 km WSW of Los Toldos and S of Cerro Bravom (MACN 23506), 1 km ENE of Rodeo Pampa, km 59 on Rte 7 (MACN 23508); Tucumán, Hualinchay, on road to Cafayate (MACN 23451). BOLIVIA: Chuquisaca, 2 km E of Chuhuayaco (S. Anderson 1997), 11 km N and 16 km W of Padilla (S. Anderson 1997); Tarija, 1 km E of Iscayachi, Río Tomayapo (S. Anderson 1997), Tapehua (S. Anderson 1997).

SUBSPECIES: We treat *Akodon caenosus* as monotypic (but see Remarks, below).

NATURAL HISTORY: In Argentina, most of the records for this species come from Yungas environments, from the lowest elevational belt to high-elevation grass-

lands (Mares, Ojeda, Braun et al. 1997; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). Jayat et al. (2010) extended the species' range into Chacoan environments near the ecotone with Yungas forests, and into the lower elevational limits of the High Andean grasslands. Although individuals in reproductive condition have been recorded throughout the year in northwestern Argentina, most were reproductively active between November and January (M. M. Díaz and Barquez 2007; Jayat et al. 2010). The highest proportion of molting animals in this area was found in the fall and winter (Mares, Ojeda, Braun et al. 1997; M. M. Díaz and Barquez 2007; Jayat et al. 2010). Across its range, *A. caenosus* may coexist with several other species of *Akodon*, depending on latitude and elevation. In the ecotone between highland grasslands and upper belts of Yungas forest in northernmost Argentina, at 1,400 m, *A. caenosus* was captured alongside *A. budini* and *A. sylvanus*. At the same latitude in grasslands above 2,000 m, *A. caenosus* is sympatric with *A. boliviensis*. In both Yungas areas and Chaco-Yungas ecotone of Tucumán province, the species was caught together with *A. spegazzinii*. It may be sympatric with *A. simulator*, another broadly distributed species in northwestern Argentina, over most of the latter's distribution range (Capllonch et al. 1997; Mares, Ojeda, Braun et al. 1997; M. M. Díaz et al. 2000; M. M. Díaz and Barquez 2007; Jayat, Ortiz, Miotti 2008; Jayat et al. 2010). In Bolivia, *A. caenosus* may be found at localities also inhabited by one or more of five *Akodon* species, including *A. albiventer*, *A. boliviensis*, *A. fumeus*, *A. simulator*, and *A. varius* (S. Anderson 1997).

REMARKS: Although Thomas (1918b) originally described *caenosus* as a subspecies of *Akodon puer* (= *A. lutescens* J. A. Allen), two years later (Thomas 1920a), he elevated *caenosus* to species status, a decision followed by Cabrera (1961), Barquez et al. (1980), and Mares, Ojeda, and Kosco (1981). Vitullo et al. (1986) and Apfelbaum and Reig (1989) considered specimens from León, Jujuy province (the type locality of *caenosus*) as *A. puer*, and Myers et al. (1990) accepted this conclusion (but see Hershkovitz 1990b) and retained *caenosus* as a subspecies of *A. puer* inhabiting northwestern Argentina (see also M. A. Barros et al. 1990). S. Anderson (1997) also recognized three subspecies for *A. puer* but noted the priority of the name *lutescens* over *puer*. Since then, the nomenclature used for this species has been constantly changing (see Capllonch et al. 1997; Mares, Ojeda, Braun et al. 1997; M. M. Díaz 1999; M. M. Díaz et al. 1999, 2000; Musser and Carleton 2005; Pardiñas, D'Elía et al. 2006; M. M. Díaz and Barquez 2007). M. M. Díaz et al. (1999) described *A. aliquantulus*, based on a few specimens from the ecotone between upper Yungas forest and highland grassland in Tucumán province, and assigned it

Map 64 Selected localities for *Akodon caenosus* (●). Contour line=2,000 m.

to the *boliviensis* group, based on its morphology. Jayat et al. (2010) subsequently placed the name *aliquantulus* in synonymy with *A. caenosus*.

The karyotype of this species consists of $2n=34$, $FN=40$, based on specimens from León, Jujuy province, and El Cadillal, Tucumán province, in Argentina (Barquez et al. 1980; Vitullo et al. 1986, as *A. puer*).

Akodon cursor (Winge, 1887)

Cursorial Grass Mouse, Cursorial Akodon

SYNONYMS:

Habrothrix cursor Winge, 1887:25; type locality "Lagoa Santa," Minas Gerais, Brazil.

[*Akodon* (*Akodon*)] *cursor*: E.-L. Trouessart, 1897:536; name combination.

[*Akodon*] *arviculoides cursor*: Thomas, 1913b:406; name combination.

A[*akodon*]. *c*[*ursor*]. *cursor*: Reig, 1987:382; name combination.

DESCRIPTION: Medium sized and sexually dimorphic, with males averaging larger than females: mean head and body length 120.40 ± 9.30 mm s.d. ($N=212$) for males and 115.15 ± 10.02 mm ($N=198$) for females, tail length 93.16 ± 11.11 mm ($N=206$) versus 89.7 ± 9.21 mm ($N=196$), and mass 54.20 ± 11.70 g ($N=201$) versus 43.23 ± 10.57 g ($N=180$). Tail always shorter than head and body, averaging about 77% of that length in both sexes; ears sparsely covered by short agouti fur; dorsal pelage homogeneous dark to golden brown, sides slightly paler, and venter grayish or yellowish with unicolored hairs; white patch present in gular region in some specimens.

Skull supraorbital region with rounded margins, without crests; zygomatic plates with straight anterior borders, not reaching maxillary; jugals small; incisors with rounded lateral margins, relatively short, only occasionally reaching anterior margin of M1; distinct depressions present on posterior palate; palatal bridge short and narrow; mesopterygoid fossa narrow, beginning at posterior border of M3, anterior border smoothly rounded, occasionally with small median projection; foramen ovale larger than lacerate foramen; stapedia and sphenofrontal foramina and squamosal groove present; and upper incisors opisthodont. Condylolincisive length averages $28.10 \pm \text{s.d. } 1.27 \text{ mm}$ ($N=254$) in males and $27.14 \pm 1.19 \text{ mm}$ ($N=223$) in females; upper molar series length $4.49 \pm 0.17 \text{ mm}$ ($N=266$) in males and $4.46 \pm 0.18 \text{ mm}$ ($N=228$) in females. Data for four syntypes measured by L. Geise (unpubl. data), condylolincisive length $29.64 \pm 0.40 \text{ mm}$, upper molar series $4.51 \pm 0.07 \text{ mm}$, and least interorbital breadth $5.03 \pm 0.11 \text{ mm}$. Gall bladder present, distinguishing *A. cursor* from similar and often sympatric *A. montensis* (Geise, Weksler, and Bonvicino 2004).

DISTRIBUTION: *Akodon cursor* occurs in the Atlantic Forest in the Brazilian states of Paraíba, Pernambuco, Bahia, Espírito Santo, Minas Gerais, Rio de Janeiro, São Paulo, and Paraná. A record of the species from Misiones province, Argentina is unconfirmed (Pardiñas, D'Elía, and Cirignoli 2003). Fossils of *A. cursor* are known from Quaternary deposits of the Lagoa Santa caves, Minas Gerais (Winge 1887; Voss and Myers 1991).

SELECTED LOCALITIES (Map 65; localities of specimens for which molecular and/or chromosomal data are available; see Remarks, below): BRAZIL: Bahia, Chapada Diamantina, Morro da Torre da TeleBahia, Lençóis (L. G. Pereira and Geise 2009), Ilhéus (Geise and Pereira 2008), Nova Viçosa (MNRJ 47922), Una (FAG 002); Espírito Santo, Cariacica (LGA 325); Minas Gerais, Estação Ecológica de Acauã, 17 km N of Turmalina (LC 81), Rio das Velhas, Lagoa Santa (type locality of *Habrothrix cursor* Winge); Paraíba: Fazenda Alagamar, 9 km S and 6 km E of Mamanguape (UFPB 4366), João Pessoa (UFPB 112); Paraná, Ilha Rasa, Guaraqueçaba (MHNCI [P 682]); Pernambuco, Bom Conselho (PMN 165; see Furtado 1981), Mata do Macuco, Sítio Bituri, Brejo da Madre de Deus (UFPE 1096), São Lourenço da Mata (UFPB 3523); Rio de Janeiro, Casimiro de Abreu (Geise et al. 2005); São Paulo, Fazenda Intervalles, Capão Bonito (MVZ 182072), Ubatuba (MNRJ 55728).

SUBSPECIES: *Akodon cursor* is monotypic.

NATURAL HISTORY: Geise (2012) summarized the literature on ecology, behavior, and other aspects of the natural history of this species. *Akodon cursor* is a member of the forest and open area (grassland) fauna in the

Atlantic Forest of eastern Brazil; it also occurs in contact areas between the eastern *campo cerrado* and inland forest isolates, such as in the Chapada Diamantina in Bahia state (L. G. Pereira and Geise 2007) and in Caatinga (F. F. Oliveira and Langguth 2004). Males typically have larger home ranges than females. In one long-term study at Restinga de Barra de Maricá (Maricá, Rio de Janeiro state), Gentile et al. (1997) documented home ranges from 0.12 to 0.68 ha (mean 0.28 ha, s.d. 0.14, $N=24$). At the same site, food preferences varied according to environmental conditions (Cerqueira et al. 2003). Sexually active females on Ilha do Cardoso (São Paulo state) were present throughout the year, although there was a decrease during the coldest months (June through August), with rainfall affecting pregnancy rates (Bergallo and Magnusson 1999). The gestation period in laboratory colonies ranged from 21 to 24 days (mode, 23 days; Mello and Mathias 1987), and a postpartum estrus was observed in 53% of females in a sample of 389 litters, occurring between the first and fifth days following birth. Litter size ranged from 1 to 10 (mean 4.64) with no skew in sex ratio. Birth weight averaged 3.95 g for males and 3.88 g for females (De Conto 2007).

This species inhabits both primary forest and degraded forest fragments (Oliifiers et al. 2004). At localities from Rio de Janeiro state, *A. cursor* has been found from sea level to elevations above 1,000 m (Geise et al. 2005). G. A. B. Fonseca and Kierulff (1989) and Stallings (1989) regarded *A. cursor* as an insectivore-omnivore. Ectoparasites from specimens taken at Itatiaia include a rich assemblage of fleas, including *Adorapsylla antiquorum*, *Craneopsylla minerva minerva*, *Polygenis atopus*, *P. dentei*, *P. pradoi*, and *P. rimatus* (Moraes et al. 2003).

REMARKS: Earlier synoptic treatments of *Akodon* regarded *cursor* as a subspecies of *A. arviculoides* (Wagner), along with *montensis* Thomas (Gyldenstolpe 1932; Ellerman 1941) and *tapirapoanus* J. A. Allen (Cabrera 1961). The names *arviculoides* and *tapirapoanus* are now placed in synonymy with *lasiurus* and *lenguarum*, respectively, in *Necromys* (see *Necromys* account, and Reig 1978, 1987), and *montensis* has been elevated to species status in *Akodon* (see that account).

The widespread distribution of *A. cursor* was originally recognized by Thomas (1902a:60) based on several Brazilian specimens, but this species is not easily distinguishable from the largely sympatric *A. montensis* (see below), based on external morphological features. This great similarity has led to substantial confusion concerning these taxa and, therefore, the boundaries of their geographic ranges. Karyotypic differences became one of the most commonly used ways to distinguish the two, once it was evident that two nonoverlapping chromosomal groups comprised this complex in southern Brazil. We now regard those animals with

a $2n=14$, 15, or 16 as *A. cursor*, and those with $2n=24$ or 25 as *A. montensis*. Cerqueira et al. (1994) were the first to apply the name *A. cursor* to specimens with 14, 15, and 16 chromosomes, an action supported by Rieger et al. (1995) who documented a specimen from near the type locality of *A. cursor* as having the $2n=14$ karyotype. Subsequent authors uniformly began to associate this karyotype with *A. cursor* (e.g., Sbalqueiro and Nascimento 1996; Geise et al. 1998; Geise et al. 2001; Fagundes and Nogueira 2007). Within its range of diploid numbers, however, is a remarkably variable karyotype, with 28 cytotypes now described (see Fagundes et al. 1998).

Following the realization that *cursor*-like animals of the Atlantic Forest were divisible into two karyotypic groups, additional character complexes were found to distinguish between *A. cursor* and *A. montensis*. These include cranial features, the most useful being upper molar series length and least interorbital breadth (Geise et al. 2005; P. R. Gonçalves et al. 2007), and also mtDNA cytochrome-*b* sequences (Geise et al. 2001). More recently, Pereira (2006) and Geise et al. (2007) documented two phylogeographic groups of cytochrome-*b* sequences through broad sampling across the species' range, with the division between them close to the Rio Jequitinhonha in southern Bahia state. These two groups differed by an average molecular distance (Kimura 2-parameter) of 3.6%,

Map 65 Selected localities for *Akodon cursor* (●). Contour line = 2,000 m.

further demonstrating that *A. cursor* exhibits a substantial degree of both cytological and molecular polymorphism. Population analysis of nuclear microsatellites (A. Cunha 2005) also indicated strong differentiation among populations, without indication of isolation-by-distance among sampled areas.

Akodon dayi Osgood, 1916

Day's Grass Mouse; Dusky Akodon

SYNONYMS:

Akodon dayi Osgood, 1916:208; type locality "Todos Santos, Chaparé River, Bolivia" Todos Santos (16.804°S, 65.143°W), Cochabamba, Bolivia.

[*Akodon (Chalcomys) dayi*: Tate, 1939:187; name combination.

Akodon tapirapoanus dayi: Cabrera, 1961:447; name combination but not *Zygodontomys tapirapoanus* J. A. Allen [= *Necromys lenguarum* (Thomas)].

Akodon urichi dayi: S. Anderson, 1985:12; name combination.

DESCRIPTION: Large, with moderately short tail; total length averages about 200 mm, tail length 80 mm, greatest length of skull 29.5 mm, and upper toothrow 4.8 mm. Dorsal coloration rich blackish brown, slightly paler on sides and rufous ventrally; ears blackish; fore- and hindfeet diagnostically brownish black above; moderately short tail uniformly blackish; no eye-ring present. Skull large and robust, with interorbital region hourglass in shape, with squared but not beaded edges; temporal ridges well defined; and zygomatic notches moderately broad. Upper incisors opisthodont. Procingulum of M1 with well-developed anteromedian flexus. Gall bladder present. Myers (1990:29) described type series in detail, and S. Anderson and Olds (1989) illustrated molar and other anatomical traits.

DISTRIBUTION: Lowland areas and up into the Yungas to at least 2,450 m elevation, from Pando to west-central Santa Cruz in Bolivia, including the departments of Cochabamba, Santa Cruz, and La Paz (Anderson 1997). No fossils are known for *A. dayi*.

SELECTED LOCALITIES (Map 66): BOLIVIA: Beni, El Consuelo (B. D. Patterson 1992b); Cochabamba, 25 km W of Comarapa (S. Anderson 1997), Todos Santos (Osgood 1916); La Paz, Chulumani (B. D. Patterson 1992b), Ixiamas (S. Anderson 1997); Pando, Bella Vista (S. Anderson 1997), Remanso (S. Anderson 1997); Santa Cruz, 6 km W of Ascención [= Ascención de Guarayos] (S. Anderson 1997), Ayacucho (S. Anderson 1997), 2.5 km NE of El Refugio, Parque Nacional Noel Kempff Mercado (USNM 584503; Emmons et al. 2006), Las Lomitas, 15 km S of Santa Cruz (S. Anderson 1997).

SUBSPECIES: *Akodon dayi* is monotypic.

Map 66 Selected localities for *Akodon dayi* (●). Contour line = 2,000 m.

NATURAL HISTORY: Little is known about the population ecology or behavior of this species. *Akodon dayi* occupies mesic areas between 250 and 2,450 m, including savannas, lowland dry forests, and moist forests (Myers 1990; S. Anderson 1997). Embryo counts range from 2 to 5 (mean: 3) for five pregnant females, with pregnancies recorded in March, June, and July. Nonpregnant females were recorded in June, July, and August, and two juveniles were collected in March.

REMARKS: S. Anderson and Olds (1989) and S. Anderson (1997) presented external and cranial measurements. Braun et al. (2008) reported high divergence values of molecular variation between two individuals referred to this species, suggesting the possibility that the current concept of *A. dayi* is composite. These authors found a sister relationship between *A. dayi* and *A. toba* and included both in a lowland clade of the *varius* group (see also Jayat et al. 2010). Cabrera (1961:447) regarded *dayi* as a subspecies of *Akodon tapirapoanus* (J. A. Allen), but S. Anderson (1997:418) correctly noted that *tapirapoanus* should be placed in *Bolomys* (= *Necromys*), not *Akodon*.

Akodon dolores Thomas, 1916

Dolores Grass Mouse, Córdoba Akodon

SYNONYMS:

Akodon dolores Thomas, 1916h:334; type locality “Yacanto, near Villa Dolores, south-western slopes of the

Sierra de Cordova. Alt. 900 m,” Yacanto (32.063°S, 65.024°W), San Javier, Córdoba, Argentina.

Akodon neocenus Thomas, 1919c:213; type locality “Neuquen, Rio Limay, Upper Rio Negro, Patagonia,” clarified as Neuquén (38°57’S, 68°04’W, 259 m, Confluencia, Neuquén; Argentina by Pardiñas et al. (2007).

Akodon varius neocenus: Gyldenstolpe, 1932a:103; name combination.

Akodon molinae J. R. Contreras, 1968:10; type locality “Vivero del Ministerio de Asuntos Agrarios, Laguna Chasicó, Partido de Villario, Provincia de Buenos Aires,” = Ex vivero Humboldt, junction of Arroyo Chasicó and Laguna Chasicó (ca. 38.645°S, 63.015°W), Villarino, Buenos Aires, Argentina.

Akodon varius molinae: Massoia, Morici, and Lartigau, 1993:34; name combination.

Akodon varius dolores: Massoia, Morici, and Lartigau, 1993:34; name combination.

DESCRIPTION: One of larger-bodied species, with head and body length >110 mm, tail >80 mm, greatest length of the skull >30 mm, and upper tooththrow >4.5 mm. Dorsal color pale olive brown to olive gray, some individuals with reddish tint; venter pale, drab white to gray; distinction between dorsal and ventral color moderately abrupt. Pale eye-ring present. Fur long and dense; ears large, up to 18 mm long; tail usually short, bicolored, and densely furred. Skull robust and bowed, with strongly flared zygomatic arches, especially broad zygomatic plates with round and long upper free borders, short nasals, wide interorbital constriction with squared supraorbital region, well-developed temporal and mastoid ridges, and posterolateral palatal pits at level of anterior border of mesopterygoid fossa. Capsular projection of mandible pointed but lies below coronoid process. Upper incisors opisthodont and robust; procingulum of M1 labially compressed; anteromedian flexi/ids usually absent in adult individuals; and anterior portion of M2 more transversally expanded than posterior part.

DISTRIBUTION: As is currently understood, the range of *A. dolores* is broadly coincident with the lowland semi-arid areas of the Monte Desert and Espinal in central Argentina. Recorded localities are distributed from Tucumán and Santiago del Estero provinces south to southwestern Buenos Aires, reaching the Ventania hill system, and to northeastern Chubut province in Patagonia. The western boundary of this distribution roughly coincides with the Monte-Huayquerías limit in Mendoza province (J. R. Contreras and Rosi 1981; Myers 1990; Braun et al. 2008; Pardiñas 2009; Nabte et al. 2009; Jayat, Ortiz, Pacheco, and González 2011). The known fossil record is restricted to the Holocene of southeastern Buenos Aires province

and northern Patagonia (Pardiñas 1999a; Udrizar Sauthier 2009).

SELECTED LOCALITIES (Map 67): ARGENTINA: Buenos Aires, Arroyo de los Loros (Pardiñas, Abba, and Merino 2004), Bahía Blanca (Pardiñas, Abba, and Merino 2004), Cabaña San José (Pardiñas, Abba, and Merino 2004), Puesto El Chara (Pardiñas, Abba, and Merino 2004); Catamarca, Trampasacha (Jayat, Ortiz, Pacheco, and González 2011); Chubut, Estancia La Irma (Nabte et al. 2009), Estancia Los Nogales (CNP-E 402), Laguna La Blanca (De Santis and Pagnoni 1989); Córdoba, Chucul (Wittouck et al. 1995), Villa de María del Río Seco (Wittouck et al. 1995); La Pampa, 15 km SW of Chamaicó, Loma Loncovaca (Tiranti 1998), Colonia Gobernador Ayala (Sieghentaler et al. 1993), Estancia El Puma, Chicalcó (Sieghentaler et al. 1990), 10 km SW of Santa Rosa, Chacra la Lomita (Tiranti 1998); La Rioja, Ambil (Massoia et al. 1999); Mendoza, La Pega (J. R. Contreras and Rosi 1980b), Rincón del Atuel (J. R. Contreras and Rosi 1980b); Neuquén, Barda Negra, Parque Nacional Laguna Blanca (Massoia and Pastore 1997), 3–5 km upstream Chos Malal, along Río Neuquén (Tiranti 1996b); Río Negro, Cerro Castillo [= Cerro Guacho] (Pardiñas and Massoia 1989), El Rincón [= Establecimiento El Rincón] (Pardiñas, Teta et al. 2003), Estancia Liempi (Nabte et al. 2009), San Carlos (Pardiñas 2009); Santiago del Estero, INTA “La María” Research Station, 2.9 km W of station entrance (Jayat, Ortiz, Pacheco, and González 2011), ca. 30 km N of Pozo Hondo, along Rte 34 (Jayat, Ortiz, Pacheco, and González 2011); Tucumán, ca. 4 km NW of Las Cajas (Jayat, Ortiz, Pacheco, and González 2011).

SUBSPECIES: We treat *Akodon dolores* as monotypic (but see Remarks).

NATURAL HISTORY: *Akodon dolores* is nocturnal (J. R. Contreras 1979b). This species has a broad habitat range, having been collected in Espinal forests of *Prosopis caldenia* (Tiranti 1998a), in halophytic shrub communities (Tiranti 1998a), mixed shrublands (Teta, Pereira, Fracassi et al. 2009), borders of grasslands and cultivated fields (Polop et al. 1985; Tiranti 1998a), clumps of grass near watercourses (J. R. Contreras 1966), Chaco Serrano transition with palms (Tiranti 1998a), rocky hilly environments (Pardiñas, Abba, and Merino 2004; Teta et al. 2005), and deforested areas where there is adequate shrub or litter cover (Tiranti 1998a; Corbalán 2005). Some populations also occur in urbanized areas (E. Castillo et al. 2003). Polop et al. (1985), Polop and Sabattini (1993), Bonaventura et al. (1998), Corbalán and Ojeda (2004), Corbalán (2005), Corbalán et al. (2006), Tabeni et al. (2006), and Teta et al. (2005) addressed habitat use, microhabitat selection, and/or abundance by habitat. R. A. Ojeda (1989) studied response to natural fires.

Corbalán and Ojeda (2005) and Teta et al. (2005) determined mean home range size from 785–924 m² in central and west-central Argentina, respectively, with those of males larger than females. Highest population densities occurred during the autumn (J. R. Contreras 1979b; Polop et al. 1993), following a prolonged reproductive season from August to March or April (M. C. Navarro 1991; Teta, Pereira, Fracassi et al. 2009). Piantanida (1981) examined fertility, postnatal development, and growth in a laboratory population, and determined a mean embryo count of 7.3 but a reduced mean litter size of 4.6. Apfelbaum and Blanco (1985) examined levels of allozyme variation in central Argentina populations.

This species is omnivorous in its diet, with local and seasonal differences in the degree of insectivory or herbivory (J. R. Contreras 1979b; R. L. Martínez et al. 1990; C. M. Campos, Ojeda et al. 2001; Castellarini et al. 2003; Gianonni et al. 2005). Ectoparasites from animals captured in northwestern Patagonia (from specimens referred to as *A. neocenus*) include the fleas *Barreropssylla excelsa*, *Ectinorus onychiisonychius*, *Plocopsylla wolffsohni*, *Sphinctopssylla ares*, *Tetrapsyllus (Tetrapsyllus) rhombus*, and *T. (T.) tantillus* (Autino and Lareschi 1998; Lareschi and Mauri 1998) and the sucking lice *Hoplopleura aitkeni* and *H. varia* (D. Castro and Cicchino 1998). The ectoparasite assemblage recorded from populations in Mendoza province was also diverse, including mites (*Ornithonyssus bacoti*), fleas (*Ectinorus (Ectinorus) barrerai*, *Craneopssylla minerva wolffhuegeli*, *Polygenis (Polygenis) bohlsi bohlsi*, *P. (P.) platensis*, *P. (P.) rimatus*, *P. (Neopolygenis) pulche*), and lice (*Hoplopleura aitkeni*) (Autino and Lareschi 1998; Lareschi and Mauri 1998; Lareschi and Linardi 2009).

REMARKS: Our concept of *A. dolores* includes *molinae* J. R. Contreras and *neocenus* Thomas as synonyms; these names are available for trinomial usage as might prove to be appropriate in the future. The close relationship between *A. dolores* and *A. molinae* was initially suggested by karyotypic and cross-breeding studies (Myers 1990, and the references therein), with conspecificity proposed by Hershkovitz (1990b), and later documented by phylogenetic analysis of mtDNA sequences (Braun et al. 2008). Some authors maintain the validity of both *dolores* and *molinae* by attributing to the former a diploid complement of 34–40 (e.g., Tiranti 1998a; Musser and Carleton 2005) instead of the $2n=42-44$ of typical *molinae* (N. O. Bianchi et al. 1971). However, topotypes of *A. dolores* have a $2n=42-44$ karyotype (Wittouck et al. 1995). This supports the proposition that *dolores* Thomas is a senior synonym of *molinae* J. R. Contreras. If further studies demonstrate that the $2n=34-40$ cytotype is specifically distinct, a new name may have to be coined for that

taxon. Populations of *Akodon dolores* with $2n=34-40$ are mainly distributed along the eastern flank of the Sierra de Córdoba (N. O. Bianchi et al. 1971; N. O. Bianchi and Merani 1984; Wittouck et al. 1995), extending to at least southern Catamarca province (N. O. Bianchi et al. 1979). As has been discussed by several authors, those with this distributional range are apparently allopatric relative to those with $2n=42-44$ (see Tiranti 1998a). Although the two cytotypes do not overlap, or even contact one another, they are completely interfertile in experimental crossbreeding studies (Wittouck et al. 1995). Furthermore, Wittouck et al. (1995) found no differences in cranial measurements between populations of the two cytotypes from opposite sides of Sierra de Córdoba.

As for supporting the inclusion of *neocenus* in the synonymy of *A. dolores*, we note that Thomas (1916h), in his original concept of *neocenus*, included specimens from populations that J. R. Contreras (1968) later used in his description of *molinae*. Myers (1990) supported the validity of *neocenus*, but he examined only a small sample of specimens from central Argentina—one of these he referred to *A. dolores*, a second to *A. molinae*, and the remaining 11 to *A. neocenus*. Myers (1990) also reported sympatry between *neocenus* and *molinae* in southwestern Buenos Aires province. The conspecificity of *neocenus* and *molinae*, however, is supported

by karyotypic, molecular, and morphological data. First, one near topotype of *neocenus*, caught at Cipoletti, Río Negro, had a $2n=42$ (N. O. Bianchi et al. 1971). Second, a study in progress that includes topotypes of *dolores*, *molinae*, and *neocenus* has indicated very low levels of molecular divergence among these specimens and a lack of reciprocal monophyletic lineages that would support species status (G. D'Elía and U. F. J. Pardiñas, unpubl. data). Finally, both external as well as craniodental morphology, despite some variation in overall color, is very similar among populations referred to the different supposed species. The hypothesis of only one large species of *Akodon* living in central Argentina does make biogeographic sense as well because the distribution of the entire complex is broadly coincident with the xerophytic shrublands and woodlands of the Monte Desert and Espinal.

The separation of *A. dolores* from to *A. toba* requires further study because the latter has a similar $2n=42-44$ karyotype (Myers 1990) and also occupies similar environments in the Chacoan region (see that account). Phylogenetic analyses of DNA sequences indicate that *A. dolores* and *A. toba* represent reciprocally monophyletic lineages, but available specimens within the range of *toba* are relatively few, and levels of genetic divergence among lineages are low (<3%; Braun et al. 2008).

Akodon fumeus Thomas, 1902

Smoky Grass Mouse, Smoky Akodon

SYNONYMS:

Akodon fumeus Thomas, 1902b:137; type locality "Choro, 3500 m," Cochabamba, Bolivia.

Akodon mollis fumeus: Gyldenstolpe, 1932a:106; name combination.

DESCRIPTION: Medium sized, with average total length 171.2 mm, tail length 76.2 mm, ear length 15.9 mm, and hindfoot length 21.4 mm. Dorsal pelage dark brown with rufous overtones, not sharply differentiated from venter; pale ring present around each eye. Tail sparsely furred, not sharply bicolored. Skull with relatively flat dorsal profile in lateral view, narrow and pointed rostrum, distinctively swollen frontal sinuses, moderately developed zygomatic arches, relatively broad zygomatic plates, unusually shallow zygomatic notches, and smoothly rounded to squared but never beaded interorbital region. Squamosoalisphenoid groove conspicuous on lateral wall of braincase; mesopterygoid fossa broad and usually with rounded anterior margin that lacks median spine; parapterygoid fossae deeply excavated with lateral margins slightly or moderately convex. Upper incisors orthodont. M1 with pronounced anteromedian flexus and prominent mesoloph and mesostyle; M2 with well-developed anteroloph and parastyle that projects to edge of tooth; M3 relatively small, with outline that varies from oval to figure-8 shaped. Lower m1 also with well-

Map 67 Selected localities for *Akodon dolores* (●). Contour line = 2,000 m.

developed anteromedian flexid and conspicuous anterolabial cingulum; m2 with conspicuous anterolabial lophid and well-developed posterolophid; and m3 relatively simple, about two-thirds length of m2. Mean condyloincisive length 23.48 mm, mean upper molar series length 4.07 mm.

DISTRIBUTION: *Akodon fumeus* occurs on eastern Andean slopes from Puno department in southeastern Peru through Bolivia to northwestern Argentina, in Salta and Jujuy provinces (Myers and Patton 1989b; S. Anderson 1997; M. F. Smith and Patton 2007; Tarifa et al. 2007; Jayat et al. 2010). No fossils are known.

SELECTED LOCALITIES (Map 68): **ARGENTINA:** Jujuy, Río Las Capillas, 15 km N of Las Capillas on Rte 20 (Jayat et al. 2010); Salta, Finca Alto Verde (Jayat et al. 2010), Parque Nacional Baritú, near Río Baritú (M. M. Díaz et al. 2000). **BOLIVIA:** Cochabamba, Palmar, 101 km by road SW of Epizana, Siberia cloud forest, Cordillera Oriental (Myers and Patton 1989b), Yungas de Cochabamba (Myers and Patton 1989b); La Paz, Bellavista (S. Anderson 1997), 35 km by road N of Caranavi, Serranía Bellavista (S. Anderson 1997), Huaraco (S. Anderson 1997), Khallutaka [near Laja] (S. Anderson 1997), 10 km by road N of Sorata, Moyabaya, Río Challapampa (S. Anderson 1997); Santa Cruz, Guadalupe, 10 km S of Vallegrande (S. Anderson 1997); Tarija, Caiza (S. Anderson 1997), Erquis (S. Anderson 1997). **PERU:** Puno, Sandia (Myers and Patton 1989b).

SUBSPECIES: *Akodon fumeus* is monotypic.

NATURAL HISTORY: *Akodon fumeus* lives mostly in forested regions of the eastern Andean slopes, from 700 m to at least 3,800 m at the ecotone with Puna-like grasslands. Across this extensive elevational range, *A. fumeus* occupies a diversity of forest types, from high-elevation *Polylepis* woodlands, cloud forest, and *Podocarpus* and *Alnus* forests (Myers and Patton 1989b; S. Anderson 1997; M. F. Smith and Patton 2007; Tarifa et al. 2007; Jayat et al. 2010). S. Anderson (1997) reported Bolivian females with embryos in October and November, and non-pregnant females in June, July, and September. None of the 75 specimens captured in May 2006 in northernmost Salta province, Argentina (J. P. Jayat et al., unpubl. data), were reproductively active. In August 2006, three females still had a closed vagina, but five males had semiscrotal testes. *Akodon fumeus* may be sympatric or contiguously allopatric with several other *Akodon* species, including *A. aerosus*, *A. albiventer*, *A. boliviensis*, *A. caenosus*, *A. dayi*, *A. mimus*, *A. lutescens*, *A. kofordi*, *A. pervalens*, *A. siberiae*, *A. simulator*, *A. subfuscus*, and *A. varius* (Myers and Patton 1989b; Patton and Smith 1992b; S. Anderson 1997; S. Anderson and Yates 2000; Salazar-Bravo, Yensen et al. 2002; Salazar-Bravo and Yates 2007; Tarifa et al. 2007). In northernmost Argentina, *A. fumeus* was captured at the same localities

Map 68 Selected localities for *Akodon fumeus* (●). Contour line=2,000 m.

and in the same habitats as *A. budini*, *A. caenosus*, and *A. simulator* (Jayat and Ortiz 2010; Jayat et al. 2010).

REMARKS: Gyldenstolpe (1932), Cabrera (1961), and Hershkovitz (1990b) regarded *fumeus* as a subspecies of *A. mollis*, but Myers and Patton (1989b) established its specific status and allied it to *A. kofordi*, grouping the two together in an informal *fumeus* group. Recent molecular studies confirmed the close relationship between *A. fumeus* and *A. kofordi* but placed both species in the *boliviensis* group (M. F. Smith and Patton 2007). These two species have been confused in the recent literature, as S. Anderson (1997) assigned Bolivian specimens to *A. fumeus* but that actually represent *A. kofordi* (Salazar-Bravo, Yensen et al. 2002). M. M. Díaz and Barquez (1999) added this species to the fauna of Argentina on the basis of one record for Jujuy province. M. M. Díaz and Barquez (2007) reported additional Argentinean localities, but most of the specimens assigned by these authors to *A. fumeus* were reidentified by Jayat et al. (2010) as *A. sylvanus* or *A. budini*. However, all the specimens from Salta province, as well as a few from Jujuy province, assigned to *A. sylvanus* by Jayat, Ortiz et al. (2007) also were misidentified, and represent *A. fumeus* (see Jayat et al. 2010).

Akodon iniscatus Thomas, 1919

Intelligent Grass Mouse; Patagonian Akodon

SYNONYMS:

Akodon iniscatus Thomas, 1919b:205; type locality "Valle de Lago Blanco, Koslowsky region, Patagonia,

46°S”; restricted to Estancia Valle Huemules (45°57'S, 71°31'W, 593 m, Río Senguerr, Chubut, Argentina (Pardiñas et al. 2007:406).

Akodon iniscatus collinus Thomas, 1919b:206; type locality “Maiten, W. Chubut. 700 m.” El Maitén (42.050°S, 71.160°W), Cushamen, Chubut, Argentina.

Akodon nucus Thomas and St. Leger, 1926b:636; type locality “Chos Malal, 800 m.” Chos Malal (37.376°S, 70.270°W), Chos Malal, Neuquén, Argentina.

Akodon iniscatus iniscatus: Cabrera, 1961:442; name combination.

Akodon iniscatus nucus: Cabrera, 1961:443; name combination.

DESCRIPTION: Small, with head and body length 80–110 mm, tail length 50–80 mm, greatest length of skull <27 mm, and upper tooththrow <4.5 mm. Dorsal color darkly grizzled olivaceous brown to uniformly brown; venter gray and moderately demarcated from dorsum; white spot variably present on chin. Tail short, well haired, and bicolored. Skull delicate and bowed. Samples from northwestern part of species' range larger than those to south, with broader rostrum, wide zygomatic plates with long upper free borders, subparallel zygomatic arches, narrower mesopterygoid fossa, larger pterygoids, and moderately opisthodont upper incisors. M1 and m1 in all samples with persistent anteromedian flexus/flexid and greatly reduced M3 and m3.

DISTRIBUTION: *Akodon iniscatus* inhabits northern Argentinean Patagonia, ranging from southwestern Buenos Aires, La Pampa, and probably southern Mendoza provinces south through Río Negro, Neuquén, and Chubut provinces to at least the northeastern portion of Santa Cruz province (Roig 1965; Pardiñas and Galliari 1999; Pardiñas, Teta et al. 2003; Pardiñas 2009), and extends, barely, into Aysén region, Chile. The occurrence of *A. iniscatus* in southern Mendoza province, first mentioned by Cabrera (1961; see also Massoia et al. 1994a, who recorded this species from Laguna de la Niña Encantada [about 35°09'S]), needs confirmation; these records may be of misidentified *A. spegazzinii* (Pardiñas, Teta, Formoso, and Barberena 2011). The northeastern portion of the historic range has apparently retracted considerably because of anthropogenic agroecosystem expansion, as recent surveys in this region have failed to encounter *A. iniscatus* (see Teta, Pereira, Fracassi et al. 2009). Thus, the historic record of this species from Estación Perú is indicated as disjunct from the main portion of the species range (Map 66). Fossils attributed to *A. iniscatus* have been described from the Middle Pleistocene of Mar del Plata (Reig 1987) and Bahía Blanca (Pardiñas and Deschamps 1996), Buenos Aires province. A rich Holocene record for this rodent is also available from several caves in Chubut and Neuquén

provinces, Patagonia (Pardiñas 1999a; Udrizar-Sauthier 2009; F. J. Fernández et al. 2012).

SELECTED LOCALITIES (Map 69): ARGENTINA: Buenos Aires, Bahía San Blas (Pardiñas and Galliari 1999), Carmen de Patagones (Thomas 1919b), Estación Perú (Thomas 1919b); Chubut, Astra (Nabte et al. 2006), Buenos Aires Chico (CNP-E 49), Estancia Valle Huemules (Thomas 1919b), Isla Escondida (UP 283), 20 km S of Lelque (M. A. Barros et al. 1990), Los Altares (Pardiñas, Teta et al. 2003), 36 km W of Los Altares (CNP-E 51), Paso del Sapo (Pardiñas, Teta et al. 2003), Puerto Lobos (CNP-E 190), Punta Delgada (Pardiñas, Teta et al. 2003); La Pampa, La Humada (Tiranti 1989); Mendoza, General Alvear (Roig 1965); Neuquén, Barrancas (F. J. Fernández et al. 2012), Estancia Corcel Negro (CNP-E 88), Paraje La Querencia (Pardiñas, Teta et al. 2003), Riscos Bayos (Pardiñas, Teta et al. 2003); Río Negro, Barda Esteban, Pilcaniyeu (CNP-E 417), Choele Choel (MACN 28.110); Santa Cruz, Cañadón Minerales (CNP-E 365), Puerto Deseado (Thomas 1919b). CHILE: Aysén, 1 km E of Coyhaique Alto (M. F. Smith and Patton 1999; FMNH 129843).

SUBSPECIES: Currently, *A. iniscatus* is regarded as monotypic. However, the taxon *nucus* Thomas and Saint Leger, sometimes listed as a full species (Galliari et al. 1996; Hershkovitz 1990b; Reig 1987), was retained as a subspecies of *A. iniscatus*, pending critical revision, by M. A. Barros et al. (1990) and Pearson (1995). M. F. Smith and Patton (2007) provided mtDNA cytochrome-*b* sequence from a specimen of *nucus* to support the conspecificity of this taxon with typical *A. iniscatus*. However, typical *nucus* populations have several diagnostic morphological and morphometric features, as discussed by M. A. Barros et al. (1990) and Pardiñas (2009). Whether these character differences justify subspecies or species status remains to be determined.

NATURAL HISTORY: This is the most common but also one of the most poorly known *Akodon* species in Patagonia (Pardiñas 2009). It has been regularly confused with *Abrothrix olivacea* (see discussion in Thomas 1919b; B. D. Patterson et al. 1984). Many ecological data concerning this species come from coastal areas in northeastern Chubut and have been presented in meeting abstracts but not formally published. *Akodon iniscatus* primarily inhabits the Monte Desert biome and sub-Andean steppe grasslands, generally from sea level to 900–1,000 m. This rodent is particularly abundant in the eastern lowlands of the Monte Desert where it is apparently replaced by *A. olivacea* toward the central basaltic plateau (Pardiñas 2009). It is a common prey species for several species of owls (see Pardiñas 1999a; Nabte et al. 2008, Trejo and Lambertucci 2008). Antinuchi and Busch (1999) examined renal morphology and studied the physiology of a population near Puerto Madryn, Chubut. Historical data and current

collections suggest that its range, especially at the northern and eastern boundary, has recently retracted, in part due to the expansion of agroecosystems such as those in Buenos Aires province (Pardiñas, Abba, and Merino 2004). Ectoparasites reported include the fleas *Agastopsylla boxi boxi*, *Craneopsylla minerva wolffhuegeli*, *Ectinorus ixanus*, *E. levipes*, *E. onychius onychius*, *Eritranis andricus*, *Hectopsylla (Hectopsylla) gracilis*, *Listronius fortis*, *Neotyphloceras crassispina*, *Polygenis (Polygenis) platensis*, *P. (P.) rimatus*, *Tetrapsyllus rhombus*, and *T. tantillus*, and the ticks *Amblyomma tigrinum* and *Ixodes* sp. (Smit 1987; Autino and Lareschi 1998; Lareschi and Mauri 1998).

REMARKS: M. F. Smith and Patton (2007) placed *A. iniscatus* in their *varius* group, based on mtDNA cytochrome-*b* sequences. With an expanded mtDNA analysis, Jayat et al. (2010) included *iniscatus* in a subclade (termed the *dolores* group) of Myers's (1990) *varius* group, composed of *A. dolores*, *A. molinae*, *A. toba*, and *A. dayi*. B. D. Patterson et al. (1984:14) argued that *Mus infans* Philippi might be a synonym of *nucus* (and thus of *A. iniscatus*) and not of *Abrothrix olivacea* (cited as *xanthorhina*), as Osgood (1943b) had proposed. This hypothesis has not as yet been examined adequately (see the *Abrothrix olivacea* account herein).

M. A. Barros et al. (1990) reported a $2n=33-34$ karyotype from specimens collected in Neuquén (*nucus*) and Chubut (*iniscatus*) provinces. Tiranti (1999) reported the same karyotype for animals obtained at Parque Nacional Laguna Blanca, Neuquén province.

Map 69 Selected localities for *Akodon iniscatus* (●). The apparently isolated population on the northeastern edge of the range is shown as disjunct from the main distribution (see Distribution). Contour line=2,000m.

Akodon josemariarguedasi Jiménez, Pacheco, and Vivas, 2013

Arguedas's Grass Mouse, Arguedas's Akodont

SYNONYMS:

Akodon orophilus: Pacheco, Córdova, and Velásquez, 2012:107; part; not *Akodon orophilus* Osgood.

Akodon josemariarguedasi Jiménez, Pacheco, and Vivas, 2013:232; type locality "Galloganán, Ambo, Huánuco, Peru, 3420 m. 10° 09'S, 76° 08'W."

DESCRIPTION: Large *Akodon*, with mean total body length 192.3 mm, tail length 89 mm, ear length 15.6 mm, and hindfoot length 22.8 mm; greatest skull length ranges from 26.1–27.5 mm and upper molar series length 3.9–4.4 mm. Distinguished from congeners by the following combination of characters: dorsal pelage coloration uniformly brownish olive, strongly contrasting with smoky gray to whitish venter; fur hairs with paler gray bases; tail dark and moderately countershaded; nasals extend posterior to premaxillofrontal suture, posterior end blunt with serrated contour; lacrimals large; zygomatic plates with anterior margin less slanting, with either convex or straight anterior edges; antorbital bridge moderately wide; zygomatic notches somewhat deep; palate narrow; maxillary toothrows somewhat short; mandible delicate with thin and large condylar process, and deeper lunar notch; internal fossatus between paracone and protocone present on M1.

DISTRIBUTION: *Akodon josemariarguedasi* is only known from the montane cloud forest between 2,900 to 3,800 m in Huánuco department, south of the Río Hualaga, Peru (C. F. Jiménez et al. 2013). We extend the species range to Junín department, based on the suggestion by C. F. Jiménez et al. (2013) and examination of specimens in the MVZ (J. L. Patton, pers. comm.). It is not known from the fossil record.

SELECTED LOCALITIES (Map 70): PERU: Huánuco, Galloganán (type locality of *Akodon josemariarguedasi* Jiménez, Pacheco, and Vivas), Hacienda Exito (FMNH 24495), Hatuncucho (C. F. Jiménez et al. 2013), Ichocán (C. F. Jiménez et al. 2013), mountains, 15 mi NE Huánuco (FMNH 23657), Palmapampa (C. F. Jiménez et al. 2013), Unchog [= Bosque Unchog], pass between Churrubamba and Had. Paty, NNW Acomayo (LSUMZ 27952); Junín, 16 km NNE (by road) Palca (MVZ 173057).

SUBSPECIES: *Akodon josemariarguedasi* is monotypic.

NATURAL HISTORY: *Akodon josemariarguedasi* is a montane forest inhabitant, co-occurring with the sigmodontines *Thomasomys kalinowskii*, *T. incanus*, *Microryzomys minutus*, *M. altissimus*, and *Oligoryzomys* sp. (C. F. Jiménez et al. 2013). This species is largely insectivorous, consuming primarily adult beetles (as *A. orophilus*, see Noblecilla and Pacheco 2012).

REMARKS: C. F. Jiménez et al. (2013) separated *A. josemariarguedasi* from *A. orophilus*, supporting the hypothesis that the latter was a complex of species (see that account). Both morphological and karyological data suggest that *josemariarguedasi* is a member of the *aerosus* group. *Akodon josemariarguedasi* has a $2n=22$ and $FN=40$ karyotype (originally referred to *A. orophilus* by Pacheco, Córdova, and Velásquez 2012:107); all autosomes are biarmed (8 metacentric and 2 submetacentric pairs), but both sexchromosomes are uniarmed, with the Y chromosome about a third of the length of the X chromosome.

C. F. Jiménez et al. (2013:234) highlighted the potential occurrence of *Akodon josemariarguedasi* in Junín department based on data in Patton and Smith (1992b) for specimens collected east of Palca. Both M. F. Smith and Patton (1993) and Coyner et al. (2013) had referred these specimens to *A. orophilus* in their respective molecular phylogenetic analyses. However, J. L. Patton examined the series of specimens in the MVZ, using the character descriptions and illustrations in C. F. Jiménez et al. (2013), and determined that they do represent *A. josemariarguedasi*, as suggested by these authors. The holotype of *josemariarguedasi* is an adult individual (MUSM 22754; C. F. Jiménez et al. 2013:Fig. 5), regrettably too old to exhibit details of occlusal morphology.

Map 70 Selected localities for *Akodon josemariarguedasi* (●) and *Akodon orophilus* (○). Contour line = 2,000 m.

Akodon juninensis Myers, Patton, and Smith, 1990

Junín Grass Mouse, Junín Akodon

SYNONYM:

Akodon juninensis Myers, Patton, and Smith, 1990:41; type locality “22 km N La Oroya (by road), Depto. Junín, Peru, 4040 m (at the junction of roads to Junín [Hwy 31] and Tarma [Hwy 201]).”

DESCRIPTION: Medium-sized *Akodon* with body length averaging 149.4 mm, tail length 61.8 mm, ear length 12.2 mm; and hindfoot length 19.5 mm. Dorsal coloration brownish to pale olivaceous, heavily lined with black; hairs of ventral region with whitish or buffy tips; hairs on chin and sometimes upper throat monocolored and white; yellowish eye-ring present but inconspicuous compared with other members of *boliviensis* group; tail densely furred and sharply bicolored. Skull relatively narrow, with especially narrowed zygomatic notches; interorbital region hourglass in shape, with sides rounded anteriorly to squared or nearly squared on posterior part of orbit; both postglenoid and subsquamosal foramina smaller than in other members of *boliviensis* group; tympanic hook slender to medium sized; mesopterygoid fossa broad with anterior border usually gently rounded or square and lacking median spine; foramen ovale very small and sometimes completely enclosed by bone. Most molar features as described for other species of the *boliviensis* group, but some differences include M1 with anteromedian flexus unusually shallow and always lacking metalophule, and small M3 with shallow metaflexus. Mean condyloincisive length 20.06 mm, upper molar series length 3.74 mm.

DISTRIBUTION: *Akodon juninensis* is known only from the central Peruvian departments of Ancash, Junín, and Lima, on both eastern and western slopes of the Andes, and on the Pacific slope in Huancavelica and Ayacucho departments, at elevations above 2,700 m (Myers et al. 1990; Pacheco 2002). This species is not known from the fossil record.

SELECTED LOCALITIES (Map 71): PERU: Ancash, 25 mi S of Huaras (MVZ 137958); Ayacucho, 18 km E (by road) of Puquio (MVZ 174261); Huancavelica, Hacienda Piso, Luroja (FMNH 75561); Junín, 22 km N of La Oroya (type locality of *Akodon juninensis* Myers, Patton, and Smith), Pomacocha, Yauli Valley (MVZ 137967), near San Blas (UMMZ 120285); Lima, Zarate, 6 mi E of Pueblo San Bartolomé (MVZ 119931); Pasco, 10 mi NE of Cerro de Pasco (MVZ 119933).

SUBSPECIES: We treat *Akodon juninensis* as monotypic, although Myers et al. (1990) documented slight geographic variation in craniodental morphometric traits.

NATURAL HISTORY: *Akodon juninensis* primarily occupies dense bunchgrass in well-drained and fine-grained

soils, and sparse perennial forests at elevations between 2,700 m and 3,800 m. Other sigmodontines coexisting with *juninensis* are *Abrothrix jelskii*, *Auliscomys pictus*, *Phyllotis andium*, *P. xanthopygus*, *Calomys sorellus*, *Neotomys ebriosus*, and an undescribed species of *Oligoryzomys* (see Carleton and Musser 1989).

REMARKS: In their original description, Myers et al. (1990) assigned *A. juninensis* to the *boliviensis* group. Their analyses of 26 allozyme loci suggested a close relationship with *A. boliviensis*, *A. lutescens*, and *A. subfuscus*, three other members of the *boliviensis* group in southern Peru. Both M. F. Smith and Patton (2007) and Jayat et al. (2010) recovered *A. juninensis* as a member of a clade containing *A. fumeus* and *A. kofordi* at the base of the remainder of *boliviensis* group taxa, based on mtDNA cytochrome-*b* sequences. Because of this relationship, the similarity of the karyotypes, and the small genetic distances among these species, M. F. Smith and Patton (2007) expanded the *boliviensis* group as advocated by Myers et al. (1990) to include both *A. kofordi* and *A. fumeus*.

The karyotype of *A. juninensis* consists of a $2n=40$, $FN=40$. The autosomal complement consists of 18 pairs of acrocentrics, one of which is significantly larger than the others, which grade evenly in size from medium to small, and one pair of small metacentrics. The X chromosome is an acrocentric, and the morphology of the Y chromosome is unknown (Myers et al. 1990).

Map 71 Selected localities for *Akodon juninensis* (●). Contour line = 2,000 m.

Akodon kofordi Myers and Patton, 1989

Koford's Grass Mouse, Koford's Akodon

SYNONYM:

Akodon kofordi Myers and Patton, 1989b:14; type locality "Aqualani, 9 km N by road Limbani, Depto. Puno, Peru, elevation 2840 m."

DESCRIPTION: Medium sized, with average total length 173.9 mm, tail length 77.6 mm, hindfoot length 22.5 mm, and ear length 15.3 mm. Overall color dark olivaceous brown without patches of contrastingly colored fur; no trace of eye-ring; tail well haired to unaided eye, unicolored or faintly bicolored; hindfeet clothed with banded hairs. Skull with narrow and pointed rostrum, distinctively swollen frontal sinuses, and moderately developed and laterally flared zygomatic arches; zygomatic notches relatively broad; interorbital area neither remarkably constricted nor broad, with rounded sides that become increasingly squared with age; zygomatic plates relatively broad, with ventral roots directly below dorsal roots; relatively inconspicuous squamosoalisphenoid groove present; incisive foramina broad but of average length for *Akodon*, reaching anteroloph of M1; mesopterygoid fossa distinctly broad, usually lyre-shaped and with well-developed median spine present on anterior border. Dentally, similar to *A. fumeus* but paraflexus of M1 remarkably deep, extending almost to posterior limit of paracone; small section of paraflexus becomes isolated with wear, forming distinctive island. Condylolincisive length of type series averages 23.15 mm, upper molar series length 3.95 mm.

DISTRIBUTION: *Akodon kofordi* is known from the Marcapata and Limbani drainages on the eastern Andean slope in Cusco and Puno departments of southern Peru, south to Cochabamba department in central Bolivia. Recorded localities range in elevation between 1,800 and 3,700 m (Myers and Patton 1989b; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007). No fossils are known.

SELECTED LOCALITIES (Map 72): **BOLIVIA:** Cochabamba, Cocapata (Tarifa et al. 2007), 4.4 km (by road) N of Tablas Monte (Salazar-Bravo, Yensen et al. 2002). **PERU:** Cusco, Amacho (FMNH 75483); Puno, Aqualani, 9 km N by road of Limbani (type locality of *Akodon kofordi* Myers and Patton).

SUBSPECIES: *Akodon kofordi* is monotypic.

NATURAL HISTORY: This species occupies moist bunch grass, disturbed shrubby areas, and forest (including *Alnus* cloud forest and *Polylepis* woodlands) at the contact between high-elevation elfin forest and Puna (Myers and Patton 1989b; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007). At the type locality in southeastern Peru, *A. kofordi* was common along rock walls of old terraces and buildings and in thick clumps of grass and shrubs in the relatively more open and disturbed areas (Myers and Patton

1989b). In Bolivia, this species was captured in open *Polyllipis* woodland (with trees 2–3 m tall) and at the base of steep shale slopes, in secondary cloud forest dominated by *Alnus* (40% cover), *Cecropia* shrubs (40–90% cover), with 10% to 80% forb cover in tree-fall clearings, and with moss covering the rocks, vines, and tree trunks (Salazar-Bravo, Yensen et al. 2002). In both areas, up to 70% of specimens were captured adjacent to streams. Other *Akodon* found in sympatry, or near sympatry, with *A. kofordi* included *A. aerosus*, *A. fumeus*, *A. lutescens*, *A. mimus*, and *A. subfuscus* (Myers and Patton 1989b; Patton and Smith 1992b; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007).

REMARKS: Myers and Patton (1989b) allied *A. kofordi* with *A. fumeus* because of similar morphological attributes, grouping both into a *fumeus* group. MtDNA sequence analyses (M. F. Smith and Patton 2007) confirmed this sister relationship but showed that both taxa were part of their broader *boliviensis* group.

The karyotype of *A. kofordi*, as described by Myers and Patton (1989b) for specimens from Peru, is composed of a $2n=40$, $FN=40$. The autosomal complement includes 18 pairs of uniarmed elements, one of which is notably larger than the others, which grade evenly in size from medium to small, and a single pair of very small metacentric elements. The X chromosome is a medium-sized subtelocentric with very short second arms, and the Y is a very small acrocentric equal in size to one of the small biarmed autosomes. This karyotype is identical, or nearly so, to those of other mem-

bers of the *boliviensis* complex, particularly *A. boliviensis*, *A. lutescens*, and *A. subfuscus* (Myers and Patton 1989b; Myers et al. 1990).

Akodon lindberghi Hershkovitz, 1990

Lindbergh's Grass Mouse, Lindbergh's Akodon

SYNONYMS:

Plectomys paludicola Borchert and Hansen, 1983:237; *nomen nudum* (see Hershkovitz 1990b:21–23).

Akodon lindberghi Hershkovitz 1990b; type locality “Matosa, a former *fazenda* now part of the Parque Nacional de Brasília, about 20 km NW of Brasília, Distrito Federal, Brazil; altitude about 1,100 m.”

DESCRIPTION: Small, with head and body length 67–93 mm, tail length 49–74 mm, hindfoot length (without claw) 17–20 mm, and ear length 11–16 mm. Dorsal pelage thick, long, and lax, uniformly dark olivaceous agouti in color; sides of body lighter, but without distinct lateral line; underparts from chin to tail base not sharply defined from the sides, hairs buffy to ochraceous terminally and slaty basally. Vibrissae short, not extending beyond pinna when laid back; tail dark brown above, slightly paler beneath, thinly haired, with scales visible; hindfeet thinly covered above by grayish or buffy hairs, but brown scaly skin exposed; claws comparatively thick, moderately curved, and only limitedly covered by short ungual hairs. Eight mammae distributed in pectoral, postaxial, abdominal, and inguinal pairs. Skull delicate, with relatively short rostrum and globular braincase; interorbital region symmetrically biconcave with squared supraorbital margins, and relatively broad in relation to zygomatic arches (least interorbital breadth >38% of zygomatic breadth); nasals broad and short, not extending posteriorly beyond lacrimals; frontoparietal suture U-shaped and colinear with frontosquamosal suture; frontal never contacts squamosal dorsally; zygomatic plates very narrow, with posterior margin barely reaching level of M1 protocone; zygomatic notches shallowly incised so that anterodorsal edge of plates weakly projected in relation to dorsal zygomatic root; incisive foramina wide and long, extending posteriorly beyond protocone of M1 and angled outward at their posterior ends; auditory bullae comparatively small; mesopterygoid fossa comparatively wide, roof with wide sphenopalatine vacuities; parapterygoid fossae wide proximally, becoming wider distally. Greatest skull length 21.7–24.7 mm; upper molar series length 3.6–4.1 mm.

DISTRIBUTION: The scattered records for this species suggest a wide distribution from the central portion of the Brazilian Cerrado in Goiás state and the Distrito Federal to the Atlantic Forest in the states of Minas Gerais and Rio de Janeiro. No fossils are known.

SELECTED LOCALITIES (Map 73): BRAZIL: Distrito Federal, Matosa, Parque Nacional de Brasília (type locality

Map 72 Selected localities for *Akodon kofordi* (●). Contour line = 2,000 m.

of *Akodon lindberghi* Hershkovitz); Minas Gerais, Juiz de Fora (Queirolo and Granzinoli 2009), Parque Nacional da Serra da Canastra (Queirolo and Granzinoli 2009), Sítio Maglândia, Simão Pereira (MNRJ 48026).

SUBSPECIES: *Akodon lindberghi* is monotypic.

NATURAL HISTORY: *Akodon lindberghi* has a marked preference for grassland-dominated habitats in the Cerrado and Atlantic Forest, being captured more frequently in open areas, especially in wet grasslands or near swamps, with few found in forested patches (Borchert and Hansen 1983; Hershkovitz 1990b; Geise et al. 1996; Queirolo and Granzinoli 2009). Records from the Atlantic Forest, therefore, include localities where the forest cover has been significantly altered by human activities, suggesting that this species might be extending its original range, owing to the fragmentation of semideciduous and evergreen forests (Queirolo and Granzinoli 2009). In the Cerrado of central Brazil, local densities appear to be low in relation to those of other sympatric sigmodontines; however, at the few localities where this species has been recorded in the Atlantic Forest, it is as common as the other local rodents. Breeding activity is markedly higher during the rainy season, and the highest densities are observed during the dry season, the period of greatest production of grass seeds (Queirolo and Granzinoli 2009). De Conto and Cerqueira (2007) studied reproduction and life history in captives. A litter size varied from 1 to 4, with a modal number of 3 and mean of 2.72, and was negatively correlated with birth weight. The gestation period was 23

Map 73 Selected localities for *Akodon lindberghi* (●).

days, with a postpartum estrus within a short time following parturition. The sex ratio at birth was not significantly different from 1:1, nor was there significant dimorphism in neonatal birth weight. Males and females attain sexual maturity in 26 to 61 days and 30 to 56 days, respectively, with females mating successfully at 47 to 54 days of age. The mortality of neonates raised by a female in the male's absence was lower, suggesting that only the female is with the young under natural conditions (De Conto and Cerqueira 2007).

REMARKS: Borchert and Hansen (1983) referred to mice collected from what is now the type locality of *A. lindberghi* under the name *Plectomys paludicola*. Despite the lack of any voucher specimens or formal description of *P. paludicola*, Hershkovitz (1990b:21–23) linked this name, which he treated as a *nomen nudum*, to the specimens he subsequently collected and described as *A. lindberghi*.

The karyotype of *A. lindberghi* is $2n=42$, FN=42 chromosomes (Svartman and Almeida 1994; Geise et al. 1996).

Akodon lutescens J. A. Allen, 1901

Altiplano Grass Mouse, Altiplano Akodon

SYNONYMS:

Hesperomys (Habrothrix) xanthorhinus: Thomas, 1884: 450; part; not *Abrothrix xanthorhina* Waterhouse.

Akodon lutescens J. A. Allen, 1901b:46; type locality "Tirapata, [Puno,] Peru, (about 15,000 ft)"; spelling emended to *lutescens* by J. A. Allen (1901b:46).

Akodon puer Thomas, 1902b:136; type locality "Choquecamate, 4000 m," Cochabamba, Bolivia.

Akodon andinus lutescens: Sanborn, 1949c:315; name combination.

Akodon puer lutescens: Myers, Patton, and Smith, 1990: 70; name combination.

Akodon puer puer: Myers, Patton, and Smith, 1990: 67; name combination.

Akodon lutescens lutescens: S. Anderson, 1997:422; name combination.

Akodon lutescens puer: S. Anderson, 1997:422; name combination.

DESCRIPTION: Small species with total body length averaging 139.2mm, tail length 59.0mm, hindfoot length 18.5mm, and ear length 12.4mm. Dorsal coloration pale grayish or olive brown, moderately to heavily lined with black; ventral pelage grayer than dorsum, with few white hairs on chin; moderately conspicuous eye-ring present; tail sharply bicolored, with narrow dark dorsal stripe. Skull with shallow and narrow zygomatic notches, weakly flared zygomatic arches, relatively broad interorbital region, and small braincase; zygomatic plates slender, with anterior borders that slope gently backward from bottom to top; tympanic hook particularly narrow and delicate (illustrated in Myers et al. 1990:Fig. 16); posterior ascending process of alisphen-

noid not reaching level of squamosoalisphenoid groove; incise foramina short in comparison with most other members of *boliviensis* group, but still extend to anterior part of M1; mesopterygoid fossa very narrow, with strongly squared anterior margin, usually with median spine; mandible very slender. Cheek teeth resemble those of *A. boliviensis*, but molar series shorter and M3 generally oval in outline, never figure-8 shaped, lacking deep hypoflexus and deep metaflexus. Condylincisive length averages 20.7 mm, upper molar series length 3.6 mm.

DISTRIBUTION: *Akodon lutescens* inhabits the Altiplano and eastern Andean slopes from Puno department, Peru to Chuquisaca department in south-central Bolivia, at elevations between 1,130 m to 4,560 m (Myers and Patton 1989a; Myers et al. 1990; Patton and Smith 1992b; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007). Argentinean records of this species (see Pardiñas, D'Elía et al. 2006; Jayat, Ortiz, and Miotti 2008; P. E. Ortiz et al. 2011a) actually apply to *A. caenosus*. M. M. Díaz and Barquez (2007) recorded both *lutescens* (as *Akodon lutescens puer*) and *Akodon caenosus* from Yungas environments in Jujuy province, but the broadly comparative study by Jayat et al. (2010) failed to confirm any records of *A. lutescens* from Argentina. No fossils are known.

SELECTED LOCALITIES (Map 74): **BOLIVIA:** Cochabamba, Ayopaya (Myers et al. 1990), 15 mi ENE of Tiraque (MVZ 119923); La Paz, 12 km by road SW of Jesús de Machaca, Río Desaguadero (S. Anderson 1997), Pelehuco (S. Anderson 1997), Río Aceramarca (S. Anderson 1997); Oruro, 1 km W of Huancaroma (S. Anderson 1997); Santa Cruz, above Cocapata on old Cochabamba to Santa Cruz road (S. Anderson 1997), 1 km N and 8 km W of Comarapa (Myers et al. 1990). **PERU:** Cusco, 20 km N (by road) of Paucartambo, km 100 (MVZ 173788); Puno, 11 km W and 12 km S of Ananea (MVZ 173073), 36 km SE by road of Macusani (Myers et al. 1990), 6 km S (by road) of Pucara (MVZ 173398), 5 km W of Puno (Myers et al. 1990), 12 km S of Santa Rosa [de Ayaviri] (Myers et al. 1990).

SUBSPECIES: In addition to *caenosus* Thomas, now regarded as a valid species, both Myers et al. (1990) and S. Anderson (1997) recognized the subspecies *lutescens* J. A. Allen from southern Peru and extreme northern Bolivia and *puer* from west-central Bolivia.

NATURAL HISTORY: In Peru, *Akodon lutescens* has been found exclusively in high Puna grasslands, almost always associated with the coarse and spiny *Festuca* bunchgrass that dominates well-drained and hard soils (Myers et al. 1990). In Bolivia, records for this species also come primarily from high-elevation Puna grasslands and eastern Andean slopes, but the species is also known from Yungas

cloud forest (S. Anderson 1997; Myers et al. 1990). A single female collected in March had four embryos; all others obtained between March and September were not pregnant (S. Anderson 1997). *Akodon lutescens* may be sympatric or contiguously allopatric with several other *Akodon* species, including *Akodon aerosus*, *A. albiventer*, *A. boliviensis*, *A. fumeus*, *A. kofordi*, *A. mimus*, *A. siberiae*, *A. subfuscus*, and *A. varius* (Myers et al. 1990; Patton and Smith 1992b; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; Tarifa et al. 2007).

REMARKS: J. A. Allen (1901b:46) initially spelled the species epithet *lutesens*, but amended the name to *lutescens* later on the same page, a spelling that has been in subsequent use in virtually all publications, from Trouessart (1904:435) to Musser and Carleton (2005:1096). Myers et al. (1990:71–73) encapsulated the confusing history of this species relative to that of other named *Akodon* from the Altiplano of Peru and Bolivia, although they erred in ignoring the priority of J. A. Allen's (1901b) *A. lutescens* over Thomas's (1902b) *A. puer* (see S. Anderson 1997:421–422). Osgood (1944), in his description of *Akodon boliviensis subfuscus*, noted that *lutescens* might be a synonym of *boliviensis*. In the same paper, Osgood described *Akodon andinus polius*, and later Sanborn (1949c) stated that Osgood believed *polius* might be a synonym of *lutescens*, thus associating Allen's *lutescens* with *Akodon* (now *Abrothrix*) *andinus*, a decision followed by Cabrera (1961). Both Myers et al. (1990) and Hershkovitz (1990b) recognized

Map 74 Selected localities for *Akodon lutescens* (●). Contour line = 2,000 m.

that the true affinities of Allen's *lutescens* were not with *andinus* but with the *Akodon boliviensis* group of mice. Furthermore, Myers et al. (1990), using allozyme as well as morphological comparisons, documented broad sympatry without interbreeding between *lutescens* and both *boliviensis* and *subfuscus*, thus falsifying Osgood's (1944) hypothesis and validating the specific status of *A. lutescens*.

The karyotype of *A. lutescens* is $2n=40$, FN=40 (Myers et al. 1990). As with other species of the *boliviensis* group, the autosomal complement consists of 18 pairs of uniarmed elements, with one pair notably larger and the others grading evenly from medium sized to small, and with one pair of small metacentrics about one-half the size of the smallest acrocentric autosome. The X chromosome is a medium-sized subtelocentric and the Y is a small acrocentric, considerably smaller than the smallest uniarmed autosome.

Akodon mimus (Thomas, 1901)

Thespian Grass Mouse, Hoci-cudo-like Akodon

SYNONYMS:

Oxymycterus mimus Thomas, 1901b:183; type locality "Limbane [= Limbani], Dept. Puno. Alt. 2600m," Peru.

Microxus mimus: Thomas, 1909:237; name combination, type species of *Microxus* Thomas.

Akodon (Abrothrix) mimus: Sanborn, 1950:15; name combination.

Akodon (Microxus) mimus: Cabrera, 1961:458; name combination.

[*Abrothrix*] *mimus*: Hershkovitz, 1966:86; name combination.

Akodon mimus: Patton and Smith, 1992b:91; name combination.

DESCRIPTION: Moderately large with average total length 190.9mm, tail length 94.1mm, hindfoot length (with claw) 24mm, and ear length 18.3mm. Overall color uniformly gray-brown, with dorsum and venter only weakly contrasting; no eye-ring; whitish spot on chin present in many specimens. Tail proportionally long, equal to head and body length, and unicolored dark. Skull notable for elongated and narrow rostrum, very shallow and narrow zygomatic notches, broad interorbital region, nonflared zygomatic arches, swollen braincase, and, especially, very narrow zygomatic plates that slant posteriorly from bottom to top. Mesopterygoid fossa conspicuously broadened, with rounded anterior margin. Condylolincisive length averages 24.51mm, the upper molar series 4.50mm.

DISTRIBUTION: *Akodon mimus* inhabits upper elfin forests on the eastern Andean slopes from Puno department in southern Peru to Santa Cruz department in Bolivia, at elevations between 2,000 and 3,700m (Patton and Smith 1992b; S. Anderson 1997). No fossils are known.

SELECTED LOCALITIES (Map 75): BOLIVIA: Cochabamba, 25 km W of Comarapa, Siberia (UMMZ 155962), Corani (S. Anderson 1997), 17km E of Totora, Tinkusiri (S. Anderson 1997), Yungas del Palmar (S. Anderson 1997); La Paz, Cocapunco (S. Anderson 1997), Saynani (S. Anderson 1997), 10 km by road N of Sorata, Moyabaya (S. Anderson 1997), 30km by road N of Zongo (S. Anderson 1997). PERU: Puno, 4 mi N of Limbani (MVZ 116109), 14 km W of Yanahuaya (MVZ 171752).

SUBSPECIES: *Akodon mimus* is monotypic.

NATURAL HISTORY: *Akodon mimus* is a dweller of the more humid parts of the Yungas, from cloud forests to the transition between these and the high-elevation grasslands. Specimens from near Yanahuaya in southern Peru were obtained in forest dominated by epiphyte-laden trees, cecropias, bamboos, and tree ferns. In the Siberia Cloud Forest spanning the boundary of Cochabamba and Santa Cruz departments, Bolivia, *A. mimus* was trapped on the mossy, fern-laden, and humid forest floor (Hinojosa et al. 1987). *Akodon mimus* was the most common species of rodent in the Yungas forests of La Paz department, Bolivia (J. Vargas et al. 2007). There, it was trapped in humid primary and secondary forest. A single individual was obtained in the moist, high-elevation grassland bordering forest communities, near a stream. Across its latitudinal and elevational range, *A. mimus* may co-occur with several other *Akodon* species, including *A. aerosus*, *A. boliviensis*, *A. fumeus*, *A. kofordi*, *A. lutescens*, *A. siberiae*, and *A. subfuscus*. S. Anderson (1997) recorded 38 nonpregnant females through the autumn to the end of winter (May, June, July, and September), with pregnant females obtained only in October (with a mean number of embryos=2.0) and one lactating female in June.

REMARKS: *Akodon mimus* is the type species of *Microxus*, a nominal taxon that has, at times, been treated either as a subgenus of *Akodon* (Cabrera 1961) or as a valid akodontine genus (Gyldenstolpe 1932; Ellerman 1941; Reig 1987). Allozymes as well as both nuclear and mtDNA sequences support the inclusion of *mimus* in the genus *Akodon* (Patton et al. 1989; M. F. Smith and Patton 1991, 1993, 2007; D'Elía 2003a). However, the skull and dental morphology of *mimus* are very distinctive compared with that of other *Akodon*, and especially its narrowed zygomatic plates that slant posteriorly from bottom to top. As Thomas (1920h:241) noted, "the long head, especially the long muzzle, and the small eyes, give the *Microxus* quite a different aspect to that of the *Akodon* with its blunt snout and normal eyes, and I now feel no hesitation in considering them as belonging to different genera." This differentiation is partially supported by several phylogenetic reconstructions based on DNA sequences, which place *mimus* as sister to *Deltamys* (M. F. Smith and Patton 2007).

Map 75 Selected localities for *Akodon mimus* (●). Contour line=2,000 m.

Akodon mollis Thomas, 1894

Soft-furred Grass Mouse, Soft-furred Akodont

SYNONYMS:

Hesperomys olivaceus: Thomas, 1882:110; part; not *Mus olivaceus* Waterhouse.

Acodon mollis Thomas, 1894b:363; type locality “Tumbes, [Tumbes,] N Peru.”

[*Akodon* (*Akodon*)] *mollis*: E.-L. Trouessart, 1897:538; name combination.

Akodon mollis altorum Thomas, 1913b:404; type locality “Cañar. Alt. 2600 m,” Cañar, Ecuador.

Akodon mollis mollis: Gyldenstolpe, 1932a:106; name combination.

Akodon mollis fulvescens Hershkovitz, 1940b:2; type locality “The Río Mira Valley, parish of La Carolina, Ibarra, Imbabura Province, Ecuador; subtropical forest of the western slope of the western Andes; altitude about 900 meters.”

DESCRIPTION: Medium-sized with head and body length 81–113 mm, tail length 55–92 mm, hindfoot length (without claw) 18–26 mm, ear length 8–18 mm, greatest skull length 23.71–29.37 mm, and upper molar series length 3.5–4.7 mm. Dorsal pelage soft and variable in color, from dark olive to yellowish brown, contrasting with paler, usually grayish or dull buff under parts; lateral line, if present, narrow and weakly developed; dorsal surfaces of both forefeet and hindfeet pale brown to gray, covered with basally dark banded hairs; ungual tufts grayish or light brown,

with distal margin of most hairs ending at or just surpassing claws. Tail short, moderately to well furred, distinctly to indistinctly bicolored, with darker hairs above. Vibrissae short, not extending beyond pinna when laid back. Eight mammae in pectoral, postaxial, abdominal, and inguinal pairs. Skull compact with fairly robust rostrum; interorbital region broader than muzzle, with narrowest point centrally located and with smooth supraorbital edges; nasals narrow and extend posteriorly beyond suture between maxillary, frontal, and lacrimal; parietal and occipital bones in contact, isolating narrow interparietal from squamosal; alisphenoid strut present; zygomatic plates broad with slightly, posteriorly inclined anterior margin and posterior border reaching protocones of M1s; zygomatic notches moderately to well developed; maxillary and mandibular diastemata long, as are incisive foramina, which extend posteriorly past anterior margin of M1s, reaching to level protocones in some specimens; and carotid circulation pattern 1 (*sensu* Voss 1988).

DISTRIBUTION: *Akodon mollis* is distributed from northwestern Peru to northern Ecuador (and likely occurs in southern Colombia) and across an extensive elevation range from near sea level to above 4,900 m. An isolated population occurs on the coast of southern Peru in Tacna department. In central and northern Peru, this species occurs along the Pacific coast and adjacent western slopes of the Andes, west of the Río Marañón (see C. F. Jiménez et al. 2013), but its distribution farther north becomes restricted to the higher elevations on both the western and eastern slopes of the Andes and throughout the inter-Andean valleys to near the snow line. Fossil *Akodon* from the Late Pleistocene and Holocene of Ecuador (Fejfar et al. 1993) probably belong to this species.

SELECTED LOCALITIES (Map 76): ECUADOR: Azuay, Molleturo, Cuenca (AMNH 61990); Carchi, Páramo del Artesón, Comuna La Esperanza (EPN 9641); Cotopaxi, Hacienda Sr. Cepeda, 10 km NW of Chugchilán (QCAZ 11281); Imbabura, sector “Los Cedros,” Manduroyacu, Reserva Ecológica Cotacachi-Cayapas (EPN 7583); Loja, Laguna Negra, Bosque Protector Colomobo-Yacurí (QCAZ 11281), Puyango, Alamor (AMNH 47358); Morona-Santiago, Cerro Bosco, forest surrounding the Pacifictel Transmitting/Receiving Antenna (QCAZ 4812); Napo, Oyacachi, El Chaco County (AMNH 63842). PERU: Ancash, Huari, Yanacocha (MUSM 24072), 1 km N and 12 km E of Pariacoto (MVZ 135676), 4 km S and 8 km E of Recuay (MVZ 137975); Cajamarca, Contumaza, Bosque Cachil, entre Cascas y Contumaza (VPT 1673), Cutervo, San Andrés de Cutervo (UMMZ 176689), Hacienda Taulis (MVZ 121157); Huánuco, Chinchuragra, Punchao (Jiménez et al. 2013); La Libertad, 10 mi WNW of Santiago de Chuco (137980), 5 km NE of Pacasmayo (MVZ 137679), 5 mi SW of Otuzco (MVZ 137961); Piura, Cerro

Chinguela, Huancabamba (Jiménez et al. 2013), Cerro Chinguela, ca. 5 km NE of Zapalache (LSUMZ 27149), Morropón, Chalaco (MUSM 21691), 2 km W of Porculla Pass (MVZ 137969); Tacna, Morro de Sama, 65 km W of Tacna (MVZ 143697).

SUBSPECIES: Hershkovitz (1940b) reviewed geographic variation in morphology and delineated three subspecies based primarily on differences in dorsal color and minor craniodental traits: *A. m. mollis* from northwestern Peru, *A. m. altorum* from the intermontane valleys in Ecuador, and *A. m. fulvescens* from the eastern Andean slopes in Ecuador.

NATURAL HISTORY: *Akodon mollis* occupies a wide variety of habitats across its large latitudinal and elevational range, including dry coastal areas on the Pacific coast, cloud forest and evergreen to semideciduous forests on upper slopes on both sides of the Andes, and grasslands at high elevations (D. F. Alvarado-Serrano 2005, pers. comm.). It is, however, most commonly found in grassland and shrubby habitats at elevations above 2,000 m (Alvarado-Serrano 2005; Voss 2003). As noted by Barnett (1999), *A. mollis* may be the most common mouse in high-elevation grasslands of Ecuador, often comprising >60% of all captures; it is one of the few sigmodontine species in the northern Andes that can be regularly found in highly disturbed environments such as introduced *Pinus* or *Eucalyptus* plantations. Little is known about the ecology, but based on an analysis of specimens from Parque Nacional El Cajas, *A. mollis* is a predominantly nocturnal generalist, with at least two reproductive cycles per year and two to four embryos per pregnancy (Barnett 1999).

REMARKS: Originally considered to be a northern representative of *Hesperomys* (now *Abrothrix*) *olivaceus* (Thomas 1882:110, 1884:456), this species is currently grouped with four other *Akodon* species (*A. aerosus*, *A. torques*, *A. orophilus*, and *A. affinis*) in a weakly supported clade of Andean-slope *Akodon* based on mtDNA sequences (M. F. Smith and Patton 1993, 1999, 2007). With the exception of *A. mollis*, which was described from the northwestern coast of Peru and occurs at low to high elevations, all other species in this clade are restricted to montane habitats in the central and northern Andes. To date, however, all samples of *A. mollis* included in the published molecular analyses are from high-elevation populations and are in a complex set of paraphyletic relationships with samples of other species in the clade (M. F. Smith and Patton 1993; Alvarado-Serrano 2005, unpubl. data). Therefore, until samples from coastal areas at or near the type locality of *mollis* and additional data that can resolve phyletic relationships become available, the proposition that *A. mollis*, as construed herein and by earlier authors, is a species complex with currently undefined boundaries and an unknown number of included taxa remains a hypothesis

to be tested. Certainly, the conspecific status of each described subspecies needs adequate assessment (Voss 2003).

Myers and Patton (1989b) suggested that *A. mollis* was allied to *A. fumeus*, *A. kofordi*, also Andean species of *Akodon* based on commonality in some morphological traits. However, the phyletic propinquity of both *A. fumeus* and *A. kofordi* with species in the broader *boliviensis* group (M. F. Smith and Patton 2007) falsifies Myers and Patton's hypothesis. Alvarado-Serrano et al. (2013) examined the extent of phenotypic differentiation across the species' range in Peru using geometric morphometric and ecomorphological analyses of skull shape. This ecologically widespread species exhibited little phenotypic specialization across their range, with the exception of samples from the high-elevation puna. From molecular genetic analyses, geographic isolation alone did not explain this localized phenotype.

Karyotypes with $2n=22$ have been recorded from Ancash department, Peru (Patton and Smith 1992b), and central Ecuador (Lobato et al. 1982), and $2n=36-38$ for specimens from Piura department, Peru (Patton and Smith 1992b). The Ecuadorean specimens had a fundamental number of 43–44 (Lobato et al. 1982). This geographic diversity of chromosomal complements underscores the earlier comment that *A. mollis* likely represents a complex of separate species.

Map 76 Selected localities for *Akodon mollis* (●). The population on the coast of SW Peru is presumed to be disjunct from the main distribution. Contour line = 2,000 m.

Akodon montensis Thomas, 1913

Montane Grass Mouse, Montane Akodont

SYNONYMS:

Akodon arviculoides montensis Thomas, 1913b:405; type locality “Paraguay. Type from Sapucay [= Sapucaí], [Paraguari].”

Akodon cursor montensis: Massoia, 1980b:22; name combination.

Akodon montensis: Geise, Canavez, and Seuáñez, 1998: 158; first use of current name combination.

DESCRIPTION: Medium sized similar to but somewhat smaller than *A. cursor*. Males usually larger than females, with head and body length averaging 115.21 ± 8.13 mm (N=46) versus 108.83 ± 11.10 mm (N=38), tail length 93.01 ± 10.13 mm (N=48) versus 88.41 ± 8.44 mm (N=35), and mass 43.31 ± 11.14 mm (N=48) versus 36.43 ± 12.83 mm (N=35; Geise et al. 2005). Tail in both sexes always shorter than head and body length, approximately 81%. Greatest skull length averages 27.15 ± 1.06 mm (N=52) mm in males and 25.71 ± 1.21 mm (N=39) in females; the upper molar series length averages 4.23 ± 0.18 mm (N=91) for both sexes combined. Very similar to *A. cursor* in external morphology, but two species differ in craniodental morphometry (Christoff 1997; Geise et al. 2005), in distribution of allozyme variants (Rieger et al. 1995), are reciprocally monophyletic in mtDNA sequences (Geise et al. 2001; D’Elía et al. 2003), and have distinct karyotypes (Fagundes and Yonenaga-Yassuda 1998; Geise et al. 1998). *Akodon montensis* also lacks a gall bladder, which is present in *A. cursor* (Geise, Weksler, and Bonvicino 2004).

DISTRIBUTION: *Akodon montensis* is widespread from eastern Paraguay (Myers 1982; Gamarra de Fox and Martin 1996), northeastern Argentinian gallery forests along rivers or wetlands in the provinces of Formosa, Chaco, Corrientes, and Misiones (Massoia and Fornes 1962; Pardiñas, D’Elía, and Cirignoli 2003), and along the southern coast of Brazil from Rio Grande do Sul state in the south to Rio de Janeiro and eastern of Minas Gerais states in the north (Geise et al. 2001, 2005). Reig (1987) reported *A. montensis* from the Middle Pleistocene (Ensenadan) of southeastern Buenos Aires province, which is noteworthy because this locality is extralimital to the present range of the species (Pardiñas, D’Elía, and Cirignoli 2003).

SELECTED LOCALITIES (Map 77): ARGENTINA: Chaco, Estación Experimental Colonia Benítez, INTA (Massoia and Fornes 1962); Corrientes, El Sombrero (J. R. Contreras et al. 2003), Santa Tecla, Rte 12, km 1287 (Pardiñas, D’Elía, and Cirignoli 2003); Formosa, Estación Experimental El Colorado, INTA (Massoia 1971b), Estancia Guaycolec (Massoia, Heinonen Fortabat, and Diéguez

1997); Misiones, Arroyo Itaembé Miní, bridge over Rte 12 (Massoia 1983), Concepción de la Sierra (Pardiñas, D’Elía, and Cirignoli 2003), Reserva Privada UNLP “Valle del Arroyo Cuña Pirú” (Pardiñas, D’Elía, and Cirignoli 2003). BRAZIL: Mato Grosso do Sul, Fazenda Maringá, 54 km W of Dourados (MVZ 197459), Fazenda Princesinha (Cáceres et al. 2007); Minas Gerais, Estação Biológica de Caratinga, Caratinga (MNRJ 31450), Jambreiro, Nova Lima (MNRJ [LG 207]); Paraná, Mananciais da Serra, Piraquara (MNRJ [JAO 965]); Rio Grande do Sul, Rota do Sol, Tainhas–Terra de Areia (Valdez and D’Elía 2013); Rio de Janeiro, Sítio Xitaca, Debossan, Nova Friburgo (MNRJ 35925); São Paulo, Estação Ecológica do Bananal, Bananal (MZUSP [EEB 563]), Fazenda Passes, Santo Antônio do Aracanguá (MNRJ [EDH 61]). PARAGUAY: Amambay, Parque Nacional Cerro Corá (Gamarra de Fox and Martin 1996); Paraguari, Sapucaí (type locality of *Akodon arviculoides montensis* Thomas); San Pedro, Ganadera Jejui (UMMZ 174897).

SUBSPECIES: *Akodon montensis* is monotypic.

NATURAL HISTORY: Less is known about the natural history of *A. montensis* in comparison to its close relative *A. cursor*. The species apparently prefers closed and dense forest understory and more pristine habitats at elevations above 800 m in Rio de Janeiro state (Geise et al. 2001, 2005; Geise, Pereira et al. 2004). Where *A. montensis* and *A. cursor* are sympatric, the two species are elevationally segregated, with *A. montensis* at higher elevations (Geise et al. 2001). In Santa Catarina state, where *A. montensis* was also among the most frequently trapped species (Cherem and Perez 1996), it is found at sea level in the mangrove–coastal forest interface (as on Ilha Santa Catarina; Graipel et al. 2001). In Paraguay, individuals exhibited a preference for either forest with little understory or dense vegetative cover on or near the ground (Goodin et al. 2009). And in Misiones, Argentina, this species was the dominant member of the small mammal assemblage in both secondary forest and other anthropogenic disturbed habitats (Cirignoli et al. 2011). At most trapping sites in Brazil, *A. montensis* was also among the most frequently trapped species, typically comprising more than 70% of all captures (Davis 1945b; Cherem and Perez 1996). Based on long-term studies at Teresopolis and other sites in Rio de Janeiro state, home ranges were large, with individual movements between trapping sessions between from 100 and 370 m (Davis 1945b). Püttker, Bueno et al. (2013) described survival rates, population change rates, and capture probability for populations in different forest cover landscapes. Fontes et al. (2007) reported large and sexually dimorphic home ranges, with the space used by males larger ($1,460 \pm 934$ m²) than that of females ($1,092 \pm 1007$ m²). Reproduction is seasonal, with a peak during the rainy season (Couto and Talamoni 2005),

with litter sizes ranging between 3 and 5 (Graipel et al. 2001). Graipel et al. (2003) found these animals to be most active at the beginning and end of each night, although they recorded 23% of captures during daylight hours. Horn (2005) provided evidence that *A. montensis* functions as a seed disperser for at least two important native plants, *Ficus organensis* and *Piper cf. solmisianum*. *Akodon montensis* harbors a hantavirus (Goodin et al. 2009).

REMARKS: The validity of specific status for *A. montensis* and its separation from *A. cursor* has been the subject of interest for many years. Cytogenetic studies showed two distinct sets of diploid complements, 24–25 and 14–15, making clear the existence of two symorphic species (see Fagundes and Yonenaga-Yassuda 1998; Geise et al. 1998). Because the $2n=14-15$ karyotype was found at Lagoa Santa, type locality of *A. cursor* Winge, these diploid complements were assigned to that species; the $2n=24-25$ was then assigned to *A. montensis*. DNA phylogenetic analyses clearly show that both species are valid because both sets of karyomorphs form reciprocally monophyletic groups (Geise et al. 2001). In a more extensive DNA phylogenetic analysis, G. D'Elía (unpubl. data) found one topotype of *montensis* part of the $2n=24-25$ clade identified by Geise et al. (2001), supporting the association of *montensis* Thomas with these karyotypes (Pardiñas, D'Elía, and Cigrignoli 2003). Cestari and Imada (1968) incorrectly used the name *A. arviculoides cursor* for specimens with $2n=24$ and collected in São Paulo state, Brazil. Phylogenetic reconstruction based on mtDNA cytochrome-*b* sequences

documented that *A. montensis* is part of a well-supported clade also containing *A. cursor*, *A. mystax*, *A. paranaensis*, *A. reigi*, and an undescribed species sometimes referred to as “*A. aff. cursor*” (M. F. Smith and Patton 2007). Valdez and D'Elía (2013) detailed phylogeographic structure in relation to Pleistocene refugia hypotheses for the Atlantic Forest.

Akodon mystax Hershkovitz, 1998

Caparaó Grass Mouse, Caparaó Akodont

SYNONYM:

Akodon mystax Hershkovitz 1998; type locality “Arrozal, Pico da Bandeira, western slope Mt. Caparaó, Minas Gerais, Brazil, elevation 2300m.”

DESCRIPTION: Small, very similar externally to *A. lindberghi*, with head and body length 66–101mm, tail length 48–76mm, hindfoot length (without claw) 17–20mm, and ear length 11–18mm. Dorsal fur soft and long, and of overall grayish-brown tone, slightly grayer than *A. lindberghi*; sides somewhat paler than dorsum with phaeomelanic bands generally very pale yellow color; ventral pelage weakly delimited from dorsum, but also grayish in tone due to hair with dark gray basal bands and terminal whitish bands; small cluster of short melanic bands above rhinarium visible in some specimens, providing what looks like dark rostral patch. Tail well furred and bicolored, with blackish hairs dorsally and whitish hairs ventrally; short hairs with dark basal and silvery apical bands, resulting in overall light gray tone, cover dorsal surfaces of both forefeet and hindfeet; well-developed unguis tufts present, with most hairs extending past tips of claws. Vibrissae short, not extending beyond pinna when laid back. Eight mammae distributed in pectoral, postaxial, abdominal, and inguinal pairs. Skull appears delicate with relatively short rostrum and globular braincase; interorbital region symmetrically biconcave with rounded supraorbital edges and relatively broad in relation to zygomatic arch breadth (least interorbital breadth >38% of zygomatic breadth); nasal bones broad and short, not extending posteriorly beyond lacrimals; incisive foramina wide and long, as in *A. lindberghi*, extending posteriorly past M1 protocone and expanded laterally at posterior end; frontoparietal suture wide, U-shape and not colinear with frontosquamosal suture, producing narrow area of dorsal contact between squamosal and frontal; zygomatic plates narrow with posterior margin barely reaching level of M1 protocone, and anterodorsal edge weakly projected in relation to dorsal zygomatic root; zygomatic notches shallowly incised; masseteric crest evident at base of each zygomatic plate. Greatest skull length 22.62–25.58mm, upper molar series length 3.63–4.1mm.

DISTRIBUTION: *Akodon mystax* is known only from the highest elevation zone (1,800–2,900m) in the vicinity

Map 77 Selected localities for *Akodon montensis* (●). Contour line = 2,000m.

of Pico da Bandeira, on the border between Minas Gerais and Espírito Santo states in southern Brazil (Hershkovitz 1998). This species is not known in the fossil record.

SELECTED LOCALITIES (Map 78): BRAZIL: Minas Gerais, Pico da Bandeira, Parque Nacional do Caparaó (type locality of *Akodon mystax* Hershkovitz).

SUBSPECIES: *Akodon mystax* is monotypic.

NATURAL HISTORY: This species occurs in the cool-humid, high-elevation grasslands called *campos de altitude* found above 1,800 m on Mt. Caparaó (Bonvicino et al. 1997; P. R. Gonçalves et al. 2007). The highest densities have been found in bamboo patches (*Chusquea* spp.) and bunchgrasses (*Cortadeira*) that grow on shallow hygrophilic soils and among rocky outcrops. No *A. mystax* were captured in the gallery montane forest at 2,500 m. One female contained four embryos. Hershkovitz (1998) stated that the blackish rostral patch was more frequent in males than in females.

REMARKS: P. R. Gonçalves et al. (2007) clarified the identification of a specimen treated as *A. mystax* by Geise et al. (2001) and by Pardiñas, D'Elía, and Cirignoli (2003), both of whom had suggested a possible sister relationship between *A. mystax* and *A. lindberghi*. M. F. Smith and Patton (2007) placed *A. mystax* in their *cursor* group, as the well-supported sister of *A. paranaensis*. Two karyotypes, one with $2n=42$, $FN=42$ (P. R. Gonçalves et al. 2007), and a second with $2n=44$ (Bonvicino et al. 1997), have been reported for topotypes.

Map 78 Single known locality for *Akodon mystax* (●).

Akodon orophilus Osgood, 1913

El Dorado Grass Mouse, Utcubamba Akodont

SYNONYMS:

Akodon mollis orophilus Osgood, 1913:98; type locality "six miles west of Leimabamba [= Leymebamba], [Amazonas,] Peru (in mountains near headwaters of Utcubamba River)."

Akodon mollis orientalis Osgood, 1913:99; type locality "Poco Tambo, between Chachapoyas and Rioja, [San Martín,] Peru. Altitude about 6000 ft."

Microxus orophilus: Thomas, 1926e:615; name combination.

Microxus orophilus orientalis: Thomas, 1926e:616; name combination.

[*Akodon*] *orphilus*: Thomas, 1927a:370; name combination.

[*Akodon orophilus*] *orientalis*: Osgood, 1943b:197; name combination.

Akodon orophilus orophilus: Cabrera, 1961:446; name combination.

DESCRIPTION: Medium-sized species (measurements of holotype: total length 192 mm, head and body length 107 mm, tail length 85 mm, hindfoot length 23 mm, greatest length of skull 26.8 mm, basal length 24.5 mm, zygomatic breadth 13.3 mm, interorbital breadth 4.9 mm, nasals 10.8×2.8 mm, incisive foramina 5.8 mm, diastema 6.8 mm, and upper molar series 4.4 mm). Similar to *A. mollis altorum* from Ecuador, but averages slightly larger and more fulvous in color; two species, however, exhibit marked cranial differences. Skull in *A. orophilus* with laterally compressed and attenuate rostrum; nasals slender and elongate; zygomatic plates narrow, with anterior edge convex, slanting posteriorly from base; braincase broader and more smoothly rounded than that of *A. mollis* or *A. m. altorum*, without temporal ridges.

Akodon o. orientalis slightly larger, with longer tail and much darker overall coloration than *A. o. orophilus*. External measurements of holotype include total length 201 mm, head and body length 116 mm, tail length 85 mm, and hindfoot length 24 mm. Craniodental measurements include zygomatic breadth 13.8 mm, breadth of braincase 13 mm, interorbital breadth 5.5 mm, nasals 10.6×3.4 mm, palatine foramina 5.7 mm, diastema 7 mm, and upper molar 4.6 mm. Upper parts deep mummy brown in general appearance; hairs annulated, with dark umber and tipped blackish; under parts heavily washed with tawny russet; tail and feet entirely blackish. Skull of *orientalis* with same general form of slender rostrum and narrow, receding zygomatic plates as in *orphilus* but braincase larger (Osgood 1913).

Akodon orophilus distinguishable from other members of *aerosus* group by uniform olive green general coloration; dorsal and ventral pelage not strongly contrasting; contours of posterior edge of nasals smooth, tapering, and

V-shaped; lacrimals small; zygomatic plates slanted, with anterior edge sigmoid or slightly convex; antorbital bridge moderately wide; zygomatic notches wide and intermediate in depth; incisive foramina penetrate between first upper molars, but comparatively short; diastema intermediate in length; and jaw moderately robust, with delicate capsular projection (C. F. Jiménez et al. 2013).

DISTRIBUTION: This species occurs in wet elfin forests on eastern Andean slopes east of the Río Marañón in Amazonas and northern San Martín departments of northern Peru, between 1,900 to 2,860 m (C. F. Jiménez et al. 2013). Specimens that Patton and Smith (1992b) assigned to this species from Cajamarca department are *Akodon mollis*; those originally referred to *orophilus* from Huánuco and Junín departments (see M. F. Smith and Patton 1993, 1999, 2007) are *Akodon josemariarguedasi* (see that account and C. F. Jiménez et al. 2013). Osgood (1943b:197) remarked that in northern Peru, *A. mollis altorum* and *A. orophilus* were separated only by the canyon of the Río Marañón (see also C. F. Jiménez et al. 2013:238), and, contrary to Thomas's supposition (1920h), these two taxa are not "respectively lowland and highland" forms, but forms of the western, central, and eastern Cordilleras. We treat the reported occurrences of *orophilus* in Ecuador (Barnett 1999; P. Moreno and Albuja 2005) as belonging to *Akodon mollis*, following C. F. Jiménez et al. (2013:240).

SELECTED LOCALITIES (Map 70): PERU: Amazonas, Cordillera Colán, E of La Peca (LSUMZ 21859), Leimbamba, ca. 20 km W by road (FMNH 129234), 6 road km SW of Lake [= Laguna] Pomacochas (LSUMZ 19236), 5 km N and 5 km E of Pomacocha [= Florida] (MVZ 135672), Tambo Ventija [= Ventilla], near Molinopampa (Osgood 1914b); San Martín, Poco Tambo [= Puca Tambo], 50 mi E of Chachapoyas (type locality of *Akodon mollis orientalis* Osgood), Puerto del Monte, ca. 30 km NE of Los Alisos (Patton and Smith 1992b).

SUBSPECIES: Two subspecies are currently recognized, *A. o. orophilus* and *A. o. orientalis*, both originally described as subspecies of the widespread *A. mollis*. According to Osgood (1914b:163), "as a species, *Akodon mollis* has continuous distribution from the arid west coast up to an altitude of at least 12,000 feet and thence across the mountains and down into the upper part of the eastern forest or montagna . . . Four well-marked subspecies are recognizable. Their more important characters may be summarized as follows: Rostrum shorter and broader, zygomatic plate upright in front. Pelage short; color paler: *A. mollis*; Pelage long; color darker: *A. m. altorum*. Rostrum longer and slenderer, zygomatic plate with receding front edge. Feet grayish; tail bicolor: *A. m. orophilus*. Feet and tail wholly blackish: *A. m. orientalis*." Osgood (1913) reported intergradation between *orophilus* and *orientalis* in the region of

Puca Tambo and related color differences to environmental conditions.

NATURAL HISTORY: Collections at Utcubamba were made in a swampy mountain glade near the source of a western branch of the Río Utcubamba, about six miles west of Leimebamba, elevation 8,000 ft (Osgood 1914b). Specimens identified as *orophilus* were obtained in the "heavily wooded canyons, which increased in number after we crossed the Marañón, associated with *Thomasomys*, *Rhipidomys*, and *Oryzomys albigularis* [= *Nephelemys albigularis*] and it generally out-numbered any of these. It was found also in open swamps at high altitudes living in long grass or rushes quite after the manner of northern voles of the genus *Microtus*. In certain of these places, the labyrinthine runways, open burrows, and fresh grass cuttings so familiar to the northern collector were found in great numbers. In other places, as for example heavy woods or rocky stream beds, the Akodons seemed to lead wandering lives and have as retreats only natural openings in or near the ground" (Osgood 1914b:164). Osgood (1914b) stated that *orientalis* was found in "the dense, humid, but relatively cool forest which forms the practically unbroken cover of the lower slopes of the eastern Andes. In this region it is possible that its range may overlap that of *Akodon aerosus* which is found slightly lower down." *Akodon orophilus* has been trapped with *Hylaeamys yunganus*, *Microryzomys minutus*, *Nephelemys albigularis*, *Thomasomys notatus*, and *T. ischyrius* in montane forests of Amazonas department. The species may be very common, especially in corn and potato agricultural plots, comprising 46% of all animals captured in a 12-night survey during July and August 2007 (C. F. Jiménez et al. 2013).

REMARKS: Thomas (1920h, 1926e) discussed the generic allocation of *orophilus* and *orientalis* when he described *surdus* and *torques*, which were based on the collections obtained by Edmund Heller from Machu Picchu and its surroundings. Thomas (1920h:237) wrote "[*Akodon surdus*] differs from its nearest ally, *A. mollis*, by its stouter build and smokier color, without tinge of buffy. The animal is of interest in connection with its strong external resemblance to the species here called *Microxus torques*. The two are found, respectively, at low (5,000–6,000 feet) and high (8,000–14,000 feet) altitudes and apparently represent the lowland and highland forms of northern Peru, distinguished by Osgood merely as subspecies of *A. mollis* [i.e., *orophilus* and *orientalis*]." Thomas (1920h:240) further added "[*torques*] is distinguishable from *M. mimus* by its broader and less characteristically *Microxine* zygomatic plate, but is otherwise very similar to that animal. Osgood's *Akodon mollis orophilus* is said to be 'more fulvous than *A. m. altorum*,' which is anything but the case with the present animal; and his *A. m. orien-*

talis is a low-land form and much darker in color . . . But, on the other hand, I quite admit that while the zygomatic plate of the earlier described species [*mimus*] was strongly and characteristically different from that of *Akodon*, that of *M. torques* (and I presume of *Akodon mollis orophilus* and *orientalis*) is more or less intermediate between the two. We have therefore to decide whether *Microxus* shall be amalgamated with *Akodon*, ignoring its peculiar zygomatic plate, or whether we shall recognize *Microxus* and put *torques*, *orophilus*, and *orientalis* into it, where they would form a group of species annectent with *Akodon*.” Osgood (1943b:197) later treated *orophilus* as a distinct species and also discussed its generic position, saying “a re-examination of my original collections, together with series of *torques* and much additional material, leads to the conclusion that *orophilus* is specifically but not generically distinct from *mollis*, at least not in northern Peru.” Cabrera (1961) placed all these forms in *Akodon* and treated *torques* as a subspecies of *orophilus*.

C. F. Jiménez et al. (2013) described a karyotype for specimens from Amazonas department with $2n=26$, $FN=40$, with 8 pairs of biarmed and 3 pairs of uniarmed autosomes, a large biarmed X, and a small uniarmed Y. Specimens with other karyotypes originally assigned to *A. orophilus* ($2n=26$, from Ayacucho department [Hsu and Benirschke 1973], and $2n=22$, from Huánuco department [Pacheco, Córdova, and Velásquez 2012]) are referable instead to *A. torques* (Patton and Smith 1992a,b) and *A. josemariarguedasi* (C. F. Jiménez et al. 2013), respectively.

Akodon paranaensis Christoff, Fagundes, Sbalqueiro, Mattevi, and Yonenaga-Yassuda, 2000

Paraná Grass Mouse, Paraná Akodont

SYNONYM:

Akodon paranaensis Christoff, Fagundes, Sbalqueiro, Mattevi, and Yonenaga-Yassuda, 2000:844; type locality “Piraquara (Estação Ecológica Canguiri), Paraná, Brazil.”

DESCRIPTION: Similar externally and cranially to *A. cursor* and *A. montensis* but distinguishable by karyotype and cranial dimensions (particularly least interorbital breadth and molar series length). The head and body length 88–125 mm, tail length 60–92 mm, ear length 15–19 mm, and hindfoot length (without claw) 22–24 mm. Dorsal pelage soft and long, with overall gray olivaceous tone and without clear distinction from either lateral or ventral pelage; venter grayish or creamy; forefeet and hindfeet grayish brown above, covered by banded hairs with dark base and white tip, and with long unguis tufts that extend beyond tip of each claw. Vibrissae short, not extending past pinnae when laid back. Tail bicolored, especially near base, with scales exposed and clearly visible to eye among short

bristles. Eight mammae distributed in pectoral, postaxial, abdominal, and inguinal pairs. Skull elongated with pronounced rostrum and globular braincase and symmetrically biconcave and relatively narrow (least interorbital breadth <5.1 mm or 34% of zygomatic breadth) interorbital region, especially in comparison to *A. cursor*; nasals pointed and long, but do not extend posterior to lacrimals in most specimens; frontoparietal suture U-shaped and collinear with frontosquamosal suture so that frontal never contacts squamosal dorsally; zygomatic plates wide with straight anterior borders in most specimens; anterodorsal edges of plates square and projected anteriorly in relation to dorsal zygomatic root, forming deeply incised zygomatic notches; incisive foramina long, usually reaching level of the protocones of M1s. Greatest skull length 26–31 mm, upper molar series length 4.4–4.9 mm.

DISTRIBUTION: *Akodon paranaensis* is found in southern and southeastern Brazil, extending westward to northeastern Argentina (Misiones province) and eastern Paraguay. Northeastern populations occur on isolated mountaintops in the Serra da Mantiqueira (states of Minas Gerais and Rio de Janeiro), those in the south are at lower elevations (P. R. Gonçalves et al. 2007). No fossils are known, but *Habrothrix clivigenis* Winge, a fossil *Akodon* from Capão Secco Cave in Minas Gerais, Brazil, is very similar to *A. paranaensis*. These two taxa require careful comparison, not just to extend a temporal range but also in regard to name priority.

SELECTED LOCALITIES (Map 79): ARGENTINA: Misiones, Parque Provincial Islas Malvinas (Liascovich and Reig 1989). BRAZIL: Minas Gerais, Serra do Papagaio, Itamonte (Gouveia 2009); Paraná, Estação Ecológica do Canguiri (Christoff et al. 2000), Mangueirinha (Hass 2001), Salto Caxias Dam, lower Rio Iguaçu (Casella and Cáceres 2006), Tijucas do Sul (Hass 2001); Rio de Janeiro, Campos do Itatiaia, Parque Nacional do Itatiaia (P. R. Gonçalves et al. 2007); Rio Grande do Sul, Cambará do Sul, Parque Nacional da Serra Geral (MNRJ [LMT 294]), Itapeva, Torres (Tiepolo 2007), Pelotas (Tiepolo 2007), Santa Maria (T. G. Santos et al. 2008), Três Barras, margins of Rio Uruguai, Aratiba (Christoff et al. 2000), Venancio Aires (Schleiber and Christoff 2007); Santa Catarina, Urubici, Morro da Igreja, Parque Nacional de São Joaquim (MNRJ [LMT 304]). PARAGUAY: Alto Paraná, Reserva Biológica Limoy (de la Sancha 2010); Canindeyú, Reserva Natural del Bosque de Mbaracayú (de la Sancha 2010), Reserva Natural Privada Morombí (de la Sancha 2010); Itapúa, Estancia Pabel, 0.3 km E of houses (D’Elía, Mora et al. 2008), Reserva de Recursos Manejados San Rafael (de la Sancha 2010).

SUBSPECIES: *Akodon paranaensis* is monotypic.

NATURAL HISTORY: This species inhabits primary and secondary tropical forests as well as grasslands and shrubby

transitional habitats (Christoff et al. 2000; Schleiber and Christoff 2007). In southern Brazil, the species is broadly distributed in humid montane forests dominated by *Araucaria angustifolia*, a tree that occurs in temperate regions above 900 m (Christoff et al. 2000). In southeastern Brazil, it appears to be limited to isolated high-elevation habitats such as the *campos de altitude* and montane forests, which occur above 1,800 m in the Serra da Mantiqueira and Serra do Mar ranges (P. R. Gonçalves et al. 2007). In Paraguay, this is primarily an insectivorous-omnivorous species, with stomach contents containing both coleopterans and a substantial proportion of fruit (de la Sancha 2010). Casella and Cárceres (2006) suggested, based on the high proportion of intact seeds found in the stomach contents, that *A. paranaensis* might play an important role as a seed disperser. R. C. Oliveira et al. (2012) isolated the Jabora strain of hantavirus (JABV) from specimens of *A. paranaensis* collected in Santa Catarina state, Brazil.

REMARKS: The karyotype of *A. paranaensis* is now understood to be $2n=44$, FN=44 (Christoff et al. 2000; Geise et al. 2001). Specimens with this karyotype, however, were previously identified as *A. serrensis* (Liascovich and Reig 1989; Sbalqueiro 1989) until Christoff et al. (2000) corrected this assignment. Previous authors had also identified *Akodon* populations with $2n=44$ from Mt. Itatiaia, in southeastern Brazil, and from Misiones, Argentina, as allied to *A. mystax* (Geise et al. 2001; Geise, Pereira et al. 2004; Pardiñas, D'Elía, and Cirignoli 2003—specimens referred to as *Akodon* sp. 2), and Geise, Pereira et al. (2004)

Map 79 Selected localities for *Akodon paranaensis* (●). Contour line = 2,000 m.

incorrectly referred to specimens of this species as *A. reigi*. Morphological and molecular comparisons, including the type series, showed that these samples actually belong to *A. paranaensis* (P. R. Gonçalves et al. 2007; D'Elía, Mora et al. 2008). Nevertheless, *A. paranaensis* is a member of the *cursor* species group identified by M. F. Smith and Patton (2007), and is sister to *A. mystax* in this group.

Akodon pervalens Thomas, 1925

Tarija Grass Mouse, Tarija Akodont

SYNONYMS:

Akodon sylvanus pervalens Thomas, 1925b:579; type locality "Carapari [= Caraparí], 1000 m.," Tarija, Bolivia.

?*Akodon tartareus*: Thomas, 1926c:322; part; not *Akodon tartareus* Thomas.

Akodon varius pervalens: Cabrera, 1961:449; name combination.

Akodon pervalens: Myers, 1990:19; first use of current name combination.

DESCRIPTION: Large with total body length averaging 209 mm, tail length 93 mm, ear length 19.4 mm, and hindfoot length 24.6 mm. Dorsal coloration dark grayish or brownish olive; ventrally fur with very dark bases and buffy tips; eye-ring lacking; no white spot on either chin or throat; tail unicolored dark above and below. Skull broad and heavy, with broad but smoothly rounded interorbital region with no traces of supraorbital ridges; zygomatic notches deep and broad; frontal sinuses inflated; zygomatic arches slightly expanded laterally; braincase not inflated; zygomatic plates low and broad, with straight anterior borders; incisive foramina extend posteriorly to protocone of M1; mesopterygoid fossa relatively broad, with anterior border rounded, without medial process, and straight and parallel lateral margins; parapterygoid fossae slightly narrower than mesopterygoid fossa, with convex lateral borders that diverge slightly posteriorly; auditory bullae large and globular. Upper incisors orthodont but with slight tendency toward proodonty. M1 with well-developed anteromedian flexus and mesoloph that extends nearly to lateral tooth margin; M2 also has conspicuous mesoloph and penetrating paraflexus; M3 with poorly developed paraflexus and weakly developed hypoflexus and metaflexus. The m1 with well-developed anteromedian flexid, anterolabial cingulid, and mesolophid; m2 lacks ectolophid and mesolophid; m3 S-shaped, with well-developed hypoflexid and mesoflexid. Mean condyloincisive length 28 mm, upper molar series 4.70 mm.

DISTRIBUTION: *Akodon pervalens* is known from only six localities in Chuquisaca and Tarija departments in south-central Bolivia, between 900 and 2,100 m (S. Anderson 1997). However, S. Anderson (1997) himself indicated the dubious taxonomic status of all the specimens he

referred to this species, thus the need for a comprehensive restudy. Yepes (1933) assigned specimens from northernmost Argentina to this species, but Pardiñas, D'Elía et al. (2006) concluded, based on a reexamination of voucher specimens, these did not represent *A. pervalens*. No fossils are known.

SELECTED LOCALITIES (Map 80): BOLIVIA: Chuquisaca, Tihumayu (S. Anderson 1997), Tola Orko, 40 km from Padilla (S. Anderson 1997); Tarija, Caraparí (type locality of *Akodon sylvanus pervalens* Thomas), 8 km by road N of Cuyambuyo (S. Anderson 1997), Pino [= Pinos] (S. Anderson 1997).

SUBSPECIES: *Akodon pervalens* is monotypic.

NATURAL HISTORY: Virtually nothing is known about the natural history of this species. It has been captured in humid Yungas forest, Chaco woodland, and semiarid inter-Andean valleys. It may co-occur with *A. boliviensis*, *A. fumeus*, *A. simulator*, *A. toba*, and *A. varius* (S. Anderson 1997).

REMARKS: *Akodon pervalens* was originally described as a subspecies of *A. sylvanus*, as Thomas (1925b:579) referred to his new taxon as “like *A. sylvanus* of Jujuy in all essential respects, but larger, with longer tail, and the colour inconspicuously less obscure. Skull larger, heavier throughout, with broader interorbital region, longer braincase, and slightly larger bullae.” Cabrera (1961) was the first to separate *pervalens* from *A. sylvanus*, but treated *pervalens* as a subspecies of *A. varius*. Myers (1990), how-

ever, tentatively treated *pervalens*, *sylvanus*, and *varius* as three separate species. The status of *A. pervalens* as a full species, supported by some authors (Myers 1990; S. Anderson 1997; Musser and Carleton 2005; M. M. Díaz and Barquez 2007), and the proper delineation of its distribution require further studies focused on topotypical material (see Jayat, Ortiz et al. 2007) and the reexamination of the specimens assigned to this species by S. Anderson (1997). Both Thomas (1925b) and Myers (1990) mentioned a superficial resemblance between *A. pervalens* and *A. montensis*.

Akodon philipmyersi Pardiñas, D'Elía, Cirignoli, and Suárez, 2005

Philip Myers's Grass Mouse, Jesuita Akodont

SYNONYM:

Akodon philipmyersi Pardiñas, D'Elía, Cirignoli, and Suárez, 2005:465; type locality “ARGENTINA: Province of Misiones, Department of Posadas, Estancia Santa Inés, Ruta No. 105 km 10 (27°31'32"S, 55°52'19"W, 95 m).”

DESCRIPTION: Small species distinguished by condyloincisive length <24 mm, zygomatic breadth <1.3 mm, maxillary toothrow length <4.10 mm, tail short (40% of head and body length), short rostrum (mean incisive foramen length 5.6 mm), short and wide nasals almost covering rostrum in dorsal view, zygomatic plates very narrow almost without free upper border, mesopterygoid fossa wide with median palatine process on anterior border, interorbital constriction wide (4.3–4.6 mm), and auditory bullae medium in size. Gall bladder present.

DISTRIBUTION: This species is known from only two localities in southern Misiones province, Argentina. It is not known from the fossil record.

SELECTED LOCALITIES (Map 81): ARGENTINA: Misiones, Estancia Santa Inés (type locality of *Akodon philipmyersi* Pardiñas, D'Elía, Cirignoli, and Suárez), Parada Leis (Pardiñas, D'Elía et al. 2005).

SUBSPECIES: *Akodon philipmyersi* is monotypic.

NATURAL HISTORY: *Akodon philipmyersi* is found in natural grasslands of southern Misiones Province, some of which have been converted to yerba mate (*Ilex paraguayensis*) fields. Specimens were obtained at night in a portion of a field covered by tall (2 m) grasses. Of 12 captured in March and for which reproductive data are available, four females were pregnant (with three or more embryos) and six males had scrotal testes (≥5 mm in length). The topotypical series of 13 specimens, obtained in May 2009, included nine males (five with scrotal testes) and four females (three pregnant). These data suggest that this species is reproductively active at least until the middle of the autumn. *Akodon philipmyersi* is the type host of the recently

Map 80 Selected localities for *Akodon pervalens* (●). Contour line = 2,000 m.

Map 81 Selected localities for *Akodon philipmyersi* (●).

described laelapid mite *Androlaelaps ulysespardinasi* (Lar-eschi 2011).

REMARKS: Pardiñas, D'Elía, and Cirignoli (2003) originally discovered this species in an owl pellet sample collected at the type locality, and referred to it as *Akodon* sp. 1. Specimens trapped subsequently allowed Pardiñas, D'Elía et al. (2005) to confirm that the owl pellet materials represented a previously undescribed species. Molecular and morphological analyses suggested that *A. philipmyersi* may be the sister taxon to the *A. mystax*–*A. lindberghi* complex (Pardiñas, D'Elía et al. 2005; P. R. Gonçalves et al. 2007). The karyotype has a $2n=36$, $FN=42$ (Pardiñas, D'Elía et al. 2005).

Akodon polopi Jayat, Ortiz, Salazar-Bravo, Pardiñas, and D'Elía, 2010

Polop's Grass Mouse, Polop's Akodont

SYNONYMS:

Akodon polopi Jayat, Ortiz, Salazar-Bravo, Pardiñas, and D'Elía, 2010:34; type locality "Pampa de Achala, 6 km E (by highway 34) from antenna repetidora La Posta, 2200 m (31°36'44.5"S, 64°48'48.7"W), San Alberto Department, Córdoba Province, Argentina."

Akodon viridescens Braun, Mares, Coyner, and Van Den Bussche, 2010:393; type locality "Argentina: San Luis: Coronel Pringles, 9 km N Paso del Rey, elevation 4,800 feet (1,455 m)."

DESCRIPTION: Medium-sized with total body length 150–188 mm, tail length 60–76 mm, ear length 14–16 mm, and hindfoot length (with claw) 21–25 mm. Fur dense and soft; dorsal coloration uniform buffy brown lightly spattered with black hairs; venter contrasts with dorsum with buffy or tawny tinged hairs separating them; chin with small but clearly evident white patch; tail bicolored, blackish brown above and whitish below. Claws on forefeet and hindfeet somewhat longer than in other species of *boliviensis* group. Skull heavily constructed relative to other members of group; rostrum relatively short and broad; frontal sinuses clearly inflated; zygomatic notches broad and deep; interorbital region hourglass in shape, with rounded to slightly squared borders and with posterior margins with greater tendency to be sharply squared than typical for other species; both temporal and lambdoid ridges well developed; zygomatic plates relatively broad, with anterior margin straight and vertical in most individuals; hamular process relatively robust but variable in extent; incisive foramina long, reaching posteriorly to hypoflexus of M1; mesopterygoid fossa narrow, a rounded anterior margin and slightly divergent lateral margins; parapterygoid fossae only weakly excavated, broader than mesopterygoid fossa, with generally straight lateral margins that diverge posteriorly. Mandible robust for a *boliviensis* group member, with deeper horizontal ramus and broader coronoid process; angular process ends just anterior to condyloid process; masseteric crest reaches level of anterior margin of m1 or slightly beyond. Upper incisors essentially orthodont, but somewhat proodont in many individuals. M1 with well developed procingulum and anteromedian flexus, and with both small anteroloph and mesoloph present, and, on lingual side, visible tiny enteroloph in some specimens; M2 with reduced procingulum, vestigial mesolophs, and weakly developed postero-flexus; M3 with paraflexus and metaflexus always present in young specimens, but hypoflexus present only in a few individuals. The m1 with deep anteromedian flexid and clearly defined anterolabial cingulum; young individuals bear well-developed ectostylid, and, on lingual side, young individuals show well-developed metastylid and relatively robust mesolophid; m2 with anterolabial cingulum and small ectostylid, but reduced mesolophid; m3 large and S-shaped. Axial skeleton with 13–14 thoracic ribs and with 13–14 thoracic, 8 lumbar, and 26–27 caudal vertebrae ($N=6$). Greatest skull length 24.0–28.0 mm, upper molar series 4.14–4.64 mm.

DISTRIBUTION: *Akodon polopi* is known from fewer than 10 localities in Córdoba and San Luis provinces in central Argentina. All localities are in the Central Pampean Ranges, between elevations of 1,300 to 2,250 m (Polop 1989, 1991; Priotto et al. 1996; Kufner et al. 2004; Braun

et al. 2010; Jayat et al. 2010). No fossils are known for this species.

SELECTED LOCALITIES (Map 82): ARGENTINA: Córdoba, Cerro de Oro (Priotto et al. 1996), Pampa de Achala (type locality of *Akodon polopi* Jayat, Ortiz, Salazar-Bravo, Pardiñas, and D'Elía); San Luis, 9 km N of Paso del Rey (type locality of *Akodon viridescens* Braun, Mares, Coyner, and Van Den Bussche).

SUBSPECIES: *Akodon polopi* is monotypic.

NATURAL HISTORY: This species is found in highland grasslands dominated by *Festuca* and *Stipa*, intermingled with scattered patches of woodland and rocky outcrops (Polop 1989, 1991; Braun et al. 2010; Jayat et al. 2010). None of the specimens captured by Jayat et al. (2010) at the end of the winter in 2008 (August) nor most of those collected by Braun et al. (2010) in April and May showed signs of reproductive activity. This suggests that the species is reproductively active in late spring and summer and agrees with previous studies in which the greatest number of pregnancies occurred in November and December, and in which the average embryo counts was 4.7 (range: 3 to 7; Polop 1989). Few specimens captured in fall and winter were molting (Braun et al. 2010; Jayat et al. 2010). Other sigmodontines captured with *A. polopi* and in the same habitat were *Calomys musculus*, *Oxymycterus rufus* (given as *O. paramensis* in Polop [1989]), *Oligoryzomys flavescens*, *Phyllotis xanthopygus*, and *Reithrodon auritus* (Braun et al. 2010; Jayat et al. 2010). *Akodon polopi* was the dominant cricetid at the sites where it was collected, typically making up more than 70% of all animals captured (Kufner et al. 2004; Jayat et al. 2010), although Polop (1989, 1991) recorded a smaller relative abundance (34–53%).

REMARKS: Polop (1989) originally thought that *Akodon polopi* was an undescribed species, but before it was formally described this taxon was subsequently treated in the literature as *A. boliviensis* (Polop 1991; Morando and Polop 1997), *A. alterus* (Priotto et al. 1996), or *A. spegazzinii* (D'Elía 2003a; D'Elía et al. 2003; Kufner et al. 2004; Pardiñas, D'Elía et al. 2005; P. R. Gonçalves et al. 2007; M. F. Smith and Patton 2007). Based on morphological similarities, possession of the same karyotype, its paraphyletic position relative to *A. polopi*, and the allocation of a specimen (UP AC008 from Pampa de Achala, Córdoba, Argentina) to both taxa in their original descriptions, D'Elía et al. (2011) demonstrated that *A. viridescens* (Braun et al. 2010) is a junior synonym of *A. polopi*.

The karyotype of *A. polopi* is $2n=40$, with 18 acrocentric and one small metacentric autosomal pair, a chromosomal complement similar to many other members of the *boliviensis* group. The X chromosome is a large subterminal, and the Y is a small metacentric (Polop 1989; Pinna-Senn et al. 1992; Braun et al. 2010).

Map 82 Selected localities for *Akodon polopi* (●). Contour line = 2,000 m.

Akodon reigi E. M. González, Langguth, and Oliveira, 1998

Reig's Grass Mouse, Reig's Akodont

SYNONYM:

Akodon reigi E. M. González, Langguth, and Oliveira, 1998:2; type locality "Paso Averías, Departamento de Lavalleja, Uruguay (Lat. 33°60'S; Long. 54°40'W)."

DESCRIPTION: Medium to large species, morphologically very similar to *A. paranaensis*, with commonalities between them including traits useful in distinguishing both from *A. cursor* and *A. montensis*. Externally, *A. reigi* shares with *A. paranaensis* the same overall gray olivaceous tone of dorsal pelage, bicolored tail, and grayish hairs covering dorsal surfaces of both forefeet and hindfeet. Shared cranial characters between these species include relatively narrow interorbital region (least interorbital breadth <5.1 mm), long upper molar series (>4.5 mm), and wide zygomatic plates with straight anterior border. Condylincisive length 25–27 mm; upper molar series length 4.5–4.8 mm. Differs from *A. montensis* in karyotype, with $2n=44$ rather than $2n=24-25$.

DISTRIBUTION: *Akodon reigi* occurs in central and eastern Uruguay, including the departments of Tacuarembó, Durazno, Cerro Largo, Maldonado, and Lavalleja, and in the southernmost portion of Rio Grande do Sul state, Brazil (E. M. González et al. 1998; E. M. González and Martínez Lanfranco 2010). It is not known as a fossil.

SELECTED LOCALITIES (Map 83): BRAZIL: Rio Grande do Sul, Reserva Ecológica do Taim (E. M. González

et al. 1998). URUGUAY: Durazno, Arroyo Cordobés y Río Negro (E. M. González and Martínez Lanfranco 2010); Lavalleja, Paso Averías (E. M. González et al. 1998); Maldonado, Hostería La Laguna, N de Maldonado (E. M. González and Martínez Lanfranco 2010); Río Negro, Paso de las Piedras (E. M. González et al. 1998); Tacuarembó, Tacuarembó (E. M. González and Martínez Lanfranco 2010).

SUBSPECIES: *Akodon reigi* is monotypic.

NATURAL HISTORY: In Uruguay and southern Brazil this species has been trapped in subtropical gallery forests at sites with dense litter or at the interface of forested habitats and grasslands. It is especially common in swampy areas and avoids open grassland habitats. Substantial variation in year-to-year capture rates suggests irregular fluctuations in population density (E. M. González and Martínez Lanfranco 2010). Breeding probably occurs from the spring to autumn, with autumn being when the number of juvenile dispersers greatly increases (E. M. González et al. 1998).

REMARKS: Morphological and cytogenetic evidence suggested that the populations of *Akodon* from southern Brazil, northeastern Argentina, Paraguay, and Uruguay with $2n=44$ comprised a single morphologically diagnosable unit. Some of these samples had been previously allocated to *A. cursor montensis* (e.g., Ximenez and Langguth 1970). Phylogenetic analyses of mtDNA cytochrome-*b* sequences, however, indicated moderate

levels of divergence between Brazilian and Uruguayan populations (Pardiñas, D'Elía, and Cirignoli 2003; P. R. Gonçalves et al. 2007; D'Elía, Mora et al. 2008). D'Elía, Mora et al. (2008) reported that haplotypes recovered from populations assigned to *A. paranaensis* (i.e., those from Brazil, northern Argentina, and Paraguay) and to *A. reigi* (those from Uruguay) form two reciprocally monophyletic groups, diverging on average by 5.9% genetic distance. This level of divergence indicates that these samples comprised two genetically divergent lineages of *Akodon*, despite the similarities in morphology and chromosome number. Therefore, we provisionally maintain *A. paranaensis* and *A. reigi* as distinct species, although we contend that any morphological differences between these species are unclear and should be tested by analysis of geographically intermediate populations, especially those from the southernmost part of Rio Grande do Sul state where the ranges of both species interdigitate (P. R. Gonçalves et al. 2007).

The karyotype of *A. reigi* has a $2n=44$ and $FN=44$ (E. M. González et al. 1998).

Akodon sanctipaulensis Hershkovitz, 1990
São Paulo Grass Mouse, São Paulo Akodont

SYNONYM:

Akodon sanctipaulensis Hershkovitz, 1990b:23; type locality "Primeiro Morro, São Paulo, Brazil," about 24°22'S and 47°49'W (Hershkovitz 1990b:3).

DESCRIPTION: Medium sized with markedly darker pelage than potentially co-occurring *A. cursor*, *A. montensis*, and *A. reigi*. Head and body length 73–100 mm, tail length 58–75 mm, ear length 12–16 mm, and hindfoot length (without claw) 23–24 mm. Both dorsal and lateral pelage very dark in tone owing to reduction in ochraceous bands on guard hairs and expanded melanic bands; dorsal, flank, and ventral pelage color not distinct; tail weakly bicolored and covered with short hairs that leave scales exposed; hairs with dark basal bands and white tips cover both forefeet and hindfeet, and ungual tufts long, extending beyond distal limits of claws; vibrissae short, not extending beyond pinna when laid back. Skull slender, with distinctively narrow, long, and pointed rostrum and globular braincase (greatest skull length 23.24–24.61 mm, the upper molar series length from 4.0–4.5 mm); interorbital region symmetrically biconcave and relatively broad (least interorbital breadth >40% of zygomatic breadth); nasals long, terminating posteriorly at level of lacrimals in most specimens; frontoparietal suture U-shaped and colinear with frontosquamosal suture so that frontal never contacts squamosal dorsally; zygomatic plates moderately wide with straight or slightly reclined anterior borders; anterodorsal edge of plate projected in relation to dorsal zygomatic root,

Map 83 Selected localities for *Akodon reigi* (●). Contour line = 2,000 m.

forming a moderately incised zygomatic notch; incisive foramina long, usually reaching level of protocones of M1s.

DISTRIBUTION: *Akodon sanctipaulensis* is known from only four localities on the north bank the Rio Juquiá and Rio Etá on the Atlantic coastal plain in São Paulo state, Brazil (Hershkovitz 1990b). This species has no fossil record.

SELECTED LOCALITIES (Map 84): BRAZIL: São Paulo, Iporanga (Hershkovitz 1990b), Morretinho (Hershkovitz 1990b), Primeiro Morro (type locality of *Akodon sanctipaulensis* Hershkovitz), Quadro Penteado (Hershkovitz 1990b).

SUBSPECIES: *Akodon sanctipaulensis* is monotypic.

NATURAL HISTORY: Little is known of the ecology of this species. The few localities are in the Parque Estadual Turístico do Alto Ribeira (PETAR), one of the largest remaining remnants of montane and submontane dense evergreen forest in the Atlantic Forest domain of coastal Brazil.

REMARKS: This is the least known species of *Akodon* in southeastern Brazil. Data on its karyotype are lacking, and no additional specimens have been collected at or near the type locality since A. M. Olalla obtained the original series in 1961. The series examined by Hershkovitz (1990b) is composed of young individuals and a few subadults, and most with damaged skulls, limiting any comparisons with adults of other *Akodon*. One of the specimens included in the original description (FMNH 94513) lacks an antero-medial flexus on the procingulum of M1, a condition also

found in *Akodon serrensis*. The similarity of this specimen to *A. serrensis* suggests that the original series of *A. sanctipaulensis* may actually be composite. Nevertheless, the skull of the holotype (FMNH 94516), a subadult, is different from those of *A. serrensis* and adults of *A. cursor* and *A. montensis*, especially in the rostral and interorbital regions (Christoff et al. 2000; P. R. Gonçalves et al. 2007). Because these portions of the skull are considerably influenced by age, further analysis of young and subadults of other co-occurring *Akodon* species from southeastern Brazil is warranted to reassess the status of *A. sanctipaulensis*.

Akodon serrensis Thomas, 1902

Serra do Mar Grass Mouse, Serra do Mar Akodont

SYNONYMS:

Akodon serrensis Thomas, 1902a:61; type locality "Roça Nova, situated at an altitude of about 1000 metres . . . in the Serro do Mar of the Province of Paraná, and on the railway between Paranagua and Curitiba" (Thomas 1902a:59). Roça Nova, Serra do Mar, Paraná, Brazil, 25°28'S 49°01'W (see Emmons, Leite et al. 2002:24).

A[kodon]. serrensis var. *leucogula* Miranda-Ribeiro, 1905: 188; type locality "Retiro de Ramos," Serra de Itatiaia, Rio de Janeiro, 2,200 m, Brazil.

Akodon serrensis serrensis: Gyldenstolpe, 1932a:104; name combination.

Akodon serrensis leucogula: Gyldenstolpe, 1932a:104; name combination.

DESCRIPTION: Moderately large, with total length ca. 170 mm, tail length ca. 80 mm; similar to *A. cursor* and other related *Akodon* species from southeastern Brazil (i.e., *A. montensis*, *A. paranaensis*) in size, general bauplan, and color pattern. Fur thick and woolly (Thomas 1902a:61) with hairs of back 8 to 9 mm; general color above finely grizzled olivaceous by fine mixture of blackish and yellowish hairs; under surface ochraceous and line of demarcation on flanks not sharply marked; anal area and cheeks more rich ochraceous. Ears of moderate size, dark brown; manus and pes dull brown above. Tail long, finely ringed, almost naked, covered by minute hairs brown above, dull white below. Skull strongly built, greatest length ca. 27 mm, upper toothrow ca. 5 mm, with pointed rostrum, broad interorbital region usually without sharp borders, flat profile, and unridged braincase. Incisive foramina especially broad, not extending backwards to M1 protocone and with very well-developed palatal process of premaxillary; mesopterygoid fossa also broad and mesopterygoid roof perforated by paired sphenopalatine vacuities. Molars unique among *Akodon*, with occlusal features wearing rapidly with wear, coronal surface crested, main cusps almost in opposite pattern, M1 procingulum without anteromedial flexus, M3 large, m1 procingulum narrow, and m3 subequal in length to m2.

Map 84 Selected localities of *Akodon sanctipaulensis* (●). Contour line = 2,000 m.

DISTRIBUTION: Originally thought to be restricted to the Serra do Mar of coastal Brazil, *A. serrensis* is now known across the Atlantic Forest, from Espírito Santo state in the north (ca. 20°30'S) to Rio Grande do Sul state in the south (29°45'S) (P. P. D. Oliveira and Geise 2006; Gislene Gonçalves, pers. comm. to Lena Geise), and extending into Misiones province, Argentina (J. Pereira et al. 2005). In the north, *A. serrensis* appears restricted to elevations above 1,200m, reaching 2,700m on Pico da Neblina, Caparaó. In the south, this species is found at elevations as low as 400m (Moconá area, Misiones, Argentina; U. F. J. Pardiñas, unpubl. data). Justo and De Santis (1977:47) were the first to report this species in Argentina, based on a specimen from “río San Antonio, 32 km al norte de Bernardo de Irigoyen.” Although dismissed by subsequent authors (Galliari et al. 1996; Pardiñas, D'Elía, and Cirignoli 2003; J. Pereira et al. 2005), this record likely represents an actual occurrence of this species. J. Pereira et al. (2005) documented the first corroborated record from Misiones, based on a specimen from Reserva Privada de Vida Silvestre Urugua-í, and Testoni et al. (2012) extended the species's range into Santa Catarina state, Brazil. It is likely that Quaternary fossils from Lagoa Santa, described as *Habrothrix angustidens* by Winge (1887), are of this species (see Remarks).

SELECTED LOCALITIES (Map 85): ARGENTINA: Misiones, Reserva Privada de Vida Silvestre Urugua-í (J. Pereira et al. 2005), RP 2, 6km NE of Arroyo Paraíso (CNP-E 449). BRAZIL: Espírito Santo, 4km N of Castelinho (MNRJ 32631), Parque Nacional do Caparaó (L. Geise, pers. comm.); Minas Gerais, Fazenda da Onça (UFMG 1857), Mata do Banco (MZUFV 1900), Mata do Sossego (MNRJ 35910), 13 km SE of Posses (UFMG 1855), Serra das Cabeças, Parque Estadual da Serra do Brigadeiro (MZUFV 1267); Paraná, Fazenda Panagro (P 566), Represa de Guaricana (MZUSP 29128), Roça Nova (P 888); Rio de Janeiro, Fazenda Marimbondo (HGB 457), Parque Nacional da Serra dos Órgãos, base da Pedra do Sino, Campo das Antas (MNRJ 69806), Sítio Xitaca, Debossan (MNRJ 35912); Rio Grande do Sul, São Francisco de Paula (G. Gonçalves, pers. comm. to L. Geise); Santa Catarina, Alta da Boa Vista (Testoni et al. 2012), Fazenda Gateados (Testoni et al. 2012), Reserva Biológica Estadual do Sassafrás (Testoni et al. 2012); São Paulo, Boracéia (MZUSP 9469), Fazenda Intervalos (MZUSP 27226), Parque Nacional da Bocaina (HGB [DB 15]), Serra da Fartura (L. Geise, pers. comm.).

SUBSPECIES: Miranda-Ribeiro (1905) described *A. serrensis* var. *leucogula* based on subtle color differences between a specimen obtained at Retiro de Ramos, Rio de Janeiro, and Thomas's (1902a) description of *serrensis*. Although Christoff et al. (2000:849) found no morphologi-

cal reason to treat *leucogula* as valid, there is a moderate degree of divergence in mtDNA cytochrome-*b* sequences (G. D'Elía, unpubl. data) that suggests more than one evolutionary unit in the species. It remains for future analyses to determine whether these lineages deserve recognition as subspecies, and, if so, whether *leucogula* Miranda-Ribeiro would apply to one of them.

NATURAL HISTORY: *Akodon serrensis* replaces *A. cursor* at elevations above 1,600m in the Serra do Brigadeiro, Minas Gerais state, although both species were the most abundant rodents along the gradient between 1,200 and 1,800m that spans forest and upper elevation grasslands (J. C. Moreira et al. 2009). Here, adults of both sexes were statistically monomorphic, although males averaged slightly larger than females in several cranial measures (Rodarte and Lessa 2010). Musser and Carleton (1993) stated that the wide variation in morphometry, described by Kosloski (1997) from specimens identified as *A. serrensis* from Paraná state, may have included other *Akodon* species (*A. paranaensis* or *A. reigi*) in the sample. Barros-Battesti et al. (1998) listed a wide range of ectoparasites for specimens collected at Tijucas do Sul, Paraná state, Brazil, including the mites *Androlaelaps fahrenheitsi* and *A. rotundus*, the sucking louse *Hoplopleura imparata*, the staphylinid beetle *Amblyopinus* sp., and the fleas *Craneospylla minerva*, *Polygenis pradoi*, *P. pygaerus*, *P. rimatus*, and *P. tripus*. *Akodon serrensis* shares most of its ectoparasite fauna with *A. montensis*. Specimens collected in the Serra da Bocaina (São Paulo state) and the Serra de Itataia (Rio de Janeiro) were infested with the fleas *C. minerva*, *Polygenis atopus*, *P. dentei*, *P. frustratus*, *P. pradoi*, and *P. rimatus* (Moraes et al. 2003).

REMARKS: On morphometric grounds, Christoff et al. (2000) identified karyotyped specimens with $2n=46$ as *A. s. leucogula*. These authors also clarified the karyological diversity among species of *Akodon* in southeastern Brazil and attributed the $2n=44$ diploid complement to their newly described *A. paranaensis* rather than *A. serrensis*, as previous authors had done (Liascovich and Reig 1989; Sbalqueiro 1989; see the account for *A. paranaensis*).

Robert S. Voss (pers. comm.) has concluded that the name *Habrothrix angustidens*, as applied by the fossil species from Lagoa Santa described by Winge (1887), is a senior synonym of *A. serrensis*. Therefore, after justification for this conclusion is published, *serrensis* Thomas will become a subjective junior synonym of *angustidens* Winge, and *angustidens* will become the proper name for this species.

The allocation of *A. serrensis* to the genus *Akodon* has been questioned as the result of several molecular genetic analyses, the first by D'Elía (2003a) who obtained a clade composed of *Thaptomys*+*serrensis* and well apart from *Akodon* (see also Geise et al. 2001). Additional stud-

Map 85 Selected localities for *Akodon serrensis* (●). Contour line=2,000 m.

ies using other molecular markers and somewhat different taxonomic coverage have supported this result (e.g., D'Elía et al. 2003; M. F. Smith and Patton 2007; P. R. Gonçalves 2006; P. R. Gonçalves et al. 2007). D'Elía's (2003a) phylogenetic hypothesis supported early inferences based on chromosomal data as to the distant position of *serrensis* vis-à-vis other *Akodon* species of southeastern Brazil (e.g., Geise et al. 1998; Christoff et al. 2000). More recent studies on chromosomal evolution in the Akodontini (e.g., Hass 2006; Hass et al. 2008), as well as a reevaluation of morphology (U. F. J. Pardiñas et al., unpubl. data) strongly suggest that *serrensis* Thomas represents an undescribed and monotypic akodontine genus.

Akodon siberiae Myers and Patton, 1989
Cochabamba Grass Mouse, Cochabamba Akodont

SYNONYM:

Akodon siberiae Myers and Patton, 1989a:4; type locality "28 km by road W of Comarapa, Cochabamba Dept., Bolivia, elevation 2800 m, 17°51'S, 64°40'W."

DESCRIPTION: One of largest species, with average body length 191.1 mm, tail length 89.1 mm, ear length 18.5 mm, and hindfoot length 24.1 mm. Overall color very dark, with dorsum medium to dark brown heavily lined with black; sides slightly paler but with same black streaking; venter paler, clothed with hairs basally slate gray but pale buff or tan tips; small and rather inconspicuous area of contrasting white hairs on the chin; ears clothed on anterior surfaces with agouti hairs near pinna base but mostly

black or dark brown hairs near edges; forefeet and hindfeet sparsely furred with mixture of whitish and agouti hairs. Claws rather long, slightly curved, and strongly built. Tail unicolor or slightly bicolor, appearing naked to unaided eye. Skull with long and narrow rostrum; narrow and shallow zygomatic notches; zygomatic arches flared posteriorly and midsections converging anteriorly; broad interorbital region with sides rounded anteriorly but squared, never beaded, posteriorly; conspicuously swollen frontal sinuses; and exceptionally broad and inflated braincase. Zygomatic plates narrow, with dorsal root slightly posterior to ventral root; incisive foramina long, ending at level of paracones of M1s; mesopterygoid fossa broad, with rounded anterior margin that sometimes with small median spine; parapterygoid fossae relatively broad, with slightly convex lateral margins. Upper incisors relatively delicate and nearly orthodont. Molars moderately hypsodont although not especially high crowned; M3 unusually elongate, with distinctive figure-8 shape due to penetrating mesoflexi and hypoflexi. Average condyle-incisive length 24.88 mm, upper tooththrow length 4.81 mm.

DISTRIBUTION: *Akodon siberiae* is known only from the vicinity of the type locality in the Siberia Cloud Forest of Cochabamba and western Santa Cruz departments, central Bolivia, between 1,800 and 3,100 m (Myers and Patton 1989a; S. Anderson 1997). No fossils are known.

SELECTED LOCALITIES (Map 86): BOLIVIA: Cochabamba, 4.4 km N of Tablas Monte (S. Anderson 1997), Colomi (S. Anderson 1997); Santa Cruz, 28 km by road W of Comarapa (type locality of *Akodon siberiae* Myers and Patton), 1 km N and 8 km W of Comarapa (MSB 210746).

SUBSPECIES: *Akodon siberiae* is monotypic.

NATURAL HISTORY: All records of *Akodon siberiae* are from cloud forest on the eastern Andean slopes of the Bolivian Andes (Myers and Patton 1989a; S. Anderson 1997). S. Anderson (1997) reported four females with embryos in September. This species has been recorded in sympatry with *A. boliviensis*, *A. fumeus*, *A. mimus*, *A. lutescens*, and *A. varius* (S. Anderson 1997).

REMARKS: Myers and Patton (1989a) believed that *Akodon siberiae* was related to *Akodon budini*, the type species of *Hypsomys*, because of similarities in morphology and karyotype. M. F. Smith and Patton (2007) and Jayat et al. (2010) found this relationship well supported by mtDNA cytochrome-*b* sequences, with the two species being related to other members of their *aerosus* group of *Akodon*, which also included *A. aerosus*, *A. affinis*, *A. albiventer*, *A. mollis*, *A. orophilus*, and *A. torques*. The karyotype of *A. siberiae*, $2n=38$, $FN=40$, is virtually identical to that of *A. budini* (Myers and Patton 1989a). The overall chromosome complement of *A. siberiae* consists of 16 pairs of evenly graded unarmed elements, one pair of very large

Map 86 Selected localities for *Akodon siberiae* (●). Contour line = 2,000 m.

subtelocentrics, one pair of medium-large submetacentrics, and a single pair of very small metacentrics. The morphology of the sex chromosomes is unknown because only a female has been karyotyped, but comparisons to other *Akodon* suggest that the X chromosomes of this individual are likely the medium-sized submetacentric pair (Myers and Patton 1989a).

Akodon simulator Thomas, 1916

Gray-bellied Grass Mouse, White-throated Akodont

SYNONYMS:

Akodon simulator Thomas, 1916h:335; type locality "Villa Nouges, San Pablo. Alt. 1200 m," Tucumán, Argentina.

Akodon glaucinus Thomas, 1919a:116; type locality "Chumbicha . . . about 60 kilometres due south-west of the town of Catamarca . . . 600 m," Catamarca, Argentina (Thomas 1919a:115).

Akodon tartareus Thomas, 1919g:155; type locality "Tartagal, 600 m.," Salta, Argentina (Thomas 1919g:154).

Akodon varius simulator: Thomas, 1926d:604; name combination.

Akodon varius glaucinus: Gyldenstolpe, 1932a:102; name combination.

Akodon simulator simulator: Myers, 1990:21; name combination.

Akodon simulator glaucinus: Myers, 1990:23; name combination.

Akodon simulator tartareus: Myers, 1990:25; name combination.

DESCRIPTION: Large, with average total length 192.7 mm, tail length 81.6 mm, ear length 18.8 mm, and hindfoot length (with claw) of 24.1 mm. General coloration brownish gray, suffused on back with yellowish or reddish highlights, and darker or paler depending on individuals and localities; yellowish or reddish highlights on back become more intense posteriorly so that rump more ochraceous tawny; flanks and venter grayish white or washed buffy, with change from dorsal to ventral pattern abrupt; diffuse white patch on chin, and prominent eye-ring present; tail bicolored, dorsally brown or blackish brown and ventrally whitish or buffy; dorsal surface of hindfeet covered with whitish hairs. Skull large and heavily built (greatest skull length ranges from 27.5–29.0 mm, upper molar series length from 4.7–4.8 mm); rostrum relatively short and comparatively narrow; zygomatic notches shallow; interorbital region hourglass in shape, with squared supraorbital edges along posterior half of orbit; zygomatic arches not strongly flared; zygomatic plates broad, vertically oriented, and with straight anterior margin; incisive foramina generally extend posteriorly to protocones of M1s; mesopterygoid fossa relatively broad, with anterior margin either slightly rounded or squared. Upper incisors with tendency to proodonty and molars exhibit slight hypsodonty. M1 with weakly developed anteromedian flexus and anteroloph, with small mesoloph present and partially coalesced with paracone, and poorly developed posteroflexus; M2 with remnant of anteroloph, weak mesoloph, and relatively shallow protoflexus and hypoflexus; M3 greatly reduced, with paraflexus isolated as deep pit. Anteromedian flexid and anterolabial cingulum well developed on m1, which possesses well-defined mesolophid and mesostylid, and prominent posterolophid; m2 with large hypoconid, shallow protoflexid, and tiny ectolophid; m3 with well-defined mesoflexid and hypoflexid, but protoflexid very small.

DISTRIBUTION: *Akodon simulator* is distributed along the lower Andean slopes of northwestern Argentina, in La Rioja, Catamarca, Tucumán, Salta, and Jujuy provinces, and in southern Bolivia, in Tarija department, over an elevational range of 400 to 3,000 m (Myers 1990; S. Anderson 1997; Capllonch et al. 1997; Mares, Ojeda, Braun et al. 1997; M. M. Díaz et al. 2000, Pardiñas, D'Elía et al. 2006; M. M. Díaz and Barquez 2007; Jayat, Ortiz, and Miotti 2008). This species is known from the Late Pleistocene of Catamarca province and the Late Holocene of Tucumán province (P. E. Ortiz et al. 2011a). Several specimens morphologically very similar to *A. simulator* have been collected in recent field trips to La Rioja and San Juan provinces, west-central Argentina, in unusual environments for the species. If these are determined to represent *A. simulator*, its distributional

range and ecological parameters will be significantly extended.

SELECTED LOCALITIES (Map 87): ARGENTINA: Catamarca, access to the town of Catamarca by Rte 38 (PEO-e 193), El Espinillo, Campo del Pucará, Las Estancias (PEO-e 101); Jujuy, El Simbolar, 25 km SW of Palma Sola (CML 1992), 1.5 km E of Tiraxi on Rte 29 Catamarca (CML 4898); La Rioja, Cuesta La Cébila, 1 km from Chumbicha by Rte 60 (CML 3751); Salta, Aguarray (MACN 3223), 27 km W of Aguas Blancas (MACN 17517), Arroyo Salado, 7 km E of Rosario de la Frontera, al lado del ACA (PEO-e 33), Cafayate (CML 852), El Corralito, ca. 23 km SW of Campo Quijano by Rte 51 (Jayat, Ortiz, and Miotti 2008), Embarcación (MACN 16439); Tucumán, 2 km S of Gobernador Garmendia by Rte 34 (PEO-e 72). BOLIVIA: Tarija, 1 km S of Camatindi (S. Anderson 1997), Tablada (S. Anderson 1997).

SUBSPECIES: Once treated as a subspecies of *A. varius* (Thomas 1926d; Cabrera 1961), Myers (1990) raised *A. simulator* to full species as a member of his *varius* group. He also considered *glaucinus* Thomas and *tartareus* Thomas to be subspecies of *A. simulator*; these latter two are regarded herein as species.

NATURAL HISTORY: *Akodon simulator* occupies the ecotone of Chaco and Yungas forests and all elevational belts of the Yungas, including highland grasslands (Pardiñas, D'Elía et al. 2006; Jayat, Ortiz, and Miotti 2008). In these areas, it has been recorded in forests, secondary growth, grasslands, cutover areas, and along rivers and streams. Few data are available on its reproductive biology or other population attributes. M. M. Díaz and Barquez (2007) reported females in Jujuy province with closed vaginas in January, May, June, and July, and females with open vaginas and/or lactating in May. They recorded males with scrotal testes in January and May, and with abdominal testes in May, June, and July. In Catamarca province, Mares, Ojeda, Braun et al. (1997) noted reproductively inactive males and females in July, and males with large scrotal testes and females with open vaginas in February and December. Embryo counts ranged from five to eight. These authors also recorded molting individuals during July and December. S. Anderson (1997) reported two females with no embryos in August. *Akodon simulator* is nocturnal and common throughout its range (Jayat, Ortiz, and Miotti 2009; Jayat and Ortiz 2010). Many sigmodontine species, such as *Akodon caenosus*, *A. spegazzinii*, *Oligoryzomys* cf. *O. flavescens*, *Calomys musculinus*, and *Andinomys edax*, share much of its range (S. Anderson 1997; M. M. Díaz et al. 2000; Barquez, Díaz, and Ojeda 2006; Jayat, Ortiz, and Miotti 2008, 2009; Jayat et al. 2010; Jayat and Ortiz 2010). In highland grasslands, this species has been trapped along with *A. boliviensis*, *Grao-*

mys edithae, *Necromys lactens*, *N. lasiurus*, *Phyllotis osilae*, *P. xanthopygus*, and *Reithrodon auritus* (Dalby and Mares 1974; Mares, Ojeda, Braun et al. 1997; M. M. Díaz et al. 2000; P. E. Ortiz, Cirignoli et al. 2000; Jayat, Ortiz, and Miotti 2008). It has been reported as a reservoir of hantavirus in Jujuy and Salta provinces (Pini et al. 2003; Puerta et al. 2006).

REMARKS: Braun et al. (2008) recovered, based on mtDNA sequences, a monophyletic *Akodon varius* group, placed *A. simulator* (plus *A. varius*) in a Yungas forest clade, and recommended recognizing *glaucinus*, *simulator*, and *tartareus* as full species. However, in more recent and broader taxonomic studies, the *A. varius* species group (*sensu* Myers 1990) was not recovered as a monophyletic unit in any analysis (Jayat et al. 2010). The primarily Yungas species, *A. simulator* and *A. varius*, formed a clade only distantly related to the one containing the mostly lowland species *A. dayi*, *A. dolores*, *A. iniscatus*, *A. molinae*, and *A. toba*. In this analysis, the Yungas clade formed part of a larger central Andean clade also composed of the *A. aerosus* species group plus *A. albiventer*.

Barquez et al. (1980) reported the karyotype of *A. simulator* (as *A. varius*), based on specimens from Catamarca and Tucumán provinces. This karyotype has $2n=42-41$ and $FN=42$, with polymorphism in the largest autosomes and X chromosome; the Y chromosome is a small submetacentric or subtelocentric. Liascovich et al. (1990) recorded eight different karyomorphs, with diploid numbers 38, 39, 40, 41, and 42, but a constant $FN=42$ for specimens from Tucumán province.

Map 87 Selected localities for *Akodon simulator* (●). Contour line = 2,000 m.

Akodon spegazzinii Thomas, 1897

Spegazzini's Grass Mouse, Spegazzini's Akodont

SYNONYMS:

Akodon spegazzinii Thomas, 1897d:216; type locality "Lower Cachi," Salta, Argentina; it is likely that Thomas referred to the lower course of the Río Cachi, which passes through the town of Cachi (25°07'11.93"S, 66°09'47.00"W, 2,341 m, Salta province), close to the junction with the Río Calchaquí (see Jayat et al. 2010).

Akodon tucumanensis J. A. Allen, 1901c:410; type locality "Tucuman, Argentina, alt. 450 m.," San Miguel de Tucumán, Tucumán, Argentina; the type was collected by L. Dinelli (misspelled as Dionelli in J. A. Allen, 1901c), a famous naturalist who worked in northwestern Argentina.

Akodon alterus Thomas, 1919d:496; type locality "Otro Cerro," Catamarca, Argentina (= Otro Cerro, 28°45'S, 66°17'W, 2,023 m, Capayán, Catamarca, about 4 km SSE of Cerro Catalán; Pardiñas et al. 2007).

Akodon leucolimnaeus Cabrera, 1926:320; type locality "Laguna Blanca, Catamarca (3,100 m de altura)," Argentina.

Bolomys (?) *leucolimnaeus*: Gyldenstolpe, 1932a:119; name combination.

Akodon [(*Bolomys*)] *leucolimnaeus*: Ellerman, 1941:415; name combination.

Akodon boliviensis spegazzinii: Cabrera, 1961:441; name combination.

Akodon boliviensis tucumanensis: Cabrera, 1961:441; name combination.

Akodon lactens leucolimnaeus: Cabrera, 1961:454; name combination.

Akodon minoprioi J. R. Contreras and Rosi, 1981; *nomen nudum*.

[*Akodon*] *spegazzinii spegazzinii*: Myers, Patton, and Smith, 1990:62; name combination.

[*Akodon*] *spegazzinii tucumanensis*: Myers, Patton, and Smith, 1990:62; name combination.

Akodon oenos Braun, Mares, and Ojeda, 2000:218; type locality "Argentina: Mendoza Province: Departamento La Valle, La Pega (32°48'S, 68°40'W)," an old winery NE Ciudad de Mendoza.

DESCRIPTION: Medium sized with total length 93–196 mm, tail length 46–83 mm, ear length 12–21 mm, and hindfoot length (with claw) 18–25 mm. Overall coloration markedly variable among both individuals and populations, ranging from ochraceous brown to ruddy brown, fulvous brown, or buffy brown, all in darker or paler tones; dorsal coloration uniform from head to rump with base color interrupted by scattered black or dark brown hairs; yellow eye-ring always present but may be variable in expression; ventral color ranges from buffy to ruddy gray or ochraceous gray, contrasting only slightly with dorsum;

few isolated white hairs rather than conspicuous patch of white present on chin; tail conspicuously bicolored, dorsally brown or blackish brown and ventrally whitish or buffy. Skulls with stout rostrum; zygomatic notches relatively narrow; frontal sinuses lightly swollen; interorbital region hourglass in shape, with rounded or slightly squared margins but without overhanging borders; breadth of zygomatic plates highly variable, with anterior margin straight to slightly concave; incisive foramina generally extend to anterior border of hypocones of M1s; mesopterygoid fossa intermediate in breadth relative to other members of *boliviensis* group, with anterior margin slightly rounded or squared and with straight to slightly divergent lateral borders; parapterygoid fossae similar in breadth or slightly broader than mesopterygoid fossa, relatively shallow, and with straight or slightly convex lateral margins diverging posteriorly. Mandibular ramus delicate; anterior end of masseteric crest situated just behind level of anterior border of m1; delicate coronoid process delicate extends just above the condyle; condyle extends behind posterior margin of angular process. Upper incisors orthodont. M1 with well-developed anteromedian flexus, conspicuous anteroloph, short mesoloph, small enteroloph, and weakly developed posteroflexus; M2 with remnant of anteroloph, relatively well-developed paraflexus, weak mesoloph, and very shallow protoflexus and posteroflexus; M3 with paraflexus and metaflexus clearly visible in most specimens, although tooth lacks figure-8 shape because hypoflexus is vestigial; m1 with well-developed anteromedian flexid and anterolabial cingulum, tiny ectostylid, and vestigial mesolophid; m2 with very shallow protoflexid and tiny ectolophid; m3 retains remnant of protoflexid, mesoflexid, and transverse and conspicuous hypoflexid, giving this tooth an S-shape. Vertebral column with 13–14 thoracic ribs, 7–8 lumbar, and 23–26 caudal vertebrae (N=19). Greatest skull length 22.24–27.00 mm, upper molar series 3.80–4.60 mm.

DISTRIBUTION: *Akodon spegazzinii* is distributed along the eastern slopes of the Andes in northwestern and central Argentina, with reliable records from the provinces of Salta, Tucumán, Catamarca, and Mendoza, and at elevations from 400 to 3,500 m (Jayat et al. 2010, 2011; Pardiñas, Teta, D'Elía, and Diaz 2011). Records from La Rioja province (Thomas 1920g; cited as *A. alterus*) need confirmation; we have not seen these specimens. The fossil record for *A. spegazzinii* is from two sites in the Tafí valley, Tucumán province, of both Middle-Upper Pleistocene (P. E. Ortiz and Pardiñas 2001) and Lower Holocene ages (P. E. Ortiz and Jayat 2007a), and from additional Upper Pleistocene and Upper Holocene localities in Catamarca and Tucumán provinces (P. E. Ortiz 2001; P. E. Ortiz et al. 2011a,b).

SELECTED LOCALITIES (Map 88): ARGENTINA: Catamarca, El Bolsón (JPJ 2058), ca. 2 km SE of Huaico

Hondo, on Rte 42, E of Portezuelo (MACN 23430), Laguna Blanca (type locality of *Akodon leucolimnaeus* Cabrera), Loma Atravesada, ca. 3 km NW of Leandro Vega ranch, NW of Chumbicha (JPJ 1158); La Rioja, Cueva de Díaz, Sierra de Famatina (MACN 24040); Mendoza, Laguna Llanquanelo (Pardiñas, Teta, D'Elía, and Diaz 2011), Villavicencio, 2 km S of Rte 32 (Braun et al. 2000); Salta, Arroyo Salado, 7 km E of Rosario de la Frontera, on the side of ACA (PEO-e 34), ca. 2 km NNE of Cachi Adentro, on the road to Las Pailas (MACN 23495), Campo Quijano, ca. 5 km NW, Km 30 on RN 51, Quebrada del Toro (JPJ 139), Santa Rosa de Tastil (MACN 15643); Tucumán, La Tranquera, northern border Los Chorrillos farm, on highway 205 (JPJ 1773), San Miguel de Tucumán (type locality of *Akodon tucumanensis* J. A. Allen).

SUBSPECIES: Cabrera (1961) treated *A. spegazzinii* and *A. tucumanensis* as subspecies of *A. boliviensis* and *A. alterus* as a synonym of *A. boliviensis tucumanensis*. Myers et al. (1990) excluded *A. spegazzinii* and *A. tucumanensis* from the synonymy of *A. boliviensis*. These authors viewed *spegazzinii* as a valid species, listed *tucumanensis* as a subspecies of *spegazzinii*, and regarded *alterus* as “properly allied” to *spegazzinii*. Blaustein et al. (1992) studied *alterus* and *tucumanensis* and found minor qualitative and morphometric differences and identical cytogenetic characteristics. The sample of *A. spegazzinii* from southern Mendoza (representing *oenos* Braun, Mares, and Ojeda) was both the most geographically and genetically distant of those studied by Jayat et al. (2010). Whether this represents a simple isolation-by-distance pattern or reflects a step cline that might support the trinomial status of *oenos* needs further testing.

NATURAL HISTORY: *Akodon spegazzinii* occupies varied habitats, from the ecotone between Chacoan and Yungas forests to semiarid Monte, pre-Puna, Puna, and high Andean environments. In more xeric areas, this species occurs only in grassy microhabitats usually along watercourses (Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). There are few published observations on reproduction and molting for this species, but Mares et al. (1997) recorded pregnant and lactating females in December and February in the Monte Desert of central Catamarca province. The number of embryos ranged from five to eight. All males caught in these months had large scrotal testes, and two were molting. Jayat et al. (2010) stated that reproduction appears to occur throughout the year, although with a clear peak between November and April in Yungas environments. In this environment, most of these mice were molting in fall and winter (April to August). In northern Mendoza province, *A. spegazzinii* occupies low-elevation halophytic desert scrub at the base of the Andean and pre-Andean ranges. Males with abdominal or subscrotal testes

and females with closed vaginas were caught in August and September: males with scrotal testes in February, October, and December, and pregnant females (embryo range: 3–5) in October and December. Population density at La Pega (the type locality of *oenos* Braun, Mares, and Ojeda) was estimated as 21 animals/ha, with a biomass of 461 g/ha, although only eight individuals were captured (J. R. Contreras and Rosi 1981). The home range of a single individual was calculated to be less than 300 m². *Akodon spegazzinii* is a common species throughout its distribution. It is chiefly nocturnal although it can be caught during the day (Mares, Ojeda, Braun et al. 1997). At localities above 3,000 m in Puna and high Andean habitats, *A. spegazzinii* is sympatric with *Calomys lepidus*, *Eligmodontia* sp., *Graomys edithae*, *Neotomys ebriosus*, *Phyllotis xanthopygus*, and *Reithrodon auritus* (Dalby and Mares 1974; P. E. Ortiz, Cirignoli et al. 2000; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). In grasslands, it was caught with *Necromys lactens*, *N. lasiurus*, and *Phyllotis osilae*. In forested areas of the Yungas, *A. spegazzinii* coexists with *Abrothrix illutea*, *Oligoryzomys* sp., *Oxymycterus paramensis*, *O. wayku*, and *Phyllotis anitae* (M. M. Díaz et al. 2000; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). In the ecotone between Yungas and Chaco, *A. spegazzinii* was caught with *Calomys fecundus*, *Calomys musculinus*, *Graomys chacoensis*, *Holochilus chacarius*, and *Necromys* sp. Other species broadly distributed in the region, such as *Akodon caenosus*, *A. simulator*, *Oligoryzomys* cf. *flavescens*, *C. musculinus*, and *Andinomys edax*, have also been found in sympatry with *A. spegazzinii*. In addition, in Monte Desert environments *Akodon albiventer*, *A. dolores*, *Andalgalomys olrogi*, *Eligmodontia bolsonensis*, *E. moreni*, *Graomys griseoflavus*, and *Phyllotis xanthopygus* all co-occur with *A. spegazzinii* (Mares, Ojeda, Braun et al. 1997; M. M. Díaz et al. 2000; P. E. Ortiz, Cirignoli et al. 2000; Pardiñas, Teta, D'Elía, and Diaz 2011).

REMARKS: Until recently, treatments of the nominal forms *spegazzinii* Thomas, *tucumanensis* J. A. Allen, *alterus* Thomas, and *leucolimnaeus* Cabrera has been variable, with each hypothesis lacking a defensible basis (e.g., M. M. Díaz et al. 2000; Musser and Carleton 2005; Pardiñas, D'Elía et al. 2006; M. M. Díaz and Barquez 2007). *Akodon leucolimnaeus*, considered a synonym of *Necromys lactens* for many decades (e.g., Cabrera 1961; Reig 1987; Musser and Carleton 1993), was recently placed in the *boliviensis* group of *Akodon* (Galliari et al. 1996) and treated as full species (Musser and Carleton 2005; Pardiñas, D'Elía et al. 2006) in *Akodon*. Following a comprehensive study of thousands of specimens of *Akodon* trapped from Jujuy to Catamarca provinces, Jayat (2009) produced the first detailed analysis of the *boliviensis* group of *Akodon* in Argentina. He included in *A. spegazzinii* other putative species whose taxonomic status had been debated, including

alterus, *leucolimnaeus*, and *tucumanensis* (see Myers et al. 1990:60–62). Jayat (2009; see also Blaustein et al. 1992) documented that *A. spegazzinii* is a medium-sized species that exhibits substantial phenotypic variation, especially in pelage color, which ranges from darker in lowland populations (previously referred to *tucumanensis*) to brownish and reddish in medium- to high-elevation populations (e.g., *alterus* and *leucolimnaeus*). Subsequently, Jayat et al. (2010) corroborated this morphologically based hypothesis with an expanded morphometric and molecular sequence analyses based on extensive samples, which included both topotypes and samples representing of all nominal forms. They concluded that there were two pairs of nominal taxa, *A. spegazzinii* + *A. alterus* and *A. tucumanensis* + *A. leucolimnaeus*, with each pair consisting of taxa that were indistinguishable between from each other. However, there were significant differences in several measurements between pairs. These authors also demonstrated that specimens from type localities (Cachi, Laguna Blanca, vicinity of Otro Cerro, and Yungas forest in Tucumán) exhibited no clear or consistent morphological differences from each other. Furthermore, topotypes of the nominal taxon (*spegazzinii*, *tucumanensis*, *alterus*, and *leucolimnaeus*) all formed part of a single monophyletic assemblage of haplotypes. Pardiñas, Teta, D'Elía, and Diaz (2011) extended these analyses to include specimens representing *oenos* Braun, Mares and Ojeda, documenting that this taxon was part of the same morphological and molecular assemblage. This combination of a broad array of studied morphological characters and molecular analyses lends strong support to the hypothesis that *tucumanensis* J. A. Allen, *alterus* Thomas, *leucolimnaeus* Cabrera, and *oenos* Braun, Mares and Ojeda are best considered junior synonyms of *A. spegazzinii* Thomas.

The taxonomic status of *A. spegazzinii* with respect to *A. boliviensis*, however, remains a debatable issue. Based on a small series of specimens, Myers et al. (1990) proposed that *spegazzinii* was a valid species, and much of the data available to date support this hypothesis. For example, these two allopatric taxa are reciprocally monophyletic with respect to mtDNA sequences, and each is clearly identifiable in morphometric multivariate space and by qualitative morphological traits (Jayat et al. 2010). The two taxa also have largely different habitat preferences and distinctly different karyotypes, including heteromorphism in the largest autosomal pair and the X chromosome in *A. spegazzinii* (A. L. Gardner and Patton 1976; Barquez et al. 1980; Myers et al. 1990).

Barquez et al. (1980; as *A. boliviensis*) described the karyotype of *A. spegazzinii* based on 10 specimens from Catamarca, Salta, and Tucumán provinces, with $2n=40$, $FN=40-41$, and an autosomal complement consisting of

Map 88 Selected localities for *Akodon spegazzinii* (●). Contour line = 2,000 m.

one pair of large and heteromorphic chromosomes (acrocentric or subtelocentric), 17 pairs of acrocentrics that grade in size from medium to small, and a single pair of very small metacentrics. The X chromosome is large and may be subtelocentric or acrocentric; the Y is a small submetacentric. Karyotypes of samples allocated to *A. varius neocenus* (N. O. Bianchi et al. 1971) or *A. varius* (N. O. Bianchi and Merani 1984) are of *A. spegazzinii*, as were some of those grouped as *A. neocenus* in the analysis of allozyme variation (Apfelbaum and Reig 1989).

Akodon subfuscus Osgood, 1944

Puno Grass Mouse, Puno Akodont

SYNONYMS:

Akodon boliviensis subfuscus Osgood, 1944:195; type locality “Limbari, Puno, Inambari drainage, Peru. Altitude about 9,000 feet.”

A[kodon]. subfuscus: Myers and Patton, 1989a:28; first use of current name combination.

Akodon subfuscus subfuscus: Myers, Patton, and Smith, 1990:80; name combination.

Akodon subfuscus arequipae Myers, Patton, and Smith, 1990:86; type locality “15 km S Callalli, Depto. Arequipa, Peru, elevation 4150 m.”

DESCRIPTION: Small, with mean total length 159.6 mm, tail length 68.2 mm, hindfoot length 20.6 mm, and ear length 13.8 mm. Dorsal coloration uniform from head to rump, olivaceous to grayish brown and heavily lined with black; faint buffy or yellowish eye-ring pres-

ent; venter clearer than dorsum, with tip of hairs dark buff to whitish; most specimens with small patch of all-white hairs on chin; tail sharply bicolored and moderately furry, with middorsal stripe. Skull with weakly flared zygomatic arches; narrow, shallow zygomatic notches; interorbital region with sides usually rounded or squared posteriorly; weakly developed temporal and mastoid ridges; narrow zygomatic plates; slender tympanic hook; and narrow to moderately open mesopterygoid fossa with clearly squared anterior margin typically bearing median spine. M1 with well-developed parastyle and mesostyle, and metalophule usually present but tiny; M2 with anterior cingulum and conspicuous mesostyle; M3 small and usually oval in outline. Both m1 and m2 with ectostylid usually present, and anterior cingulid generally present on m3.

DISTRIBUTION: *Akodon subfuscus* is widely distributed in the high-elevation Puna grasslands of southern Peru, from the western Andean slopes in Ayacucho and Arequipa departments, through the highlands of Apurimac and Cusco departments and the eastern Andean slopes in Cusco and Puno departments, and then south to at least Cochabamba department in Bolivia. Most records for this species are from elevations above 2,500 m, but the species may occur at elevations as low as 1,900 m (Myers and Patton 1989a; Myers et al. 1990; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; R. Vargas 2005; Solari 2007; Tarifa et al. 2007). Fossils of this species are unknown.

SELECTED LOCALITIES (Map 89): **BOLIVIA:** Cochabamba, Cocapata (Tarifa et al. 2007), Cuesta Cucho (S. Anderson 1997); La Paz, Alaska Mine (Myers et al. 1990), Ayane [= Yani] (S. Anderson 1997), Pelechuco (S. Anderson 1997). **PERU:** Apurimac, 36 km S (by road) of Chalhuanca (Myers et al. 1990); Arequipa, 28 km NE (by road) of Arequipa (MVZ 136253), 15 km S of Callalli (type locality of *Akodon subfuscus arequipae* Myers, Patton, and Smith), Salinas, 22 mi E of Arequipa (MVZ 116074), 2 km W of Sumbay (MVZ 174078); Ayacucho, 2 mi SE of Huanta (MVZ 141321), 32 km NE (by road) of Pampamarca (MVZ 174248), 10 mi WNW of Puquio (Myers et al. 1990), San Miguel Tambo (Myers et al. 1990); Cusco, 55.4 km N (by road) of Calca (MVZ 166720), 5 km N of Huancarani (MVZ 172369), 32 km NE (by road) of Paucartambo, km 112 (MVZ 151572), 90 km SE (by road) of Quillabamba (MVZ 166721), 16 km SW of Yauri (MVZ 174222); Puno, Limbani (type locality of *Akodon boliviensis subfuscus* Osgood), 6.5 km SW of Ollachea (MVZ 172984).

SUBSPECIES: In their review of the *boliviensis* group, Myers et al. (1990) recognized two subspecies, one of which they described as new: *A. s. subfuscus*, characterized by larger size, darker pelage, a broader mesopterygoid fossa, and a distribution largely across the northern Altiplano and

eastern Andean slopes; and *A. s. arequipae*, a smaller and paler taxon predominantly limited to the western side of the Altiplano and upper slopes of the western Andes. The difference in size is most noticeable in adult animals, for which several craniodontal measurements are 5–10% larger in *subfuscus* than in *arequipae*. There are several dental differences, including an absent or tiny mesostylid on m1 in *arequipae* versus an unusually large mesostylid in *subfuscus*. Data from 26 allozyme loci, however, failed to separate populations assigned to the two subspecies by the morphological criteria of their respective diagnoses.

NATURAL HISTORY: In Peru, *A. subfuscus* inhabits bunchgrass at high Andean elevations, where it is easily trapped in grass clumps mixed with shrubs and in areas of grass and large rocks. It is also common along the base of stone walls bordering agricultural plots (Myers et al. 1990; Solari 2007). In Bolivia, this species occurs in fragmented *Polylepis* woodlands between 3,200 and 3,800 m elevation in Puna and Yungas environments, and treeless grassland Puna created by repeated human-caused fires (Salazar-Bravo, Yensen et al. 2002; R. Vargas 2005; Tarifa et al. 2007). Solari (2007) recorded high proportions of arthropods (adults and larvae) in stomach contents (with a mean of 59.3%), and which showed little variation seasonally or between the sexes in southern Peru. Plant material was also important in the diet of this species, comprising 26% of the total volume analyzed. Solari (2007) stated that *A. subfuscus* exhibited only a slight specialization for insectivory, with a niche breadth (following the Levins metric) of 4.53, which overlapped extensively (0.98) with that of the sympatric but typically habitat-segregated *A. torques*. *Akodon subfuscus* occurs, or is contiguously allopatric, with several other *Akodon* in high areas of Peru and Bolivia, including *A. aerosus*, *A. boliviensis*, *A. fumeus*, *A. juninensis*, *A. kofordi*, *A. lutescens*, *A. torques*, and *A. varius* (Myers et al. 1990; Patton and Smith 1992b; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; R. Vargas 2005; Solari 2007; Tarifa et al. 2007).

REMARKS: Although it was originally described as a subspecies of *A. boliviensis*, Myers et al. (1990) raised *A. subfuscus* to specific level based on substantive craniometric, soft anatomical (including male phallus and palatal rugae), and allozyme differences. They included *A. subfuscus* in their *boliviensis* group, a hypothesis since corroborated by phylogenetic analyses of mtDNA cytochrome-*b* sequences (M. F. Smith and Patton 1993, 2007; Jayat et al. 2010).

The karyotype has $2n=40$, FN=40. The autosomal complement is identical to that described for *A. boliviensis* and *A. lutescens*. The X chromosome is a medium-sized subtelocentric, as in *A. lutescens*, but the Y is a very small acrocentric (Myers et al. 1990).

Map 89 Selected localities for *Akodon subfuscus* (●). Contour line=2,000m.

Akodon surdus Thomas, 1917

Silent Grass Mouse, Slate-bellied Akodont

SYNONYM:

Akodon surdus Thomas, 1917g:2; type locality “Huadquiña, 5,000 feet”; Hacienda Huadquiña is on the southern margin of the Río Urubamba, Santa Teresa, La Convención, Cusco, Peru (ca. 13.13°S, 72.59°N; see route map of the Peruvian expedition in Bingham 1916).

DESCRIPTION: A dark-colored species resembling *A. mollis*; comparatively large, with head and body length 110mm, tail length 80mm; stout and heavily built; fur rather coarse; dorsum dark olivaceous gray dorsal and venter soiled grayish, but only vaguely separable; medium length ears; forefeet and hindfeet grayish brown above but blackish on soles; tail fairly long, finely haired, and essentially unicolorous but only slightly paler below. Skull robust (greatest length 28mm, upper molar series 4.9mm), with domed profile; interorbital region broad with squared edges; zygomatic plates broad, project forward from bottom to top, with straight anterior border; incisive foramina widely open; auditory bullae moderately sized. Myers (1990) distinguished *surdus* by its short, crisp, dark fur, relatively flat cranial profile, generally rounded interorbital region, small interparietal, and very shallow but moderately broad zygomatic notches.

DISTRIBUTION: This species is known only from the vicinity of Machu Picchu in the mid-elevation montane forest of the Urubamba Valley in Cusco department, Peru,

at elevations between 600 and 2,000m (Thomas 1917g, 1920h). No fossils are known for *A. surdus*.

SELECTED LOCALITIES (Map 90): PERU: Cusco, Huadquiña (type locality of *Akodon surdus* Thomas), Idma (Thomas 1920h), Machu Picchu (ZMUM 16986; Patton and Smith 1992a), Paltaybamba [= Paltaibamba] (Thomas 1920h), Santa Ana (Thomas 1920h).

SUBSPECIES: *Akodon surdus* is monotypic.

NATURAL HISTORY: Nothing is known about the ecology of this species. The few specimens available were trapped in very wet mid-montane forest on the steep slopes of the Urubamba Valley.

REMARKS: *Akodon surdus* has been treated as a species by most authors since its description (Reig 1987; Myers 1990; Hershkovitz 1990b; Musser and Carleton 2005), but Patton and Smith (1992b) suggested it *surdus* was best regarded as a local variant of *A. aerosus* confined to the Urubamba Valley. Specimens from localities to the west and south of the Urubamba Valley along the eastern flank of the southern Peruvian Andes, and in the same moist forest habitat, are uniformly treated as *A. aerosus* (see that account), and mtDNA sequences obtained from skin samples of museum specimens of *A. surdus* from Machu Picchu were placed in the same monophyletic clade as all geographic samples of *A. aerosus* from southern Peru (Patton and Smith 1992a). Samples of both *A. surdus* and *A. aerosus* in southern Peru do share the same dark color tones

Map 90 Selected localities for *Akodon surdus* (●). Contour line=2,000m.

and general cranial attributes, but careful and direct comparisons among them have yet to be made. Therefore, M. F. Smith and Patton (2007:846), in establishing the *aerosus* group of *Akodon* based on mtDNA sequences, concluded “while data are as yet unavailable, *A. surdus* . . . is likely a member of this group, either as a distinct species or perhaps conspecific with *aerosus*.”

Akodon sylvanus Thomas, 1921

Forest Grass Mouse, Woodland Akodont

SYNONYMS:

Akodon sylvanus Thomas, 1921d:184; type locality “Sierra de Santa Barbara, S.E. Jujuy. Type from Sunchal, 1200 m”; clarified by Jayat, Ortiz et al. (2007) as Sunchal (24°15'S, 64°26'W, 1,454 m), Santa Bárbara department, Jujuy province, Argentina.

Akodon sylvanus sylvanus: Gyldenstolpe, 1932a:104; name combination.

Akodon azarae sylvanus: Cabrera, 1961:441; name combination.

DESCRIPTION: Medium-sized species with body length 151–203 mm, tail length from 68–89 mm, ear length from 14–21 mm, and hindfoot length (with claw) from 22–27 mm. Dorsal color uniform along body, olivaceous brown finely streaked with black hairs, generally not contrasting with ventral color; ears same color as dorsum; eye-ring either absent or weakly developed; white spotting on chin barely developed; tail only slightly bicolored, with somewhat paler venter. Skull relatively narrow and elongated, with prominent rostrum, average zygomatic notches in breadth and depth, slightly expanded zygomatic arches, and uninflated braincase; interorbital region with rounded margins; mesopterygoid fossa relatively narrow, with rounded or squared anterior border without medial process. Upper incisors orthodont. Molars more hypsodont than other species of *boliviensis* group. M1 with well-developed anteroloph-parastyle, mesoloph may extend to buccal edge of tooth; mesoloph and paraflexus of M2 less developed than those structures on M1; M3 with poorly developed paraflexus but conspicuous hypoflexus. Proto-stylid of m1 well developed but metastylid, mesolophid, and mesostylid tiny; m2 without evidence of either ectolophid (ectostylid) or mesolophid; m3 with well-developed hypoflexid and mesoflexid. Greatest skull length 25.30–28.30 mm; upper molar series length 4.04–4.70 mm. Axial skeleton with 7 cervical, 13 thoracic, 7 lumbar, and 27–29 caudal vertebrae, and 13 ribs (N=10).

DISTRIBUTION: *Akodon sylvanus* is known from only a few localities in the Sierra de Santa Bárbara and the surrounding area, all in southeastern Jujuy province, Argentina, and between 900 and 2,400 m (M. M. Díaz and Barquez 2007; Jayat, Ortiz et al. 2007, 2008; Jayat et al. 2010). No fossils are known.

SELECTED LOCALITIES (Map 91): ARGENTINA: Jujuy, El Simbolar, 25 km SW of Palma Sola (CML 2029), Finca El Piquete, margin of Río Volcán, ca. 5 km from junction of Río Tamango and logging road (MACN 23490), La Antena, Sierra del Centinela, S of El Fuerte (MACN 23434), La Herradura, 12 km SW of El Fuerte, on Rte 6 (CNP-E 1485).

SUBSPECIES: *Akodon sylvanus* is monotypic.

NATURAL HISTORY: *Akodon sylvanus* occupies forest and high-elevation grasslands of the Yungas ecoregion as well as grasslands in the Chacoan ecoregion (M. M. Díaz and Barquez 2007; Jayat, Ortiz et al. 2007; Jayat, Ortiz, and Miotti 2008; Jayat et al. 2010). Reproductive activity begins in early spring (late August), with all individuals caught during winter (June) reproductively inactive. Almost all individuals trapped in grasslands between June and October were molting (Jayat, Ortiz et al. 2007; Jayat et al. 2010). *Akodon sylvanus* has been caught sympatrically with *A. caenosus*, *A. budini*, and *A. simulator*. It is the most common species in its restricted range, comprising 40–60% of all sigmodontines caught in the La Herradura (N=50) and Sierra del Centinela (N=46) areas (Jayat, Ortiz et al. 2007; Jayat et al. 2010).

REMARKS: Thomas (1921d) described *A. sylvanus*, based on specimens from southeastern Jujuy province, Argentina. Four years later (Thomas 1925b), he erected *A. sylvanus pervalens*, from Tarija department, Bolivia, a taxon now recognized as unrelated to *A. sylvanus* and probably allied to the *varius* group (see that account). Thomas

Map 91 Selected localities for *Akodon sylvanus* (●). Contour line = 2,000 m.

(1921d:184–185) characterized *sylvanus* as “A large species of the *arenicola* [i.e., *azarae*] group . . . this Santa Barbara *Akodon* has a curious resemblance to the *A. arenicola hunteri* of the Parana Delta, with which it agrees closely in size and colour.” Cabrera (1961) treated *sylvanus* as a valid subspecies of *A. azarae*. Myers (1990) regarded *azarae*, *sylvanus*, and *pervalens* as different species, as did Musser and Carleton (2005) and Pardiñas, D’Elía et al. (2006). Jayat, Ortiz et al. (2007) and Jayat et al. (2010), based on both molecular and morphological character analyses, validated *A. sylvanus* as a species and placed it in the *boliviensis* group. Jayat et al. (2010) reidentified, as *Akodon fumeus*, specimens wrongly referred to *A. sylvanus* by Jayat, Ortiz et al. (2007), from the Baritú area (northern Salta province) and Las Capillas (Jujuy province), and thereby redefined the distribution and morphologic characteristics of *A. sylvanus*.

Akodon toba Thomas, 1921

Toba Grass Mouse, Toba Akodont

SYNONYMS:

Akodon toba Thomas, 1921b:178; type locality “Jesemathla, Northern Chaco. Alt. 100 m.”; according to Pine and Wetzel (1976:651), “This place is apparently the same as ‘Estancia Yesamathla’ . . . 76–80 km E Juan de Salazar,” at roughly 23.07°S and 58.48°W, Presidente Hayes, Paraguay.

Akodon varius toba: Cabrera, 1961:450; name combination.

DESCRIPTION: Large with total body length 183–203.7 mm, tail length 87–85.1 mm, average hindfoot length 25.5 mm, and ear length 19–20 mm. Dorsal pelage strongly olivaceous, finely ticked with gray; eye-ring present but not clearly defined; venter frosted grayish, white, or buffy, color that contrasts strongly with dorsum; some specimens with white spot on chin less conspicuous than in most members of *varius* group; tail sharply bicolored. Skull strongly bowed in lateral view and with notably well-developed and widely expanded zygomatic arches; zygomatic notches unusually broad and deep; supraorbital and temporal ridges well developed; interorbital region with squared edges that become beaded in older individuals; zygomatic plates notably broad with slightly concave anterior margin; incisive foramina reach posteriorly to level of M1 protoflexus; both mesopterygoid and parapterygoid fossae proportionally narrow. Mandible strongly built for genus, with coronoid process clearly surpassing condyle height, which extends slightly posterior to vertical plane of angular process. Upper incisors generally opisthodont. Upper molars not particularly hypsodont but possess marked anteromedian flexus on M1, tiny mesoloph and poorly developed posteroflexus poorly developed on both M1 and M2, remnant anteroloph on M2, and well-developed paraflexus and metaflexus on

M3. Of the lower molars, m1 with well-developed anteromedian flexid and anterolabial cingulum; m2 with shallow protoflexid; and m3 proportionally large, with well-developed mesoflexid and transverse hypoflexid. Greatest skull length 28.5–29.5 mm; upper molar series length from 4.7–5.2 mm.

DISTRIBUTION: *Akodon toba* occurs primarily in Chaco environments of southeastern Bolivia, western Paraguay, southern Brazil, and northern Argentina, at elevations below 1,000 m (Massoia 1971c; Myers 1990; S. Anderson 1997; Jayat et al. 2006; Bonvicino, Oliveira, and D’Andrea 2008; Braun et al. 2008; Cáceres et al. 2008). A few records extend into the forested Yungas habitats, reaching elevations of 1,500 m (see Myers 1990; M. M. Díaz et al. 2000; M. M. Díaz and Barquez 2007). Specimens referred to *A. toba* from Yungas environments in Jujuy and Salta provinces, especially those located some distance from Chaco environments and at elevations above 700 m (such as those mentioned by Myers 1990; M. M. Díaz et al. 2000; and M. M. Díaz and Barquez 2007) should be reexamined. Jayat, Ortiz, and Miotti (2009) suggested that several of these specimens are, in fact, *A. simulator*. No fossils are known for *A. toba*.

SELECTED LOCALITIES (Map 92): ARGENTINA: Formosa, Parque Nacional Río Pilcomayo (Massoia 1971c); Jujuy, Villa Carolina, Río Lavallén (M. M. Díaz and Barquez 2007); Santiago del Estero, Bandera (Jayat et al. 2006). BOLIVIA: Chuquisaca, 2 km S and 10 km E of Tiquipa, Laguna Palmar (S. Anderson 1997); Santa Cruz, 4 km N and 1 km W of Santiago de Chiquitos (S. Anderson 1997), Tita (S. Anderson 1997); Tarija, 3 km WNW of Caraparí (S. Anderson 1997). BRAZIL: Mato Grosso, Corumbá, 7 km WSW of Urucum, São Marcus road (Myers 1990). PARAGUAY: Alto Paraguay, 50 km WNW of Fortín Madrejón, Cerro León (Myers 1990); Boquerón, Estancia Iparoma, 19 km N of Filadelfia (Myers 1990); Presidente Hayes, 8 km NE of Juan de Salazar (Braun et al. 2008), 69 km by road NW of Villa Hayes (Myers 1990).

SUBSPECIES: *Akodon toba* is monotypic.

NATURAL HISTORY: *Akodon toba* occupies several habitats in the Chacoan ecoregion, including patches of forest intermingled with palm savanna, marshland, thorn forest, semiarid scrublands, and gallery forest (Massoia 1971c; Myers 1990; Pardiñas and Teta 2005). In Paraguay, Yahnke et al. (2001) recorded a strong preference for grassland habitats, although *A. toba* was also captured in other habitats, such as croplands, forest, and thorn scrub. S. Anderson (1997) reported females with no embryos for August and October. One female with a closed vagina and one male with semiscrotal testes were caught in November in eastern Jujuy province (P. Jayat, unpubl. data). One of these specimens was molting.

Akodon toba is sympatric with many of the sigmodontines documented for dry Chaco environments (Massoia 1971c; Myers 1990; Gamarra de Fox and Martin 1996; S. Anderson 1997; Yahnke et al. 2001). In eastern Argentina, this species was found with the widely distributed *A. azarae*, and there are isolated populations in humid Chaco environments, where it coexists with species typically associated with the floodplain and gallery forests of the Río Paraguay (Pardiñas and Teta 2005).

Known ectoparasites reported for *A. toba* are the mite *Androlaelaps rotundus* and the flea *Craneopsylla minerva minerva* (Gettinger and Owen 2000; Lareschi et al. 2003). Whitaker and Abrell (1978) reported on ectoparasites for the Paraguayan specimens they referred to *A. varius* but which are most likely *A. toba*.

REMARKS: *Akodon toba* was treated as a subspecies of *A. varius* by Cabrera (1961), likely following Thomas (1921b:178–9), who noted that “[*A. toba*] skull is, on the whole, most like that of *A. simulator* [regarded by Cabrera as a subspecies of *varius*] and its allies of North Argentina west of the Chaco.” Myers (1990) treated *A. toba* as a full species, a decision supported by subsequent authors (Musser and Carleton 2005; Pardiñas, D’Elía et al. 2006). Recent mtDNA molecular-based analyses placed *A. toba* close to *A. dolores* and in a clade that also included other lowland species such as *A. dayi* and *A. iniscatus* (including *nucus*) rather than to the Yungas forest clade of which *A. varius* is a member (Braun et al. 2008; Jayat et al. 2010). Jayat et al. (2010) referred to the lowland assemblage of species as the *dolores* group. Although more limited in taxon coverage, this group

was also recovered by D’Elía’s (2003a) combined mtDNA and nucDNA analyses, although he incorrectly identified a specimen of *A. toba* as *A. varius*.

A. L. Gardner and Patton (1976) reported a karyotype of *A. toba* from Paraguayan specimens as $2n=40$ and $FN=40$, but Myers (1990) reported $2n=42$ or 43 and $FN=44$ for specimens from the central and northern Chaco of Paraguay. In the $2n=42$ complement, the first autosomal pair is heteromorphic, composed of two large metacentrics or one metacentric and one subtelocentric. The autosomes form a size-graded series of unarmed elements, with the smallest pair being very small metacentrics. The sex chromosomes are acrocentric (Myers 1990), but A. L. Gardner and Patton (1976) reported a subtelocentric X and a submetacentric Y.

Akodon torques (Thomas, 1917)

Cloud Forest Grass Mouse, Cloud Forest Akodont

SYNONYMS:

Microxus torques Thomas, 1917g:3; type locality “Matchu [sic] Picchu, 10,000 feet,” Machu Picchu (13.163°S, 72.544°W), Cusco, Peru.

[*Akodon*] *torques*: Thomas, 1927a:370; first use of current name combination.

Microxus (?) *torques*: Gyldenstolpe, 1932a:134; name combination.

Akodon orophilus torques: Cabrera, 1961:446; name combination.

DESCRIPTION: Somewhat larger than *A. mimus* (total length about 195 mm), with close, soft, and woolly fur, smoky to olivaceous gray dorsally and slightly paler ventrally. Ears short and colored like dorsum; forefeet and hindfeet grayish brown above, with soles flesh colored, not blackish; tail proportionally long (averaging about 94 mm), finely haired, and brown above. Skull slightly bowed in lateral profile; condyloincisive length averages about 24.4 mm, upper toothrow about 4.3 mm; rostrum somewhat elongated, but not to degree found in *A. mimus*; interorbital region broad, with smooth or only slightly squared edges; zygomatic plates intermediate in width, not as narrow as in *A. mimus* nor broad as in *A. aerosus*; anterior border slants posteriorly from base to top, but not to degree as *A. mimus*; incisive foramina quite open and elongated, extending to anterior one-third of M1s.

DISTRIBUTION: *Akodon torques* occurs in the upper elfin forests on the eastern slope of the Andes, from Junín, Ayacucho, and Cusco departments, Perú, at elevations between 2,000 and 3,500 m (Patton and Smith 1992b:92). This species is replaced in similar habitats by *A. orophilus* to the north and by *A. mimus* to the south. In lower elevation montane forest, it is replaced by *A. aerosus* and in the bunch grass habitats above tree line by *A. subfuscus*. No fossils are known.

Map 92 Selected localities for *Akodon toba* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 93): PERU: Ayacucho, Puncu, ca. 30km NE of Tambo (Patton and Smith 1992a); Cusco, Amacho (Patton and Smith 1992a), La Convención (USNM 582129), Lucma, Cosireni Pass, Quirapata (USNM 194679), Machu Picchu (type locality of *Microxus torques* Thomas), 1km below of Marcapata (LSUMZ 19337), 32km NE (by road) of Paucartambo, km 112 (MVZ 166758), 54km NE (by road) of Paucartambo, km 134 (MVZ 171736), 90km SE (by road) of Quillabamba (MVZ 166723), Tres Cruces, 18km N of Paucartambo (MVZ 115749); Junín, Satipo, Cordillera de Vilcabamba (USNM 582178).

SUBSPECIES: *Akodon torques* is monotypic.

NATURAL HISTORY: *Akodon torques* is syntopic with, but segregated by habitat from, *A. subfuscus*, being found commonly in the dense moss mats under canopies formed by trees or large shrubs. In the highland grasslands (“pajonal”) of Parque Nacional Manu, east of Paucartambo in the humid Puna of the Cordillera Oriental, Cusco department, Peru (3,300 to 3,800 m), *A. subfuscus* and *A. torques* represent 35% of total captures. In this same area, *A. torques* is primarily insectivorous, consuming mostly arthropod larvae (Solari 2007). In large series collected in May and July in Cusco department, most females were nulliparous, none were pregnant, but parous adults had embryo scar counts ranging from two to four. Old males collected at the same time were scrotal with enlarged accessory glands, although most males were not in reproductive condition (data from specimen labels in the MVZ collection).

REMARKS: Thomas (1917g, 1920h) placed *torques* with *Microxus* instead of *Akodon* after comparing it with the type species of his genus *M. mimus*, although he recognized that the former has “[a] less characteristically *Microxine* zygomatic plate” (Thomas 1920h:240). Ellerman (1941) maintained the validity of *Microxus* although he placed *torques*, without explanation but probably following Thomas (1927a), in *Akodon*. Later, Osgood (1943b:197) wrote that *torques* was probably a subspecies of *A. orophilus*, stating “it is difficult to find any external distinction between *torques* and *orientalis* [which, in 1913, he had described as a subspecies of *orphilus*] and the only cranial character appears to be the somewhat wider braincase of *torques*.” Cabrera (1961) followed Osgood and treated *torques* as a subspecies of *A. orophilus*. Subsequently, both allozyme (Patton et al. 1989) and mtDNA cytochrome-*b* sequences (Patton and Smith 1992a,b; M. F. Smith and Patton 1991, 1993, 2007) provided support for species status of *torques*. The most recent phylogenetic reconstructions based on cytochrome-*b* favored a close relationship between *A. torques* and both *A. orophilus* and *A. mollis* (M. F. Smith and Patton 2007). Patton et al. (1990)

Map 93 Selected localities for *Akodon torques* (●). Contour line = 2,000 m.

illustrated striking differences in rostral depth and length as well as features of the zygomatic plates in comparisons among *A. torques*, *A. mimus*, and *A. aereus*. Although *A. torques* shares more narrowed and posteriorly upward slanting zygomatic plates with *A. mimus*, but not to the degree found in the latter, it is more similar to *A. aereus* in its somewhat shorter and deeper rostrum.

Diploid numbers range from 26 in Ayacucho department (specimens called *Akodon orophilus* by Hsu and Benirschke 1973) to 22 in the Urubamba drainage or 24 in the Cosñipata drainage, both in Cusco department, Peru (Patton et al. 1990; Patton and Smith 1992b).

Akodon varius Thomas, 1902

Variable Grass Mouse, Variable Akodont

SYNONYMS:

Akodon varius Thomas, 1902b:134; type locality “Cochabamba, [Cochabamba,] 2400 m.,” Bolivia.

Akodon varius varius: Gyldenstolpe, 1932a:102; name combination.

DESCRIPTION: One of larger species, with average total length ca.193.5 mm. Dorsal pelage medium brown; individual hairs with yellow phaeomelanin band 1–3 mm long and dark tips 0.1–0.5 mm long; saturate eumelanic guard hairs abundant; combination of dark-tipped underfur and black guard hairs results in heavily streaked dorsal appearance; top of head, shoulders, middorsal region,

and rump same hue, tending gradually to paler coloration on sides; distinct pale eye-ring present; chin white or gray; throat and ventral hairs gray basally with white to buffy tips; dorsal surfaces of forefeet and hindfeet whitish. Individual rump hairs 11–13 mm long. Tail relatively long (44% of the total length), bicolored, and densely furred. Skull bowed in lateral view; interorbital region sharply squared, not beaded, weakly to moderately divergent to hourglass in shape; zygomatic arches moderately flared; nasals long; zygomatic plates proportionally narrow; incisors slightly opisthodont, less proodont than other related species (Myers 1990).

DISTRIBUTION: *Akodon varius* occurs along the eastern Andean slopes in Bolivia over a broad elevational range from 365 m (SE of Santa Cruz) to at least 3,200 m (Serranía Sama; S. Anderson 1997). No fossils are known for *A. varius*.

SELECTED LOCALITIES (Map 94): BOLIVIA: Cochabamba, Chaparé (S. Anderson 1997), 15 mi E of Tapacari (S. Anderson 1997); Potosí, Río Cachimayo (S. Anderson 1997); Santa Cruz, Cerro Colorado (S. Anderson 1997), Palmarito, Río San Julián (S. Anderson 1997); Tarija, 3 km WNW of Caraparí (S. Anderson 1997), 11.5 km N and 5.5 km E of Padcaya (S. Anderson 1997).

SUBSPECIES: *Akodon varius* is monotypic.

NATURAL HISTORY: S. Anderson (1997) provided data on 21 females, none with embryos, taken in May (1), July (14), August (4), and September (2). Ectoparasites from Paraguayan specimens identified as *A. varius* (but that are probably *A. toba*) are the mites *Androlaelaps rotundus*, *A. fahrenheitzi*, *Andalgalomacarus paraguayensis*, *Paratrombicula enciscoensis*, and *Paraguacarus callosus*, fleas of the genus *Polygenis* sp., and sucking lice of the genus *Hoplopleura* sp. (Whitaker and Abrell 1987).

REMARKS: Cabrera (1961) treated *neocenus*, *pervallens*, *simulator*, and *toba* as subspecies of *A. varius*, but Myers (1990) ranked each of these as full species and placed all in his *varius* group, which he based on morphological similarity, not on determined phyletic propinquity. Jayat et al. (2010) failed to recover as monophyletic the assemblage of species Myers (1990) placed in his *varius* group; rather, the predominantly Yungas species *A. simulator* and *A. varius* formed a clade that was not sister to one that included the lowland species *A. dayi*, *A. dolores*, *A. imiscatus* (including *nucus*), and *A. toba*. Jayat et al. (2010) termed this latter clade the *dolores* group. The Yungas clade (i.e., *A. varius* group *sensu stricto*) is also part of a larger, central Andean clade connected to both the *A. aerosus* species group and to *A. albiventer*. Braun et al. (2008), in a study focused on the systematics of the *A. varius* group, also provided a molecular-based phylogeny in which two clades (i.e., *A. varius* group *sensu stricto* and *A. dolores*

Map 94 Selected localities for *Akodon varius* (●). Contour line = 2,000 m.

group) were recovered, but the likely polyphyly of an *A. varius* species group *sensu lato* was not testable because of the design of their study.

Akodon sp. $2n = 10$

Mato Grosso Grass Mouse, Mato Grosso Akodont

SYNONYMS:

Akodon sp.: M. J. de J. Silva and Yonenaga-Yassuda, 1998:47.

Akodon sp. nov.: T. D. Lambert, Malcolm, and Zimmerman, 2005:984.

Akodon sp. n.: M. J. de J. Silva, Patton, and Yonenaga-Yassuda, 2006:469.

DESCRIPTION: Large species morphologically similar to *A. cursor* and *A. montensis*: external measurements of two adult males include total length ?/221 mm, tail length ?/90 mm, hindfoot length, with and without claw, 23/25 and 26/27 mm, respectively; and mass 52/51 g. Pelage slightly crisp and markedly agouti, brownish above and somewhat paler gray below; forefeet and hindfeet covered by yellowish hairs and claws by dense, ungual tufts. Skull strongly built (condyloincisive length 27.6/28.7 mm), with relatively broad interorbital region (5.0/5.2 mm) and short rostrum; anterior edges of zygomatic plates straight; incisive foramina long and widely open; mesopterygoid fossa U-shaped; maxillary toothrow long (4.57/4.72 mm); alisphenoid strut variably present.

DISTRIBUTION: This species is restricted to central Brazil, with known localities in Mato Grosso (M. J. de J.

Silva and Yonenaga-Yassuda 1998) and Pará states (T. D. Lambert et al. 2005). Specimens reported by Pine et al. (1970) as *Akodon* sp. from Serra do Roncador may belong to this form. No fossils are known for this species.

SELECTED LOCALITIES (Map 95): BRAZIL: Mato Grosso, Vila Rica (M. J. de J. Silva and Yonenaga-Yassuda 1998), Gaúcha do Norte (M. J. de J. Silva and Yonenaga-Yassuda 1998); Pará, Programa de Assentamento Benfica I, Itupiranga (MNRJ 69785), Pinkaiti Research Station, Kayapó Indigenous Area (T. D. Lambert et al. 2005).

SUBSPECIES: Species presumably monotypic.

NATURAL HISTORY: This species apparently occurs in a transitional and highly seasonal area between the Amazon rain forest and the Cerrado dry forest (M. J. de J. Silva and Yonenaga-Yassuda 1998). T. D. Lambert et al. (2005) noted the abundance of this *Akodon* in the Kayapó Indigenous Area, where the forest structure, despite the lack of human disturbance, is very heterogeneous, with numerous open areas and dense understory. They trapped *Akodon* sp. exclusively on the ground; it was the third most common of 12 sigmodontines, after *Euryoryzomys emmonsae* and *Hylaeamys megacephalus*.

REMARKS: First detected by a unique karyotype with the lowest diploid number known to date for a sigmodontine rodent (M. J. de J. Silva and Yonenaga-Yassuda 1998), this species remains undescribed. The diploid number is 10

in most individuals, although one female was found with $2n=9$ and a presumptive XO sex chromosome system. In samples from Mato Grosso, individuals may be homozygous for a biarmed or uniarmed autosomal pair, with heterozygotes identified (M. J. de J. Silva 1999). GTG-banded metaphase comparisons between *Akodon* sp. ($2n=10$) and *A. cursor* ($2n=16$) indicated that the karyotypic differentiation between these species involved several complex chromosomal rearrangements, including tandem fusions, Robertsonian rearrangement, and pericentric inversions (M. J. de J. Silva 1999). Phylogenetic analyses of the mtDNA cytochrome-*b* gene (M. J. de J. Silva et al. 2006) also supported species status for this $2n=10$ *Akodon*. Animals from Gaúcha do Norte and Vila Rica shared almost identical haplotypes and were grouped into a strongly supported monophyletic group recovered as the sister to *A. cursor* cytomorphs with $2n=14$, 15, and 16. Fagundes and Nogueira (2007) confirmed the absence of shared species-specific haplotypes among *A. sp.* $2n=10$, *A. cursor*, and *A. montensis* using polymerase chain reaction restriction fragment length polymorphism analysis of the mtDNA cytochrome-*b* gene.

Genus *Bibimys* Massoia, 1979

Ulyses F. J. Pardiñas, Guillermo D'Elía, and Pablo Teta

Dramatic pink and enlarged upper lips make representatives of this genus among the most easily distinguishable small sigmodontine rodents in the field; unfortunately, this trait is poorly preserved in museum specimens. *Bibimys* is known from isolated localities in tropical and subtropical eastern South American lowlands, where it inhabits grasslands close to forested areas in Argentina, Brazil, and Paraguay. Winge (1887), Massoia (1979b), Pardiñas (1996), P. R. Gonçalves, Oliveira et al. (2005), and D'Elía et al. (2005) have been the major contributors to our knowledge of this genus. The information provided here is largely based on the conclusions reached by D'Elía et al. (2005), supplemented by our unpublished data obtained from recently trapped specimens.

Bibimys is a small sigmodontine (head and body length <130 mm; tail <80 mm) with soft and dense pelage. The anterior part of the snout, from just below the nostrils to the opening of the mouth, is strikingly swollen, making it bulbous. The entire area from just dorsal to the rhinarium to the lower lips is covered with remarkably short, bristle-like, all-white hairs that extend stiffly and straight outward from the lips; the skin underlying these hairs is distinctively reddish in living/fresh specimens, although this color becomes lost in both skins and fluid-preserved specimens. Mystacial vibrissae are 2.0 to 2.5 cm long, dark

Map 95 Selected localities for *Akodon* sp. $2n=10$ (●).

brown proximally, and whitish distally. Hairs in the submental region are longer than those on the swollen muzzle, less dense, and entirely white, as opposed to the remaining ventral hairs, which are a dark slate at their base. The ears are small and rounded and finely haired, and the tail is bi-colored. The forefeet are dorsally covered with hair, either proximally gray and distally whitish or entirely whitish. There is a greatly reduced claw-bearing pollex, and there are five palmar pads, including three reduced interdigital and two larger metacarpal pads. There are no carpal vibrissae. The hindfeet are skin colored, with unguis tufts mainly whitish but with some dark brown hairs with white tips, the longest extending beyond the tips of the claws. The hindfoot claws are long; those on digits 2–4 are longer than one-third of the length of the digits, and are paler in color than the skin of the pes. The hallux has a claw similar in size to that of digit V and about half the length of the other three claws. The plantar surface has two metatarsal pads, including a reduced hypothenar and thenar, and four interdigital pads (P. R. Gonçalves, Oliveira et al. 2005; D'Elía et al. 2005).

The skull is robust and domed in lateral profile. The premaxilla has a well-developed gnathic process forming a projecting plate anterior to the incisors. The nasals project anteriorly beyond the premaxillae, and they are distally partly inflected dorsally. The interorbital region is squared, not beaded or ledged, and is hourglass in shape. Zygomatic notches are moderately deep and broad; the anterior margins of the zygomatic plates are nearly vertical. The anterior half of the zygomatic arch is flattened and expanded dorsoventrally. The braincase is inflated, and its width is subequal to the zygomatic breadth.

The incisive foramina are large and reach the level of the protocones of the M1s. The palate is long, extending well past the posterior faces of the M3s. The mesopterygoid fossa is narrower than either parapterygoid fossa; its anterior margin is squared and lacks a median spine. The alisphenoid strut is present, and a crest connects the squamosal root of the zygomatic arch to a slender hamular process. The subsquamosal foramen is small; the tegmen tympani is enlarged and reaches the squamosal. The stapedial foramen and posterior opening of the alisphenoid canal are large; both squamosal-alisphenoid groove and sphenofrontal foramen are absent. The mandible is short, with an inconspicuous capsular projection, a distally slender and high coronoid process, a dorsoventrally expanded condyloid process (internally excavated), and a short angular process. The inferior ridge of the masseteric crest is sharp and well marked.

Upper incisors are strongly opisthodont. The molars are terraced and moderately hypsodont. The anteromedian flexus/-id is present in M1–2/m1–2; mesoloph/-ids in

M1–2/m1–2 are fused with parolophule/entolophulid. The M3 is rounded in occlusal outline and has a persistent hypofossette and posterofossette, but there is no evidence of a hypoflexus. The m3 is rectangular with a large, oblique hypoflexid; its length is slightly less than that of m2. A full description of molar occlusal and root patterns is available in Pardiñas (1996).

External and cranial measurements of *Bibimys* species are available in Massoia (1979b), P. R. Gonçalves, Oliveira et al. (2005), and D'Elía et al. (2005). Pardiñas (1996) provided dental measurements.

Skeletal element counts from four *B. chacoensis* specimens are 13 ribs, 13 thoracic vertebrae, six lumbar vertebrae, three sacral vertebrae, and 26–29 caudal vertebrae. A gall bladder is present. The stomach is unilocular and hemiglandular. Geise et al. (2006) noted a pair of paravaginal mammae in female specimens, a condition unique for Sigmodontinae. A specimen (CNP 1891) from Las Palmas, a topotype of *B. chacoensis*, shows the same condition. Massoia (1979b) and P. R. Gonçalves, Oliveira et al. (2005) described glans and bacular morphology. According to P. R. Gonçalves, Oliveira et al. (2005), the glans penis is an elongated, laterally compressed, rod-like structure uniformly covered by small spines except on the crater rim. A major median groove extends along the length of its ventral surface. The bacular mound is an expanded structure, covered by spinous epidermis with three distally directed lobules on its extremity but without traces of lateral digits. The proximal end of the bacular base is paddle-like and without a conspicuous notch. The dorsal papilla is a finger-like structure, flattened dorsoventrally or slightly divided into three lobes. The urethral process is a bifurcated projection that extends beyond the ventral opening.

Dyzenchouz and Massarini (1999) reported the karyotype of *B. torresi*, and P. R. Gonçalves, Oliveira et al. (2005) reported the same for *B. labiosus*. Both species have $2n=70$, but vary in FN: 76 in *B. torresi* and 72 in *B. labiosus*. In addition, *B. torresi* shows C-bands on the X chromosome and in pair 3; *B. labiosus* has C-bands only on the X chromosome. A new karyomorph, reported for a specimen referred to *B. labiosus* collected in Minas Gerais state, Brazil, had a $2n=68$, FN=80 (Geise et al. 2006).

Massoia (1979b) put *Bibimys* in the Scapteromyini based on molar morphology, a hypothesis generally accepted by subsequent authors (Reig 1980; Musser and Carleton 1993). However, when envisioning and delineating the scapteromyine group, Hershkovitz (1966a) explicitly excluded *B. labiosus* (*Scapteromys labiosus* at that time), stating that *labiosus* morphologically resembled *Akodon azarae*. His conclusions were based mainly on the cranial and molar morphology of *B. labiosus* as portrayed by Winge (1887). Recent phylogenies based on mtDNA cytochrome-*b* and nucDNA

IRBP sequences (D'Elía 2003a; D'Elía et al. 2005) support Hershkovitz's (1966a) conclusion. *Bibimys* is not closely related to either *Scapteromys* or *Kunsia* but rather appears as the sole member of one of the five main clades in the Akodontini. However, in topologies obtained by analysis of IRBP sequences alone tend to place *Bibimys* closer to *Scapteromys* (D'Elía, Luna et al. 2006) or *Kunsia* (G. D'Elía, unpubl. data). Thus, for the present, the phylogenetic position of *Bibimys* in the Akodontini remains unclear.

Currently, *Bibimys* contains three living species, *B. chacoensis*, *B. labiosus*, and *B. torresi*, each characterized by complex nomenclatorial histories and a scarcity of available specimens for study. In addition, these taxa were erected over the course of more than a century and without cross-comparisons. As a result, the taxonomic status of all nominal forms remains uncertain, a problem exacerbated by the general lack of specimens and little knowledge of their natural history. The level of variation of the mtDNA cytochrome-*b* gene among the species of *Bibimys* is extremely low (D'Elía et al. 2005), surprisingly so considering the geographic distances among studied populations and their high degree of isolation. Observed variation is much lower than that reported among species in other akodontine genera and even lower than interpopulation variation seen in some akodontine species (summarized in M. F. Smith and Patton 1991, 1993). Pardiñas (1996) and D'Elía et al. (2005) addressed the degree of morphological variation. These authors, working with small samples, failed to find definitive anatomical traits or morphometric ranges that reliably delimit the named species of *Bibimys*. They thus claimed that recognition of a single species composed of several subspecies better represented the known diversity in the genus. Newly available specimens of *Bibimys* may allow a much deeper understanding of variation within the genus. For example, at the time of the redescription made by P. R. Gonçalves, Oliveira et al. (2005), *B. labiosus* was known only from six specimens, one of them the lectotype. Subsequently, however, Geise et al. (2006) reported the capture of 17 individuals of this taxon from a single locality, Poços de Caldas, Minas Gerais state, Brazil.

Bibimys has been recorded from several paleontological and archaeological sites in the Pampean region of Argentina. The oldest record comes from the late Pleistocene of Constitución, southeastern Buenos Aires province (Pardiñas, Cione et al. 2004). Several late Holocene occurrences from across the eastern Pampean region indicate a wider distributional range for this rodent until at least the eighteenth century (Pardiñas 1996; M. Silveira et al. 2010; Teta et al. 2013). In Brazil, fossil specimens have come from the Late Pleistocene-Holocene beds of Lapa da Escrivânia Nr. 5, Minas Gerais (Winge 1887).

REMARKS: *Bibimys* is hard to trap using Sherman or kill traps and traditional baits. Most of the data regarding distribution in Argentina have come from the analysis of owl pellets (Massoia 1983, 1988b; Massoia, Chebez, and Heinonen Fortabat 1989a, 1989b, 1989c, 1989d; Massoia, Tiranti, and Torres 1989). Its frequency in owl pellets, although moderate, is great enough to indicate that its apparent rarity is perhaps a sampling artifact. The use of pitfall traps in Brazil has resulted in several new localities in the last decade (e.g., Casado et al. 2006).

SYNONYMS:

Scapteromys: Winge, 1887:39; part (description of *labiosus*); not *Scapteromys* Waterhouse.

Akodon: Shamel, 1931:427; part (description of *chacoensis*); not *Akodon* Meyen.

Bibimys Massoia, 1978:56; *nomen nudum*.

Bibimys Massoia, 1979b:2; type species *Bibimys torresi* Massoia, by original designation.

KEY TO THE SPECIES OF *BIBIMYS*

1. Length of M1–3 usually >4 mm; range restricted to east-central Argentina *Bibimys torresi*
- 1'. Length of M1–3 usually <4 mm; range outside of east-central Argentina 2
2. Dorsal coloration strongly olivaceous; condylobasal length usually ≤23.8 mm; range northeastern Argentina and eastern Paraguay *Bibimys chacoensis*
- 2'. Dorsal coloration less olivaceous, almost brownish; condylobasal length usually ≥23.8 mm; southeastern Brazil *Bibimys labiosus*

Bibimys chacoensis (Shamel, 1931)

Pink-lipped Mouse, Swollen-nosed Mouse, Chacoan Akodont

SYNONYMS:

Akodon chacoensis Shamel, 1931:427; type locality "Las Palmas, Chaco, Argentina." According to the itinerary of Alexander Wetmore (1926:3), the collector of the type, he arrived at Puerto Las Palmas on July 12, 1920, and immediately traveled to "the little village of Las Palmas, headquarters for a large estancia, that covered 60 leagues of land." There, Wetmore worked until August 2. Thus, the type specimen of *chacoensis* was secured somewhere around the current town of Las Palmas (ca. 27.0485°S, 58.6889°W), Bermejo, Chaco province, Argentina.

Bibimys chacoensis: Massoia, 1980c:285; first use of current name combination.

DESCRIPTION: General characters as in generic description. Overall coloration olivaceous with some buff around eyes, on sides of head, and flanks; darker middorsal line present, almost black from shoulders to the tail; underparts whitish, with buffy tinge; both dorsal and ventral hairs

with slate gray bases (guard hairs ca. 11 mm; cover hairs ca. 8 mm); feet appear dark brown (foreclaws ca. 2.6 mm), with some hairs whitish at their tips; toes white. Compared with *B. torresi*, *B. chacoensis* has a more whitish venter, head and flanks are paler, and tail only slightly haired.

DISTRIBUTION: This species occurs in a narrow band from eastern Chaco province (Argentina), through eastern Paraguay, to southern Misiones and northwestern Corrientes provinces (Argentina). For many years after its original description, *B. chacoensis* was known only from the type locality and vicinity in Chaco province (Shamel 1931; J. R. Contreras 1984c). D'Elía et al. (2005), on morphological and geographical grounds, referred the Argentinean records from Misiones province, formerly regarded as of *B. labiosus* (see Massoia 1983, 1993), to *B. chacoensis*. Then several new localities were discovered in eastern Paraguay, filling the gap between records from Chaco and Misiones provinces (D'Elía, Mora et al. 2008). Even more recently, this species was recorded in northwestern Corrientes (C. Galliari and U. F. J. Pardiñas, unpubl. data). The geographic range displayed by *B. chacoensis* resembles that of *Chacodelphys formosa*, a small opossum (Teta and Pardiñas 2007). Most of the Argentinean records for *B. chacoensis* come from owl pellets. No fossils are known.

SELECTED LOCALITIES (Map 96): ARGENTINA: Chaco, Las Palmas (type locality of *Akodon chacoensis* Shamel); Corrientes, Santo Tomé (CNP-E uncataloged); Misiones, El Dorado (D'Elía et al. 2005), Estación Experimental INTA Cuartel Río Victoria (Massoia 1980b), Los Helechos (Massoia, Chebez, and Heinonen Fortabat 1989b), Santa Inés (D'Elía et al. 2005). **PARAGUAY:** Itapuá, Estancia Parabel, 0.3 km E of house (D'Elía, Mora et al. 2008), Parque Nacional San Rafael (D'Elía, Mora et al. 2008).

SUBSPECIES: *Bibimys chacoensis* is monotypic.

NATURAL HISTORY: Trapping data suggest that *B. chacoensis* inhabits perisylvan grasslands, including severely disturbed habitats, from humid Chaco to northern Campos ecoregions. The type specimen was secured in a small patch of marsh grasses in savanna. Field notes available for some Paraguayan specimens indicate that they were trapped in small patches of humid grassland near or within remnants of evergreen forest. Four males collected from July to September had scrotal testes. A female caught in January had a closed vagina, while another, taken in November, was lactating and had the vagina open (D'Elía, Mora et al. 2008).

REMARKS: Shamel (1931:427) stated that A. Wetmore acquired the holotype of *B. chacoensis* on June 20, 1920. However, this must be an error because Wetmore did not arrive in Argentina until June 21, 1920, and he worked the Las Palmas area between July 12 and August 2 (Wetmore 1926:2–3); the correct date of collection is probably July 20, 1920.

Map 96 Selected localities for *Bibimys chacoensis* (●) and *Bibimys torresi* (○).

Bibimys labiosus (Winge, 1887)

Lagoa Santa Pink-lipped Mouse, Lagoa Santa Swollen-nosed Mouse, Lagoa Santa Akodont

SYNONYMS:

Scapteromys labiosus Winge, 1887:39; type locality “Lagoa Santa [19°39’S, 43°54’W],” Minas Gerais, Brazil.

Bibimys labiosus: Massoia, 1980c:285; first use of current name combination.

DESCRIPTION: General characters as in the generic description. Pelage soft, long, and dense; color of dorsum homogeneous brownish, becoming somewhat paler on sides; some guard hairs with yellow-orange subapical band, producing black-lined pattern in combination with adjacent dark guard hairs; underparts whitish and sharply demarcated in color from dorsum. Area around mouth, from nostrils down (including lower lip) covered with densely distributed, short, white hairs that form round, white, velvety area on of muzzle in preserved skins. Mystacial vibrissae 2 to 2.5 cm long, dark brown proximally and whitish distally. Tail densely haired, with individual hairs extending over about two rows of scales, entirely dark brown on the upper surface of tail but with proximal dark brown and distal whitish halves on ventral surface (see P. R. Gonçalves, Oliveira et al. 2005).

DISTRIBUTION: This species was long known exclusively from animals, both extant and fossil, secured by Peter Lund in 1834 at the type locality and that were the basis of Winge’s description. Recent trapping efforts in Brazil, however, have recorded the species at several additional localities that collectively expand the known range from northern Rio

Map 97 Selected localities for *Bibimys labiosus* (●).

Grande do Sul northeast to Minas Gerais and Rio de Janeiro states in Brazil (Paglia et al. 1995; P. R. Gonçalves, Oliveira et al. 2005; Bonvicino, Oliveira, and D'Andrea 2008). Regrettably, most of these locality details remain unpublished (see Casado et al. 2006; Geise et al. 2006).

SELECTED LOCALITIES (Map 97): BRAZIL: Minas Gerais, Lagoa Santa (type locality of *Scapteromys labiosus* Winge), Viçosa, Mata do Paraíso (Paglia et al. 1995), Ouro Branco (G. Lessa et al. 2009), Poços de Caldas (Geise et al. 2006); Rio de Janeiro, Teresópolis, Vieira (Bonvicino, Oliveira, and D'Andrea 2008); São Paulo, Atibaia (Geise et al. 2006); Rio Grande do Sul, Aratiba (Casado et al. 2006).

SUBSPECIES: *Bibimys labiosus* is monotypic.

NATURAL HISTORY: Specimens from Viçosa were trapped in pitfall buckets placed in a disturbed patch of Atlantic Forest (Paglia et al. 1995). No other information on the ecology, behavior, or life history of this species is known.

Bibimys torresi Massoia, 1979

Torres's Pink-lipped Mouse, Torres's Swollen-nosed Mouse, Torres's Akodont

SYNONYMS:

Bibimys torresi Massoia, 1978:56; *nomen nudum*.

Bibimys torresi Massoia, 1979b:3; type locality "borde de camino de tierra y a orillas del canal de endicado de la Estación Experimental Agropecuaria Delta del Paraná del INTA [34.175061°S, 58.868071°W]," Campana, Buenos Aires, Argentina.

DESCRIPTION: General characters as in generic description. Large, with mass up to 40+ g (comparative measurements in D'Elía et al. 2005). Pelage long (hairs ca. 9 mm) and silky; individual hairs gray-based with ochraceous tips, giving general agouti appearance, especially yellowish on flanks and cheeks; hairs around snout, axillae, and genitalia with some orange tinge; ears small and rounded, externally and internally covered by short, delicate, cream-colored hairs; underparts cream, with the fur gray at base; dorsal and ventral colorations contrast sharply; tail bicolored, brown above and orange below, covered by short hairs; scale annulations quite visible; mystacial vibrissae short, not reaching pinna when laid backward; unguis shorter than claws.

DISTRIBUTION: *Bibimys torresi* is restricted to the islands and margins of Delta del Paraná in northern Buenos Aires and southernmost Entre Ríos provinces of Argentina. It is known from only six localities, half of which have produced only materials recovered from owl pellets. The prehistoric record of the Late Holocene, however, indicates a larger range, one reaching to 38°S and including coastal and hilly wet environments (Pardiñas 1995b, 1999b; Teta et al. 2004; Teta et al. 2013).

SELECTED LOCALITIES (Map 96): ARGENTINA: Entre Ríos, Isla Ibicuy (Massoia 1983); Buenos Aires, Estación Experimental INTA Delta del Paraná (Massoia 1979b), San Fernando, Establecimiento Carabelas (E. M. González 1997).

SUBSPECIES: *Bibimys torresi* is monotypic.

NATURAL HISTORY: The few specimens obtained by trapping (<10) came from long-term (>1 year) efforts. These data suggest a nocturnal activity pattern and presence in habitats near water bodies or flooded areas covered by dense tall grass and hydrophilic vegetation. *Bibimys torresi* is a secondary prey item of the Barn Owl (*Tyto alba*) in the Delta del Paraná, Argentina (Massoia 1983). Pardiñas (1996) hypothesized fossorial habits. *Bibimys torresi* is the type-host of *Hoplopleura massoiai* (see D. Castro and González 2003), a louse also shared by *B. chacoensis* (see Gugliemone and Nava 2011).

REMARKS: The original version of the type locality as given by Massoia (1979b) is somewhat ambiguous, a fact that may explain Musser and Carleton's (2005:1104) mixture of two separate localities ("confluence of Arroyo Las Piedras with Arroyo Cucarachas" and "Estación Experimental del INTA, Canal 6," which are separated by ca. 6 km).

Genus *Blarinomys* Thomas, 1896

Pablo Teta and Ulyses F. J. Pardiñas

The monotypic *Blarinomys*, with its adaptations for fossorial living, is one of the more distinctive genera of sigmo-

odontine rodents (Hershkovitz 1966a:95). The single species, *Blarinomys breviceps*, is known from a limited number of localities in the Atlantic Forest of southeastern Brazil and extreme northeastern Argentina. Matson and Abravaya (1977) reviewed the morphology, fossil record, and ecology of the genus; Geise et al. (2008) added karyological information, new morphological data, and provided a gazetteer of known localities. K. Ventura et al. (2012) provided the first phylogeographic assessment of *Blarinomys* and reported eight distinct karyomorphs, indicating impressive karyotypic diversity in this fossorial rodent. The present account is largely based on these three contributions.

In general appearance, this small sigmodontine resembles the North American short-tailed shrews of the genus *Blarina*, hence the name *Blarinomys* (Thomas 1896). The body form is highly modified for fossorial life, with a short and conical head, extremely reduced eyes hidden in the fur, very small and well haired pinnae, and a short, unicolorous, and sparsely haired tail (usually <50% of head and body length). The manus has long, pointed claws and a strongly reduced fifth digit. The pes has short and curved claws. The palms and soles of the feet are naked, except for the heel. The pelage is short, crisp, and velvety, and more or less uniform dark slate gray throughout, with reddish or brownish tips to the hairs. The dorsum is slightly iridescent with a ruby tinge. Under parts are gray-brown, scarcely differentiated from the dorsum. The tip of the muzzle and chin are whitish. The hands and feet are brown above (Gyldenstolpe 1932; Matson and Abravaya 1977). The head and body length ranges from 91–122 mm, tail length 30–59 mm, hindfoot length 16–21 mm, and ear length 8–10 mm. Both Abravaya and Matson (1975) and Geise et al. (2008) documented reverse sexual dimorphism, with females larger than males.

The skull is very distinctive among sigmodontines, short but conical in the rostral region and broadened posteriorly. The braincase is short, laterally rounded, and almost flat dorsally. The interorbital region is broad, tubular throughout, and smooth, with an almost undistinguishable constriction. Frontal sinuses are well inflated. Nasals are subequal in length to the frontals and extend beyond the anterior end of the premaxillae. Zygomatic plates are narrow and reduced, their anterior borders posteriorly slanting from bottom to top. Masseteric tubercles are well developed. The interparietal is extremely reduced or absent. Lambdoidal crests are well-developed, even in juveniles. The infraorbital foramina are large. Incisive foramina are expanded in their posterior half, and extend posteriorly to the level of the procingula of M1s. The palate is wide and short. The mesopterygoid fossa is remarkably broad and parallel sided, and extends to the posterior roots of M3s. Each parapterygoid fossa is narrower than the mesoptery-

goid fossa, and well excavated. The hamular process of the squamosal is thin, defining subequal postglenoid foramen and subsquamosal fenestra. An alisphenoid strut is present. The tegmen tympani is well developed and contacts the squamosal. The mandibular ramus is slender; the capsular projection absent; the coronoid process well developed, with a broad base and slightly backward oriented; and the angular process delicate.

The upper incisors are orthodont with a straight dentine fissure. The molar rows are slightly convergent posteriorly. The molars are hypsodont, with high, crowns; main cusps are opposite to each other; and enamel folds wear quickly with age to leave simple indented surfaces in subadults and adults. M1 has a reduced procingulum with a shallow median anteroflexus. M3 is small but shows a central hypofossetus. Both m1 and m2 have reduced mesolophids.

Geise et al. (2008:7) described and figured a unilocular-hemiglandular stomach. However, these authors failed to note that the glandular epithelium is contained in a pouch-like diverticulum that apparently opens into the main chamber of the stomach by a minute aperture. In addition, Geise et al. (2008) stated that they observed a bordering fold, but, from the inspection of their figure, there is no clear indication of this structure. The stomach of *Blarinomys* seems to be very similar to those of *Brucepattersonius* (Hershkovitz 1998:229–230) and *Oxymycterus* (Vorontsov 1960:365; Carleton 1973:15; Hershkovitz 1994:7 and 9).

SYNONYMS:

Oxymycterus: Winge, 1887:34; part (description of *breviceps*); not *Oxymycterus* Waterhouse.

Blarinomys Thomas, 1896:310; type species *Oxymycterus breviceps* Winge, by original designation.

Blarinomys breviceps (Winge, 1887)

Atlantic Forest Burrowing Mouse, *Blarinine Akodont*

SYNONYMS:

Oxymycterus breviceps Winge, 1887:34; type locality “Lapa do Capão Seco [= Lapa do Capão Seco],” Lagoa Santa, Minas Gerais, Brazil (name appears first in list on p. 4).

Blarinomys breviceps: Thomas, 1896:310; generic description and first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Blarinomys breviceps* is found mostly in forested areas from sea level to about 1,600 meters in the Brazilian states of Bahia, Espírito Santo, Minas Gerais, Rio de Janeiro, and São Paulo, and the Argentinean province of Misiones (Massoia 1993; C. R. Silva et al. 2003; Massoia et al. 2006). Despite a few localities near sea level (S. F. Reis et al. 1996; see also Moojen 1952b and Avila-Pires 1960), most collections from the northern portion of the range are from middle to high elevations (750 to 1,500 m;

Geise et al. 2008). Matson and Abravaya (1977) regarded the species as chiefly montane. This species is primarily an Atlantic Forest dweller, but a few records are from localities transitional between it and the Cerrado (e.g., Serra do Ouro Branco; V. B. Pereira et al. 2010). The only known fossils are from the Quaternary cave deposits at Lagoa Santa, Minas Gerais, the type locality (Winge 1887; Voss and Myers 1991). The species is apparently not found in that area today (C. R. Silva et al. 2003). The nearest known modern locality to the type locality is Estação de Proteção e Desenvolvimento Ambiental de Peti, about 60 km ESE of Lagoa Santa (Paglia et al. 2005).

SELECTED LOCALITIES (Map 98): ARGENTINA: Misiones, Puerto Esperanza (Massoia 1993), R. N. E. San Antonio (Massoia et al. 2006), San Martín (Massoia et al. 2006). BRAZIL: Bahia, Fazenda Imbaçuaba, 30 km N of Prado (Geise et al. 2008), Ilhéus (Moojen 1952b), RPPN da Serra do Teimoso (Geise et al. 2008); Espírito Santo, Castellingho (Abravaya and Matson 1975), Reserva Florestal Nova Lombardia (Abravaya and Matson 1975); Minas Gerais, Boca da Mata (Avila-Pires 1960b), Jacutinga (Oehlmeyer et al. 2010), Juiz de Fora (Granzinolli and Motta-Junior 2006), Lapa do Capão Seco (type locality of *Oxymycterus breviceps* Winge), Mata do Paraíso (Geise et al. 2008), Parque Estadual da Serra do Ouro Branco (V. B. Pereira et al. 2010); Rio de Janeiro, Fazenda Marimbondo (Geise et al. 2008); São Paulo, Fazenda João XXIII (C. R. Silva et al. 2003), Parque Estadual da Cantareira (Nieri-Bastos et al. 2004), Parque Estadual Turístico do Alto Ribeira (C. R. Silva et al. 2003), Reserva Florestal do Morro Grande (Pardini and Umetsu 2006).

SUBSPECIES: *Blarinomys breviceps* is monotypic (but see Remarks).

NATURAL HISTORY: Little is known about this rare sigmodontine rodent. It has been caught in both primary and secondary growth forests (C. R. Silva et al. 2003; Paglia et al. 2005), and in moderately disturbed habitats such as forest fragments in agricultural areas (Oehlmeyer et al. 2010). Abravaya and Matson (1975) reported catching five individuals with snap traps baited with corn and placed in leaf litter, but most Brazilian specimens have been obtained in pitfall buckets (Pardini and Umetsu 2006; Geise et al. 2008; V. B. Pereira et al. 2010). *Blarinomys* uses galleries under the leaf litter at depths up to 25 cm (V. B. Pereira et al. 2010).

Males with scrotal testes were collected in January and February; pregnant females were trapped in September, January, and February. Litter size varied from 1 to 2 (Abravaya and Matson 1975). The diet consists primarily of invertebrates, with stomachs containing arthropods of six different orders, mostly insects (90%), but also arachnids (S. F. Reis et al. 1996). Davis (1944) and Abravaya and Matson (1975)

reported that captive animals were docile and accepted a wide variety of insects, mainly orthopterans, roaches, and lepidopteran pupae and larvae, but refused fruit and seeds except for those of oranges (Geise et al. 2008).

REMARKS: Tate (1932d, 1932h) believed that *Mus fossorius* and *Mus talpinus*, two extinct species named by Lund (1840b, 1841c), might be species of *Blarinomys*. Paula Couto (1950) included *M. fossorius*, a taxon described on the basis of an isolated humerus, in the genus *Nectomys*, while Winge (1887) and Hershkovitz (1966a) believed that its affinities were indeterminable. Paula Couto (1950) also referred *M. talpinus* to *Blarinomys*, although Winge (1887) included this species in *Oxymycterus*. Moojen (1965), on the other hand, considered *talpinus* a species of *Juscelinomys*. João A. Oliveira (in Pardiñas et al. 2002:222) believed that *Mus talpinus* was referable to *Brucepattersonius* (see that account and the one for *Juscelinomys*), and, after the examination of the holotype, Pardiñas and Teta (2013a) formally placed *talpinus* Lund in the synonymy of *Brucepattersonius*.

Recently described geographic variation in karyotypic, morphological, and molecular characters supports the possibility that more than one species is contained in our present concept of *B. breviceps*. For example, Fagundes and Costa (2008) described a $2n=45$, FN=51 karyotype from a specimen caught at Reserva Biológica de Duas Bocas, Cariacica, Espírito Santo, which is substantially different from the $2n=28$, FN=48 known for specimens from Rio de Janeiro (Geise et al. 2008). Gudinho and Ximenez (2010) reported variation in several morphological traits (e.g., foramen magnum morphology, anterior expansion of the nasals) between northern and southern populations in Brazil. Fi-

Map 98 Selected localities for *Blarinomys breviceps* (●).

nally, mtDNA cytochrome-*b* sequence analyses (K. Ventura et al. 2012; also K. Ventura 2009) have identified two evolutionary lineages, one found north and one south of the Rio Doce fluvial system in eastern Brazil. Pairwise divergences between members of these clades ranged from 4.9–8.4%. These authors also identified eight distinct karyomorphs, including $2n=52$ (50A, XX), $2n=52$ (48A, XY+2Bs), $2n=45$ (42A, XY+1B), $2n=43$ (37A, XX+4Bs), $2n=37$ (34A, XY+1B), $2n=34$ (32A, XX), $2n=31$ (27A, XX+2Bs), and $2n=28$ (26A, XY), all with the same number of autosomal arms (FN=50).

Genus *Brucepattersonius* Hershkovitz, 1998

Júlio Fernando Vilela, Pablo R. Gonçalves,
and João A. de Oliveira

The genus *Brucepattersonius* was recently proposed for a clade of shrew-like akodonts from southeastern-southern Brazil and northeastern Argentina. Museum records have been obtained from both coastal and interior portions of the Atlantic Forest domain, from the Brazilian states of Minas Gerais and Espírito Santo to Rio Grande do Sul, and westward to the Argentinean province of Misiones. In addition to *B. iheringi* (Thomas 1896), which was originally described as an *Oxymycterus*, seven other recently described forms (Hershkovitz 1998; Mares and Braun 2000a) have been assigned to the genus, namely, *B. soricinus* (type species of *Brucepattersonius*), *B. griserufescens*, *B. igniventris*, *B. albinasus*, *B. paradisi*, *B. misionensis*, and *B. guarani*, the last four based on single specimens, and the last three from closely adjacent localities in the department of Guaraní, Misiones province, Argentina. The type specimen of *B. albinasus* is indistinguishable, both in mtDNA cytochrome-*b* sequence and cranial morphology, from *B. griserufescens*, which was described from a nearby locality (J. F. Vilela et al. 2006). The apparently extinct *Oxymycterus talpinus* Winge, 1887, described from the Pleistocene-Holocene cave faunal assemblage of Lapa da Serra das Abelhas, Lagoa Santa, Minas Gerais, is here assigned to the genus *Brucepattersonius* based on comparisons with *Oxymycterus iheringi* (= *B. iheringi*) by Thomas (1896), J. A. Oliveira (1998), and Pardiñas and Teta (2013a).

The species of *Brucepattersonius* are small akodontine rodents (total length 194–221 mm), with small eyes, relatively large ears (16–19 mm), long and tapered rostrum, moderately developed forefoot and hindfoot claws with whitish unguis tufts, and tail varying from shorter to a fourth longer (82–112 mm) than the combined head and body length (93–128 mm). The hindfoot, with claw, averages 25 mm in adults of all species, and usually between 24 and 26 mm. The dorsal fur is long and soft, owing to guard

hairs that are proximally thin and distally thickened. Dorsal coloration is generally dark brown to grayish brown, but some forms have a reddish-brown dorsum (e.g., *B. igniventris*). The sides vary from slightly paler to almost as dark as the dorsum, and the venter can be weakly to strongly set off from the lateral coloration. In the latter case, the ventral pelage is usually paler and grayish, sometimes with a touch of ochraceous. Despite the supposed taxonomic significance of chromatic variation in the genus (see Hershkovitz 1998; Mares and Braun 2000a), current museum holdings seem to show that there are high levels of intraspecific variation in pelage color, preventing a clear-cut distinction among nominal forms based on pelage color alone (J. F. Vilela et al. 2006).

The skull is delicately built, with a narrow and elongated rostrum and smooth, subglobular braincase. The nasals have rounded or bluntly pointed tips that extend anteriorly beyond the incisors but do not form a distinct tube as in *Oxymycterus*. The lateral premaxillary walls become free from their contact with the nasals at or slightly posterior to the plane of incisors. The interorbital region is very broad and wider than the rostrum and is slightly biconcave or amphoral in shape, without crests or ridges. The supraorbital edges of frontals are rounded, and their antorbital portions are considerably inflated due to expanded frontal sinuses. The interparietal is very reduced and quite narrowed anteroposteriorly. Incisive foramina can be long, extending posteriorly to the level of the paraflexi of M1s, or short, not reaching the level of the anterior edges of M1s. The bony palate is short and wide, and the mesopterygoid fossa extends anteriorly to the posterior limits of the third molars. A large stapedial foramen is present, coalesced with a deep petrotympanic fissure. A sphenofrontal foramen and an anterior opening in the alar fissure are also present, providing evidence of superior and inferior branches of the stapedial artery, conforming to the basic or primitive pattern of carotid circulation (Bugge 1970; Carleton 1980; Voss 1988). There is no bony alisphenoid strut, and the buccinator-masticatory and accessory oval foramina are coalesced to form a unique foramen. Auditory bullae barely touch the squamosal anteriorly through the tegmen tympani, which overlaps with a reduced posterior suspensory process. A second point of attachment of the auditory complex to the squamosal is provided by a slender hamular process, which shows a median ridge that extends from the posterior tip of the hamular process to coalesce with the squamosal process of the zygomatic arch. The mandible is slender and smooth, and without a defined incisor root capsule.

Molar rows are very nearly parallel sided, aside from greater width of first molars as compared with third molars; opposing cusps are oblique. Molars are tetralophodont,

quadritubercular, and hypsodont; cusps of unworn teeth are narrow and pointed; the occlusal surface is crested; upper and lower first molars have anteromedian flexi and flexids; anteroloph present; mesolophs (and -ids) are absent; upper and lower third molars are rounded and simplified with paracone and protocone as the sole pronounced cusps; and upper incisors are short, narrow, and usually orthodont.

The stomach is bilocular-discoglandular, and the glandular epithelium is contained in a pouch-like diverticulum that opens into the main chamber of the stomach by a minute orifice (Hershkovitz 1998:Fig. 20), a condition found in insectivorous rodents (Carleton 1973). Although Hershkovitz (1998) suggested that the gall bladder is present in *Brucepattersonius*, Geise, Weksler, and Bonvicino (2004) did not find it in specimens from Itatiaia, Rio de Janeiro state, Brazil. Females have six mammae, one thoracic and two inguinal pairs (Thomas 1896).

The baculum is long, a distally thin shaft that becomes gradually wider to an enlarged cuneiform base. Two lateral indentations are present, one near the distal end and another near the base; in lateral view, the baculum is markedly curved, and the lateral indentations do not form a conspicuous lateral enlargement of the base. Lateral condyles are located almost in the proximal extremity on each side of the base and are separated by a shallow median depression. The distal end is rounded, but the tip more squared. Both lateral and medial cartilaginous digits are lacking (J. A. Oliveira 1998).

Part of the information that follows is based on our examination of newly available specimens that have not been previously published and on comparisons with type specimens, particularly of Brazilian taxa. Unlike many other sigmodontine genera in which the number of species currently recognized underestimates true diversity, the number of those recognized for *Brucepattersonius* likely overrepresents that diversity. For example, the three supposed species of *Brucepattersonius* from Misiones province in Argentina (Mares and Braun 2000a) were described from single individuals captured at localities separated by only a few kilometers. Our inability to examine the type specimens has prevented us from making unequivocal decisions regarding their taxonomic status. We thus follow herein the taxonomic structure, diagnostic characters, and key for species originally provided by Mares and Braun (2000a). Morphological and molecular comparisons of larger samples from Misiones province, comparisons that include the holotypes of *B. paradisus*, *B. misionensis*, and *B. guarani*, are critically required to evaluate the true species diversity in the Misiones region as well as the relationships of these forms to previously described species from Brazil (see J. Pereira et al. 2005; Cirignoli et al. 2011).

SYNONYMS:

Hesperomys (Oxymycterus): Ihering, 1893:109; part (listing of *nasutus*); not *Oxymycterus* Waterhouse.
Oxymycterus: Winge, 1887:36; part (description of *talpinus*); not *Oxymycterus* Waterhouse.
Microxus: Thomas, 1909:237; part (listing of *iheringi*); not *Microxus* Thomas.
 ?*Microxus*: Gyldenstolpe:134; part (listing of *iheringi*); not *Microxus* Thomas.
Akodon (Microxus): Cabrera, 1961:458; part (listing of *iheringi*); neither *Akodon* Meyen nor *Microxus* Thomas.
Juscelinomys: Moojen, 1965:284; part (listing of *talpinus*); not *Juscelinomys* Moojen.
Brucepattersonius Hershkovitz, 1998:227; type species *Brucepattersonius soricinus* Hershkovitz, by original designation.

KEY TO THE SPECIES OF *BRUCEPATTERSONIUS*
(ADAPTED FROM HERSHKOVITZ 1998 AND MARES AND BRAUN 2000A):

1. Length of incisive foramina 5.8 mm or more 2
- 1'. Length of incisive foramina less than 5.8 mm 4
2. Tail length < 90% of head and body length; under parts grayish with ochraceous wash
 *Brucepattersonius soricinus*
- 2'. Tail length ≥ 90% to head and body length 3
3. Under parts primarily grayish
 *Brucepattersonius griserufescens*
- 3'. Under parts primarily reddish or orange
 *Brucepattersonius igniventris*
4. Dorsum uniform gray, venter scarcely paler
 *Brucepattersonius iheringi*
- 4'. Dorsum reddish-brown or grayish brown 5
5. Dorsal and ventral colorations not sharply demarcated laterally; dorsum reddish-brown; chin ochraceous; pterygoid wings robust and with distinctive knobs at tips; zygomatic arches thick; rostrum wider (>5 mm), with well-developed nasolacrimal capsules
 *Brucepattersonius paradisus*
- 5'. Dorsal and ventral colorations sharply demarcated laterally; dorsum dark-brown to grayish brown; chin whitish; pterygoid wings delicate and lacking knobs at tips; zygomatic arches thin; rostrum narrower (<5 mm), with poorly developed nasolacrimal capsules 6
6. M3 one-half the length of M2; tail bicolored
 *Brucepattersonius misionensis*
- 6'. M3 < one-half the length of M2; tail unicolored.
 *Brucepattersonius guarani*

Brucepattersonius griserufescens Hershkovitz, 1998

Gray-bellied Bruceie

SYNONYMS:

Brucepattersonius griserufescens Hershkovitz, 1998:233; type locality “Terreirão, Parque Nacional do Caparaó, Minas Gerais, Brazil, elevation 2400 meters.”

Brucepattersonius albinasus Hershkovitz, 1998:235; type locality “Pico da Bandeira, Parque Nacional de Caparaó, Minas Gerais, Brazil, elevation, 2700 meters.”

DESCRIPTION: Stated to be largest species in genus by Hershkovitz (1998), but mean head and body length 103 mm (range: 93–109 mm) similar or even smaller than other species described by him. Tail length for 10 specimens from Caparaó, including holotype, average 103 mm (range 97–112 mm). Dorsum uniformly brownish or dark brown from rostrum to tail base; pelage silky and fluffy, with hairs about 10 mm long that possess narrow subterminal ochraceous orange band and gray hair base entirely concealed beneath long lax fur; sides of trunk and limbs like back; underparts predominantly to entirely grayish, variably washed pale ochraceous and more or less defined from sides; tail uniformly brown, dorsal hairs about 1 scale long, and ventral hairs, plus tip and terminal pencil, whitish and about three scales long; scales visible to eye; ears brown, partly hidden in fur; digital and facial vibrissae whitish, rostral vibrissae when laid back reach ear bases; hands and feet pale brown to grayish above, palms pigmented or unpigmented, soles brown; manual claws 2 mm long; pedal claws 4 mm long.

Skull smooth, without crests or ridges; rostrum long, slender, and tapered, with nasal tips rounded and extended slightly beyond incisors, but without expansion or formation of trumpet; zygomatic plates little exposed when viewed from above; interorbital region wide, with rounded edges; incisive foramina short, with posterior edges that do not reach level of M1 protoflexi, with posterior portions narrower than anterior and median portions; sphenopalatine vacuities laterally expanded and oblong in shape, mastoid perforated by conspicuous foramen or fenestra; palatal bridge extends to posterior plane of M3s; capsular process only weakly pronounced.

DISTRIBUTION: Known from the higher elevations of the Caparaó, Mantiqueira, and Serra dos Órgãos massifs, in the Atlantic Forest of southeastern Brazil, and at elevations from 1,800 to 2,400 m.

SELECTED LOCALITIES (Map 99): BRAZIL: Espírito Santo, Santa Clara do Caparaó, Parna Caparaó, vertente nordeste (MNRJ 69581); Minas Gerais, Alto Caparaó, Parna Caparaó, vertente sudoeste (Hershkovitz 1998), Itamonte, Brejo da Lapa (MNRJ 60602), Fazenda do Itaguaré, Passa Quatro (UFMG 1891); Rio de Janeiro, Macaé de Cima, Pirineus (MNRJ 69762), Teresópolis, Vale das Antas (MNJR 77118).

SUBSPECIES: We treat *Brucepattersonius griserufescens* as monotypic.

NATURAL HISTORY: On the Caparaó Massif in southeastern Brazil, Bonvicino et al. (1997) obtained individuals in submontane secondary forest, montane scrub, but primarily in undisturbed humid montane forest. Other details of population of natural history are lacking.

REMARKS: J. F. Vilela et al. (2006) placed *albinasus* Hershkovitz, the “white-nosed Bruceie,” for which there is only the holotype (MNRJ 32017), in synonymy with *B. griserufescens* based on molecular and morphological characters (J. F. Vilela et al. 2006). The supposedly diagnostic tuft of hair on the tip of the tail was found to be indistinguishable from the condition found in some individuals in a larger series assignable to *B. griserufescens*, and the white “nose,” actually the region around the rhinarium, was interpreted as an additional case of incomplete penetrance of genotypes and intraspecific variation *sensu* Axenovich et al. (2004). Specimens from Itamonte in the Serra da Mantiqueira, assigned to *B. griserufescens* by Bonvicino et al. (1998), as well as those from Serra dos Órgãos may constitute a separate taxonomic unit (J. F. Vilela 2005).

The karyotype consists of $2n=52$, FN=52 (Svartman and Cardoso de Almeida 1993b), with 24 pairs of acrocentric chromosomes that vary in size from large to small, plus a small pair of metacentric chromosomes; the X and Y chromosomes are medium and small acrocentrics (J. F.

Map 99 Selected localities for *Brucepattersonius griserufescens* (●) and *Brucepattersonius igniventris* (○).

Vilela 2005). Bonvicino et al. (1998) recorded an inversion polymorphism resulting in an FN of 53 in specimens from Itamonte, Minas Gerais state.

Brucepattersonius guarani Mares and Braun, 2000

Guarani Brucie

SYNONYM:

Brucepattersonius guarani Mares and Braun, 2000a:9; type locality “Argentina: Misiones Province: Departamento Guaraní, 6 km NE by Highway 2 of Jct. Highway 2 and Arroyo Paraíso. The elevation at the type locality is 360 m (1,180 ft.); ca. 2 km W Parque Provincial Moconá.

DESCRIPTION: Medium sized, with head and body length 101 mm, and tail 91 mm; ears originally described as small and rounded, but reported length (18 mm) slightly longer than the mean of all Brazilian species. Dorsum dark brown, with numerous and long guard hairs dark at their tips and becoming gradually paler basally; banded hairs with dark gray base along most of length, narrow pale-colored middle band (about 0.5 mm in length), and dark tip (about 0.5 mm); sides similar to dorsum in color, gradually lightening toward venter, which is washed with ochraceous, but hairs gray basally and with cinnamon-buff tips; general coloration of throat smoky gray; chin within distinct patch of white hairs; tip of muzzle with very small patch of white hairs; ears dark, outer surfaces gray; hindfeet brown, covered with hairs whitish basally, light brownish in middle, and whitish at tip; tail described as unicolored, but hairs brownish black above and bicolored below (brownish basally with whitish tips), extending over two to three scale rows; about 19 scales per cm at base of tail.

Skull slender, with delicate rostrum, and blunt posterior ends of nasals that extend beyond premaxillofrontal suture; nasolacrimal capsules not well developed; zygomatic plates markedly inclined posteriorly from bottom to top; zygomatic arches delicate, slightly expanded laterally; incisive foramina long, extending posteriorly to anterolingual conules of M1s, and with prevomerine process of premaxilla at least three-fourths the length of the opening; pterygoid wings delicate, tips without distinct knob. Mandible slender, with posterior extension of condyloid process about equal to that of angular process, which itself is not especially delicate and lacks a distinct lateral hook. M3 less than or equal to one-half length of M2.

DISTRIBUTION: *Brucepattersonius guarani* is known only from its type locality.

SELECTED LOCALITIES (Map 100): ARGENTINA: Misiones, 6 km NE by Hwy 2 of junction Hwy 2 and Arroyo Paraíso (type locality of *Brucepattersonius guarani* Mares and Braun).

SUBSPECIES: *Brucepattersonius guarani* is monotypic.

Map 100 Single known locality for *Brucepattersonius guarani* (●).

NATURAL HISTORY: The holotype, taken in November 1990, had a closed vagina and was molting. Unidentified roundworms were found in the intestines (Mares and Braun 2000a). Nothing else is known about the natural history of this species.

REMARKS: The holotype appears to be a subadult, based on the relatively unworn molars, its nonreproductive status, and molt condition.

Brucepattersonius igniventris Hershkovitz, 1998

Red-bellied Brucie

SYNONYM:

Brucepattersonius igniventris Hershkovitz, 1998:232; type locality: “Iporanga (Petar) State Park [= Parque Estadual Turístico do Alto Ribeira], southwestern São Paulo, Brazil.”

DESCRIPTION: Mean and range values for four specimens include head and body length 116 mm (114–118 mm), tail length 93 mm (86–99 mm), hindfoot with claw 24 mm (22–25 mm), and ear length 17 mm (16–18 mm). Dorsal pelage fine, soft, appressed, 7–8 mm long; coloration from snout to rump reddish brown, sides slightly more reddish and merging into reddish orange of cheeks, chin, throat, arms, and belly; broad orange lateral line separates reddish brown dorsum from reddish venter. Tail shorter than head plus body, uniformly brownish in color, thinly clothed with scales clearly visible, and terminating in short, thin pencil of whitish to brownish hairs; digital tufts of three middle

toes of forefeet and hindfeet whitish, those on the outer toes sparse or absent; manual claws small and thin; vibrissae fine, longest barely reaching ear base when laid back. Skull slender; rostrum attenuated; nasal tips project well beyond incisors; palate long, extending to posterior plane of M3s; incisive foramina long, with posterior limits near the level of protoflexi of M1s, or, if not reaching this plane, posterior portion of incisive foramina wider than median portion.

DISTRIBUTION: Known only from two localities in the Atlantic Forest of southeastern São Paulo state, Brazil.

SELECTED LOCALITIES (Map 99): BRAZIL: São Paulo, Capão Bonito (MZUSP [AB107]), Iporanga (Petar) State Park (type locality of *Brucepattersonius igniventris* Hershkovitz).

SUBSPECIES: *Brucepattersonius igniventris* is monotypic.

NATURAL HISTORY: The few known specimens have been collected in secondary forest. Little else is known about the natural history of this species.

REMARKS: Despite being easily distinguished by pelage color from other Brazilian species, preliminary molecular analyses (J. F. Vilela et al., unpubl. data) which include the specimen from Capão Bonito suggest that this form is not distinct from *B. soricinus*. See also M. F. Smith and Patton (1999) and Remarks for *B. soricinus*.

Brucepattersonius iheringi (Thomas, 1896)

Ihering's Brucie

SYNONYMS:

Hesperomys nasutus: Hensel, 1872b:43; part; not *Mus nasutus* Waterhouse.

Oxymycterus talpinus Winge, 1887:36; type locality "Lapa da Escrivania [= Lapa da Escrivânia] Nr. 5," Lagoa Santa, Minas Gerais, Brazil.

Hesperomys (Oxymycterus) nasutus: Ihering, 1893:109; part; not *Mus nasutus* Waterhouse.

Oxymycterus Iheringi Thomas 1896:308; type locality "Taquara, Rio Grande do Sul," Brazil.

M[icroxus]. iheringi: Thomas 1909:237; name combination.

Microxus (?) *iheringi*: Gyldenstolpe, 1932a:134; name combination.

Microxus iheringii C. O. da C. Vieira, 1953:145; incorrect subsequent spelling of *Oxymycterus Iheringi* Thomas.

Akodon (Microxus) iheringi: Cabrera, 1961:45; name combination.

[*Oxymycterus rutilans*] *iheringi*: Hershkovitz, 1966a:86; name combination.

Brucepattersonius iheringi: Hershkovitz, 1998:240; first use of current name combination.

DESCRIPTION: Medium sized, with mean and ranges for four specimens, including holotype, of head and body

length 100 mm (89–113 mm), tail length 100 mm (94–107 mm), hindfoot length 23 mm (22–26 mm), and ear length 17 mm (15–18 mm); fur soft and thick; upper parts and sides overall grayish, under parts uniform grizzled brown, scarcely paler than sides. Skull slender; incisive foramina short, with posterior limits not reaching level of M1 protoflexus, with posterior portions narrower than anterior and median portions; sphenopalatine vacuities absent or reduced to longitudinal slits; mastoid completely ossified without distinct foramina.

DISTRIBUTION: The core distribution of this species consists of the *Araucaria* forest on the Brazilian Meridional Plateau and the coastal forests of southern Brazil. Its elevation range is from near sea level to 1,000 m in the mountainous regions of the Aparados da Serra (Rio Grande do Sul state) and Piraquara (Paraná state). C. O. da C. Vieira (1955) suggested that this species occurs in Uruguay, a possibility that has not been corroborated, including by voucher specimens in collections (Massoia 1963b).

SELECTED LOCALITIES (Map 101): ARGENTINA: Misiones, Aristóbulo del Valle, Cuña Piru (MLP 16.VII.02.09), Dos de Mayo (Massoia and Fornes 1969), Puerto Gisela (Massoia 1963b), Sierra de La Victoria (MACN-BR18950), Tobunas, Rte 14, Km 352 (Massoia 1963b). BRAZIL: Rio Grande do Sul, Aratiba (MNRJ [CRB 1944]), Cambará do Sul, Parque Nacional da Serra Geral (MNRJ 78511), Osório, Morro Osório (MNRJ 49798), Sapiroanga, Alto Ferrabraz, Morro Ferrabraz (MNRJ 49800), Taquara (type locality of *Oxymycterus iheringi* Thomas), Tôrres, Faxinal Norte Lagoa Itapeva (MNRJ 49802); Santa Catarina, Caldas da Imperatriz, Parque Estadual Serra do Tabuleiro (UFSC [ZOO] 735), Jaborá (MNRJ 69785).

SUBSPECIES: *Brucepattersonius iheringi* is monotypic.

NATURAL HISTORY: Field notes indicate that this mouse has been most frequently captured in forests with dense litter and herbaceous cover; captive animals have tried to burrow under the litter placed in cages. Specimens recorded by Massoia (1963b) were trapped at night in wooded areas, one on the border of a rocky stream, the other in a low brushy area on the edge of a path.

REMARKS: Note that the fossil species *talpinus* Winge is herein tentatively placed in the synonymy of *iheringi* Thomas. Should careful analyses of available specimen confirm this hypothesis, Winge's name would have priority over that of Thomas.

Hershkovitz (1998) reported on the mean and extremes of measurements from at least 11 specimens from Misiones province, Argentina, including ones from Tobuna and Puerto Gisela, referred by Massoia (1963b) and Massoia and Fornes (1969) to *O. iheringi*, but which Hershkovitz (1998) simply called *Brucepattersonius* sp. Mares and Braun (2000a) did not assign any specimens collected

Map 101 Selected localities for *Brucepattersonius iheringi* (●).

previously in Misiones to the species they described. J. F. Vilela (2005) examined 16 specimens from Misiones, except holotypes. He identified a single evolutionary lineage in that province, one that extends into adjacent Rio Grande do Sul, Brazil, based on external morphology and craniodental morphometric analysis.

Brucepattersonius iheringi shares the same chromosomal complement, including morphologies of autosomes and sex chromosomes, as *B. griserufescens*, with $2n=52$, $FN=52$ (J. F. Vilela 2005).

Brucepattersonius misionensis Mares and Braun, 2000
Misiones Brucie

SYNONYM:

Brucepattersonius misionensis Mares and Braun, 2000a:7; type locality "Argentina: Misiones Province: Departamento Guaraní, jct. Hwy 21 and Arroyo Oveja Negra, approx. 2 km W Parque Provincial Moconá."

DESCRIPTION: Dorsal pelage brownish; dark guard hairs numerous and long, banded with dark gray base (about 8 mm), yellowish middle (about 1 mm in length), and dark tip (<1 mm); sides and flanks similar in color to dorsum, although slightly paler, gradually merging into color of venter; ventral hairs whitish basally (about 2 mm), banded neutral gray in middle (about 6 mm in length), and tipped ivory yellow; ears rounded, their outer surfaces edged with hairs colored similarly to those of dorsum; tail bicolored, olive brown above and lighter

below, clothed in short hairs that have brownish bases and whitish tips; tail with 16 scales per cm, measured at base; forefeet whitish and covered with hairs entirely whitish or that have light brownish bases and whitish tips; ungual tufts surround nails of forefeet, but do not extend beyond tips. Skull slender; rostrum delicate; tips of nasals bluntly pointed and deflected slightly downward; posterior ends of nasals blunt and extend beyond premaxillofrontal suture; nasolacrimal capsules not well developed; zygomatic arches delicate; incisive foramina long, with prevomerine process of premaxilla extending less than three-fourths their length; pterygoid wings delicate, with tips lacking distinct knob. Mandible slender; condylar process extends beyond angular process; and angular process has delicate hook. M3 longer than one-half length of M2.

DISTRIBUTION: This species is known only from its type locality in Misiones province, Argentina.

SELECTED LOCALITIES (Map 102): ARGENTINA: Misiones, junction Hwy 21 and Arroyo Oveja Negra, approximately 2 km W of Parque Provincial Moconá (type locality of *Brucepattersonius misionensis* Mares and Braun).

SUBSPECIES: *Brucepattersonius misionensis* is monotypic.

NATURAL HISTORY: The holotype, caught under a log uphill from the nearby river in December 1990, was molting and had testes that measured 13×6 mm.

Map 102 Single known locality for *Brucepattersonius misionensis* (●).

REMARKS: Together with *B. guarani*, the holotype of which is an old adult and molting specimen, *B. misionensis* was described primarily on the basis of pelage characters. These two taxa may prove to be synonyms of *B. paradisus*, the first of the three species described by Mares and Braun (2000a) from closely spaced localities, or even of *B. iheringi* (see earlier and J. F. Vilela 2005).

Mares and Braun (2000a) described a $2n=52$, FN=52 karyotype with large to small uniarmed to subtelocentric autosomes and X and Y chromosomes indistinguishable from the autosomes.

Brucepattersonius paradisus Mares and Braun, 2000

Paradise Brucie

SYNONYM:

Brucepattersonius paradisus Mares and Braun, 2000a:3; type locality "Argentina: Misiones Province: Departamento Guaraní, jct. Hwy 2 and Arroyo Paraíso. The elevation at the type locality is 197m."

REMARKS: Size medium, with head and body length 108 mm and tail 90 mm. Ears <19 mm in length, and rounded; hindfeet long, narrow, base of middle digits slightly webbed; manual digits 3 mm in length, pedal digits 5 mm. Overall dorsal coloration reddish brown; dorsal fur long and rather lax, about 10 mm in length on midrump, with dark gray basal band (about 8 mm), followed by yellowish-buffy band (about 1 mm) and dark tip (<1 mm); sides and flanks similar in color to dorsum, although slightly paler, with gradual transition from dorsum to venter, which is strongly washed with bright ochraceous; ventral hairs grayish basally, for about 50% of length; hairs of check, throat, and chin pinkish cinnamon; tip of muzzle has small patch of white hairs; outer surfaces of ears furred with hairs like those of dorsum; hindfeet dark gray and scantily clothed with hairs with brownish bases and whitish tips, with skin visible; ungual tufts extend beyond nails of hindfeet; forefeet covered with reddish brown hairs, ungual tufts surround nails, but generally do not extend beyond tips; tail essentially unicolored, overall dark gray in color, but caudal hairs unicolored dorsally and with dark bases and whitish tips ventrally; caudal hairs sparsely distributed, extending over fewer than two scale rows, underlying epidermal scales generally visible by eye, about 17 scales per cm at base of tail; tip of tail ends in short tuft of hairs 2 mm long. Skull with robust rostrum that gradually diverges posteriorly due to well-developed nasolacrimal capsules; gnathic process well developed but does not extend beyond nasals; nasal tips blunt when viewed in lateral profile, upturned, posterior ends blunted and not extending past premaxillofrontal suture; interorbital region moderately broad and hourglass in shape, with no ridges or ledges; zygomatic arches thick, slightly convergent anteriorly and slightly expanded laterally; zy-

gomatic plates narrow and inclined posteriorly from bottom to top, anterior borders convex; zygomatic notches shallow; incisive foramina long, prevomerine processes of premaxilla extend at least three-fourths length of opening and wider than one-half of greatest width; superior masseteric ridges present; pterygoid wings robust, tips with distinct knob; palate with very shallow grooves in which oblong posterior palatine foramina are located; small posterolateral palatal pits present; mesopterygoid fossa "heart-shaped," extending anterior to posterior root of M3. Mandible slender, with coronoid process well developed and condyloid process extending just slightly beyond delicate angular process with distinct lateral hook. Molar rows parallel sided or slightly convergent posteriorly; molars tetralophodont, quadritubercular, and hypsodont; M3 greater than one-half length of M2. Upper incisors orthodont.

DISTRIBUTION: *Brucepattersonius paradisus* is known only from its type locality.

SELECTED LOCALITIES (Map 103): ARGENTINA: Misiones, junction Hwy 2 and Arroyo Paraíso (type locality of *Brucepattersonius paradisus* Mares and Braun).

SUBSPECIES: *Brucepattersonius paradisus* is monotypic.

NATURAL HISTORY: The single known specimen was collected in rainforest, among rocks, 6 m uphill from the nearby river. It was molting and pregnant with two embryos,

Map 103 Single known locality for *Brucepattersonius paradisus* (●).

one in each uterine horn. The stomach was full of hair that was the same color as the animal.

REMARKS: The possibility that *B. paradisus* is conspecific with *B. iheringi* requires appropriate comparison of the holotype with series of the latter species (see J. F. Vilela 2005).

Brucepattersonius soricinus Hershkovitz, 1998

Short-tailed Bruceie, Soricine Bruceie

SYNONYM:

Brucepattersonius soricinus Hershkovitz, 1998:232; type locality "Ribeirão Fundo, São Paulo, Brazil."

DESCRIPTION: Described as one of smallest species, *B. soricinus* has relatively shortest tail (Hershkovitz 1998). Mean values for 26 specimens include head and body length 99 mm, tail length 88 mm, hindfoot length (with claw) 25 mm, and ear length 16 mm. Pelage moderately appressed, fur about 8 mm long, insufficient to conceal pinnae; dorsum brownish to dark brownish, crown to rump brown, hairs with tips minutely tipped blackish, followed by ochraceous orange band and dark gray base; guard hairs entirely blackish; sides paler than back, with wider ochraceous bands, basal portions gray; side color merges into grayish chest and belly that may be washed reddish, with hairs broadly banded pale ochraceous with bases dark gray; throat and chin dominantly gray, hairs directed forward; coloration of forelimbs and hindlimbs like that of trunk; digital vibrissae sparse, facial vibrissae short, hardly reaching ear base when laid back. Skull broad; nasal bones long, tapered, extending anterior of incisors by 1–2 mm, tips either rounded or blunt, not squared, and trumpet shaped; premaxillary bones do not reach nasal tips; zygomatic arches weak, barely spreading beyond greatest width of braincase; zygomatic plates narrow, markedly reclined posteriorly from bottom to top, hardly visible when viewed from above; interorbital region smooth, wide; braincase smooth and subglobular in shape; interparietal only 1 or 2 mm in depth; incisive foramina long and narrow, terminating slightly behind anterior plane of M1s; palate extends to or slightly behind posterior plane of M3; sphenopalatine vacuities absent. Molars tetralophodont and hypsodont; molar rows parallel sided or slightly convergent posteriorly; both M1 and m1 with median fold; enamel of anterior margin of m1 more or less crenulated, mesoloph(id)s may be present or absent; cusps ovate to subtriangular, cuspids subprismatic, opposing pairs in echelon. M3 about two-thirds size of m2.

DISTRIBUTION: This species occurs in southeastern and southern Brazil, in the states of São Paulo and Paraná, reaching the Mantiqueira massif at its northern limits.

SELECTED LOCALITIES (Map 104): BRAZIL: Minas Gerais, Itamonte, Brejo da Lapa (MNRJ 48018); Paraná,

Ortigueira (MZUSP 31623), Piraquara, Mananciais da Serra (MNRJ 78421), Telêmaco Borba (MNRJ 68342); São Paulo, Bananal, Reserva Ecológica do Bananal (MZUSP 33713), Cotia, Reserva Morro Grande (MNRJ 78678), Estação Biológica de Boracéia (MVZ 183036), Tapiraí (MZUSP [AB 201]).

SUBSPECIES: *Brucepattersonius soricinus* is monotypic.

NATURAL HISTORY: This species has been collected in the interior of well-preserved relicts of moist broadleaf forest (*floresta ombrófila densa*), under ground litter (Serra de Paranapiacaba; Umetsu and Pardini 2007), in native vegetation in early stages of regeneration, in mosaics of forest remnants, and in anthropogenic habitats (Caucaia do Alto; Umetsu and Pardini 2007). At Reserva Florestal de Morro Grande, this species was caught with a relative frequency, among 22 other species of small mammals (592 captured in all) of (0.9%) in secondary forest and 1.2% in mature, primary forest, with an overall frequency 1% (Pardini and Umetsu 2006). A specimen (MNRJ 48018) from Itamonte, Minas Gerais state, was captured in *floresta ombrófila densa*. Known localities range in elevation from sea level to more than 2,000 m.

REMARKS: We suggested earlier that *B. igniventris* might not be specifically distinct from *B. soricinus*, based on the high similarity in their mtDNA cytochrome-*b* sequences. M. F. Smith and Patton (1999), in fact, in their analysis of generic relations among sigmodontine rodents,

Map 104 Selected localities for *Brucepattersonius soricinus* (●).

allocated specimens from Base do Carmo, Fazenda Interales, Capão Bonito (*igniventris*), and Estação Biológica de Boracéia (*soricinus*) to *Brucepattersonius* “sp. 1” because they formed part of a single clade with very similar cytochrome-*b* haplotypes. J. F. Vilela et al. (2006) also noted that the haplotypes from these two localities formed a strongly supported clade relative to *B. griserufescens* (including *albinasus*).

Genus *Deltamys* Thomas, 1917

Ulyses F. J. Pardiñas and Pablo Teta

The monotypic genus *Deltamys* lives in humid grasslands, gallery forest, and marshes of central-eastern Argentina, Uruguay, and southern Brazil. Since the original description, this taxon has been considered to be a full genus (Gyldenstolpe 1932; Massoia 1980a) or a subgenus of *Akodon* (Ellerman 1941; Cabrera 1961; Massoia 1964; Reig 1987; Musser and Carleton 1993). The morphological analyses of Bianchini and Delupi (1994) and E. M. González and Massoia (1995), supplemented by chromosomal data (Gentile de Fronza et al. 1979, 1981; E. C. Castro et al. 1991), supported the generic status of *Deltamys*. Massoia (1964), Bianchini and Delupi (1994), E. M. González and Massoia (1995), E. M. González and Pardiñas (2002), and Teta, Cueto, and Suárez (2007) provided summaries of taxonomy, morphology, and/or natural history of *Deltamys*. However, we stress that the genus is still poorly known, and the extent and pattern of geographic variation deserve further exploration (see Montes et al. 2008). As noted in the introduction to the genus *Akodon*, the phyletic relationship of *Deltamys* vis-à-vis *Akodon* remains unresolved.

Deltamys kempfi is a small mouse (head and body length <100 mm), with conspicuously small eyes and dark-colored and velvety pelage. The dorsum is shiny blackish brown, and the venter is dull brownish gray. The guard hairs have dark tips and pale bases, and the under fur is grayish (Massoia 1964). A white patch on the chin is present in some populations (Massoia 1964; Bianchini and Delupi 1994). The tail, only faintly bicolored, is slightly shorter than the head plus body and is finely haired throughout. Mean Based upon 39 males and 29 females from the Ciudad Autónoma de Buenos Aires, Argentina, the ratio of tail length to head and body length was 0.8, and the ear length did not exceed 12 mm (Teta, Cueto, and Suárez 2007:Table 1). Males were significantly larger and heavier than females (Teta, Cueto, and Suárez 2007). The hindfeet are narrow and have six plantar pads and moderately long claws (ca. 2.5 mm in adults); ungual tufts are whitish or brown and are typically shorter than claws. At least in the Argentinean literature, inability to distinguish between *D. kempfi* and

Akodon azarae has often clouded the utility of anatomical (Bianchini and Delupi 1994) and parasitological (Lareschi 2000) data. *Deltamys* differs from *A. azarae* in having darker coloration, more conspicuous tail scales, and a narrower and more gracile skull, especially in regard to the rostrum, anterior portions of the frontal bones, and the zygomatic arches.

The skull is relatively long and narrow, and with a characteristic tubular-shaped interorbital region. Nasals and premaxillae project slightly beyond the incisors, and the premaxillae have moderately developed gnathic processes. The braincase is slender and inflated, while the interparietal is exceedingly slender. Zygomatic plates are narrow, with straight anterior borders and greatly reduced upper free borders. In the squamosal region, the very weak and slender descending hamular process divides the subequal subsquamosal foramen and postglenoid fenestra. A stout alisphenoid strut is present; the carotid circulatory pattern is type 1 (*sensu* Voss 1988). The tegmen tympani and the suspensory process of the squamosal are both well developed. Incisive foramina are relatively narrow, sharply pointed posteriorly, and end at the level of the M1 protocones. The postdiastemal portion of the palate is long and wide. The anterior border of the mesopterygoid fossa is wide, not reaching past the posterior edges of the M3s. The parapterygoid plates are flat and narrow. Auditory bullae are flattened, and their ventral borders do not extend below a plane defined by the molar surfaces. Periotic capsules are small, and paroccipital processes are little developed.

The mandible is elongated, slender, and low, with the masseteric crest scarcely developed. The coronoid process is relatively long, projected backward, and the condyloid process is elongated. The capsular projection, which lies at the level of the middle part of the sigmoid notch, is weakly developed.

The upper incisors are orthodont, ungrooved, and fronted by orange enamel. The molars have a moderately developed tubercular hypsodonty with usually crested crowns. As in many akodontines, in *D. kempfi* the teeth wear rapidly, losing their occlusal pattern. The M1 usually exhibits a moderately developed anteromedian flexus, but one shorter than in *Akodonazarae*. As in M2, the anteroloph and mesoloph are absent. M3 is subcylindrical. The lower molars are enlarged and simplified. The m1 is slightly larger than m2 in young individuals, or subequal to shorter in adults and senile animals; its procingulum is wide but anteroposteriorly compressed with a shallow, but distinguishable, anteromedian flexid in juveniles. The m1 appears to be divided into two subequal lobules by the opposition of the hypoflexid and the mesoflexid; m2 shows a weakly developed protoflexid; and m3 is transversely compressed, with a short hypoflexid. E. M. González and Pardiñas (2002) provided mean cranial, mandibular, and dental measurements.

Steppan (1995:Table 5) reported, based on two individuals from Uruguay, that *D. kempfi* has 13 thoracic, 6 lumbar, and 29–30 caudal vertebrae. Teta, Cueto, and Suárez (2007) provided information, based on individuals from northeastern Buenos Aires province, Argentina, on previously unknown details of the soft anatomy. There are two complete diastemal and four incomplete interdental palatal rugae, resembling the pattern described for the *boliviensis* group of *Akodon* (Myers et al. 1990). Dissection of two individuals revealed the existence of a gall bladder, the typical condition in the tribe. The stomach is unilocular-hemiglandular, with a nearly semicircular bordering fold and shallow incisura angularis. The glans penis is short and stocky, and covered by small epidermal spines imbedded in individual pits. The cartilaginous distal baculum is well developed, with the lateral digits about three-fourths the length of the medial digit. Only the medial bacular mound extrudes distally from the crater rim and is thus visible externally. Urethral flaps are long, taper distally, with well-separated tips, and extend beyond the crater rim so as to be visible externally. The osseous baculum is short and stout with a laterally flared base. In general, male genital morphology of *Deltamys* is similar to that of *Akodon* spp.

SYNONYMS:

Deltamys Thomas, 1917c:98; type species *Deltamys kempfi* Thomas, by original designation.

[*Akodon*] (*Deltamys*): Ellerman, 1941:414; as subgenus, with *kempfi* Thomas listed as sole species.

REMARKS: Although *Deltamys* has been uniformly regarded as monotypic, containing the single species *D. kempfi*, both chromosomal and molecular sequence diversity suggest at least two, possibly more species than currently recognized (e.g., K. Ventura et al. 2011; see below).

Deltamys kempfi Thomas, 1917

Delta Mouse or Kemp's Mouse (Ratón Aterciopelado)

SYNONYMS:

Deltamys kempfi Thomas, 1917c:98; type locality: "Isla Ella, in the delta of the Rio Parana, at the top of the La Plata Estuary" (Thomas 1917:95). The exact location of this island had been uncertain until, after a detailed survey of historical and geographic sources, Pardiñas et al. (2007) tentatively located Isla Ella at 34°22'S, 58°38'W, Delta del Paraná, Buenos Aires, Argentina.

Akodon ([*Deltamys*]) *kempfi*: Ellerman, 1941:414; name combination.

Akodon (Deltamys) kempfi: Cabrera, 1961:451; name combination.

Akodon obscurus obscurus: Barlow, 1963: 22; name combination but not *Akodon* [= *Necromys*] *obscurus* Waterhouse.

Deltamys kempfi langguthi Massoia, 1980a:179; *nomen nudum*.

Deltamys kempfi kempfi: E. M. González and Massoia, 1995:3; name combination.

Deltamys kempfi langguthi E. M. González and Massoia, 1995:3; type locality: "Uruguay, Montevideo, Parque Lecocq" (ca. 34°47'S, 56°22'W, 20m), Montevideo, Uruguay.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Deltamys kempfi* occurs in a small portion of southeastern South America, from northeastern Buenos Aires province (ca. 36°30'S) and southern Entre Ríos province, through Uruguay to the Brazilian state of Rio Grande do Sul (ca. 29°). In Argentina, it is known from Delta del Paraná and from several localities bordering the Río de La Plata estuary, to at least the southernmost tip of Samborombón Bay (Udrizar Sauthier, Abba et al. 2005; Teta, Cueto, and Suárez 2007). In Uruguay, it is known from the departments of Colonia, San José, Montevideo, Canelones, Maldonado, Rocha, Lavalleja, Treinta y Tres, Cerro Largo, Durazno, Tacuarembó, and Rivera (E. M. González 2001; E. M. González and Pardiñas 2002; E. M. González, unpubl. data). Brazilian records are from several coastal localities in Rio Grande do Sul state (Montes et al. 2008). A fossil record for *D. kempfi* is unknown.

SELECTED LOCALITIES (Map 105): ARGENTINA: Entre Ríos, Arroyo Brazo Largo and Arroyo Brazo Chico (Massoia 1983); Buenos Aires, Canal 6 and Paraná de las Palmas (Massoia and Fornes 1964a), Reserva Ecológica Costanera Sur (Teta, Cueto, and Suárez 2007), Reserva El Destino (Udrizar Sauthier, Abba et al. 2005), Arroyo Las Tijeras (CNP 2377). BRAZIL: Rio Grande do Sul, Tôrres (E. C. Castro et al. 1991), Osório (Montes et al. 2008), Charqueadas (Montes et al. 2008), Tapes (E. C. Castro et al. 1991), Taim (Sbalqueiro et al. 1984). URUGUAY: Rivera, Minas de Corrales (E. M. González and Massoia 1995); Tacuarembó, Paso Baltasar, Arroyo Tres Cruces (E. M. González and Massoia 1995), Treinta y Tres, Arrozal 33 (E. M. González and Massoia 1995), Lavalleja, Paso Averías, Río Cebollatí (E. M. González and Massoia 1995); Rocha, Parque Nacional Santa Teresa (E. M. González and Massoia 1995), Laguna de Castillos (Gambarotta et al. 1999); Colonia, Playa Ferrando, 2 km E Cnia. Sacramento (E. M. González and Massoia 1995), Puente del arroyo Pereira sobre RN 1 (E. M. González and Massoia 1995); Canelones, Laguna del Cisne (E. M. González and Massoia 1995); Montevideo, Parque Lecocq (E. M. González and Massoia 1995).

SUBSPECIES: E. M. González and Massoia (1995) segregated populations from Uruguay and Brazil, as *D. k. langguthi*, from the nominotypical race represented by Argentinean samples. However, neither D'Elía et al. (2003)

nor Montes et al. (2008) found support for the recognition of subspecies. We currently regard *D. kempfi* as monotypic.

NATURAL HISTORY: *Deltamys kempfi* inhabits marshy environments, particularly borders of wetlands, flooded grassland, and places with reeds and straws usually without trees (E. M. González and Pardiñas 2002). Less commonly, it is also found in woodland with a high diversity of trees and shrubs (E. M. González 1996). Most of the documented captures in Argentina were made in swamps dominated by the sedges *Scirpus giganteus* and *Schoenoplectus californicus*, relatively pure stands of the Pampa grass *Cortaderia selloana*, or in areas of dense grassy cover in humid, wooded environments (Massoia 1964; Bianchini and Delupi 1994; Teta, Cueto, and Suárez 2007). In Uruguay, E. M. González and Pardiñas (2002) collected *D. kempfi* in traps placed on floating vegetation. Despite a predilection for wet environments, this species exhibits no special external adaptations for aquatic life and has no greater swimming ability than other mice of similar size and morphology.

Bianchini and Delupi (1994) considered that the long rostrum, morphology of both manus and pes, and claw length were indicative of digging habits and an animalivorous diet. L. M. Miller and Anderson (1977) found that body proportions of *D. kempfi* correspond to those of fossorial species. Animals kept in captivity sometimes dug but usually foraged on the ground and looked for resting sites on the surface (Massoia 1964). The nest of *D. kempfi*, made with plant fibers, is spherical and sometimes placed in hollow logs (Massoia 1964). In Uruguay, one nest with three young was found in a fallen palm (*Syagrus capitata*), with the cavity entrance 30 cm above ground level (E. M. González and Pardiñas 2002). Trapping data indicate that *D. kempfi* is nocturnal. Little is known of the diet; the few stomachs examined contained insects, a few pieces of seeds, and limited remains of green plants. Barn (*Tyto alba*), Burrowing (*Athene cunicularis*), and Great Horned Owls (*Bubo virginianus*) are known predators (Massoia 1983; E. M. González and Saralegui 1996; Teta, Malzof et al. 2006; see E. M. González and Pardiñas 2002 for review).

In northeastern Buenos Aires province, males with scrotal testes and females with open vaginas were caught mostly in late winter, spring, and summer; pregnant and lactating females were recorded in spring and summer (Teta, Cueto, and Suárez 2007). In Uruguay, Gonzalez (2001) found lactating females in November (late spring) and with embryos in December and February (summer). Thus, the reproductive season seems to start at the late winter/early spring and to last until the end of summer/early autumn. Weights of reproductive individuals were 19–29 g in males and 17–28 g in females (Teta, Cueto, and Suárez 2007). Population structure in northeastern Buenos Aires province suggested

significant early spring recruitment to the late spring and summer population. Animals of intermediate age constituted the majority of individuals in autumn and winter and to a lesser extent in spring and summer. Very old animals were found mostly in spring and summer. The life span was at least 18 months in one individual, and 9 and 15 months in two others (Teta, Cueto, and Suárez 2007). Overall sex ratio, in this same study area, was 55.1% males and 44.9% females.

Autino and Lareschi (1998) and Lareschi and Mauri (1998) studied ectoparasites in Argentinean populations, including dermanyssoid mites and fleas. Individuals from coastal localities on the Río de La Plata in Argentina (Navone et al. 2009) were parasitized by the fleas *Polygenis* (*Neopolygenis*) *atopus* and *P. (P.) bohlsi bohlsi*, the mite *Androlaelaps mauri*, the flukes *Levinseniella* (*Monarrhenos*) *cruzi*, the tapeworm *Rodentolepis* sp., and the nematode *Stilestrongylus* sp. Other parasites found in *D. kempfi* from Buenos Aires province, Argentina, included the mites *Eulaelaps stabularis* and *Laelaps paulistanensis*, and the fleas *P. (Polygenis) platensis* and *P. (Polygenis) rimatus* (Autino and Lareschi 1998; Lareschi and Mauri 1998). *Deltamys kempfi* is the type host of *Androlaelaps mauri*; this mite appears to be host specific and is ubiquitous on this rodent throughout its distribution in Argentina and Uruguay (Lareschi and Gettinger 2009). Recca et al. (1996) regarded this species as rare in Argentina, but it is likely that the scarcity of records for this country is an artifact produced by misidentification of *Deltamys* specimens as *Akodon azarae*.

REMARKS: The recent phylogeographic analysis by Montes et al. (2008), based on mitochondrial and nuclear gene sequences, obtained a topology composed of two reciprocally monophyletic clades roughly north and south of Lagoa dos Patos (Brazil). Thus, a strict application of a phylogenetic species concept would support the hypothesis that each clade constitutes to a separate species. Montes et al. (2008) also claimed that there are differences in skull proportions between these two groups, but the small size of the samples analyzed means that these results should be taken with caution. Clearly, the potential existence of more than one species in what is now understood as *D. kempfi* requires further exploration.

Barlow (1969:23), following personal communication with S. Anderson and his own observations, considered this species conspecific with *Necromys obscurus* (given as *Akodon obscurus obscurus*). Because of this, and taking into account the locations of the collecting localities, his observations concerning the natural history of “*A. o. obscurus*” in Uruguay may have been based on a mixture of data from these two different species. Ximénez et al. (1972) partly clarified this situation, stating that at least the specimens housed at the AMNH were in fact referable

to *Deltamys*. A critical reexamination of the entire series referred by Barlow (1963) to *Akodon obscurus obscurus* is needed to resolve the uncertainty (see E. M. González and Massoia 1995).

The karyotype of *Deltamys kempi* is highly variable, with $2n=35$, 36, 37, and 38, but $FN=38$ (E. C. Castro et al. 1991). Gentile de Fronza et al. (1981) recorded a somatic complement of 36 acrocentric chromosomes and a single submetacentric chromosome. Chromosome studies on 28 specimens collected from two Brazilian populations revealed seven different karyotypes, due to two autosomal centric fusions (chromosomes 2 with 3 and 9 with 15) in homozygous and heterozygous states, and a Y-autosome translocation present in all males (E. C. Castro et al. 1991). Four autosomal centric fusions were found in 44% of specimens, with each rearrangement restricted to a different locality (E. C. Castro et al. 1991). In parts of its range, the species exhibits an uncommon multiple sex-chromosome determining mechanism of the type $X_1X_1X_2X_2/X_1X_2Y$ (Sbalqueiro et al. 1984), unique among sigmodontines. However, specimens from Esmeralda, Rio Grande do Sul, southern Brazil, had a $2n=40$, $FN=40$ karyotype, with a normal XX/XY sex chromosome system. These are allopatric to the main distribution of *D. kempi*. Phylogenetic analyses based on mtDNA grouped these specimens as sister to other *D. kempi* samples, and at a divergence up to 12% (K. Ventura et al. 2011). Both chromosomal and molecular differences prob-

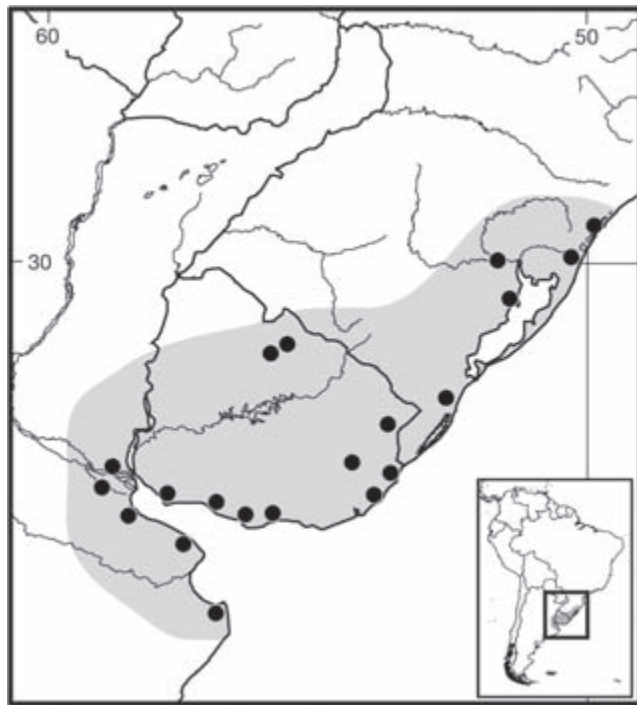

ably signify separate species status and highlight the need for a revision of the genus.

Genus *Gyldenstolpia* Pardiñas, D'Elía, and Teta, 2009

Ulyses F. J. Pardiñas and Alexandra M. R. Bezerra

This genus was recently erected for species that had previously been placed under the name *Kunsia fronto* and its relatives, a group of sigmodontines poorly known from a few, scattered fossil and Recent specimens from the Chaco and Cerrado biomes of central South America (Hershkovitz 1966a; Pardiñas, D'Elía, and Teta 2009). *Gyldenstolpia* includes two species, *G. fronto* (Winge) and *G. planaltensis* (Avila-Pires), known collectively from five localities (Bezerra 2011). There are indications that these sigmodontines were widespread in the past (Pardiñas, D'Elía, and Teta 2009).

The history of *Gyldenstolpia* started with Winge (1887) naming *Scapteromys fronto*, based on a fossil consisting of a fragment of the anterior part of a skull found in Lapa da Escrivânia Nr. 5, one of the richest fossil sites excavated by Peter Lund in the vicinity of Lagoa Santa, Minas Gerais state, Brazil. Gyldenstolpe (1932b) added a second piece to the puzzle when he described *Scapteromys chacoensis* on the basis of a single specimen, a broken skull and an imperfect skin, from the Río de Oro in the Argentinean Chaco. Gyldenstolpe (1932b:2) discussed the resemblance between the two supposedly separate species, stating that “the present species [*S. chacoensis*] seems . . . most closely allied to the subfossil form named *Scapteromys fronto* by Winge. This species is, however, only known from some rather incomplete skull fragments found in caves, and external comparison between the two forms is therefore impossible. It is rather unlikely, that they are identical as their respective type-localities are situated far from each other.” Hershkovitz (1966a) erected *Kunsia* to contain *chacoensis* and *fronto* as well as the giant forms *tomentosus* Lichtenstein, 1830, *principalis* Lund, 1840, and *gnambiquarae* Miranda-Ribeiro, 1914. Moreover, Hershkovitz (1966a) subsumed *chacoensis* Gyldenstolpe into *fronto* Winge while retaining it as a valid subspecies. Hershkovitz, though recognizing that both taxa were known from only a single specimen from their respective type localities, hypothesized larger distributional ranges for both. Based on a larger series of specimens secured during the construction of the city of Brasília, Distrito Federal, Brazil, Avila-Pires (1972) proposed *planaltensis* as a new subspecies for *K. fronto*. That same year Reig (1972) referred to *K. fronto* a fossil mandibular fragment from the Quaternary deposits in Tarija department, Bolivia, thus extending the prehistoric distribution of the genus to that country. Finally, Pardiñas,

Map 105 Selected localities for *Deltamys kempi* (●).

D'Elía, and Teta (2009) revised the “scapteromyine” genera (see the introduction to the Akodontini), based on morphological characters, separating the large and smaller forms of *Kunsia* and placing the latter in their new genus *Gyldenstolpia*. These authors also preliminarily discussed part of the fossil record associated with this group, a matter that requires more thorough investigation.

Morphologically, *Gyldenstolpia* appears to be close to *Scapteromys* and *Kunsia* and probably can be placed in the *Scapteromys* division in the Akodontini (*sensu* D'Elía 2003a), pending investigation beyond reported similarities among the included genera (Pardiñas, D'Elía, and Teta 2009). Karyological and molecular data are totally lacking for this group of taxa.

Gyldenstolpia is characterized by a unique combination of traits, including large size, short tail (ca. 55% of combined head and body length), hispid dorsal hair, and small tail scales, each covered by three hairs; small and rounded ears; unicolored manus and pes; large nasals with acute posterior ends reaching the level of the lacrimals; distinctive enlargement of the zygomatic arches; large incisive foramina reaching the level of the protocones of M1s; a denticulate and open U-shaped coronal suture; a carotid circulatory pattern with an enlarged stapedia foramen and carotid canal, with evidence of the supraorbital branch of the stapedia artery on the inferior surface of the squamosal and alisphenoid bones (pattern type 1, *sensu* Voss 1988); conspicuous coronal hypsodonty; well-developed mesolophid, protolophid, and protoconulid on both first and second lower molars; and first lower molar with three roots.

Species of *Gyldenstolpia* are large sigmodontines (total length about 300 mm, weight about 150 g) with a semi-fossorial bauplan exemplified by moderately short (ca. 10% of head and body length), rounded, and semihidden ears and short and somewhat hispid dorsal pelage; small eyes, thick and short tail (tail about 110 mm), and well-developed and powerful claws on both forefeet and hindfeet (about 4.5 and 3.7 mm in length, respectively). Coloration of the back, pes, manus, and tail is dark wood brown to grayish-brown; upper parts of the body with a glistening greenish sheen visible under certain lighting conditions; the ventral surface is a not sharply contrasting grayish-white. The hindfoot has a naked plantar surface and six pads: an elongated and distally rounded thenar, a very reduced hypothenar, and four interdigital pads subequal in size. The unicolored tail has rigid hairs and subrhomboidal scales. As currently understood, there are four pairs of mammae.

The skull is solidly built with a somewhat triangular outline when viewed dorsally, especially in *G. fronto*; the skull of *G. planaltensis* is more elongated. The rostrum is moderately long, and the zygomatic notches are both

well developed and concealed by large upper free borders of the zygomatic plates. The nasofrontal suture is U- or V-shaped and extends posteriorly to the point of contact of the premaxilla with the frontal. The interorbital region is hourglass in shape, but not especially constricted, with the lateral frontal borders varying from smoothly to more sharply divergent backward. The frontal sinuses are well inflated. The zygomatic plates are broad and medium in height; the zygomatic arches are robust, flare outward, and are dorsoventrally enlarged along their anterior one third. Postorbital processes are present and conspicuous. The incisive foramina are narrow but long, reaching posteriorly to the level of the M1 protocones. The palate is short and narrow; the anterior border of the mesopterygoid fossa is at the level of the posterior edges of the M3s. Sphenopalatine vacuities are reduced to lateral slits. The auditory capsules are medium sized and flat. A well-developed alisphenoid strut divides the foramen ovale. The subsquamosal fenestra is typically closed in adults by an enlarged hamular process, and an expanded tegmen tympani partially closes the postglenoid foramen.

The upper incisors are orthodont to slightly opisthodont; the enamel band is orange, and the dentine fissure is straight. The molars are quite hypsodont with alternating main cusps and usually planate occlusal surfaces. The procingulum of M1 lacks an anteromedian flexus; the mesolophids are greatly reduced to absent in M1–2, and M3 is noticeably cylindrical in shape. Features that characterize the lower molars include a reduced, subcircular procingulum on m1 without an anteromedian flexid, well-developed mesolophids on m1–3, and noticeable protoconulids associated with protoconids on m1. The mandible is robust, short, and moderately high, with a well-developed capsular projection.

The highly fragmented distribution of *Gyldenstolpia* is also shared by other sigmodontines in Chaco and Cerrado biomes. For example, *Juscelinomys*, a Cerrado specialist, was originally described from Brasília, Distrito Federal (Moojen 1965), and was more recently recorded from northeastern Bolivia, about 1,500 km to the west (Emmons 1999b). The known range of *Kunsia* consists of a number of isolated localities distributed across 3,000 km from the Pampas del Heath in northern Bolivia to Lagoa Santa in east-central Brazil (Bezerra, Carmignotto et al. 2007; Terán et al. 2008; Pardiñas, D'Elía, and Teta 2009). Other sigmodontines with larger and more continuous distributions also show disjunct areas of occupation, separated by large gaps (e.g., *Cerradomys*; Percequillo et al. 2008). It is unclear at present if this fragmented distributional pattern is an artifact of limited knowledge or reflects a disjunction of suitable habitats across the arid diagonal that includes the Chaco, Cerrado, and Caatinga biomes of central South America.

All nominal taxa of *Gyldenstolpia* are classified as Endangered, both in the 2011 IUCN Red List (Pardiñas, D'Elía et al. 2008) and the official list of Brazilian species at risk of extinction (A. B. M. Machado et al. 2008). The few and old records of *G. planaltensis*, in addition to its fragmented distribution, suggest that this species is already extinct or headed for extinction due to the loss of its specialized habitat (Bezerra 2011). The conservation status of *G. fronto* is presumably worse because this species is known only from the type series.

SYNONYMS:

Scapteromys: Winge, 1887:44; part (description of *fronto*); not *Scapteromys* Waterhouse.

Kunsia: Hershkovitz, 1966a:112; part (listing of *fronto*); not *Kunsia* Hershkovitz.

Gyldenstolpia Pardiñas, D'Elía, and Teta, 2009:552; type species *Scapteromys fronto* Winge, by original designation.

REMARKS: Although the date printed on the journal issue in which *Gyldenstolpia* was published reads "jul./dez.2008" (i.e., July/December 2008), this issue of the *Arquivos do Museu Nacional* was not released until 2009, and thus that year must be taken as the year of publication for nomenclatural purposes. Recognized species and subspecies in *Gyldenstolpia* are based on few and fragmentary specimens of different ages and geographic provenances. Morphological features that putatively distinguish these entities are subtle and perhaps merely reflect poorly assessed intrapopulational variation. Soft anatomy is almost unknown for any representative of *Gyldenstolpia*, despite the capture of several specimens in early 1990; no specimen as yet has been preserved in fluid. The classification used here is that of Pardiñas, D'Elía, and Teta (2009).

KEY TO THE SPECIES OF *GYLDENSTOLPIA*:

1. Skull robust; anterior border of the zygomatic plates moderately projected forward; upper toothrow >7.5 mm
..... *Gyldenstolpia fronto*
- 1'. Skull more delicate; anterior border of the zygomatic plates rounded; upper toothrow <7.5 mm.
..... *Gyldenstolpia planaltensis*

Gyldenstolpia fronto (Winge, 1887)

Fossorial Giant Rat

SYNONYMS:

Scapteromys fronto Winge, 1887:44; type locality "Lapa da Escrivania [= Lapa da Escrivânia] Nr. 5," a cave-chamber excavated by Peter W. Lund near Lagoa Santa, Minas Gerais, Brazil. The exact location of this cave is unknown, but was probably not far from the city of Lagoa Santa, 20 km N Belo Horizonte, Minas Gerais.

Scapteromys chacoensis Gyldenstolpe, 1932b:1; type locality "Argentine [*sic*], Rio de Oro, Chaco Austral" (caught in 'Lagunas de agua [*sic*] dulce'); Gyldenstolpe, 1932b:2). According to Pardiñas et al. (2007), the holotype of *chacoensis* was taken somewhere along the river where it crosses the northeastern part of Chaco province, Argentina.

Kunsia fronto fronto: Hershkovitz, 1966a:116; name combination.

Scapteromys fronto chacoensis: Hershkovitz, 1966a:116; *lapsus calami*.

G[yldenstolpia]. fronto fronto: Pardiñas, D'Elía, and Teta, 2009:554; name combination.

G[yldenstolpia]. fronto chacoensis: Pardiñas, D'Elía, and Teta, 2009:554; name combination.

DESCRIPTION: General characters as for the genus. Largest of two species, with total length ca. 330 mm, length of upper toothrow ca. 8.2 mm. Skull robust with more constricted interorbital region, with lateral frontal borders moderately sharp and divergent posteriorly, and projected anterior upper border of zygomatic plates.

DISTRIBUTION: The known present-day range of *G. fronto* is limited to a single locality in the northeastern corner of Chaco province, Argentina. Winge (1887) recorded subfossils from cave deposits near Lagoa Santa, Minas Gerais, Brazil.

SELECTED LOCALITIES (Map 106): ARGENTINA: Chaco, Río de Oro (type locality of *Scapteromys chacoensis* Gyldenstolpe).

SUBSPECIES: Pardiñas, D'Elía, and Teta (2009) recognized two subspecies, *G. fronto chacoensis* and †*G. fronto fronto*, both restricted to their respective type localities. *Gyldenstolpia f. chacoensis* is slightly larger than *G. f. fronto* and characterized by a U-shaped nasofrontal suture (V-shaped in *fronto*), a slightly acute anteriormost point of the nasals (condition unknown in *fronto*), the anterior border of zygomatic plates with distinct dorsal spines (less conspicuous in *fronto*), sharp lateral edges of the frontals (smooth in *fronto*), and a straight jugal-maxillary suture (condition unknown in *fronto*).

NATURAL HISTORY: No details of ecology have been reported.

REMARKS: *Gyldenstolpia f. fronto* is known from only four fossils of Quaternary age recovered in two caves from the Lagoa Santa area, Lapa da Escrivânia Nr. 5, the type locality, and Lapa da Serra das Abelhas (Pardiñas, D'Elía, and Teta 2009). According to Winge (1887:4), *fronto* was not represented in the recent fauna sampled by Lund from Minas Gerais state, Brazil. The holotype and unique specimen of *G. f. chacoensis* was collected in 1896, and there have been no new records since then. It is highly likely that *G. fronto* is now extinct.

Map 106 Selected localities for *Gyldenstolpia fronto* (○) and *Gyldenstolpia planaltensis* (●). Contour line = 2,000 m.

Gyldenstolpia planaltensis (Avila-Pires, 1972)

Cerrado Giant Rat

SYNONYMS:

Kunsia fronto planaltensis Avila-Pires, 1972:421; type locality “Parque Zoológico de Brasília, Distrito Federal,” Jardim Zoológico de Brasília Sgt. Sílvio Delmar Hollembach [15°51'S, 47°56'W], Brasília, Distrito Federal, Brazil (see Pardiñas, D'Elía, and Teta 2009:566).

Gyldenstolpia planaltensis Pardiñas, D'Elía, and Teta, 2009:564; first use of current name combination.

DESCRIPTION: General characters as for the genus; smaller than *G. fronto*, with total length ca. 275 mm, length of upper toothrow ca. 7.3 mm. Skull more delicate, with more elongated interorbital region, frontals with smooth lateral edges, and anterior edges of zygomatic plates not specially projected as spines.

DISTRIBUTION: Bezerra (2011) reviewed known localities; *G. planaltensis* is endemic to the central plateau of west-central Brazil, with two occurrences near Brasília, Distrito Federal, and one in the Serra do Roncador, Mato Grosso state.

SELECTED LOCALITIES (Map 106): BRAZIL: Distrito Federal, Planaltina, Águas Emendadas Ecological Station (Marinho-Filho et al. 1998, cited as *Kunsia tomentosus*, see Bezerra, Carmignotto et al. 2007; Pardiñas, D'Elía, and Teta 2009), Sgt. Sílvio Delmar Hollembach Brasília Zoological Garden (type locality of *Kunsia fronto planaltensis* Avila-Pires); Mato Grosso, Ribeirão Cascalheira, R3 Serra do Roncador (Bezerra 2011).

SUBSPECIES: *Gyldenstolpia planaltensis* is monotypic.

NATURAL HISTORY: The semifossorial bauplan of *G. planaltensis* suggests specialization for life in palustrine habitats and a digging search strategy for food (see Pardiñas, D'Elía, and Teta 2009). There is no indication of burrow use or construction by this species. Available data suggest that this rodent lives in grasslands that are probably at least seasonally flooded, and is associated with marshes and/or other fresh water bodies (Avila-Pires 1972; Langguth, Limeira, and Franco 1997; Marinho-Filho et al. 1998). The specimen from Serra do Roncador, Mato Grosso state, was caught in a transect of 7 km × 20 m, through a vegetation type described as “cerrado *sensu stricto*” (Bezerra 2011), a plant association of the Cerrado biome that is dominated by dense savanna in which trees and shrubs, ca. 3–8 m in height, comprise up to 40% of the arboreal cover. Data concerning feeding habits, reproduction, parasitology, predators, or other aspects of the natural history are lacking.

REMARKS: The specimen from Serra do Roncador departs slightly in cranial morphology from the series of *planaltensis* collected in Brasília, Distrito Federal, particularly in shape of the zygomatic plates. Until samples of some size are available from multiple localities, the significance of this apparent difference will remain obscure.

Genus *Juscelinomys* Moojen, 1965

Louise H. Emmons

Species of this genus are medium-sized, soft-furred rats with an akodontine body shape very like that of *Oxymycterus* spp. The pelage is reddish or olivaceous, and the short tail is 60–70% of the head and body length, thick at the base, tapering to the tip, and completely clothed above with stiff blackish or reddish hairs. The ears are short and well clothed with hair on both sides. The toes of the fore-foot are short, with greatly elongated claws on the middle three digits. The genus can be distinguished from all other Akodontini by the combination of broad and unusually long mesopterygoid fossa and narrow and extremely long parapterygoid plates with smoothly convex posterior margins. It can be distinguished from *Oxymycterus* by the absence of the trumpet-shaped forward projection of the nasals and premaxillaries beyond the incisors that is typical of that genus (description largely from Moojen 1965; and Emmons 1999b). The lower first molar has an antero-medial flexus. In *Juscelinomys* spp., the mandible is slender and dorsoventrally narrow; the sigmoid notch between the coronoid and condyloid processes is long, shallow, and nearly horizontal, and the coronoid process is a short, slender, posteriorly pointing hook, extending about a third of

the way across the notch (measured to the edge of the articular surface of the condyloid process). The angular process is slender below a deep notch and slender coronoid process (illustrated in Emmons 1999b). In *Oxymycterus* spp., the mandible is deep, with the sigmoid notch short, and the coronoid process generally strongly hooked so as to reach higher than the robust condyloid process. The angular process is short and blunt, below a shallow notch (illustrated in Hershkovitz 1994), but not always (Jayat, D'Elía et al. 2008). The fully haired, thick tail is distinctive. *Kunsia* has such a tail, but does not otherwise resemble *Juscelinomys*.

Jayat, D'Elía et al. (2008:35) supported a close relationship between *Juscelinomys* and *Oxymycterus* but showed that *Juscelinomys huanchacae* may fall in the clade of *Oxymycterus* spp.: "in the ML [maximum likelihood] analysis *Oxymycterus* appears paraphyletic with respect to *Juscelinomys* or, depending on the placement of the root of the tree, to a clade formed by the remaining outgroups. As this study was not designed to test akodontine generic limits nor relationships among genera, we do not further discuss this issue." Pending a more thorough analysis, Moojen's genus is retained for these species. The two known species are from the Cerrado biome in grass-dominated habitats.

This genus was erected in 1965 to include one living species from central Brazil and provisional inclusion of Winge's (1887:36) *Oxymycterus talpinus*, a Lund fossil from Lagoa Santa. Moojen (1965) admitted that Winge's figures of *Oxymycterus talpinus* were not detailed enough for certain assignment. I exclude it from the genus because the cheek teeth of the specimen from which Winge's figure of the holotype was drawn are not the correct shape for the genus (Winge 1887:plate II, Fig. 13; L. H. Emmons, pers. obs. of a recent photo; see also *Brucepattersonius* account, which includes *Oxymycterus talpinus* Winge in the synonymy of *B. iberingi*). "*Juscelinomys vulpinus* (Winge, 1887)," listed by G. A. B. Fonseca et al. (1996:28) among living species of Brazil, is an apparent confusion with *talpinus* Winge. Lund's *Mus vulpinus* is considered a synonym of *Cerradomys subflavus* (Musser and Carleton 2005; see that account) and is not near *Juscelinomys*. Emmons (1999b) described two additional species of *Juscelinomys* from Bolivia, each from a single specimen. Subsequently, Emmons and Patton (2012), based on a larger series of specimens, and including molecular comparisons, reduced *J. guaporensis* to a subjective synonym of *J. huanchacae*. Because Moojen (1965) did not explicitly designate a type for the genus, in which he included two species, I here select *J. candango* Moojen as the type species of *Juscelinomys*.

SYNONYM:

Juscelinomys Moojen, 1965:281; type species *Juscelinomys candango* Moojen, by subsequent designation, herein.

KEY TO THE SPECIES OF *JUSCELINOMYS*:

1. Upper parts ochraceous orange lined with black; ear length <15 mm; M1 with anteromedian flexus
 *Juscelinomys candango*
- 1'. Upper parts olivaceous (hairs agouti); ear length ≥16 mm; M1 lacking anteromedian flexus
 *Juscelinomys huanchacae*

Juscelinomys candango Moojen, 1965

Candango Akodont

SYNONYM:

Juscelinomys candango Moojen, 1965:281; type locality "terrenos da Fundação Zoobotânica de Brasília (alt. 1,030 m), Distrito Federal," Brazil.

DESCRIPTION (from Moojen 1965 and Emmons 1999b): Medium sized, with head and body length 128–155 mm, with short tail about 70% of head and body length. Upper parts strongly tinged rusty orange, with individual hairs gray-based and with either orange or black tips, so overall impression of pelage is reddish, streaked with black; mystacial area, cheeks, and eye-rings pure orange; nose completely hairy except between nostrils; under parts orange-buff, with sharp transition from dorsal color on sides; ventral hairs pale based, but with some individuals having sooty patches on under parts, which may be due to soiling. Ears small (12 to 15 mm) and fully haired on back and on internal, lateral surface; tail short and broad at the base, fully clothed with hairs, black basally with orange tips; generally blackish above and more orange below. Feet dusky washed with ochraceous; ungual tufts sparse, on hind toes few hairs do not reach tips of claws. Vibrissae fine and inconspicuous; mystacials reach to just behind eye when pressed back; no genitals evident; two inconspicuous superciliary vibrissae.

Skull slightly convex dorsally in lateral view, with frontal bones adjacent to nasals (frontal sinus) slightly swollen; each zygomatic arch in lateral view forms smooth, downward curve to meet squamosal; incisive foramina reach to centers of M1s, are broad and parallel sided posteriorly, but narrow with slight step for anterior one-quarter of their length; parapterygoid fossa broad anteriorly with lateral edge forming nearly straight line from behind toothrow; supraorbital edges smooth and without beading, and viewed dorsally, narrowest part of interorbital constriction rounded and does not form sharp angle. Both upper and lower first molars have anteromedian flexi; anteroloph/ids and mesoloph/ids prominent in M1/m1 and M2/m2.

DISTRIBUTION: *Juscelinomys candango* known only from its type locality in the Distrito Federal, Brazil.

SELECTED LOCALITIES (Map 107): BRAZIL: Distrito Federal, Fundação Zoobotânica de Brasília (type locality of *Juscelinomys candango*).

SUBSPECIES: *Juscelinomys candango* is monotypic.

NATURAL HISTORY: This species is known from *campo cerrado* habitat in the Cerrado biome of central Brazil, an area of grasslands with sparse trees (see photos in Hershkovitz 1998). It uses burrows, to which lead bare access paths packed with dirt excavated from these burrows. Two tunnels, oval in cross-section and 9 cm at the widest diameter, leave the surface and meet at a nest chamber about 80 cm belowground. The nests are poorly furnished with pieces of grass and fine roots. Moojen (1965) included photos of living animals and of a burrow. Stomachs contained unidentified fibrous plant material and 10 to 20 large ants. Moojen (1965) noted that the tail is fragile and that several specimens have short or missing tails.

REMARKS: In the original description, Moojen (1965) designated the holotype as female MNRJ 22.807. The specimen has been renumbered, and it is now catalogued as MNRJ 23870. I am confident that the short ear-length given in Moojen's (1965) original table (there are no measurements on the skin labels) was measured from the notch because he states of the holotype "orelha interna, 15 mm." Although he was not the collector and may not have made the measurements himself, his manual for preparation of specimens shows the ear as measured from the internal notch (Moojen 1943b), which I assume was then the standard in his research group. This species is known from

only nine specimens collected in 1960 by three collectors or projects (Pedro Brito, Ary, and O. P. Belem). Despite intensive efforts to capture additional individuals (e.g., Hershkovitz 1998), no others have ever been found. I have captured *J. huanchacae* quite easily with standard bait and large Sherman or Tomahawk traps, so the rarity of *J. candango* is likely to be genuine and not just a result of low trapability. Because it may be critically endangered or extinct, efforts should be made to document its presence and location.

Juscelinomys huanchacae Emmons, 1999

Huanchaca Akodont

SYNONYMS:

Juscelinomys huanchacae Emmons, 1999b:3; type locality "Bolivia: Santa Cruz; Provincia Velasco, Serranía de Huanchaca, Parque Nacional Noel Kempff Mercado, Campamento "Huanchaca II." [S] 14°31'25"; W 60°44'22", elev. 700 m."

Juscelinomys guaporensis Emmons, 1999b:4; type locality "Bolivia: Santa Cruz; Prov. Velasco, Parque Nacional Noel Kempff Mercado, Flor de Oro; 13°33.25'S; 61°00.51'W, elev. 210 m."

DESCRIPTION: General color uniform olivaceous, with color derived from mixture of yellow- and black-tipped hair; pelage 10–12 mm long at midback, with pale gray base, darkening to blackish at midlength, either tipped black or broadly ochraceous yellow with or without a narrow terminal black tip; color of sides similar to that of dorsum. Ventral pelage uniformly gray-based, tinged with buff or pale gray; sides of muzzle paler, washed with ochraceous yellow; chin and circumoral region whitish or yellowish; ears well-clothed inside and out with short, pale-tipped hairs, rim with slight, pale fringe; hair of forefeet and hindfeet with dusky bases and white tips; unguis tufts silvery. Claw of central digit of manus 5–6 mm in length. Tail completely covered with stiff hairs, predominately black, contrasting with body color above; paler, washed with pale buff below, palest near base, but not conspicuously bicolored. Four pairs of mammae, one pectoral, one axillary, one lower abdominal, and one inguinal. Vibrissae short, fine, and inconspicuous; mystacial vibrissae reach to behind eye; no genal vibrissae evident; and two superciliary vibrissae difficult to distinguish from pelage hairs; no vibrissae evident on forelegs.

Skull narrow, and rostrum broad; posterior part of supraorbital ridge sharp and not beaded. When viewed laterally, forward projection of frontal bones beside nasals (frontal sinus) slightly to markedly inflated dorsally, most prominently in younger individuals, producing marked convexity of skull. Anterior premaxillary bones and nasals not projected forward and upward into trumpet shape beyond incisors. Incisive foramina long and wide;

Map 107 Selected localities for *Juscelinomys candango* (●) and *Juscelinomys huanchacae* (○). Contour line = 2,000 m.

bony palate shorter than toothrows, with anterior margin of mesopterygoid fossa reaching forward of posterior edges of M3s; sphenopalatine vacuities present; carotid arterial circulation characterized by prominent squamosal-alisphenoid groove and sphenofrontal foramen; foramen ovale opens lateral to parapterygoid processes, nearly in vertical plane, and covered with broad alisphenoid strut; trough for maxillary-buccinator nerve above foramen ovale broad and prominent auditory bullae small, appressed to basioccipital bone; stapedia foramen and carotid canal large and prominent. Posterior tip of jugal-squamosal suture on internal face of zygomatic arch does not extend onto bend on squamosal portion. Mandible slender; small, sharply hooked coronoid process at same height as condyloid process, with wide, shallow notch between them; angular process of mandible slender. An anteromedian flexus present on m1, but absent on M1. Toothwear rapidly eliminates most occlusal detail. Incisors faced with orange enamel.

DISTRIBUTION: *Juscelinomys huanchacae* is known from eastern Bolivia, only from the type locality and three other localities in Parque Nacional Noel Kempff Mercado. The maximum distance between known localities is 117 km.

SELECTED LOCALITIES (Map 107): BOLIVIA: Santa Cruz, Campamento Huanchaca II, Parque Nacional Noel Kempff Mercado (type locality of *Juscelinomys huanchacae* Emmons), Campamento Los Fierros, Parque Nacional Noel Kempff Mercado (USNM 584512), Campamento Mangabalito, Parque Nacional Noel Kempff Mercado (USNM 584508), Puesto Flor de Oro, Parque Nacional Noel Kempff Mercado (type locality of *Juscelinomys guaporensis* Emmons).

SUBSPECIES: I treat *Juscelinomys huanchacae* as monotypic.

NATURAL HISTORY: The type locality (Huanchaca II) is on the Huanchaca or Caparuch tableland massif (meseta) at 700 m in a patch of wet open savanna with scattered short trees. Other specimens were captured in well-drained grasslands interspersed with woody shrubs and trees in the lowlands at the foot of the tableland (200 m elevation). This species was readily captured and recaptured in large Sherman traps with oatmeal-based baits. A male and female were often successively captured in a given trap. Stomach contents included adult ants and insect larvae as well as small amounts of plant tissue. Many females were pregnant or lactating in early October (late dry–early rainy season), but few other months were sampled. Embryo numbers were 1 to 3 (N=3). Burrows were not identified.

The tail-skin breaks easily and slips off at any point along its length, and many individuals have short or entirely missing tails. Study skins are extremely greasy, and exude oil. Over 12 years of trapping a standard plot,

Emmons (2009, and unpubl. data) observed the population of this species go to apparent extinction (0 individuals captured) for three successive years, followed by partial recovery, two more years of absence, then presence again in 2012. This suggests that this species may be susceptible to population swings that lead to local extinction of fragmented demes, a possible scenario also in the case of *J. candango*. Agroindustry and cattle raising on grasslands planted with exotic species have already destroyed much of the natural savannas of the Cerrado, particularly in the region between the localities of the two *Juscelinomys* species. Biofuel production threatens nearly all of the rest. *Juscelinomys candango* is not currently known to occur at any locality, and *J. huanchacae* is known only from sporadic presence in savanna fragments. Targeted conservation action may be needed to ensure a future for this genus.

Genus *Kunsia* Hershkovitz, 1966

Alexandra M. R. Bezerra

The genus *Kunsia* contains a single species, *K. tomentosus* (Lichtenstein, 1830), distributed in tropical open grasslands and savannas at elevations from 60 to 750 m in central Brazil and northern Bolivia (Musser and Carleton 2005; Bezerra, Carmignotto et al. 2007; Terán, Ayala, and Hurtado 2008). Fossil specimens of *Kunsia* are known from Brazilian cave deposits (Winge 1887) at Lagoa Santa in Minas Gerais state, some of which may date from the Late Pleistocene. Except as noted otherwise, the following account is based on Hershkovitz (1966a), Bezerra, Carmignotto et al. (2007), and Pardiñas, D'Elía, and Teta (2009), which should be consulted for additional details concerning taxonomy, morphology, and geographic distribution.

Kunsia tomentosus is a rare, large, semifossorial rodent, the largest of the extant Sigmodontinae (head and body length 185–287 mm and mass 241–654 g). It has harsh and dense fur; proportionally short limbs with large and powerful feet and claws; small and round ears; and a unicolored, short tail (less than half of the head plus body length) sparsely covered with short, unbanded hair and large subrectangular scales, with five to seven hairs per scale. The dorsum is dark gray, and the venter is grayish, without a sharp demarcation laterally between dorsal and ventral colors. The pinnae are covered with short hairs colored like the dorsal pelage. There are four pairs of mammae.

There are five digits on the manus; digits II to V have long claws (almost equal in length to the digit), and the pollex is reduced with a pointed nail. The plantar surface of the manus has five pads: three interdigital pads (II, III,

IV) and two proximal (carpal) pads, the thenar (at base of the pollex) and the hypothenar. The interdigital pads are small, rounded, and equidistant. The carpal pads are larger, elongate, wide, and separated. There is corrugated skin between the pads. The hindfeet have five digits, the shortest of which are digits I and V. The plantar surfaces of the hindfeet have four small and rounded interdigital pads and two tarsal pads (a reduced hypothenar and a thenar pad). The thenar pad appears elongated in dry skin preparations, but can be seen to be a small oval pad in fresh specimens. Corrugated skin also occurs between the distal pads and the thenar and hypothenar pads; the remainder of the plantar surface is smooth. There is no webbing between digits in either manus and pes.

The skull is robust, with thick bones; the rostrum is strong and short; the interorbital region is narrow; and both occipital and lambdoidal crests are well developed. Zygomatic arches have a medial dorsoventral widening involving both the jugal and maxilla. Zygomatic plates are high and very broad, with their anterior borders nearly perpendicular and adjacent to the nasolacrimal capsules; a well-developed spine is present on the upper corner. Zygomatic notches are well developed but appear nearly closed. Nasal bones are scalloped distally; the nasofrontal suture is straight. Incisive foramina extend posteriorly to the level of the anterior roots of M1s. The mesopterygoid fossa is wide and may have a short palatine median process on its anterior border, giving it a W-shape. Tympanic bullae are inflated. The carotid circulation is primitive (pattern 1 of Voss 1988), with a large stapedia foramen, a groove on the inside of the squamosal and alisphenoid, and a sphenofrontal foramen present. Some specimens show a conspicuous small foramen on the alisphenoid bone anterior to the squamosal-alisphenoid groove, at the intersection with masticatory-buccinator nerve trough (see Carleton and Musser 1989:Fig. 20B). The mandible is robust, with a short transverse portion and high ascending ramus, short coronoid process, wide and rounded condyloid process, and a short angular process that defines a shallow lunar notch. The capsular projection is well developed, and located medially between the coronoid and condyloid processes.

Kunsia has strong, smoothly faced, and orthodont upper incisors. The upper molar rows are parallel; molars are conspicuously and unilaterally hypsodont; and upper molars, when worn, are planed and trilophodont, as major folds become closed quickly with wear. M1 is transversally expanded, with the procingulum narrowing anteroposteriorly. An anteromedian flexus/flexid persists on both M1 and m1 in all wear stages. Mesoloph and mesolophids are greatly reduced or absent. M3 is cylindrical in occlusal outline; it retains a major mesofossette but lacks a hypoflexus. The first lower molar has four roots and an anterolabial

cingulum. Occlusal surfaces of both M3 and m3 are subtriangular in outline and reduced in size relative to M2 and m2, respectively.

Vertebrae counts for *Kunsia* are 12 thoracic, 6 lumbar, 3 sacral, and 23 caudal. Miranda-Ribeiro (1914) discussed several aspects of postcranial anatomy.

The stomach is unilocular-pouched, with an incisura angularis that does not extend beyond the level of the esophageal opening. Both the antrum and corpus are covered by cornified epithelium, and glandular epithelium is confined to a diverticulum located on the greater curvature of the stomach. A large, saccular gall bladder is present.

The male phallus of *Kunsia* (described and figured by Bezerra 2005) is straight, elongate, and subcylindrical, with simple spinous epidermis covering the body wall and edge of the crater. The bacular mound is spineless and slightly trifurcate, and is supported by a reduced tridigitate bacular cartilage. The urethral flap is bilobed, and the dorsal papilla is simple, dorsoventrally flattened, and spineless. The proximal portion of the osseous baculum has a heart-like shape.

SYNONYMS:

Mus: Lichtenstein, 1830:plate 33, Fig. 1, and unnumbered text; part (description of *tomentosus*); not *Mus* Linnaeus.

Mus: Lund, 1840b [1841c:276]; part (description of *principalis*); not *Mus* Linnaeus.

Scapteromys: Winge, 1887:42; part (listing of *principalis*); not *Scapteromys* Waterhouse.

Scapteromys: Miranda-Ribeiro, 1914:37; part (description of *gnambiquarae*); not *Scapteromys* Waterhouse.

Kunsia Hershkovitz, 1966a:112; type species *Mus tomentosus* Lichtenstein, by original designation.

REMARKS: *Kunsia* was originally included two species: *K. fronto* (Winge) and *K. tomentosus* (Lichtenstein) (Hershkovitz 1966a; Musser and Carleton 2005). However, the recent review by Pardiñas, D'Elía, and Teta (2009) transferred *fronto* to the new genus *Gyldenstolpia*, leaving *Kunsia* monotypic, with the single species *K. tomentosus*.

Kunsia tomentosus (Lichtenstein, 1830)

Woolly Giant Rat

SYNONYMS:

Mus tomentosus Lichtenstein, 1830:plate 33, Fig. 1, and unnumbered text page; type locality "waldigen Gegenden am Uruguay"; country unknown, restricted to the Río Uruguay in southeastern Brazil (Hershkovitz 1966a:120).

Mus principalis Lund, 1839b:208; *nomen nudum*.

Mus principalis Lund, 1840b [1841c:276]; type locality "Rio das Velhas's Floddal" (Lund 1841c:292, 294) but

listed as “Lapa da Escrivania [= Lapa da Escrivânia] Nr. 5” (Winge 1887:42), a cave excavated by P. W. Lund near Lagoa Santa, Minas Gerais, Brazil.

[*Hesperomys* (*Scapteromys*)] *tomentosus*: Peters, 1861:147; name combination.

H[*esperomys*. (*Scapteromys*)] *tomentosus*: Thomas, 1884:449; name combination.

Scapteromys principalis: Winge, 1887:42; name combination.

[*Scapteromys*] *tomentosus*: E.-L. Trouessart, 1897:534; name combination.

Scapteromys gnambiquarae Miranda-Ribeiro, 1914:37; type locality not given in the original description, but restricted to Campos Novos, Mato Grosso, Brazil, by Massoia and Fornes (1965a:6; see also Moojen 1952b:80).

Scapteromys principalis principalis: Massoia and Fornes, 1965a:4; name combination.

Scapteromys principalis gnambiquarae: Massoia and Fornes, 1965a:6; name combination.

Kunsia tomentosus tomentosus: Hershkovitz, 1966a:119; name combination.

Kunsia tomentosus principalis: Hershkovitz, 1966a:122; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: Recent records of *Kunsia tomentosus* are from Goiás, Mato Grosso, Rondônia, and Amazonas states, in Brazil, and northern and eastern Bolivia from Beni, La Paz, and Santa Cruz departments (Hershkovitz 1966a; Emmons 1999b; J. A. Miranda et al. 1999; Santos-Filho, Silva, and Silva 2001; F. H. G. Rodrigues et al. 2002; Bezerra, Carmignotto et al. 2007; Terán, Ayala, and Hurtado 2008). Pleistocene remains are known from Lagoa Santa, Minas Gerais (Lund 1839b, 1840b, 1841c; Winge 1887) and Japonês Cave in Bella Vista Municipality, Mato Grosso do Sul, Brazil (Salles et al. 2006). Hershkovitz (1966a) gave an elevational range from 200 to 1,000 m; Bezerra, Carmignotto et al. (2007) recorded localities from 60 to 750 m.

SELECTED LOCALITIES (Map 108): BOLIVIA: Beni, San Joaquín, Monte del Río Machupo (USNM 364760); La Paz, Abel Iturralde, Pampas del Heath (Terán, Ayala, and Hurtado 2008); Santa Cruz, Km 45 E of Aserradero Moira (Ibañez et al. 1994), Mangabalito, Parque Nacional Noel Kempff Mercado (Terán, Ayala, and Hurtado 2008, a correction of Margabalito cited by D’Elía and Pardiñas [2004] and Bezerra, Carmignotto et al. [2007]). BRAZIL: Amazonas, Humaitá, Escola Agrotécnica de Humaitá (Bezerra, Carmignotto et al. 2007); Goiás, Mineiros, Parque Nacional das Emas (F. H. G. Rodrigues et al. 2002); Mato Grosso, Campos Novos, Serra do Norte, Chapada dos Parecis (type locality of *Scapteromys gnambiquarae* Miranda-Ribeiro), Porto Estrela, Estação Ecológica Serra

das Araras (Bezerra, Carmignotto et al. 2007), Expedition Base Camp, 260 km north of Xavantina, Serra do Roncador (Bezerra, Carmignotto et al. 2007); Minas Gerais, Lagoa Santa, near Rio das Velhas (type locality of *Mus principalis* Lund); Rondônia, Vilhena, Fazenda Planalto (J. A. Miranda et al. 1999).

SUBSPECIES: Hershkovitz (1966a) recognized two subspecies, the widely distributed nominotypical form (with *Scapteromys gnambiquarae* Miranda-Ribeiro regarded as a synonym) and *K. t. principalis* Lund, restricted to Lagoa Santa, Minas Gerais state, Brazil. Pardiñas, D’Elía, and Teta (2009) followed suit, but concluded that differences between the two supposed taxa are subtle and may simply represent individual or age variation.

NATURAL HISTORY: *Kunsia* is known from tropical grasslands and savannas in the Cerrado and Pampas biomes in Brazil and Bolivia, respectively. Three records are also known from savanna enclaves on the southern and southwestern margins of the lowland Amazon rainforest, including Vilhena and Humaitá in Brazil and the Pampas del Heath on the border of Bolivia and Peru (Bezerra, Carmignotto et al. 2007; Terán, Ayala, and Hurtado 2008). Emmons (1998) recorded the species from lowland savanna to pampas on top of the Serranía Huanchaca in the Parque Nacional Noel Kempff Mercado in eastern Bolivia. Probably because of their large size, *K. tomentosus* has not been trapped often, and most specimens have been taken in pitfall and Tomahawk traps, but the single specimen from La Paz department, Bolivia, was captured in a medium-sized Sherman trap (7.62 × 8.89 × 22.86 cm). The few data available indicate that *K. tomentosus* is semifossorial, feeding on the roots of grasses and other vegetation as well as arthropods. Breeding may be seasonal, as pregnant females were captured in the dry season (July, a female with three embryos at Estação Ecológica Serra das Araras, Mato Grosso) and early wet season (October, a female with one embryo at Parque Nacional das Emas, Goiás). A young individual was captured in early wet season (October) at Parque Nacional das Emas (F. H. G. Rodrigues et al. 2002; Bezerra, Carmignotto et al. 2007).

REMARKS: The type locality of *K. tomentosus* is questionable, even as restricted by Hershkovitz (1966a) to the Rio Uruguay, in southeastern Brazil, between the states of Rio Grande do Sul and Santa Catarina. This site is well south of the known type of habitat and geographic range for the species, with the closest locality in the Parque Nacional das Emas in Goiás state, Brazil, nearly 1,000 km to the north (Bezerra, Carmignotto et al. 2007).

The karyotype of *K. tomentosus* consists of $2n=44$ and $FN=42$, with 21 pairs of acrocentric autosomes, a medium-sized acrocentric X chromosome, and a small acrocentric Y (J. A. Miranda et al. 1999).

Map 108 Selected localities for *Kunsia tomentosus* (●); ? = approximate position of type locality, as restricted by Hershkovitz (1966a). Contour line = 2,000 m.

Genus *Lenoxus* Thomas, 1909

James L. Patton

This is a medium-sized rat, generally dull blackish washed with gray above, with paler grayish sides, and gray-brown venter tinged slightly with buff. The ears are small but exposed, and thinly haired. The tail is moderately long (equal to or greater than head and body length), uniformly gray-brown above and below, and with a white tip that may extend as much as a quarter of its length and that strongly contrasts with the basal portion. The tail is thinly haired with the scale annuli quite visible. The plantar surfaces of the hindfeet are naked, except for that of the heel; the dorsal surface is gray contrasting with white toes. The claws of both manus and pes are short, not stoutly developed as in *Oxymycterus*. The skull is long and narrow with a basally broad but elongated snout, long and tapering nasals, a broad interorbital region with rounded margins, obsolete parietal ridges, weak and posteriorly diverging zygomatic arches, narrow and posteriorly upwardly slanting zygomatic plates, shallow zygomatic notches, long but posteriorly broad incisive foramina, broad mesopterygoid fossa penetrating anteriorly to the third molars, no posterior-lateral palatal pits, and small tympanic bullae. Reig (1987) regarded the genus as closely related to *Oxymycterus* on general morphological grounds. However, as Thomas (1909:237) noted, “this striking species has none

of the peculiar appearance characteristic of *Oxymycterus*, and there is no doubt it should form a distinct genus.”

I have found that, based on specimens in the Museum of Vertebrate Zoology, *Lenoxus* possesses a unilocular-discoglandular stomach, with the glandular epithelium confined to a diverticulum located on the greater curvature, a morphology more similar to that of *Oxymycterus* than to *Scapteromys* (as described by Carleton 1973).

Lenoxus contains the single species, *L. apicalis* J. A. Allen.

SYNONYM:

Lenoxus Thomas, 1909:236; type species *Oxymycterus apicalis* J. A. Allen, 1900, by original designation.

Lenoxus apicalis (J. A. Allen 1900)

White-tailed Akodont

SYNONYMS:

Oxymycterus apicalis J. A. Allen 1900a:224; type locality “Juliaca, Peru, altitude 6000 feet,” corrected to “Inca Mines [= Santo Domingo Mine], about 200 miles north-east of Juliaca, on the east side of the Andes, on the Inambari River [Río Inambari],” Puno, Peru, by J. A. Allen (1901b:41).

Lenoxus apicalis: Thomas, 1909:236; first use of current name combination.

Lenoxus apicalis apicalis: Sanborn 1950:15; name combination.

Lenoxus apicalis boliviae Sanborn 1950:16; type locality “Nequejahuira, Unduavi River. Altitude, 8000 feet,” La Paz, Bolivia.

DESCRIPTION: As for the genus.

DISTRIBUTION: Known from cloud forest and upper montane forest on the eastern Andean slopes of southern Peru and northern Bolivia, at elevations between 1,500 and 2,500 m.

SELECTED LOCALITIES (Map 109): BOLIVIA: La Paz, Ñequejahuira, Río Unduavi (type locality of *Lenoxus apicalis boliviae* Sanborn), Okara (S. Anderson 1997), Serranía Bella Vista (S. Anderson 1997), Ticunhuaya (S. Anderson 1997). PERU: Puno, Inca Mines, Río Inambari (type locality of *Oxymycterus apicalis* J. A. Allen), 6 mi N of Limbani (MVZ 116666), Ocanaque, 10 mi N of Limbani (MVZ 116112), 14 km W of Yanahuaya (MVZ 171512).

SUBSPECIES: Sanborn (1950) regarded Bolivian samples as constituting a subspecies (*boliviae* Sanborn) distinct from the nominotypical form from southern Peru, and S. Anderson (1997) used this name for all samples from Bolivia. My own limited comparison of samples from the Limbani Valley, which contains the type locality of *apicalis*, with those from the San Juan Valley near the Bolivian border and those from Bolivia, however, suggests that the species is monotypic.

Map 109 Selected localities for *Lenoxus apicalis* (●). Contour line=2,000 m.

NATURAL HISTORY: Peruvian specimens were trapped in runways along moss-covered tree roots or among dense ferns on the floor of elfin forest in southern Peru (C. B. Korfod and J. L. Patton field notes, MVZ archives). Sanborn (1950) noted that the Bolivian localities of Nequehajira and Okara are drier and less heavily forested than the area around the type locality at Inca (= Santo Domingo) Mine in southern Peru. No other published data on natural history are available.

Genus *Necromys* Ameghino, 1889

Ulyses F. J. Pardiñas, Pablo Teta, Pablo E. Ortiz, Jorge Pablo Jayat, and Jorge Salazar-Bravo

Necromys is one of the few highly polytypic sigmodontine genera that remain unrevised. With a midcontinental distribution, encompassing more than 5,400 km, from Trinidad and Tobago to central Argentina, and up to 30 included nominal forms, these mice have presented a continuous challenge for students of rodent systematics (Musser and Carleton 2005). Most contributions on *Necromys* taxonomy are based on a single kind of evidence and focused on a small geographic area or have limited species coverage. Some exemplars deserving special mention are studies based on dimensions and morphology of Bolivian populations of *N. amoenus*, *N. lactens*, and *N. lenguarum* (S. Anderson and Olds 1990), the morphometric analyses of geographic variation in *N. lasiurus* (Macêdo and Mares 1987)

and *N. urichi* (J. Ventura et al. 2000), and the clarification of species boundaries between *N. benefactus* and *N. obscurus* from central Argentina and Uruguay (Galliari and Pardiñas 2000). Two substantive studies established the baseline for our current understanding of the genus and this account of *Necromys* systematics. The first, which remains largely unpublished, was Reig's (1972) morphological analyses, with a shortened version of his conclusions appearing in Reig (1987) and partial results published posthumously in Reig (1994). The second is the molecular phylogenetic analyses of D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) based on mtDNA cytochrome-*b* sequences with broad taxonomic and geographic coverage (see below).

The complex taxonomic and nomenclatural history of *Necromys* is explained in part by the large geographic distribution of the genus but mostly by the morphological similarity of species in the genus to several species of *Akodon* (Akodontini) and *Zygodontomys* (Oryzomyini). In fact, the confusion among these three genera has persisted despite the fact that rodent systematists have reached important taxonomic conclusions, some of which have been partially overlooked. For example, Tate (1939:188) was clear in removing *lasiurus* from *Zygodontomys* when he wrote, "the forms from south of the Amazon typified by *tapirapoanus* are not *Zygodontomys* but *Akodon*. They can be distinguished easily by their blackish instead of whitish feet and by the extension of the palatal foramina backward as narrowed, pointed slits" (see also Voss 1991a:24, footnote). However, Hershkovitz (1962:205) reinserted the notion of a "Southern Group" of *Zygodontomys* to include *lasiurus* and several allied nominal forms. Thinking along the same lines as Tate, Massoia and Fornes (1967a) correctly removed these southern representatives from *Zygodontomys* and erected *Cabreramys* to contain *benefactus*, *obscurus*, and *lenguarum*.

Most of the nominal forms of *Necromys* were named during two time periods: the second half of the nineteenth century for those of Brazil, and the first decades of the twentieth century for those from the Andes. The generic allocation of the entities described during these times was initially to a growing yet vague concept of *Akodon*, particularly with *A. varius* and putatively related species. Gradually, however, Thomas (1902b, 1910c) and Gyldenstolpe (1932) moved several species of *Necromys* to *Zygodontomys*, a genus widespread in northern South America and southern Central America. This is not surprising because *Zygodontomys* is an unusual oryzomyine that has many features of the akodontine bauplan. In fact, the first solid clues for differentiating *Akodon* from *Zygodontomys* arose from chromosome and genital data, not from skull and molar morphology. By the time that Tate (1932h) assembled his review of "Akodont" rodents, species of *Necromys* were intermingled with those of *Akodon* and *Zygodontomys*.

Meanwhile, a poorly known Andean form (*amoenus*) remained in the nominal genus *Bolomys*, erected by Thomas (1916i) to contain forms with contrasting dorsal and ventral coloration and large inflated bullae. Three decades after Tate's treatment, Hershkovitz (1962) made an attempt to order this complex of taxa. He subsumed many Brazilian names under *lasiurus* and allocated this species to his "Southern Group" of the genus *Zygodontomys*.

Many genus-group taxa have a major systematic architect; for *Necromys*, this was Osvaldo Reig. Reig tested, by direct comparison with type material, the numerous taxonomic insights scattered in several papers of Oldfield Thomas. Also, for the southern nominal forms (*benefactus* and *obscurus*), he built on the taxonomic contributions made by Massoia and Fornes (1967a). Reig (1972:119–120) arrived at five fundamental conclusions with regard to the context and content of *Necromys*: (1) *Bolomys*, as redefined on the basis of its type species *Akodon amoenus*, is a valid and distinctive genus; (2) *A. amoenus* and *A. obscurus*, genotype of *Cabreramys*, are inseparable at the generic level, thus *Cabreramys* is a junior synonym of *Bolomys*; (3) *Akodon albiventer* does not belong to *Bolomys*; (4) *A. lactens* is a valid species of *Bolomys*; and (5) Hershkovitz's "Southern Group" of *Zygodontomys* and *Akodon arviculoides* are also to be included in *Bolomys*. In 1987, Reig published his main findings concerning this new consolidated and clarified *Bolomys*. Several years before, however, Massoia (1985b) had found a critical piece of this complex puzzle. In revising materials in the collections made by the famous paleontologist Florentino Ameghino and housed at the Museo Argentino de Ciencias Naturales "Bernardo Rivadavia" in Buenos Aires, Massoia realized that the specimens on which Ameghino had based the name *Necromys conifer* were morphologically indistinguishable from *Akodon benefactus*, a realization that made *Necromys* Ameghino, 1889 a senior synonym of *Bolomys* Thomas. Although Reig (1989) quickly accepted this nomenclatural conclusion, other contemporaries (Voss 1991a,b, 1992; S. Anderson 1997; M. M. Díaz 1999) were reluctant to use *Necromys*. As a result, both *Necromys* and *Bolomys* were used interchangeably for many years. Even after Massoia and Pardiñas (1993) fully documented the correspondence between the two generic names, the priority of *Necromys* was not firmly established until the treatise of Musser and Carleton (2005). In the intervening period, the *urichi* group from northern South America, which had been traditionally placed in the subgenus *Chalcomys* of *Akodon*, was found to belong with *Necromys*, as based on molecular phylogenetic analyses (M. F. Smith and Patton 1991, 1993; D'Elía 2003a). None of the authors, from Thomas (1916i) to Reig, Kiblicky, and Linares (1971), who had viewed *urichi* from a morphological viewpoint, had recognized the similarities between it and species of *Necromys*.

Seven living and one fossil species are currently recognized in *Necromys* (Musser and Carleton 2005; D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008). Isolated in northern South America (i.e., Venezuela, Colombia, and Trinidad and Tobago), the *N. urichi* complex inhabits forests, grasslands, shrublands, and montane areas. Along eastern Andean slopes and up to Puna habitats are three species that replace one another from north to south: *N. punctulatus*, *N. amoenus*, and *N. lactens*. Only a few Ecuadorean and Colombian specimens, all with ambiguous geographic provenance, are known for *N. punctulatus* (Voss 1991b). *Necromys amoenus* and *N. lactens* have widespread and parapatric Andean ranges, collectively extending from 12°S in southern Peru to 29°S in Argentina. A third group of species extends throughout the eastern lowlands south of the Rio Amazonas. This group comprises an endemic Chacoan representative, *N. lenguarum*, and the very similar and more widespread *N. lasiurus* that is distributed primarily in Cerrado, Caatinga, and other lowlands in tropical, subtropical, and temperate areas of the east-central midcontinent but also extends into the Chaco. Finally, a coastal grassland-shrubland specialist, *N. obscurus*, exhibits a disjunct distribution in southern Uruguay and eastern Buenos Aires province, Argentina. Most of the species of *Necromys* have small (e.g., *N. obscurus*, ca. 15,000 km²) to medium-sized (e.g., *N. lactens*, ca. 100,000 km²) ranges, with that of *N. lasiurus* contrasting strongly, as it covers more than 4 million km², from fragmented grasslands in the Amazon Basin to the northern boundary of Patagonia.

A comprehensive morphology-based assessment of *Necromys* diversity is still needed. Reig's (1972) attempt to make one was restricted to molar comparisons, and S. Anderson and Olds (1989) focused on only a few species. The extensive phenotypic variation seen in some species, especially in color but also in size, has contributed to the confusion regarding species boundaries and thus geographic ranges (Macêdo and Mares 1987; J. Ventura et al. 2000).

Members of *Necromys* are generalized akodontines in external morphology, with heavy bodies, medium-sized eyes and ears, short limbs and tails, and unspecialized forefeet and hindfeet that cause them to be easily confused with several species of *Akodon* (especially those of the *A. varius* species group in the case of the southern *Necromys* and with *saturatus* of the northern *N. urichi* complex). Size in *Necromys* varies from small in Andean forms, with combined head and body length of about 100 mm, to large in lowland forms, in which it reaches 130 mm (the holotype of *N. tapirapoanus*) or 133 mm (syntype of *N. obscurus*). *Necromys obscurus* has been stated to be the largest species (Massoia and Fornes 1967a; Galliari and Pardiñas 2000), but some Amazonian and Chacoan species are of equal or larger size (Macêdo and Mares 1987; S. Anderson

and Olds 1990). In addition, there is significant variation in size within species; for example, in *N. lasiurus*, populations assigned to the nominal form *temchuki* are markedly larger than the southernmost populations of the nominal form *benefactus* (Massoia and Fornes 1967a; Massoia 1980c, 1982; J. R. Contreras 1982a). The length of the tail is always shorter than that of the head and body; *Necromys* is considered to be a short-tailed taxon, especially in comparison with *Akodon* (S. Anderson and Olds 1990). Although this is true for the many forms of *Necromys* that have tails that range in length between 50–65% of the head and body length (e.g., *benefactus*, *lasiurus*, *punctulatus*, *negrito*, *orbis*, *obscurus*, *tapirapoanus*), Andean forms such as *N. amoenus* have longer tails (about 75% of the head and body length), and the tail is even longer in the *urichi* complex (about 80% in *meridensis*). Typically, in *Necromys* the hindfoot is relatively narrower than in any species of *Akodon*, and digit V is much shorter in relation to IV. In *Akodon*, the claw of digit V extends to the most proximal interphalangeal joint of IV, but in *Necromys* the claw of V extends either only about one-half or two-thirds the length of the proximal phalanx of IV or does not extend past the anteriormost interdigital pad (Massoia and Fornes 1967a; Voss 1991a). Claws of both forefoot and hindfoot are large (except in *N. urichi*; Reig, Kiblicky, and Linares 1971) and curved; in the hindfoot, the claw of digit III is greater than 50% of the length of this digit itself (Voss 1991a).

Necromys has a short rostrum, deep and often wide zygomatic notches, a posteriorly divergent interorbital region with ridged edges, relatively narrow incisive foramina, narrow parapterygoid fossae, reduced or absent pterygoid bridges, and anterior face of upper incisors that extends anterior to the premaxillae, a reduced anteromedian flexus on M1, and lacks an anteromedian flexid on m1 (S. Anderson and Olds 1990:15). The Andean forms *N. amoenus* and *N. lactens* are characterized by paler, proodont to orthodont upper incisors, broad interorbits, and short free upper edges of the zygomatic plates. In contrast, lowland *Necromys* populations now referred to as *N. lasiurus* and *N. languarum* have orthodont, saturated orange upper incisors; larger nasals; interorbits with posteriorly divergent edges; and zygomatic plates with well-developed upper free borders. *Necromys obscurus* differs somewhat from other species owing to its inflated frontal sinuses, smooth edges of the frontal bones, U-shaped frontoparietal suture, and a well-developed capsular process that is centrally located between the coronoid and condyloid processes. Apparently, all *Necromys* species share a well-developed alisphenoid strut partially covering the anterior opening of the alisphenoid canal, although this strut is weaker in *N. amoenus* and *N. lactens*. Many species of *Necromys* lack the pterygoid bridge, a delicate boney bar

that crosses the posterior opening of the alisphenoid canal (S. Anderson and Olds 1990:Fig. 6).

Reig (1978) described the extinct species *Necromys bonapartei*, based on a fragmentary mandible with two molars and found by José Bonaparte in Monte Hermoso, southwestern Buenos Aires province, Argentina. The available information attached to this fossil indicates that it came from the upper part of the Lower Pleistocene Monte Hermoso Formation (Pardiñas and Tonni 1998). However, a study in progress of the holotype and only known specimen of *N. bonapartei* casts doubt on its generic allocation. Several traits shown by this specimen are more similar to those of phyllotines, especially the absence of mesolophids, the robustness of the masseteric crest, and the proportions of M2 as compared to M1. Thus, if *bonapartei* were excluded from the genus, the oldest remains attributed to *Necromys* would be those reported from Pliocene deposits exposed near Miramar, Buenos Aires province (Reig 1972, 1994, cited as “*Bolomys* sp. A”). The referred material, a fragmentary left dentary, makes it difficult to differentiate this taxon from generalized akodontines such as *Akodon*. Voglino and Pardiñas (2005) recorded *Necromys* cf. *N. lasiurus* (cited as *benefactus*) in a micromammal assemblage from northeastern Buenos Aires province with an age close to the Brunhes-Matuyama paleomagnetic boundary (ca. 0.78 mya). The genus is apparently also present in the Middle-Late Pleistocene of the Tarija Basin, Bolivia (Stepan 1996; referred to *Bolomys*). Late Pleistocene and Holocene records of *Necromys* are widespread, documenting its presence in central (Pardiñas, Teta, and D’Elía 2010) and northwestern Argentina (P. E. Ortiz et al. 2011b), southern Bolivia (Hoffstetter 1968; Pardiñas and Galliari 1998c), and southeastern Brazil (Winge 1887; Salles et al. 2006). The Late Pleistocene type species of the genus, *N. conifer*, is from northeastern Buenos Aires province (Ameghino 1889). *Necromys* spp. have undergone significant changes in abundance and distribution during the last millennia or recent centuries according to fossil evidence from the Pampean region of Argentina, which conclusively documents regional extinctions and population fragmentation (Pardiñas 1999b; Galliari and Pardiñas 2000).

Most species of *Necromys* possess a karyotype with 34 chromosomes (Reig 1987; Tiranti 1996a). Vitullo et al. (1986) described the diploid autosomal complement as consisting of acrocentrics except for a single metacentric pair, the smallest in the series. A $2n=34$ (FN 34) has been reported for the species and nominal forms *N. amoenus*, *N. obscurus*, *N. benefactus*, *N. lasiurus*, and *N. temchuki* (N. O. Bianchi et al. 1971; A. L. Gardner and Patton 1976; Vitullo et al. 1986; Tiranti 1996a; Fagundes and Yonenaga-Yassuda 1998); a minor variant, $2n=33$, was found in animals referred to *N. lasiurus* and from Serra dos Cavalos, Pernambuco, Bra-

zil (Maia and Langguth 1981; Svartman and Cardoso de Almeida 1993c). In contrast, animals published under the names *N. urichi meridensis* and *N. urichi venezuelensis* have a diploid number of 18, with the autosomal complement consisting of entirely metacentric chromosomes (N. O. Bianchi et al. 1971; Reig, Kiblicky, and Linares 1971; Reig, Olivo, and Kiblicky 1971).

Akodon and *Necromys* have been recognized as closely related genera, according to morphological, electrophoretic, and mtDNA sequence data (Reig 1987; M. F. Smith and Patton 1999). Phylogenetic reconstructions place *Necromys* sister to the clade *Akodon-Thaptomys* (M. F. Smith and Patton 1993, 1999), to *Thaptomys* (D'Elía et al. 2003), or to *Thalpomys* (D'Elía 2003a), depending upon the gene sequence studied. D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) conducted the most recent phylogenetic analysis of *Necromys* phylogeny. These authors found a three-lineage polytomy at the base of *Necromys*: one clade comprised *N. urichi* and *N. amoenus*, a second was formed by only *N. lactens*, and a third included all lowland species occurring south of Amazonia. Given this polytomy, an alternative classificatory option would be to recognize three genera: *Necromys* for the morphologically homogeneous lowland forms; *Bolomys* for *amoenus* and *urichi* (and probably *punctulatus*); and a third unnamed genus for *lactens*.

SYNONYMS:

Ratton Brants, 1827:187; part (inclusion of *Ratton colibreve*, which was based on Azara's [1802:86] "*el colibreve*"; suppressed for the purpose of Principle of Priority [but not Homonymy] by the International Commission [ICZN 1982:Opinion 1232]).

Mus: Waterhouse, 1837:16; part (description of *obscurus*); not *Mus* Linnaeus.

Habrothrix: Winge, 1887:31; part (listing of *lasiurus*); not *Habrothrix* Wagner.

Necromys Ameghino, 1889:120; type species *Necromys conifer* Ameghino, by original designation.

Abrothrix: J. A. Allen and Chapman, 1893:217; part (series used in subsequent description of *urichi* J. A. Allen and Chapman referred to as *Abrothrix caliginosus* [now = *Melanomys caliginosus*]); not *Abrothrix* Waterhouse.

Acodon: Thomas, 1894b:361; part (description of *punctulatus*); not *Acodon* Agassiz nor *Akodon* Meyen.

Akodon: J. A. Allen and Chapman, 1897a:19; part (description of *urichi*); not *Akodon* Meyen.

Zygodontomys: Thomas, 1902a:61; part (listing of *brachyurus*); not *Zygodontomys* J. A. Allen.

Akodon (*Chalcomys*): Thomas, 1916i:338; part (listing of *urichi*, *venezuelensis*, and *meridensis*); not *Akodon* Meyen nor *Chalcomys* Thomas.

Bolomys Thomas, 1916i:337; type species *Akodon amoenus* Thomas, by original designation.

Akodon [(*Akodon*)]: Ellerman, 1941:410; part (listing of *arviculoides*, *lenguarum*, *obscurus*, *chapmani*, *meridensis*, *urichi*, and *venezuelensis*); not *Akodon* Meyen.

Akodon [(*Bolomys*)]: Ellerman, 1941:415; part (listing of *amoenus*, *lactens*, *negrito*, and *orbis*); name combination.

Cabreramys Massoia and Fornes, 1967a:418; type species *Mus obscurus* Waterhouse, by original indication.

KEY TO THE SPECIES OF *NECROMYS*:

1. $2n=18$; length of tail about 80% of head and body length; range in Venezuela, Colombia, and Trinidad and Tobago *Necromys urichi*
- 1'. $2n=34$; length of tail <80% of head and body length
2. Isolated populations in Colombia and Ecuador. *Necromys punctulatus*
- 2'. Andean ranges of Peru, Bolivia, and Argentina; and lowlands of Bolivia, Brazil, Paraguay, Argentina, and Uruguay 3
3. Upper incisors pale, distinctly proodont; range in Andes of Peru, Bolivia, and Argentina. 4
- 3'. Upper incisors shiny orange, orthodont; range in lowlands of Bolivia, Brazil, Paraguay, Argentina, and Uruguay 5
4. Head and body length ca. 100 mm; auditory bullae enlarged, rounded; sphenopalatine vacuities present *Necromys amoenus*
- 4'. Head and body length ca. 120 mm; auditory bullae small, flattened; sphenopalatine vacuities absent. *Necromys lactens*
5. Head and body length ca. 110 mm; foreclaws as large as corresponding digits; interorbital region without marked edges; frontal sinuses well inflated *Necromys obscurus*
- 5'. Head and body length ca. 115–130 mm; foreclaws shorter than corresponding digits; interorbital region with marked constriction point and posteriorly divergent frontal edges; frontal sinuses not well inflated. . . 6
6. Populations mostly restricted to Boreal Chaco; nasals long, obscuring incisors when skull viewed from above *Necromys lenguarum*
- 6'. Populations mostly restricted to arid to mesic lowlands of Paraguay, Brazil, and Argentina; nasals shorter *Necromys lasiurus*

Necromys amoenus (Thomas 1900)

Pleasant Akodont

SYNONYMS:

Akodon amoenus Thomas, 1900h:468; type locality "Callalla, rio Colca, near Sumbay, [Arequipa,] Peru, elevation 3500 m."

Bolomys amoenus: Thomas, 1916i:340; name combination.

Akodon [(*Bolomys*)] *amoenus*: Ellerman, 1941:415; name combination.

Necromys amoenus: Massoia, 1985b:4; first use of current name combination.

DESCRIPTION: Small, with head and body length 95–103 mm (N=11); upper parts yellowish brown, finely streaked with black hairs; sides more clear and richly colored, yellowish buff on muzzle, side of head, and side of rest of the body, forming well-defined lateral line in some specimens; under parts whitish, sharply contrasting with rest of body; hairs on chin and, in some cases, throat completely white. Vibrissae relatively short, and ears densely furred with hairs of same general hue as muzzle. Most specimens show well-developed eye-ring. Forefeet and hindfeet with ochraceous dorsal hue; claws covered with dense tuft of hairs. Tail short (63–79 mm; N=11), bicolored, dorsally ochraceous brown or blackish brown, and ventrally white or ochraceous. Skull with short rostrum (even shorter than *N. lactens*), zygomatic notches proportionally broad and deeply excavated, zygomatic arches bowed outward, and interorbital region with squared and posteriorly divergent dorsolateral margins; nasals short, not surpassing anterior plane of upper incisors; zygomatic plates relatively broad, with straight or slightly concave anterior margins that slant slightly backward from bottom to top; temporal crests relatively weak, but lambdoidal crests well developed; mesopterygoid fossa relatively broad and parapterygoid fossae narrow; bullae large for genus. Mandible delicate but body relatively deep; masseteric ridges extend to anterior face of m1 and end at level of mental foramen; capsular projection conspicuous, located under sigmoid notch and slanted backward. Upper incisors notably proodont, faced with whitish or yellowish enamel. Molars robust, broad, and with almost completely transversely oriented principal cusps; M1 with relatively small procingulum, shallow anteromedian flexus in young specimens, tiny anteroloph, and well-developed mesoloph; M2 with trace of mesoloph; M3 with hypoflexus and mesoflexus, the latter tending to form island. Lower m1 with deep anteromedian flexid, anterolabial cingulum, ectolophid, and tiny mesolophid; m2 conserves labial structures but is reduced; m3 S-shaped.

Axial skeleton with 13 thoracic, 6 lumbar, and 23–26 caudal vertebrae (Steppan 1995); phallus and baculum described by Spotorno (1986), stomach by Dorst (1973b); estimates of heart size in relation to body size reported by Dorst (1973a).

DISTRIBUTION: *Necromys amoenus* is known from relatively few localities in Altiplano grasslands above 3,200 m in southern Peru and western Bolivia and from high grasslands of the eastern Andean slopes in Salta province, Argentina, at 3,100 m (S. Anderson and Olds 1990; S. Anderson 1997; Salazar-Bravo, Yensen et al. 2002; Musser

and Carleton 2005; Jayat et al. 2006; Jayat, Ortiz, and Miotti 2008).

SELECTED LOCALITIES (Map 110): ARGENTINA: Salta, 1 km ENE Rodeo Pampa, km 59 on Rte 7 (MACN 24849). BOLIVIA: Chuquisaca, Potolo (= Estancia Puyayoj), 22 km S and 13 km E of Icla (Salazar-Bravo, Yensen et al. 2002); Cochabamba, Colomi (BM 266), 9.5 km by road SE of Rodeo, then 2.5 km on road to ENTEL antenna (AMNH 260890); La Paz, 2.5 km S of Tacacoma (Salazar-Bravo, Yensen et al. 2002); Tarija, Serranía del Sama (MSB 67194). PERU: Arequipa, 15 km S of Callalli (MVZ 174058); Cusco, 20 km N (by road) of Paucartambo, km 100 (MVZ 171563); Puno, 11 km W and 12 km S of Ananea (MVZ 172894), Hacienda Ontave (MVZ 141329), 36 km SE (by road) of Macusani (MVZ 173202), Puno (AMNH 213552), 12 km S of Santa Rosa (MVZ 172878).

SUBSPECIES: We treat *Necromys amoenus* as monotypic (but see Remarks).

NATURAL HISTORY: Of three specimens collected in August in high-elevation grasslands of northwestern Argentina, one male had semiscrotal testes, and all were molting. These specimens were caught in rocky places intermingled with sparse grasses. Salazar-Bravo, Yensen et al. (2002) reported two specimens caught at the base of rock outcrops, on rocky soils among ferns and mosses in the *Bosque húmedo-montano subtropical* life zone. An additional specimen mentioned by Salazar-Bravo, Yensen et al. (2002) came from a barley field surrounded by *Polylepis* woodlands in the *Bosque húmedo-montano templado*. This species is apparently mostly insectivorous but with some variation between localities (Pizzimenti and DeSalle 1980; Dorst 1973b). Individuals are diurnal and often associated with open grassy places, dominated by *Stipa ichu* or *Tola*

Map 110 Selected localities for *Necromys amoenus* (●). Contour line = 2,000 m.

(*Parastrephia lepidophylla*) (Pearson 1951). Reynafarja and Morrison (1962) and Morrison et al. (1963) examined hematocrit values and myoglobin levels with respect to high-elevation adaptation.

REMARKS: *Necromys amoenus* is the type species of *Bolomys*, which was later considered to be a junior synonym of *Necromys* (Massoia 1985b; Reig 1989; Massoia and Pardiñas 1993).

D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) suggested that *N. amoenus* might be a composite of more than one species. They found a deep phylogeographic break between haplotypes in Cusco and Puno departments, southern Peru, and ones from Tarija, in southern Bolivia, and from Salta, in northwestern Argentina, with large genetic divergence between clades.

Necromys lactens (Thomas 1918)

White-chinned Akodont

SYNONYMS:

Akodon lactens Thomas, 1918b:188; type locality "Leon [= León], Jujuy, Argentina, elevation 1500 m."

Akodon orbus Thomas, 1919d:497; type locality "Otro Cerro" Catamarca, Argentina (= Otro Cerro, 28°45'S, 66°17'W, 2,023 m, Capayán, Catamarca, about 4 km SSE of Cerro Catalán; Pardiñas et al. 2007).

Bolomys negrito Thomas, 1926a:312; type locality "Las Paras [= Las Pavas], about 4000 m" Tucumán, Argentina.

Bolomys lactens: Thomas, 1926d:605; name combination.

Bolomys orbus: Gyldenstolpe, 1932a:119; name combination.

Akodon [(*Bolomys*)] *lactens*: Ellerman, 1941:415; name combination.

Akodon [(*Bolomys*)] *negrito*: Ellerman, 1941:415; name combination.

Akodon [(*Bolomys*)] *orbus*: Ellerman, 1941:415; name combination.

Necromys lactens: Massoia, 1985b:4; first use of current name combination.

DESCRIPTION: Medium size, with head and body length 98–124 mm (N=29, age class 3 from northwestern Argentina); upper parts buffy brown, finely lined with black; sides paler and richly colored, fulvous or cinnamon in some specimens; under parts often cinnamon, but with varying intensity. All examined individuals from high-elevation grasslands of northwestern Argentina with contrasting white spot on chin and/or throat. Vibrissae relatively short, and ears densely furred with hairs of same color as rest of dorsum. Some specimens with well-developed eye-ring. Claws relatively long and covered with tuft of white hairs. Tail short (57–77 mm, N=30 specimens of age class 3 from northwestern Argentina), bicolored, dorsally blackish brown and whitish or buffy in ventral view. Skull with short ros-

trum, zygomatic notches relatively narrow and shallow, and interorbital region ridged with posteriorly divergent dorsolateral margins; nasals short, not surpassing anterior plane of upper incisors; zygomatic plates relatively broad, with slightly concave anterior margins and slanted slightly backward, from bottom to top; incisive foramina end posteriorly at about level of protoflexus or anterior face of protocone of M1; mesopterygoid fossa relatively broad, with anterior margin rounded or slightly squared, with or without median spine, and lateral sides diverge slightly backward; parapterygoid fossae narrow, with straight lateral edges that diverge slightly posteriorly. Mandible delicate but with relatively deep body; masseteric ridge extends to anterior face of m1 and ends at same level as mental foramen; capsular projection conspicuously expressed as backwardly slanting knob located under sigmoid notch. Upper incisors proodont, with anterior face whitish or yellowish. Molars robust, broad, and with principal cusps almost completely transverse; M1 with well-developed, fan-shaped procingulum with shallow anteromedian flexus in young specimens; some individuals with a small mesostyle; posteroflexus tending to form enamel island in young specimens; M2 occasionally with trace of mesoloph and posteroflexus tending to form island; M3 large, with deeply penetrating mesoflexus and hypoflexus. Lower m1 with well-developed procingulum with deep anteromedian flexid (forming island in some young specimens), anterolabial cingulum, and trace of ectolophid and mesolophid in some individuals; m2 with anterolabial cingulum; m3 large and S-shaped.

DISTRIBUTION: *Necromys lactens* occurs between 1,400 and 4,000 m in the eastern Andean highlands of south-central Bolivia and northwestern Argentina (S. Anderson and Olds 1990; S. Anderson 1997; P. E. Ortiz, Cigrignoli et al. 2000; Musser and Carleton 2005; Jayat and Pacheco 2006; Jayat et al. 2006; Jayat, Ortiz, and Miotti 2008; M. M. Díaz and Barquez 2007). The fossil record for *N. lactens* is restricted to two localities in the Tafí valley, Tucumán, Argentina, representing the Middle-Upper Pleistocene and the Pleistocene-Holocene boundary (P. E. Ortiz and Pardiñas 2001; P. E. Ortiz and Jayat 2007b; P. E. Ortiz et al. 2011b).

SELECTED LOCALITIES (Map 111): ARGENTINA: Catamarca, ca. 2 km SE of Huaico Hondo, on Rte 42, E of Portezuelo (MACN 23484), Otro Cerro (type locality of *Akodon orbus* Thomas); Jujuy, La Antena, Sierra del Centinela, S of Fuerte (MACN 23492), León (type locality of *Akodon lactens* Thomas); Salta, ca. 15 km W of Escoipe, on Rte 33 (Jayat, Ortiz, and Miotti 2008); Tucumán, Las Paras (type locality of *Bolomys negrito* Thomas). BOLIVIA: Chuquisaca, 14 km N of Monteagudo, Cañon de Herida, Río Bañado (S. Anderson 1997); Cochabamba,

14 km SE of Rodeo (S. Anderson and Olds 1993); Tarija, Rancho Tambo, 61 km by road E of Tarija (S. Anderson 1997), Serranía del Sama (S. Anderson 1997).

SUBSPECIES: We treat *Necromys lactens* as monotypic.

NATURAL HISTORY: In northwestern Argentina, *N. lactens* principally inhabits high-elevation grasslands between 1,500 and 3,100 m, in the highest vegetation belts of the *Yungas* ecoregion (M. M. Díaz et al. 2000; Jayat and Pacheco 2006; M. M. Díaz and Barquez 2007; Jayat, Ortiz, and Miotti 2008). M. M. Díaz and Barquez (2007) reported specimens caught near water at Cerro Hermoso and Chilcayoc, Jujuy province, Argentina. These authors registered females with closed vaginas and males with abdominal testes in July and September, and a female with developed mammae in July. Additional unpublished data suggest that *N. lactens* reproduces mainly between November and April and molts primarily during fall and winter (May to July). In this region, the species is mainly diurnal.

REMARKS: Capllonch et al. (1997) resurrected *orbis* (as *Bolomys orbis*), based on a single specimen from Tucumán province (northwestern Argentina), but Pardiñas and Galliari (1998b) criticized this decision. Phylogenetic studies conducted by D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) recovered *N. lactens* as one of the three main lineages in the genus. The geographic structure of the mtDNA variation these authors observed was consistent with a history molded by the high-altitude grasslands of the central Andes. Their study included haplotypes obtained from near the type localities of *lactens* Thomas, *negrito* Thomas, and *orbis* Thomas, all found to be closely related with molecular divergence about 2%.

Map 111 Selected localities for *Necromys lactens* (●). Contour line = 2,000 m.

Necromys lasiurus (Lund, 1840)

Hairy-tailed Akodont

SYNONYMS:

Mus lasiurus Lund, 1838:50; *nomen nudum*.

Mus lasiotis Lund, 1838:50; *nomen nudum*.

[*Mus*] *lasiolis* Lund, 1839a:233; *nomen nudum*; incorrect subsequent spelling of *Mus lasiotis* Lund.

Mus lasiuuro Lund, 1839b:208; *nomen nudum*.

Mus lasiurus Lund, 1840b:50 [1841c:280]; type locality "Rio das Velhas's Floddal," Lagoa Santa, Minas Gerais, Brazil.

Mus lasiotis Lund, 1840b:50 [1841c:280]; type locality "Rio das Velhas's Floddal"; refined to "Curvelo, una localidad ubicada al WNW de Lagoa Santa en el valle del Rio das Velhas a los 18°45'S, 44°25'W, Brasil" by Langguth (1975:45).

Hesperomys arviculoides Wagner, 1842a:361; type locality "Brasilia" = the country of Brazil, not the capital city of Brasília (see comments in Ximénez and Langguth 1970:3).

Hesperomys orobinus Wagner, 1842a:361; type locality "Brasilia" = Brazil (see comments in Ximénez and Langguth 1970:3).

Mus renggeri Pictet and Pictet, 1844:76, plates 21, 22, and 23, Fig. 7; type locality "Bahia," Brazil; not *renggeri* Waterhouse (= *Abrothrix olivacea*).

Hesperomys brachyurus Wagner, 1845:147; type locality "Itararé," São Paulo, Brazil.

Akodon fuscinus Thomas, 1897c:496; type locality "Source, Marajó Island"; interpreted as a misspelling of Soure (0.721°S, 48.504°W), Ilha Marajó, Pará, Brazil by Hershkovitz (1962:205).

Necromys conifer Ameghino, 1899:120; type locality "Mercedes, Olivera y Luján, en la provincia de Buenos Aires," Argentina.

Akodon benefactus Thomas, 1919c:214; type locality "Bonifacio, South-west Buenos Ayres, Province; alt. 50"; Laguna Alsina (= Estación Bonifacio; 36.809°S, 62.245°W), Argentina.

Zygodontomys arviculoides: Tate, 1932h:17; name combination.

Zygodontomys brachyurus: Tate, 1932h:17; name combination.

Zygodontomys fuscinus: Tate, 1932h:17; name combination.

Zygodontomys lasiurus: Tate, 1932h:17; name combination.

Zygodontomys orobinus: Tate, 1932h:17; name combination.

Zygodontomys pixuna Moojen, 1943a:8; type locality "Crato, Ceará," Brazil.

Zygodontomys lasiurus brachyurus: Hershkovitz, 1962:206; name combination.

Zygodontomys lasiurus fuscinus: Hershkovitz, 1962:205; name combination.

Zygodontomys lasiurus lasiurus: Hershkovitz, 1962:206; name combination.

Zygodontomys lasiurus pixuna: Hershkovitz, 1962:206; name combination.

Cabreramys benefactus: Massoia and Fornes, 1967a:421; name combination.

Cabreramys temchucki Massoia, 1980a:179; *nomen nudum*.

Cabreramys temchuki Massoia, 1982:91; type locality “Costa del Arroyo Zaimán, Villa Miguel Lanús, Departamento Capital, Provincia de Misiones, República Argentina”; Arroyo Zaimán (ca. 27.418°S, 55.891°W).

Bolomys temchuki temchuki: J. R. Contreras, 1982a:174; name combination.

Bolomys temchuki elioi J. R. Contreras, 1982a:174; type locality “Mantilla Cué, frente a Laguna Paiva, Las Lomas, Departamento Capital, Provincia de Corrientes”; Laguna Paiva (ca. 27.480°S 58.740°W), Argentina.

Bolomys temchuki liciae J. R. Contreras, 1982a:175; type locality “Colonia Río Tragadero, 2 km al norte de Resistencia, Departamento San Fernando, Provincia del Chaco”; Río Tragadero (ca. 27.390°S, 58.939°W), Argentina.

Necromys lasiurus: Massoia, 1985b:4; first use of current name combination.

Necromys pixuna: Massoia, 1985b:4; name combination.

Necromys temchuki: Massoia, 1985b:4; name combination.

[*Necromys*] *lasiotis*: Musser and Carleton, 2005:1130; incorrect subsequent spelling of *Mus lasiotis* Lund.

DESCRIPTION: Medium sized, with head and body length 118–138 mm, tail length 66–96 mm. Considerable variation in pelage color throughout distributional range; dorsal color olivaceous gray to dark brown, usually with well-defined agouti pattern; rump and sides generally paler and more ochraceous tawny; venter whitish to gray, sometimes washed with buff, with individual hairs dark gray at their bases; limit between dorsal and ventral color poorly defined; eye-ring either absent or ill-defined by buffy or cinnamon hairs. Ears small, rounded, and sparsely haired; tail bicolored and covered by moderately dense, short hairs. Manus and pes broad, dorsally brownish, with well-developed nails; ungual tufts whitish. Skull strongly built; rostrum short; zygomatic notches deep; interorbital region converges anteriorly and with weakly beaded supraorbital margins; incisors foramina long, reaching protocone of M1, more or less parallel sided but with anterior part wider than posterior; palate short, without conspicuous posterolateral pits. Upper incisors orthodont with orange enamel. Main cusps of molars slightly alternate anteroposteriorly. Massoia and Fornes (1967a), Crespo (1969), and Macêdo and Mares (1987) provided external and cranial measurements.

DISTRIBUTION: As here understood (i.e., to include the nominal taxa *benefactus* Thomas, *conifer* Ameghino, and *temchuki* Massoia), *N. lasiurus* has one of the largest distributions of any sigmodontine. Geographic limits are not totally understood, but specimens assigned to this species are known from the Ilha do Arapiranga in the Brazilian state of Pará (approximately 1°20'S), from southern Buenos Aires province (38°40'S), from close to the Brazilian Atlantic coast, and from the Sierra de Ambato (66°W) in the Argentinean Andes. The species occurs widely in eastern and central Brazil, from the Atlantic coast of the state of Pará west to Rondônia state. In Paraguay, it is primarily restricted to the eastern portion of the country, but some populations also are found west of the Río Paraguay where overlaps occur with the range of *N. lenguarum*. In Argentina, *N. lasiurus* is nearly continuously distributed throughout the northeastern portion of the country although it is absent east of the Río Paraná in Entre Ríos province and the southern portion of Corrientes province. West of the Río Paraná, *N. lasiurus* has a continuous distribution to at least southern Santa Fe province (J. R. Contreras 1982a). Isolated populations occur in east-central Argentina, in Córdoba, La Pampa, and Buenos Aires provinces (Galliari and Pardiñas 2000; Teta, González-Fischer et al. 2010).

SELECTED LOCALITIES (Map 112): ARGENTINA: Buenos Aires, Bonifacio (type locality of *Akodon benefactus* Thomas), Fulton (Galliari and Pardiñas 2000), Laguna Chasicó (LTU 85), Monte Hermoso (Galliari and Pardiñas 2000), Olavarría (CNP 2333), Ramallo (Galliari and Pardiñas 2000); Catamarca, Las Chacritas, ca. 28 km NNW of Singuil (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008); Chaco, Colonia Río Tragadero, 2 km N of Resistencia (type locality of *Bolomys temchuki liciae* Contreras); Córdoba, Río Ceballos (Galliari and Pardiñas 2000); Corrientes, Santo Tomé (CNP-E 650–2); La Pampa, 20 km SE of Luán Toro, Estancia la Florida (J. R. Contreras and Justo 1974), Quehué, Estancia Los Molinos (Tiranti 1996), Laguna Guatraché (Galliari and Pardiñas 2000); Santa Fe, Berna (CNP 531). BRAZIL: Alagoas, Anadia (Libardi 2013), Capela (Libardi 2013); Bahia, Feira de Santana (Libardi 2013), Mucugê, Parque Nacional da Chapada Diamantina, Rio Cumbuca (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008); Ceará, Crato (type locality of *Zygodontomys pixuna* Moojen), Serra Baturité, Pacoti (Libardi 2013); Maranhão, Ribeirãozinho, Imperatriz (Libardi 2013), UTE Ponta Madeira, São Luis (Libardi 2013); Mato Grosso, Casa de Pedra, Chapada dos Guimarães (Libardi 2013), Posto Jacaré (Libardi 2013), Rodovia 7 Placas, Cabeceira, Rio Cuiabá (Libardi 2013); Mato Grosso do Sul, Corumbá (Godoi et al. 2010); Minas Gerais, Caratinga, Fazenda Montes Claros (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008),

Lagoa Santa (type locality of *Mus lasiurus* Lund); Pará, Alter do Chão (Lima Francisco et al. 1995), Ilha de Arapiranga (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008), Souré (type locality of *Akodon fuscinus* Thomas); Pernambuco, Caruaru (Maia and Langguth 1981), Parque Nacional do Catimbau (Geise et al. 2010); Rio Grande do Sul, Rondinha, Parque Estadual Florestal de Rondinha (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008); São Paulo, Itararé (type locality of *Hesperomys brachyurus* Wagner). PARAGUAY: Alto Paraguay, Palmar de Las Islas (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008); Presidente Hayes, 8 km NE of Juan de Zalazar (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008).

SUBSPECIES: Macêdo and Mares (1987) assessed geographic variation in *N. lasiurus*, retaining *fuscinus* Thomas and *lasiurus* Lund as subspecies. J. R. Contreras (1982a) described *elioi* and *liciae* as subspecies of *Bolomys temchuki* Massoia. Divergence in the mtDNA cytochrome-*b* gene for specimens studied by D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) ranged from 0–3.9% and from 1.3–6.3% at the intrapopulation and interpopulation levels, respectively. These authors noted two clades in *N. lasiurus*, one from localities as far from each other as the Ilha do Arapiranga (in Pará, Brazil) and Paraguay, and the other occupying all remaining localities, including specimens from near the type locality at Lagoa Santa, Minas Gerais, Brazil. Despite its large geographic distribution and great range of morphological variation, *N. lasiurus* exhibits little phylogeographic structure. When all haplotypes were analyzed together, tests of neutrality supported a recent increase in population size, likely leading to range expansion. In combination with the lack of phylogeographic structure, these results are consistent with the hypothesis that *N. lasiurus* has recently invaded several regions where it is currently found (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008).

NATURAL HISTORY: *Necromys lasiurus* is found in grasslands, along the borders of cultivate fields, abandoned croplands, or even in secondary or gallery forests (Crespo 1969; Dietz 1983; Ellis et al. 1997; Geise, Paresque et al. 2010). It is basically a diurnal rodent with more pronounced crepuscular and nocturnal activity in the dry season than in the wet season (E. M. Vieira et al. 2010). In grassland areas, it is a moderately abundant species, reaching densities up to 19.02 individuals/ha in central Brazil (Becker et al. 2007) and 33.8 individuals/ha in east-central Argentina (De Villafañe et al. 1973). Diet varies both geographically and seasonally to include variable quantities of seeds, green vegetation, and arthropods (Ellis et al. 1998; Talamoni et al. 2008).

The reproductive season in east-central Argentina extends through the spring and summer, from October to February (Mills, Ellis, McKee et al. 1992). Parreira and

Cardoso (1993) determined seasonal variation in spermatogenic activity in southeastern Brazil. The average number of embryos varies from 4.2 (central Brazil; Dietz 1983) to 6.2 (east-central Argentina; Mills, Ellis, McKee et al. 1992). C. R. de Almeida et al. (1982) and Piantanida and Nani (1993) studied its reproduction and growth under laboratory conditions. Home range size varied both seasonally and by sex from 0.02 to 0.52 ha (Santos Pires et al. 2008). J. A. Oliveira et al. (1998) examined relative age and age structure in natural populations in northeastern Brazil, and Cangussu et al. (2002) studied sexual dimorphism of submandibular glands.

Necromys lasiurus is a reservoir for at least two hantavirus strains: Macielin, from the Pampas region of Argentina, which has not yet been associated with human disease (Enría and Levis 2004), and Araraquara, from the central plateau and southeastern portion of Brazil, which appears to be the most virulent strain infecting humans in South America (L. T. M. Figueiredo et al. 2009; G. G. Figueiredo et al. 2010). A long list of ectoparasites has been associated with this species, including mites (*Androlaelaps fahrenheitsi*, *A. rotundus*, and *Eulaelaps stabularis*), fleas (*Polygenis adelus*, *P. axius*, *P. bohlsi*, *P. pradoi*, *P. pygaerus*, *P. frustratus*, *P. massoi*, *P. platensis*, *P. rimatus*, *P. tripus*, *P. occidentalis*, *P. tripopsis*, *Adoratopsylla antiquorum*, *A. intermedia*, *Craneopsylla minerva minerva*, *Ctenocephalides felis felis*, *Xenopsylla cheopis*, and *X. brasiliensis*), and lice (*Hoplopleura imparata* and *H. misionalis*) (Autino and Lareschi 1998; D. Castro and Cicchino 1998; Lareschi and Mauri 1998; Linardi and Guimarães 2000). Endoparasitic nematodes are abundant, and include *Syphacia alata*, *Protospirura numidica criceticola*, *Pterigodermatites (Paucipectines) zygodontomys*, *Litomosoides carinii*, *L. silvai*, *Stilestrongylus freitasi*, *Trichuris laevitesticis*, and *Strongyloides venezuelensis* (Quentin, 1967, 1968; Quentin et al. 1968; M. Robles 2008, 2010; and Suriano and Navone 1994).

REMARKS: Langguth (1975) and Hershkovitz (1990a) discussed the convoluted history of the use of Lund's *lasiurus* and *lasiotis*, with the latter often causing confusion with *Thalpomys lasiotis* Thomas (see that account). Paula Couto (1950: footnote 66) regarded *Mus lasiotis* Lund as a synonym of *Hesperomys* (= *Calomys*) *expulsus* Lund.

The current concept of *N. lasiurus* (see D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008) includes several nominal forms with complex taxonomic histories, such as *Hesperomys arviculoides*, *Akodon benefactus*, and *Cabreramys temchuki*. Cabrera (1961) and Reig (1978) placed Pampean populations of *N. lasiurus*, previously treated as *N. benefactus*, in part or totally in *N. obscurus*. Alternatively, Massoia and Fornes (1967a) and Galliari and Pardiñas (2000) regarded both *benefactus* and *obscurus* as valid species, although their comparisons were generally limited to

Argentinean samples. Even so, Galliari and Pardiñas (2000) recognized the similarities between *benefactus* and *lasiurus*, placing both in the same morphological group of species. According to Massoia and Pardiñas (1993) and Galliari and Pardiñas (2000), the fossil species *N. conifer* Ameghino is a senior synonym of *benefactus* Thomas, although the latter authors preferred to retain *benefactus* as the name for this species for reasons of familiarity (but see Musser and Carleton 2005). Hershkovitz (1962) revised Brazilian populations of *N. lasiurus* as part of his “Southern Group” of the genus *Zygodontomys*. However, A. L. Gardner and Patton (1976), Maia and Langguth (1981), and Voss and Linzey (1981) supported the inclusion of these populations in either *Akodon* or *Bolomys* (= *Necromys*) on karyological and morphological grounds. Macêdo and Mares (1987) regarded *N. lenguarum*, currently recognized as a valid species, as a synonym of *N. lasiurus*. Indeed, the morphological discrimination and distributional limits of these two species require refinement (see below). *Hesperomys arviculoides* Wagner, sometimes listed as a valid species (Gyldenstolpe 1932; Cabrera 1961; Ximénez and Langguth 1970), was considered related to *N. obscurus* (Galliari and Pardiñas 2000) or as a synonym of *N. lasiurus* (Macêdo and Mares 1987; Reig 1978, 1987). Musser and Carleton (2005) demonstrated that *Cabreramys temchucki* Massoia, 1980, is a *nomen nudum*; the availability of *temchuki* actually dates from Massoia’s (1982) explicit diagnosis of the species.

Libardi (2013) addressed nongeographic variation in Brazilian populations based on morphometrics of 1,572 specimens; this author also constructed detailed maps of the distribution of *N. lasiurus* in Brazil. Reported specimens

Map 112 Selected localities for *Necromys lasiurus* (●). Contour line = 2,000 m.

of *N. lasiurus* from the Pampas del Heath in southeastern Perú (Pacheco et al. 1995; Emmons, Romo et al. 2002) have been tentatively reassigned to *N. lenguarum* (Pacheco et al. 2009).

Necromys lenguarum (Thomas, 1898)

Paraguayan Akodont

SYNONYMS:

Akodon lenguarum Thomas, 1898f:271; type locality “Waikthlatingwaialwa, Northern Chaco of Paraguay,” Presidente Hayes, Paraguay (an old Chacoan mission located at about 23°25’S and 58°10’W [see Paynter 1989, under the spelling Waikthlatingwayalwa]).

Zygodontomys tapirapoanus J. A. Allen, 1916c:528; type locality “Tapirapoan [= Tapirapuã], Rio Sepotuba, Mato Grosso, Brazil.”

[*Akodon*] *tapirapoanus*: Tate, 1939:188; name combination.

Akodon (*Akodon*) *tapirapoanus tapirapoanus*: Cabrera, 1961:447; name combination.

Akodon (*Akodon*) *obscurus lenguarum*: Cabrera, 1961:444; name combination.

“*Zygodontomys* [?] *lasiurus*] *lenguarum*”: Hershkovitz:1962:206; name combination.

“*Zygodontomys* [?] *lasiurus*] *tapirapoanus*”: Hershkovitz:1962:207; name combination.

Cabreramys lenguarum: Massoia and Fornes, 1967a:422; name combination.

Bolomys lenguarum: Reig, 1978:167; name combination.

Bolomys lenguarum tapirapoanus: S. Anderson and Olds, 1989:19; name combination.

Necromys lenguarum: Massoia, 1985b:4; first use of current name combination.

DESCRIPTION: Medium sized, with total body length of holotype 191 mm, tail 76 mm, ear length 14 mm, and hindfoot length 21 mm. Dorsal pelage dark gray, with more yellowish on rump; sides paler; venter whitish, with tips of hairs white or with slight yellowish tinge; forefeet and hindfeet uniformly pale gray above. Tail bicolored, blackish above and whiter below. Skull heavily built; nasals short, supraorbital region broad and beaded, and zygomatic plates low and broad, with straight anterior margin; incisive foramina wide and short, not constricted posteriorly. Upper incisors slightly proodont. Greatest skull length 28.5 mm, upper molar series length 4.7 mm (dimensions of holotype).

DISTRIBUTION: *Necromys lenguarum* occurs in isolated grassland patches in southeastern Perú (Pacheco et al. 2009), eastern Bolivia, western Paraguay, southwestern Brazil, and possibly northern Argentina (Galliari et al. 1996), inhabiting Chacoan lowlands below 1,300 m elevation. Galliari et al. (1996) cited the first possible specimens for Argentina, from Pampa Bolsa, Chaco province

(PROBBAS, numbers 800 to 832). M. M. Díaz and Barquez (2007) mentioned a possible record from Jujuy province, Argentina (Ingenio La Esperanza) in the collection of Elio Massoia. These Argentinian specimens should be reexamined in the course of a comprehensive taxonomic review of the genus. Similarly, many of the localities in Bolivia, given by S. Anderson (1997), should be treated with caution because they could be *N. lasiurus*, a species with a much wider distribution and ecological amplitude (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008).

SELECTED LOCALITIES (Map 113): ARGENTINA: Chaco, Pampa Bolsa (Galliari et al. 1996); Jujuy, Ingenio La Esperanza (M. M. Díaz and Barquez 2007). **BOLIVIA:** Chuquisaca, Río Limón (S. Anderson 1997; D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008); Santa Cruz, 4.5 km N and 1.5 km E of Cerro Amboró, Río Pitisama (S. Anderson 1997), Estancia San Marcos, 6 km W of Ascención (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008), 4 km N and 1 km W of Santiago de Chiquitos (S. Anderson 1997), Velasco, Parque Nacional Noel Kempff Mercado, Campamento Los Fierros (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008). **BRAZIL:** Mato Grosso, Tapirapoã, Rio Sepotuba (type locality of *Zygodontomys tapirapoanus* J. A. Allen). **PARAGUAY:** Alto Paraguay, Laguna Placenta (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008); Presidente Hayes, Waikthlatingwialwa (type locality of *Akodon lenguarum* Thomas). **PERU:** Madre de Dios, Pampas del Heath (Pacheco et al. 2009).

SUBSPECIES: S. Anderson (1997) maintained *tapirapoanus* J. A. Allen, with type locality in Mato Grosso, western Brazil, as a subspecies, but the validity of this nominal form at either specific or subspecific levels requires further evaluation.

NATURAL HISTORY: All the localities reported by D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) for *N. lenguarum* are situated in seasonally dry environments of the *Chaco Seco* ecoregion. Tapirapoã, the type locality of *tapirapoanus* J. A. Allen, is in the Cerrado of west-central Brazil. The record in southern Peru (Pacheco et al. 2009) is from the Pampas del Heath, which spans the border with Bolivia, a moist grassland isolated in the lowland rainforest of the Río Madre de Dios Basin. This species has not been studied in regard to other aspects of its ecology or behavior.

REMARKS: The taxonomic status of *N. lenguarum* is unresolved. It has been considered as either conspecific with *N. lasiurus* (Macêdo and Mares 1987; Pardiñas, D'Elía et al. 2006; Cáceres et al. 2008) or a separate species (Reig 1987; S. Anderson and Olds 1990; S. Anderson 1997; Galliari and Pardiñas 2000; D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008). The reciprocally monophyletic relationship of this taxon as compared with a broad array of geographic samples of *N. lasiurus*, derived from mtDNA analyses, offers

Map 113 Selected localities for *Necromys lenguarum* (●). Contour line = 2,000m.

strong support for the specific separation of these two taxa (D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008). However, these authors remarked that the valid application of the name *lenguarum* to the sister clade to *N. lasiurus* was not properly tested because no topotypical specimen was analyzed. Rather, specimens of *Necromys* collected in the area of the type locality of *N. lenguarum* were all referable to *N. lasiurus*. Thus, D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008) argued that several taxonomic issues must be resolved before the taxonomic status of *N. lenguarum* is firmly established. Therefore, we restrict the distributional range of *N. lenguarum* to those localities listed by D'Elía, Pardiñas, Jayat, and Salazar-Bravo (2008), the type localities of *lenguarum* Thomas and of its junior synonym, *tapirapoanus* J. A. Allen, and that from southern Peru, which is most likely of this species (see Pacheco et al. 2009).

Necromys obscurus (Waterhouse, 1837)

Dark-furred Akodont

SYNONYMS:

Ratton colibreve Brants, 1827:186; based on Azara's (1802:86) "*el colibreve*"; ruled by the International Commission (ICZN 1982:Opinion 1232) to be a vernacular name and unavailable for use in zoological nomenclature.
Mus obscurus Waterhouse, 1837:16; type locality "Maldonado," Maldonado, Uruguay.

Hesperomys obscurus: Wagner, 1843a:516; name combination.

Akodon obscurus: E.-L. Trouessart, 1897:536; name combination.

Zygodontomys obscurus: Reig, 1964:211; name combination.

Cabreramys obscurus: Massoia and Fornes, 1967a:419; name combination, as the type species of *Cabreramys* Massoia and Fornes.

Bolomys obscurus: Reig, 1978:167; name combination.

Necromys obscurus: Massoia, 1985b:4; first use of current name combination.

Necromys obscurus bonapartei: Massoia, 1985b:4; name combination.

“*Bolomys* sp. C”: Reig, 1994:104; name combination.

Necromys obscurus scagliarum Galliari and Pardiñas, 2000:219; type locality “mouth of Arroyo Corrientes, Mar del Plata (38°01’S, 57°31’30”W, General Pueyrredón county, Buenos Aires Province, Argentina.”

N[*ecromys*]. *obscurus obscurus*: Galliari and Pardiñas, 2000:214; name combination.

DESCRIPTION: Largest species in genus, with head and body length averaging ca. 110 mm and tail ca. 75 mm. Fur rather long and somewhat glossy; dorsum varies from dark chestnut brown to blackish brown; individual hairs blackish at base and tip and yellowish in middle, giving general agouti appearance; guards hairs entirely blackish and long (ca. 13 mm); flanks and cheeks tinged with orange or buffy; ventral hairs gray based with yellowish to orange tips; in some individuals, a white spot on the chin. Ears small and rounded, dark brown skin covered by short buffy hairs; tail bicolored, dark brown above and grayish below, with scales evident to naked eye. Manus and pes both dark, but pes covered dorsally by short buffy hairs; second interdigital pad usually larger than the first and third; claws on digits I, III, and IV longer than the corresponding digit. Skull with short nasals, U-shaped frontoparietal suture, slightly marked supraorbital borders, and U-shaped mesopterygoid fossa. Mandible with short, robust, and slightly backwardly curved coronoid process; well-developed capsular projection covers base of sigmoid notch. Procingulum of M1 fan shaped. Massoia and Fornes (1967a) and Galliari and Pardiñas (2000) provided external and cranial measurements. Carleton (1973), Voss and Linzey (1981), and Hooper and Musser (1964) described stomach morphology, male accessory glands, and male genitalia, respectively.

DISTRIBUTION: This species has a disjunct distribution with two main geographic centers, one in southern Uruguay and the other in east-central Argentina (Galliari and Pardiñas 2000). Uruguayan populations are mostly restricted to the coast in San José, Maldonado, Montevideo, and Canelones departments (E. M. González and Martínez Lanfranco 2010). There is an unconfirmed report for Rivera department (Mones et al. 2003), which would provide an extension to the north of about 350 km. Argentinean occurrences are from the southeastern corner of Buenos Aires province, including coastal environments as well as grasslands and hilly areas (Reig 1964; Massoia and Fornes

1967a; Galliari and Pardiñas 2000; Teta, González-Fischer et al. 2010). The fossil record of *N. obscurus* is restricted to the Late Holocene in Buenos Aires province (Pardiñas 1999b). The reference by Teta et al. (2004) to *Necromys* sp. from two archaeological sites in northeastern Buenos Aires is to this species. These past occurrences for *N. obscurus* indicate a wider distribution than at present and that partially connected Argentinean and Uruguayan populations. Sympatric occurrence of *N. lasiurus* and *N. obscurus*, not presently known, has been recorded in Late Holocene coastal assemblages (Pardiñas and Tonni 2000; Pardiñas 1999b).

SELECTED LOCALITIES (Map 114): ARGENTINA: Buenos Aires, Arroyo de las Brusquitas (Fornes and Massoia 1965), Estación Deferrari (Teta, González-Fischer et al. 2010), Estación San José (Teta, González-Fischer et al. 2010), INTA Balcarce (Galliari and Pardiñas 2000), Laguna Mar Chiquita (Bó et al. 2002), Punta Negra, Necochea (Galliari and Pardiñas 2000). URUGUAY: Canelones, Arroyo Trova Vieja (MACN 17442), Laguna del Cisne (E. M. González and Fregueiro 1999); Maldonado, Maldonado (type locality of *Mus obscurus* Waterhouse); Montevideo, Bañados de Carrasco (Galliari and Pardiñas 2000), Parque Lecocq (E. M. González 1996), Villa Colón (Massoia and Fornes 1967a); San José, Bañados del Arazatí (E. M. González and Martínez Lanfranco 2010), Barra del Río Santa Lucía (Galliari and Pardiñas 2000).

SUBSPECIES: Two geographically disjunct subspecies are currently recognized, based on morphology. The nominotypical form ranges along a narrow band bordering the La Plata River and the Atlantic Coast of Uruguay, whereas *N. o. scagliarum* is known from a few localities in southeastern Buenos Aires province (Galliari and Pardiñas 2000). These morphologically defined subspecies are not molecularly divergent (D’Elía, Pardiñas, Jayat, and Salazar-Bravo 2008). Massoia (1985b) treated the fossil form *bonapartei* Reig as a subspecies of *N. obscurus*.

NATURAL HISTORY: *Necromys obscurus* is mostly diurnal and cursorial, although it exhibits some tendency toward fossoriality (Fornes and Massoia 1965). It has been captured in low to moderate numbers in grasslands, the borders of cultivated fields, moist areas near lagoons and streams along the coast, and among rocks in hilly environments (Reig 1964; E. M. González and Martínez Lanfranco 2010). It is omnivorous, including such arthropods as beetles and crickets and plants in its diet (E. M. González and Martínez Lanfranco 2010). This mouse is a minor component of the diet of the Barn Owl (*Tyto alba*) in southeastern Buenos Aires province (Leveau et al. 2006; Teta, González-Fischer et al. 2010). E. M. González and Martínez Lanfranco (2010) recorded reproductive activity in spring and winter months, and Reig (1965) noted

Map 114 Selected localities for *Necromys obscurus* (●); those in Argentina and Uruguay are mapped as disjunct (see Distribution). Contour line = 2,000 m.

that sperm production was most prevalent in November and January. Navone et al. (2010) provided a complete list of known parasites. D'Elía, Pardiñas, Jayat et al. (2008) placed *N. obscurus* in the IUCN Near Threatened category.

REMARKS: Brants (1827) based his *Ratton colibreve*, a probable synonym of *N. obscurus* (Langguth 1966a), on the “*colibreve*” in Azara’s Spanish edition (1802), which was described from an individual acquired in Montevideo, Uruguay. Brants’s name, however, was rejected by the International Commission (ICZN 1982:Opinion 1232).

The diploid number is $2n = 34$, based on specimens from southeastern Buenos Aires (N. O. Bianchi et al. 1971).

Necromys punctulatus (Thomas, 1894)

Ecuadorean Akodont

SYNONYMS:

Acodon punctulatus Thomas, 1894b:361; type locality “Ecuador (probably Pallatanga).”

Akodon punctulatus: E.-L. Trouessart, 1897:536; name combination.

Zygodontomys punctulatus: Gyldenstolpe, 1932a:114; name combination.

Zygodontomys punctulatus punctulatus: Cabrera, 1961:464; name combination.

Zygodontomys brevicauda punctulatus: Hershkovitz, 1962:204; name combination.

Bolomys punctulatus: Voss, 1991b:4; name combination.

N[ecromys]. punctulatus: Galliari and Pardiñas, 2000:226; first use of current name combination.

DESCRIPTION: Medium sized, with total length ca. 200 mm; tail ca. 71 mm. Dorsal pelage short and crisp; over-

all dorsal color black finely lined with gray and yellow that turns cheeks, sides of neck, and flanks to olive; under parts dirty yellowish white. Ears small, well haired, and brown; tail short and bicolored. Both manus and pes brownish white above; digit V of pes short, barely reaching the base of digit IV. Skull dorsally convex in lateral profile with short muzzle and long, narrow braincase; strongly beaded to slightly overhanging supraorbital edges; and long palatal foramina nearly twice length of molar series (Thomas 1894b).

DISTRIBUTION: Thomas (1894b:362) gave the holotype as probably from Pallatanga, an Ecuadorean town on the Pacific slope of the western Andean cordillera. Voss (1991b:6–7) discussed in detail the geographic provenance of the few specimens of *N. punctulatus* then available, summarizing “at least two independent records from Ecuador and one rather more dubious record from eastern Andean Colombia.”

SELECTED LOCALITIES (Map 115): ECUADOR: Chimborazo, Pallatanga (type locality of *Acodon punctulatus* Thomas). COLOMBIA: Cundinamarca, Bogotá (Voss 1991b).

SUBSPECIES: *Necromys punctulatus* is monotypic.

NATURAL HISTORY: Nothing is known about the ecology or behavior of this species.

REMARKS: After a review of all available specimens of this species, Voss (1991b) removed *punctulatus* from *Zygodontomys* and noted its resemblance to, if not conspecificity with, *N. lasiurus*. Thomas (1894b:362) also recognized a possible connection to *N. lasiurus*, although he later (Thomas 1900h:469) allied *punctulatus* with *N. amoenus*, writing in reference to the latter “an isolated species, apparently only allied to *A. punctulatus*, from which it is distinguishable by its very different colour.” This potential relationship, overlooked by Voss (1991b) and incorrectly referenced by Musser and Carleton (2005:1130), deserves further exploration. The geographic provenances of the known specimens of *N. punctulatus* make its being a northern Andean expression of *N. amoenus* biogeographically defensible. If it were such, then this could explain the mensural differences between the holotype of *punctulatus* (perhaps partially a result of age) as compared with *N. lasiurus*, specifically its smaller size (the length of the upper molar series of *punctulatus* is 4.2 mm [Thomas 1894b:362] versus >4.5 mm for samples of *lasiurus* [Macêdo and Mares 1987]). However, one specimen figured by Voss (1991b:Fig. 1) and identified as *N. punctulatus* (AMNH 36312) appears more like *N. lasiurus*, especially with respect to the orientation of the upper incisors and the nature of the interorbital constriction. Clearly, additional specimens of this rare mouse are needed to assess both its systematic status and relationships to other members of the genus.

Map 115 Selected localities for *Necromys punctulatus* (●). Contour line = 2,000 m.

Necromys urichi (J. A. Allen and Chapman, 1897)
**Northern Grass Mouse, Ratón campestre,
 Ratón mochilero**

SYNONYMS:

Akodon urichi J. A. Allen and Chapman, 1897a:19; type locality “Caparo, Trinidad,” Trinidad and Tobago.

Akodon venezuelensis J. A. Allen, 1899b:203; type locality “Quebrada Seca, near Cumana, [Sucre,] Venezuela.”

Akodon meridensis J. A. Allen, 1904b:329; type locality “Merida (alt. 1630 m.), [Mérida,] Venezuela.”

Akodon chapmani J. A. Allen, 1913c:600; type locality “Chipaque (altitude 8500 feet), Eastern Andes, [Cundinamarca,] Colombia.”

Chalcomys aerosus saturatus Tate, 1939:187; type locality “Mt. Auyan-tepui plateau, middle R[ío]. Caroni, [Bolívar,] Venezuela, 6000 ft.”

Akodon urichi tobagensis Goodwin, 1962:6; type locality “Speyside, St. John Parish, eastern Tobago, the West Indies, at an altitude of 300 feet,” Trinidad and Tobago.

Necromys urichi: Musser and Carleton, 2005:1131; first use of current name combination.

DESCRIPTION: Medium sized (smaller than *N. lasiurus* and *N. lenguarum*, but slightly larger than *N. amoenus*).

Pelage grizzled and short, with hairs about 3–4 mm long over middle rump; dorsal color dark, rusty chestnut finely intermixed with black; venter washed with yellowish, or pale to medium gray tips, but always with dark-based hairs; hair tips of chin, throat, and around inguinal area gray in most specimens; dorsal-ventral pelage transition undefined; eye-ring present. Ears dark brown, thinly covered with short, dark rusty brown hairs; tail slightly more than one-third of total length, uniformly dark, sparsely haired, and without tuft. Manus and pes covered dorsally with short, dark ochraceous hairs; ungual tufts present on both front and hindfeet, but more developed in latter; hindfoot about 20% of head and body length, narrow, with digits I and V much shorter than digits II to IV; claw of digit V about two-thirds length of first phalanx of digit IV in holotype (AMNH 7725/6110). Skull with short rostrum and relatively broad interorbital region; zygomatic notches comparatively (to other species in genus) narrow and shallow; supraorbital shelves present, converging toward middle of orbits; ledge over orbit heavy in some specimens, approaching incipient bead; zygomatic arches widest across squamosal roots and therefore convergent anteriorly; zygomatic plates relatively broad; rostrum conical in lateral view, tapering forward from zygomatic root; nasal bones long (ca. 40% of the condylobasilar length), projecting anteriorly such that distal portion of premaxillary bones and incisors hidden beneath nasals and cannot be seen from above; incisive foramina long and broad, posteriorly reaching protocone of M1, widest at, or near to, premaxillomaxillary suture and tapering slightly posteriorly; hard palate basically flat, with barely conspicuous palatal gutters; palate of intermediate length, with mesopterygoid fossa broad, wide, approximately parallel, and with U-shaped anterior margin, extending between maxillae and reaching level of posterior border of M3s; roof of mesopterygoid fossa without sphenopalatine vacuities (holotype and various individuals from northeastern Venezuela with tiny perforations but never large vacuities, but some individuals from southern populations with large vacuities); distinct posterior palatal pits absent; parapterygoid fossae slightly concave dorsally (not flat, as in other species), with straight lateral margins, posteriorly divergent, narrower than mesopterygoid fossae; foramen ovale about size of M3 and often partially hidden by pterygoid bridge of variable width. Upper incisors orthodont, enamel colored dull yellow-orange to saturated orange (in holotype). Molars moderately short-crowned, robust, and with main cusps alternating along longitudinal plane. Procingulum broad and conspicuously divided into anterolingual and anterolabial conules by deep anteromedian flexus (lost in very old individuals). Both M1–2 with paralophules and well-developed anterolophs and mesolophs; M3 about half size of M2, with well-developed hypoflexus and metaflexus

(clearly visible in young individuals, but not holotype). The m1 lacks anteromedian flexid but does possess anterolabial cingulum, ectolophid, and mesolophid; m2 with same structures as m1 but about two-thirds its size; m3 about two-thirds size of m2, elongated and figure-8 shaped. Mandible with mental foramen opening dorsally at diastema; capsular process distinct and slightly slanted backward; superior and inferior masseteric ridges meet below m1; coronoid process slightly higher than condyloid process, which extends dorsally slightly beyond angular process. Vertebral column with 13 thoracic, six lumbar, and 24–27 caudal elements (Steppan 1995). Structure of phallus and baculum similar to those of *Akodon surdus* and *Akodon boliviensis* (Hooper and Musser 1964).

DISTRIBUTION: *Necromys urichi* is known from over 70 localities in northern South America, including confirmed reports from Colombia, Venezuela, and Trinidad and Tobago; reports of the species from northern Brazil are based on the several Venezuelan localities near the Brazilian-Venezuelan border. As currently understood, *N. urichi* occurs in moist habitats from near sea level to over 3,600 m in elevation and appears to be able to tolerate a range of climatic and ecological zones. The range of the species appears to be somewhat disjunct with a large number of localities forming a NE-SW arc from Trinidad and Tobago, through the lowlands of northern Venezuela, adjacent Colombia, and across the Cordillera de Mérida Andes into southwestern Colombia. It appears again in southern and western Venezuela and perhaps northernmost Brazil, in areas associated with or, close to, the foothills of the tepuis, where it is also found at several elevations (J. A. Allen and Chapman 1897a; Handley 1976; O. J. Linares 1998; M. F. Smith and Patton 1999; Musser and Carleton 2005; D'Elía et al. 2008).

SELECTED LOCALITIES (Map 116): COLOMBIA: Cauca, La Gallera (AMNH 32467); Cundinamarca, Chipaque (type locality of *Akodon chapmani* J. A. Allen); La Guajira, Las Marimondas, Fonseca (USNM 280805); Meta, Finca El Buque, Villavicencio (NMNH 507258). TRINIDAD AND TOBAGO: Tobago, Speyside (AMNH 184789); Trinidad, Caparo (AMNH 6110), Princetown (J. A. Allen and Chapman 1897a). VENEZUELA: Amazonas, Cerro Duida, Cabecera Del Cano Culebra, 40 km NNW of Esmeralda (USNM 406120), Cerro Neblina, Camp XI (USNM 560866); Apure, Nulita, 29 km SSW of Santo Domingo, Selvas De San Camilo (USNM 418446); Bolívar, Arabopo, Mt. Roraima (AMNH 75640); Carabobo, La Copa, 4 km NW of Montalban (USNM 442343), Auyan-tepui (type locality of *Chalcomys aerosus saturatus* Tate), 85 km SSE of El Dorado, km 125 (USNM 387978), 45 km NE of Icabarú, Santa Lucia de Surukun (USNM 495663); Falcón, Cerro Socopo, 84 km NW of Carora

(USNM 442354); Guárico, Parque Nacional Guatopo, 15 km NW of Altagracia (USNM 387980); Mérida, Mérida (type locality of *Akodon meridensis* J. A. Allen), Mucubají, 3.25 km ESE of Apartaderos (USNM 579557); Monagas, San Agustín, 5 km NW of Caripe (USNM 409941); Sucre, Manacal, 26 km ESE of Carupano (USNM 416718), Quebrada Seca (AMNH 14743); Vargas, Pico Ávila, 5 km NNE of Caracas, near Hotel Humboldt (USNM 371213).

SUBSPECIES: As currently understood, *Necromys urichi* may be a composite of several taxa, involving at least the three nominal ones (*saturatus*, *meridensis*, and *venezuelensis*), in addition to the nominate form. Morphometric analyses of Venezuelan populations and the analyses of mtDNA cytochrome-*b* gene sequences indicated that these taxa deserve equal taxonomic rank (M. F. Smith and Patton 1999; J. Ventura et al. 2000; D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008). Clearly, more comprehensive studies are needed to build consensus as to hierarchical rank (species or subspecies) appropriate for these taxa.

NATURAL HISTORY: Specimens in Venezuela have been trapped in savannas as well as evergreen, cloud, and deciduous forests, but almost always on the ground, near streams, and in rocky, grassy areas with thick herbaceous vegetation (Handley 1976; Aagaard 1982; O. J. Linares 1998; Voss 1992). A study of over nine months in the páramos of the Cordillera de Mérida showed that animals trapped in the wet season were larger, on average, than those trapped in the dry season. Also, males were larger and heavier than females (Aagaard 1982). In the premontane humid forest of the Coastal Range in Venezuela, a study over 22 months found a mean population density of 2.9 animals per hectare (range: 0.6–5.9) and a mean residence time on the study area of just over three months for males and four months for females. This population was slightly female biased (1:1.22), and the estimated juvenile survivorship was 55%. Animals were active day and night. Average litter size was 5, and females averaged 3.6 litters per year. Sexual maturity was reached at 2.7 months; reproduction occurred throughout the year but with a peak from May and June, at the onset of the rainy season (O'Connell 1989). Goff and Brennan (1978), Fain and Lukoschus (1982), and P. T. Johnson (1972) detailed arthropod ectoparasites, Arcay (1982) protozoan parasites, and Vogelsang and Espin (1949) nematodes.

REMARKS: J. A. Allen and Chapman (1893:217) provisionally assigned specimens from Trinidad to *Abrothrix caliginosus* (now = *Melanomys caliginosus*), but later used the same series in their description of *Akodon urichi* (J. A. Allen and Chapman 1897a:19). Tate (1939:187), in his description of *Chalcomys aerosus saturatus* from Mt. Auyan-tepui, also reported on a series of specimens he called "*Chalcomys aerosus near chapmani*" from the

lower slopes of the same tepui. These are paler than *saturatus* and similar in coloration to J. A. Allen's *chapmani* from Colombia.

The phylogenetic position of *N. urichi* in the genus requires thorough reevaluation, a process that may refine the content and context of *Necromys*. Phylogenetic studies based on mitochondrial and nuclear gene data support the hypothesis that *N. urichi* is closely related to other species in *Necromys* (M. F. Smith and Patton 1999; D'Elía 2003a; D'Elía, Pardiñas, Jayat, and Salazar-Bravo 2008) and that this relationship is best characterized by a three-group basal polytomy (see above). As currently understood on morphological grounds, *N. urichi* is the most divergent *Necromys*. In fact, combinations of characters currently presumed to be diagnostic for *Necromys* (e.g., size and shape of zygomatic notches, length of rostrum, narrow parapterygoid and mesopterygoid fossae, size and shape of the foramen ovale, lack of an anteromedian flexus in M1, size and shape of the hypo-, meso-, and metaflexi) are not present in *N. urichi*. Only a single character diagnostic of *Necromys* is present in the holotype of *N. urichi* (AMNH 7725); that is that digit V, including claw, does not extend beyond half of the proximal phalanx of digit IV. In combination, these are trenchant character differences that need to be evaluated in a phylogenetic context when more nuclear sequence data are available for species in the genus.

Reig and Kiblicky (1968b) and Reig, Olivo, and Kiblicky (1971) described a karyotype with $2n=18$, composed of eight pairs of metacentric autosomes of decreasing size and heteromorphic sex chromosomes. N. O. Bianchi et al. (1971) reported a lack of X0 females in this species, an observation supported by Hoekstra and Edwards (2000).

Map 116 Selected localities for *Necromys urichi* (●). Contour line = 2,000 m.

Genus *Oxymycterus* Waterhouse, 1837

João A. de Oliveira and Pablo R. Gonçalves

The genus *Oxymycterus*, as treated here, includes 15 species: *O. amazonicus*, *O. caparaoe*, *O. dasytrichus*, *O. delator*, *O. hiska*, *O. hucucha*, *O. inca*, *O. josei*, *O. juliacae*, *O. nasutus*, *O. nigrifrons*, *O. paramensis*, *O. quaestor*, *O. rufus*, and *O. wayku*. Records are from localities ranging from the southern bank of the Rio Amazon in eastern Brazil and western Brazilian and southern Peruvian Amazonia to southern Buenos Aires province in Argentina. Within this range, records are more densely concentrated in eastern Brazil and the Bolivian-Peruvian Andes and eastern slopes, but also throughout Paraguay and central Brazil. Pleistocene and Recent material has been reported from Lagoa Santa, southeastern Brazil, but of the fossil species described from there and referred to *Oxymycterus* by Winge (1887), only *Oxymycterus cosmodus*—based on a fragment of maxilla with the first upper molar and recovered from Lapa da Serra das Abelhas (Hansen 2012:67)—is currently included in the genus (Voss and Myers 1991). As for the fossil nominal forms proposed by Ameghino (1889) in *Oxymycterus*, none are currently assigned to the genus (Massoia and Pardiñas 1993; Pardiñas 2000), despite fossils referable to extant species from Argentinean sites (P. E. Ortiz and Pardiñas 2001; Pardiñas et al. 2002).

The smallest species of *Oxymycterus* is *O. hucucha*, whereas the largest specimens recorded have been assigned to *O. quaestor*. Adult head and body lengths in the genus range from 99–197 mm, and tail length varies from 70–156 mm. Among the different species, tail length varies from shorter than (about 60%) to approximately equal to head and body length. Hindfoot length (with claw) varies from 21–42 mm, and ear length (from notch) ranges from 14–27 mm.

Species of this genus are quite variable in size and pelage length and color, but the genus can be easily recognized by the long muzzle, small eyes, and by the long and strong claws both in forefeet and hindfeet. The tail is shorter than the head and body; the ears usually protrude above the fur of the head but vary in length among species, so the combination of ear and hindfoot lengths is useful in distinguishing among sympatric forms of similar body size.

The dorsal pelage of *Oxymycterus* is usually dense, and sometimes hispid and shiny. As in most sigmodontines, dorsal guard hairs have an expanded stiffer distal portion and thinner and more flexible base. The boundary between these two sections, located, in all species of the genus, near the midlength of the hair, is usually a constricted region that causes the expanded distal portion of the hair to bend backward. Guard hairs of the back and sides are usually of two kinds, both cylindrical and thin at their bases and with a

grayish proximal portion: a longer type, 10–18 mm in length among species, with a thickened, dark brown to black distal segment, and a shorter, thinner type 7.5–15 mm in length, tipped with a yellow-orange to reddish-brown 0.3–4.5 mm subapical band. Both kinds of guard hairs are also present laterally, but the first type gradually becomes less common progressing ventrad, and the subapical band in the second type gets longer toward the venter. Ventral hairs have grayish bases becoming yellowish distally. Very often the hair bases of the chin, and rarely those of the chest, are pure white.

Skulls of *Oxymycterus* are relatively long and narrow, mainly owing to the nasal tube that projects beyond the upper incisors, the anterior extremity of which is contributed equally to by nasals and premaxillaries. Prenasal ossification (the *os rostri*) is present in all species, although usually being lost during preparation, providing a more pointed appearance to an otherwise squared anterior end of the nasals. The nasal tube may be trumpet-shaped with a high anterior nasal aperture, owing to an upward flaring of the nasals, or the aperture may be below and inconspicuous. Zygomatic plates are relatively narrow, not forming obvious zygomatic notches, and have markedly curved anterior margins, a morphology approached only by *Brucepattersonius*, *Blarinomys*, *Juscelinomys*, and *Lenoxus*.

Considerable variation is found among species in the width of the inferior zygomatic root and in the curvature formed by the anterior margin of the zygomatic plates, which may be smoothly to strongly curved anteroposteriorly, without any remarkable anterodorsal knob just anterior to their upper zygomatic roots. The incisive foramina are very long, usually reaching the anterior third or half of the first molars. The anterior end of the mesopterygoid fossa is often at the level of the third molars, usually with their posterior edges, but consistent deviation from this is found among certain populations or species. The interparietal is reduced in comparison with that of other sigmodontines, but also shows considerable variation in shape and size in some species. All species possess the primitive murid pattern of carotid arterial circulation, including large stapedial and sphenofrontal foramina and a squamosal-alisphenoid internal groove (pattern 1 of Voss 1988).

Compared with other akodont skulls, the rostrum is rather elongated in *Oxymycterus*, notwithstanding that in some species (*O. rufus*, *O. amazonicus*, and *O. delator*) this character is less conspicuous. In cranial morphology, the genera *Juscelinomys*, *Lenoxus*, and *Brucepattersonius* are the most similar to *Oxymycterus*. However, *Oxymycterus* is unique among this group in having prenasal ossifications (*os rostri*) and in the structure of the nasal tube, which is formed by equal contributions of the nasal and premaxillary bones.

Upper incisors are opisthodont, and molars are narrow, moderately hypsodont, and cusps are highly crested. M1 is

marked by a well-incised anteromedian flexus and is twice the length of M2, which is twice as long as M3. The major cusps and internal dentine structures conform to the tetralophodont pattern of akodontines, with an anteroloph(id) and a reduced median loph(id) instead of a well-developed mesoloph. These structures become rather worn in most subadult and adult individuals, so the teeth commonly lose much of the enamel folding complexity of the occlusal surfaces. Although dental morphology has been regarded as conservative in the genus (Hershkovitz 1994), F. G. Hoffmann et al. (2002) reported that young individuals of *O. josei* differ from *O. nasutus* in having a protostyle and a well-marked enterostyle on the M1 and by analogous differences in the m1.

Vertebral counts are 7 cervical, 13 thoracic, 6 lumbar, and 26–33 caudal elements in complete tails. The tail scales are annularly arranged, 13–16 rings per centimeter, and usually have three bristles about 2–3 mm long extending from beneath each scale. The tail ranges from moderately to fairly hirsute, the scales unconcealed to almost concealed in some species. The tail can be unicolorous to moderately bicolored, darker above and lighter below.

Forefeet and hindfeet are relatively long and narrow (hindfoot length with claw varies from 16–32% of the head and body length in adults among different species), and covered dorsally with short hairs to the distal phalanges. The palmar surfaces are naked, with two conspicuous metacarpal pads and three smaller interdigital pads. The plantar surfaces bear four interdigital pads, with the two middle ones larger. The hypothenar pad is slightly smaller than the fourth interdigital pad, and is situated halfway between it and the thenar pad, which is as large as the two middle interdigital pads. Ungual tufts are usually short, but can be as long as the claws in the hindfeet. Digits II through IV bear long, strong, and keeled claws, in both the manus and pes; those of the manus are usually slightly larger. The claw on digit III is the longest, ranging from 2.5–4.5 mm in the different species, as measured in a straight line from the tip of the phalanx in ventral view. Claws of digits II and IV are usually subequal in size, and both are slightly shorter than the third digit's claw, hardly surpassing 4 mm in the largest animals. As in other akodontine rodents, the pollex is atrophied but bears a small claw, 1–2 mm long, that hardly reaches beyond the distal ends of the metacarpals. The fifth manual digit is reduced, with a small to medium-sized claw (1–3 mm long), often reaching the level of the distal phalanx of the fourth digit. The hallux and the fifth pedal digit are of subequal lengths, reaching the level of the distal edges of the interdigital pads, the former bears a larger claw (1.5–2.5 mm long versus 1–1.5 mm for digit V).

Four pairs of mammae, one each in pectoral, thoracic, abdominal, and inguinal positions, are present in all spe-

cies of the genus. Hershkovitz (1994) reported only six pairs of nipples for *O. amazonicus*, but close inspection of specimens housed in the Museu Nacional (MNRJ 32896) and Museu Goeldi (MPEG 8994, 8995) indicates that the mammae count for this species is the same as in others.

Hooper and Musser (1964) described the glans penis of *Oxymycterus* as having a crenate crater rim with essentially no bordering band of spineless tissue, dissimilar bacular mounds, and a robust spinous urethral flap. The baculum is long with a straight shaft and a broadened base. Despite considerable age-related variation, the baculum varies among species in *Oxymycterus* in the shape of the proximal end, developmental extent of lateral condyles, and shape of the distal end (J. A. Oliveira 1998). Soft parts of the glans also vary among species and populations, including size of the dorsal papilla and the spinous ornamentation of the urethral flap (P. R. Gonçalves 2006).

The stomach is bilocular-discoglandular with glandular epithelium contained in a pouch-like diverticulum, characteristics found in insectivorous rodents (Hershkovitz 1994). The gall bladder is usually present, but Geise, Weksler, and Bonvicino (2004) detected intrapopulation variation with respect to this character in *O. dasytrichus*. Specimens referred to *O. dasytrichus* from Ilha Grande, off the southwestern coast of Rio de Janeiro state, lack a gall bladder (Geise, Weksler, and Bonvicino 2004).

REMARKS: J. A. Oliveira (1998) provided detailed histories and descriptions, along with photographs of the skulls, of the type specimens of most nominal taxa of *Oxymycterus*.

KEY TO THE SPECIES OF OXYMYCTERUS:

1. Hindfoot (with claw) about 30mm long or less, not exceeding 32 mm; ear length (from notch) <20mm in length; upper molar series usually <5.3 mm, not exceeding 6mm. 2
- 1'. Hindfoot (with claw) usually >30 mm; ear length (from notch) >20 mm; upper molar series usually >5.3 mm, and not shorter than 5 mm 12
2. Ratio between length of nasal tube (measured from anterior border of incisive alveolus to anteriormost tip of premaxillary) to that of molar series <0.5. 3
- 2'. Ratio between length of nasal tube (measured from anterior border of incisive alveolus to anteriormost tip of premaxillary) to that of molar series >0.5. 5
3. Nasals short, not reaching level of upper zygomatic root, interparietal reduced (ratio of interparietal breadth/braincase breadth usually <0.5); dorsal pelage bright rufous. *Oxymycterus rufus*
- 3'. Nasals long, reaching level of upper zygomatic root; interparietal relatively larger (ratio of interparietal breadth/braincase breadth usually >0.5); dorsal pelage blackish or dark brown 4
4. Palate shorter, not extending posteriorly beyond M3, leaving anterior end of presphenoid visible in ventral view; frontal sinuses less inflated; pelage dark brown *Oxymycterus amazonicus*
- 4'. Palate longer, extending posteriorly beyond M3 and covering anterior end of presphenoid so that it is not visible in ventral view; frontal sinuses more inflated; pelage blackish *Oxymycterus delator*

5. Length of hindfoot with claw \leq or about 23 mm
 *Oxymycterus hucucha*
- 5'. Length of hindfoot with claw $>$ 23 mm 6
6. Found on Atlantic coast of Brazil or Uruguay 7
- 6'. Found in eastern Andes of Peru, Bolivia, or Argentina . 9
7. Zygomatic plate wide, greatest width equal to or $>$ 2.2 mm *Oxymycterus josei*
- 7'. Zygomatic plate narrow, width generally $<$ 2 mm, rarely exceeding 2.2 mm 8
8. Incisive foramina long, extending well beyond posterior limit of inferior root of zygomatic plate; ectotympanic portion of bulla less expanded anterolaterally, resulting in smaller and conical bullae
 *Oxymycterus nasutus*
- 8'. Incisive foramina short, not extending beyond posterior limit of inferior root of zygomatic plate; ectotympanic portion of bulla more expanded anterolaterally, resulting in more quadrangular bullae . . . *Oxymycterus caparaoe*
9. Pelage showing contrast in color between anterior and posterior parts of dorsum or homogeneously dark or blackish brown; interorbital region and nasal tube relatively narrower; zygomatic plate relatively larger (ratio between the interorbital constriction and zygomatic breadth $<$ 0.42; ratio between width of zygomatic plate and width of nasal tube $>$ 0.49) 10
- 9'. Pelage color paler and homogeneously brown throughout dorsum; interorbital region and nasal tube relatively larger; zygomatic plate relatively narrower (ratio between interorbital constriction and zygomatic breadth $>$ 0.42; ratio between width of zygomatic plate and width of nasal tube usually $<$ 0.49) 11
10. Head and anterior part of dorsum of general olive-grayish color, strongly lined with black, becoming more brownish or ochraceous brown toward rump; narrower braincase and zygomatic notches; claws on forefeet and hindfeet moderately developed; less expanded zygomatic arches; incisive foramina longer and with straight edges; lunar notch of mandible symmetrically excavated *Oxymycterus paramensis*
- 10'. Head and dorsal pelage blackish brown with slight ochre or reddish hue; claws on forefeet and hindfeet strong and long, those of digit III reaching more than 6 mm on forefoot and 5 mm on hindfoot; well-expanded zygomatic arches; incisive foramina shorter; asymmetrical due to more excavated ventral portion
 *Oxymycterus wayku*
11. Size averages larger (hindfoot with claw $>$ 25 mm); skull longer, with occipitonasal length usually $>$ 31 mm; if smaller, ratio between zygomatic breadth and occipitonasal length usually $>$ 0.46 . . . *Oxymycterus nigrifrons*
- 11'. Size averages smaller (hindfoot with claw \leq 25 mm); skull shorter, with occipitonasal length usually $<$ 31 mm; ratio between zygomatic breadth and occipitonasal length \geq 0.46 *Oxymycterus hiska*
12. Andean-Amazonian distribution 13
- 12'. Atlantic distribution (west to Río Paraguay) 14
13. Ratio between width of zygomatic plate and width of nasal tube $>$ 0.53 *Oxymycterus inca*
- 13'. Ratio between width of zygomatic plate and width of nasal tube usually \leq 0.53 *Oxymycterus juliaca*
14. Interorbital region relatively broad and nasal tube less elongated, ratio between interorbital width and occipitonasal length generally $>$ 0.17; if lower, ratio between length of nasal tube (measured distally from anterior margin of upper incisors) and length of upper molar row $<$ 0.6; dorsal pelage varying from olivaceous to dark brown, not markedly lined with black
 *Oxymycterus dasytrichus*
- 14'. Interorbital region relatively narrow and nasal tube more elongated, ratio between interorbital width and occipitonasal length generally $<$ 0.17; if higher, ratio between length of nasal tube and length of upper molar row $>$ 0.6; dorsal pelage varying from dark yellow gray to dark orange, markedly lined with black, in some specimens providing a metallic iridescent sheen
 *Oxymycterus quaestor*

Oxymycterus amazonicus Hershkovitz, 1994

Amazonian Hociendo

SYNONYM:

Oxymycterus amazonicus Hershkovitz, 1994:23; type locality "Fondlândia, right bank, lower Rio Tapajóz [sic], Pará, Brazil, 3°40'S, 55°30'W."

DESCRIPTION: Dorsal and lateral coloration of generally dark-brown from head to base of tail, with some specimens paler and more reddish-brown; ventral color varies from orange to reddish orange, with hairs of throat generally paler or even whitish; hindfeet covered dorsally by dark-brown hairs. Head and body length of adults 140–148 mm, tail length 86–95 mm, hindfoot length (with claw) 28–29 mm, and ear length 16–20 mm. Skull with comparatively short and wide rostrum and robust braincase, similar in structure and size to *O. delator* but with frontal sinuses less inflated; nasals longer than in *O. delator* but do not project anteriorly beyond perpendicular plane of anterior incisor border, hardly forming the typical trumpet-shaped nasal tube of genus; zygomatic plates quite variable in width, but their curvature less pronounced than in most species; zygomatic notches relatively broad, correlated with wide infraorbital foramina; incisive foramina relatively wide, specially along maxillary region, and robust palatine septum present; bony palate shorter than *O. delator* not extending posteriorly beyond level of M3, leaving anterior end of presphenoid visible in ventral view.

DISTRIBUTION: Lower Amazon, including regions along the lower parts of Tocantins, Xingú, and Tapajós rivers, southwestward along middle and upper tributaries of Aripuanã and Tapajós rivers to northwestern Mato Grosso state, at least to the southern edge of Serra do Norte (= Serra dos Parecis); to the west, *Oxymycterus amazonicus* has been recorded on the Rio Jamari, an upper affluent of Rio Madeira Basin, in the state of Rondônia.

SELECTED LOCALITIES (Map 117): BRAZIL: Mato Grosso, Aripuanã, Alto do Rio Madeira (MNRJ 46705), Apiacás (MZUSP 35159), Campos Novos (AMNH 37101), Juruena (MZUSP 35162); Pará, Agrovila União, 18 km S and 19 km W of Altamira, Rio Xingu (USNM 521485), BR 165, Santarém to Cuiabá, Santarém (USNM 544637), Fazenda São Raimundo, km 42 (estreito), São João do Araguaia, Marabá (MPEG 10140), Fordlândia, Rio Tapajós (type locality of *Oxymycterus amazonicus* Hershkovitz), [near] Jatobal, 73 km N and 45 km W of Marabá (USNM 519787), Piquiatuba, Rio Tapajós (AMNH 94809); Rondônia, Alto Paraíso (MNRJ 79724).

SUBSPECIES: *Oxymycterus amazonicus* is monotypic.

NATURAL HISTORY: Specimens of *O. amazonicus* from near Altamira (Pará) have been obtained in secondary forest and in *capoeiras* (areas of secondary growth brush) intermixed with rice or manioc plantations, as documented on specimen labels. A specimen from Apiacás, Mato Grosso state, was found from the stomach of a *Bothrops*.

Map 117 Selected localities for *Oxymycterus amazonicus* (●).

REMARKS: *Oxymycterus amazonicus* is closely related to *O. delator*, based on phylogenetic analysis of mtDNA cytochrome-*b* sequences (F. G. Hoffmann et al. 2002), differing by only 2.9% p-distance. See also remarks under *O. delator*.

Oxymycterus caparaoe Hershkovitz, 1998

Mt. Caparaó Homicudo

SYNONYMS:

Oxymycterus caparaoe Hershkovitz, 1998:244; type locality “Arrozal, Parque Nacional do Caparaó, Minas Gerais, Brazil, elevation 2400 m.”

O[xymycterus]. caparaonense F. G. Hoffmann, Lessa, and Smith, 2002:415; incorrect subsequent spelling of *caparaoe* Hershkovitz.

Oxymycterus caparaoe Musser and Carleton, 2005:1157; incorrect subsequent spelling of *caparaoe* Hershkovitz.

DESCRIPTION: Overall dorsal coloration predominantly dark brown (individual hairs with blackish tips, narrow orange subterminal band, and slate gray base); sides of body slightly more orange due to wider pheomelanin band; venter orange but with slaty base showing through; ears dark brown and hindfeet covered dorsally by grayish brown hairs (gray basally and white apically). Pelage long and lax. Head and body length of adults 110–139 mm, tail length 80–104 mm, hindfoot length (with claw) 27–31 mm, and ear length 18–20 mm. Rostrum markedly elongated and narrow, with nasals and premaxillary bones parallel sided and combined to form well projected trumpet-shaped nasal tube; nasals with caudal limits anterior to line linking upper zygomatic roots; zygomatic plates slender, notably curved anteroposteriorly and not considerably arched laterally, delimiting narrow infraorbital foramina and reduced zygomatic notches; interorbital region broad due to laterally inflated supraorbital margins and frontal sinuses, which remain visible in ventral view up to level of M2; incisive foramina relatively short, not extending beyond posterior margin of inferior root of zygomatic plates; bony palate relatively short, not extending posteriorly beyond M3; bullae large and quadrangular, with ectotympanic anteriorly expanded.

DISTRIBUTION: This species is known only from the western slope and altiplano of the Pico da Bandeira, Parque Nacional do Caparaó, along the boundary between the states of Espírito Santo and Minas Gerais, at elevations from 2,100 to 2,400 m.

SELECTED LOCALITIES (Map 118): BRAZIL: Espírito Santo and Minas Gerais: Arrozal, Parque Nacional do Caparaó, 3.0 km N and 0.1 km W of Pico da Bandeira (type locality of *Oxymycterus caparaoe* Hershkovitz).

SUBSPECIES: *Oxymycterus caparaoe* is monotypic.

Map 118 Single known locality for *Oxymycterus caparae* (●).

NATURAL HISTORY: This species has been encountered only at high elevations (>2,100m) on Mt. Caparaó, in close association with the *campos de altitude*, a series of cool-humid grasslands that occur atop the highest summits and altiplano of southeastern Brazil (Bonvicino et al. 1997; Safford 1999). Trapping records of topotypical specimens deposited in MNRJ indicate higher abundance in areas with hygrophilic soils dominated by bunchgrasses (*Cortadeira* spp.) and Andean bamboo (*Chusquea* spp.), which form a cluttered and dense herbaceous cover that is probably used for nesting places.

REMARKS: Hershkovitz (1998) considered *O. caparae* closely related to *O. nasutus*, as both two species share an extremely long and narrow rostrum, relatively narrow and curved zygomatic plates, and relatively small hindfeet. Despite these morphological similarities, however, *O. caparae* can be distinguished from *O. nasutus* by its overall darker dorsal color, relatively larger size, shorter incisive foramina, broader interorbit, and anteroposteriorly inflated and quadrangular bullae.

Oxymycterus dasytrichus (Schinz, 1821)
Atlantic Forest Hociudo, or “rato-bubo” (Bahia), “rato-porco” (Pernambuco), and “trioréu” (São Paulo)

SYNONYMS:

Mus dosytrichos Schinz, 1821:288; type locality “Camamú unweit Bahia,” Brazil (as given by Wied-Neuwied [1826] for the “Rato Bubo” of Schinz [1821]); modified

by Cabrera (1961) to “Rio Mucuri, Bahia, Brazil,” and further to “lower Rio Mucuri” by Avila-Pires (1965), the locality of provenance of the second specimen described by Wied-Neuwied (1826).

H[yputadaeus]. dasytrichos Wied-Neuwied, 1826:425; unjustified emendation of *dosytrichos* Schinz, name combination, and redescription of *Mus dosytrichos* Schinz; Avila-Pires (1965) designated a lectotype.

L[emmus]. dasytrichos: J. B. Fischer, 1829:293; name combination.

Mus dasytrichos: J. B. Fischer, 1829:293; name combination.

Arvicola dasytrichos: Lesson, 1842:147; name combination.

Hesperomys [Oxymycterus] rostellatus Wagner, 1842a:361; type locality “Brasília”; restricted by Gyldenstolpe (1932) to “Eastern Brazil, Bahia” and further restricted by Hershkovitz (1994) to “São Salvador, or Salvador, Bahia, Brazil, 12°59’S, 38°31’W, sea level.”

H[esperomys]. rostellatus: Wagner, 1843a:514; name combination.

Oxymycterus hispidus Pictet, 1843a:211, plates IV and V; no type locality given, but listed by Baud (1977) as “Iles Eos” [= Ilhéus?], Bahia, Brazil (see J. A. Oliveira 1998 for further details concerning the type locality).

O[xymycterus]. rostellatus: Pictet, 1843a:213; name combination.

M[us]. hispidus: Schinz, 1845:179; name combination; not *Mus hispidus* Lichtenstein.

M[us]. hispidulus Schinz, 1845:179; unjustified emendation of *hispidus* Pictet.

Oxymycterus hispidus: Schinz, 1845:180; name combination.

M[us]. rostellatus: Schinz, 1845:189; name combination.

Hesperomys rufus: Burmeister, 1854:183; name combination; part; not *Mus rufus* G. Fischer.

O[xymycterus]. rufus: Burmeister, 1855a:10; name combination; part; not *Mus rufus* G. Fischer.

Hesperomys (Oxymycterus) rufus: E.-L. Trouessart, 1880b:142; name emendation (see Remarks) and name combination; listed as synonym of but not *rufus* G. Fischer.

Hesperomys (Oxymycterus) dasytrichos: E.-L. Trouessart, 1880b:142; name combination, listed as synonym of *O. rufus nasutus*.

Oxymycterus rufus: Winge, 1887:36, plate 1, Figs. 10–11; plate 2, Fig. 14; part; not *rufus* G. Fischer.

[Oxymycterus] dasytrichus: E.-L. Trouessart, 1897:539; emendation of *dosytrichos* Schinz and first use of current name combination; listed as a synonym of *O. rufus*.

Oxymycterus Roberti Thomas, 1901g:530; type locality “Rio Jordão, in the district of Araguay [= Araguari], S.W. Minas Geraes [= Minas Gerais],” Brazil.

Oxymycterus angularis Thomas, 1909:237; type locality “São Lourenço [= São Lourenço da Mata], near Pernambuco. Alt. 30m,” Pernambuco, Brazil.

Hypudaeus dasytrichus: Tate, 1932h:17; name combination.

Oxymycterus rufus dasytrichus: Cabrera, 1961:468; name combination.

Oxymycterus hispidus hispidus: Cabrera, 1961:466; name combination.

Oxymycterus quaestor: Avila-Pires and Gouveia, 1977:25–26; part.

Oxymycterus rosettellatus Vorontsov, 1979:95, Fig. 47; incorrect subsequent spelling of *rostellatus* Wagner.

Oxymycterus angularis: Mares, Willig, Streilen, and Lacher, 1981:4, 117; name combination.

Oxymycterus rufus dasytrichos: Hershkovitz, 1987:37; name combination.

DESCRIPTION: Dorsal color dark-brown to paler brownish red, without strong lining of black; ventral color dark gray to paler, cinnamon buff or pinkish buff. Head and body length of adults 125–197 mm, tail length 90–156 mm, hindfoot length 30–42 mm, and ear length 18–26 mm. Skull robust, proportionally larger in width dimensions of braincase, interorbital region, and zygomatic plates, with relatively longer molar tooth rows (mean 5.6 mm) than most other species of Atlantic coast; nasals long and wide, slightly flared upward at distal ends, with posterior limits extending to line connecting upper zygomatic roots; zygomatic plates wide, with slightly curved anterior margins delimiting broad zygomatic notches and wide infraorbital foramina; premaxillary part of septum of incisive foramina relatively large, approximately two-thirds of septal length, and maxillary portion often thick and sometimes expanded; interparietal characteristically very large.

DISTRIBUTION: *Oxymycterus dasytrichus* occurs throughout eastern Brazil in the states of Pernambuco, Alagoas, Sergipe, Bahia, Minas Gerais, Espírito Santo, Rio de Janeiro, São Paulo, and Paraná, in both coastal forests and isolated interior forest remnants.

SELECTED LOCALITIES (Map 119): BRAZIL: Alagoas, Matriz de Camaragibe, Fazenda Santa Justina, 6 km SSW of Matriz de Camaragibe (UFPB 6960), São Miguel dos Campos, Mangabeiras (MZUSP 7551); Bahia, Palmeiras, Chapada Diamantina, Gerais da Cachoeira da Fumaça (MNRJ 67798), Reserva Biológica Pau Brasil, 15 km NW of Porto Seguro (UFPB 576), Rio Mucuri (AMNH 559), Três Braços, 37 km N and 34 km E of Jequié (USNM 545060); Espírito Santo, Cachoeiro de Itapemirim, 4 mi N of Castelinho (MNRJ 32880), Reserva Florestal Nova Lombardia (MNRJ 32874); Goiás, Anápolis (MNRJ 3357[skull]/AMNH 134881[skin]); Minas Gerais, Além Paraíba (MNRJ 5375), Araguari, Rio Jordão (BM 1.11.3.51), Boca da Mata, km 104–105 on the road from Lagoa Santa to Conceição do

Mato Dentro (MNRJ 13406), Fazenda Esperança, Serro (USNM 282591), Lagoa Santa (ZFMK 397), Passos (MNRJ 12853); Pernambuco, Garanhuns (MNRJ 27218), Macaparana: Fazenda Água Fria (UFPB 6961), São Lourenço da Mata (BM 3.10.1.56); Rio de Janeiro, Angra dos Reis (MNRJ 2566), Fazenda Velha, Tijuca (MNRJ 32857); São Paulo, Barra do Guaraú, Cananéia (MZUSP 24887), Fazenda Intervales (Base do Carmo), Capão Bonito (MVZ 183125), Salto de Pirapora (MZUSP 22693), Varjão, Bertioiga (USNM 484400); Sergipe, Fazenda Cruzeiro, 13 km SSE of Cristinápolis (MNRJ 66570).

SUBSPECIES: We treat *Oxymycterus dasytrichus* as monotypic.

NATURAL HISTORY: This species occurs both in lowland and mountainous regions up to elevations of 1,800 m, in seasonally flooded *várzea* forest and humid open areas near or in forests; in agricultural crop fields, such as sugar cane, coffee, corn, and bananas; and in the tall, pioneer grasses characteristic of secondary formations in the Atlantic Forest of eastern Brazil. M. V. Vieira et al. (2009) documented higher abundances in forest fragments surrounded by rural properties than in those near urban areas in Rio de Janeiro state. *Oxymycterus dasytrichus* has been found in sympatry with other species of the genus in a number of localities in eastern Brazil, throughout the states of Bahia (*O. delator*), Minas Gerais (*O. rufus*, *O. delator*) and São Paulo (*O. judex*) (J. A. Oliveira 1998; P. R. Gonçalves and Oliveira 2004; Geise, Pereira et al. 2004). On the eastern slopes of the Serra deltatiaia (on the border of Rio de Janeiro and Minas Gerais states), *O. dasytrichus* more abundant in submontane forests, becoming increasingly rare at higher elevations (>2,000 m) where *O. delator* becomes more frequent (Geise, Pereira et al. 2004). Habitat information by collector A. Robert on the label of the type specimen of *O. roberti* reads “Foret/Endroit humide.” Also based on label comments, at Anápolis in Goiás state, C. Lako and R. M. Gilmore in 1937 collected individuals amid coffee, corn, and sugar cane fields apparently adjacent to a forest or at the margins of creeks. Pregnant females with two to four embryos have been obtained in August and September at Caruaru, Pernambuco, and from April to November at Viçosa, Alagoas. Both laelapine mites (*Androlaelaps*) and staphylinid beetles (*Amblyopinodes*) parasitize animals on Ilha Grande, Rio de Janeiro state (Martins-Hatano et al. 2002; Bittencourt and Rocha 2002).

REMARKS: Schinz (1821) spelled the specific epithet of his new species *dosytrichos*, and Wied-Neuwied (1826) subsequently gave the variant spelling *dasytrichos*. E.-L. Trouessart (1897) later Latinized Wied-Neuwied’s name to *dasytrichus*, the spelling that has been in prevailing use since then. We thus regard Trouessart’s spelling *dasy-*

trichus as a justified emendation of both *dosytrichos* Schinz and *dasytrichos* Wied-Neuwied (ICZN 1999:Art. 33.2.3.1). Avila-Pires (1965) designated a lectotype for *H[ypudaeus]. dasytrichos* Wied-Neuwied, 1862, a subjective junior synonym of Schinz's (1821) *Mus dosytrichos*, without commenting on the applicability of his action to Schinz's name.

Molecular analyses (F. G. Hoffmann et al. 2002; P. R. Gonçalves and Oliveira 2004) have confirmed the separation of this species from other Atlantic forms, such as *O. quaestor* (including *O. judex*) and *O. rufus*, as had been previously suggested on the basis of morphological comparisons (J. A. Oliveira 1998). The concept of *O. dasytrichus* adopted here includes samples from the northern limits of the range (in Alagoas and Pernambuco states) that have been traditionally referred to as *O. angularis* Thomas, as well as samples from the western (inland) localities such as the "forests bordering the upper Rio Paranaíba," which formed the basis for Thomas' (1901g) description of *O. roberti*, and those from Parnaguá, Piauí, tentatively regarded as representatives of *O. hispidus* by J. A. Oliveira (1998). This concept is based on cranial morphometric patterns, which indicate that these samples represent extremes of a continuum that encompasses the entire range of the "*dasytrichus* and *angularis* groups" (*sensu* J. A. Oliveira 1998) rather than separate and isolated units. Moderate levels of sequence divergence have been found

between samples from Bahia state and those from southeastern Brazil, suggesting well-defined geographic structure uncorrelated with the smooth morphological cline revealed so far (P. R. Gonçalves and Oliveira 2004; P. R. Gonçalves 2006). More comprehensive molecular and morphological sampling of the entire geographic range of *O. dasytrichus* is needed to test the taxonomic scheme presented here.

Oxymycterus delator Thomas, 1903

Spy Hocicudo, Rato-da-Vereda, Hocicudo-Purpúreo de Paraguay

SYNONYMS:

Oxymycterus delator Thomas, 1903b:489; type locality: "Sapucay [= Sapucaí], [Paraguari,] Paraguay."

Oxymycterus roberti: Myers, 1982:85; part; not *Roberti* Thomas, 1903b.

Oxymycterus roberti: Marinho-Filho, Reis, Oliveira, Vieira, and Paes, 1994:151; part; not *Roberti* Thomas, 1903b.

DESCRIPTION: Dorsal color of dark tones, with black predominating because of quite short subapical phaeomelanin bands in banded hairs; samples from Paraguay and central Brazil darkest, those from northeastern and southeastern Brazil less marked blackish; marked patch of paler hairs present above cheeks in most specimens. Ventral pelage distinct from sides and dorsum, generally buffy but darkened in some regions due to visibility of slate-colored hair bases. Tail with relatively long hairs, spanning 3–4 scales, with scales visible to eye in most specimens; tail unicolored and blackish, similar in color to hindfeet and ears. Head and body length of adult specimens 115–174 mm, tail length 70–120 mm, hindfoot length 23–31 mm, and ear length 16–20 mm. Skull with proportionally larger zygomatic plates and basicranial length than other species; most distinctive features inflated anterior part of frontal bones, rounded and heightened braincase, and very angular supraorbital edges. Rostrum reduced and markedly reclined downward, with nasals less projected anteriorly and less flared, not forming typical trumpet-shaped nasal tube, a condition approached only by *O. amazonicus* and *O. rufus*. Incisive foramina wide with septum usually elevated and with thick maxillary part, sometimes expanded at contact with premaxillary part; palate long, extending posteriorly beyond M3 and covering anterior end of presphenoid.

DISTRIBUTION: *Oxymycterus delator* ranges from eastern Paraguay to northeastern Brazil, along a belt of open formations that extends across the states of Mato Grosso, Mato Grosso do Sul, Paraná, São Paulo, Minas Gerais, Bahia, Goiás, Tocantins, Piauí, the western part of Ceará, and the Distrito Federal.

SELECTED LOCALITIES (Map 120): BRAZIL: Bahia, Abaíra, Mata do Tijuquinho, Chapada Diamantina

Map 119 Selected localities for *Oxymycterus dasytrichus* (●).

(MNRJ 67832), Cocos, Fazenda Sertão Formoso (MNRJ 66037), Lençóis, Chapada Diamantina (MNRJ 67558); Ceará, Guaraciaba do Norte (MNRJ 33162); Goiás, Rio das Almas, Jaraguá (MZUSP 3913); Mato Grosso, UHE Manso (UNB 777), 264 km N of Xavantina, Serra do Roncador (BM 80.475); Minas Gerais, Itamonte (MNRJ 46651), Parque Nacional Grande Sertão Veredas (MZUSP 35167); Paraná, Jaguariaiva (MHNCI [PMC 1705]); Piauí, Estação Ecológica de Uruçuí-Una (MZUSP 30349); São Paulo, Itapetininga (USNM 460550), Paranapiacaba (MZUSP 35157); Tocantins, Peixe (MZUSP 35158), Ponte Alta do Tocantins, Estação Ecológica Serra Geral do Tocantins (MZUSP 35163). PARAGUAY: La Cordillera, 1.6 km by road S of Tobati (UMMZ 125953); Misiones, Refugio Faunístico "Atingy" (TK 60856, to be deposited in MNHNP; R. D. Owen, pers. comm.); Paraguari, Sapucay (BM 3.4.7.18).

SUBSPECIES: We treat *Oxymycterus delator* as monotypic.

NATURAL HISTORY: *Oxymycterus delator* is a common member of the small mammal community of the Brazilian Cerrado, being frequently trapped in ecological studies and inventories in central Brazil, most of which have treated this species as *O. roberti* (Alho 1982; Ernest and Mares 1986; Mares et al. 1986; Nitikman and Mares 1987; Gettinger and Ernest 1995; Marinho-Filho et al. 1998; Lacher and Alho 2001). Among the Cerrado physiognomies, the wet grasslands known locally as *veredas* and *campos* are the preferred habitat of *O. delator*. The easternmost populations of the species are associated with montane grasslands (*campos de altitude*) and Cerrado enclaves in Minas Gerais, São Paulo, and Paraná states. The species is apparently sensitive to impacts on herbaceous vegetation cover, as local abundances seem to be greatly reduced after fires. Borchert and Hansen (1983) note the prevalence of earthworms (74%) and insects, especially termites, in stomachs. Predation experiments by Redford (1984) revealed that *O. delator* discriminates between types of termites, preferring species with mechanically based defenses to those with chemically based defenses. These rats generally find termite nests by gleaning the ground surface and uncovering hidden trails. Few reproductive data are available. Males are apparently more territorial than females, and mark their territory with urine and feces (Alho 1982). Pregnant females with up to four embryos were collected in November in Parque Nacional da Chapada dos Veadeiros, Goiás state, and in February and July in Serra do Roncador, Mato Grosso state, Brazil (Bonvicino, Lindbergh, and Maroja 2002; Bonvicino, Lemos, and Weksler 2005).

REMARKS: This species was previously considered to be restricted to Paraguay and possibly adjacent Brazil (Moojen 1952b), but J. A. Oliveira (1998) documented an expansive distribution across the wide belt of open forma-

Map 120 Selected localities for *Oxymycterus delator* (●).

tions from Paraguay to northeastern Brazil. F. G. Hoffmann et al. (2002) detected low sequence (cytochrome-*b*) divergence between *O. delator* and *O. amazonicus*. P. R. Gonçalves (2006), in a more comprehensive phylogeographic analysis based on both mitochondrial and nuclear genes, revealed that samples of *O. amazonicus* are nested within an expanded *O. delator* clade, resulting in a paraphyletic *O. delator*. Nevertheless, samples representing both *O. amazonicus* and *O. delator* are diagnosable for a number of morphological attributes. Consequently, we continue to recognize the two as separate species. The karyotype is $2n=54$, $FN=62$ (Svartman and Cardoso de Almeida 1993b; Bonvicino, Lemos, and Weksler 2005).

Oxymycterus hiska Hinojosa, Anderson, and Patton, 1987

Small Yungas Homicudo

SYNONYMS:

Oxymycterus hiska Hinojosa, Anderson, and Patton, 1987: 14; type locality "14 km W of Yanahuaya, department of Puno, Peru, at 2210 m elev.; lat. 14°19'S and long. 69°21'W," near Abra Marracunca, on the ridge separating the drainages of the Río Huari Huari and Río Tambopata.

Oxymycterus paramensis nigrifrons: S. Anderson, 1997: 439; part; not *Oxymycterus paramensis nigrifrons* Osgood.

DESCRIPTION: Small, with head and body length 97–126 mm, tail length 77–91 mm, hindfoot length (with claw) 23–25 mm, ear length 13–16 mm, and mass of adult specimens 30–44 g. Dorsal pelage short and fine, glossy in appearance, and colored blackish gray with hairs on both dorsal and ventral surfaces tipped ochraceous, especially in older individuals, so that younger animals appear darker, almost black. Tail uniformly blackish brown from base to tip above and below; caudal scales readily visible to eye. Skin of dorsal and palmar surfaces of pes dark, with sparsely distributed hairs on dorsum blackish; ungual hairs of hindfeet do not reach claw tips. Skull also small, with condyloincisive length 23.5–25.9 mm; narrow (1.46–1.76 mm) zygomatic plates slant distinctly backward from bottom to top; relatively long and parallel-sided incisive foramina reach protocone of M1s; relatively long nasal tube (ratio of tube length to maxillary toothrow length, 0.57) flared distally to form slight to well-developed trumpet; short tooth rows (4.79–5.01 mm); and anteroloph of M1 divided by shallow anteromedian flexus into equal-sized conules.

DISTRIBUTION: This species is known from only a few specimens obtained at elevations from 600 to about 3,500 m, in the Yungas of the southern part of Cordillera de Carabaya (Puno, Peru), the Cordillera Real (La Paz, Bolivia), and the Siberia Cloud Forest of the Cordillera Oriental (Cochabamba department, near the border with Santa Cruz department, Bolivia).

SELECTED LOCALITIES (Map 121): BOLIVIA: Cochabamba, Yungas near Pojo, Carrasco (ZFMK 92403); La Paz, Mapiro, Larecaja (AMNH 72889), Okara (AMNH 72750), Tacacoma (AMNH 91601). PERU: Puno, 14 km W of Yanahuaya (type locality of *Oxymycterus hiska* Hinojosa, Anderson, and Patton).

SUBSPECIES: *Oxymycterus hiska* is monotypic.

NATURAL HISTORY: The holotype and other specimens obtained at the type locality were collected in mossy runways, under logs, or around tree roots in low montane humid forest dominated by epiphyte-laden trees, cecropias, bamboos, and tree ferns. The specimen from Yungas near Pojo (Cochabamba), obtained by J. Niethammer in August 1951, has the information “in urwald” (= in primary forest, or jungle) written on the label. A female was taken at 2.5 km S Tacacoma, La Paz department, Bolivia, ca. 3,500 m, in humid subtropical montane forest and in mixed *Polylepis* woodland, composed of dense, epiphyte-covered trees of short stature (5–6 m) on a 30–40° slope (Salazar-Bravo, Yensen et al. 2002). The holotype and other females obtained at the type locality showed signs of recent reproductive activity in late July and early August, suggesting a breeding season at the end of the rainy season (March or April) (Hinojosa et al. 1987).

Map 121 Selected localities for *Oxymycterus hiska* (●). Contour line = 2,000 m.

REMARKS: J. A. Oliveira (1998) assigned Bolivian specimens from La Paz department, Bolivia, previously referred to *Oxymycterus paramensis nigrifrons* by S. Anderson (1997), to *O. hiska*. Salazar-Bravo, Yensen et al. (2002) corroborated the presence of *O. hiska* in Bolivia. The record from Mapiro is based on an incomplete specimen, but if confirmed would suggest possible sympatry with *O. inca*. *Oxymycterus hiska* is morphometrically similar to *O. nigrifrons*, with which it is possibly sympatric in the upper Río Inambari drainage (Puno department, Peru).

Oxymycterus hucucha Hinojosa, Anderson, and Patton, 1987

Quechuan Hocicudo, Hucucha

SYNONYMS:

Oxymycterus hucucha Hinojosa, Anderson, and Patton, 1987:15; type locality “28 km by road W of Comarapa (Santa Cruz) but in the department of Cochabamba, Bolivia, at 2800 m elev.; lat. 17°51’S and long. 64°40’W.”

Oxymycterus hucucha: Salazar-Bravo and Emmons, 2003:147; incorrect subsequent spelling of *hucucha* Hinojosa, Anderson, and Patton.

DESCRIPTION: Smallest species in genus (only slightly smaller than *O. hiska*), with head and body length 99–109 mm, tail length 71–75 mm, hindfoot length 21 mm, ear length 14–15 mm, and mass 26–36 g. Coloration similar to that of *O. hiska*, but tips of dorsal hairs conspicuously paler and more reddish. Ungual tufts also longer, some

Map 122 Selected localities for *Oxymycterus hucucha* (●). Contour line = 2,000 m.

reaching claw tips on pes. Skull also similar to that of *O. hiska*, but narrower across rostrum, interorbital region, and braincase, and smaller in most other dimensions (see Hinojosa et al. 1987).

DISTRIBUTION: *Oxymycterus hucucha* is known from only a few localities in the vicinity of the Siberia Cloud Forest, Cochabamba and Santa Cruz departments, Bolivia.

SELECTED LOCALITIES (Map 122): BOLIVIA: Cochabamba, 28 km W of Comarapa (type locality of *Oxymycterus hucucha* Hinojosa, Anderson, and Patton), 20 mi E of Totorá (MVZ 119948).

SUBSPECIES: *Oxymycterus hucucha* is monotypic.

NATURAL HISTORY: The holotype and two other specimens were collected in the Siberia Cloud Forest, a humid forest with trees 6 m in height, trunks covered with lichens, and dense ground cover comprising lichens, ferns, and mushrooms in central Bolivia (Hinojosa et al. 1987). There is no other information on this species.

REMARKS: This very distinctive small species is cranio-metrically closest to *O. paramensis* (J. A. Oliveira 1998).

Oxymycterus inca Thomas, 1900

Inca Hociudo, Hociudo Castaño del Perú

SYNONYMS:

Oxymycterus inca Thomas, 1900:298; type locality “Perené, Ucayali watershed, Department of Junin, E. Peru. Altitude 800 m.”

Oxymycterus iris Thomas, 1901a:183; type locality “San Ernesto, near Mapiri, Upper Beni River, [La Paz,] Bolivia. Alt. 1000 m.”

Oxymycterus inca Reig, 1987:361; incorrect subsequent spelling of *inca* Thomas.

Oxymycterus inca inca: Cabrera, 1961:467; name combination.

Oxymycterus inca iris: Cabrera, 1961:467; name combination.

DESCRIPTION: Moderate sized, with adult head and body length 135–184 mm, tail length 85–122 mm, hindfoot length 29–35 mm, ear length 19–23 mm. Overall dorsal color tones brown, notably grizzled with black on crown and along midline, becoming paler on sides. Ventral pelage predominantly dark orange, slate-colored base of hairs completely covered by orangish tips, with characteristically pale, banded hairs extending along undersurface of forelimbs, with clear strip of yellowish orange hairs extending to the wrists. Forefeet, hindfeet, and tail dark brown; tail unicolored and moderately hairy, with hairs spanning four tail scales in length near base and becoming longer toward tip. Skull with proportionally long upper toothrows (5.2–5.9 mm), wide rostrum (4.32–5.25 mm), and relatively short orofacial dimensions. Cranial morphology resembles that of Atlantic coast *O. dasytrichus*, from which it differs by the relatively narrower bullae (5.2–5.8 mm), braincase (13.3–14.9 mm), and interorbital constriction (5.9–6.9 mm).

DISTRIBUTION: This species occurs along affluents of the upper Río Ucayali in Junín department, Peru, and in the lowlands in Santa Cruz department, Bolivia, extending eastward into the western Amazon of Acre state, Brazil. Records from La Paz, Bolivia, are from lower montane affluents of the Río Beni system; the sole record from western Brazil is from lowland tropical rainforest. All records are from localities at 1,000 m or below.

SELECTED LOCALITIES (Map 123): BOLIVIA: La Paz, Guanay (AMNH 72747), San Ernesto, Mapiri (type locality of *Oxymycterus iris* Thomas); Santa Cruz, 6 km by road W of Ascención (AMNH 262258), Ayacucho (AMNH 263344), Buenavista, Ichilo (BM 26.12.4.62), Estancia Cachueta Esperanza (AMNH 260603), Santa Cruz de la Sierra, Andrés Ibáñez (MNRJ 22787). BRAZIL: Acre, Sena Madureira (USNM 546292). PERU: Junín, Perené (type locality of *Oxymycterus inca* Thomas).

SUBSPECIES: We recognize two subspecies, *O. i. inca* from Peru and Santa Cruz department, Bolivia, and *O. i. iris* from La Paz department Bolivia.

NATURAL HISTORY: Few data are available on habitat, behavior, food, or reproduction (S. Anderson 1997)—available information is restricted to collectors’ notes recorded on specimen labels. Specimens from San

Ernesto (Mapiri, La Paz department, Bolivia) were captured in grasses during the daytime (P. O. Simmons, on specimen labels). Females captured in June 1964, near La Merced, Junín, Peru, were either lactating or had placental scars from four to six embryos; males collected in the same period had scrotal testes (label notes by T. B. Seifert, N. E. Coon, F. J. Myers, D. R. Seidel, and D. Castanon). This species was found only at sites with the highest diversity of rodents and marsupials, which was probably related to the presence of bamboo in forest habitats of the upper Río Urubamba valley in southeastern Peru (Solari et al. 2001). Jiménez-Ruiz and Gardner (2003) reported parasitic nematodes in Bolivian specimens.

REMARKS: Cabrera (1961) treated the nominal forms *inca*, *iris*, *juliaca*, and *doris* as subspecies of *O. inca*, an arrangement followed in most subsequent taxonomic lists. Morphometric analyses by J. A. Oliveira (1998) revealed that samples from Junín, Peru (including the holotype of *O. inca*), La Paz, Bolivia (including the type series of *O. iris*), and Santa Cruz, Bolivia, are different from other samples from Peru and Bolivia and that included the type specimens of *O. juliaca* and *O. doris*. Therefore, we treat *juliaca* and *doris* as belonging to a separate species, for which the name *O. juliaca* is the older (see *O. juliaca* account). J. A. Oliveira (1998) interpreted the morphometric variation among the samples from Junín (Peru), La Paz (Bolivia), and Santa Cruz (Bolivia) as suggestive of subspecific differentiation. Therefore, the samples from Junín and Santa Cruz are assigned to

O. inca inca, and the sample from La Paz is recognized as *O. inca iris*. Morphological and genetic studies of additional samples of *O. inca* are pending in order to properly evaluate the taxonomic status of the subspecies we recognized.

Oxymycterus josei F. G. Hoffmann, Lessa, and Smith, 2002

Cook's Hociendo

SYNONYM:

Oxymycterus josei F. G. Hoffmann, Lessa, and Smith, 2002:411; type locality "West margin of Arroyo Tarariras, Balneario Las Flores, Departamento de Maldonado, Uruguay."

DESCRIPTION: Medium sized with reddish to dark-brown pelage and occasional white spots on venter; dorsal pelage of most specimens long and resembles that of *O. rufus* from Córdoba province, Argentina, with light ochraceous buffy color strongly lined with black. Adult head and body length 122–172 mm, tail length 75–104 mm, hindfoot length 24–29 mm, ear length 15–18 mm, and mass 36–125 g. Skull with relatively short rostrum, inflated frontal sinuses, and downward dorsal profile without distal flaring of nasal tube, conditions also seen in *O. rufus* and *O. delator*. Zygomatic plates relatively wide, approaching conditions also in *O. rufus* and *O. delator* when compared with sympatric *O. nasutus* (García-Olaso 2008), but narrower than those of other large-sized species such as *O. dasytrichus*. Interorbital region with rounded margins, braincase walls parallel and not rounded, both supraoccipital and lambdoidal ridges well developed, and interparietal reduced. Ventrally, incisive foramina elongated and ovate, extending beyond anterior conule of M1s. Baculum resembles that of *O. rufus*, with longitudinally enlarged proximal end and reduced lateral condyles with small lateral spikes, characters not present in sympatric *O. nasutus* (J. A. Oliveira 1998).

DISTRIBUTION: This species is known only from southwestern Uruguay, south of the Río Negro, in the departments of Soriano, Colonia, San José, Canelones, and Maldonado (F. G. Hoffmann et al. 2002).

SELECTED LOCALITIES (Map 124): URUGUAY: Maldonado, Las Flores (MVZ 183266); Soriano, 3 km E of Cardona (AMNH 206205).

SUBSPECIES: *Oxymycterus josei* is monotypic.

NATURAL HISTORY: F. G. Hoffmann et al. (2002) reported sympatry between *O. josei* and *O. nasutus* at two localities in Maldonado, Uruguay. They stated that Barlow's (1969) data on the natural history of *O. nasutus* needed reevaluation because *O. josei* was not recognized at the time of his studies.

REMARKS: *Oxymycterus josei* was described as very similar in morphology to *O. nasutus*, differing by larger size, broader zygomatic plates, and a few dental traits

Map 123 Selected localities for *Oxymycterus inca* (●). Contour line = 2,000 m.

Map 124 Selected localities for *Oxymycterus josei* (●).

(F. G. Hoffmann et al. 2002). The discriminating value of the dental characters was later questioned by García-Olaso (2008) based on comparisons with sympatric *O. nasutus*. J. A. Oliveira (1998) remarked on the similarities of dorsal pelage color pattern and baculum between *O. josei* and *O. rufus*. Phylogenetic analyses of mtDNA cytochrome-*b* sequences placed *O. josei* as sister to *O. rufus*, but differing only by 1.7–1.9% corrected pairwise sequence divergence (F. G. Hoffmann et al. 2002; P. R. Gonçalves and Oliveira 2004; Jayat, D'Elía et al. 2008).

Oxymycterus juliacae J. A. Allen, 1900

Upper Yungas Inca Hociudo

SYNONYMS:

Oxymycterus juliacae J. A. Allen, 1900a:223; type locality “Juliaca, [Puno,] Peru”; corrected to “Inca Mines [= Santo Domingo Mine], about 200 miles northeast of Juliaca, on the east side of the Andes, on the Inambari River [= Río Inambari],” Puno, Peru, by J. A. Allen (1901b:41).

Oxymycterus doris Thomas, 1916j:478; type locality “Charuplaya, Upper Mamoré, 65°5'W., 16°S', [Beni,] Bolivia, Alt. 1350m.”

Oxymycterus inca juliacae: Cabrera, 1961:467; name combination.

Oxymycterus inca doris: Cabrera, 1961:467; name combination.

Oxymycterus juliacae doris: J. A. Oliveira, 1998:284; name combination.

DESCRIPTION: Moderate sized, head and body length 125–155 mm, tail length 95–140 mm, hindfoot length 27–36 mm, and ear length 19–24 mm. Dorsal color overall dark brown, slightly darker on posterior part of back and rump; venter drab brown. Dark hairs cover dorsal surfaces of forefeet and hindfeet. Short hairs, extending over 2–3 scales in length, uniformly cover the tail. Skull with proportionately long tooththrows (5.0–5.8 mm), wide zygomatic breadth (15.1–17.8 mm), and wide interorbital constriction (6.3–6.9 mm), contrasting with all species except *O. dasytrichus*.

DISTRIBUTION: *Oxymycterus juliacae* occurs in upper montane and cloud forests in tributaries of the Río Inambari (Cusco and Puno departments, Peru) and Río Chaparé (Cochabamba department, Bolivia), at elevations between 1,000 and 2,700 m.

SELECTED LOCALITIES (Map 125): BOLIVIA: Cochabamba, Charuplaya, Río Securé (type locality of *Oxymycterus doris* Thomas), Incachaca (AMNH 38641), Yungas, N of Locotal (AMNH 38646). PERU: Cusco, Hacienda Cadena, Marcapata FMNH 65706; Puno, Inca Mines (type locality of *Oxymycterus juliacae* J. A. Allen).

SUBSPECIES: We treat *Oxymycterus juliacae* as monotypic.

NATURAL HISTORY: Based on data from specimen labels, this species is a terrestrial inhabitant of the upper montane and cloud forests.

Map 125 Selected localities for *Oxymycterus juliacae* (●). Contour line = 2,000 m.

REMARKS: The type locality, originally given as Juliaca (15°30'S, 70°00'W), situated west of Lake Titicaca on the Andean Altiplano, was corrected to Inca Mines [= Santo Domingo Mine] on the eastern Andean slope (J. A. Allen 1901b). Following Cabrera (1961), most authors have listed *Oxymycterus juliacae* as either a valid subspecies or a synonym of *O. inca* Thomas. However, J. A. Oliveira (1998) documented the morphometric distinctness of *O. juliacae* relative to *O. inca* and the conspecificity of *doris* Thomas with the former.

Oxymycterus nasutus (Waterhouse, 1837)

Darwin's Hociudo, Long-nosed Hociudo

SYNONYMS:

Mus nasutus Waterhouse, 1837:16; type locality "Maldonado," Maldonado, Uruguay.

Mus (Oxymycterus) nasutus: Waterhouse, 1837:21; name combination.

O[xymycterus]. nasutus: Pictet, 1843a:211; first use of current name combination.

H[esperomys]. nasutus: Wagner, 1843a: 514; name combination.

Holochilus nasutus: Gray, 1843b:114; name combination.

M[us]. nasutus: Schinz, 1845:179; name combination.

Hesperomys (Oxymycterus) nasutus: Thomas, 1884:450; name combination.

Oxymycterus rufus nasutus: Cabrera, 1961:468; name combination.

DESCRIPTION: Adult specimens with head and body length 123–131 mm, tail length 87–97 mm, hindfoot length 27–28 mm, and ear length 17–18 mm. Dorsal pelage color quite variable; specimens from Uruguay vivid dark orange, heavily lined with black (particularly on head and middorsum), but paler on sides; those from Brazil much darker and duller, without black lined characteristic, or intermediate between two chromatic extremes. Venter in both extremes paler than dorsum, but of same overall hue. Forefeet and hindfeet well-haired, light to more strongly brown above. Tail slightly bicolored to unicolored; hairs about 2–3 scales in length. Skull with protruded, narrow, and trumpet-shaped rostrum; braincase elongated. Overall appearance very similar to that of *O. caparaoe* but with relatively longer incisive foramina, narrower interorbital region, and smaller bullae.

DISTRIBUTION: *Oxymycterus nasutus* ranges through Uruguay and the southern Brazilian states of Rio Grande do Sul, Santa Catarina, and Paraná. It occurs at sea level in the southernmost localities of Uruguay and Rio Grande do Sul, but occupies progressively higher elevations (up to 1,700 m) at more northern localities.

SELECTED LOCALITIES (Map 126): BRAZIL: Paraná, Castro (MZUSP 2497), Estação Ecológica Canguiri,

Piraquara (MNRJ 78463); Rio Grande do Sul, Camará do Sul (MNRJ 46696), Eldorado do Sul, Charqueadas (MNRJ 46689), Estação Ecológica do Taim (MNRJ 46664), São Lourenço do Sul (BM 85.6.26.19). URUGUAY: Canelones, Arroyo Tropa Vieja (MNRJ 42435); Maldonado, 15 km N of San Carlos (FMNH 29249); Rocha, Cerro Largo, 6 km SE of Melo (AMNH 206172), 22 km SE of Lascano (AMNH 206189).

SUBSPECIES: *Oxymycterus nasutus* is monotypic.

NATURAL HISTORY: This species inhabits wet grasslands and steppes (*campos sulinos*) that dominate much of the plains of Uruguay and southern Brazil, and that are scattered throughout the southern Brazilian plateau. *Oxymycterus nasutus* can be the most abundant small mammal species in these habitats in the high-elevation grasslands in the states of Rio Grande do Sul and Santa Catarina. It occurs in sympatry with the larger *O. judex judex* in Brazil, with *O. josei* in Uruguay, and probably with *O. quaestor* in Paraná state in its northernmost distributional limits. Some ecological observations made by Barlow (1969) in his study of Uruguayan rodent populations are worth mentioning, although they should be interpreted with caution because he probably included *O. josei* in the animals he studied (F. G. Hoffmann et al. 2002). Barlow reported that *O. nasutus* was most frequently trapped in wet meadows with stands of bunch grass and in tall grass near streams and rivers, but never occurred in inundated marshes where more hydrophilic cricetids (e.g., *Holochilus* and *Scapteromys*) were present. These rats commonly used trails of *Cavia* and *Hydrochoerus* as pathways through the tall grass. Stomach contents revealed a predominantly arthropod-based diet, but also included small quantities of earthworms (Oligochaeta), slugs (Gastropoda), and plant material. Barlow's detailed description of the habitats and habits of Uruguayan rodents is one of the first to note that specimens of *Oxymycterus* have a distinct and strong scent when caught, similar to acrylic aldehyde, to which he attributed a putative warning function. The species exhibited diurnal activity pattern, with peaks during dusk and dawn hours, in southern Brazil (Paise and Vieira 2006). Barlow (1969) reported litter sizes ranging from one to six embryos.

REMARKS: The type specimen was acquired by Charles Darwin during his stay in Maldonado, Uruguay, and is the type species of the genus. Cabrera (1961) questioned the species status of *O. nasutus*, regarding it as a subspecies of *O. rufus*. Since then, J. A. Oliveira (1998), F. G. Hoffmann et al. (2002), and P. R. Gonçalves and Oliveira (2004) have presented morphological and/or molecular evidence for its status as a species. Congeneric species sympatric with *O. nasutus* differ consistently from it in size, external morphology, and craniodental traits (F. G. Hoffmann et al. 2002).

Map 126 Selected localities for *Oxymycterus nasutus* (●).

Oxymycterus nigrifrons Osgood, 1944

Elfin Forest Hocićudo

SYNONYMS:

Oxymycterus paramensis nigrifrons Osgood, 1944:197; type locality: "Limbani, Puno, Inambari drainage, Peru. Altitude about 9,000 feet."

Oxymycterus nigrifrons: J. A. Oliveira, 1998:254; first use of current name combination.

DESCRIPTION: Adults with head and body length 117–133 mm, tail length 79–96 mm, and hindfoot length 23–27 mm. Overall dorsal color light brownish, neither particularly darker in any region nor lined with black; ventral color paler yellowish wash, but with dark gray bases of hairs apparent. Hairs of forefeet and hindfeet almost totally nonpigmented, and those of tail short (2–3 scales in length), dark above and nonpigmented below, but still providing overall unicolored aspect and notably light brownish tone. Skull relatively long (occipitonasal length >31 mm), narrow, and with sharper angles; toothrow length (4.3–5.2 mm) comparatively short.

DISTRIBUTION: *Oxymycterus nigrifrons* is known from the type locality, in the elfin forests of the southern Cordillera Carabaya (Puno department, Peru) at 3,350 m, and from the Cordillera Real in La Paz department, Bolivia, at elevations from 2,000 to 2,700 m.

SELECTED LOCALITIES (Map 127): BOLIVIA: La Paz, Ñequejahuira (AMNH 72751), 18 km by road N of

Map 127 Selected localities for *Oxymycterus nigrifrons* (●). Contour line = 2,000 m.

Zongo, Cuticucho (UMMZ 156084), 30 km by road N of Zongo, Cement Mine (UMMZ 155943). PERU: Puno, Limbani (type locality of *Oxymycterus paramensis nigrifrons* Osgood).

SUBSPECIES: *Oxymycterus nigrifrons* is monotypic.

NATURAL HISTORY: Habitat descriptions (field notes of G. G. H. Tate, cited in Boom 1981) of collecting localities along the Río Aceramarca, Bolivia, indicate that the species inhabits cold temperate forests, second-growth brush, and fields in valleys edged by abrupt cliffs with Puna vegetation on the tops.

REMARKS: *Oxymycterus nigrifrons* was described as a subspecies of *O. paramensis* on the basis of pelage characters, and was named after a supranarial blackish patch regarded as distinctive. J. A. Oliveira (1998), however, documented that the type series from Limbani (Puno department, Peru) was craniometrically different from *O. paramensis* from the Altiplano and was related to samples from the elfin forests of the upper Yungas of La Paz, Bolivia, here regarded as conspecific, as well as different from *O. hiska*, a smaller form from similar elevation and habitat.

Oxymycterus paramensis Thomas, 1902

Páramo Hocićudo, Huacucho

SYNONYMS:

Oxymycterus paramensis Thomas, 1902b:139; type locality "Choquecamate [= Choquecamata], [Cochabamba], 4000 m," Bolivia.

Oxymycterus akodontius Thomas, 1921k:615; type locality “Higuerilla.—2000 m., in the Department of Valle Grande, about 10 km. east of the Zenta range and 20 km. of the town of Tilcara,” Jujuy, Argentina. Pardiñas et al. (2007) equated Higuerilla (an abandoned ranch) to the modern village of Pampichuela (23°32'S, 65°02'W, 1,735 m).

Oxymycterus paramensis jacentior Thomas, 1925b:580; type locality “Carapari [= Caraparí], 1000 m., about 35 kilometres north of Yacuiba, on the way toward the town of Tarija, [Cochabamba,] Bolivia.”

Oxymycterus paramensis paramensis: Gyldenstolpe, 1932a: 130; name combination.

Oxymycterus rutilans paramensis: Hershkovitz, 1966a: 127; name combination.

Oxymycterus inca doris: S. Anderson, 1997:438; name combination; part, not *doris* Thomas.

Oxymycterus akodontinus Mares, Ojeda, Braun, and Barquez 1997:124; incorrect subsequent spelling of *akodontius* Thomas (see Remarks).

DESCRIPTION: Adult individuals with head and body length 105–160 mm, tail length 75–124 mm, hindfoot length 25–32 mm, and ear length 15–23 mm. Dorsal color predominantly deep olive buff, strongly lined with black on anterior half of body, and brownish with less contrasting black lines over rump; ventral color pale buff to yellowish gray, with gray base of individual hairs visible; tail bicolored along length and well haired, with individual hairs extending over 4–5 scales; scales not visible. Dorsal surfaces of both hands and feet covered by ochraceous or buff colored hairs. Young specimens generally darker, with noticeably darker feet and tail, and relatively more limited contribution of yellowish distal parts of hairs to general ventral color. Skull slender, with proportionally large values for basisphenoid and premaxilla lengths than in other species; toothrow length longer and rostral tube wider, but both incisive foramina and palatal length shorter than in sympatric *O. nasutus*.

DISTRIBUTION: *Oxymycterus paramensis* occurs throughout the Andean Altiplano from Cusco department (Peru), south through La Paz, Cochabamba, and Tarija departments, Bolivia, and on the eastern Andean slopes in Chuquisaca and Tarija departments, Bolivia, south to Jujuy and Salta provinces, Argentina.

SELECTED LOCALITIES (Map 128): ARGENTINA: Jujuy, Caimancito (FMNH 41280), León (BM 18.1.1.33); Salta, Sierra de Aguaray, Tartagal (FMNH 35251). BOLIVIA: Chuquisaca, 2 km E of Chuhuayacu (AMNH 263889), Tola Orco, 40 km from Padilla, Tomina (USNM 276603); Cochabamba, Arani (FMNH 46151), Chapare (BM 34.9.2.166), Choquecamata (type locality of *Oxymycterus paramensis* Thomas), Pocona (BM 34.9.2.167),

17 km E of Totorá, Tinkusiri (AMNH 264209), Vinto (AMNH 38625); La Paz, Caracato (AMNH 248999); Tarija, Caraparí (type locality of *Oxymycterus paramensis jacentior* Thomas), 3 km SE of Cuyambuyo (AMNH 264206), 4.5 km E of Iscayachi (AMNH 244203), Tapehua (AMNH 264201). PERU: Cuzco, Chospayoc, Urubamba (USNM 194699), Paso Ocobamba (BM 22.1.1.990), W of Pilcopata, Consuelo (FMNH 123960).

SUBSPECIES: We regard *Oxymycterus paramensis* as monotypic (but see Remarks).

NATURAL HISTORY: Brief microhabitat descriptions from localities distributed throughout the range are written on specimen labels, such as “rounded hills covered with grass” (specimens from Ocobamba Paso, Ollantaytambo, Peru); “in stone pile,” “in grassy place,” “in grass hill side,” “in rock wall,” or “rocky hillside at base of *Puya raimondii*” (specimens from Cochabamba, Bolivia, labels by P. O. Simmons and D. C. Schmitt); “tiene sus cuevas en tierra humeda, como *Ctenomys*, raro” (type series of *O. akodontius*, labels by E. Budin); or “cazado en un cerco de ramas,” “habita las barrancas humadas entre los pinos,” and “habita entre ramas de pinos” (holotype of *jacentior*, label also by E. Budin). Malygin and Rosmiaret (2005) included *O. paramensis* in a group of species inhabiting transitional biotopes, boundary areas between forest and open spaces, where individuals refuged in burrows, consumed seeds and grasses, and maintained low densities despite an average of five embryos per litter.

A single specimen obtained in Tucumán province, Argentina, came from the most humid part of a transition forest (Barquez et al. 1991) related to the Yungas, from the basal stratum to the highland pastures (P. E. Ortiz and Pardiñas 2001). R. A. Ojeda and Mares (1989) also collected specimens in lower montane and transitional humid forested habitats and on stream banks in Salta province, Argentina, where the species seems to be restricted to humid forests and secondary vegetation (Mares, Ojeda, and Kosco 1981; Mares, Ojeda, and Barquez 1989). Jiménez-Ruiz and Gardner (2003) reported parasitic nematodes in Bolivian specimens, and Pia et al. (2003) noted predation by the Culpeo (*Lycalopex culpaeus*).

REMARKS: Although considering *O. paramensis* to be distributed along a wide latitudinal range in the Andean Altiplano, Thomas (1925b) recognized *O. p. jacentior* as a subspecies of lower elevations in northern Argentina. Osgood (1944) described *O. paramensis nigrifrons* from Limbani, Puno department, Peru, on the basis of pelage characters. Cabrera (1961) also regarded *nigrifrons* as a subspecies of *O. paramensis* and extended the range of *O. p. jacentior* to extreme southern Bolivia and to the provinces

of Salta and Jujuy in Argentina, an arrangement that was followed by S. Anderson (1997) for Bolivian samples. However, J. A. Oliveira (1998), using principal component and discriminant analyses of craniometric characters, showed that samples referred to *O. p. paramensis* and *O. p. jacentior* by Anderson (1997), as well as the type specimen of *O. akodontius*, were indistinguishable but were divergent from the type series and other samples identified as *O. nigrifrons*, which is here recognized as a distinct species. J. A. Oliveira (1998) also documented that young and subadult individuals of *O. paramensis* have a darker pelage, similar to the type series of *O. akodontius*. Furthermore, Jayat, D'Elía et al. (2008) found that mtDNA cytochrome-*b* haplotypes referred to *O. paramensis paramensis* and *O. paramensis jacentior* are not reciprocally monophyletic. Thus, *O. paramensis* is here regarded as monotypic, pending further analyses including topotypical specimens, a survey of diagnostic characters, and a more precise definition of geographic limits among putative species or subspecies in this group.

The supposed record of *O. "akodontinus"* from Andalgalá in Catamarca province, Argentina, cited by Mares, Ojeda, Braun et al. (1997), is based on a specimen (MACN 50.434) acquired by J. A. Crespo in 1950. Pardiñas, D'Elía et al. (2006) reidentified this specimen as *Abrothrix illutea*.

Kajon et al. (1984) reported a karyotype with $2n=54$, $FN=64$ for specimens they identified as *O. akodontius* and from San León de Jujuy in northwestern Argentina.

Map 128 Selected localities for *Oxymycterus paramensis* (●). Contour line = 2,000 m.

Oxymycterus quaestor Thomas, 1903

Quaestor Hocicudo, *Rato-Quati*, *Rato-Mineiro*

SYNONYMS:

Hesperomys rufus: Burmeister, 1854:183; part; not *Mus rufus* G. Fischer.

Oxymycterus rufus: Pelzeln, 1883:75; part; not *Mus rufus* G. Fischer, 1814.

Oxymycterus quaestor Thomas, 1903a:226; type locality "Roça Nova, Paraná, altitude 1000m," Brazil.

Oxymycterus judex Thomas, 1909:238; type locality "Joinville, Santa Catarina," Brazil.

Oxymycterus misionalis Sanborn, 1931b:1; type locality "Rio Paranay [= Río Paranay Guazú], an affluent of Rio Parana, near Caraguatay, about 100 miles south of Rio Iguassu, Misiones Territory, Argentina." Pardiñas et al. (2007:397) restricted the type locality to the "confluence of the río Paranay-Guazú with the río Paraná (26°41'S, 54°49'W, 122m), Libertador General San Martín, Misiones."

Oxymycterus questor Gyldenstolpe, 1932a:131; incorrect subsequent spelling of *quaestor* Thomas.

Oxymycterus hispidus judex: Cabrera, 1961:466; name combination.

Oxymycterus hispidus quaestor: Cabrera, 1961:467; name combination.

Oxymycterus hispidus misionalis: Cabrera, 1961:467; new name combination.

Oxymycterus rutilans: Roguin, 1986:1018; not *Mus rutilans* Olfers [= *Oxymycterus rufus*].

DESCRIPTION: Large, with adult head and body length 135–180 mm, tail length 97–143 mm, hindfoot length 34–40 mm, and ear length 21–26 mm. Overall dorsal coloration dark orange brown strongly lined with black, sometimes more intensely black on crown and middorsum, to reddish brown without black. Ventral pelage dark yellowish gray to dark orange. Skull elongated, with largest dimensions of occipitonasal, mandibular, incursive foramina, and nasal lengths in genus. Zygomatic plates, palate, and rostrum proportionally narrow; maxillary in area of toothrow uninflated. Proportionally smaller interparietal and narrower interorbital region distinguish this species from *O. dasytrichus*, with which it may overlap broadly in distribution.

DISTRIBUTION: *Oxymycterus quaestor* is known from eastern Paraguay and northeastern Argentina east through northern Rio Grande do Sul to southern São Paulo states, Brazil; an isolated population is present in the Serra dos Órgãos in Rio de Janeiro state.

SELECTED LOCALITIES (Map 129): ARGENTINA: Misiones, Dos de Mayo, Guarany (FMNH 122696), Puerto Gisela, San Ignacio (BM 24.6.6.50). **BRAZIL:** Paraná, Roça Nova (type locality of *Oxymycterus quaestor* Thomas), Rio Paranapanema, Fazenda Caioá, Cambará

(MZUSP 1275), Usina Hidroelétrica de Guaricana, Morretes (MNRJ 79073); Rio Grande do Sul, Usina Hidroelétrica de Itá, right margin Rio Uruguay (MNRJ 62143), Victor Graeff (MNRJ 79072); Rio de Janeiro, Teresópolis (FMNH 26585), Serra de Macaé (MZUSP 2770); Santa Catarina, Florianópolis (BM 14.1.26.33), Joinville (type locality of *Oxymycterus judex* Thomas), Pinheiros, Anitápolis (UFSC 473); São Paulo, Fazenda Intervalos (Base do Carmo), Capão Bonito (MZUSP 29011), Posto Indígena Icatu, Braúna (MZUSP 3740), Teodoro Sampaio (USNM 309164). PARAGUAY: Alto Paraná, Puerto Bertoni (BM 21.4.21.4).

SUBSPECIES: We treat *Oxymycterus quaestor* as monotypic.

NATURAL HISTORY: Graipel et al. (2006) recorded individuals on the ground in humid and disturbed vegetations, and at low densities relative to other species of rodents and marsupials on Ilha Santa Catarina, Brazil. At this locality, reproduction was apparently seasonally bimodal, with young specimens found in both late spring-summer (November and February) and winter months (April to July). Reproductive females (as judged by perforated vaginae) were captured in July and January, and lactating females in October. All adult males exhibited scrotal testes. Individuals are apparently short lived, as the average residence period was about 76 days; a higher percentage of females was considered resident, with one female exhibiting the maximum persistence in the area of 180 days.

REMARKS: Thomas (1909) described *O. judex* to distinguish larger specimens with a more robust braincase from *O. quaestor*, which he had described six years earlier (1903). Sanborn (1931) described *O. misionalis*, distinguishing it from *O. judex* by its larger size. Subsequently, Cabrera (1961) treated *quaestor* Thomas as a subspecies of *O. hispidus*, together with *judex* Thomas and *misionalis* Sanborn, in an arrangement that has been followed by most subsequent authors. As understood here, following J. A. Oliveira (1998) and P. R. Gonçalves and Oliveira (2004), *O. hispidus* is a junior synonym of *O. dasytrichus*, a widely distributed species from eastern Brazil (see that account) and distinct from other large forms from southern Brazil and the Misiones region of Argentina. J. A. Oliveira's (1998) morphometric analyses showed that the holotype, paratype, and one topotype of *O. quaestor* were included in a morphological continuum together with the types and samples assigned to *O. judex* and *O. misionalis*. Musser and Carleton (2005) treated *O. judex* and *O. misionalis* as junior synonyms of *O. quaestor*, based on the molecular results of F. G. Hoffmann et al. (2002).

Map 129 Selected localities for *Oxymycterus quaestor* (●). The disjunct populations in the Serra dos Órgãos, Rio de Janeiro state, Brazil, are mapped separately.

Oxymycterus rufus (G. Fischer, 1814)

Red Hociçudo, Rat Roux, Ratón Hociçudo de Azara, Hociçudo Común, Hociçudo Rojuzochico, Yaguarasapá, Anguya Pihã

SYNONYMS:

Mus rufus G. Fischer, 1814:71; based on Azara's (1801:94) "*rat cinquième ou rat roux*"; type locality "Paraguay"; restricted by Rengger (1830:231) to "von Asuncion." Hershkovitz (1994:36) wrote that the type locality "was said to have been found at 32°30'S in the Río Paraná drainage system; this restricts the type locality to northern Entre Ríos, Argentina." Galliari et al. (1996) criticized Hershkovitz's (1994) restriction of the type locality and argued that the type locality of Azara's animal should be restricted to San Ignacio Guazú, Paraguay, as this was the place of residence of the priest Nosèda, who obtained the specimen Azara (1801) described. J. R. Contreras and Teta (2003) noted, however, that Nosèda had actually resided at three, closely adjacent places in the Paraguayan department of Misiones (Santa María de Fe, Santiago, and San Ignacio Guazú), all approximately 250 km SE of Asunción; Azara's "*rat roux*" could thus have come from any of these three localities. Here, we select a neotype for Fischer's *Mus rufus* and, by that action, restrict the type locality of *O. rufus* (G. Fischer, 1814) to "Estancia San Juan Poriahú, Depto. San Miguel, Provincia Corrientes, Argentina (27.71667°S, 57.19389°W)" (see Remarks).

Mus ?rutilans Illiger, 1815:108; *nomen nudum*.

M[us]. rutilans Olfers, 1818:209; based on Azara's (1801) "*rat cinquième ou rat roux*."

H[esperomys]. rufus: Wagner, 1843a:595; name combination.

O[xymycterus]. rufus: Burmeister, 1855a:10; part; first use of current name combination.

[*Hesperomys (Oxymycterus)*] *rufus*: E.-L. Trouessart, 1880b:142; name combination.

Oxymycterus platensis Thomas, 1914d:244; type locality "Ensenada, La Plata. Sea Level," Buenos Aires, Argentina.

Oxymycterus nasutus: Bertoni, 1914b:10; part; not *Mus nasutus* Waterhouse.

Oxymycteris rutilans: Hershkovitz, 1959b:339; name combination.

Mus nasutus: Hershkovitz, 1959b:339; part; not *Mus nasutus* Waterhouse.

Oxymycterus rufus platensis: Cabrera, 1961:469; name combination.

Oxymycterus rufus rufus: Cabrera, 1961:469; name combination.

Oxymycterus rutilans: Echave Llanos and Vilchez, 1964:187; name combination.

Oxymycterus rutilans rutilans: Hershkovitz, 1966a:127; name combination.

Oxymycterus rutilans platensis: Massoia and Fornes, 1969:316; name combination.

Oxymycteris [sic] rutilans: A. L. Gardner and Patton 1976: 28, Table 2; name combination.

DESCRIPTION: Moderate sized, with adult head and body length 129–161 mm, tail length 69–118 mm, hindfoot length 27–32 mm, ear length 14–20 mm, and mass 61–130 g. Dorsal coloration varies as function of prevalence of one of two types of guard hairs (banded and unbanded), but also varying intensity and length of ochraceous subapical band of banded hair. General dorsal color thus cinnamon brown, strongly lined with black over head and middorsum and ochraceous tawny on rump and sides, to paler dorsum in which black component is less conspicuous; some individuals strongly reddish, notably those from Buenos Aires coast and region of La Plata Delta, but also populations from Minas Gerais state, Brazil, where entire pelage, especially on ventral surface, ochraceous orange; specimens from Córdoba province, Argentina, among palest, with general color of entire dorsum pale ochraceous buff, but strongly lined with black, resembling some specimens of *O. josei*. Skull medium-sized, with relatively wide braincase and moderately protruded rostrum; nasal tube not markedly flared, with weak dorsal inflexion when viewed laterally, and dorsal outline of nasals not forming parallel plane in relation to diastemal region. Palatine septum delicate, with maxillary portion particularly thin, providing keeled appearance in ventral view. Interparietal triangular and greatly reduced in relation to other species. Lacrimal laterally reduced and

rectangular, generally conforming to antorbital wall. Posterior extension of bony palate variable, short (reaching posterior border of M3s) in Minas Gerais specimens or long (extending beyond M3s) in most Argentinean specimens.

DISTRIBUTION: *Oxymycterus rufus* occurs in Argentina, from southern Buenos Aires province, at least from Bahía Blanca and the Atlantic coast to Ensenada, La Plata, Buenos Aires province, and to the lower Río Paraná, including the Delta region and the provinces of Corrientes (Goya) and Entre Ríos (Gualeda y Guaychú). It has been recorded from as far west as Villa Dolores, Córdoba province. P. R. Gonçalves and Oliveira (2004) recorded isolated populations in Minas Gerais state, Brazil.

SELECTED LOCALITIES (Map 130): ARGENTINA: Buenos Aires, Abra del Hinojo, Sierras de Curamalal (TTU 64489), Arroyo Brusquitas, Miramar (UMMZ 115501), Bahía Blanca (MHNG 611.52), Ensenada, La Plata (type locality of *Oxymycterus platensis* Thomas), Mar del Tuyú, General Lavalle (FMNH 122697), Tandil (TTU 33153), Valeria del Mar (MVZ 134244); Córdoba, Candonga (ZSM 1955/236), Espinillo, Río Cuarto (TTU 66588), Noetinger (BM 17.1.25.36), Villa Dolores (BM 16.1.6.32); Corrientes, Goya (BM 98.12.3.23), San Miguel, San Juan Poriahú (MLP 26.XII.01.5); Entre Ríos, Gualeda y Guaychú (TTU 33155), Yuquerí (MZUSP 573). **BRAZIL:** Minas Gerais, Ouro Preto (MNRJ 14568), Viçosa (MNRJ 65522).

SUBSPECIES: We treat *Oxymycterus rufus* as monotypic.

NATURAL HISTORY: In Argentina, *O. rufus* avoids woodlands, preferentially inhabiting grasslands and steppes with dense herbaceous cover, such as the *pastizales altos de los médanos* (tall dune grasses), along margins of small creeks and lagoons, and the rocky outcrops in the sierras (Bonaventura et al. 1991). The same habitat preference seems to hold for Brazilian representatives of the species, which have also been frequently trapped in exotic and native grasslands near water bodies (Paglia et al. 1995; G. Lessa et al. 1999). Temporal activity patterns, however, seem to be more variable, with both diurnal and nocturnal activity reported for Argentinean populations (Massoia 1961; Kravetz 1972). As are other species of the genus, *O. rufus* feeds primarily on small soil invertebrates, with 70–85% of its diet composed of arthropods, annelids, and nematodes, with plant mass accounting for only 15–20% (Kravetz 1972; O. V. Suárez 1994). Reproductive intensity is higher during the spring and summer months (November to March), with a mean litter size of four embryos (range: 2–5) (Reig 1965; V. R. Cueto et al. 1995c). Mark-recapture data suggest a polygynous mating system because males have larger home ranges than females and stronger territoriality during the mating season (V. R. Cueto et al. 1995b). Both longevity

and local residence of individuals are relatively long, probably spanning two breeding seasons, as suggested by the persistence of marked individuals for more than 24 months (V. R. Cueto et al. 1995b). Individuals exhibit considerable jumping capability, readily escaping from 40 liter buckets used in pitfall traps (P. R. Gonçalves, pers. obs.)

REMARKS: Musser et al. (1998) discussed the validity of the binomials proposed by Gotthelf Fischer (1814) for the sigmodont rodents described by Azara (1801). Their conclusions with respect to the availability of most of these names, which support Langguth's (1966b) original petition to the International Commission, are followed here with respect to the priority of *Mus rufus* (G. Fischer) over the names provided by Illiger (1815), Olfers (1818), and Desmarest (1819c) for Azara's (1801) "*rat cinquième ou rat roux*." One of the two primary arguments for disregarding Fischer's names, the inconsistent usage of binomial nomenclature (Sabrosky 1967), does not apply to the combination *Mus rufus* as used both in the index and in the main text of Fischer's work.

Brants (1827), Rengger (1830), Burmeister (1854), and Winge (1887) each concluded that specimens from eastern Brazil represented Azara's "*rat cinquième ou rat roux*." Importantly, Burmeister (1854) explicitly regarded *Hypudaeus dasytrichos* Wied-Neuwied and *Hesperomys (Oxymycterus) rostellatus* Wagner as synonyms of *O. rufus*. Cabrera (1961) adhered to this view in his treatment of subspecies and most subsequent authors followed his position. However, recent morphological and molecular analyses (P. R. Gonçalves and Oliveira 2004) have supported the validity of *O. rufus* and *O. dasytrichus* as distinct species, as they are treated herein. Furthermore, these analyses did not support recognition of subspecies of *O. rufus*. Hence, as did Gonçalves and Oliveira, we use the name *O. rufus* to refer to the species that is widespread in Buenos Aires, Córdoba, Corrientes, and Entre Ríos provinces in Argentina and known from a few localities in Minas Gerais state, Brazil.

As yet, no museum specimens are known from Paraguay, the supposed origin of the specimen Azara (1801) referred to as the "*rat cinquième ou rat roux*." A series of *O. rufus* from Estancia San Juan Poriahú, Corrientes province, Argentina, housed in the Museo de La Plata (MLP) is the geographically nearest sample to the region of probable provenance of Azara's animal. This Argentinean locality is located some 75 km SW, 92 km SW, and 105 km SW from Santiago, San Ignacio Guazú, and Santa María de Fe, respectively, the three localities in Misiones department, Paraguay, suggested by J. R. Contreras and Teta (2003) as putative potential provenances for Azara's specimen. Therefore, we select as a neotype for *O. rufus* (G. Fischer 1814) the specimen MLP 26.XII.01.05 (original number 191), an adult male collected by Mariano L. Merino and Augustín

Abba on September 23, 1999. This specimen is represented by a skull, mandible, postcranial skeleton, and stuffed skin missing the left forefeet and hindfeet, which were cleaned and preserved as part of the postcranial skeleton. The skull is complete and still preserves the prenasal ossification. External measurements are total length = 252 mm, tail length = 105 mm, hindfoot length (with claw) = 30.5 mm (27 mm without claw), ear length = 17 mm, and mass = 110 g; cranial measurements (as defined in J. A. Oliveira 1998) include occipitonasal length = 38.5 mm, incisive foramina length = 8.4 mm, upper toothrow length = 5.01 mm, zygomatic plate width = 2.7 mm, zygomatic breadth = 16.4 mm, nasal length = 15.1 mm, least interorbital breadth = 6.0 mm, braincase breadth = 14.3 mm, mandible length = 19.6 mm. The skin of the neotype has a dark cinnamon brown dorsal color, strongly lined with black toward the midline and less in the laterals, without strong reddish tones. The ventral pelage is generally ochraceous with the gray bases of hairs showing through, except on the chin, where a small patch of white hairs is present. The tail is moderately haired and mostly dark brown, except on its ventral surface around the tail base, where the hairs are less pigmented. Claws are well developed and keeled, measuring 5.1 mm in length on the longest digit of the manus and 5.8 mm on the longest digit of the pes. The skull has the typical morphology of *O. rufus*, with the nasal tube moderately protruded but

Map 130 Selected localities for *Oxymycterus rufus* (●). The disjunct populations in Minas Gerais state, Brazil, are mapped separately. Contour line = 2,000 m.

not markedly flared in lateral view, wide zygomatic plates, palatine septum of incisive foramina with a keeled maxillary part, long bony palate, reduced interparietal, and alisphenoid strut absent on both sides of cranium. Molars are worn, with enamel folds and islets obliterated, as typical of adult individuals of *Oxymycterus* spp.

Five additional specimens collected at the same locality and on the same date are preserved (MLP 26.XII.01.6, 26.XII.01.7, 26.XII.01.8, 26.XII.01.9, 26.XII.01.10). P. R. Gonçalves and Oliveira (2004) included this series and the neotype in a craniometric analysis of *O. rufus* and showed that the samples from Argentina form a morphological cline spanning samples from Corrientes province in the northwest to Buenos Aires in the southeast.

Oxymycterus wayku Jayat, D'Elía, Pardiñas, Miotti, and Ortiz, 2008

Ravine Hociúdo

SYNONYM:

Oxymycterus wayku Jayat, D'Elía, Pardiñas, Miotti, and Ortiz, 2008:40; type locality "Argentina, Province of Tucumán, Department of Trancas, 10 km by road south of Hualinchay on the trail to Lara (26 19'20.2"S, 65 36'45.5"W, 2316 m)."

DESCRIPTION: Intermediate in size relative to other hociúdos, with adult head and body length 124–144 mm, tail length 77–97 mm, hindfoot length 28–32 mm (with claw), ear length 17–21 mm, and mass 44.5–76.5 g. Pelage blackish brown with slight ochre or reddish hue (juvenile specimens darker, almost black), with dorsal hairs dark gray for most of length but tips ochraceous; guard hairs completely black and extend well beyond underfur, up to 3.5 mm on rump. Coloration of flanks similar to that of dorsum. Venter paler, with ochre color intermingled with ash-gray hair bases; chin with conspicuous white spot that, in some specimens, extends onto throat. Tuft of black hairs with ochre tips immediately anterior to ear extends posteriorly to the middle of the pinnae. Forefeet and hindfeet dark gray, almost black; claws long and robust, with forefoot and hindfoot digit III 6.4 and 5.1 mm long, respectively, covered by white unguis tufts that contrast sharply with darkness of the body, thighs, and feet. Tail almost completely black, only slightly paler ventrally, and densely covered by hairs. Skull long and robust (mean condyloincisive length of adults 30.37 mm), with rounded braincase and expanded zygomatic arches. Rostrum wide (mean rostral width 5.93 mm) and robust, with frontal sinuses inflated; zygomatic plates narrow and delicate; incisive foramina markedly short and oval in shape, their posterior margins not reaching level of the protoflexus of M1. Mandible delicate, low, and elongated, with lunar notch well developed but asymmetrically excavated.

DISTRIBUTION: *Oxymycterus wayku* is distributed along the eastern humid slopes of the Sierra del Aconquija and Cumbres Calchaquíes ranges, between 800 and 2,400 m elevation, in Tucumán province, Argentina. The suitable habitat occurs along a narrow strip about 200 km long, from the northeastern end of the Cumbres Calchaquíes in southern Salta province to the Sierra de Narváez on the boundary between Tucumán and Catamarca provinces.

SELECTED LOCALITIES (Map 131; from Jayat, D'Elía et al. 2008, except as noted): ARGENTINA: Tucumán, 10 km by road S of Hualinchay (type locality of *Oxymycterus wayku* Jayat, D'Elía, Pardiñas, Miotti, and Ortiz), La Angostura, Los Sosa, Reserva Provincial La Florida.

SUBSPECIES: *Oxymycterus wayku* is monotypic.

NATURAL HISTORY: *Oxymycterus wayku* appears to be rare across its known, limited range. Only five of the more than 400 total animals collected in the vicinity of the type locality belong to this species, which is otherwise known from only two additional complete specimens and the cranial remains of a few individuals recovered from Barn Owl (*Tyto alba*) pellets. Most specimens were trapped in the ecotone between montane forest and highland grasslands, at the upper elevational limit of Yungas forests (*Bosque Montano*, *sensu* A. D. Brown et al. 2001). This vegetation belt develops on wet slopes between 1,500 and 3,000 m and represents the landscape with maximum heterogeneity in the Yungas. The holotype was caught in alder forest (*Alnus acuminata* [Betulaceae]) with an

Map 131 Selected localities for *Oxymycterus wayku* (●). Contour line=2,000 m.

understory of grasses dominated by *Festuca*, *Deyeuxia*, and *Stipa*, with deep soils, a well-developed organic horizon, abundant leaf detritus and fallen log cover, and on steep slopes interrupted by rocky outcroppings. Two additional specimens were collected at a lower elevation in montane rainforest (*Selva Montaña*), a vegetation belt between 700 and 1,500 m and dominated by evergreen trees. One female collected in the fall (late April to early May) exhibited signs of reproductive activity; males collected in July or early spring were reproductively inactive.

REMARKS: Molecular phylogenetic analysis did not recover a consistent sister relationship between *O. wayku* and other species, but placed it in a large clade that included *O. nasutus*, *O. paramensis*, *O. hiska*, *O. josei*, *O. judex*, *O. misionalis*, *O. quaestor*, and *O. rufus* (see Jayat, D'Elia et al. 2008).

Genus *Podoxymys* Anthony, 1929

Ulyses F. J. Pardiñas and Pablo Teta

This genus is perhaps the least known among living akodontines. Reported specimens total six, five from the original series used by H. E. Anthony (1929) in his description of *Podoxymys roraimae*, and an additional young female obtained by an expedition organized by the La Salle National History Museum of Caracas, Venezuela, in 1989. All specimens came from the summit of the Roraima Tepui, the place that inspired Sir Arthur Conan Doyle's novel *The Lost World*, on the borders between Guyana, Venezuela, and Brazil.

Podoxymys was described as "a rodent which appears somewhat intermediate in character between *Akodon* and *Oxymycterus*" and with the "external appearance that of a dark-colored, long-tailed *Akodon*, with long slender claws (which suggest the generic name); skull with long, slender rostrum, narrow zygomatic plate and general appearance of *Oxymycterus*" (Anthony 1929:4). *Podoxymys* is small (total length = 196 mm; tail length = 95 mm; measurements from the holotype). Its pelage is long and lax (hairs on the back 10–11 mm in length), dorsally blackish slate at base and for most of the length of the hair, with only the tip being colored; sides of head and under parts slightly lighter in tone than back. Dorsal surfaces of the manus and pes are clove-brown. The tail is about half of the total length, very sparsely haired, and unicolored brown. Ears are partially hidden in the long pelage. Eyes are rather small. Claws of the forefeet are long (that on digit III extending 3 mm beyond the fleshy tip of the digit), slender, strongly compressed laterally, and moderately curved; those of hindfeet are slightly shorter. Palmar and plantar morphology have not been described, but based on the drawings in Hinojosa et al. (1987:Fig. 6B), the pollex has a developed claw; dig-

its I and V of the hindfoot are reduced, the former reaching the second phalanx of digit II in a pattern roughly like that of *Akodon mimus*.

The skull is long and slender (greatest length of skull = 27.5 mm), with the rostrum elongated and the zygomatic notches inconspicuous. The nasals are long and project forward, totally covering the incisors in dorsal view and combine with the premaxillaries to form a moderately developed trumpet. A noticeable gnathic process is present. The interorbital region is broad, greater than the rostral width, with rounded edges but without a definite constriction point. Zygomatic arches scarcely flare laterad beyond the level reached by the braincase, and are weak and thread-like at midpoint. The braincase is moderately inflated and evenly rounded, with a U-shaped coronal suture and a reduced interparietal. The zygomatic plates are narrow with upward and backwardly sloping anterior edges. The incisive foramina are long, widely open posteriorly and parallel sided, and reach posteriorly to the protocones of M1s. The palate is short, terminating in a broad mesopterygoid fossa. Auditory bullae are moderate sized and only slightly inflated. The basicranial region is proportionally long. Anthony (1929) did not describe the dentition of *Podoxymys*, recoding only the length of the maxillary tooththrow (4.4 mm for the holotype) and providing a general indication that its molars are somewhat weaker than in *Akodon aerosus*.

Pérez-Zapata et al. (1992), on the basis of a newly collected juvenile specimen, reported additional morphological traits and the karyotype. They stated that *Podoxymys* has a tail as long as or only slightly longer than the head and body, claws of hindfeet as long as in *Akodon*, and ears covered by dense pelage. Cranially, the nasals reach posteriorly well behind the maxillofrontal suture (see also Hinojosa et al. 1987:Fig. 7B). The mandible is slender and elongated, with a short coronoid process and a small capsular projection. The upper incisors are opisthodont and the upper molars brachydont and bunodont, and with the main cusps in opposite pairs. The procingulum of M1 is slightly reduced and has a well-developed anteromedian flexus; the mesoloph is well developed in M1 and M2, reaching the labial margin in both. In the lower dentition, there is a reduced procingulum on m1, with a distinct anteromedian flexid (overlooked by Pérez-Zapata et al. 1992:218, but clearly visible in their figure); mesolophids are present on both m1 and m2; and posterolophids are well developed and directed backward.

The stomach of *Podoxymys* is unilocular-hemiglandular, with a reduced area of glandular epithelium and with some cornified epithelium occupying part of the antrum to the right of the esophageal opening (Carleton 1973:Fig. 5A). The caecum is well developed but very short, only 4.4% of the total intestine length; the large intestine is also short

(Pérez-Zapata et al. 1992). A gallbladder is present (Voss 1991a).

SYNONYMS:

Podoxymys Anthony, 1929:4; type species *Podoxymys roraimae* Anthony, by original designation.

Podoxomys Carleton, 1973:15; incorrect subsequent spelling of *Podoxymys* Anthony.

Podoximys O. J. Linares, 1998:273, incorrect subsequent spelling of *Podoxymys* Anthony.

Microxus: O. J. Linares, 1998:274, part (listing of *roraimae*); not *Microxus* Thomas.

Podoxymys roraimae Anthony, 1929

Roraima Akodont

SYNONYMS:

Podoxymys roraimae Anthony, 1929:4; type locality "Mt. Roraima, British Guiana; altitude 8600 feet." Interpreted as "Guyana, Mazaruni-Potaro Dist., summit of Mt Roraima, 8600 ft (2621 m)" by Musser and Carleton (2005:1164), but restricted by O. J. Linares (1998:274) to the southwestern corner of Tepui Roraima (ca. 5.144°N, 60.762°S), between 2,580 and 2,700 m, Bolívar, Venezuela.

Podoxomys roraimae: Carleton, 1973:15; name combination.

Podoxymys roraimi Hinojosa, Anderson, and Patton, 1987:12; incorrect subsequent spelling of *roraimae* Anthony.

Podoximys roraimae: O. J. Linares, 1998:273; name combination.

Microxus roraimae: O. J. Linares, 1998:274; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Podoxymys roraimae* is known only from the vicinity of its type locality.

SELECTED LOCALITIES (Map 132): VENEZUELA: Bolívar, summit of Roraima Tepuí (type locality of *Podoxymys roraimae* Anthony).

NATURAL HISTORY: All known specimens come from an area dominated by small trees of the genus *Bonnetia* [Clusiaceae], now highly altered due to wood extraction and tourism (O. J. Linares 1998). Pérez-Zapata et al. (1992) reported the capture of one individual, together with four specimens of *Rhipidomys macconnelli*, in a carpet of *Sphagnum* moss in which there were various small cavities.

REMARKS: The putative presence of *Podoxymys roraimae* in Brazil (see Bonvicino, Oliveira, and D'Andrea 2008) or in adjoining tepuis of Venezuela and Guiana (see O. J. Linares 1998) needs confirmation by vouchered specimens.

The karyotype consists of a $2n=16$, FN=26, with five pairs of large biarmed and three pairs of telocentric chro-

Map 132 Single known locality for *Podoxymys roraimae* (●). Contour line=2,000 m.

mosomes; each chromosome pair is very distinctive in size and morphology (Pérez-Zapata et al. 1992).

Genus *Scapteromys* Waterhouse, 1837

Guillermo D'Elía and Ulyses F. J. Pardiñas

Swamp rats of the genus *Scapteromys* are among the largest members of the tribe Akodontini, and are easily distinguished in the field. They occur through east-central and northern Argentina, the southern coast of Brazil, southern Paraguay, and Uruguay, living near watercourses, including large rivers, small creeks, ponds, and swamps (Hershkovitz 1966a; D'Elía and Pardiñas 2004). Charles Darwin, the collector of the holotype of *Scapteromys tumidus*, wrote, "This rat was caught in so wet a place amongst the flags bordering a lake, that it must certainly be partly aquatic in its habits" (Waterhouse 1839:58). *Scapteromys* is an excellent swimmer, propelling itself by horizontal undulations of the tail and by means of all four limbs (Massoia and Fornes 1964c). *Scapteromys* is also able to climb trees, a behavior considered an adaptation for living in seasonally inundated areas (Barlow 1969; Sierra de Soriano 1969). *Scapteromys* is mainly nocturnal and feeds primarily on insects and oligochaetes, but also on leeches and vegetation (Barlow 1969; Massoia 1961).

Massoia and Fornes (1964c), Hershkovitz (1966a), Sierra de Soriano (1969), D'Elía and Pardiñas (2004), and Pardiñas, D'Elía, and Teta (2009) have described external and craniodental morphology. These are large rats (head and body length about 180 mm, tail length about 85 mm; mean values of adult males) with their external form

adapted for palustrine and subaquatic life. The pelage is thick, soft, and glossy; the upper parts of head and body are somewhat blackish; and the underside of the head, chest, and belly are more or less gray washed with buffy to ochraceous. The tail is well developed but not thick, covered by stiff but not hispid dark brown pelage; each tail scale has three hairs, with ventral keel hairs usually long; a terminal pencil is present. The ears are small, rounded, and covered by hairs on both surfaces. The forefeet are well developed but not markedly enlarged, digits II–V are strong, and claws are slender and of equal length. Hindfeet are strong and elongate, their length (including claws) approximately 24% of the head and body length; the claws are slender. There are narrow bands of webbing between the first phalanges of the three middle digits and along the inner side of each outer digit.

The skull of *Scapteromys* is mostly without crests or ridges. The rostrum is slender and the nasals are rounded distally, taper proximally, and extend well behind the maxillofrontal sutures. The zygomatic plates are strong, with their posterior edges reaching to the level of the alveoli and strongly inclined laterally. Lacrimal bones are conspicuous. The zygomatic arches are not enlarged at their midpoints. The braincase is globular with a well-developed coronal suture. The hamular process is slender, bisecting the subsquamosal and postglenoid openings so as to make them subequal in size. The alisphenoid strut is typically absent. The carotid circulatory pattern conforms to pattern 1 of Voss (1988), with a large stapedial foramen and both squamosal-alisphenoid groove and sphenofrontal foramen present. The palate is flat, short, and narrow (*sensu* Hershkovitz 1962), typically extending behind the posterior faces of M3s. The mandibles are rather weak and elongated with comparatively low horizontal rami and ascending processes; the capsular projection of the incisor does not form a tubercular process (Reig 1972). The incisors in *Scapteromys* are relatively weak and ungrooved. Molars are hypsodont, terraced in juveniles and young adults but planate in full adults, with the main cusps alternating. *Scapteromys* has a molar pattern similar to those of *Kunsia*, *Gyldenstolpia*, and *Bibimys*, characterized by a general akodontine bauplan slightly more complex than that observed in *Akodon* and related genera (e.g., *Necromys*, *Thaptomys*). Mesolophs and mesolophids are typically well developed and fused with mesostyles/stylids. The occlusal surface of each M3 is rounded in outline but retains a central enamel ring like that of abrotichines. The first lower molar has a moderately developed anteromedian flexid and a labiolophulid. Vertebral counts for *Scapteromys* typically include 13 thoracic, 6 lumbar, 3 sacral, and 29 caudal elements (Steppan 1995).

The stomach, described for specimens of *S. tumidus*, is unilocular and discoglandular; the wall of the antrum is

more thickly muscular than that of sigmodontines, having a hemiglandular stomach (Carleton 1973). A gall bladder is present (Voss 1991). The male phallus was described by Hooper and Musser (1964) and further detailed by Hershkovitz (1966a). The glans is nearly twice as long as wide and laterally compressed, almost entirely covered with spines; the tapered distal portion is furrowed longitudinally. Hershkovitz (1966a) reported a limited degree of variability, and Hooper and Musser (1964) detailed differences between the male phallus of *S. aquaticus* and *S. tumidus*. Hooper and Musser (1964:29) stated that the phallus of *Scapteromys* was “set well apart . . . from all other South American examples at our disposal” in morphological details, a view strongly criticized by Hershkovitz (1966a:131) who considered the characters as typically sigmodontine. Males possess bulbourethral, ampullary, vesicular, and prostate accessory glands; paired preputial glands are large (Hershkovitz 1966a; Voss and Linzey 1981).

Hershkovitz (1966a) and Massoia (1980c) established the basis of the current contents of *Scapteromys* by removing some species previously allocated to the genus and placing them into the new genera *Kunsia* and *Bibimys*. One species Hershkovitz assigned to *Kunsia*, *fronto* Winge, is now the type species of its own genus (see the account for *Gyldenstolpia*). Therefore, as currently understood, *Scapteromys* includes two living species (but, see Remarks under both species), whose taxonomic history, together with that of the genus, we summarize next.

Waterhouse (1837:15) described *Mus tumidus* from Maldonado, Uruguay, and five pages later (i.e., p. 20) erected *Scapteromys* as a new subgenus of *Mus* with *tumidus* designated as its type species. Therefore, though when *tumidus* and *Scapteromys* were described in the same work and *tumidus* as the then sole species of *Scapteromys*, *tumidus* was originally placed in *Mus* and, as such, as indicated by the use of parentheses to contain the authority and year of description, it is considered to have been only secondarily treated as a *Scapteromys*. Subsequently, Waterhouse (1839:57) again described *tumidus* but included it (on p. 77) in his new comprehensive genus *Hesperomys* while ignoring his earlier *Scapteromys*. Fitzinger (1867b) was the first to use *Scapteromys* at the genus level, although some authors continued to consider *Scapteromys* as a subgenus of *Hesperomys* (e.g., Thomas 1884). Thomas (1917c) referred a series of *Scapteromys* collected at Isla Ella, Argentina, to the species *S. tomentosus* (a species currently allocated to the genus *Kunsia*), stating that those specimens differed from *S. tumidus* only in color. Three years later, Thomas (1920b) noticed that his previous assignment of the specimens from Isla Ella to *tomentosus* was wrong and described a new species, *S. aquaticus*, based on these specimens. Remarkably, Thomas made no comment regarding

his previous statement about the similarity of his new form *aquaticus* to *tumidus*. During the following four decades, taxonomic references to *Scapteromys sensu stricto* were limited to a handful of citations in general treatises on mammal taxonomy (e.g., Gyldenstolpe 1932; Ellerman 1941; Cabrera 1961), mammal lists (e.g., Devicenzi 1935), or accounts of nomenclatural history (e.g., Tate 1932d).

Massoia and Fornes (1964c) analyzed variation in skull, teeth, and external morphology within and between Argentinean and Uruguayan populations of *Scapteromys*, stating that morphological differences between *aquaticus* and *tumidus* were minor and limited to the shape of the frontoparietal suture and the width of the mesopterygoid fossa. These authors also mentioned that individuals of *S. tumidus* are brownish and seemed slightly larger than the blackish *S. aquaticus*. Massoia and Fornes (1964c) considered the two forms as only subspecifically distinct on the basis of individuals of intermediate phenotypes. However, Massoia and Fornes indicated that the correspondence between the trenchant characters they used to define and diagnose the two supposed subspecies and their geographic distributions was not absolute. Subsequently, Hershkovitz (1966a) argued that the characters enumerated by Massoia and Fornes (1964c) were highly variable, dismissed recognition of two different forms, and stated that *Scapteromys* consisted of a single species, *S. tumidus*, without subspecies.

Scapteromys exhibits considerable karyotypic diversity that appears to be geographically structured. Samples from Argentina (Fronza et al. 1976; Brum-Zorrilla et al. 1986), Paraguay (see D'Elía and Pardiñas 2004), and one Brazilian population (Bonvicino et al. 2013) have a $2n=32$ complement, while those in Uruguay are $2n=24$ (Brum-Zorrilla 1965; Brum-Zorrilla et al. 1972, 1986). Diploid numbers of 24, 34, and 36 have also been reported from Brazilian populations (T. R. O. Freitas et al. 1984). Brum-Zorrilla et al. (1972, 1986) proposed that individuals with $2n=32$ correspond to *S. aquaticus* (distributed in Argentina) and those with $2n=24$ to *S. tumidus* (distributed in Uruguay). T. R. O. Freitas et al. (1984) also suggested the existence of an undescribed species in Brazil. In spite of all this, Hershkovitz's (1966a) view of a single species in the genus continued to prevail among several taxonomists and ecologists (e.g., Musser and Carleton 1993; V. R. Cueto et al. 1995a; Eisenberg and Redford 1999). Finally, D'Elía and Pardiñas (2004) analyzed populations of *Scapteromys* from Argentina, Paraguay, and Uruguay, and showed that DNA haplotypes fell into two well differentiated and strongly supported reciprocally monophyletic clades that were geographically segregated and mostly congru-

ent with patterns of morphological and chromosomal variation. In light of these results, D'Elía and Pardiñas (2004) suggested that *S. aquaticus* be considered a species distinct from *S. tumidus*. We follow this scheme here, but see Remarks under both species regarding the status of Brazilian populations. A third species, *Scapteromys meridionalis*, was described by Quintela et al. (2014) after this volume went into production; it extends the geographic and habitat range of the genus to the *Araucaria angustifolia* biogeographic province in the Brazilian states of Rio Grande do Sul, Santa Catarina, and Paraná.

REMARKS: Reig (1994) described *S. hershkovitzii* from the Upper Pliocene (Vorohué Formation) of southeastern Buenos Aires province, Argentina, which constitutes the only known fossil species of the genus. However, restudy of this form suggests that it belongs to an undescribed extinct genus more closely related to *Kunsia* and *Gyldenstolpia* (Pardiñas, D'Elía, and Teta 2009).

SYNONYMS:

Mus (Scapteromys) Waterhouse, 1837:20; type species *Mus (Scapteromys) tumidus* Waterhouse, by original designation.
Hesperomys Waterhouse, 1839:75, 77; part (inclusion of *Mus tumidus*).
Hesperomys: Wagner, 1843a:515; part (listing of *tumidus*); not *Hesperomys* Waterhouse.

KEY TO THE SPECIES OF SCAPTEROMYS:

1. Frontoparietal suture more or less resembling an open U or V, anterior border of mesopterygoid fossa square with a bluntly pointed median palatine process; $2n=32$ *Scapteromys aquaticus*
- 1'. Frontoparietal suture resembling a W, anterior border of mesopterygoid fossa rounded, without a median palatine process; $2n$ not 32 *Scapteromys tumidus*

Scapteromys aquaticus Thomas, 1920

Argentinean Swamp Rat

SYNONYMS:

Scapteromys tomentosus: Thomas, 1917c:96; initial reference to specimens from Isla Ella, Buenos Aires, Argentina; not *Scapteromys tomentosus* E.-L. Trouessart.
Scapteromys aquaticus Thomas, 1920b:477; type locality "Isla Ella" (see Thomas 1917c:95, who gave locality as "Isla Ella, in the delta of the Rio Parana, at the top of the La Plata Estuary"); according to Pardiñas et al. (2007:402) "Isla Ella is a small island (ca. 1 km²) surrounded by the streams Espera and Esperita (34°22'S, 58°38'W, Primera Sección Delta del Paraná, Tigre, Buenos Aires, Argentina)."

DESCRIPTION: Slightly smaller than *S. tumidus*. Dorsal coloration gray or dark brown and belly grayish white.

Cranially, frontoparietal suture typically U- or V-shaped, and mesopterygoid fossa narrower than in *S. tumidus* and with pointed median palatine process.

DISTRIBUTION: Wetlands in east-central and northern Argentina in Buenos Aires, Corrientes, Chaco, Entre Ríos, Formosa, and Santa Fe provinces, in southern Paraguay (D'Elía and Pardiñas 2004; Pardiñas, D'Elía, and Teta 2009), and in the Brazilian state of Rio Grande do Sul close to the border with Argentina (Bonvicino et al. 2013). Reig (1994:113) mentioned a locality “in the vicinity of Santa Clara del Mar,” citing a personal communication with J. R. Contreras, in southeastern Buenos Aires province, Argentina. This locality is about 170 km south of the southernmost record reported here; we do not include it as we have been unable to verify its validity.

SELECTED LOCALITIES (Map 133): **ARGENTINA:** Buenos Aires, General Lavalle (D'Elía and Pardiñas 2004), Isla Ella, Delta del Paraná (type locality of *Scapteromys aquaticus* Thomas), Isla Martín García (CNP-E 652–2), Punta del Indio (D'Elía and Pardiñas 2004), Ramallo (D'Elía and Pardiñas 2004); Chaco, Selvas del Río de Oro (D'Elía and Pardiñas 2004); Corrientes, Ahoma Sur, Empedrado (D'Elía and Pardiñas 2004), Paraje Uguay, Esteros del Iberá (CNP 2521), Santo Tomé (CNP-E 650–4); Formosa, 17 km W of Colonia Villafañe (D'Elía and Pardiñas 2004), Laguna Naick Neck, INTA IPAF-NEA (LTU 582), Misión Francisca Tacaaglé (CNP-E, not cataloged); Santa Fe, Estero La Zulema, 4 km NE of Estación Guaycurú (J. R. Contreras 1966), La Matilde, 16 km N of Alejandra (J. R. Contreras 1966), Puerto Ocampo (D'Elía and Pardiñas 2004). **BRAZIL:** Rio Grande do Sul, São Borja (Bonvicino et al. 2013). **PARAGUAY:** Caaguazú, Estancia San Ignacio, 24 km NNW of Carayao (D'Elía and Pardiñas 2004); Misiones, Isla Yaciretá (D'Elía and Pardiñas 2004); Paraguairí, Costa del Río Tebicuary (D'Elía and Pardiñas 2004); Presidente Hayes, 24 km W of Villa Hayes (D'Elía and Pardiñas 2004).

SUBSPECIES: *Scapteromys aquaticus* is monotypic.

NATURAL HISTORY: V. R. Cueto et al. (1995a) studied demographic structure of a population in the Delta del Paraná, Argentina, by capture-mark-recapture methods over a two-year period. Density variation was limited despite seasonal reproduction, with major intensity during the spring and summer. Individuals persisted in the sampling area for longer than 20 months, which supports a minimal longevity of two years. Density, residence, and reproduction were higher in microhabitats with a more extensive vegetative cover with a height of at least 0.50 m. Massoia and Fornes (1964c; see also Massoia 1961) also studied the natural history of *S. aquaticus* in the Delta del Paraná and coastal wetlands of Buenos Aires province, Argentina. The species was frequently encountered in flooded places dominated by stands of *Cortaderia* sp. and *Scirpus giganteus*.

A variety of vocalizations were recorded, including a sharp cry by nestling young and a sonorous adult call. In contrast with *S. tumidus* (see below), *S. aquaticus* apparently feeds preferentially on oligochaetes rather than beetles. The parasites of *S. aquaticus* have been well surveyed based on animals collected in the Delta del Paraná and several Argentinean coastal localities (see Navone et al. 2009). Lareschi (2006) found no host sexual dimorphism in ectoparasite abundances, except for the mite *Laelaps manguinhosi* being significantly more common on male rats. The staphylinid beetle *Amblyopinodes gahani gahani* was also found on *S. aquaticus*. Known internal parasites include hellgramdilloid nematodes of the genus *Malvinema* (Digiani et al. 2003) and the digenean nematodes *Conspicuum minor* (Dicrocoeliidae), *Echinoparyphium scapteromae* (Echinostomatidae), *Echinostoma platensis* (Echinostomatidae), and *Levinseniella (Monarrhenos) cruzi* (Microphallidae) (Lunaschi and Drago 2007 and references therein). M. Robles, Bain, and Navone (2012) recently described a new capillariine nematode, *Capillaria alainchabaudi*, with *S. aquaticus* as the type host.

REMARKS: On the basis of mtDNA variation, D'Elía and Pardiñas (2004) assigned specimens collected at Las Cañas, Río Negro department, Uruguay, to this species despite a *tumidus*-like karyotype that had been reported for the same locality (Brum-Zorrilla et al. 1972). E. M. González and Martínez Lanfranco (2010) dismissed this assignment, however, and placed all Uruguayan popu-

Map 133 Selected localities for *Scapteromys aquaticus* (●).

lations of *Scapteromys* in *S. tumidus*. More recent work (G. D'Elía, unpubl. data) substantiates the presence of specimens with *aquaticus*-like mtDNA but *tumidus*-like karyotype at Las Cañas as well as at an additional nearby locality. Further studies are needed to clarify the basis for discrepancy between the mitochondrial gene tree and the diploid complement, especially the possible role of reticulation through hybridization. Until this issue is adequately resolved, we take a conservative posture and assign all Uruguayan populations of *Scapteromys* to *S. tumidus*. The karyotype has $2n=32$, FN=40; autosomes include three large pairs of submetacentrics or subtelocentrics, two small pairs of submetacentrics, and 10 pairs of acrocentrics grading in size from medium to small; the X chromosome is a medium acrocentric, the Y a small subtelocentric (Bonvicino et al. 2013).

Scapteromys tumidus (Waterhouse, 1837)

Uruguay Swamp Rat

SYNONYMS:

Mus tumidus Waterhouse, 1837:15; type locality "Maldonado," Maldonado, Uruguay.

Mus (Scapteromys) tumidus: Waterhouse, 1837:21; name combination.

[*Hesperomys*] *tumidus*: Waterhouse, 1839:75, 77; name combination (assignment of *Mus tumidus* Waterhouse to *Hesperomys* Waterhouse).

Hesperomys tumidus: Wagner, 1843:515; name combination.

Scapteromys tumidus: Fitzinger, 1867b:80; first use of current name combination.

DESCRIPTION: Slightly larger and heavier than *S. aquaticus* (especially populations in Uruguay and southernmost Brazil). Dorsal coloration brownish to ochraceous brown and venter ivory white. Skull with frontoparietal suture typically W-shaped, mesopterygoid fossa broad and without median palatine process on anterior border.

DISTRIBUTION: This species ranges across most of Uruguay and along a narrow coastal strip in the Brazilian states of Rio Grande do Sul, Santa Catarina, and Paraná (T. R. O. Freitas et al. 1984; J. González 1994; D'Elía and Pardiñas, 2004).

SELECTED LOCALITIES (Map 134): BRAZIL: Paraná, Nova Tirol (T. R. O. Freitas et al. 1984); Rio Grande do Sul, Bagé (T. R. O. Freitas et al. 1984), Cambará do Sul (T. R. O. Freitas et al. 1984), Esmeralda (T. R. O. Freitas et al. 1984), Porto Alegre (Hensel 1872b), Taim (T. R. O. Freitas et al. 1984). **URUGUAY:** Artigas, La Isleta, Colonia Artigas (Massoia and Fornes 1964c); Colonia, Arroyo Artilleros, Santa Ana (D'Elía and Pardiñas 2004); Maldonado, Barra del Arroyo Maldonado (type locality of *Mus tumidus* Waterhouse); Rivera, Estancia La Quemada (D'Elía and

Pardiñas 2004); Rocha, Arroyo La Palma, Ruta 15km 10, La Paloma (D'Elía and Pardiñas 2004).

SUBSPECIES: *Scapteromys tumidus* is monotypic.

NATURAL HISTORY: Little is known about the ecology of this species. Field observations in Uruguay (Barlow 1969:27) indicate that this rat is usually trapped in marshy or low places where *Eryngium* sp. and *Cortaderia selloana* are the dominant plants. Swamp rats seem not to make runways of their own, but frequently use runways constructed by *Cavia aperea*; they also dig to obtain food, but there is no evidence that they excavate burrows. Vocalizations are often heard when the animals are in distress. Most have been trapped at dusk or during the night; diurnal activity is limited to juveniles and subadults and may be correlated with high population levels. *Scapteromys tumidus* is largely insectivorous; stomach contents of 11 individuals trapped in April and May were 85% invertebrate, mostly Coleoptera and particularly scarabaeid beetles (Barlow 1969:28). In Uruguayan populations, males were reproductively active every month of the year except January, June, and July, with a peak of testis size in April and May; pregnant females were taken in the spring and summer (Barlow 1969). These rats are good swimmers despite limited interdigital webbing (Serra de Soriano 1969:485). The tick *Ixodes longiscutatum* (see Venzal et al. 2001) and the nematode *Anisurptodera scapteromi* (Ganzorig et al. 1999) parasitize this species.

REMARKS: Uruguayan and lowland Brazilian populations have a $2n=24$, FN=40 karyotype; highland Brazilian

Map 134 Selected localities for *Scapteromys tumidus* (●).

populations comprise two karyomorphs, $2n=34$ (northern Rio Grande do Sul state) and $2n=36$ (Paraná state). The latter karyotypic forms likely belong to at least one undescribed species (T. R. O. Freitas et al. 1984; see also Tiepolo 2007, Pedó et al. 2010). These individuals exhibit striking morphological and molecular differences from both *S. aquaticus* and *S. tumidus* (Tiepolo 2007; G. D'Elía and U. F. J. Pardiñas, unpubl. data) as well as extensive karyotypic diversity. The treatment of all Brazilian populations of *Scapteromys* as *S. tumidus*, with the exception of the single record assigned to *S. aquaticus* (see above), is a conservative position followed here and requires a comprehensive study of Brazilian specimens and the naming of new taxa. According to the few published data, animals with $2n=34$ and 36 are restricted to localities above 800m, in the coastal Serra do Mar.

Genus *Thalpomys* Thomas, 1916

Ulyses F. J. Pardiñas and Pablo Teta

The genus *Thalpomys* is endemic to the Brazilian Cerrado and includes two living species, *T. cerradensis* Hershkovitz and *T. lasiotis* Thomas. For many years, *Thalpomys* was both very poorly known and constituted a highly confusing generic concept. Its complex taxonomic and nomenclatural history, paradoxically tortuous considering the limited information available for the genus, has been addressed by several authors (e. g., Langguth 1970; Reig 1987) but not fully resolved until Hershkovitz's (1990a) treatment. The present account is largely based on the results of the last and with recent additions provided by A. F. B. Andrade, Bonvicino et al. (2004).

Both species of *Thalpomys* are small (head and body length 80–101 mm; mass <30g) with the general bauplan of *Akodon*. The overall pale or bright phaeomelaninic color contrasts sharply with the dusky olivaceous or blackish coat of other akodontines. The tail is of medium length (<65% of head and body length) and well haired, which obscures the scales. The pinnae are of medium length, rounded, and covered by short hairs both surfaces. The pes and manus have white hairs on the upper surface and the ungual tufts are shorter than the claws (Bonvicino, Oliveira, and D'Andrea 2008). Hershkovitz (1990a) noted that the coloration of *Thalpomys* is unique among akodontines, resembling that of some oryzomyines such as *Oligoryzomys*.

The skull of *Thalpomys* is characterized by strongly developed supraorbital ledges that extend posteriorly as crests or beading along the length of parietals (thus resembling the condition in *Graomys* [Phyllotini]). This condition is unusual in the Akodontini, although some species of *Necromys* have a roughly similar configuration (a re-

semblance noted by Winge [1887] when he described *T. lasiotis*). The nasals are tapered distally and with rounded tips, proximally extending beyond the premaxillary sutures. The rostral width is subequal to the least interorbital width. The frontoparietal suture is U- to V-shaped. Zygomatic arches are more or less bowed, and converge anteriorly. The braincase is moderately inflated, with its dorsal contour rounded. Zygomatic plates are medium to high, broad anteroposteriorly, similar to those in many *Akodon* species, and have straight anterior borders. Incisive foramina are well developed and reach posteriorly to the protocones of the M1s. The palate is wide, flat, and extends to slightly behind the posterior faces of the M3s; posterolateral palatal pits range in size from small to large. The mesopterygoid fossa (subequal in width to each parapterygoid fossa) is parallel sided and with its anterior border square; sphenopalatine vacuities are conspicuous. Auditory bullae are well inflated, and the distance between them at the basisphenoid-basioccipital suture is about the same as the greatest width of the mesopterygoid fossa.

Upper incisors are orthodont to slightly proodont, and do not extend beyond the nasal tips when viewed from above; their anterior faces are covered with pale orange enamel. Molars are parallel sided, moderately hypsodont, and possess terraced crowns and a simplified occlusal topology. The anteromedian flexus is obvious in unworn M1s but rapidly decays with wear. Upper molars have their major cusps subtriangular in outline and possess a moderate-sized hypoflexus and a wide transverse mesoflexus, both reaching the molar midline. Cusps of opposite sides are subequal in size; flexi are nearly transverse, especially on M1 and M2. The occlusal view of M3 is nearly oval. Lower molars display a characteristic occlusal pattern with a reduced and compressed procingulum on m1, lack an anteromedian flexid, and have crown flexids that nearly touch. The anterolabial conulid of m1 is reduced in size, subequal to the entoconid in size, and narrowly oval to subtriangular in shape. Minute mesolophids are present on both m1 and m2.

Thalpomys has three pairs of mammae, one each in pectoral, abdominal, and inguinal positions. Bacular and penis morphology are similar to other akodontines, based on a single individual of *T. cerradensis*. Geise, Weksler, and Bonvicino (2004) reported the presence of the gall bladder in one specimen of *T. lasiotis*. No other data about soft anatomy are available.

The two species currently recognized overlap in distribution, with sympatry or near-sympatry at one locality in Bahia state (Fazenda Sertão do Formoso, Jaborandi [A. F. B. Andrade, Bonvicino et al. 2004]) and two in the Distrito Federal (Parque Nacional de Brasília [Hershkovitz 1990a])

and Reserva Ecológica do IBGE [A. F. B. Andrade, Bonvicino et al. 2004]). A. F. B. Andrade, Bonvicino et al. (2004) documented unique karyotypes and reciprocally monophyletic mtDNA lineages that are consistent with the two named taxa.

SYNONYMS:

[?] *Hesperomys*: Burmeister, 1854:177; part (included *lasiotis* Lund [= *Mus lasiurus* Lund, = *Necomys lasiurus*] as species); not *Hesperomys* Waterhouse.

Habrothrix: Winge, 1887:29; part; (description of *lasiotis*); not *Habrothrix* Wagner.

Thalpomys Thomas, 1916i:339; type species *Habrothrix lasiotis* Winge, by original designation.

[*Akodon*] (*Thalpomys*): Ellerman, 1941:409; name combination.

Akodon: Langguth, 1975:47; part (*reinhardti* as unnecessary replacement name for *lasiotis* Winge); not *Akodon* Meyen.

KEY TO THE SPECIES OF THALPOMYS:

1. Size larger, mean head and body length >90 mm, greatest adult skull length >25 mm; postpalatal pits large; sphenoidal sinus large; diploid number 36 *Thalpomys cerradensis*
- 1'. Size smaller, mean head and body length <90 mm, greatest adult skull length <25 mm; postpalatal pits small; sphenoidal sinus small; diploid number 38 *Thalpomys lasiotis*

Thalpomys cerradensis Hershkovitz, 1990

Cerrado Akodont

SYNONYM:

Thalpomys cerradensis Hershkovitz, 1990a:777; type locality "Parque Nacional de Brasília, Distrito Federal, Brazil" (elevation ca. 1,100 m).

DESCRIPTION: Larger than *T. lasiotis* with only marginal overlap in external and some cranial measures. Pelage dense and stiff; general coloration of dorsal surface of head and body tawny; individual hairs tricolored with tips black, middle orange-buffy, and base blackish; guard hairs blackish; sides of body paler than back; chin pale buff; check and eye-ring ochraceous orange; vibrissae short, extending to base of ears; tail brownish above and pale buff beneath; hindfoot small, pale buff above, with outer toes short; claws (1 mm) barely extend to base of adjacent toes.

DISTRIBUTION: Cerrado biome in central Brazil, in the states of Bahia, Goiás, and Mato Grosso, and in Distrito Federal.

SELECTED LOCALITIES (Map 135; from A. F. B. Andrade, Bonvicino et al. 2004, except as noted): BRAZIL: Bahia, Cocos, Sertão do Formoso, Jaborandi; Dis-

trito Federal, Parque Nacional de Brasília (type locality of *Thalpomys cerradensis* Hershkovitz); Goiás, Baliza; Mato Grosso, Cuiabá, Xavantina, 260 km N of Serra do Roncador (Hershkovitz 1990a).

SUBSPECIES: *Thalpomys cerradensis* is monotypic.

NATURAL HISTORY: Specimens of *T. cerradensis* have been caught in open grasslands (*campo limpo*), wet prairies with palms (*veredas*), and sparsely wooded savannas in the Brazilian Cerrado (Hershkovitz 1990a; Bonvicino, Cerqueira, and Soares 1996). According to E. M. Vieira and Baumgarten (2009), *T. cerradensis* is more active immediately after sunset and in the last three hours before sunrise. This species is one of the first to recolonize burned grasslands in the Cerrado, reaching population peaks <2 years after fires (Henriques et al. 2006). This rodent represents 10.7% of the diet of the Barn Owl (*Tyto alba*), based on pellet analyses from the state of Bahia; however, no specimens were caught with traps in this same area (Bonvicino and Bezerra 2003). *Thalpomys cerradensis* is parasitized by the botfly *Megacuterebra apicalis* (E. M. Vieira 1993).

REMARKS: Specimens from Serra do Roncador are paler throughout than ones from elsewhere, especially the underparts (Hershkovitz, 1990a). Specimens recorded as *Akodon* sp. nov.? by Pine et al. (1970:669) and as *Akodon* sp. 1 by Mares, Braun, and Gettinger (1989:13) represent *T. cerradensis*.

The karyotype consists of $2n = 36$, $FN = 34$ (A. F. B. Andrade, Bonvicino et al. 2004).

Map 135 Selected localities for *Thalpomys cerradensis* (●).

Thalpomys lasiotis Thomas, 1916

Hairy-eared Akodont

SYNONYMS:

[?] *Hesperomys lasiotis*: Burmeister, 1854:177; name combination.

Habrothrix lasiotis Winge, 1887:29; type locality "Lagoa Santa," Minas Gerais, Brazil.

T[halpomys]. lasiotis Thomas, 1916i:339; redescription of *Habrothrix lasiotis* Winge, with the same type locality.

Akodon [(Thalpomys)] lasiotis: Ellerman, 1941:414; name combination.

Akodon reinhardti Langguth, 1975:47; unnecessary replacement name for *lasiotis* Thomas.

DESCRIPTION: A smaller version of *T. cerradensis* but with longer and more lax fur, more saturate color throughout, and slightly less complex molar occlusal pattern. Hershkovitz (1990a) provided measurements of craniodental variables.

DISTRIBUTION: This species is restricted to Cerrado formations in central Brazil, in the states of Bahia, Minas Gerais, Rondônia, and São Paulo, and the Distrito Federal. Hershkovitz (1990a) considered the skin-only specimen recorded by C. O. da C. Vieira (1955) from São Paulo state as of dubious provenance.

SELECTED LOCALITIES (Map 136; from A. F. B. Andrade, Bonvicino et al. 2004, except as noted): BRAZIL: Rondônia, Vilhena); Bahia, Sertão do Formoso, Jaborandi; Distrito Federal, Parque Nacional de Brasília (Hershkovitz 1990a); Minas Gerais, Lagoa Santa (type locality of *Thalpomys lasiotis* Thomas); São Paulo, Estação de Ferro Noroeste, Braúna (C. O. da C. Vieira 1955); Minas Gerais, Parque Nacional Serra da Canastra, São Roque de Minas, Serra da Canastra, Poços de Caldas.

SUBSPECIES: *Thalpomys lasiotis* is monotypic.

NATURAL HISTORY: Capture sites of *T. lasiotis* in the Cerrado have mostly been in open grasslands (*campo limpio*), open grasslands mixed with low shrubs (*campo cerrado*), open grasslands with scattered shrubs and trees (*campo sujo*), wet grasslands with water-saturated soil (*campo umido*), and wild grasslands with small natural earthen mounds without trees or underbrush (*campo de murumndus*) (Dietz 1983; Mares, Braun, and Gettinger 1989; Hershkovitz 1990a; Bonvicino and Bezerra 2003; R. Ribeiro et al. 2011; C. R. Rocha et al. 2011). Dietz (1985) documented a unimodal reproductive period during the wet season at Serra da Canastra, Minas Gerais, but R. Ribeiro et al. (2011) found breeding during the dry season at a locality in the northeastern part of the Distrito Federal. Near Brasília, Alho and Pereira (1985) recorded males with scrotal testes from August to October and pregnant females from September to May. Finally, at a site in northeastern Distrito Federal, reproductive activity began

at the end of the dry season (August) and lasted through the end of the rainy season (March), with pregnant females recorded from November through March (R. Ribeiro et al. 2011). Pregnant females carried two to three embryos (reviewed by Hershkovitz 1990a). Mean biomass varied between 1.2 and 19.6 g/ha and mean home range size for 26 individuals was 2,278 m² (Alho and Pereira 1985). Densities per hectare expressed as the minimum number of individuals known alive for the months of July and August (winter) at two sites in the vicinity of Brasília were 0.5 and 0.6 (Lacher et al. 1990) and 0.5 to 1.6 (R. Ribeiro et al. 2011). R. Ribeiro et al. (2011) provided data on home range size and dispersal distances. L. A. Pereira (1982, fide Armada et al. 1984) found *T. lasiotis* to be the second most abundant rodent, after *Necromys lasiurus*, in the Cerrado. At least three species of laelapid mites (*Androlaelaps foxi*, *A. pachyptilae*, and *A. fabrenholzi*) and some undetermined Acariformes are external parasites of this species (Mares, Braun, and Gettinger 1989).

REMARKS: Both Langguth (1975) and Hershkovitz (1990a) documented that *Thalpomys lasiotis*, the type species of *Thalpomys* Thomas, is not Lund's *Mus lasiotis* (1840b:50, 1841c:280), as has often been assumed (e.g., Cabrera 1961). Rather, it is the species Winge (1887:29) described and figured as *Hesperomys lasiotis*, and which Winge mistakenly attributed to Lund. Lund's *lasiotis* is a junior synonym of *Mus lasiurus* Lund, which is now regarded as a valid species of *Necromys* Ameghino (see that account). Langguth (1975:47) unnecessarily renamed Winge's *Hesperomys lasiotis* as *Akodon reinhardti*, placing it in a sub-

Map 136 Selected localities for *Thalpomys lasiotis* (●).

genus, *Thalpomys*. Thomas (1916:339) becomes the author of *Thalpomys lasiotis*, even though he gave the type species as the misidentified “*T. lasiotis* (*Mus lasiotis*, Lund; *Habrothrix lasiotis*, Winge)” (ICZN 1999:Art. 11.10).

Armada et al. (1984) and A. F. B. Andrade, Bonvicino, et al. (2004) recorded a karyotype with $2n=38$, FN=38, with apparently geographically fixed morphological differences in the X chromosome.

Genus *Thaptomys* Thomas, 1916

Pablo Teta, Ulyses F. J. Pardiñas, and Guillermo D’Elía

In current usage, the genus *Thaptomys* includes only the single species *Thaptomys nigrita*, which is restricted to moist tropical forest and second-growth forest in south-eastern Brazil, eastern Paraguay, and northeastern Argentina (Massoia 1963a; Hershkovitz 1998). Ellerman (1941), Cabrera (1961), and Musser and Carleton (1993) all listed *Thaptomys* as a subgenus of *Akodon*. Reig (1987) included *nigrita* in the genus *Akodon*, subgenus *Akodon* (*Akodon*). Hershkovitz (1990b; see also Hershkovitz 1998) reintroduced the concept of *Thaptomys* as a valid genus based on morphological and karyotypic data. Subsequent molecular-based phylogenetic analyses recovered *nigrita* outside of *Akodon* (*sensu stricto*). These analyses recovered, with weak support, *Thaptomys* as sister either to *Akodon* s.s. (M. F. Smith and Patton 1999), to “*Akodon*” *serrensis* (D’Elía 2003; D’Elía et al. 2003), or to an *Akodon-Deltamys*-“*A.*” *serrensis* clade (M. F. Smith and Patton 2007).

Thaptomys is modified for a semifossorial life. The fur is velvety and short; eyes are very small; ears are short; and the tail is short, usually equal to or less than 50% of the head and body length, and very thinly haired (the short stiff hairs brown above, whitish below, not concealing scales). Manual claws are long and fine; pedal claws are shorter. Palms and soles are naked, with prominent pads. The dorsum is dark brown or glistening olive brown to reddish brown, finely grizzled with ochraceous brown and intermixed with some longer blackish brown hairs. The under parts are ochraceous to dull brownish gray washed with buff, the hairs dark slaty at their bases. The mean and ranges of external measurements of 12–17 adults from Brazil are: total length, 96 mm (82–116 mm), length of tail, 45 mm (30–50 mm), length of hindfoot, 19 mm (16–20 mm), and length of ear, 11 mm (10–12 mm). Females have three to four pairs of mammae (Gyldenstolpe 1932; Hershkovitz 1998).

The skull is rather strongly built, with a short and thick rostrum and short nasals that do not extend to the level of the incisors. The interorbital region is wide, with a moderate constriction and marked supraorbital edges. The brain-

case is smooth and square; the supraoccipital bone is inclined forward; the interparietal is small; and the parietals are moderately ridged. Zygomatic arches are delicate. Zygomatic plates are broad, with almost vertical anterior borders, very short upper free borders, and an excrescence at the base, at the point of origin of the superficial masseter. Incisive foramina are longer than the molar rows, parallel sided, narrow, and extend to the level of the protocones of M1s. The palate is short, flat, and wide. The mesopterygoid fossa is broad; sphenopalatine vacuities are absent (Gyldenstolpe 1932; Hershkovitz 1998). The carotid circulation pattern is pattern 1 (*sensu* Voss 1988); a thick alisphenoid strut is present. Massoia (1963a) and Hershkovitz (1990b, 1998) provided cranial measurements. The mandible is robust, with a prominent capsular projection directed toward the condyle and with a robust coronoid process; the mental foramen is large and clearly visible in lateral view.

Upper incisors are long, opisthodont to slightly proodont. Molars are hypsodont, moderately high crowned, and small; the unworn crowns are terraced. An anteromedian flexus of M1 is well defined; the paralophule in both M1 and M2 is fused to the mesoloph, and both are coalescent with the paracone; M3 is reduced, but with an enamel ring usually present. The first lower molar has a conspicuous anterolabial cingulum with a well-developed anteromedian flexid, oblique main cusps, and a short posterolophid. The mesolophid in both m1 and m2 is reduced, but both teeth have a well-developed ectolophid. The third lower molar is bilophodont, lacking the posteroflexid (details from Hershkovitz 1998).

The vertebral count is 7 cervical, 19 thoracolumbar, 2 sacral, and 23–24 caudal elements (Steppan 1995; Hershkovitz 1998).

Thaptomys possess a single pair of prostates (Voss and Linzey 1981). A gall bladder is absent, both in Brazilian (Geise, Weksler, and Bonvicino 2004) and Argentinean specimens (LTU 846, 858, 877, 879). The stomach is hemiglandular-unilocular, with a reduced glandular area (our dissection of two specimens, LTU 877, 879 from Misiones, Argentina).

DESCRIPTION: As for the genus.

DISTRIBUTION: *Thaptomys nigrita* is found in southeastern Brazil, from Bahia south through Minas Gerais, São Paulo, Paraná, Santa Catarina, and Rio Grande do Sul states into southeastern Paraguay and the Argentinean province of Misiones (Massoia 1963a; Myers and Wetzel 1979; Gamarra de Fox and Martin 1996; Hershkovitz 1998; J. C. Moreira and Oliveira 2011).

SELECTED LOCALITIES (Map 137; from J. C. Moreira and Oliveira 2011, except as noted): ARGENTINA: Misiones, San Ignacio, San Ignacio (Massoia 1993), Candelaria, Arroyo Yabebyri (Massoia 1993), Oberá, Campo Ramón (Massoia 1993). BRAZIL: Bahia, Fazenda Almada, Fazenda Ribeirão da Fortuna, Vila Brasil; Espírito Santo, Santa Teresa; Minas Gerais, Boca da Mata, Conceição do Mato Dentro (Avila-Pires 1960b); Rio Grande do Sul, Taquara (type locality of *Hesperomys subterraneus* var. *henseli* Leche); São Paulo, São João da Boa Vista, Fazenda Intervals, Capão Bonito; Paraná, Fênix; Santa Catarina, Corupá. PARAGUAY: Itapúa, Ape Aime (TK 66003), 8 km N of San Rafael (Myers and Wetzel 1979).

SUBSPECIES: Two subspecies, *T. n. nigrita* and *T. n. subterraneus*, have been generally recognized since Cabrera (1961), a view supported by Massoia’s (1963a) morphological assessment (but see Remarks).

NATURAL HISTORY: Little is known about this semi-fossorial rodent. Specimens have been collected in both primary and second-growth forest and in grasslands near forest (Davis 1947; Myers and Wetzel 1979). In Paraguay, they have been trapped in wet tropical forest along runways through grass, in woodpiles, and next to fallen logs (Myers and Wetzel 1979). In Brazil, they were found under logs and tree roots (Davis 1947). *Thaptomys nigrita* is strongly terrestrial and mostly diurnal (Davis 1947). This species makes tunnels in the leaf litter or in the soft earth (Davis 1947; Hershkovitz 1998). In São Paulo state, Brazil, females with perforated vaginas were trapped in April-May and September-October, while males with descended testes were found in May and October. Breeding between April and May is consistent with the trapping of juveniles between May and August (Olmos 1992). The observed number of embryos in four females from Brazil ranged from three to five (Davis 1947). Several specimens were collected with a single trap in a small area on consecutive days, suggesting some degree of sociality or at least that a single burrow system is used by more than one individual (U. F. J. Pardiñas, unpubl. data on captures made in Misiones, Argentina).

REMARKS: Thomas (1902a:62; see also Tate 1932h:2), when describing specimens from São Paulo, referred to at that time as *Akodon subterraneus*, was the first to associate *orycter* Lund with that form and with *nigrita*. Paula Couto (1950) directly equated *Mus orycter* with *Akodon (Abrothrix) nigrita*. Later, Avila-Pires (1960b:39) listed *orycter* in the synonymy of *Thaptomys nigrita*. However, none of these authors indicated explicitly that they had examined the original material referred by Lund to *orycter*. The holotype (fixed by monotypy; ICZN 1999:Art. 73.1.2) of *Mus orycter* is a large skull fragment housed in the Natural History Museum of Denmark (ZMK 1/1845:13239, figures at http://www.zmuc.dk/VerWeb/lund/lund_mammals.html) and illustrated by Winge (1887) in plate II, Fig. 8 and by Hansen (2012:56–57). Accordingly, the type locality of *orycter* Lund is fixed at “Lapa da Serra das Abelhas,” where this fossil originated (Winge 1887:27; Hansen 2012:56). From inspection of the holotype, the morphology (including nasal length, zygomatic plates with short upper free borders, wide interorbital region with well-inflated frontal sinuses, presence of a visible excrescence at the point of origin for the superficial masseter, and large incisive foramina that are parallel sided and narrow) is in agreement with that of *Thaptomys*, which validates Thomas’s (1902a) early impression. However, further studies are needed to determine whether *orycter* Lund represents a distinct (perhaps extinct?) species of *Thaptomys* or whether it is a synonym of *T. nigrita* as we treat it here.

Karyological, molecular, and morphometric data combine to suggest greater taxonomic diversity in the currently recognized single species. The diploid complement of *T. nigrita* across most of its range is $2n=52$, FN=52 (Yonenaga-Yassuda 1975; K. Ventura et al. 2010). This karyomorph is composed of 24 pairs of acrocentric autosomes that gradually decrease in size, a minute metacentric pair, a medium-sized metacentric X chromosome, and a subtelocentric medium-sized Y (Paresque et al. 2004). Ventura et al. (2004) found a second, $2n=50$, FN=48, karyomorph in animals from Una, Bahia state, and suggested that this population represents an undescribed species. Phylogeographic analyses (K. Ventura et al. 2010) based on mtDNA cytochrome-*b* sequences recovered two main clades whose distribution broadly corresponded with those of the two karyomorphs, one restricted to a small area in central-eastern Brazil ($2n=50$), and another widely distributed in southeastern Brazil and perhaps Argentina and Paraguay ($2n=52$). The latter clade is composed of three geographically structured subclades. Silva Gómez (2008) obtained similar results with broader geographic sampling that included Argentinean populations and referred Bahia as well as São Paulo populations to separate undescribed species, while placing samples from Rio de Janeiro, Es-

Map 137 Selected localities for *Thaptomys nigrita* (●).

pírito Santo, and Minas Gerais in *T. nigrita* and those from Paraná, Santa Catarina, Rio Grande do Sul, and Misiones to *T. subterraneus*. J. C. Moreira and Oliveira (2011), using morphometrics and qualitative morphological character analyses, failed to find differences between northeastern and southeastern populations, reporting only subtle metric differences in cranial descriptors. Thus, these authors were unable to reject the hypothesis that the differences found between northern and southern populations of *Thaptomys* simply constitute those of a widely distributed polytypic species. The possibility that *T. nigrita* might be composite, comprising two or more species, thus remains an open question.

Tribe Ichthyomyini Vorontsov, 1959
Robert S. Voss

The tribe Ichthyomyini includes five genera and 17 species, of which four genera and 13 species are known to occur in South America. In Central America, the tribe ranges from southern Mexico through Guatemala, El Salvador, and Costa Rica, to eastern Panama. In South America, ichthyomyines occur from Colombia southward to Bolivia and eastward to the Guianas and Brazil. Although ichthyomyines share numerous derived morphological traits that are not observed in other New World cricetids (Voss 1988), currently available molecular results do not support ichthyomyine monophyly (J. J. Martínez et al. 2012; Parada et al. 2013), a noteworthy anomaly. Ichthyomyines are unknown from any island fauna, and there is no fossil record. Except as noted otherwise, this account is abstracted from Voss (1988), which should

be consulted for additional details concerning taxonomy, comparative morphology, geographic distributions, and natural history.

Ichthyomyines are small to medium-sized (35–155 g) semiaquatic carnivorous rodents that are morphologically distinctive in many external, skeletal, and visceral characters. The eyes and pinnae are small (*Anotomys* lacks visible external ears altogether), and the blunt rostrum is provided with numerous ventrally recurved mystacial vibrissae; genal vibrissae (present in most other Sigmodontinae) are absent. There are six mammae (in postaxial, abdominal, and inguinal pairs), the hindfeet are provided with a more or less distinct fringe of stiff hairs along the plantar margins, and the tail is well haired (lacking visible epidermal scales). The cranium is distinctive in dorsal view, lacking any trace of zygomatic notches; the supraorbital margins are smoothly rounded, without beads or sharp edges; and the braincase is smooth in lateral aspect, without any temporal ridges. In lateral view, a well-developed gnathic process of the premaxillae (projecting between the upper incisors) is invariably present, and a distinct bony tubercle for the origin of the superficial masseter is usually present at the base of the inferior zygomatic root. The infraorbital foramen is large and oval in cross-section (not narrowed ventrally as in most other muroids). The bony palate is smooth and produced posteriorly behind the toothrows; the posterolateral palatal pits are small, simple, and inconspicuous. The parapterygoid fossae are narrow and not deeply excavated, and the bony roof of the mesopterygoid fossa is not perforated by large sphenopalatine vacuities. The buccinator-masticatory and accessory oval foramina are widely separated by a stout vertical strut of the alisphenoid. The small auditory bullae are firmly anchored to the skull by broad overlap between the tegmen tympani and a posterior suspensory process of the squamosal. The tympanic membrane pars flaccida (present in all other Sigmodontinae) is absent, and there is no subsquamosal fenestra.

Ichthyomyine molars are tetralophodont (lacking well-developed mesolophs and mesolophids) with the principal cusps arranged in opposite labial-lingual pairs. The unworn anterocone of M1 has two functional cusps, but the anteromedian flexus is shallow, indistinct, or absent. The upper and lower third molars (M3/m3) are small or absent. The first and second upper molars have three roots each, whereas the lower first and second molars each have two roots; third molars (M3/m3) have variable root morphologies.

Counts of axial skeletal elements include 13–14 ribs, 19–20 thoracolumbar vertebrae, 4–5 sacral vertebrae, and 30–33 caudal vertebrae. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and first thoracic vertebrae, and the third (not the sec-

ond) thoracic vertebra has a greatly elongated neural spine. The entepicondylar foramen of the humerus is absent.

The glandular epithelium of the stomach is variously reduced from the hemiglandular condition (Carleton 1973), the caecum is simple and very small, and a gall bladder is either present or absent. Male accessory secretory organs conform to the widespread condition among other Sigmodontinae (Voss and Linzey 1981). The glans penis is complex but taxonomically variable, with a terminal crater containing one to three bacular mounds, one or two dorsal papillae, two lateral papillae, and a bifurcate urethral process.

KEY TO THE GENERA OF ICHTHYOMYINI:

1. Carotid circulation primitive (pattern 1 of Voss 1988); five plantar pads on manus (hypothenar and third interdigital pads separate); stomach with glandular epithelium between esophagus and pyloric sphincter 2
- 1'. Carotid circulation derived (patterns 2 or 3 of Voss 1988); five or fewer plantar pads on manus; stomach with glandular epithelium restricted to oval patch on greater curvature 3
2. Hindfoot narrow, with weakly developed fringe of stiff hairs; claw of pedal digit V extends to but not beyond first interphalangeal joint of dIV; ears clearly visible above fur of head; philtrum present; tail < head and body length. *Neusticomys*
- 2'. Hindfoot broad, with well-developed fringe of stiff hairs; claw of pedal digit V extends well beyond first interphalangeal joint of dIV; ears buried in fur of head; philtrum present or absent; tail > head and body length *Chibchanomys*
3. Adult dorsal pelage dull gray-black when fresh (fading to dull rust color in old museum skins); pinnae visibly absent; tufts of pure white fur over external auditory canals; philtrum absent; superciliary vibrissae present; carotid circulation pattern 2 *Anotomys*
- 3'. Adult dorsal pelage glossy grizzled-brownish; pinnae visibly present; ear region without conspicuous tuft of white fur; philtrum present or absent; superciliary vibrissae absent; carotid circulation pattern 3 4
4. Manus with five plantar pads (hypothenar and third interdigital pads separate); nasal bones short, revealing nasal orifice in dorsal view; supraorbital foramina on dorsal surface of frontals in large adults; occipital condyles produced posteriorly well behind the rest of the occiput; gall bladder absent *Ichthyomys*
- 4'. Manus with four or fewer plantar pads (hypothenar and third interdigital pads always fused); nasal bones long, concealing nasal orifice in dorsal view; supraorbital foramina opening laterally within the orbits; occipital condyles not produced posteriorly behind the rest of the occiput; gall bladder present *Rheomys*

REMARKS: The key above includes *Rheomys*, a genus currently known only from Central America, but which is almost certainly present on the Colombian side of the mountainous divide (Serranía de Pirre, Serranía del Darién) that forms the political boundary between that country and Panama.

Genus *Anotomys* Thomas, 1906

The genus *Anotomys* contains a single species, *A. leander* Thomas, 1906, which is known to occur only in northern Ecuador between 2,800 and 4,000 m.

Anotomys leander is a medium-sized ichthyomyine (recorded adult weights range from 40 to 60 g) with body pelage that is dull gray-black dorsally and abruptly silvery white ventrally; there are tufts of pure white fur over the ear region (where no pinnae are visible), and the tail is unicolored-brownish. The philtrum (a naked median groove that extends from the rhinarium to the upper lip in most Sigmodontinae) is absent, supraorbital vibrissae (absent in other ichthyomyines) are present, and the external ears are reduced to low ridges of skin that are buried beneath the fur of the head. The manus has only four planar pads because the hypothenar and third interdigital pads are fused. The large hindfeet (averaging about one-third of head and body length) are conspicuously webbed and provided with a dense fringe of silvery hairs, the plantar surface is heavily pigmented (blackish), the hypothenar pad is absent, and the claw of digit V extends to the base of the claw on digit IV. The tail is longer than the combined length of head and body.

The nasal bones are long, concealing the nasal orifice from dorsal view. The rostrum is narrow (with dorsally exposed nasolacrimal capsules), and the interorbital region is also narrow in proportion to the inflated braincase. The supraorbital foramina open laterally (within the orbits), not onto the dorsal surface of the frontals. The condyles are not produced posteriorly behind the rest of the occiput and are not dorsally visible. In lateral view, the dorsal profile of the skull is distinctively flat over the rostrum and orbits, but abruptly convex over the braincase. The posterior edge of the inferior zygomatic root of each zygomatic plate is located above (not anterior to) the anterocone of M1, and the tip of the masseteric process never projects ventrally below the plane of the molar alveoli. The carotid arterial supply conforms to pattern 2 (of Voss 1988), with a large stapedia foramen but without a squamosal-alisphenoid groove for the supraorbital stapedia ramus. The lower third molar (m3) is small, without a large posterior lobe corresponding to the entoconid-hypoconid cusp pair.

There are 14 ribs, 20 thoracolumbar vertebrae, and 5–6 sacral vertebrae. Gastric glandular epithelium is restricted

to a broad band that crosses the greater curvature on the right-hand side of the stomach, and a gall bladder is present. The penis has a single bacular mound bearing two large dorsolateral spines and is supported by a single cartilaginous digit; two dorsal crater papillae are present. Other skeletal, visceral, and reproductive characters conform to those of the tribe.

SYNONYMS:

Anotomys Thomas, 1906a:86; type species *Anotomys leander* Thomas, 1906, by original designation.

Anotomys leander Thomas, 1906

Earless Water Mouse

SYNONYM:

Anotomys leander Thomas, 1906a:87; type locality “Mount Pichincha,” Pichincha, Ecuador.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Anotomys leander* is known only from three identifiable localities (two of which are so close together as to be indistinguishable on a large-scale map) at recorded elevations of 2,800 and 4,000 m in northern Ecuador (see Remarks).

SELECTED LOCALITIES (Map 138): ECUADOR: Napo, 6.9 km by road W of Papallacta (AMNH 244605); Pichincha, Mount Pichincha (type locality of *Anotomys leander* Thomas).

SUBSPECIES: *Anotomys leander* is monotypic.

NATURAL HISTORY: The only available natural history information about *Anotomys leander* comes from 12 specimens that were trapped along the banks of a torrential

Map 138 Selected localities for *Anotomys leander* (●). Contour line = 2,000 m.

mountain stream between 3,600 and 3,800 m near Papalacta, Provincia de Napo, Ecuador. The bordering vegetation at this locality (where another ichthyomyine, *Neusticomys monticolus*, was also trapped) included grassy páramo, mossy elfin forest, and a shrubby ecotone at the forest edge. Dissected stomachs from these specimens contained the remains of numerous small aquatic arthropods, principally the immature stages (larvae or nymphs) of caddisflies (Trichoptera: Hydropsychidae, Limnephilidae, Rhyacophilidae), mayflies (Ephemeroptera: Baetidae), stoneflies (Plecoptera: Gripopterygidae), net-winged midges (Diptera: Blephariceridae) and other benthic insects. An adult female caught in the late dry season (March) had a single large embryo in utero.

REMARKS: A published record of *A. leander* from the western Andes of Colombia (Cuervo Díaz et al. 1986) appears to be unvouchered and cannot be confirmed (M. Gómez-Laverde, pers. comm.).

Genus *Chibchanomys* Voss, 1988

The genus *Chibchanomys* contains two species that inhabit high elevations in the Andes of Colombia, Ecuador, and Peru. A juvenile specimen from Bolivia (unassignable to species) has also been referred to this genus (S. Anderson 1997).

Species of *Chibchanomys* are small ichthyomyines (recorded adult weights range from 35 to 50 g) with dull gray-black (not glossy brownish) dorsal body pelage and silvery or pale-gray venters. Supraorbital vibrissae (present in *Anotomys*) are absent, and the pinnae (visibly absent in *Anotomys*) are small and concealed in the fur of the head. The manus has five separate plantar pads (thenar, hypothenar, and three interdigitals). The pes is provided with a well-developed fringe of stiff, silvery hairs, and the claw of pedal digit V extends beyond the first interphalangeal joint of digit IV. The tail is longer than the combined length of the head and body.

The nasal bones are long, concealing the nasal orifice from dorsal view, and the rostrum is narrow with dorsally exposed nasolacrimal capsules. The interorbital region is narrow in proportion to the inflated braincase. The supraorbital foramina open laterally (within the orbits), not onto the dorsal surface of the frontals. The occipital condyles are not produced posteriorly behind the rest of the occiput, so they are not dorsally visible. In lateral view, the dorsal cranial profile is more or less flat over the rostrum and interorbit but convex over the braincase. The posterior edge of the inferior zygomatic root of each zygomatic plate is located above (not anterior to) M1, and the tip of the masseteric tubercle does not project below the plane of the molar alveoli. The carotid arterial morphology conforms to pattern 1 (of Voss 1988), with a large stapedia foramen and a prominent squamosal-alisphenoid groove for the supraorbital stapedia

ramus. The lower third molar (m3) is small, without a large posterior lobe corresponding to the entoconid-hypoconid cusp pair.

There are 13 to 14 ribs, 19 thoracolumbar vertebrae, and 4 sacral vertebrae. The stomach is nearly hemiglandular, with gastric glandular epithelium present between the esophagus and the pyloric sphincter; and a gall bladder is present. The penis has three bacular mounds supported by a tridigitate bacular cartilage, and a single dorsal crater papilla. (Postcranial, visceral, and genital characters are based on *Chibchanomys trichotis* because relevant anatomical preparations are not available from *C. orcesi*.)

SYNONYMS:

Ichthyomys: Thomas, 1897e:220; part (description of *trichotis*); not *Ichthyomys* Thomas.

Rheomys: Thomas, 1906b:421; part (listing of *trichotis*); not *Rheomys* Thomas.

Anotomys: Handley, 1976:53; part (listing of *trichotis*); not *Anotomys* Thomas.

Chibchanomys Voss, 1988:321; type species *Ichthyomys trichotis* Thomas, by original designation.

KEY TO THE SPECIES OF *CHIBCHANOMYS*:

1. Philtrum (naked median groove from rhinarium to upper lip) present; rhinarium unpigmented (brownish on dry skins); metatarsal formula (relative lengths of bones) III > IV > II > V > I; orbicular apophysis of malleus present *Chibchanomys orcesi*
- 1'. Philtrum absent; rhinarium pigmented (blackish on dry skins); metatarsal formula IV > III > II = V > I; orbicular apophysis of malleus absent *Chibchanomys trichotis*

REMARKS: A single immature Bolivian specimen referred to *Chibchanomys* by S. Anderson (1997) is not referred to either of the species recognized here.

Chibchanomys orcesi Jenkins and Barnett, 1997

Orces's Andean Water Mouse

SYNONYM:

Chibchanomys orcesi Jenkins and Barnett, 1997:124; type locality "Lake Luspa, Las Cajas, Provincia Azuay, Ecuador, 02°50'S 79°30'W, altitude 3700 m."

DESCRIPTION: See keys (above) and Jenkins and Barnett (1997).

DISTRIBUTION: *Chibchanomys orcesi* is known from 2,400 to 3,700 m in southern Ecuador and central Peru.

SELECTED LOCALITIES (Map 139): ECUADOR: Azuay, Las Cajas, Lake Luspa (type locality of *Chibchanomys orcesi* Jenkins and Barnett). PERU: Huánuco, Cordillera Carpath (LSUMZ 14406).

SUBSPECIES: *Chibchanomys orcesi* is monotypic.

NATURAL HISTORY: Everything that is known about the ecology and behavior of *C. orcesi* was summarized

by Barnett (1999), whose observations were based on six specimens trapped along small mountain streams bordered by grassy páramo vegetation or pastures near Las Cajas, Provincia Azuay, Ecuador. Dissected stomachs from two kill-trapped specimens contained the remains of aquatic insects (mayfly naiads and caddisfly larvae) and unidentified fish. A single live-trapped animal from the same locality and maintained in captivity for four months was almost exclusively nocturnal, emerging from its burrow at night to capture small fish in an artificial stream.

REMARKS: The Peruvian specimen (LSUMZ 14406) here referred to *Chibchanomys orcesi* was originally reported as *Anotomys leander* by A. L. Gardner (1971) and subsequently identified as *C. trichotis* by Voss (1988). However, the qualitative morphological characters of LSUMZ 14406 more closely resemble those of *C. orcesi* than of *C. trichotis*. External measurements reported by Jenkins and Barnett (1997:Table 1) suggest that *C. orcesi* has much smaller hindfeet (19 to 24 mm) than do *C. trichotis* and the Peruvian specimen (30 to 33 mm), but some of this disparity may be an artifact of different measurement

protocols; measured by the American method (heel to tip of longest claw), the dry hindfoot of BM 82.816 (the holotype of *orcei*) is 28 mm.

A. L. Gardner (1971) karyotyped LSUMZ 14406 and reported a diploid number ($2n$) of 92 chromosomes and a fundamental number (FN) of 98 or 100 autosomal arms; the X chromosomes were thought to be the largest biarmed pair.

Chibchanomys trichotis (Thomas, 1897)

Northern Andean Water Mouse

SYNONYMS:

Ichthyomys trichotis Thomas, 1897e:220; type locality allegedly “W. Cundinamarca, in low country near to Magdalena R[iver]” in Colombia, but the holotype was probably collected in the Cordillera Oriental near Bogotá (Voss 1988).

Rheomys trichotis: Thomas, 1906b:421; name combination.

Anotomys trichotis: Handley, 1976:53; name combination.

Chibchanomys trichotis: Voss, 1988:321; first use of current name combination.

DESCRIPTION: See keys (above), Thomas (1897e), and Voss (1988: 322–324).

Map 139 Selected localities for *Chibchanomys orcesi* (●). Contour line=2,000m.

Map 140 Selected localities for *Chibchanomys trichotis* (●). Contour line=2,000m.

DISTRIBUTION: *Chibchanomys trichotis* is known from elevations between 2,400 and 2,900m in the Táchira Andes of western Venezuela and in the Cordillera Oriental near Bogotá, Colombia.

SELECTED LOCALITIES (Map 140): COLOMBIA: Cundinamarca, San Cristobal (FMNH 71226). VENEZUELA: Táchira, Buena Vista (USNM 442606).

SUBSPECIES: *Chibchanomys trichotis* is monotypic.

NATURAL HISTORY: Five specimens of *Chibchanomys trichotis* were trapped along the banks of a small mountain stream bordered by cloud forest near Buena Vista, Estado Táchira, Venezuela. Dissected stomachs from four of these specimens contained only aquatic insects, including larval beetles (Helodidae), larval crane flies (Tipulidae), larval caddisflies (Leptoceridae), and nymphs of mayflies (Leptophlebiidae, Trichorythidae) and stoneflies (Perlidae). An adult female *C. trichotis* trapped in the middle of the dry season (January) at the same locality contained a single near-term embryo. Two specimens of *C. trichotis* collected at other localities were trapped along streams, but no additional ecological information was recorded about them.

Genus *Ichthyomys* Thomas, 1893

The genus *Ichthyomys* contains at least four valid species that occur in lowland and montane habitats from central Panama southward to central Peru and eastward to the coastal cordilleras of northern Venezuela.

Species of *Ichthyomys* are large ichthyomyines (recorded adult weights range from 85 to 155 g) with glossy brownish dorsal fur and countershaded (whitish or silvery) under parts. The philtrum is always present and broad, supraorbital vibrissae are absent, and the small external ears are always visible above the fur of the head. The manus has five separate plantar pads, including the thenar, hypothenar, and three separate interdigital pads. The hindfoot varies in size (its average length ranging from about one-fifth to almost one-third of head and body length in different species) but is always broad, with pigmented plantar epithelium (blackish on dried skins), and a well-developed natatory fringe of stiffened (usually silvery) hairs; the claw of digit V always extends beyond the first interphalangeal joint of digit IV. The tail may be shorter than, equal to, or longer than the combined length of the head and body; it is unicolored (all dark) in some species and bicolored (dark above, white below) in others.

The skull is highly distinctive in several respects. The nasal bones are short and truncated anteriorly so as to expose the nasal orifice in dorsal view, and the rostrum is broad with expanded lateral margins that conceal the nasolacrimal capsules from above. The supraorbital foramina

open laterally (near the orbital margins) in young animals, but migrate dorsally as the interorbital region constricts in most adult specimens. The zygomatic processes of the maxilla and squamosal are strongly developed in old adults, flaring widely from the rostrum and braincase, respectively. The lambdoidal crests are likewise well developed in large adults, and the occipital condyles are produced posteriorly behind the rest of the occiput. In lateral view, the skull is diagnostically flattened from the tips of the nasals to the occiput, without any conspicuous convexity over the braincase. The posterior edge of the inferior zygomatic root of each zygomatic plate is always located anterior to M1, and the tip of the masseteric tubercle sometimes projects ventrally to or below the plane of the molar alveoli. The incisive foramina have straight, subparallel lateral margins. The carotid arterial circulation conforms to pattern 3 (of Voss 1988), with or without a tiny stapedial foramen, and lacking any grooves or foramina for the stapedial rami; instead, the ophthalmic and internal maxillary circulations are provided by an endocranial anastomosis of the internal carotid. In most species (*Ichthyomys pittieri* is the only exception), m3 is a distinctly bilobed tooth with subequal protoconid/metaconid and entoconid/hypoconid cusp pairs.

There are 13 ribs, 19 thoracolumbar vertebrae, and 4 sacral vertebrae in all examined skeletons. The gastric glandular epithelium is restricted to a broad band that crosses the greater curvature on the right-hand side of the stomach, and the gall bladder is absent. The penis has three bacular mounds (supported by a tridigitate bacular cartilage) and a single dorsal crater papilla. Other skeletal, visceral, and reproductive characters conform to those of the tribe.

SYNONYMS:

Habrothrix: Winge, 1891:20; part (description of *hydrobates*); not *Habrothrix* Wagner.

Ichthyomys Thomas, 1893a:337; type species *Ichthyomys stolzmanni* Thomas, by original designation.

KEY TO THE SPECIES OF *ICHTHYOMYS*:

1. Tail sharply bicolored (dark above, white below); hindfoot very large (>39 mm); in Andean foothills of eastern Ecuador and Peru *Ichthyomys stolzmanni*
- 1'. Tail unicolored (dark above and below); hindfoot smaller (<38 mm) 2
2. Tail (measured from dorsal flexure to fleshy tip) distinctly shorter than head and body length (obtained by subtracting length of tail from total length); upper molars very small (crown length M1–M3 <3.7 mm); lower third molar (m3) not bilobed (without a distinct entoconid-hypoconid cusp pair); in Serranía de Aroa and coastal cordilleras of northern Venezuela)
 *Ichthyomys pittieri*

- 2'. Tail about as long as combined length of head and body; upper molars larger (crown length >4.0 mm); m3 bilobed 3
3. Incisors, rostrum, zygomatic plates, zygomatic arches, and lambdoidal crests massively developed in older adults; in Pacific lowlands and foothills of western Ecuador *Ichthyomys tweedii*
- 3'. Incisors, rostrum, zygomatic plates, and zygomatic arches much narrower, even in old adults; lambdoidal crests usually inconspicuous; in high Andes and adjacent foothills of Ecuador, Colombia, and western Venezuela *Ichthyomys hydrobates*

REMARKS: In the absence of many qualitative character differences, species of *Ichthyomys* are less easily keyed out than species of other ichthyomyine genera. Indeed, *I. tweedii* and *I. hydrobates* are principally distinguished by ontogenetically variable morphometric traits such as size and correlated allometric proportions that are hard to reduce to simple ratio comparisons, hence the ambiguity of the last key couplet. However, where the ranges of these two species are juxtaposed on the Andean slopes of western Ecuador, the local form of *I. hydrobates* can be identified by the absence of distinct lateral parapterygoid margins (Voss 1988:Fig. 37B), which are always well developed in *I. tweedii*.

Ichthyomys hydrobates (Winge, 1891)

Silver-bellied *Ichthyomys*

SYNONYMS:

Habrothrix hydrobates Winge, 1891:20; type locality "Sierra de Mérida," Mérida, Venezuela.

Ichthyomys hydrobates: Thomas, 1893a:338; first use of current name combination.

Ichthyomys söderströmi de Winton, 1896:512; type locality "Rio Machangara," near Quito, Pichincha, Ecuador.

Ichthyomys nicefori Thomas, 1924a:165; type locality "Neighborhood of Bogotá," Cundinamarca, Colombia.

Ichthyomys hydrobates hydrobates: Cabrera, 1961:509; name combination.

Ichthyomys hydrobates nicefori: Cabrera, 1961:510; name combination.

Ichthyomys hydrobates soderstromi: Cabrera, 1961:510; name combination.

DESCRIPTION: See keys (above) and Voss (1988:334).

DISTRIBUTION: *Ichthyomys hydrobates* is known to occur in the Andes of western Venezuela, in the eastern and western Andes of Colombia, and in the western Andes of northern Ecuador; recorded elevations range from about 1,000 to 2,800 m.

SELECTED LOCALITIES (Map 141): COLOMBIA: Cauca, Cerro Munchiquito (USNM 294985); Cundina-

marca, Paima (BM 23.11.13.9). ECUADOR: Pichincha, Guápulo (AMNH 39593). VENEZUELA: Mérida, La Mucuy (UMMZ 156375); Táchira, Paso Hondo, Río Potosí (Ochoa and Soriano 1991).

SUBSPECIES: Cabrera (1961) recognized three subspecies as did Voss (1988:334), who commented "each name is the descriptor of a single local population" present in Venezuela (nominotypical form), Colombia (*nicefori*), and Ecuador (*soderstromi*).

NATURAL HISTORY: All specimens of *Ichthyomys hydrobates* for which the ecological circumstances of capture have been recorded were trapped or caught by hand along the banks of streams or irrigation canals; although most were taken in agricultural landscapes, the original vegetation throughout the range of this species was probably cloud forest. *Ichthyomys hydrobates* has been collected sympatrically with other ichthyomyines, including *Neusticomys monticolus* (at Guarumal, Provincia Pichincha, Ecuador) and *N. mussoi* (at Paso Hondo, Estado Táchira, Venezuela). Unfortunately, no dietary data are available from this species.

REMARKS: As currently recognized, *Ichthyomys hydrobates* is very widely distributed across dissected mountainous terrain and includes diagnosably different local populations. Whether the three nominal taxa currently synonymized under this binomen are really conspecific remains to be convincingly demonstrated.

Map 141 Selected localities for *Ichthyomys hydrobates* (●) and *Ichthyomys pittieri* (○). Contour line = 2,000 m.

Ichthyomys pittieri Handley and Mondolfi, 1963

Pittier's *Ichthyomys*

SYNONYM:

Ichthyomys pittieri Handley and Mondolfi, 1963:417; type locality “near the head of the Río Limón, Parque Nacional de Rancho Grande, Estado Aragua, Venezuela.”

DESCRIPTION: See keys (above), Mondolfi and Handley (1963), Voss (1988:334–336), and F. J. García, Machado et al. (2012).

DISTRIBUTION: *Ichthyomys pittieri* is known from a few scattered localities in the coastal cordilleras and adjacent hills of northern Venezuela, at elevations ranging from 700 to 1,750 m (F. J. García, Machado et al. 2012).

SELECTED LOCALITIES (Map 141): VENEZUELA: Aragua, Rancho Grande (type locality of *Ichthyomys pittieri* Handley and Mondolfi); Vargas, Naiguatá (MBUCV I-2803). Yaracuy, Finca El Jaguar, 21 km NW of Aroa (MHNS 8114).

SUBSPECIES: *Ichthyomys pittieri* is monotypic.

NATURAL HISTORY: All known specimens of *Ichthyomys pittieri* have been trapped or captured by hand in small streams or drainage canals bordered by lower montane forest. Captive animals consumed a wide range of small aquatic animals but evinced a marked preference for pseudoscorpion crabs, which were killed and eaten in a stereotypical manner (Voss et al. 1982). The stomach contents of one specimen contained aquatic insects (Trichoptera and Ephemeroptera; F. J. García, Machado et al. 2012). An old adult female trapped at Finca El Jaguar, Estado Yaracuy, Venezuela, contained four embryos (field notes of H. G. Castellanos, 26 July 1987).

REMARKS: Schmid et al. (1988) karyotyped a female specimen of *Ichthyomys pittieri* and reported a diploid number ($2n$) of 92 chromosomes and a fundamental number (FN) of 98 autosomal arms, apparently identical to the karyotype that A. L. Gardner (1971) reported for *Chibchanomys orcesi*.

Ichthyomys stolzmanni Thomas, 1893

Stolzmann's *Ichthyomys*

SYNONYMS:

Ichthyomys stolzmanni Thomas, 1893a:339; type locality “Chanchamayo,” Junín, Peru.

Ichthyomys orientalis Anthony, 1923b:7; type locality “near Rio Napo,” Napo, Ecuador.

Ichthyomys stolzmanni orientalis: Cabrera, 1961:510; name combination.

Ichthyomys stolzmanni stolzmanni: Cabrera, 1961:510; name combination.

DESCRIPTION: See keys (above), Thomas (1893a), Anthony (1923b), Voss (1988:336–337), and Pacheco and Ugarte-Núñez (2011).

DISTRIBUTION: *Ichthyomys stolzmanni* is known only from one locality in the eastern Andean piedmont of Ecuador and from four localities in Peru, ranging in elevation from 2,800 to 3,400 m.

SELECTED LOCALITIES (Map 142): ECUADOR: Napo, Río Napo [probably near Tena] (AMNH 62382). PERU: Ayacucho, Arizona (Pacheco and Ugarte-Núñez 2011), El Bagrecito (Pacheco and Ugarte-Núñez 2011), Vischongo, Río Ponacochas (Pacheco and Ugarte-Núñez 2011); Junín, Chanchamayo (type locality of *Ichthyomys stolzmanni* Thomas).

SUBSPECIES: Although Voss (1988) recognized *I. s. orientalis* (in Ecuador) and *I. s. stolzmanni* (in Peru) as valid subspecies, Pacheco and Ugarte-Núñez (2011) found that these nominal taxa could not be distinguished by any phenotypic criterion and concluded that *I. stolzmanni* is monotypic.

NATURAL HISTORY: According to Pacheco and Ugarte-Núñez (2011), *Ichthyomys stolzmanni* is common along Andean streams in the Puna biome of south-central Peru, where this species is locally known as *mayo sonso*, a derogatory term that applies to a riverine animal that causes damage (*I. stolzmanni* is apparently a major predator of non-native trout in local fish farms). Standard trapping methods are ineffective for this species, most individuals having been captured by hand or in fishing nets.

Map 142 Selected localities for *Ichthyomys stolzmanni* (●) and *Ichthyomys tweedii* (○). Contour line = 2,000 m.

Ichthyomys tweedii Anthony, 1921

Tweedy's *Ichthyomys*

SYNONYMS:

Ichthyomys tweedii Anthony, 1921b:1; type locality "Portovelo, Prov. del Oro, Ecuador; altitude, 2000 ft."

Ichthyomys caurinus Thomas, 1924d:541; type locality "below Gualea," Pichincha, Ecuador.

Ichthyomys hydrobates caurinus: Cabrera, 1961:509; name combination.

Ichthyomys hydrobates tweedii: Cabrera, 1961:510; name combination.

DESCRIPTION: See keys (above), Anthony (1921b), Thomas (1924d), and Voss (1988:337–338).

DISTRIBUTION: *Ichthyomys tweedii* is known from the lowlands and Andean foothills (near sea level to about 1,350 m) of western Ecuador and central Panama. It presumably also occurs in geographically intermediate regions, such as the Pacific lowlands of western Colombia.

SELECTED LOCALITIES (Map 142): ECUADOR: El Oro, Portovelo (type locality of *Ichthyomys tweedii* Anthony); Imbabura, Paramba (BM 99.11.3.4); Pichincha, Mindo (UMMZ 126300).

SUBSPECIES: I treat *Ichthyomys tweedii* as monotypic.

NATURAL HISTORY: The only natural history information about South American populations of *Ichthyomys tweedii* comes from eight specimens that were trapped between 1,290 and 1,330 m near Mindo, Provincia Pichincha, Ecuador. All were taken along small streams bordered by dense secondary vegetation. Stomachs dissected from these specimens contained the remains of fish (Characidae), crabs (Pseudothelphusidae), roaches (Blattidae), dobsonfly larvae (Corydalidae), and other aquatic insects. A female specimen collected in the late wet season (May) at this locality contained two newly implanted embryos in utero.

Genus *Neusticomys* Anthony, 1921

As currently constituted (by Voss 1988), *Neusticomys* includes *Daptomys* Anthony, 1929, as a synonym and contains the most plesiomorphic (least aquatically adapted) ichthyomyine species. Based on published records, the genus is known to occur in montane habitats in Colombia and Ecuador, and from lower montane and lowland habitats in Venezuela, Brazil, the Guianas, and Peru.

Species of *Neusticomys* are small to medium-sized (30–75 g) ichthyomyines with dull gray-black or glossy-brownish dorsal body pelage; the ventral pelage is colored more or less like the dorsum, slightly paler in some specimens but never abruptly white or silvery. Supraorbital vibrissae are absent, but a philtrum is always pres-

ent, and the small pinnae are distinctly visible above the fur. The manus has five separate plantar pads including the thenar, hypothenar, and three interdigitals. The hindfoot is always small (its length consistently less than one-fourth of the head and body length) and narrow, with inconspicuous interdigital webs and weakly developed fringing hairs; the plantar surface is unpigmented or weakly pigmented (pink in fresh specimens, brownish on dried skins), and the claw of digit V extends just to or slightly beyond the first interphalangeal joint of digit IV. The tail is less than or equal to the combined length of the head and body, and is invariably unicolored (dark above and below).

The nasals are long, concealing the nasal orifice from dorsal view. The rostrum is moderately to very broad, with nasolacrimal capsules that are partially or completely concealed from dorsal view. The interorbital region is broad in proportion to the uninflated braincase, and the supraorbital foramina open laterally (within the orbits), not onto the dorsal surface of the frontals. The condyles are concealed from dorsal view (in *N. monticolus*) or are produced slightly behind the rest of the occiput (in other congeners). The dorsal cranial profile is almost flat, without a conspicuous bulge over the braincase. The posterior edge of the inferior zygomatic root is anterior to M1 in some species and above the anterocone of that tooth in others; the tip of the masseteric tubercle is above or below the plane of the molar alveoli. The incisive foramina are subparallel or have weakly convex lateral margins. The carotid arterial supply conforms to pattern 1 (of Voss 1988), the osteological traces of which include a large stapedia foramen (for the stapedia artery) and a prominent squamosal-alisphenoid groove and sphenofrontal foramen (which transmit the supraorbital stapedia ramus). The third mandibular molar (m3), when present, lacks a distinct posterior lobe corresponding to the entoconid-hypoconid cusp pair.

There are 13 to 14 ribs, 19 thoracolumbar vertebrae, and 4 sacral vertebrae. The stomach is nearly hemiglandular, with gastric glandular epithelium between the esophagus and the pyloric sphincter, and the gall bladder is present. The penis has three bacular mounds (supported by a tridigitate bacular cartilage) and a single dorsal papilla. Other external, skeletal, and visceral characters conform to those of the tribe.

SYNONYMS:

Neusticomys Anthony, 1921b:2; type species *Neusticomys monticolus* Anthony, by original designation.

Daptomys Anthony, 1929:1; type species *Daptomys venezuelae* Anthony, by original designation.

REMARKS: Voss (1988:339) synonymized *Daptomys* with *Neusticomys* for reasons that now seem less compelling.

Although all the species here included in *Neusticomys* can be diagnosed from other ichthyomyines by a number of shared primitive attributes, there appears to be no evidence that they form a monophyletic group. Instead, *N. monticolus* shares at least one conspicuous apomorphy (dull gray-black adult pelage) with *Anotomys* and *Chibchanomys*, whereas all of the lowland forms (*ferreirai*, *mussoi*, *oyapocki*, *peruviensis*, and *venezuelae*) share other derived traits inter se (notably the dorsal exposure of the occipital condyles; Ochoa and Soriano 1991). Future analyses of ichthyomyine relationships as based on molecular sequence data and other characters not analyzed by Voss (1988) may justify the recognition of *Daptomys* as a valid taxon.

KEY TO THE SPECIES OF *NEUSTICOMYS*:

1. Adult dorsal fur dull gray-black (when fresh, foxing with age to brownish-gray in old museum specimens); rostrum narrow, with dorsally exposed nasolacrimal capsules; occipital condyles not projecting posteriorly beyond rest of occiput, not exposed dorsally *Neusticomys monticolus*
- 1'. Adult dorsal fur glossy brownish; rostrum broad, nasolacrimal capsules not dorsally exposed; occipital condyles projecting posteriorly behind rest of occiput, exposed dorsally. 2
2. Molars 2/2 or 3/2 (M3 may be absent, m3 always absent) 5
- 2'. Molars 3/3 (M3/m3 present) 3
3. Ears and feet covered with dark hairs; posterior edge of inferior zygomatic root of zygomatic plates above M1 anterocone *Neusticomys venezuelae*
- 3'. Inside of ears and dorsal surface of feet covered with pale (cream-colored) hairs; posterior edge of inferior zygomatic root anterior to M1. 4
4. Hindfoot about 30 mm, crown length of M1–M3 about 3.8 mm *Neusticomys peruviensis*
- 4'. Hindfoot about 21 mm, crown length of M1–M3 range from 3.3–3.4 mm *Neusticomys mussoi*
5. Upper third molar absent (molars 2/2) *Neusticomys oyapocki*
- 5'. Upper third molar present (molars 3/2) *Neusticomys ferreirai*

Neusticomys ferreirai Percequillo, Carmignotto, and de Silva, 2005

Ferreira's Ichthyomyine

SYNONYM:

Neusticomys ferreirai Percequillo, Carmignotto, and de Silva, 2005:874; type locality "near Juruena, 20 km W of the west bank of the Rio Juruena, Matto Grosso, Brazil."

DESCRIPTION: See keys (above) and Percequillo et al. (2005).

DISTRIBUTION: *Neusticomys ferreirai* is an Amazonian lowland species known from two localities between the Rio Madeira and the Rio Tapajós and another between the Rio Xingu and the Rio Tocantins (C. L. Miranda et al. 2012).

SELECTED LOCALITIES (Map 143): BRAZIL: Mato Grosso, Aripuanã (C. L. Miranda et al. 2012), Juruena (type locality of *Neusticomys ferreirai* Percequillo, Carmignotto, and de Silva); Pará, Floresta Nacional Tapirapé-Aquiri, Marabá (C. L. Miranda et al. 2012).

SUBSPECIES: *Neusticomys ferreirai* is monotypic.

NATURAL HISTORY: All of the five known specimens of *Neusticomys ferreirai* were taken in pitfall traps in primary lowland forest; none were taken in streams (Percequillo et al. 2005; C. L. Miranda et al. 2012). The female holotype was pregnant with five large embryos, the most yet reported from any ichthyomyine. The stomach of the paratype contained the remains of unidentified crustaceans.

REMARKS: *Neusticomys ferreirai* is phenotypically similar to *Neusticomys oyapocki* (see Percequillo et al. 2005:Table 2), notably in lacking m3, and it seems plausible that these species are allopatric sister taxa separated by the lower Amazon. The karyotype of *N. ferreirai* ($2n=92$, FN=98; Percequillo et al. 2005) closely resembles those of other ichthyomyines, as previously described in the literature (e.g., *Chibchanomys orcesi*, *Ichthyomys pittieri*).

Map 143 Selected localities for *Neusticomys ferreirai* (■), *Neusticomys oyapocki* (○), and *Neusticomys venezuelae* (●).

Neusticomys monticolus Anthony, 1921

Montane Ichthyomyine

SYNONYM:

Neusticomys monticolus Anthony, 1921b:2; type locality “Nono Farm, ‘San Francisco’ near Quito,” Pichincha, Ecuador.

DESCRIPTION: See keys (above), Anthony (1921b), and Voss (1988:343–344).

DISTRIBUTION: *Neusticomys monticolus* is known from elevations between about 1,800 and 3,800 m in Andean Ecuador and Colombia. In Ecuador, *N. monticolus* has been collected in both the eastern and western cordilleras from about 2°S northward to the equator. In Colombia, *N. monticolus* has been collected in the western Andes (Cordillera Occidental) to about 6°N, and in the Central Andes (Cordillera Central) to about 5°N (Gómez-Laverde 1994; Velandia-Perilla and Saavedra-Rodríguez 2013).

SELECTED LOCALITIES (Map 144): COLOMBIA: Antioquia, Santa Barbara (FMNH 71221); Huila, San Antonio (FMNH 71224); Risaralda, La Pastora (ICN 12118); Valle del Cauca, Pichindé (HTC 3365). ECUADOR: Bolívar, Sinche (AMNH 66848); Chimborazo, Pauchi (AMNH 62920); Napo, 8.2 km W of Papallacta (UMMZ 155605); Pichincha, Guarumal (UMMZ 126298); Tungurahua, San Antonio (AMNH 67548).

SUBSPECIES: *Neusticomys monticolus* is monotypic.

NATURAL HISTORY: Most specimens of *Neusticomys monticolus* have been trapped in small streams bordered

by páramo vegetation or cloud forest, but a few have been taken at moist sites that were not adjacent to running water. This species occurs sympatrically with other ichthyomyines, as documented in the preceding accounts for *Anotomys leander* and *Ichthyomys hydrobates*. Dissected stomachs from eight specimens trapped at Guarumal, Pichincha province, Ecuador, contained only aquatic insects, including larval water beetles (Helodidae), larval crane flies (Tipulidae), mayfly nymphs (Baetidae, Leptophlebiidae), stonefly nymphs (Perlidae), and larval caddisflies (Calamoceratidae, Hydropsychidae). A single female specimen collected in the early wet season (mid-May) near Papallacta, Provincia Napo, Ecuador, contained two large embryos.

REMARKS: The few available specimens from the western Andes (Cordillera Occidental) of Colombia exhibit morphological differences from Ecuadorean material and may represent a distinct species.

Neusticomys mussoi Ochoa and Soriano, 1991

Musso's Ichthyomyine

SYNONYM:

Neusticomys mussoi Ochoa and Soriano, 1991:97; type locality “Paso Hondo, Río Potosí, 14 km SE Pregonero, Táchira, Venezuela (7°57'N, 71°39'W), 1,050 m elevation.”

DESCRIPTION: See keys (above) and Ochoa and Soriano (1991). Percequillo et al. (2005) tabulated qualitative character comparisons between *N. mussoi* and other lowland congeners.

DISTRIBUTION: *Neusticomys mussoi* is known only from the type locality.

SELECTED LOCALITIES (Map 144): VENEZUELA: Táchira, Paso Hondo, Río Potosí (Ochoa and Soriano).

SUBSPECIES: *Neusticomys oyapocki* is monotypic.

NATURAL HISTORY: The two known specimens of *Neusticomys mussoi* were trapped in a stream bordered by semideciduous forest, where another ichthyomyine species, *Ichthyomys hydrobates*, was also collected.

REMARKS: Although Ochoa and Soriano (1991) focused their taxonomic comparisons on the problem of distinguishing *Neusticomys mussoi* from another Venezuelan congener, *N. venezuelae*, *N. mussoi* more closely resembles a third species, *N. peruviansis*, with which it appears to differ principally in size. Noteworthy similarities between *mussoi* and *peruviansis* include their pale (cream-colored) ears and feet, together with the anterior position of the inferior zygomatic root (see key). Future phylogenetic research should test the hypothesis that *mussoi* and *peruviansis* are sister taxa, sharing a common ancestor more recently than either does with other lowland congeners (*N. ferreirai*, *N. oyapocki*, and *N. venezuelae*).

Map 144 Selected localities for *Neusticomys monticolus* (●) and *Neusticomys mussoi* (○). Contour line = 2,000 m.

Neusticomys oyapocki (Dubost and Petter, 1979)

Guianan Ichthyomyine

SYNONYMS:

Daptomys oyapocki Dubost and Petter, 1979:436; type locality “Trois Sauts, French Guyana.”

Neusticomys oyapocki: Voss, 1988: 344; first use of current name combination.

DESCRIPTION: See keys (above), Dubost and Petter (1979), Voss et al. (2001:99–102), and R. N. Leite et al. (2007:Table 1). Qualitative character comparisons of *N. oyapocki* with other lowland congeners were tabulated by Percequillo et al. (2005).

DISTRIBUTION: *Neusticomys oyapocki* is currently known from just eight lowland localities (<500m elevation) in Surinam, French Guiana and the neighboring Brazilian states of Amapá and Pará (R. N. Leite et al. 2007; Lim and Joemratie 2011; C. L. Miranda et al. 2012).

SELECTED LOCALITIES (Map 143): BRAZIL: Amapá, Fazenda Itapoã (MPEG 24252); Pará, Castanhal, Monte Dourado, Rio Jari (R. N. Leite et al. 2007), Floresta Estadual de Trombetas (C. L. Miranda et al. 2012). FRENCH GUIANA: Les Nouragues (C. L. Miranda et al. 2012), Paracou (AMNH 267597), St.-Eugène (MNHN 1995–3234), Trois Sauts (type locality of *Daptomys oyapocki* Dubost and Petter). SURINAM: Nickerie, Kutari River (Lim and Joemratie 2011).

SUBSPECIES: *Neusticomys oyapocki* is monotypic.

NATURAL HISTORY: Two French Guianan specimens of *Neusticomys oyapocki* were captured in pitfall traps that were about 5 m from small streams in primary rainforest (Voss et al. 2001), and another was captured by hand under a native house (Catzeflis, 2012). Pitfall traps were also used to collect Brazilian specimens in a managed forestry landscape (R. N. Leite et al. 2007), in rainforest (C. L. Miranda et al. 2012), and in *campo* (savanna) vegetation located at least 1 km from any forested watercourse (Nunes 2002). The single known Surinam specimen was live-trapped at a site with both upland forest and swamps (Lim and Joemratie 2011). The ecological circumstances of other collected specimens are not recorded in the literature, but the type was said to have been found “non loin des rives de l’Oyapock” (Dubost and Petter 1979:436), implying that it was not actually taken in a river or stream. Therefore, there is abundant evidence that this ichthyomyine species is not restricted to aquatic habitats.

Neusticomys peruvienis (Musser and Gardner, 1974)

Peruvian Ichthyomyine

SYNONYMS:

Daptomys peruvienis Musser and Gardner, 1974: 7; type locality “Balta (10°08’S, 17 [sic, 71]°13’W), at the point where the streams known to the local Cashinahua Indi-

ans as the Inuya and the Xumuya enter the Río Curanja, elevation 300 meters, Departamento Loreto (now Región de Ucayali), Perú.”

Neusticomys peruvienis: Voss, 1988:344; first use of current name combination.

DESCRIPTION: See keys (above) and Musser and Gardner (1974). Percequillo et al. (2005) tabulated qualitative character comparisons of *N. peruvienis* with other lowland congeners.

DISTRIBUTION: *Neusticomys peruvienis* is currently known from just two localities in the Amazonian lowlands of southeastern Peru.

SELECTED LOCALITIES (Map 145): PERU: Madre de Dios, Pakitza (Pacheco and Vivar 1996); Ucayali, Balta (type locality of *Daptomys peruvienis* Musser and Gardner).

SUBSPECIES: *Neusticomys peruvienis* is monotypic.

NATURAL HISTORY: The specimen from Balta was trapped in a small stream (Musser and Gardner 1974), but the specimen from Pakitza was trapped at least 200 m from water (Pacheco and Vivar 1996). The surrounding habitat of both captures was primary evergreen lowland forest.

REMARKS: Pacheco and Vivar (1996) drew attention to several character differences between their young adult specimen and the fully adult holotype that could reflect either ontogenetic or taxonomic variation. Additional specimens are needed to evaluate the possibility that more than one species of *Neusticomys* occurs in eastern Peru.

Map 145 Selected localities for *Neusticomys peruvienis* (●). Contour line=2,000m.

Neusticomys venezuelae (Anthony, 1929)

Venezuelan Ichthyomyine

SYNONYMS:

Daptomys venezuelae Anthony, 1929:1; type locality “Neverí [= Neverí], about 15 miles west of Cumanacoa,” Sucre, Venezuela.

Neusticomys venezuelae: Voss, 1988:344; first use of current name combination.

DESCRIPTION: See keys (above), Anthony (1929), Musser and Gardner (1974), and Voss et al. (2001:Table 25). Qualitative character comparisons of *N. venezuelae* with other lowland congeners tabulated by Percequillo et al. (2005).

DISTRIBUTION: *Neusticomys venezuelae* is currently known from only five localities, ranging in elevation from near sea level to 1,400 m, in Venezuela and Guyana.

SELECTED LOCALITIES (Map 143): GUYANA: Cuyuni-Mazaruni, Kartabo (AMNH 142818). VENEZUELA: Amazonas, Cerro Duida (USNM 406123); Bolívar, Serranía de los Pijiguaos (EBRG 11939), San Ignacio Yuruaní (AMNH 257344); Sucre, Neverí (type locality of *Daptomys venezuelae* Anthony).

SUBSPECIES: *Neusticomys venezuelae* is monotypic.

NATURAL HISTORY: All of the specimens for which habitat information has been published were trapped along small streams bordered by evergreen lowland rainforest, semideciduous forest, or montane vegetation (Anthony 1929; Musser and Gardner 1974; Handley 1976; Ochoa and Soriano 1991). Unpublished field notes (by R. S. Voss, archived in the AMNH Department of Mammalogy) additionally record that three specimens collected in 1987 near San Ignacio Yuruaní, Bolívar state, Venezuela, were trapped among wet rocks behind a waterfall; the surrounding vegetation at this locality was primary lowland rainforest. Two stomachs dissected from specimens trapped at Neverí, Sucre state, Venezuela, contained crustacean gill lamellae and unidentified insect fragments (R. S. Voss, unpublished notes). Two additional stomachs from specimens trapped at Serranía de los Pijiguaos, Bolívar state, Venezuela, contained prey fragments that Ochoa and Soriano (1991) identified as insects (Coleoptera, Orthoptera, Dictyoptera), pseudoscorpionid crabs, and leptodactylid frogs.

Tribe Oryzomyini Vorontsov, 1959

Marcelo Weksler

The oryzomyines form the most taxonomically diverse tribe of sigmodontine rodents, with 130 recognized extant species in 34 genera. Members of the tribe are distributed in the Neotropical and Nearctic (southeastern section) regions from Tierra del Fuego to the southern and eastern United

States, in the Galapagos Archipelago, and on Trinidad and Tobago. Oryzomyines are found in almost all major biomes in South America, including forests, savannas, swamps, scrublands, and semiarid environments, and at elevations ranging from sea level to above 4,000 m in the high Andes above treeline. In many of these habitats, they are among the most speciose and abundant small mammals (Voss and Emmons 1996; Eisenberg 1999). J. R. Prado and Percequillo (2013) have provided a gazetteer of localities for each genus of oryzomyine rodents in South America, based on museum records, analyzed both the geographic and habitat distribution for clades of genera identified by Weksler (2006) and Percequillo, Weksler, and Costa (2011), and presented a hypothesis for areas of original differentiation of each genus. Two years earlier, Valencia-Pacheco et al. (2011) had examined latitudinal diversification patterns in the tribe, developed a source-sink ecological hypothesis for that pattern, and argued that the Amazon Basin was the center of tribal diversity. L. F. Machado et al. (2013) have examined the phylogeny and biogeography of tetralophodont members of the tribe.

Most oryzomyines are predominantly cursorial, but some species display marked arboreal (e.g., *Oecomys*) or semiaquatic (e.g., *Holochilus*, *Lundomys*, and *Nectomys*) specializations. Oryzomyines serve as primary or secondary host and reservoirs to a wide range of disease-carrying organisms, including hantaviruses, arenaviruses, digeneans (*Schistosoma*), and trypanosomes (Fulhorst et al. 1997; Bharadwaj et al. 1997; Powers et al. 1999; Calderon et al. 1999; V. L. Rodrigues and Ferraz Filho 1984; Mello 1979; Picot 1992; A. C. Ribeiro et al. 1998; D’Andrea et al. 2000).

Oryzomyines are known in the fossil record of South America from Early to Middle Pleistocene deposits in Bolivia and Argentina (Steppan 1996; Pardiñas et al. 2002; Pardiñas 2008). In North America, oryzomyines are found in Middle to Late Pleistocene deposits of Florida, Georgia, Kansas, and Texas (reviewed by Weksler 2006). Oryzomyines are also found in Pleistocene and Recent deposits on all major Caribbean islands, in the Caribbean Netherlands, and Fernando de Noronha Island (Brazil). Each of these insular taxa are now extinct, some becoming so in historic times (G. M. Allen 1942; McFarlane and Debrot 2001; Carleton and Olson 1999; Turvey et al. 2010, 2012). Eight extinct genera are currently recognized: *Agathaeromys* Zijlstra, Madern, and van den Hoek Ostende; *Carletonomys* Pardiñas; *Dushimys* Zijlstra; *Megalomys* E.-L. Trouessart; *Noronhomys* Carleton and Olson; *Pardinamys* P. E. Ortiz, Jayat, and Steppan; *Pennatomys* Turevey, Weksler, Morris, and Nokkert; and *Reigomys* Machado, Leite, Christoff, and Giugliano.

The tribe can be diagnosed by seven putative synapomorphies (Voss and Carleton 1993; Steppan 1995; Weksler

2006; Weksler and Percequillo 2011): presence of a long palate with prominent posterolateral pits; absence of an alisphenoid strut; absence of a posterior suspensory process of the squamosal attached to tegmen tympani; absence of a gall bladder; 12 thoracic vertebrae; absence of a hemal arch on the first caudal vertebra; and fewer than 36 caudal vertebrae. The last two synapomorphies are reversed in several oryzomyine taxa. Members of the tribe can also be recognized by the soft fur (except in *Neacomys* and *Scolomys*, which have spiny fur); small, unkeeled manual claws (except in *Lundomys*, with long, ventrally keeled manual claws); a mammary complement of eight teats in inguinal, abdominal, postaxial, and pectoral pairs (except in *Handleyomys*, *Scolomys*, and *Oligoryzomys griseolus*, which have six mammae, lacking the pectoral pair); a sparsely haired tail covered with more or less conspicuous epidermal scales and lacking a terminal tuft of long hairs (the well-haired tail of *Nesoryzomys* does not appear scaly, and species of *Oecomys* and *Tanyuromys* may have weakly to prominently tufted tails); zygomatic plates without an anterodorsal spinous process (except in *Pseudoryzomys*, *Lundomys*, and *Holochilus*, which have a spinous process); nasal bones with rounded or squared posterior margins (except in *Nectomys*, *Scolomys*, and *Sigmodontomys*, which have acutely angled posterior nasal margins); a smooth posterior wall of the orbit (except in *Holochilus*, which has a well-developed postorbital ridge); a bony palate between the molar rows smooth or weakly sculpted (except in *Holochilus* and *Lundomys*, which have a well-developed median keel flanked by deep lateral gutters); an alisphenoid canal with a large anterior opening (the anterior opening of the alisphenoid canal is absent or very small in *Scolomys*); upper incisors with smoothly rounded enamel bands (the upper incisor enamel is distinctly faceted in *Holochilus*); low-crowned and bunodont or terraced molars (except in *Holochilus*, which has high-crowned, planar molars); labial flexi enclosed by a cingulum (the labial flexi are not enclosed in *Holochilus* and *Lundomys*); parallel maxillary toothrows (*Holochilus* and *Lundomys* have anteriorly convergent toothrows); a median mure connected to the protocone on M1 (except in *Holochilus*, which has the median mure connected to the paracone); a unilocular-hemiglandular stomach; and a male accessory reproductive gland complement that includes one pair each of bulbourethral, dorsal prostate, anterior prostate, vesicular, and ampullary glands, and two pairs of ventral prostate glands (except *Nesoryzomys*).

KEY TO THE GENERA OF ORYZOMYINI (MODIFIED FROM WEKSLER AND PERCEQUILLO 2011):

1. Dorsal and ventral fur with grooved spines 2
1'. Dorsal and ventral fur without grooved spines 3

2. Six mammae in inguinal, abdominal, and postaxial pairs *Scolomys*
2'. Eight mammae in inguinal, abdominal, postaxial, and pectoral pairs *Neacomys*
3. Hypothenar pad absent or vestigial 4
3'. Hindfeet with developed hypothenar pad 11
4. Hindfeet without natatory fringes (including continuous combs of stiff hairs along the plantar margins and/or webbing sometimes between the digits) 5
4'. Hindfeet with natatory fringes 8
5. Dorsal surface of hindfeet covered with dark hairs, feet appear brown 6
5'. Dorsal surface of hindfeet sparsely covered with short silvery hairs, feet appear grayish white or pale tan . . . 7
6. Hindfeet with interdigital webs *Sigmodontomys*
6'. Hindfeet without interdigital webs *Tanyuromys*
7. Interorbital region weakly beaded even in adults, mesoloph small on M1, M2, absent in M3 . . . *Pseudoryzomys*
7'. Interorbital region with strongly developed supraorbital crest in adults, mesoloph present and well developed on M1–M3 *Oryzomys*
8. Nasals with acutely pointed posterior terminus; molars brachydont, cingula closing labial folds 9
8'. Nasals with blunt posterior terminus; molars hypsodont or planar, labial folds open 10
9. Body pelage with strong countershading; upper incisors orthodont *Amphinctomys*
9'. Body pelage with weak countershading; upper incisors opisthodont *Nectomys*
10. Alisphenoid strut present; postorbital ridge present; accessory labial root on M1 present *Holochilus*
10'. Alisphenoid strut absent; postorbital ridge absent; accessory labial root on M1 absent *Lundomys*
11. Plantar pads on hindfeet highly developed, large and fleshy, interdigitals 1–4 set close together, often in contact; mystacial vibrissae long and abundant 12
11'. Pads smaller, interdigitals 1–4 displaced proximally relative to 2–3; mystacial vibrissae shorter and sparser 13
12. Venter without gular patch of self-colored hairs; palate long; supraorbital margins squared, strongly beaded or with distinct crests *Oecomys*
12'. Venter with gular patch of self-colored hairs; dorsal surface of hindfeet with distinct dark patch; palate short; supraorbital margins lightly beaded *Drymoreomys*
13. Tail much shorter than head and body 14
13'. Tail subequal to or longer than head and body . . . 15
14. Dorsal pelage grizzled or light brown . . . *Zygodontomys*
14'. Dorsal pelage dark brown *Melanomys*
15. Sphenofrontal foramen absent 16
15'. Sphenofrontal foramen present 24

16. Small mice (head and body length of adults rarely >110 mm) 17
- 16'. Medium or large rats (head and body length of young rarely <110 mm) 19
17. Anteromedian flexus present 18
- 17'. Anteromedian flexus absent
 *chapmani* group [of "*Handleyomys*"]
18. Jugal absent or vestigial; alisphenoid strut absent; stapedial foramen present (pattern 2; Voss, 1988; except in *O. rupestris*); mesoloph and mesolophid usually present (absent in *O. rupestris* and *O. fornesi*) . . *Oligoryzomys*
- 18'. Jugal present; alisphenoid strut always present; stapedial foramen absent (pattern 3; Voss, 1988); mesoloph and mesolophid always absent . . . *Microakodontomys*
19. Stapedial foramen present *Hylaeamys*
- 19'. Stapedial foramen absent or vestigial 20
20. Tail densely furred, scales not visible . . . *Nesoryzomys*
- 20'. Tail sparsely furred, appearing impression of nakedness, scales visible 21
21. Mystacial vibrissae very long; interorbital region hourglass in shape with squared margins *Sooretamys*
- 21'. Mystacial vibrissae short; interorbital region anteriorly convergent with beaded margins 22
22. First upper and lower molars without accessory roots; capsular process absent or indistinct . . *Eremoryzomys*
- 22'. First molars with accessory roots; capsular process well developed 23
23. Anterocone of M1 undivided (anteromedian flexus absent); baculum bifid *Cerradomys*
- 23'. Anterocone of M1 divided by anteromedian flexus; baculum trifid *Aegialomys*
24. Very small mice (head and body length < 100) with tail much longer than head and body length 25
- 24'. Medium-sized and large rats (head and body length > 100) with tail as long as or longer than head and body length 26
25. Pelage distinctly countershaded; foramen magnum oriented caudally; anteroconid of m1 undivided (anteromedian flexid absent) *Oreoryzomys*
- 25'. Pelage not countershaded; foramen magnum oriented posteroventrally; anteroconid of m1 divided by anteromedian flexid *Microroryzomys*
26. Superciliary vibrissae extending posteriorly beyond pinnae 27
- 26'. Superciliary vibrissae not extending posteriorly beyond pinnae 28
27. Zygomatic notch indistinct; zygomatic plates small
 *Mindomys*
- 27'. Zygomatic notch deep; zygomatic plates broad
 *Transandinomys*
28. Anterocone of M1 divided by anteromedian flexus
 *Nephelomys*
- 28'. Anterocone of M1 undivided (anteromedian flexus absent) 29
29. M1 without labial accessory root; m2 with two roots
 *Euryoryzomys*
- 29'. M1 with labial accessory root; m2 with three roots . 30
30. Six mammae in inguinal, abdominal, and postaxial pairs *Handleyomys*
- 30'. Eight mammae in inguinal, abdominal, postaxial, and pectoral pairs *alfaroi* group [of "*Handleyomys*"]

REMARKS: The generic composition of the tribe, corroborated by phylogenetic analyses of morphological and molecular data (Voss and Carleton 1993; Steppan 1995; Weksler 2003; 2006; Turvey et al. 2010; Percequillo, Weksler, and Costa 2011; Pine et al. 2012), includes pentalophodont and tetralophodont sigmodontines, as first advanced by Voss (1991) and Voss and Carleton (1993). For historical shifts in the content of Oryzomyini, see Hershkovitz (1944, 1955b, 1962), A. L. Gardner and Patton (1976), Reig (1984, 1986), Carleton and Musser (1989), Voss (1991a), Voss and Carleton (1993), and Weksler (2006).

Systematic work on the tribe, at all levels, has been very active in recent years, and work in progress indicates that the current taxonomy is not yet stable. The generic organization of the accounts follows Weksler et al. (2006), with the addition of taxa described thereafter (Percequillo, Weksler, and Costa 2011; Pine et al. 2012). The position of the following taxa is provisional: *Microakodontomys* is considered here as a valid genus based on its distinctive morphology (Weksler and Percequillo 2011) and preliminary molecular data (R. Paresque, pers. comm.; J. D. Hanson, pers. comm.), but validation awaits a published analysis. The ex-"*Oryzomys alfaroi*" group was previously included in *Handleyomys* (Weksler et al. 2006), but at least one new genus should be erected to contain the *alfaroi-chapmani-melanotis* clade (Weksler 2006; Weksler et al. 2006; Weksler and Percequillo 2011). Members of this group that reside in South America are treated herein as "*Handleyomys*."

Genus *Aegialomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

The genus *Aegialomys* is a trans-Andean endemic lineage of Oryzomyini, occurring from northern Peru to northern Ecuador as well as two islands in the Galapagos Archipelago. Two species are recognized herein, but five nominal taxa have been associated with *Aegialomys*: *bauri* J. A. Allen and *galapagoensis* Waterhouse for the insular populations, with the latter name currently assigned to all

Galapagos specimens; and *baroni* J. A. Allen, *ica* Osgood, and *xanthaeolus* Thomas, with the last name provisionally applied to all mainland populations of the genus. Patton and Hafner (1983) suggested a close phylogenetic linkage between *A. galapagoensis* and *A. xanthaeolus*, based on both morphological and molecular (protein gel electrophoresis) comparisons, a hypothesis that was supported by shared karyotypes (A. L. Gardner and Patton 1976).

The genus has never been revised and is possibly more diverse than currently understood (see Musser and Carleton 2005; Weksler et al. 2006). The most important studies dealing with this genus, aside from the original descriptions, are those of Patton and Hafner (1983) and Weksler et al. (2006). The majority of this account is based on those works, supplemented by my personal examination of voucher specimens in several North American museums. The recent distributional and ecological studies of Dowler and colleagues (Dowler and Carroll 1996; Dowler et al. 2000) have added substantially to our knowledge of the Galapagos taxa.

The genus is quite distinct from other oryzomyine genera, as apparent from the following description (largely based on Weksler et al. 2006). The dorsal pelage is very long, lax, and dense, coarsely grizzled yellowish or grayish brown; the ventral pelage is abruptly paler (superficially whitish or pale yellow), but the ventral hairs are always gray-based. Pinnae are small, do not reach the eye when laid forward, and are densely covered by short hairs. Mystacial and superciliary vibrissae do not extend posteriorly beyond the pinnae when laid back. The hindfeet are short and wide, with conspicuous tufts of unguis hairs at the base of claws of all digits; the plantar surfaces are densely covered with distinct squamae distal to the thenar pad; the hypothenar pad is large; the claw of digit I extends beyond the middle of phalanx 1 (almost to the first interphalangeal joint) of digit II, and the claw of digit V extends just beyond the first interphalangeal joint of digit IV. The tail is shorter than or about as long as the head and body in *A. galapagoensis* (head and body length 130–170 mm [mean 149.0 mm], tail length 131–165 mm [mean 149.1 mm]), and manifestly longer than the head and body in *A. xanthaeolus* (head and body length 107–183 mm [mean 142.4 mm], tail length 107–200 mm [mean 154.6 mm]). The tail is weakly to distinctly bicolored.

The skull is medium sized (greatest skull length range for the genus: 29.2–38.9 mm [mean 33.9 mm]); the rostrum is stout, and flanked by deep zygomatic notches. The interorbital region converges anteriorly, with strongly beaded supraorbital margins or developed supraorbital crests. The braincase is oblong, usually with well-developed temporal crests continuous with supraorbital crests; the lambdoidal and nuchal crests are well developed in older adults.

The posterior margin of the zygomatic plates is dorsal to the alveoli of M1s in some specimens, anterior to the M1 alveoli in others, regardless of the species. Jugals are small, and thus the maxillary and squamosal zygomatic processes broadly overlap (in lateral view) but do not contact each other. The nasals are long and tapered, extending posteriorly behind the lacrimals in *A. galapagoensis*, while extending to but usually not behind the lacrimals in *A. xanthaeolus* (shorter nasals). The lacrimals usually have longer maxillary sutures than frontal sutures. The fronto-squamosal suture is usually colinear with the frontoparietal suture. The parietals have broad lateral expansions. In ventral view, the skull also shows distinctive features, with long incisive foramina typically extending posteriorly to or between the M1 alveoli, almost parallel sided (in *A. galapagoensis*) or widest at midlength and tapering symmetrically anteriorly and posteriorly (in *A. xanthaeolus*). The palate is wide and is short to long in length: the mesopterygoid fossa penetrates anteriorly between the maxillae in *A. galapagoensis* but only occasionally in *A. xanthaeolus*; the bony roof of the mesopterygoid fossa is perforated by very large sphenopalatine vacuities; the posterolateral palatal pits are large, complex, and recessed in deep fossae. The alisphenoid strut is absent, thus the buccinator-masticatory foramen and accessory foramen ovale are confluent. The stapedial foramen and posterior opening of the alisphenoid canal are small, the squamosal-alisphenoid groove and sphenofrontal foramen are absent, and the secondary anastomosis of the internal carotid crosses the dorsal surface of the pterygoid plate, configuring the carotid circulatory pattern 3 of Voss (1988). The postglenoid foramen is large and rounded, and the subsquamosal fenestra is small but distinct in most forms (vestigial or absent in an unnamed species from coastal Ecuador; Weksler et al. 2006). The periotic is exposed posteromedially between the ectotympanic and basioccipital, but usually does not extend anteriorly to the carotid canal. The mastoid is unfenestrated or has a small but distinct posterodorsal fenestra (in specimens from coastal Ecuador). The mandible is not strongly built and has shallow superior and inferior notches; the coronoid process is falciform to weakly falciform, and is lower than the condyloid process; the capsular process is well developed in most fully adult specimens; the superior and inferior masseteric ridges are conjoined anteriorly as a single crest below m1.

Upper incisors are opisthodont, fronted with a distinctly orange enamel band. The molar series are parallel; labial and lingual cones are arranged in opposite pairs; and labial and lingual flexi of M1 and M2 do not interpenetrate along the molar midline. The anterocone of M1 is divided into anterolabial and anterolingual conules by a distinct anteromedian flexus in all examined specimens of *A. gala-*

gagoensis and in some young specimens of *A. xantheolus* (most adults of this species have a small internal fossette that seems to represent a vestigial anteromedian flexus; samples from coastal Ecuador also have an anteromedian flexus); the anteroloph is well developed and fused with the anterostyle on the labial cingulum and is separated from the anterocone by a persistent anteroflexus in *A. xantheolus* or fused to the anterocone (anteroflexus reduced or absent) in *A. galapagoensis*; the protostyle is absent; and the paracone is usually connected by an enamel ridge to the posterior moiety of the protocone. M2 has a distinct protoflexus; the mesoloph is present in most individuals of *A. xantheolus*, but is more frequently reduced in *A. galapagoensis*, being narrow and short; the mesostyle is reduced or absent in some specimens; the protocone is connected only to the paracone (not to a median mure), producing a long and single mesoflexus (with wear the mesoflexus is present as a single internal fossette). M3 has a posteroloph and diminutive hypoflexus (the latter tending to disappear with moderate to heavy wear). The accessory labial root of M1 is often present.

The anteroconid of m1 is usually without an anteromedian flexid; the anterolabial cingulum is present on all lower molars; the anterolophid is present on m1 but is absent on m2 and m3; the ectolophid is absent on m1 and m2 but is not observable on m3 due to the diminutive size of this tooth. On m2, the mesolophid shows great individual and taxonomic variation: in *A. galapagoensis*, it is more frequently reduced and sometimes partially fused to the entoconid; in *A. xantheolus*, it is usually distinct on an unworn m1 but more frequently is reduced on m2; m2 has a small hypoflexid. The m3 is reduced and morphologically similar to m2. Both accessory lingual and labial roots of m1 are present; m2 and m3 each have two small anterior roots and one large posterior root.

The fifth lumbar (17th thoracolumbar) vertebra has a well-developed anapophysis. The hemal arches of the second and third caudal vertebrae have a posterior spinous process. Patton and Hafner (1983) detailed structures of the stomach, glans penis and baculum, and male reproductive organs. The stomach is hemiglandular and unilocular, without an extension of glandular epithelium into the corpus. The glans penis is of the complex type (*sensu* Hooper and Musser 1964); nonspinous tissue on the crater rim does not conceal bacular mounds, the dorsal papilla is spineless, and the urethral processes is without subapical lobules. The baculum is a short and slender central bony digit capped by a small, trifid cartilaginous tip. Only one pair of preputial glands is present.

SYNONYMS:

[*Oryzomys (Oryzomys)*] *galapagoensis*: E.-L. Trouessart, 1904:419; name combination.

[*Oryzomys (Oryzomys)*] *bauri*: E.-L. Trouessart, 1904:419; name combination.

Oryzomys galapagoensis Gyldenstolpe, 1932a:23; incorrect subsequent spelling of *Mus galapagoensis* Waterhouse.

[*Aegialomys*] *galapagoensis*: Weksler, Percequillo, and Voss, 2006:5; first use of current name combination.

DESCRIPTION: Dorsal pelage very long, dense, and lax, light yellowish to buffy grizzled with brown; ventral pelage grayish. Tail equal in length or shorter than head and body; unicolored (in the holotype from Isla San Cristóbal) or bicolored (specimens, including holotype of *bauri* J. A. Allen, from Isla Santa Fe) and densely covered with short hairs. Hindfoot short, densely covered by short white

hairs, with thick and very long unguis tufts. Pinnae small and rounded densely covered by short hairs. Mystacial vibrissae dense and thick but very short, not reaching pinnae when laid back. Skull medium sized (skull length 32.4–35.9 mm); rostrum long and narrow; zygomatic notch narrow and moderately deep; nasals generally with distinct narrow anterior projection and extending posteriorly beyond lacrimals; incisive foramina long (length range 6.2–7.7 mm) with nearly parallel-sided lateral margins (slightly wider medially; width range 2.2–2.9 mm); posterior margins of foramina reaching level of anterocones of M1s.

Phallus elongate, with length/diameter ratio of 1.8. Male accessory reproductive glands consist of one pair of preputial, bulbourethral, ampullary, and vesicular glands and four pairs of prostates, similar to the situation in other oryzomyines (Patton and Hafner 1983).

DISTRIBUTION: This species is restricted to the Galapagos Archipelago of Ecuador, where it is known from only two islands (San Cristóbal and Santa Fe).

KNOWN LOCALITIES (Map 146): ECUADOR: Galapagos, Cerro Brujo, Bahía d' Esteban, Isla San Cristóbal (= Chatham Island; type locality of *Mus galapagoensis* Waterhouse), Isla Santa Fe (= Barrington Island), Barrington Cove (MVZ 145372).

SUBSPECIES: I treat *Aegialomys galapagoensis* as monotypic.

NATURAL HISTORY: There are few data available on the natural history of this species. The population from Isla San Cristóbal is probably now extinct (Osgood 1929; Heller 1904; Patton and Hafner 1983). As a consequence, except for the limited information about the specimen from that island that Charles Darwin secured in 1835, all available data are from the population on Isla Santa Fe. Darwin (in Waterhouse 1839:66) commented that the species was “abundant,” and exclusive to Chatham Island (= Isla San Cristóbal). He also stated that *A. galapagoensis* “frequents the bushes, which sparingly cover the rugged streams of basaltic lava, near the coast, where there is no fresh water, and where land is extremely sterile.” Darwin did not visit Isla Santa Fe during the visit of the HMS *Beagle* to the Galapagos. J. A. Allen (1892) mentioned that the species was common on Isla Santa Fe, where it was found “between the bushes near the shore, and also high up between grass and the lava rocks.” Based on data of other researchers, Patton and Hafner (1983) reported that total population size ranged from 1,000 to 2,000 individuals and that the species “breeds during the rainy season, from January through April.” Clark (1980), who studied the ecology of this species, positively correlated abundance with vegetation density, noting that food was a limiting resource. Clark (1980) also showed that males have larger home ranges than females and stated that reproduction takes place in March and May, with embryo pro-

duction limited by the quantity of rainfall. This species also shows considerable longevity, with maximum life spans of nearly two years as compared with continental Oryzomyini, which barely “survive for more than a year” (D. B. Harris and MacDonald 2007). Clifford and Hoogstraal (1980) reported on tick (*Ixodes*) parasitism.

REMARKS: It is unclear where on Chatham Island [= Isla San Cristóbal] C. Darwin collected the holotype of *galapagoensis*. Heller (1904) suggested that the specimen came from the eastern end of the island. However, itineraries of the HMS *Beagle* (FitzRoy 1839; Grant and Estes 2009) indicate that, although the island was circumnavigated from September 16–22, 1835, the only night Darwin spent on the island (and when he most likely would have obtained this animal) was that of September 21–22, near Cerro Brujo at the eastern end of Stephens Bay on the north-central coast, where the *Beagle* was anchored.

Conspecificity of the two putative taxa, *galapagoensis* Waterhouse (from Isla San Cristóbal) and *auri* J. A. Allen (from Isla Santa Fe) has been suggested at least since Osgood (1929; see also Gyldenstolpe 1932; Cabrera 1961). Patton and Hafner (1983) provided convincing support for this hypothesis, based on qualitative and quantitative analysis of the skull and soft anatomy. So far, the only observable difference between the specimen from Isla San Cristóbal and those from Isla Santa Fe involves countershading of the tail (unicolored in the former and bicolored on the latter); this trait shows considerable individual variation in several species of sigmodontines and this may also be the case in this species.

Map 146 Selected localities for *Aegialomys galapagoensis* (●). The species is believed extinct from the eastern-most island (Isla San Cristóbal [= Chatham Island]).

The karyotype of specimens from Isla Santa Fe is $2n = 56$ and $FN = 58$ (A. L. Gardner and Patton 1976); that for animals from Isla San Cristóbal is unknown.

Aegialomys xantheolus (Thomas, 1894)

[*Aegialomys*] *xantheolus*: Weksler, Percequillo, and Voss, 2006:5; first use of current name combination.

DESCRIPTION: Dorsal fur long, dense, and lax, but comparatively shorter than in *A. galapagoensis*. In some Ecuadorean samples, ventral pelage with gular and/or pectoral patch of self-colored white or cream hairs. Tail varies from bicolored (most Peruvian samples) to unicolored or weakly bicolored (several Ecuadorean samples), and longer than head and body length. Hindfoot medium in length (range: 27–38 mm), with sparse to dense (in some Peruvian specimens) ungual tufts, and short to equal to claw length (in few specimens tufts exceed claws). Skull highly variable in size (skull length 29.2–38.9 mm), but shape conserved across geographic samples. Anterior margins of nasals rounded (without distinct process observed in *A. galapagoensis*), with posterior margins not extending behind lacrimals; in-

cisive foramina long (length range: 5.3–8.6 mm), posterior margins usually reaching anterocones of M1s, anteroposterior margins rounded, and lateral margins markedly widest at midlength (width range: 1.7–3.3 mm), tapering symmetrically both anteriorly and posteriorly; palate devoid of bony excrescences; mesopterygoid fossa rarely penetrating anteriorly between maxillae; auditory bullae very inflated, and external auditory meatus wide; orbicular apophysis large and rounded.

DISTRIBUTION: *Aegialomys xantheolus* is restricted to the arid coastal and montane areas from southwestern Ecuador to southern Peru, at elevations from sea level to above 2,500 m (in the upper Río Marañón valley of northern Peru). Most of this range is covered by xerophytic vegetation, similar to other savanna-like landscapes in South America. On the coastal region of Peru and Ecuador, *A. xantheolus* occurs in the fog-shrouded "lomas," where vegetation is supported by mist from the Pacific Ocean in otherwise barren coastal desert (Hueck 1972; Ellenberg 1959).

SELECTED LOCALITIES (Map 147): ECUADOR: Guayas, Huerta Negra, 20 km ESE of Baláo, east of Tenguel (USNM 534361), Río Chongón, 1.5 km SE of Chongón (USNM 513544); Loja, Loja (USNM 461652); Los Ríos, Hacienda Santa Teresita (Abrás de Mantequilla), ca. 12 km NE of Vices (USNM 534364). PERU: Amazonas, 8 km WSW of Bagua (MVZ 135667); Ancash, 4 km by road NE of Chasquitambo, km 51 (UMMZ 155915); Arequipa, Chavina, on coast near Acari, Lomos River (USNM 277572); Cajamarca, Cajabamba, Malca (type locality of *Oryzomys baroni* J. A. Allen); Huánuco, Chinchao, Hacienda Buena Vista (USNM 304533); Ica, Hacienda San Jacinto (type locality of *Oryzomys xantheolus ica* Osgood); La Libertad, Pacasmayo (FMNH 19461), Trujillo (FMNH 19459); Lambayeque, 8 km S of Morrope (MVZ 135670); Lima, 10 km ENE of Pucusana (MVZ 137594), Cerro Azul, Río Cañete Valley, 100 m from ocean (UMMZ 161219), Lomas de Lachay, 22 km N and 11 km W of Cancay (MVZ 135665); Piura, Catacaos (USNM 304523); Tumbes, Tumbes (type locality of *Oryzomys xantheolus* Thomas).

SUBSPECIES: Cabrera (1961) listed *ica* Osgood as a valid subspecies, limiting its range to southwestern Peru, with the nominotypical form distributed from the central Peruvian coast from Lima department northward. However, pending a review of the actual patterns of geographic variation, I regard *A. xantheolus* as monotypic.

NATURAL HISTORY: Few data are available on the natural history of *A. xantheolus*. The species is subject to producing *ratadas*, or local population explosions, at several different localities in Peru, where population density may range above 250 individuals per hectare. These

numbers are among the largest observed for several species of sigmodontine rodents as well as marsupials in South America (Jaksic and Lima 2003). *Aegialomys xantheolus* is host to the flagellate protozoan *Trypanosoma rangeli* (C. M. Pinto et al. 2006).

REMARKS: This species exhibits notable variation in size throughout its range, variation that stimulated the recognition of supposed new species (*O. baroni* J. A. Allen) or subspecies (*xantheolus ica* Osgood). Several authors (e.g., Osgood 1914b; Cabrera 1961; Musser and Carleton 1993, 2005) have questioned the validity of these taxa at any level, specific or subspecific, although Weksler et al. (2006) suggested that *A. xantheolus* may be a composite. In particular, these latter authors noted that animals from the Ecuadorean coast are smaller in size and possess several distinctive features, such as the absence of a subsquamosal fenestra, a mastoid with a posterodorsal fenestra, and the presence of an anteromedian flexus on M1. Although these features appear diagnostic, further comparisons with larger series are needed to ascertain whether these Ecuadorean animals represent an undescribed lineage of *Aegialomys*. Thorough analyses can also determine whether other biological entities are hidden in what is now called *A. xantheolus*, and to which the specific epithets *baroni* and *ica* could be applied. Preferably, future research will include both karyotypic and molecular analyses in addition to morphological comparisons.

Map 147 Selected localities for *Aegialomys xantheolus* (●). Contour line = 2000 m.

Genus *Amphinectomys* Malygin, 1994

Marcelo Weksler and Michael Valqui

Amphinectomys is a monotypic genus found thus far in only two localities in the lowland Amazon forests of the Ucayali-Amazon-Yavarí interfluvial region of eastern Peru. Very little is known about its ecology, systematics, or conservation status, and more collecting effort targeted at this taxon is needed. The following description is based on a translation of Malygin et al. (1994) and the accompanying illustrations.

These semiaquatic rats are large (head and body length 187–190 mm) and heavy (mass 214–225 g), with the tail length similar to the combined head and body length (tail length 173–206 mm), long and robust hindfeet (hindfeet 53–54 mm), and short ears (ear length 24 mm). The body pelage is very soft, shiny, and glossy, with long dorsal hair (length 22 mm) and dense underfur. The dorsal color is dark brown to fulvous brown, sides are more ochraceous, and the venter is white-grayish, with hairs gray at their bases (except the chin and throat, where hairs are completely white). The limits of the lateral and ventral colors are sharply delineated, creating a conspicuous counter-shading effect. The mystacial vibrissae are dense and very long, extending beyond the pinnae when laid back. The pinnae are small, only slightly hair, appear superficially naked, and are dark brown. The manus and pes are covered dorsally with short, pale hairs. Digits II–IV of the hindfeet are much longer than I and V. Large webs of skin are present on the manus and pes between digits II, III, and IV, extending to the base of the claws. Natatory fringes are present along medial plantar margins of the metatarsus and digits I and II, and along lateral plantar margins of digits IV and V. The tail is dark, unicolored, and sparsely haired, with dark brown hairs forming a small brush, but not a well-developed pencil, at the tip. There are eight pairs of mammae, one each in inguinal, abdominal, postaxial, and pectoral positions.

The skull is robust, and deep zygomatic notches flank the rostrum. The nasals have squared or gently rounded posterior margins, extending posteriorly to approximately the same level as, or slightly beyond, the lacrimals, which usually have much longer maxillary than frontal sutures. The interorbital margins converge anteriorly and possess weakly developed, overhanging supraorbital crests. The frontosquamosal suture is colinear with the frontoparietal suture (the dorsal facet of the frontal is not in contact with the squamosal). The parietal has a broad lateral expansion, a large portion dipping below the temporal ridge. The interparietal is narrow and wedge shaped. The zygomatic arches are slightly convergent anteriorly and widest posteriorly; the jugal is robust and not constricted at its middle,

so the maxillary and squamosal processes of the zygoma are not in contact. The zygomatic plates lack an anterodorsal spinous process, and their posterior margins are level with the alveoli of the M1s. Incisive foramina are broad, short, and teardrop shaped, terminating well anterior to the alveolar line of the M1s. The palatal bridge is long, extending well behind the third molars and possessing conspicuous posterolateral palatal pits. The bony roof of the mesopterygoid fossa is perforated by reduced and narrow sphenopalatine vacuities. The postglenoid foramen is large and rounded, but the subsquamosal fenestra is absent or vestigial. The mandible is short and deep, with a large falciiform coronoid process slightly higher than the condyloid process. The capsular process is not pronounced, and the anterior masseteric ridge reaches the level of the procingulum of m1s. Upper incisors are orthodont.

SYNONYM:

Amphinectomys Malygin, 1994:198; type species *Amphinectomys savamis* Malygin, 1994, by original designation.

REMARKS: Based both on nucDNA IRBP sequences and discrete morphological characters, Weksler (2006) found *Amphinectomys* as sister to *Nectomys squamipes* and *Nectomys apicalis*, but analyses that include a comprehensive sampling of *Nectomys* are necessary for phylogenetic corroboration of *Amphinectomys* as a genus distinct from *Nectomys*.

Amphinectomys savamis Malygin, 1994

Ucayali Water Rat

SYNONYM:

Amphinectomys savamis Malygin, 1994:198; type locality “7km east Jenaro Herrera, right bank of Río Ucayali (04°55'S, 73°45'W) in the province Requena, Department of Loreto, Peru” [translation from the original in Russian].

DESCRIPTION: As for the genus.

DISTRIBUTION: *Amphinectomys savamis* is known from only two localities in the lowland Amazon rainforest of the Ucayali-Amazon-Yavarí interfluvial region of eastern Peru.

SELECTED LOCALITIES (Map 148): PERU: Loreto, 7km E of Jenaro Herrera, right bank Río Ucayali (type locality of *Amphinectomys savamis* Malygin); San Pedro, 80km NE of Jenaro Herrera (MV 970045).

SUBSPECIES: We treat *Amphinectomys savamis* as monotypic.

NATURAL HISTORY: The two collecting sites of *Amphinectomys* are part of the uninterrupted lowland tropical forest of the Ucayali-Amazon-Yavarí interfluvial region. The holotype was collected in 1991 (Malygin et al. 1994). The second known specimen was trapped in June 1997 in the Tahuayo valley, a right tributary of the Río Amazonas north-east of the Jenaro Herrera biological station (Valqui 2001).

The climate of the region is typical of rainforest close to the equator, with a mean temperature around 26.5°C, a mean rainfall for San Pedro around 2,500mm, and somewhat drier climate at Jenaro Herrera. Locals recognize a short “dry season,” in which the monthly rainfall is sometimes below 100mm; however, rain falls throughout the year. Both places are close to true *várzea* forests, although they are beyond the direct influence of seasonal flooding that, depending the relative water height, begins in November–December and ends in May–June. Deforestation is very localized and scattered, and the area still retains a very diverse mammal community (Valqui 2001). At both localities, *A. savamis* was trapped close to a small creek in primary forest. The San Pedro specimen was caught in the streambed of a small permanent creek (water 0.5–1m across, 0.5m deep), connected by a gentle slope to a 3–4m higher lying terrain. Although streams inside the forest are often covered by a dense canopy of evergreen trees, as in this case, poorly drained areas are dominated by palms (*Scheelea* sp., *Jessenia* sp.), and the canopy is not as dense. The morphological adaptations shown by *Amphinectomys* (extensive interdigital webbing, long dense hair) suggest a high specialization for amphibious life.

REMARKS: Malygin et al. (1994) posited that the closest relative of *Amphinectomys savamis* were the water rats of the genus *Nectomys*, which are similar in size and adaptations. Compared to *Nectomys*, the pelage is longer, darker,

Map 148 Selected localities for *Amphinectomys savamis* (●). Contour line=2,000m.

shinier, denser, and more colorful; the feet are whiter, and the webbing of the hindfeet extends farther up the digits; and the ear is longer. See, however, the earlier remarks regarding the need for additional molecular information to establish the phylogenetic identity of *Amphinectomys*. The coordinates given in Malygin's description also place the type locality about 8 km west of Jenaro Herrera, not east of the station. Malygin et al. (1994) reported the karyotype as $2n=50$, $FN=56$.

Genus *Cerradomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

Species of *Cerradomys* occur in the open vegetation belt that crosses South America from northeastern Brazil to southeastern Bolivia and northwestern Paraguay. The Caatinga, Cerrado, and Chaco biomes form this area, also known as the "dry diagonal" (see L. P. Costa 2003). This is the one of the few genera of Oryzomyini, along with *Aegialomys*, *Holochilus*, *Pseudoryzomys*, and a few others, that occupies these open and drier habitats. Nevertheless, the species of *Cerradomys* are predominantly associated with forested habitats that occur throughout this region, including gallery forests, moist semideciduous forest patches (*brejos*), and woodland savannas (*cerradão*). There are two exceptions to this pattern: in northeastern and south-central Brazil, three species penetrate the coastal Atlantic Forest, including the distinctive *restinga* vegetation on sandy coastal soils, with the extension of two of these possibly due to anthropogenic habitat alteration. In the central Brazilian Cerrado, one species inhabits the *cerradolcampo cerrado* ecotone, a more open habitat.

The present account is based primarily on Percequillo et al. (2008), supplemented by the studies of Bonvicino et al. (1999), Bonvicino and Moreira (2001), Langguth and Bonvicino (2002), Bonvicino (2003), and Tavares et al. (2011). Additional details on morphological variation, taxonomy, and molecular-based phylogenetic relationships can be found in these publications.

Species of *Cerradomys* are large (head and body length 119–185 mm) with the tail much longer than the head and body (tail length 129–210 mm). The hindfeet are robust but vary considerably in length (20–43 mm); ungual tufts are short and dense but do not conceal the claws. The dorsal fur is long and dense, ranging in color from buffy-yellow grizzled with dark brown to buffy-orange grizzled with black, and contrasting greatly with the paler ventral pelage. In some species, the coloration of the head contrasts with that of the body, being grayish to grizzled reddish versus orangish to brown. The ventral coloration

grades from whitish or weakly buffy grizzled to an almost pure white, buffy, or buffy-yellow. The length of hair on the tail varies from short to long among species; in some species, the tail is unicolored, but *C. langguthi* has a distinctly bicolored tail. Dense, brown hairs with buffy or orange tips cover both surfaces of the pinnae. The mystacial vibrissae are very dense and long, extending past the ears when laid back; the most dorsal vibrissae are dark brown with golden tips, and the most ventral are entirely white.

The skull of all species is robust, with the average total length from 29.4–40.4 mm. The rostrum is short and narrow, and flanked by deep and wide zygomatic notches; rostral fossae (the dorsal margins of the nasolacrimal foramina that are confluent with the zygomatic notches; see Percequillo et al. 2008) are moderately to deeply excavated. The zygomatic plates range from narrow (2.8 mm) to wide (4.4 mm), with their anterior margins straight or slightly concave; zygomatic spines are present in some species but are predominantly rounded. The interorbital region diverges strongly posteriorly; the supraorbital margins form a distinctly projecting shelf. The braincase is long, with a well-developed temporal crest. Incisive foramina are very long (6.1–8.3 mm), their lateral margins broadest at mid-length, and both ends acutely pointed. The palate is long and wide, typically with multiple posterolateral palatal pits located in very deep and wide depressions. The roof of the mesopterygoid fossa is perforated by small to very large sphenopalatine vacuities, except in *C. maribus* and *C. maracajuensis*. The anterior border of the mesopterygoid fossa reaches the level of the alveoli of the M3s in younger individuals, a condition that persists in some adults. The stapedial foramen is minute or absent, and both the squamoso-alisphenoid groove and sphenofrontal foramen are absent, configuring carotid circulatory pattern 3 of Voss (1988). The buccinator-masticatory and accessory oval foramina are confluent, thus the alisphenoid strut is absent, in all but one species (*C. scotti*). The postglenoid foramen is narrow and the subsquamosal fenestra a small aperture in most species, being obliterated in *C. scotti*. The suspensory process of the squamosal is absent, and the tegmen tympani is short and may or may not overlap the squamosal. Auditory bullae are small and globose, with a distinct stapedial process that may or may not overlap the squamosal.

The mandible has a low coronoid process that is nearly triangular and equal in height to the condyloid process. The angular process does not reach past the condyloid process posteriorly. Both superior and inferior notches are shallow, and a capsular projection of the lower incisor is present in adult specimens.

The upper incisors are opisthodont. The molars are pentalophodont or tetralophodont, and low crowned; the main cusps are arranged in opposite pairs, and the labial and lin-

gual flexi interpenetrate only slightly at the median molar plane. The paracone is connected medially to the protocone on both M1 and M2, not to the median mure, configuring a long and obliquely oriented parafossette. The posteroloph is long, fusing to the metacone only after extensive wear. One species (*C. scotti*) exhibits various degrees of reduction of both mesoloph and mesolophids, these structures being absent in some individuals. The M1 has four roots, one anterior, one posterior, and two accessory rootlets, and M2 and M3 each have two roots.

The phallus is very elongate. The distal cartilaginous baculum is extremely reduced and bidigitate due to the absence of a central digit; the cartilaginous baculum extends distal to the body of the glans penis. The bony baculum is extremely elongated, with its cartilaginous portion about one-eighth the length of its osseous portion. Urethral ventral flaps and dorsal papilla are absent. Small spines densely ornament the phallus's epidermis. The stomach is unilocular and hemiglandular.

The genus *Cerradomys* currently includes seven species: *C. goytaca*, *C. langguthi*, *C. maracajuensis*, *C. marinhus*, *C. scotti*, *C. subflavus*, and *C. vivoi*. However, based on recent morphological, karyological, and molecular evidence (Percequillo 1998, 2003; Bonvicino et al. 1999; Bonvicino and Moreira 2001), the genus is clearly more diverse, with several additional forms requiring formal description. Tavares et al. (2011) recognized two informal groups of these species based on shared external and cranial characters. One group, comprising *C. maracahuensis*, *C. marinhus*, and *C. scotti*, is characterized by a homogeneously olivaceous dorsal pelage that does not contrast sharply with the yellowish buff ventral color, a completely ossified bony roof of the mesopterygoid fossa, and a proportionally larger opening to the alisphenoid canal (larger than the outline of M3). The second group, including *C. goytaca*, *C. langguthi*, *C. subflavus*, and *C. vivoi*, has shorter dorsal and ventral fur, a sharper contrast between the dorsal and ventral colors, medium-sized to large sphenopalatine vacuities, and a smaller opening of the alisphenoid canal (equal to or less than the outline of M3). The limited molecular sequence data available (Percequillo et al. 2008), while not including all species, are at least consistent with these morphological groupings.

SYNONYMS:

Mus: Lund, 1840:279; part (description of *vulpinus*); not *Mus* Linnaeus.

Hesperomys: Wagner, 1842c:362; part (description of *subflavus*); not *Hesperomys* Waterhouse.

Calomys: Fitzinger, 1867b:86; part (listing of *vulpinus*); not *Calomys* Waterhouse.

Oryzomys: E.-L. Trouessart, 1897:526; part (listing of *vulpinus* as synonym of *vulpinoides* Schinz); not *Oryzomys* Baird.

Holochilus: C. O. da C. Vieira, 1953:134; part; not *Holochilus* Brandt.

Cerradomys Weksler, Percequillo, and Voss, 2006:8; type species *Hesperomys subflavus* Wagner, by original designation.

KEY TO THE SPECIES OF *CERRADOMYS*:

1. Roof of mesopterygoid fossa perforated by medium-sized to large sphenopalatine vacuities 2
- 1'. Roof of mesopterygoid fossa completely ossified, unperforated by vacuities or perforated by very small vacuities. 6
2. Head grayish and back orangish to reddish; tail moderately covered with hairs, uniformly colored or bicolored; hindfeet large and covered by sparse brown and brown/white hairs; alisphenoid strut absent; subsquamosal fenestra present; mesoloph and mesolophid well developed 3
- 2'. Head and back grayish; tail well-furred and sharply bicolored; hindfeet small, entirely and densely covered by short white hairs; alisphenoid strut present; subsquamosal fenestra absent in adults; mesoloph reduced; mesolophid reduced or absent *Cerradomys scotti*
3. Sphenopalatine vacuities long and wide, extending through pre- and basisphenoid, exposing the orbitosphenoid; $2n$ not 50, or if so then FN 60 or greater 4
- 3'. Sphenopalatine vacuities short and narrow, restricted to the presphenoid, barely exposing the orbitosphenoid; bony tube with distinct medial projection; very deep posterolateral palatal pits, recessed in deep palatal fossa; tail bicolored; $2n=50$, FN=56 *Cerradomys langguthi*
4. Sphenopalatine vacuities long but narrow; ratio of diastemal length to condylobasilar length <28.9%; M1 broad, width >1.5 mm; $2n=54$, FN=62 *Cerradomys subflavus*
- 4'. Sphenopalatine vacuities long but wide; ratio of diastemal length to condylobasilar length >30%; M1 narrow, width >1.45 mm; $2n=50$ or 54, FN=62–63 or 66 . . . 5
5. Tail with sparse hairs but large scales (14 per cm at midtail); lacrimals broad and posterolaterally expanded; supraorbital and lambdoidal crests pronounced; $2n=54$, FN=66 *Cerradomys goytaca*
- 5'. Tail more hirsute and with small scales (16–18 per cm at midtail); lacrimals diminutive and sometimes absent; supraorbital and lambdoidal crests slender and small; $2n=50$, FN=62–63 *Cerradomys vivoi*
6. Mesolophid reduced or absent and posterolophid absent; $2n=58$, FN=54 *Cerradomys marinhus*
- 6'. Mesolophid and posterolophid well developed; $2n=58$, FN=58 *Cerradomys maracajuensis*

Cerradomys goytaca Tavares, Pessôa, and Gonçalves, 2011

Goytacá Cerradomys

SYNONYM:

Cerradomys goytaca: Tavares, Pessôa, and Gonçalves, 2011:647: type locality “Parque Nacional Restinga de Jurubatiba, municipality of Carapebus, Rio de Janeiro, Brazil, 22°15'28"S, 41°39'49"W, 1 m altitude.”

DESCRIPTION: Small, with head and body length 116–166 mm, tail length 130–181 mm. Dorsal pelage short, overall color orange grizzled with brown; head color grayish, especially around eyes and on cheeks; venter whitish and covered by short and sparse hairs with pale gray to brownish gray bases. Tail markedly bicolored, with completely unpigmented hairs and scales on ventral surface along proximal portion, and uniformly dark above; scales large, with modal number 14 per cm near base. Ungual hair tufts over claws rarely exceed claw length. Skull large and robust; rostrum broad, lacrimals broad; zygomatic arches wide; supraorbital ridges that extend almost to occipital crest along temporal region prominent; palatal fossae deep with complex and broad posteropalatal pits; mesopterygoid roof with wide and large sphenopalatine vacuities extending broadly along presphenoid and alisphenoid (exposing the orbitosphe-noid); no alisphenoid strut; small posterior opening of alisphenoid canal; and relatively narrow upper molars. *Cerradomys goytaca* larger in most craniodental measurements than *C. langguthi* and *C. vivoi*, and significantly larger than samples of *C. subflavus* in length of diastema and breadth of rostrum.

DISTRIBUTION: *Cerradomys goytaca* is known from only five localities in coastal Espírito Santo and Rio de Janeiro states, Brazil.

SELECTED LOCALITIES (Map 149): BRAZIL: Espírito Santo, Praia das Neves, Presidente Kennedy (MNRJ 67543); Rio de Janeiro, Parque Nacional da Restinga de Jurubatiba, Carapebus (type locality of *Cerradomys goytaca* Tavares, Pessôa, and Gonçalves, 2011), Restinga de Iquipari-Grussai, Grussai, São João da Barra (MNRJ 73261), Restinga do Faroizinho, Farol de São Tomé, Campos dos Goytacazes (MNRJ 73276), Sítio Santana, Beira de Lagoa, Quissamã (MNRJ 73198).

SUBSPECIES: *Cerradomys goytaca* is monotypic.

NATURAL HISTORY: All known collecting localities are in the narrow sandy plains covered by distinctive shrubby and open vegetation, locally known as *restingas*, along the Atlantic coast of south-central Brazil (see D. Araújo 1992; Oliveira-Filho and Fontes 2000). *Cerradomys goytaca* is one of the most abundant small mammals in the Parque Nacional da Restinga de Jurubatiba, occurring in most plant formations but at higher densities

in the open shrublands that are distributed as vegetation islands in sandy plains. It is most common in patches of *Clusia hilariana* (Clusiaceae), the largest tree in these shrubland patches. Specimens have also been taken in forests that develop in more humid terrain and near lagoons. This species plays an important role as a seed predator of the palm *Allagoptera arenaria* (Grenha et al. 2010). Specimens were captured in traps placed on limbs up to 2 m above the ground, suggesting some degree of arboreal activity. Nests were found on tree branches and tangled bromeliads (Bergallo et al. 2005). Dense litter is also likely used as shelter. Pregnant females were captured in April and September, each with four embryos. In the laboratory, litters consisted of four to five pups; eyes and external ears opened four to nine days following birth, with different growth rates in the two sexes. Both macronyssid (*Ornithomyssus* sp.) and laelapid mites (*Laelaps manguinhosii*, *Gigantolaelaps goyanaensis*, and *G. vitzthumi*) parasitize this species (Bergallo et al. 2004). One individual was found with a botfly larva (Diptera, Cuterebridae).

REMARKS: Among the diagnostic features given by Tavares et al. (2011) in their description of *C. goytaca* is a unique karyotype with $2n=54$ and $FN=66$, including a single large acrocentric pair and four small biarmed pairs in the autosomal complement, a large subtelocentric X chromosome, and a medium-sized acrocentric Y chromosome.

Map 149 Selected localities for *Cerradomys goytaca* (●).

Cerradomys langguthi Percequillo, Hingst-Zaher, and Bonvicino, 2008

Langguth's Cerradomys

SYNONYM:

Cerradomys langguthi: Percequillo, Hingst-Zaher, and Bonvicino, 2008:13; type locality “Corredor São João-Fazenda Pacatuba, Sapé, State of Paraíba, Brazil, at ca. 07°02’S, 35°09’W.”

DESCRIPTION: Small, with head and body length 119–153 mm, tail length 144–195 mm. Dorsal pelage short and dense; body color orange grizzled with brown; head color contrastingly grayish; ventral body color grayish or slightly yellowish. Skull with short and narrow sphenopalatine vacuities, restricted to presphenoid and thus partially exposing orbitosphenoid; no alisphenoid strut; palatal fossae deep (complex posterolateral palatal pits).

DISTRIBUTION: *Cerradomys langguthi* occurs from the left bank of the Rio São Francisco through the Brazilian states of Pernambuco, Paraíba, Ceará, and Maranhão. In Pernambuco, Paraíba, and Ceará, records extend from the coastal lowlands to the interior highlands and mountain ranges; in Maranhão, the species is associated with lowlands of the central portion of the state.

SELECTED LOCALITIES (Map 150): BRAZIL: Ceará, Sítio Friburgo, Serra de Baturité, Pacoti (MZUSP [ARP 11]); Maranhão, Fazenda Lagoa Nova (MPEG 23482); Paraíba, João Pessoa (UFPB 31), Fazenda Pacatuba, Sapé, Corredor São João (type locality of *Cerradomys langguthi* Percequillo, Hingst-Zaher, and Bonvicino); Pernambuco, Buíque, Sítio Mata Verde (MZUSP 20604), Exu (MZUSP 18900), Fazenda Saco IBA, 6.6 km NNE of Serra Talhada (MZUSP 18905), São Vicente Ferrer (UFPB 19).

SUBSPECIES: *Cerradomys langguthi* is monotypic.

NATURAL HISTORY: *Cerradomys langguthi* inhabits several vegetation types, including the coastal lowland humid Atlantic Forest (locally called *zona da mata*), the open and relatively dry forests (locally called *agreste*) in the zone between the more humid and dense coastal forest and the more open and drier Caatinga, the Caatinga, and the forests restricted to humid slopes of mountain ranges in areas of Caatinga (*brejos*).

This species is associated with sugarcane plantations, near humid and mesic areas in Ceará and Pernambuco states (Paiva 1973; Mares, Willig et al. 1981); with natural and cultivated fields, where the rats construct nests in the wetter grass patches (Karimi et al. 1976); and with secondary forests and shade-grown coffee plantations on the slopes of Serra de Baturité (a typical *brejo*) in Ceará state (Percequillo et al. 2008).

REMARKS: In the genus, *C. langguthi* is nested in a monophyletic group along with *C. vivoi* and *C. subflavus*

Map 150 Selected localities for *Cerradomys langguthi* (●) and *Cerradomys vivoi* (○).

(Percequillo et al. 2008), as based on mtDNA cytochrome-*b* sequences. Cranially, *C. langguthi* exhibits short and narrow sphenopalatine vacuities that barely expose the orbitosphenoids; *C. subflavus* and *C. vivoi*, in contrast, have long and narrow or long and wide vacuities, respectively. There are also noticeable quantitative differences among these three species, with *C. subflavus* being significantly larger and more robust, *C. vivoi* of intermediate size, and *C. langguthi* the smallest.

The karyotype of *C. langguthi* is variable in diploid number ($2n=46$ or $48-50$) but constant in fundamental number ($FN=56$), with the variation in diploid number due to multiple centric fusions that are polymorphic in some populations (Maia and Hulak 1981; Bonvicino et al. 1999; Percequillo et al. 2008).

Cerradomys maracajuensis (Langguth and Bonvicino, 2002)

Maracaju Cerradomys

SYNONYMS:

Oryzomys maracajuensis Langguth and Bonvicino, 2002: 292; type locality “Brazil, Mato Grosso do Sul, Municipality of Maracaju (approx. 21°38’S, 55°09’W) Fazenda da Mata.”

[*Cerradomys*] *maracajuensis*: Weksler, Percequillo, and Voss, 2006:8; first use of current name combination.

DESCRIPTION: Large, head and body length 140–185 mm, and tail length 171–227 mm; hindfeet long and robust, 34–43 mm; dorsal body color coarsely grizzled, buffy brown to orange brown, and ventral body color grayish to buffy to yellow gray. Skull with shallow rostral fossae; roof of mesopterygoid fossa with small and narrow sphenopalatine vacuities or fully ossified; palatal fossae shallow, with large posterolateral palatal pits; palatal excrescences developed; all lower molars with well-developed mesolophids (but narrow and reduced in some individuals from Bolivia). Phallus lacks central cartilaginous digit of distal baculum.

DISTRIBUTION: *Cerradomys maracajuensis* occurs in open vegetation habitats of central South America, including the Cerrado in Brazil, the eastern Chaco and grasslands of Paraguay (see D'Elia, Pardiñas, Jayat, and Salazar-Bravo 2008), the Cerrado and Chaco Boreal of Bolivia, and the islands of open, Cerrado-like vegetation in southern Peru. Elevational range is from 100 m (Tacuatí, Paraguay) to 1,750 m (Pitiguaya, Bolivia), with most records from the lowland.

SELECTED LOCALITIES (Map 151): **BOLIVIA:** Beni, Boca del Río Baures (AMNH 210227), Pampa de Meio, Río Iténez (AMNH 210024); La Paz, Pitiguaya, Río Unduavi (AMNH 72641). **BRAZIL:** Mato Grosso, 264 km N of Xavantina, Serra do Roncador (BM 81.450); Mato Grosso do Sul, Fazenda Primavera, Bataiporã (MZUSP 28766); Minas Gerais, Reserva do Jacob, Nova Ponte (UFMG 1970). **PARAGUAY:** Paraguari, Sapucay (BM 3.2.3.9). **PERU:** Puno, Aguas Claras camp, Río Heath (USNM 579688).

SUBSPECIES: *Cerradomys maracajuensis* is monotypic.

NATURAL HISTORY: *Cerradomys maracajuensis* has been collected in “woods,” “bush and grass,” “brush pile in grass at edge of rice field,” “brush-swampy,” “forest,” and “brush and grass” (R. M. Gilmore, from AMNH and MNRJ museum labels on specimens collected near the type locality), dense shrubby and grassy fields (cleared forest) and adjacent dense forest (G. Schmitt, AMNH labels), gallery forest (Langguth and Bonvicino 2002), and seasonally flooded pampas (Emmons et al. 2006). Pregnant females were caught in Bolivia during June and September, with two and four embryos (S. Anderson 1997).

REMARKS: A recently described species, *C. maracajuensis* is readily distinguishable from other members of the genus (with the exception of *C. marinhoi*) by its larger size and long tail, longer and more robust hindfeet, shallower rostral fossae, narrower zygomatic notches, developed palatal excrescences, and fully ossified roof of mesopterygoid fossa (small sphenopalatine vacuities are present in some Bolivian and Paraguayan specimens). Another diagnostic feature of *C. maracajuensis* is the $2n=56$ and $FN=54$ karyotype (Bonvicino et al. 1999). Bonvicino

Map 151 Selected localities for *Cerradomys maracajuensis* (●). Contour line = 2,000 m.

(2003) hypothesized that *C. marinhoi* and *C. maracajuensis* form the most basal clade of the genus.

Cerradomys marinhoi (Bonvicino, 2003)

Marinho's Cerradomys

SYNONYMS:

Oryzomys marinhoi Bonvicino, 2003:84; type locality “Fazenda Sertão do Formoso (known formerly as Fazenda Jucurutu, 14°40'20"S 45°49'71" [sic] W, altitude around 775 m), Jaborandi municipality, Goiás, Brazil” (corrected to Bahia state, at coordinates 14°48'S, 45°57'W; see comment under Remarks).

[*Cerradomys*] *marinhoi*: Weksler, Percequillo, and Voss, 2006:8; first use of current name combination.

DESCRIPTION: Large, with head and body length 153–179 mm; tail longer than body (length 198–212 mm); hindfeet long and robust (length 38–43 mm). Dorsal body color coarsely grizzled, buffy brown to orange brown; ventral body color grayish to buffy to yellowish gray. Skull with shallow rostral fossae; roof of mesopterygoid fossa either fully ossified or with small and narrow sphenopalatine vacuities; palate with shallow fossae and large posterolateral palatal pits; mesolophid of m3 reduced or absent.

DISTRIBUTION: *Cerradomys marinhoi* is known only from two localities, one each in Bahia and Minas Gerais states, Brazil.

SELECTED LOCALITIES (Map 152): **BRAZIL:** Bahia, Fazenda Sertão do Formoso (type locality of *Oryzo-*

mys marinhuis Bonvicino); Minas Gerais, Parque Nacional Grande Sertão Veredas (MZUSP [APC 764]).

SUBSPECIES: *Cerradomys marinhuis* is monotypic.

NATURAL HISTORY: Specimens of *C. marinhuis* have been captured in seasonally flooded semideciduous forests (Percequillo et al. 2008) and in *vereda*, the periodically flooded grasslands with scattered palm trees of the genera *Mauritia* and *Mauritiella* and that usually occur along headwater streams in the Cerrado (Bonvicino 2003). Pregnant females were captured in both dry and rainy seasons, suggesting that breeding takes place throughout the year; embryo counts range from two to four, with mode of four (Bonvicino 2003:87). Bonvicino also stated that individuals of *C. marinhuis* were infested with mesostigmatid mites and ticks, *Polygenis tripus* fleas, and flies of the family Hippoboscidae.

REMARKS: The type locality specified in the original description is incorrect. As Bonvicino (2003:79) has noted, Fazenda Sertão do Formoso is “located in Jaborandi and Cocos municipalities, Bahia state” and not in Goiás state. Moreover, all specimens were captured in one particular habitat type, the geographical coordinates of which were specified by Bonvicino (2003:79). Thus, the correct type locality for this species is Fazenda Sertão do Formoso (formerly known as Fazenda Jucurutu), 14°48’S, 45°57’W, elevation about 775 m, municipality of Jaborandi, Bahia, Brazil.

Map 152 Selected localities for *Cerradomys marinhuis* (○) and *Cerradomys subflavus* (●).

Cerradomys marinhuis and *C. maracajuensis* were recovered as sister taxa in a molecular phylogenetic analysis with high bootstrap support (Bonvicino and Moreira 2001; Bonvicino 2003), and perhaps not surprisingly because the two species are remarkably similar in body and skull size, overall pelage color, and qualitative skull characters (e.g., shallow rostral fossae, ossified mesopterygoid fossa roof, and presence of palatal excrescences; see Percequillo et al. 2008). The karyotype of *C. marinhuis* consists of $2n=56$ and $FN=54$, with an entirely unarmed autosomal set whereas that of *C. maracajuensis* is $2n=56$ and $FN=58$, with two metacentric pairs (Bonvicino 2003). The absence of a mesolophid on m1 is the only diagnostic feature separating *C. marinhuis* from *C. maracajuensis*.

Cerradomys scotti (Langguth and Bonvicino, 2002)

Lindbergh's Cerradomys

SYNONYMS:

Oryzomys scotti Langguth and Bonvicino, 2002:290; type locality “Brazil, Goiás: municipality of Corumbá de Goiás (approx. 15°54’S, 48°48’W), Morro dos Cabeludos [= Morro de Cabeludo].”

Oryzomys andersoni Brooks, Baker, Vargas, Tarifa, Arani-bar, and Rojas, 2004:3; type locality “Pozo Mario, Estancia Las Conchas, Santa Cruz, Bolivia; 17°35’46.9’’S; 59°30’20.5’’W.”

[*Cerradomys*] *scotti*: Weksler, Percequillo, and Voss, 2006:8; first use of current name combination.

DESCRIPTION: Medium sized, with head and body length 125–181 mm and tail length 141–198 mm; hindfeet small (length 24–27 mm). Dorsal body color coarsely grizzled buffy brown, ventral color grayish. Tail bicolored and noticeably hirsute. Skull with deep rostral fossae and mesopterygoid fossa roof with large and wide sphenopalatine vacuities that expose the orbitosphenoid; alisphenoid strut present; palatal fossae deep (complex posterolateral palatal pits). M2 with reduced mesoloph, and mesolophid absent or reduced on m1 and m2. Central cartilaginous digit of distal baculum absent.

DISTRIBUTION: *Cerradomys scotti* occurs in the highlands of central South America, with records from the Cerrado of Brazil and eastern Bolivia and the Chaco Oriental of Paraguay. The species ranges in elevation from 250 m to about 1,180 m.

SELECTED LOCALITIES (Map 153): BOLIVIA: Santa Cruz, El Refugio Pampa, 3 km NE from camp (USNM 584583), Santa Rosa de la Roca (AMNH 263872). BRAZIL: Bahia, Fazenda Sertão do Formoso (MNRJ 61667); Maranhão, Estiva (MPEG 22670); Mato Grosso, 264 km N of Xavantina, Serra do Roncador (BM 81.439); Minas Gerais, Conquista, Usina Hidroelétrica de Igarapava (UFMG 29), Lagoa Santa (BM 88.1.9.5), Serra Azul

(COPASA, Mateur Leme) (UFMG 21); Piauí, Estação Ecológica de Uruçuí-Una (MZUSP 137); São Paulo, Estação Ecológica de Santa Bárbara (MZUSP [APC 1157]). PARAGUAY: Paraguari, Sapucaí (BM 3.4.7.13).

SUBSPECIES: I treat *Cerradomys scotti* as monotypic.

NATURAL HISTORY: *Cerradomys scotti* is most frequently captured in open habitats of the Cerrado and through the ecotone between forested and open areas (voucher data, journal notes, and collector information), in habitats locally referred to as *cerrado* and *pampa arbolada* (Emmons et al. 2006), *cerrado sensu stricto* (grassland densely covered with bushes and small trees), *cerrado rupestre* (similar to the previous, but with rocky outcrops), *campo úmido* (seasonally flooded grassland), and *campo cerrado* (grassland sparsely covered with bushes; Bonvicino, Lemos, and Weksler 2005). This is in contrast to other members of the genus that are associated more with forested habitats, such as gallery forest and woodland savanna, or *cerradão* (Percequillo et al. 2008). Langguth and Bonvicino (2002) stated that this species is also found in *veredas* and gallery forests but less frequently than in more open habitats of the Cerrado. *Cerradomys scotti* is scansorial (Alho and Villela 1984). This species may be sympatric with three other species: *C. maracajuensis* in the Brazilian states of Minas Gerais, Mato Grosso, and Mato Grosso do Sul, the Paraguayan state of Paraguari, and in Santa Cruz department, Bolivia; *C. marinhos* in Bahia state, Brazil; and *C. subflavus* in Minas Gerais and São Paulo states, Brazil.

REMARKS: *Cerradomys scotti* can be easily distinguished from its congeners by the presence of an alisphenoid strut and most notably by reduction to loss of the mesolophid in almost all individuals and of the mesoloph in many (Percequillo et al. 2008). *Cerradomys scotti*, along with *Microakodontomys transitorius*, *Akodon lindberghi*, and *Thalpomys cerradensis*, belongs to a fringe zone fauna that collectively inhabits transitional communities between open and forested habitats. Each of these species is characterized by reduction or loss of a mesoloph(id) (Hershkovitz 1993).

Based on molecular evidence, Emmons et al. (2006) suggested that *Cerradomys andersoni* and *C. scotti* are conspecific. Brooks et al. (2004) also highlighted the close relationship between the haplotype of the holotype of *C. andersoni* and specimens of *C. scotti*. The only specimen ever assigned to *C. andersoni* shares some similarities with specimens of *C. scotti* such as a bicolored tail, presence of the alisphenoid strut, and reduction of the mesoloph on M2. Additionally, this specimen is nearly identical to the holotype of *C. scotti* as well to some other Bolivian specimens of this latter species from Santa Cruz department and to some Paraguayan specimens from Sapucaí, Tobati, Altos, and Concepción departments (Percequillo et al. 2008). Thus, I feel confident in regarding *andersoni* as a

Map 153 Selected localities for *Cerradomys scotti* (●). Contour line = 2,000 m.

synonym of *C. scotti*. The karyotype of *C. scotti* is $2n = 58$ and $FN = 70$ to 72 (Bonvicino et al. 1999).

Cerradomys subflavus (Wagner, 1842)

Flavescent Cerradomys

SYNONYMS:

Mus vulpinus Lund, 1839a:233; *nomen nudum*.

Mus vulpinus Lund, 1840b [1841c:279]; type locality "Rio das Velhas's Floddal" (Lund 1841c:292), Lagoa Santa, Minas Gerais, Brazil; part; preoccupied by *Mus vulpinus* Brants.

Hesperomys subflavus Wagner, 1842c:362; type locality "Brasilia"; restricted to "Lagoa Santa, estado de Minas Gerais," Brazil by Cabrera (1961:396).

Mus subflavus: Schinz, 1845:190; name combination.

Mus vulpinoides Schinz, 1845:193; renaming of *Mus vulpinus* Lund.

Hesperomys laticeps: Burmeister, 1854:171; part; not *Mus laticeps* Lund.

Calomys vulpinus: Fitzinger, 1867b:86; part; name combination.

Calomys laticeps: Winge, 1887:51; part; not *Mus laticeps* Lund (see Percequillo 1998 and Musser et al. 1998:263, 298, concerning this usage).

Oryzomys subflavus: Thomas, 1901g:528; name combination.

[*Oryzomys (Oryzomys)*] *subflavus*: E.-L. Trouessart, 1904:421; name combination.

[*Oryzomys*] *vulpinoides*: Tate, 1932e:18; name combination.

Holochilus physodes physodes: C. O. da C. Vieira, 1953: 134; part.

Oryzomys laticeps intermedius: C. O. da C. Vieira, 1953: 137–138; part.

Oryzomys subflavus subflavus: C. O. da C. Vieira, 1955: 411; part; name combination.

[*Cerradomys*] *subflavus*: Weksler, Percequillo, and Voss, 2006:8; first use of current name combination.

DESCRIPTION: Medium sized to large, with head and body length 120–179 mm and tail length 150–210 mm. Hindfeet small (length 31–34 mm). Dorsal body color coarsely grizzled buffy to orange brown, head contrastingly grayish, and ventral color also grayish. Skull with deep rostral fossae; roof of mesopterygoid fossa with large and wide sphenopalatine vacuities exposing orbitosphenoid; palatal fossae long, deep, and narrow, with multiple posterolateral palatal pits; bony tubes of bullae short, with distinct medial lamina dorsal to carotid canal. Central cartilaginous digit of distal baculum present but reduced in size.

DISTRIBUTION: *Cerradomys subflavus* is endemic to central Brazil, in the states of São Paulo, Minas Gerais, Bahia, and Goiás.

SELECTED LOCALITIES (Map 152): BRAZIL: Bahia, Nova Viçosa (LV [MW 13]); Goiás, Anápolis (MNRJ 4345); Minas Gerais, Fazenda Triangulo Formoso, Buritizeiros (UFMG 3), Fazenda Esmeralda, 30 km E and 4 km N (by road) from Rio Casca (UFMG 1200), Lagoa Santa (type locality of *Hesperomys subflavus* Wagner), Parque Estadual do Rio Preto, 15 km S of São Gonçalo do Rio Preto (UFMG 2852), Prados (UFMG 448); São Paulo, Avanhandava, Rio Tieté (MZUSP 2872), Itapetininga (UFMG [MAM 182]), Salto de Pirapora, Bairro da Ilha (MZUSP 24599).

SUBSPECIES: I treat *Cerradomys subflavus* as monotypic.

NATURAL HISTORY: *Cerradomys subflavus* occurs in mesic habitats in the Cerrado, including gallery forest and woodland savanna (*cerradão*), and in patches of semideciduous forest of the interior Brazilian highlands. It is primarily terrestrial (Stallings 1989), although individuals have been caught in trees (G. A. B. Fonseca and Kierulff 1989).

REMARKS: The karyotype consists of $2n=54$ and $FN=62$ or 64 (E. J. C. Almeida and Yonenaga-Yassuda 1974; Bonvicino and Moreira 2001; J. C. Moreira et al. 2009).

Cerradomys vivoi Percequillo, Hingst-Zaher, and Bonvicino, 2008

Vivo's Cerradomys

SYNONYM:

Cerradomys vivoi Percequillo, Hingst-Zaher, and Bonvicino, 2008:24; type locality “Parque Zoobotânico da

Comissão Executiva do Plano da Lavoura Cacaueira (CEPLAC), situated 6 km E of Itabuna by road, state of Bahia, Brazil, at 14°48'S, 39°16'W, on sea level.”

DESCRIPTION: Size intermediate for genus, with head and body length 127–160 mm and tail length 153–200 mm; hindfeet rather small (length 30–36 mm). Dorsal pelage short and dense, colored orange grizzled with brown, head contrastingly grayish, and venter grayish or slightly yellowish. Skull with long and wide sphenopalatine vacuities; alisphenoid strut absent; palatal fossae deep, with multiple posterolateral palatal pits.

DISTRIBUTION: *Cerradomys vivoi* occurs through the Brazilian states of Minas Gerais, Bahia, and Sergipe. In Minas Gerais, most records are restricted to northern basins of the Rio Jequitinhonha and Rio São Francisco, including its right bank tributaries. In Bahia, records of *C. vivoi* are concentrated in the coastal region on the right (eastern) bank of Rio São Francisco, while in Sergipe, the only record is from the coast, near the mouth of the Rio São Francisco.

SELECTED LOCALITIES (Map 150): BRAZIL: Bahia, Parque Zoobotânico CEPLAC, 6 km E of Itabuna (type locality of *Cerradomys vivoi* Percequillo, Hingst-Zaher, and Bonvicino), Lagoa de Itaparica (MZUSP 28889), Fazenda Bolandeira, 10 km S of Una (UFMG, not cataloged), Valença, Rio Unamirim (UFPB 540); Minas Gerais, Riacho Mocambinho, Jaíba (MNRJ 34433), Fazenda Canoas, 36 km NE and 12 km W of Montes Claros (MNRJ 61662), Jequitinhonha (UFMG 1458); Sergipe, Fazenda Capivara, 7 km SE of Brejo Grande (MNRJ 30587).

SUBSPECIES: *Cerradomys vivoi* is monotypic.

NATURAL HISTORY: *Cerradomys vivoi* is associated with the drier areas of the Cerrado and Caatinga as well as the transition between these biomes and the wetter Atlantic Forest (Percequillo et al. 2008). In the drier biomes, this species inhabits secondary semideciduous and gallery forests as well as arboreal Caatinga. In the Atlantic Forest of southern Bahia (Pardini 2004), *C. vivoi* was considered absent or very rare in mature forests (including their edges) but occurred in disturbed forests, particularly those in initial stages of regeneration or more commonly in open areas (Percequillo et al. 2008). Diet consists mainly of plant material and arthropods. The only ectoparasite thus far found on *C. vivoi* is the mite *Gigantolaelaps vitzthumi* (Hingst et al. 1997).

REMARKS: See comparisons in the discussion of *C. langguthi*. There are some karyotypic similarities between *C. vivoi* ($2n=50$, $FN=64$; Bonvicino et al. 1999, as “*O. subflavus* variant 3”) and *C. langguthi*, which is characterized by population polymorphism of $2n=48$ to 50 and $FN=56$ (Percequillo et al. 2008), but the overlap is restricted to the diploid number, not to the fundamental number. Morphological differences in the autosomal complements of these

two species suggest that hybrids, if possible, would suffer meiotic incompatibilities, thus supporting recognition of both forms as separate species.

Genus *Drymoreomys* Percequillo, Weksler, and Costa, 2011

Alexandre R. Percequillo and Marcelo Weksler

Drymoreomys is a monotypic genus found in the Atlantic Forest biome of eastern Brazil, known from fewer than 20 specimens from four localities ranging in elevation from 650 m to 1,200 m. Its sole species, *D. albimaculatus* Percequillo, Weksler, and Costa (2011), first collected in 1992, is the sister group to *Eremoryzomys polius*, a taxon endemic to the dry forests of the Río Marañón basin in the northern Andes of Peru, according to phylogenetic analyses of molecular and morphological data (Percequillo, Weksler, and Costa 2011; Suárez-Villota et al. 2013).

Drymoreomys are medium-sized rodents, with moderate head and body size (length 109–149 mm) and mass (44–102 g). The tail is longer than combined head and body length (tail length 150–176 mm), the pinnae are small, and the hindfeet are wide and short (hindfoot length 26–30 mm). The dorsal pelage consists of long and dense underfur and longer and lax overfur (length of aristiforms 14–17 mm). Dorsal color ranges from dull orange to fulvous buffy weakly grizzled with reddish-brown; the ventral pelage is grayish, with distinctive white patches present in gular, thoracic, and inguinal regions (the inguinal patch is sometimes absent), and distinctively paler than the dorsal pelage. The ears are rounded and small, covered internally with short golden hairs and externally densely covered with reddish-brown hairs. The mystacial vibrissae usually extend posteriorly for a few millimeters beyond the caudal margins of the pinnae when laid back. The tail is unicolorous, densely covered with short and stiff brown hairs on dorsal and ventral surface and with very reduced scales. Forefeet are small and wide, covered by brown hairs proximally with the digits covered with white/silvery hairs. Hindfeet are short and moderately wide, densely covered above with a patch of brown hairs over the metatarsus surrounded by white/silvery hairs; conspicuous ungual tufts of long white to silvery hairs are present at the base of the claws on digits II to V; the plantar pads are very large and fleshy, and the interdigital pads are set close together.

The skull is medium sized and moderately robust, its condyloincisive length ranging from 27.1–32.4 mm. The rostrum is long (nasal length 11.25–13.51 mm) and wide (breadth of rostrum range from 4.82–5.98 mm), tapering distally; nasals and premaxillae are slightly projected anteriorly, forming a short bony rostral tube. Shallow zygo-

matic notches flank the rostrum; the zygomatic plates are not projected forward, their anterior margins are straight or slightly concave, without dorsal free margins and zygomatic spines. The interorbital region is long and narrow (least interorbital breadth ranges from 5.01–5.68 mm), anteriorly convergent, with squared to lightly beaded supra-orbital margins. The braincase is oblong, with or without weakly developed temporal crests. The incisive foramina are long (averaging about 71% of the diastema length) and widest posteriorly, sometimes extending to the level of the alveoli or anterocones of M1s; lateral margins are abruptly indented anteriorly near the premaxillomaxillary suture or sharply constricted posteriorly, near the posterior border. The palate is short and wide, without palatal excrescences, and with small to moderately large posterolateral palatal pits, single to multiple and recessed in shallow fossae. The mesopterygoid fossa reaches the level of the posterior borders of M3s (penetrating to the level of the hypocones of M3s in some specimens); the bony roof of the mesopterygoid fossa is completely ossified, or perforated only by small sphenopalatine vacuities restricted to the presphenoid (only marginally in the basisphenoid). The stapedial foramen, squamosoalisphenoid groove, and sphenofrontal foramen are absent; the posterior opening of alisphenoid canal is large and conspicuous but lacks a posterior groove or depression; and the secondary anastomosis of internal carotid artery crosses the dorsal surface of parapterygoid plate, all traits that define carotid circulatory pattern 3 (*sensu* Voss 1988). An alisphenoid strut is present as a robust bony bar separating the buccinator-masticatory and accessory oval foramina. Auditory bullae are globose, with short bony tubes; the stapedial process is long and narrow, overlapping the lateral margin of the squamosal. The posterior suspensory process of the squamosal is absent; a bony projection dorsolateral to the stapedial process is present, overlapping the squamosal; and the periotic is exposed posteromedially between the ectotympanic and the basioccipital, but does not extend anteriorly to the carotid canal in most specimens. Each mastoid is perforated by a conspicuous posterodorsal fenestra; the postglenoid foramina are large and rounded; and the subsquamosal fenestrae are large and patent.

The mandible is long and shallow; the coronoid process is large, falciform or triangular, nearly equal in height to the condyloid process; the angular process is short, not extending past the condyloid process posteriorly. Both superior and inferior notches are shallow. The capsular process is not noticeable.

Upper incisors are opisthodont, and molars are pentalophodont and high-crowned. The maxillary toothrows are subparallel or weakly convergent anteriorly; the molar series is robust and long, 4.93–5.43 mm. Labial and lingual flexi of upper molars shallowly penetrate at the

molar midline; both are arranged in opposite pairs. The labial and lingual cusps are high (molars nearly hypsodont) and compressed anteroposteriorly; labial cusps are quite distinct and project laterally. The occlusal surfaces of the labial cusps of the upper molars are oriented posteriorly; the occlusal surfaces of the lingual cusps are labially oriented. The anterocone of M1 is divided into labial and lingual conules (anteromedian flexus present); the anteroloph is well developed and fused with an anterostyle on the labial cingulum, and separated from the anterocone by a persistent anteroflexus. A protostyle is present (in most specimens) as an isolated accessory cuspule or fused to an anterior mure. An enamel bridge connects the paracone to the middle or the anterior portion of the protocone. The protoflexus of M2 is variably present; the mesoflexus is long and obliquely or transversally oriented, divided into two (labial and lingual) or three (labial, medial, and lingual) fossettes. M3 has a mesoloph, posteroloph, and persistent hypoflexus; the paracone and protocone are distinguishable on the occlusal surface; the hypocone is reduced, and the metacone is greatly reduced and completely fused with the posteroloph. The labial accessory root of M1 is possibly absent (not visible in lateral view).

Labial cusps of the lower molars are slightly anterior to the lingual cusps; the occlusal surfaces of the lingual cusps are oriented anteriorly, and those of the labial cusps are lingually oriented. The anteroconid of m1 is divided by an anteromedian flexid; the anterolabial cingulum is developed in m1 and m2, and variably present in m3; the anterolophid is present in all lower molars; the ectolophid is variably present on m1 only; and the posteroflexid on m3 is large and persistent. All lower molars have two roots, one each in anterior and posterior positions.

The axial skeleton includes 12 ribs and 19 thoracolumbar, 4 sacral, and 36–38 caudal vertebrae. The hemal arch at the boundary of the second and third caudal vertebrae has a posterior spinous process. The trochlear process of the calcaneus is long and shelf-like, positioned immediately posterior to the articular facet. The entepicondylar foramen is absent. The supratrochlear is absent in adults but is observable in young individuals.

The stomach is unilocular and hemiglandular, with the gastric glandular epithelium restricted to the antrum. The glans penis does not have lateral bacular mounds; the distal cartilaginous apparatus is tridigitate, with the central digit more robust than the lateral ones; the dorsal papilla has one apical spine; and the urethral process has a large lateral lobe. The preputial glands are very large.

SYNONYM:

Drymoreomys Percequillo, Weksler, and Costa, 2011:360; type species *Drymoreomys albimaculatus* by original designation and monotypy.

Drymoreomys albimaculatus Percequillo, Weksler, and Costa, 2011

White-throated Montane Forest Rat

SYNONYM:

Drymoreomys albimaculatus Percequillo, Weksler, and Costa, 2011:368; type locality “Brazil, Estado de São Paulo, Município de Ribeirão Grande, Parque Estadual Intervales, Base do Carmo, 700 m; 24°20'S, 48°25'W.”

DESCRIPTION: As for the genus.

DISTRIBUTION: All known specimens referred to *Drymoreomys* are from the eastern slopes of the Serra do Mar, in the coastal Brazilian Atlantic Forest, from São Paulo to Santa Catarina states, at elevations ranging from 650 m to 1,200 m.

SELECTED LOCALITIES (Map 154): BRAZIL: São Paulo, Estação Ecológica do Bananal (MZUSP 33782), Estação Biológica de Boracéia (MZUSP [BO 24]), Parque Estadual Intervales, Base do Carmo (type locality of *Drymoreomys albimaculatus*); Santa Catarina, Parque Estadual da Serra do Tabuleiro (UFSC 860).

SUBSPECIES: *Drymoreomys albimaculatus* is monotypic.

NATURAL HISTORY: Available evidence (see Percequillo, Weksler, and Costa 2011) suggests that *D. albimaculatus* is an Atlantic Forest endemic, inhabiting dense and humid montane and premontane forests. Apparently, this species does not exhibit preferences for pristine forests, as it has also been found in secondary and disturbed forests, and even in areas that were completely deforested a few decades ago. Additional evidence (Pardini and Umetsu 2006; Bueno 2008; R. Pardini, pers. comm.), however, suggests that *D. albimaculatus* inhabits areas of both pristine and disturbed forest. Females were reproductively active in June and from November to December, and males possessed scrotal testes in December, suggesting that reproduction may take place throughout the year (Percequillo, Weksler, and Costa 2011).

REMARKS: This recently discovered rat comes from one of the most densely populated areas in South America. Furthermore, the unexpected close phylogenetic relationship between *Drymoreomys* and *Eremoryzomys*, as recovered by Percequillo, Weksler, and Costa (2011) and Suárez-Villota et al. (2013), provides one of the most noteworthy sister taxon duos in South America biogeography. *Drymoreomys* is endemic to lower montane areas in the Atlantic Forest of eastern Brazil, whereas *Eremoryzomys* is an Andean endemic (760 to 2,100 m) from the valley of the lower Río Marañón in northern Peru. Each taxon is restricted to well-known Neotropical centers of endemism (P. Müller 1973; Cracraft 1985), with *D. albimaculatus* part of the Serra do Mar center and *E. polius* from the Marañón center. A closely parallel case illustrating a biogeographic connection

Map 154 Selected localities for *Drymoreomys albimaculatus* (●).

between the Brazilian Atlantic Forest and central Andes is that of *Rhagomys*. It is likely that additional discoveries of rodents or many other organismal groups will fill the large geographic gap between these two distributional areas.

Suárez-Villota et al. (2013) described a karyotype with $2n=62$, $FN=62$; the autosomal complement consists of 29 pairs of acrocentrics grading evenly from large to small plus a single pair of small metacentrics; the X chromosome is a large submetacentric, the Y a slightly small submetacentric.

Genus *Eremoryzomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

The genus *Eremoryzomys* is monotypic, with the single species, *E. polius*, limited to the upper Río Marañón valley in northern Peru. Since it was described, the validity of this species has never been questioned (see Cabrera 1961; Musser and Carleton 1993, 2005), although its phylogenetic relationships to other oryzomyines have remained unclear. Osgood (1913) emphasized the distinctness of *E. polius* in comparison with *Aegialomys xantheolus*, and Musser and Carleton (2005) declared its affinities to be obscure.

The morphology of *Eremoryzomys* is quite distinctive both in external and cranial traits. This rat is medium sized, with the head and body length 125–161 mm. The

tail is longer than the head and body (135–188 mm). The dorsal pelage is dense and harsh, coarsely grizzled grayish to brownish or yellowish gray; the ventral pelage is noticeable paler, with gray-based hairs tipped very light buff. The tail is distinctly bicolored. Ears are small and rounded, and do not reach the eye when laid forward. The hindfoot has conspicuous and dense tufts of long, white unguis hairs at the base of the claws; the hypothenar pad is large and distinct, as are other plantar pads.

The skull is medium-sized, with its condyloincisive length 29.9–36.8 mm. The rostrum is long and stout, flanked by moderately deep zygomatic notches. The interorbital region is divergent posteriorly, with beaded supra-orbital margins. The braincase is rounded, with distinct temporal crests. Posterior margins of the zygomatic plates are located above the alveoli of the M1s. The zygomatic arches are strong and flared, widest at the squamosal root; jugals are large (the maxillary and squamosal zygomatic processes are widely separated, not overlapping, in lateral view). The nasals are short and do not extend posterior to the lacrimals, which are equally sutured to the maxillary and frontal bones. The frontosquamosal suture usually is collinear with the frontoparietal suture. Incisive foramina are very long, usually extending posteriorly between the anterocones or even protocones of the M1s; the lateral margins are subparallel and widest medially. The palate is short and wide, with the anterior margin of the mesopterygoid fossa penetrating anteriorly to, or slightly between, the molar rows; the bony roof of mesopterygoid fossa is perforated by large sphenopalatine vacuities. The palate has large and complex posterolateral palatal pits recessed in deep fossae. The alisphenoid strut is usually present so that the buccinator-masticatory foramen and accessory foramen ovale are separate, but the strut is unilaterally absent on some skulls. The stapedial foramen and the posterior opening of alisphenoid canal are small, the squamosal-alisphenoid groove and the sphenofrontal foramen are absent, and the secondary anastomosis of the internal carotid crosses dorsal surface of the pterygoid plate, all features that define carotid circulatory pattern 3 (sensu Voss 1988). The postglenoid foramen is large and rounded, and the subsquamosal fenestra is large and conspicuous. The petrotic bone is exposed posteromedially between the ectotympanic and the basioccipital but does not extend anteriorly to the carotid canal; each mastoid is perforated by a small or large posterodorsal fenestra. The capsular process is indistinct or absent, and both superior and inferior masseteric ridges are usually conjoined anteriorly below m1 as a single crest.

Labial and lingual flexi of M1 and M2 do not interpenetrate. The anterocone of M1 is not divided into labial and lingual conules (but a small internal fossette ob-

viously derived from the anteromedian flexus is present); the anteroloph usually is well developed, fused with an anterostyle on the labial cingulum, and separated from the anterocone by a persistent anteroflexus; a protostyle is absent; the paracone is connected by an enamel bridge to the middle or posterior part of the protocone. The protoflexus of M2 is present but shallow; the mesoflexus is present as one or more internal fossettes (both conditions occurring on opposite sides of some specimens: e.g., AMNH 64054). Both a posteroloph and diminutive hypoflexus are present on M3, the latter tending to disappear with moderate to heavy wear. A labial accessory root of M1 is absent. The anteroconid of m1 lacks an anteromedian flexid; the anterolabial cingulum and anterolophid are present on all lower molars; an ectolophid is absent on m1 and m2; a mesolophid is variably developed on m1 and m2, large and distinct in some specimens but much reduced or absent in others; and the hypoflexid of m2 is short. Accessory roots are absent on m1; m2 and m3 each has one large anterior and posterior root.

SYNONYMS:

Oryzomys: Osgood, 1913:97; part (description of *polius*); not *Oryzomys* Baird.

Eremoryzomys Weksler, Percequillo, and Voss, 2006:10; type species *Oryzomys polius* Osgood, by original designation.

REMARKS: According to Weksler (2003, 2006), *Eremoryzomys* is the most basal lineage of a clade (Clade D) containing *Oryzomys*, *Pseudoryzomys*, *Lundomys*, *Holochilus*, *Sooretamys*, *Cerradomys*, *Nesoryzomys*, *Aegialomys*, *Amphinectomys*, *Nectomys*, *Sigmodontomys*, and *Melanomys*.

Eremoryzomys polius (Osgood, 1913)

Gray *Eremoryzomys*

SYNONYMS:

Oryzomys polius Osgood, 1913:97; type locality "Tambo Carrizal, mountains east of Balsas, [Amazonas], Peru. Altitude about 5000 ft."

Oryzomys [(*Oryzomys*)] *polius*: Cabrera, 1961:394; name combination.

[*Eremoryzomys*] *polius*: Weksler, Percequillo, and Voss, 2006:10; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: Known only from seven localities in the upper Río Marañón valley of northern Peru, in Amazonas and Cajamarca departments.

SELECTED LOCALITIES (Map 155): PERU: Amazonas, Condechaca, Río Utcubamba (BM 26.5.3.16), Tambo Carrizal, mountains E of Balsas (type locality of *Oryzomys polius* Osgood), Tingo, 30 km S and 41 km E of Bagua, Río Utcubamba (MVZ 135658); Cajamarca, Chaupe (AMNH 64054), San Ignacio (AMNH 64055).

SUBSPECIES: *Eremoryzomys polius* is monotypic.

NATURAL HISTORY: *Eremoryzomys polius* inhabits the upper Marañón Valley westward to the Cordillera Central of northern Peru, in a rain-shadow area characterized by hot and arid climate (Cracraft 1985; Osgood 1914b:145). Nothing is known about the behavior or population biology of this species. What little is known of the habitat was summarized by Osgood (1914b:145), who stated that the type series was obtained at "a dilapidated tambo on the side of the mountains directly east of and overlooking Balsas and the [Río] Marañón. A tiny spring here is surrounded by a clump of trees . . . and the steep slope below has some moderately extensive thickets of low bushes which moisture from the spring permits to flourish. Elsewhere conditions are arid with occasional bunches of grass, cactuses, or small bushes." Thomas (1926g:157) stated that Condechaca, situated a few kilometers south of Chachapoyas but north of Tambo Carrizal in the Marañón valley, "is surrounded by relatively arid foothills."

REMARKS: As with species of *Aegialomys*, *Eremoryzomys polius* appears to be an open habitat specialist. As such, members of these two genera share some resemblances

Map 155 Selected localities for *Eremoryzomys polius* (●). Contour line = 2,000 m.

(grayish dorsal coloration, long incisive foramina, mesolophid reduction) that are apparently convergences owing to adaptations to open, dry areas (Weksler 2003, 2006). Weksler et al. (2006:11) noted that “*Eremoryzomys* differs from *Aegialomys* by its much grayer dorsal pelage (the dorsal fur is distinctly yellowish or brownish in *Aegialomys*); larger jugal (the jugal of *Aegialomys* is much smaller); longer incisive foramina (these openings never extend posteriorly between the M1 protocones in *Aegialomys*); shorter palate (the mesopterygoid fossa never extends anteriorly to the molar rows in *Aegialomys*); presence of an alisphenoid strut separating the buccinator-masticatory and accessory oval foramina (the strut is invariably absent and the foramina are confluent in *Aegialomys*); absence of a distinct capsular process (although well developed in *Aegialomys*); absence of accessory roots on M1/m1 (accessory roots are normally present on these teeth in *Aegialomys*); and presence of the anterolophid on m2 and m3 (the anterolophid is absent on these teeth in *Aegialomys*).”

Genus *Euryoryzomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

According to recent revisionary work (Weksler 1996, 2006; Musser et al. 1998; Percequillo 1998, 2003), the genus *Euryoryzomys* includes six valid species: *E. emmonsae*, *E. lamia*, *E. legatus*, *E. macconnelli*, *E. nitidus*, and *E. russatus*. These studies also emphasize that some members of the genus exhibit variation in morphology, karyology, and/or molecular phylogeography that may merit taxonomic recognition. This is especially so for *E. russatus* from northeastern Brazil (Weksler 1996; Percequillo 1998; M. J. de J. Silva et al. 2000b), *E. macconnelli* from western Amazonia (Musser et al. 1998; see also Patton et al. 2000; Voss et al. 2001), and *E. emmonsae* from south central Amazonia (L. P. Costa 2003).

The species of *Euryoryzomys* are widely distributed throughout South America (hence the name, from the Greek *eurus*, meaning “far reaching or far-spread”), occurring in lowland and lower montane tropical rainforest of the Amazon Basin; Brazilian and Argentinean Atlantic Forest; Bolivian and Argentinean yungas; the semideciduous forests of Paraguay, Brazil, and Bolivia; isolated patches of rainforest (*brejos*) in the northeastern Brazilian Caatinga; and gallery forests in the Brazilian Cerrado and Paraguayan Chaco.

Species of this genus exhibit a considerable range in size (head and body length 90–96 mm; tail length 100–185 mm). The tail is longer than the head and body, except in *E. nitidus* and *E. lamia*, which have a tail as long as head and body (head and body length 113–160 mm versus tail length

108–163 mm, and head and body length 135–165 mm versus tail length 135–165 mm, respectively). The dorsal pelage is soft and dense, varying from long in most species (fur length ranges from 12–16 mm) to very long in *E. macconnelli* (fur length from 17–20 mm). The dorsal and ventral pelage coloration is variable among species, but always shows strong countershading; the dorsal color ranges from buffy-brown to reddish cinnamon brown, and the ventral color varies from grayish-white to almost pure white. The tail is always bicolored. The hindfoot is long and narrow (length 25–44 mm), and has very dense and long unguis tufts that conceal the claws. The unguis tufts are usually white.

The skull ranges from medium sized to large (mean greatest skull length varies among species from 28.8–39.2 mm), and is of lightly to moderately heavily build. The rostrum is long and narrow, flanked by narrow and shallow to deep (in *E. lamia* and *E. legatus*) zygomatic notches. Incisive foramina range from short to long (4.0–7.0 mm) and are variable in shape, with their lateral margins either nearly parallel, convex, or divergent posteriorly (width 1.9–3.2 mm); their posterior margins never reach the level of the alveoli of M1s. The interorbital region is narrow (4.4–6.5 mm in least breadth) with lateral margins divergent posteriorly; the supraorbital margins are weakly to strongly beaded, and form discrete crests that extend posteriorly onto the dorsolateral margins of braincase, which is long and narrow. The zygomatic arches project laterally and are widest at their squamosal roots; jugals are absent in almost all specimens of *E. lamia*. The zygomatic plates span a considerable range in width, from 2.6–5.2 mm; the free dorsal margins project anteriorly, with their anterior margins sloping backward from top to bottom in *E. lamia* and *E. legatus* and either straight to slightly concave. A stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen are present, defined as carotid circulatory pattern 1 (*sensu* Voss 1988). An alisphenoid strut, present in all specimens of *E. legatus*, occurs at low to moderate frequencies in *E. russatus*, *E. lamia*, and *E. nitidus*, but is absent in individuals of *E. macconnelli* and *E. emmonsae*. The palate is long and narrow, with puntiform to small posterolateral palatal pits placed either at palatal level or in a shallow palatal depression; palatal excrescences are present in most species. The mesopterygoid fossa is narrow with its anterior margin rounded; the roof of the fossa is completely ossified or perforated only by small sphenopalatine vacuities. Parapterygoid fossae are flat or only moderately concave. Auditory bullae are small and rounded, with both the bony tubes and stapedial processes long and narrow. The tegmen tympani is small, rounded, squared, or triangular, and may or may not overlap the squamosal; the suspensory process of the squamosal is absent.

The mandible is deep and robust. The coronoid and condyloid processes are equal in height, and separated by a shallow superior notch. The angular process does not extend posteriorly past the condyloid process. The capsular process is a distinct projection in most species but is absent in *E. macconnelli* and *E. emmonsae*.

Upper incisors are opisthodont, fronted by distinct orange enamel bands. Toothrows are parallel and of medium length (length 4.3–5.6 mm). Main cusps are arranged in opposite pairs and are low to high crowned. The anterocone of M1 is undivided; M1 and M2 have two distinct enamel islands between the paracone and metacone; and M3 possesses a distinct anterolabial cingulum in some species such as *E. lamia*. The first lower molar is not divided by an anteromedian flexid; m2 has a distinct ectostylid or even a narrow and delicate ectolophid. M1 has three main roots, anterior and posterior labial and lingual, as well as an accessory rootlet between the two labials and beneath the paracone; M2 and M3 each has three main roots. All lower molars have two roots, one anterior and one posterior.

The axial skeleton is composed of 7 cervical, 12–13 thoracic, 6–7 sacral, and 25–33 caudal vertebrae; thoracic vertebrae bear 12–13 ribs, or rarely 11 ribs plus a vestigial one. Hemal arches on caudal elements at the junction of the first and second and/or second and third caudal vertebrae have a distinct medial posterior process.

The stomach is unilocular and hemiglandular, with a shallow angular notch. The glans penis is of the complex type (Hooper and Musser 1964), with a well-developed, tridigitate cartilaginous baculum. Both a single dorsal papilla and urethral flap are present, and three bacular mounds are visible at the terminal crater. The basal portion of the bony baculum is wide and spatulate, barely concave.

SYNONYMS:

Mus: Brants, 1827:139; part (description of *physodes*); not *Mus* Linnaeus.

Hesperomys: Wagner, 1848:312; part (description of *rus-satus*); not *Hesperomys* Waterhouse.

Calomys: Winge, 1887:51; part (description of *coronatus*); not *Calomys* Waterhouse.

Oryzomys: E.-L. Trouessart, 1897:525; part (inclusion of *intermedius* and *nitidus* as subspecies of *laticeps*); not *Oryzomys* Baird.

Oryzomys: Avila-Pires, 1968:162; *lapsus calami* (description of *kelloggi* and *ratticeps moojeni*).

Euryoryzomys Weksler, Percequillo, and Voss, 2006:8; type species *Oryzomys macconnelli* Thomas, by original designation.

REMARKS: In 1960 (and subsequently in 1966a), Hershkovitz committed one of the most controversial and influential nomenclatural acts in the convoluted history of

oryzomyine species-group taxa (see Pine 1973; A. L. Gardner and Patton 1976; Musser et al. 1998; Weksler 2006). In a footnote comment, apparently not based on the examination of voucher specimens (especially type material) and clearly without any extensive discussion of morphological variation, Hershkovitz (1960:544) lumped under *Oryzomys laticeps/capito* (see Musser et al. 1998:10) the species of the genus *Euryoryzomys* (*boliviana*, *legatus*, and *macconnelli*) as well as those now belonging to other oryzomyine genera such as *Hylaeamys* (*goeldii*, *modestus*, *oniscus*, *perenensis*, *saltator*, and *velutinus*), *Nephelomys* (*caraculus*), and *Transandinomys* (*castaneus* [*sic*; Hershkovitz attributed the name authorship of *castaneus* to Oldfield Thomas, but this author never coined either *castaneus* or *casteneus* for any sigmodontine rodent genus according to J. E[dwards]. Hill 1990; the name *castaneus* was proposed by J. A. Allen in 1901; see Cabrera 1961], *magdalenae*, *medius*, *mollipilosus*, *rivularis*, *sylvaticus*, and *talamancae*). Moreover, Hershkovitz also mentioned that “a few other” species were also synonyms of *Oryzomys laticeps/capito*, but he never clarified the composition of this group in subsequent papers (e.g., Hershkovitz 1966a).

Through the following decades, Hershkovitz’s footnote taxonomy was followed, partially or entirely, by other authorities (most notably Cabrera [1961]), until the publication of two important but temporally widely separated contributions. A. L. Gardner and Patton (1976), in their pioneering and influential paper on the cytogenetics of Neotropical Oryzomyini, paved the way for subsequent authors by showing that, under the name *capito*, Hershkovitz (1960, 1966a) had hidden extensive morphologic, karyologic, and taxonomic diversity. And, 20 years later in their massive revision, Musser et al. (1998) defined the limits of several species historically assigned to *Oryzomys* “*capito*” (*sensu* Hershkovitz 1960), recognizing 11 species grouped into six species groups based on extensive analysis of geographic variation and, critically, on their examination of almost all available type material. Combined, these two efforts plus several subsequent contributions have been responsible for the substantial advances in the classification and nomenclature of the Oryzomyini, as now presented throughout this volume.

KEY TO THE SPECIES OF SOUTH AMERICAN

EURYORYZOMYS:

1. Lateral face of mandibular ramus without trace of capsular process. 2
- 1'. Lateral face of mandibular ramus with prominent capsular process. 3
2. Dorsal pelage very dense, lax, and long (aristiform length 17–20 mm); dorsal pelage cinnamon brown or orange brown grizzled with dark brown or black; inci-

- sive foramina short (length 4.1–6.2 mm, mean 5.4 mm) but widest posteriorly (teardrop in shape; see Musser et al. 1998:196, Fig. 82; palatal excrescences frequently present; upper molars with high cusps; enamel islands (fossettes) on M1 and M2, specially the labial fossette, quickly obliterated by wear; m1 with ectolophid frequently present; diploid number of western Brazilian Amazon and Peruvian populations $2n=64$ and fundamental number $FN=70$ and $FN=64$, respectively; of Venezuelan populations $2n=76$ and $FN=85$, and of Brazilian central Amazon $2n=58$ and $NF=90$
- *Euryoryzomys macconnelli*
- 2'. Dorsal pelage soft and short (aristiform length 12–15 mm); dorsal pelage ochraceous brown grizzled with dark brown; incisive foramina short (length 4.0–6.0 mm, mean 5.2 mm) but widest medially; palatal excrescences absent; upper molars with lower cusps, more flat-crowned; enamel islands more persistent, well resistant to wear; m1 without noticeable ectolophid; $2n=80$ and $FN=86$ *Euryoryzomys emmonsae*
3. Zygomatic plates very wide (3.7–5.2 mm), defining extremely deep zygomatic notches 4
- 3'. Zygomatic plates narrower (3.2–4.6 mm), defining moderately deep zygomatic notches 5
4. Dorsal fur long (aristiform length 15–16 mm) and dense; head and body length (135–165 mm, mean 149.4 mm) equal to tail length (135–165 mm, mean 149.2 mm) in most specimens (few specimens have tail longer or shorter than head and body length); hindfoot more robust and longer (32–37 mm, mean 34 mm); zygomatic plates very wide (4.0–5.2 mm); zygomatic notches narrow and very deep; jugal absent; alisphenoid struts present in few specimens; palate without palatal excrescences *Euryoryzomys lamia*
- 4'. Dorsal fur very long (aristiform length 17–19 mm) and dense; tail length (130–180 mm, mean 146.5 mm) exceeds head and body length (110–159 mm, mean 136.3 mm) in all specimens; hindfoot shorter (30–36 mm, mean 32.9 mm); zygomatic plates wide (3.7–4.6 mm); zygomatic notches narrow and deep; jugal present; alisphenoid struts present; palate ornate with small palatal excrescences. *Euryoryzomys legatus*
5. Tail (112–185 mm, mean 151.7 mm) longer than head and body (105–196 mm, mean 143.2 mm); restricted to eastern South America, in Atlantic Forest from Bahia to Rio Grande do Sul states, Brazil, west to Misiones province, Argentina and eastern Paraguay
- *Euryoryzomys russatus*
- 5'. Tail (108–163 mm, mean 136.1 mm) equals head and body length (113–160 mm, mean 136.2 mm); restricted to western Amazon Basin south to western Mato Grosso state, Brazil. *Euryoryzomys nitidus*

Euryoryzomys emmonsae (Musser, Carleton, Brothers, and Gardner, 1998)

Emmons's *Euryoryzomys*

SYNONYMS:

Oryzomys emmonsae Musser, Carleton, Brothers, and Gardner, 1998:233; type locality "east [= right] bank of Rio Xingu, 52 km SSW Altamira (03°39'S/52°22'W), below 100 m in Estado de Pará, Brazil."

[*Euryoryzomys*] *emmonsae*: Weksler, Percequillo, and Voss, 2006:11; first use of current name combination.

DESCRIPTION: Characterized by long tail relative to head and body length (average about 114%); small and delicate cranium, with long but slender rostrum; narrow zygomatic plates; narrow interorbital region with smooth dorsolateral margins; and narrow occiput. Incisive foramina short and wide; bony palate correspondingly long.

DISTRIBUTION: *Euryoryzomys emmonsae* is currently known from the south bank of the Rio Amazonas, throughout the Amazonian interfluvial forest between the left bank of the Rio Tocantins to the right bank of the Rio Xingu, in Pará state, Brazil. Two records from the Rio Teles Pires (a headwater tributary of the Rio Tapajós) in Mato Grosso state are included here, although these might represent an undescribed species (see below and L. P. Costa 2003). All localities range in elevation from 80 and 200 m.

SELECTED LOCALITIES (Map 156): BRAZIL: Mato Grosso, Cláudia (L. P. Costa 2003), Reserve Ecológica Cristalino, 40 km N of Alta Floresta (MVZ 197523), Vila Rica (L. P. Costa 2003), 264 km N of Xavantina, Serra do Roncador (BM 81.436); Pará, 52 km SSW of Altamira, right bank Rio Xingu (type locality of *Oryzomys emmonsae* Musser, Carleton, Brothers, and Gardner), Floresta Nacional Tapirapé-Aquiri (Patton et al. 2000), Serra Norte (MPEG 8188).

SUBSPECIES: *Euryoryzomys emmonsae* is monotypic.

NATURAL HISTORY: Data summarized by Musser et al. (1998:236) suggests that this species is typically captured on the ground and under logs in viney forests and bamboo thickets. Most collecting localities are from nonflooded (*terra firme*) forest, although some are on riverbanks where the habitat may be influenced by seasonal flooding.

REMARKS: *Euryoryzomys emmonsae* is very similar to both *E. nitidus* and *E. russatus* in morphological and karyological traits, although the size and proportions of both body and cranial parts distinguish these three species (see Musser et al. 1998). The most important diagnostic feature of this species is the absence of a capsular process on the mandibular ramus. The karyotype of *E. emmonsae* is very similar to those described for *E. nitidus* (A. L. Gardner and Patton 1976) and for *E. russatus* (M. J. de J. Silva et al. 2000b), with $2n=80$ and $FN=86$. Specimens from two localities in the drainage of the Rio Teles Pires

Map 156 Selected localities for *Euryoryzomys emmonsae* (○) and *Euryoryzomys lamia* (●).

in Mato Grosso state share similar morphological traits with *E. emmonsae* but are divergent from it in mtDNA cytochrome-*b* sequence (L. P. Costa 2003: localities 20 and 21). These likely represent an undescribed species but are included here under *E. emmonsae* because they are placed with this species in phylogenetic analyses of sequence data.

Euryoryzomys lamia (Thomas, 1901)

Buffy-sided *Euryoryzomys*

SYNONYMS:

Oryzomys lamia Thomas, 1901g:528; type locality “Rio Jordão near Araguari,” Minas Gerais, Brazil.

Oryzomys (Oryzomys) lamia: Tate, 1932e:18; name combination.

[*Euryoryzomys*] *lamia*: Weksler, Percequillo, and Voss, 2006:11; first use of current name combination.

DESCRIPTION: Dorsal pelage long and dense, with aris-tiforms 15–16 mm long and bicolored tail equal to or shorter than head and body length (average about 92%). Skull long and robust; rostrum wide; zygomatic notches deeply excavated; zygomatic plates very wide with straight anterior free margin; incisive foramina medium in length (mean 6.2 mm; range: 5.5–7.0 mm) with parallel lateral margins; palatal excrescences absent; roof of mesopterygoid fossa completely ossified; and M2 with well-developed anterolabial cingulum.

DISTRIBUTION: *Euryoryzomys lamia* is known from three localities in the semideciduous forest of the Brazilian central plateau in western Minas Gerais and southern Goiás states (Percequillo 1998) and in Cerrado habitats of northern Goiás state (Bonvicino et al. 1998).

SELECTED LOCALITIES (Map 156): BRAZIL: Goiás, Anápolis (MNRJ 4352), Fazenda Fiandeira, Parque Nacional da Chapada dos Veadeiros, 65 km SSW of Cavalcante (MNRJ 46826); Minas Gerais, Araguari, Rio Jordão (type locality of *Oryzomys lamia* Thomas).

SUBSPECIES: *Euryoryzomys lamia* is monotypic.

NATURAL HISTORY: Available evidence (Weksler 1996; Percequillo 1998) suggests that *E. lamia* is a forest-dweller, inhabiting gallery forests (along the Rio Jordão) and a luxuriant semideciduous forest locally known as *Mato Grosso de Goiás* (at Anápolis; Faissol 1952). More recent published data suggest that this species also occurs in Cerrado habitats, such as *cerradão* (a dry woodland savanna), *cerrado sensu stricto*, and *campo úmido* (both open habitats), although, in the last, two specimens were captured in the ecotone with gallery forest (Bonvicino et al. 1998).

REMARKS: Although regarded as a synonym of *Euryoryzomys russatus* by Musser et al. (1998), *E. lamia* is now recognized as a separate species (e.g., Musser and Carleton 2005; Weksler et al. 2006). These two species differ in several morphological attributes (Weksler 1996; Percequillo 1998), notably, the tail length of *E. lamia* is equal to or shorter than the head and body length while that of *E. russatus* exceeds the head and body length; *E. lamia* has much deeper zygomatic notches; and *E. lamia* has a longer palate (palatal bridge length 7.2–8.2 mm) rarely ornamented by palatal excrescences whereas *E. russatus* possesses a shorter palate (palatal bridge length 5.6–7.6 mm). Univariate and multivariate analyses also differentiate the two taxa (Weksler 1996; Percequillo 1998; Musser et al. 1998). The two species also have different karyotypes ($2n = 58$, FN = 82 for *E. lamia* [Bonvicino et al. 1998] and $2n = 80$, FN = 86 for *E. russatus* [Musser et al. 1998]) and display divergent mitochondrial and nuclear sequences (Bonvicino and Moreira 2001; Weksler 2003).

The assignment of specimens from Cavalcante, Goiás state (reported by Bonvicino et al. 1998), to *E. lamia* deserves further investigation because there are noticeable morphometric differences between these specimens and series from Anápolis and Rio Jordão (Percequillo 1998).

Euryoryzomys legatus (Thomas, 1925)

Tarija *Euryoryzomys*

SYNONYMS:

Oryzomys legatus Thomas, 1925b:577; type locality “Carapari [= Carapari], 1000 m., about 35 kilometres north of Yacuiba, on the way towards Tarija,” Tarija, Bolivia. *Oryzomys (Oryzomys) legatus*: Tate, 1932e:18; name combination.

Oryzomys laticeps: Hershkovitz, 1960:544, footnote; part; not *Mus laticeps* Lund (= *Hylaeamys laticeps* [Lund]).

Oryzomys capito legatus: Cabrera, 1961:386; name combination.

[*Euryoryzomys*] *legatus*: Weksler, Percequillo, and Voss, 2006:11; first use of current name combination.

DESCRIPTION: Most informative traits include very dense and long dorsal pelage where aristiform hairs reach 17–19 mm in length; distinctly bicolored tail longer than combined head and body length (average about 108%); small skull (greatest length 32.9–36.8 mm), more delicate than *E. lamia* (length 34.2–38.1 mm) but more robust than other species; zygomatic notches narrow and deep, similar to *E. lamia* but less excavated; zygomatic plates wide; incisive foramina short (length 4.9–6.6 mm, mean 5.5 mm) and narrow, with parallel lateral margins; bony palate with small palatine excrescences; roof of mesopterygoid fossa completely ossified; and alisphenoid strut universally present.

DISTRIBUTION: The collecting localities of *E. legatus* are in premontane and montane forests along the eastern Andean slope in extreme southern Bolivia and northernmost Argentina, at elevations from 500 to 2,100 m; there are no records of this species in the Bolivian or Argentinian lowlands.

SELECTED LOCALITIES (Map 157): ARGENTINA: Jujuy, 8.4 km E of El Palmar, Sierra Santa Bárbara (Musser et al. 1998); Salta, Santa Victoria, Parque Nacional Baritú, Arroyo Santa Rosa (MACN 20708), Piquirenda (Musser et al. 1998). BOLIVIA: Chuquisaca, 2 km E of Chuhuayaco (AMNH 263886), Tola Orco, 40 km from Padilla (USNM 271584); Santa Cruz, 1 km NE of Estancia Las Cuevas (AMNH 264182), Mataracú (FMNH 129267); Tarija, 1 km S of Camatindi (AMNH 264186), 3 km SE of Cuyambuyo (AMNH 264280).

SUBSPECIES: *Euryoryzomys legatus* is monotypic.

NATURAL HISTORY: This species is found in mesic and transitional forests of Salta province, Argentina (Mares, Ojeda, and Kosco 1981:174), where specimens were commonly acquired in “littered forested areas supporting little undergrowth,” but also caught in “dense second growth vegetation along streams and roads, and along the rocky banks of water courses.” Mares, Ojeda, and Kosco (1981) also stated that this species inhabited burrows in the forest floor, but the notes on specimen tags (MACNBR) also indicate that it frequents the canopy (*habita la selva sobre los arboles*). *Euryoryzomys legatus* feeds on vegetation and insects. S. Anderson (1997:401) summarized available information on the ectoparasites found on Bolivian specimens, including the ticks *Eulaelaps halleri* and *Schistolaelaps mazzaias* well as the flea *Polygenis (Polygenis) typus*.

REMARKS: Musser et al. (1998) treated *E. legatus* as a synonym of *E. russatus*, but it is currently recognized as a

Map 157 Selected localities for *Euryoryzomys legatus* (○) and *Euryoryzomys nitidus* (●). Contour line = 2,000 m.

separate species (Musser and Carleton 2005; Weksler et al. 2006). The two are demonstrably different by morphologic and morphometric comparisons (Weksler 1996; Percequillo 1998), with the most distinctive morphological traits of *E. legatus* being the presence of a deep and narrow zygomatic notch and an alisphenoid strut present in all specimens. Limited mtDNA sequence analyses, however, suggest that *E. legatus* is nested within samples of *E. nitidus* (Patton et al. 2000). While not refuting the species distinctness of *E. legatus*, these data do suggest that the origin of this species has been relatively recent, possibly as a peripheral isolate of a more widespread *E. nitidus*. These data also strongly support phylogenetic separation from *E. russatus*.

Euryoryzomys macconnelli (Thomas, 1910)

McConnell's *Euryoryzomys*

SYNONYMS:

Oryzomys macconnelli Thomas, 1910b:186; type locality “River Supinaam [= Supenaam], a tributary of the lower Essequibo, Demerara, British Guiana,” Pomeroun-Supenaam, Guyana (see Musser et al. 1998:278).

Oryzomys incertus J. A. Allen, 1913c:598; type locality “La Murelia (altitude 600 feet), Rio Bodoquera, Caquetá, Colombia.”

Oryzomys mureliae J. A. Allen, 1915b:630; replacement name for *Oryzomys incertus* J. A. Allen, preoccupied by *Oryzomys alfaroi incertus* J. A. Allen.

Oryzomys (Oryzomys) macconnelli: Tate, 1932e:17; name combination.

Oryzomys (Oryzomys) mureliae: Tate, 1932e:17; name combination.

Oryzomys macconnelli macconnelli: Cabrera, 1961:392; name combination.

Oryzomys macconnelli mureliae: Cabrera, 1961:392; name combination.

[*Euryoryzomys*] *macconnelli*: Weksler, Percequillo, and Voss, 2006:11; first use of current name combination.

DESCRIPTION: Medium sized, with average head and body length 143 mm; tail equal to or longer than head and body (average 104%); closely resembles *E. nitidus* but differs in very dense, lax, long (aristiforms 17–20 mm), and orange to reddish brown fur in most samples. Skull with narrower zygomatic plates with correspondingly shallower zygomatic notches; wider interorbital region; shorter and wider incisive foramina (teardrop in shape); longer bony palate; alisphenoid struts absent in majority of specimens; m1 with ectolophid frequently present; capsular process not evident.

DISTRIBUTION: *Euryoryzomys macconnelli* is distributed throughout the Amazon Basin, from eastern Ecuador to eastern Pará state, Brazil, and from northern Guyana to southern Peru (Musser et al. 1998:176, Fig. 78). Over this extensive area, elevational records range from near sea level in the eastern Amazonian lowlands and Guianan region to about 1,500 m in the tepuis of Venezuela and Andean foothills of Peru.

SELECTED LOCALITIES (Map 158): BRAZIL: Amapá, Serra do Navio (MZUSP 20521); Amazonas, Barro Vermelho, left bank Rio Juruá (Patton et al. 2000), Macaco, left bank Rio Jaú (Patton et al. 2000), PD-BFF, 82 km N of Manaus (Patton et al. 2000), alto Rio Urucu (Patton et al. 2000); Mato Grosso, Aripuanã (L. P. Costa 2003), Juruena (L. P. Costa 2003); Pará, 54 km S and 150 km W of Altamira (Musser et al. 1998), Flexal, Itaituba-Jacareacanga, km 212 (USNM 545293), Floresta Nacional Tapirapé-Aquiri (INPA 2796), Igarapé-Assu (BM 4.7.4.65), 19 km S of Itaituba (Musser et al. 1998), Serra Norte (MPEG 15101). COLOMBIA: Caquetá, La Morelia [= La Murelia], Río Bodoquera (AMNH 33756). ECUADOR: Orellana, San José Abajo (Musser et al. 1998). FRENCH GUIANA: Cayenne, Arataye (USNM 548449). GUYANA: Pomeroun-Supenaam, Supenaam River (type locality of *Oryzomys macconnelli* Thomas). PERU: Amazonas, headwaters Río Kagka (MVZ 154972); Cusco, Río San Miguel (USNM 194564); Huánuco, Hacienda Éxito, Río Cayumba (Musser et al. 1998); Junín, Perené (BM 0.7.7.31); Puno, Pampa Grande, below San Ignacio on the Río Tambopata (FMNH 79900). SURINAM: Para, Finisanti, Saramacca River (FMNH 95595). VENEZUELA: Amazonas, Cerro Duida, Cabecera del Caño Culobra, 40 km NW of Esmeralda (USNM 406044); Bolívar, Auyán-tepuí (AMNH 131119).

SUBSPECIES: As currently understood, *E. macconnelli* is monotypic, but the considerable geographic variation in karyotype and mtDNA diversity (as described here) could signal greater specific and/or subspecific diversity than currently recognized.

NATURAL HISTORY: This uncommon terrestrial species is found exclusively in primary tropical evergreen rainforest (Musser et al. 1998) and is considered a good indicator of pristine forests (Patton et al. 2000), being negatively affected by forest fragmentation (Malcolm 1991). Malcolm (1990) reported trapping density of 0.387 individuals/ha and nocturnal census density of 0.095 individuals/ha in the central Brazilian Amazon, near Manaus; these values are smaller than those reported for other sympatric oryzomyines, especially *Hylaeamys megacephalus*. Individuals of both sexes with limited to moderate wear on the upper molars were sexually mature, with pregnant or lactating females found in both the rainy and dry seasons. Embryo counts ranged from two to four (modal number three) in the western Brazilian Amazon (Patton et al. 2000).

REMARKS: *Euryoryzomys macconnelli* has been consistently considered a valid species by most authors (Gyldenstolpe 1932; Tate 1932e; Ellerman 1941; Cabrera 1961; Pine 1973; A. L. Gardner and Patton 1976; Husson 1978; Musser and Carleton 1993; Musser et al. 1998), except for Hershkovitz (1960), who incorrectly included this species in the synonymy of *Hylaeamys megacephalus* (then *Oryzomys capito*; see Musser et al. 1998).

Analyses of geographic variation in external and cranial traits exhibited no significant differences among samples (Musser et al. 1998), but karyological data (summarized by Musser et al. 1998 and Patton et al. 2000) and molecular evidence (Patton et al. 2000) suggest that *E. macconnelli* is

Map 158 Selected localities for *Euryoryzomys macconnelli* (●). Contour line = 2,000 m.

composite. Populations north of the Amazon River are quite distinct, with the Rio Negro isolating two groups, one on the eastern and northeastern (left) bank with $2n=76$, $FN=85$ and another on the west (right) bank with $2n=58$, $FN=90$. Samples from Para state, Brazil, south of the Amazon River, and those from the western reaches of Amazonia in Ecuador, Peru, and western Brazil have a similar karyotype with $2n=64$, $FN=70$. The very limited mitochondrial sequence data suggest that each karyotype, and thus geographic region, represents reciprocally monophyletic lineages.

The status of *Oryzomys mureliae* J. A. Allen as a synonym of *E. macconnelli* was pointed out early by Tate (1932e) and confirmed by Musser et al. (1998). If, however, the geographic variants in this species merit taxonomic recognition, this is an available name (Voss et al. 2001).

Euryoryzomys nitidus (Thomas, 1884)

Elegant Euryoryzomys

SYNONYMS:

Hesperomys (Calomys) laticeps: Thomas, 1882:102; part (assignment of specimens from Peru); not *Mus laticeps* Lund.

Hesperomys (Oryzomys) laticeps: Thomas, 1884:452; part (assignment of specimens from Peru); not *Mus laticeps* Lund.

Hesperomys laticeps, var. *nitidus* Thomas, 1884:452; type locality "situated between the streams of Chanchamayo and Anamayo, at a little distance from the river Tutamayo [sic]" (Thomas 1884:447), and designated as "Amable Maria" based on the selection of a lectotype (Thomas 1927b:549); type locality further refined to "Amable María, valley of Río Tulumayo, 10 km south of San Ramón, Departamento de Junín, Peru, 2000 ft" (A. L. Gardner and Patton 1976:42).

[*Oryzomys*] *laticeps nitidus*: E.-L. Trouessart, 1897:525; name combination.

Oryzomys boliviae Thomas, 1901h:536; type locality: "Mapi-ri, Upper Beni River, (about 68°W. and 15°S.). Alt. 800 m," La Paz, Bolivia.

Oryzomys nitidus: Thomas, 1920h:228; name combination.

Oryzomys (Oryzomys) nitidus nitidus: Tate, 1932e:17; name combination.

Oryzomys capito nitidus: Cabrera, 1961:386; name combination.

[*Euryoryzomys*] *nitidus*: Weksler, Percequillo, and Voss, 2006:11; first use of current name combination.

DESCRIPTION: Medium sized, with mean head and body length 136.1 mm (range: 108–163 mm) and tail nearly as long (mean length 136.2 mm; range: 113–160); short and close dorsal pelage; upper parts bright tawny or tawny brown with ochraceous highlights along sides of head and body; venter whitish gray; unicolored tail,

mottled on ventral surface near tip; dorsal surfaces of forefeet and hindfeet covered with dense white hairs, claws nearly hidden by long and dense unguis tufts; all plantar pads present; superciliary, genal, and mystacial vibrissae moderately long, not reaching past ear. Skull elongate (mean skull greatest length 33.3 mm; range: 25.5–36.3 mm) with narrow interorbital region (compared with *E. macconnelli*) bounded by dorsolateral ridges; alisphenoid struts present in about half of specimens examined; incisive foramina long (mean 5.7 mm; range: 4.6–6.8 mm) and narrow; bony palate short; zygomatic plates wide, zygomatic notches correspondingly moderately deep. M2 with short paraflexus and labial as well as medial fossettes; m2 with moderately deep entoflexid and short hypoflexid extending only halfway across tooth, with fossetid present.

DISTRIBUTION: *Euryoryzomys nitidus* is restricted to the western Amazon Basin, east of Andes in Peru and Bolivia and extending into adjacent western Brazil, as far east as the left bank of the Rio Teles Pires. It ranges in elevation from about 200 m in Brazil to 1,500 m on the eastern Andean slopes of Peru.

SELECTED LOCALITIES (Map 157): BOLIVIA: Beni, Guayaramerín, Rio Mamoré (S. Anderson 1997), Lago Victoria (S. Anderson 1997); Cochabamba, 2 km E of Villa Tunari (AMNH 247779); La Paz, La Reserva (AMNH 264722), Mapi-ri (S. Anderson 1997); Pando, Río Nareuda (S. Anderson 1997); Santa Cruz, Parque Noel Kempff Mercado, 17 km S of Los Fierros (S. Anderson 1997), San Ignacio de Velasco (Musser et al. 1998), San Rafael de Amboró (Musser et al. 1998), 4 km N and 1 km W of Santiago de Chiquitos (S. Anderson 1997), 8 km SE of Tita (AMNH 260377). BRAZIL: Acre, Igarapé Porongaba, right bank Rio Juruá (Patton et al. 2000), Manuel Urbano, Sena Madureira, BR 364 km 8 (MPEG 10609); Mato Grosso, Apicás (L. P. Costa 2003), Juruena (L. P. Costa 2003); Mato Grosso do Sul, Urucum, 22 km S of Corumbá (USNM 390109). PERU: Ayacucho, San José, Río Santa Rosa above Hacienda Luisiana (LSUMZ 16693); Huánuco, Chinchavito, at the mouth of the Río Chiraco (Musser et al. 1998); Junín, Amable Maria (type locality of *Hesperomys laticeps* var. *nitidus* Thomas); Madre de Dios, Reserva Cusco Amazónico (Woodman et al. 1991); San Martín, Moyobamba (USNM 259606); Ucayali, Balta, Río Curanja (A. L. Gardner and Patton 1976).

SUBSPECIES: I treat *Euryoryzomys nitidus* as monotypic.

NATURAL HISTORY: Based on information compiled by Musser et al. (1998:188–189; see also Patton et al. 2000), *E. nitidus* is a terrestrial inhabitant of humid tropical evergreen forests, largely restricted to Amazonian uplands on the western and southwestern border of the Amazon Basin.

The species also occurs in mature and secondary deciduous forests and gallery forests through palm savannas and Cerrado, floodplain forest (including that adjacent to seasonally inundated swamp forest), and near anthropogenic areas (such as soccer fields, old vegetable gardens, and pastures). Emmons and Patton (2005) stated that *E. nitidus* was also captured in dry forests and grassland habitats in the Parque Nacional Noel Kempff Mercado of eastern Bolivia.

The outlier locality of Urucum in Mato Grosso do Sul (also called Serra do Urucum) is an isolated massif on the western border of the Brazilian Pantanal covered with deciduous forest. This area is characterized by the presence of various Amazonian mammalian taxa, such as the marmoset *Callithrix melanura* (Vivo 1991), the titi monkey *Callicebus donacophilus*, and the tree squirrel *Hadroskiurus spadiceus* (see that account).

REMARKS: My concept of *E. nitidus* is more restricted than that of Musser et al. (1998), because I believe that samples west of the Rio Teles Pires to the west bank of Rio Xingu belong to an undescribed species (see L. P. Costa 2003), but specimens from localities on the east bank of the Rio Xingu are *E. emmonsae* (see above). Therefore, it is likely that samples from the Serra do Roncador, assigned by Musser et al. (1998) to *E. nitidus*, belong to this undescribed form. Furthermore, specimens from Paraguayan and Argentinean localities, as reported by Musser et al. (1998), are not *E. nitidus* but rather *E. russatus*. A. L. Gardner and Patton (1976) suggested that *Oryzomys boliviae* was a synonym of *E. nitidus*, based on their examination of the holotype, a hypothesis subsequently confirmed by the morphological and morphometric analyses of Musser et al. (1998). The karyotype of *E. nitidus* consists of a $2n=80$ and $FN=86$ (A. L. Gardner and Patton 1976; Patton et al. 2000).

Euryoryzomys russatus (Wagner, 1848)

Russet *Euryoryzomys*

SYNONYMS:

Mus physodes Brants, 1827:139; type locality “Provinz San Paulo,” São Paulo, Brazil; preoccupied by *Mus physodes* Olfers, a species of *Reithrodon* (see Musser et al. 1998:284).

Hesperomys russatus Wagner, 1848:312; no type locality given in original description, but the selection by Musser et al. (1998) of a lectotype for *E. russatus*, from among specimens collected by J. Natterer, unequivocally established the type locality as Ipanema, São Paulo, Brazil (= Floresta Nacional de Ipanema, 20 km NW Sorocaba, São Paulo, Brazil, 23°26'7"S, 47°37'41"W, 701 m; L. P. Costa et al. 2003).

Hesperomys physodes: Burmeister, 1854:167; name combination.

Holochilus physodes: Fitzinger, 1867b:90; name combination.

Hesperomys Darwinii?: Hensel, 1872b:48; part; not *Mus darwini* Waterhouse.

Hesperomys laticeps var. *intermedia* Leche, 1886:693; type locality “Rio dos Linos [= Rio dos Sinos], Taquara do Mundo Novo [= Taquara],” Rio Grande do Sul, Brazil.

Calomys coronatus Winge, 1887:51; type locality “Lapa da Serra das Abelhas,” Lagoa Santa, Minas Gerais, Brazil.

Hesperomys (Oryzomys) laticeps var. *intermedia*: Ihering, 1893:15; name combination.

Hesperomys leucogaster: Ihering, 1897:150; not *Hesperomys leucogaster* Wagner [= *Sooretamys angouya*].

[*Oryzomys*] *laticeps intermedia*: E.-L. Trouessart, 1897:525; name combination.

Oryzomys intermedius: Thomas, 1901g:528; name combination.

Oryzomys physodes: Thomas, 1904b:142; name combination.

Oryzomys kelloggi Avila-Pires, 1959a:2; type locality “Brasil, Minas Gerais, Além Paraíba, Fazenda São Geraldo.”

Oryzomys ratticeps moojeni Avila-Pires, 1959b:3; type locality “Brasil, São Paulo, Cananéia, Morro de São João.”

Oryzomys capito intermedius: Cabrera, 1961:385; name combination.

[*Euryoryzomys*] *russatus*: Weksler, Percequillo, and Voss, 2006:11; first use of current name combination.

DESCRIPTION: Closely similar to *E. nitidus* but with differences that allow specific recognition based on greater average external, cranial, and dental dimensions. Large (mean head and body length 151.7 mm; range: 112–185 mm) with tail equal to or longer (mean length 143.2 mm; range: 105–196). Skull robust and large (mean greatest length 34.6 mm; range: 28.3–39.2 mm); molar toothrow long (mean length 5.1 mm; range: 4.5–5.5 mm; in *E. nitidus*, average length 4.8; range: 3.9–5.6 mm). Other differences between two species include moderately long and generally brighter dorsal pelage in *E. russatus*; usually shorter incisive foramina relative to occipitonasal length in most specimens (Musser et al. 1998); presence of alisphenoid strut in less than half of examined specimens; and presence of small sphenopalatine vacuities in several specimens.

DISTRIBUTION: *Euryoryzomys russatus* is distributed along the eastern Brazilian coastal region from Bahia (lowland) to Rio Grande do Sul (montane areas), including coastal islands in São Paulo and Rio de Janeiro states, and from there to the western highlands of São Paulo state, reaching Paraguay (Caaguazú) and Argentina (Misiones), and limited to the west by the Rio Paraná in São Paulo and by the Río Paraguay in Paraguay. *Euryoryzomys russatus* is also a part of the fossil fauna of Lagoa Santa (see Remarks). Specimens from Ceará and Paraíba states are provisionally assigned to this species (see Remarks).

SELECTED LOCALITIES (Map 159): ARGENTINA: Misiones, Puerto Gisela, San Ignacio (Musser et al. 1998). BRAZIL: Bahia, Ilhéus, Almada, Rio do Braço (MNRJ 9032); Ceará, São Benedito (MNRJ 37049), Sitio Friburgo, Serra de Batuité, Pacoti (MZUSP [ARP 15]); Espírito Santo, Castelo, 3 km NE Forno Grande (MNRJ 32813), Fazenda Santa Terezinha, 33 km NE of Linhares (UFMG [LPC 27]); Minas Gerais, Lagoa Santa (ZMUC uncatalogued specimen); Paraíba, Mata do Pau Ferro, 6 km from Areia (UFPB 2046); Rio de Janeiro, Centro de Primatologia, Magé (L. P. Costa 2003); Rio Grande do Sul, Fazenda Aldo Pinto, São Nicolau (MPEG 22249), Morro do Osório (UFRGS 1080); Santa Catarina, Florianópolis, Rio Tavares, CASAN, Rodovia Estadual SC 405 (LAMAQ 168); São Paulo, Ariri (MZUSP [ARP 5]), Estação Biológica de Boracéia (MVZ 183114), Lins, Campestre (MZUSP 6160), Teodoro Sampaio (MZUSP 8859). PARAGUAY: Caaguazú, Sommerfeld Colony #11 (MNRJ 32764).

SUBSPECIES: I treat *Euryoryzomys russatus* as monotypic.

NATURAL HISTORY: *Euryoryzomys russatus* is predominantly associated with forested coastal plains and with the evergreen and semideciduous forests of the coastal highlands. This species apparently avoids open vegetation types, such as the Cerrado and Chaco, preferring primary forests (Bonvicino et al. 1997; R. Pardini, pers. comm.). In northeastern Brazil, this species is found in montane enclaves covered by moist semideciduous forest in the Caatinga (locally called *brejos*).

The abundance of this species in the Brazilian Atlantic Forest varies at both large and small geographical scales. In some areas of southeastern Brazil, *E. russatus* is the most common terrestrial species (Bergallo 1994) while in others it is less common (Olmos 1992). In northeastern Brazil where the small mammal community is dominated by *Hylaeamys laticeps*, this species is uncommon (Laemmert et al. 1946; Pardini 2004).

Bergallo (1994) reported population and reproductive data for the species in southern Brazil. The home range varied from 0.16 to 1.12 ha, with a mean size of 0.46 ± 0.31 ha; population density, averaging 5.26 ± 1.02 individuals/ha, was stable throughout the year, with no correlation between rainfall and birth frequencies. Apparently this species breeds year-round, because juveniles were captured in every month except July, November, and January, and pregnant females were recorded from March to July, August, and November. Females attained reproductive maturity by day 115 following birth and could produce more than six litters in a single year (Bergallo 1995). Püttker, Bueno et al. (2013) described survival rates, population change rates, and capture probability for populations in different forest cover landscapes.

Euryoryzomys russatus builds egg-shaped nests (15 cm long and 10 cm wide), with dry leaves and grass, under or inside fallen logs, and among the aerial roots of various species of palms (Briani et al. 2001).

REMARKS: The record of *E. russatus* from Lagoa Santa (as *Calomys coronatus* Winge; see synonymy above) is based on specimens obtained from cave deposits. Several other species described from the cave material of Lagoa Santa (e.g., *Protopithecus brasiliensis*, *Caipora bambuiorum*, *Blarinomys breviceps*, *Delomys* sp., *Sooretamys angouya*; see Hartwig and Cartelle 1996; Voss and Myers 1991; C. R. Silva et al. 2003) are members of a wet forest community that is no longer found in the region. Although the vegetation of the Lagoa Santa region today is a mosaic of Cerrado and semideciduous forest habitats, no recent specimens of any of these species have been found at or in the vicinity of Lagoa Santa. Therefore, it is reasonable to assume that *E. russatus* is now presently extinct in this part of interior Brazil.

In the early nineteenth to middle twentieth centuries, several specific names were coined for this species. Each of these is available, but *russatus* Wagner has priority (see Musser et al. 1998). Throughout history, this species was considered to be a subspecies of *Hylaeamys laticeps* (Leche 1886; E.-L. Trouessart 1897), *Hylaeamys megacephalus* (Cabrera 1961), or even a synonym of *E. nitidus* (A. L. Gardner and Patton 1976). However, the validity of *Euryoryzomys russatus* as a full species is supported by morphological (Weksler

Map 159 Selected localities for *Euryoryzomys russatus* (●). Contour line = 2,000 m.

1996; Musser et al. 1998; Percequillo 1998) and molecular (Patton et al. 2000; L. P. Costa 2003) analyses.

Euryoryzomys russatus is the only species in its distributional range to have an orange to orange-rufous dorsal pelage sharply contrasting with a grayish-white to almost pure white ventral coloration; a white foot with very long and dense unguis tufts; an M2 with two enamel islands; and a distinct capsular process on the mandibular ramus.

While I assign samples of genus *Euryoryzomys* from *brejos* in northeastern Brazil (Paraíba and Ceará states; see Weksler 1996; Percequillo 1998; M. J. de J. Silva et al. 2000b) to *E. russatus*, these are likely to represent an undescribed species, based on morphological and karyological data. These samples have smaller and more delicate skulls, with shorter and narrower incisive foramina, an anterolingual cingulum on M2, and a karyotype with $2n=76$ rather than the $2n=80$, FN=86 that characterizes *E. russatus* throughout the majority of its range (E. J. C. Almeida and Yonenaga-Yassuda 1974, as "*Oryzomys capito*"; Musser et al. 1988).

Genus *Handleyomys* Voss, Gómez-Laverde, and Pacheco, 2002

Marcela Gómez-Laverde, Robert S. Voss,
and Víctor Pacheco

The genus *Handleyomys* includes two species: *H. fuscatus*, endemic to the western Andes of Colombia, and *H. intectus*, endemic to the central Andes of Colombia; the elevational range of the genus is from about 1,700 to 2,800 m. No fossil material is known. The following account is abstracted from Voss et al. (2002), with additional information based on newly examined specimens.

Handleyomys fuscatus and *H. intectus* are both small (17–34 g) mice with tails that are about as long as the combined length of the head and body (length of head and body 80–130 mm; length of tail 75–110 mm). The adult body pelage is fine and soft, uniformly dull brownish gray dorsally, but usually darker (sometimes almost blackish) middorsally than on the flanks; the ventral pelage is dark gray frosted with paler gray or buff and is not sharply countershaded. The tail appears naked to the eye (a sparse caudal pelage is visible under magnification) and unicolorous (dark above and below). Mystacial, superciliary, genal, submental, interramal, and carpal vibrissae are present; mystacial vibrissae are neither very short nor very long, extending posteriorly to (but not beyond) the caudal margins of the pinnae when laid back against cheeks. The pinnae are not large, but they are clearly visible above the fur of the head and are sparsely covered with short dark hairs. The manus is sparsely covered dorsally with short

pale hairs; the plantar surface is unpigmented, with two carpal and three interdigital pads; and the claws are short, neither conspicuously elongated nor unusually curved. The pes is long (21–26 mm) and narrow, with the outer digits much shorter than the middle three (the claw of digit I extends to the middle of the first phalanx of digit II, and the claw of digit V extends just beyond the first interphalangeal joint of digit IV); conspicuous unguis tufts of long silvery hairs are rooted at the bases of the claws on digits II to V, but the pedal dorsum otherwise is only sparsely covered with short pale (whitish or silvery) or dark-banded hairs; the plantar surface (including the heel) is naked, weakly pigmented (grayish in life), with two metatarsal and four interdigital pads; indistinct squamae (scale-like tubercles) are sparsely distributed along the outer distal plantar surfaces, but not in the center of the sole. Unusually for an oryzomyine, there are only six mammae (in inguinal, abdominal, and postaxial pairs).

The skull has a long, tapering rostrum flanked by shallow but distinct zygomatic notches; the interorbital region is hourglass shaped, neither greatly inflated nor unusually constricted, with rounded supraorbital margins; the braincase is moderately inflated and rounded, without prominent temporal crests, ridges, or beads. The zygomatic plates are moderately broad, with their anterior edged vertical or nearly so, with a rounded (never angular or spinous) anterodorsal contour. Premaxillae are short (not produced anteriorly beyond the incisors to form a rostral tube with the nasals). Incisive foramina are neither very short nor greatly elongated, averaging about 60% of the diastemal length (not extending posteriorly between the molar rows) and are widest near the premaxillary-maxillary suture. The palatal bridge is long and wide, without a median ridge or deep lateral gutters; the posterolateral pits are usually large and often complex. The mesopterygoid fossa does not penetrate anteriorly between the molar rows, and the bony roof of the fossa is complete or perforated only by narrow slits (it is never conspicuously fenestrated). The alisphenoid strut is absent, and the buccinator-masticatory foramen and the foramen ovale are therefore confluent. The carotid arterial morphology is primitive, with the orbitofacial circulation supplied by separate supraorbital and infraorbital branches of a large stapedial artery (= pattern 1 of Voss, 1988); the course of the supraorbital stapedial ramus is marked by a prominent squamosalisphenoid groove and a sphenofrontal foramen. The postglenoid foramen is separated from the large subsquamosal fenestra by a slender hamular process of the squamosal. The tegmen tympani either does not overlap the squamosal at all, or the tegmen tympani-squamosal overlap is shallow (not involving a distinct posterior suspensory process of the latter bone). The bullae are small, the pars flaccida of the tympanic mem-

brane is present and large, and the orbicular apophysis of the malleus is well developed.

The mandible has a well-developed, falciform coronoid process, and a distinct capsular process on the lateral mandibular surface is absent. The basihyal bone (known only in *H. fuscatus*) is not strongly arched and lacks an entoglossal process; the thyrohyals are shorter than the basihyal.

The incisors are ungrooved and opisthodont. The maxillary molar rows are parallel. The principal molar cusps, arranged in opposite labial/lingual pairs, are bunodont when unworn but are quickly eroded with age to the same level as other enamelled occlusal structures (the occlusal surfaces of most adult teeth are more or less planar); the labial and lingual re-entrant folds are interpenetrating (incipiently lophodont *sensu* Voss 1993); the anterocone of M1 is not divided into labial and lingual conules (an anteromedian flexus is absent); the anteroflexus is very deep, extending lingually beyond the dental midline on M1 and M2; anterolophs and mesolophs are large, fused with corresponding (antero- and meso-) styles on the labial margins of M1 and M2; posterolophs are distinct on M1 and M2, persisting with moderate to heavy wear; M3 is subtriangular in occlusal view, smaller than more anterior teeth, with most of the same occlusal elements but usually without a distinct hypocone or posteroloph. M1 has one accessory labial root (four roots total), but M2 and M3 are each three-rooted.

The anteroconid of m1 is undivided by a median flexid and is fused with the protolophid and/or the anterolophid to enclose a persistent internal fold of uncertain homology (anteroflexid and/or protoflexid); the anterolophid is absent on m2 and m3; the anterolabial cingulum is absent or indistinct on m2, and consistently absent on m3; the mesolophids and posterolophids are large and well developed on all mandibular teeth; the ectolophids are consistently absent. The m1 has an accessory labial root and occasionally also an accessory lingual root (three to four roots total); m2 and m3 each have two small anterior roots and one large posterior root (three roots total).

Axial skeletal elements include 12 ribs, 19 thoracolumbar vertebrae, 4 sacral vertebrae, and 28–30 caudal vertebrae; hemal arches appear to be present on the caudal vertebrae of *H. fuscatus*, but not on those of *H. intectus*. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. The entepicondylar foramen of the humerus is absent.

The stomach in both species is unilocular and hemiglandular, without any extension of glandular epithelium into the corpus; the bordering fold crosses the lesser curvature slightly to the right of the incisura angularis (between that

flexure and the pylorus), and it crosses the greater curvature opposite the incisura angularis. The gall bladder is absent. The morphology of the glans penis and other male reproductive structures is unknown.

SYNONYMS:

Aepeomys: J. A. Allen, 1912:89; part (description of *fuscatus*); not *Aeepomys* Thomas.

Oryzomys: Thomas, 1921j:356 (description of *intectus*); part; not *Oryzomys* Baird.

Thomasomys: Ellerman, 1941:369; part (listing of *fuscatus*); not *Thomasomys* Coues.

?*Nectomys*: Ellerman, 1941:351 (provisional listing of *intectus*); part; not *Nectomys* Peters.

Handleyomys Voss, Gómez-Laverde, and Pacheco, 2002:5; type species *Aepeomys fuscatus* J. A. Allen, by original designation.

KEY TO THE SOUTH AMERICAN SPECIES OF *HANDLEYOMYS*:

1. Hindfeet covered dorsally with dark-banded hairs (the melanic bands distinctly visible under low magnification); nasals short, truncated posteriorly at or near the premaxillomaxillary suture; incisive foramina anteriorly constricted, with lateral margins abruptly narrowed at or near the premaxillomaxillary suture; interparietal broad (transverse dimension) relative to its depth (anteroposterior dimension). *Handleyomys fuscatus*
- 1'. Hindfeet covered dorsally with pure white or indistinctly pigmented hairs; nasals long, extending posteriorly well beyond the premaxillomaxillary suture; incisive foramina smoothly tapering, with evenly rounded lateral margins; interparietal narrow (transverse dimension) relative to its depth (anteroposterior dimension) *Handleyomys intectus*

Handleyomys fuscatus (J. A. Allen, 1912)

Colombian Western Andes Cloud Forest Mouse

SYNONYMS:

Aepeomys fuscatus J. A. Allen, 1912:89; type locality "San Antonio (near Cali, alt. 7000ft), Cauca [= Valle del Cauca], Colombia."

Thomasomys fuscatus: Ellerman, 1941:369; name combination.

Thomasomys lugens fuscatus: Cabrera, 1961:431; name combination.

Handleyomys fuscatus: Voss, Gómez-Laverde, and Pacheco, 2002:23; first use of current name combination.

DESCRIPTION: See the Key.

DISTRIBUTION: *Handleyomys fuscatus* is known only from the western Andes (Cordillera Occidental) of Colombia between 1,800 and 2,530m in the departments of Antioquia and Valle del Cauca.

SELECTED LOCALITIES (Map 160): COLOMBIA: Antioquia, Vereda La Soledad, Finca La Reina (ICN 16510–16523); Valle del Cauca, Finca La Playa (Voss et al. 2002), San Antonio (type locality of *Aepeomys fuscatus* J. A. Allen).

SUBSPECIES: *Handleyomys fuscatus* is monotypic.

NATURAL HISTORY: This apparently terrestrial and nocturnal species inhabits both primary cloud forest and adjacent secondary growth, usually in cool and very humid environments (12–18°C mean ambient temperature; >2,000 mm annual precipitation) corresponding to the vegetation zone that Espinal and Montenegro (1963) called *Bosque muy húmedo montano bajo*. Four of six known pregnant females (each with two to three embryos) were collected during the rainy season (April or June), but another was taken during the late dry/early rainy season (September), and the fourth in the dry season (February); one pregnant female was also lactating in June. The only additional recorded lactating female was captured during the rainy season (September). Juveniles have been caught during the rainy season and the late dry/early rainy seasons.

REMARKS: The karyotype is $2n=54$, FN=62; the X and Y chromosomes are both submetacentrics (A. L. Gardner and Patton 1976).

Map 160 Selected localities for *Handleyomys fuscatus* (●) and *Handleyomys intectus* (○). Contour line = 2,000 m.

Handleyomys intectus (Thomas, 1921)

Colombian Central Andes Cloud Forest Mouse

SYNONYMS:

Oryzomys intectus Thomas, 1921j:356; type locality “Medellin. Santa Elena,” Antioquia, Colombia.

?*Nectomys intectus*: Ellerman, 1941:351; suggested name combination.

Oryzomys (*Oryzomys*) *intectus*: Tate, 1932e:16; name combination.

Handleyomys intectus Voss, Gómez-Laverde, and Pacheco, 2002:24; first use of current name combination.

DESCRIPTION: See the Key.

DISTRIBUTION: *Handleyomys intectus* is known only from the central Andes (Cordillera Central) of Colombia between 1,700 and 2,800 m, in the departments of Antioquia, Quindío, and Risaralda.

SELECTED LOCALITIES (Map 159): COLOMBIA: Antioquia, Santa Elena (type locality of *Oryzomys intectus* Thomas), Ventanas (Voss et al. 2002); Quindío, Salento (Voss et al. 2002).

SUBSPECIES: *Handleyomys intectus* is monotypic.

NATURAL HISTORY: This apparently terrestrial and nocturnal species occurs in the same types of cloud forest and secondary habitats as those inhabited by *H. fuscatus*. The only recorded pregnant female was caught during the rainy season (April) and gave birth to two young in the trap; one lactating female was captured during the dry season (January). Juveniles have been caught during both rainy and dry seasons.

REMARKS: The karyotype is $2n=54$, FN=68–70; the morphology of the X and Y chromosomes is undetermined (M. L. Bueno, M. Gómez-Laverde and C. A. Delgado-V., unpubl. data).

Genus “*Handleyomys*”

“*Handleyomys*” *alfaroi* (J. A. Allen, 1891)

Alfaro’s Rice Rat

Marcelo Weksler

This species is treated here independently because of its provisional position as a member of *Handleyomys*. The ex-“*Oryzomys alfaroi*” group was included in *Handleyomys* by Weksler et al. (2006); as they explained (Weksler et al. 2006:2), however, “[pending] the description of other new genera (by M. D. Carleton and G. G. Musser, pers. com.), we provisionally transfer members of the ‘*alfaroi* group’ (herein understood to include *alfaroi*, *chapmani*, *melanotis*, *rhabdops*, *rostratus*, and *saturationis*) to *Handleyomys*, a suboptimal but phylogenetically defensible nomenclatural option previously discussed by Weksler (2006).” Unfortunately, no new genus to encompass these taxa has yet been

described. The taxon is included in the Key to genera of the *Oryzomyini*, but not in the Key to species of *Handleyomys*.

Oryzomys alfaroi agrestis Goodwin, 1959:7; type locality "12 miles southeast of Tapachula, Chiapas, Mexico; altitude 1000 feet."

Oryzomys alfaroi gracilis: Cabrera, 1961:383; name combination.

Oryzomys alfaroi palmirae: Cabrera, 1961:383; name combination.

[*Handleyomys*] *alfaroi*: Weksler, Percequillo, and Voss, 2006: 2; name combination.

DESCRIPTION: Small sized; adult head and body length 90–106 mm, tail length 89–101 mm, hindfoot length 25–28 mm, ear length 14–17, mass 20–32 g; dorsal pelage color dull yellow-brown to dark reddish-brown; sides ochraceous to orangish; venter grayish white. Fur short (<5 mm); ears usually thinly lined with blackish or orangish hairs, sometimes appearing almost hairless. Tail either uniformly dark or weakly bicolored over proximal half, then dark to tip. Skull small with short rostrum; relatively broad

and rather low braincase; slender zygomata; temporal ridges slightly developed; interorbital region broad, lateral margins slightly elevated; incisive foramina short and wide and not reaching plane of M1s; molariform teeth small.

DISTRIBUTION: This species ranges predominantly in evergreen forests of tropical Middle America, from southern Mexico through Panama, extending through low and middle elevation forests of western Colombia and northwestern Ecuador in South America. Elevational range is from near sea level to about 2,500 m.

SELECTED LOCALITIES (in South America; Map 161): COLOMBIA: Antioquia, Concordia (type locality of *gracilis* Thomas); Boyacá, Muzo (AMNH 62784); Cauca, Sabanetas (AMNH 181451); Cesar, Villanueva, Sierra Negra (USNM 280562); Cundinamarca, Volcanes, Municipio de Caparrapí (USNM 282116); Huila, La Candela (AMNH 33867); Nariño, Barbaçoas (AMNH 34219); Valle de Cauca, Palmira (type locality of *palmirae* J. A. Allen), Río Frio (AMNH 32858). ECUADOR: Chimborazo, Puente de Chimbo (AMNH 62305); El Oro, 1 km SW of Puente de Moromoro (USNM 513561); Esmeraldas, Esmeraldas (AMNH 33205); Guayas, Bucay (AMNH 61343); Imbabura, Hacienda Chinipamba, Intag (type locality of *intagensis* Hershkovitz); Los Rios, Limón (AMNH 66948); Manabí, Cerro of Pata de Pajaro (AMNH 64771); Santo Domingo de los Tsáchilas, Santo Domingo de los Colorados (AMNH 213506).

SUBSPECIES: Musser and Carleton 2005:1145) listed eight nominal taxa in their concept of "*Oryzomys*" *alfaroi*. Five of these are Middle American forms, four of which were regarded as subspecies by Hall (1981). I treat South American representatives of this species as monotypic. Pending a thorough analysis of character trends, it is unclear if the South American populations would warrant subspecific designation separate from the eastern Panamanian "*H.*" *alfaroi dariensis* (see Hall 1981).

NATURAL HISTORY: In Costa Rica, Goodwin (1946) reported that "*H.*" *alfaroi* occurred on heavily forested mountain slopes in the humid lower tropical zone. In Nicaragua, individuals were captured in a variety of habitats, including grasslands, woodlands, and along rivers, but appeared to be uncommon (J. K. Jones and Engstrom 1986). These same authors reported a pregnant female in March with three embryos. In Belize, specimens were captured in both pitfalls and traps on the forest floor, usually in damp sites with intact overstory; one pregnant female had five embryos. "*Handleyomys*" *alfaroi* was reported as prey for the Blue-crowned Motmot (*Momotus momota*) in Costa Rica (J. L. Reid and Sanchez-Gutierrez 2010). One of two individuals collected in southern Mexico tested positive for Venezuelan equine encephalitis virus antibodies (Estrada-Franco et al. 2004). Both fleas (*Jellisonia amadoi*; Ponce-Ulloa 1989)

Map 161 Selected localities for "*Handleyomys alfaroii*" (●) in South America; distribution in eastern Panama from Hall (1981) and F. A. Reid (2009). Contour line = 2,000 m.

and mites (*Gigantolaelaps trapidoi*; D. Lee and Furman 1970) have been recovered in the fur of some individuals.

REMARKS: Haiduk et al. (1979) reported a karyotype of $2n=60$, $FN=104$ for specimens collected in Veracruz, México. Almendra et al. (2014) recently documented the phylogenetic relationship of specimens of *alfaroii* from Ecuador relative to Middle American taxa based on mtDNA and nucDNA sequences.

Genus *Holochilus* Brandt, 1835

Pablo R. Gonçalves, Pablo Teta, and Cibele R. Bonvicino

Marsh rats of the genus *Holochilus* are large rodents with numerous morphological specializations for an herbivorous diet and semiaquatic mode of life (Hershkovitz 1955b). The mass of adult individuals is 160–455 g, head and body length from 130–220 mm, tail length 115–183 mm, and ear length 14–22 mm (Massoia 1976b; Barreto and Garcia-Rangel 2005). The genus is broadly distributed throughout riparian or marshy habitats in tropical lowlands (Hershkovitz 1955b). It ranges from northern Venezuela and Guyana south to the temperate grasslands

and steppes of Uruguay and east-central Argentina, including through the open habitats in the Cerrado and Chaco ecoregions of central Brazil, Bolivia, and Paraguay.

The fur is short, dense, and soft; most species are tawny to brownish dorsally, grizzled by darker guard hairs; the ventral pelage varies from ochraceous to white, with the basal hair bands always grayish; ears are relatively small, rounded, and well furred; the muzzle is short; vibrissae are short and fine, none usually reaching to the ear tip; the tail is unicolorous, sparsely haired so that scales are visible, and varies in length from shorter than to as long as the head and body length; hindfeet are long and have webbing between the digits, most pronounced between dIII and dIII, and dIII and dIV, where the membrane extends to the distal ends of the first phalanges; natatory fringes are also well developed along the plantar margins; ungual tufts are absent or very short and do not conceal the claws on either forefeet or hindfeet; the plantar surface of the hindfoot has four reduced interdigital pads, one thenar pad, and a hypothenar that is variably present across populations and species of the genus; mammae number varies from 8 (pectoral, postaxial, abdominal, and inguinal pairs) to 10 (with the addition of a thoracic pair) among populations (Gyldenstolpe 1932; Hershkovitz 1955b; Massoia 1976b; Barreto and Garcia-Rangel 2005).

The skulls of *Holochilus* are heavily built, with a short and broad rostrum and squared braincase; the interorbital region is narrower than the rostrum and has a typical amphoral morphology (hourglass shaped) with symmetrically biconcave lateral margins; supraorbital margins have developed supraorbital beads; the zygomatic plates are broad with typically concave anterior profiles, sometimes marked by anterodorsal spines in adult specimens, and with their anterior margins reaching the nasolacrimal capsules; zygomatic notches are, consequently, well incised; the palate is moderately long, with the mesopterygoid fossa rarely extending anteriorly to the level of the third molars; the palatal bridge has a complex morphology, with a median ridge and two deep lateral sulci that coalesce caudally in a well-excavated pair of posterolateral palatal pits; auditory bullae are globular and predominantly composed of the ectotympanic, which almost completely obscures the periotic in ventral view; the stapedial foramen is absent, and the correlated absence of the sphenofrontal foramen and alisphenoid vascular groove identifies the derived carotid circulation pattern 3 (*sensu* Voss 1988); and a bony alisphenoid strut separates the buccinator-masticatory foramen from the anterior opening of the foramen ovale. The mandible is robust and deep, with the coronoid process nearly vertical and extending well above the condyloid process; the sigmoid notch is broad and oval (Gyldenstolpe 1932; Massoia 1976b; Voss and Carleton 1993; Carleton and Olson 1999; Voglino et al. 2004).

Upper incisors are opisthodont and are faced with angular enamel bands that form a distinct lateral bevel. Molars are flat crowned, moderately hypsodont, with cusps and connecting lophs in a single occlusal plane. Major cusps are ovate or subtriangular in occlusal outline, nearly opposite (*brasiliensis* group) or alternating (*sciureus* group). An anteroloph is absent and a reduced mesoloph(id)-like structure may be present in some species, partially fused to a paralophule (Pardiñas 2008); M1 has four roots; m1 has two large roots (anterior and posterior) and two accessory rootlets (lingual and labial); m2 and m3 are both two-rooted. Hershkovitz (1955b), Massoia (1971a), Voss and Carleton (1993) and Pardiñas and Galliari (1998c) described tooth morphology in great detail.

The stomach is unilocular-hemiglandular, with glandular epithelium covering an extensive area of the corpus because the bordering fold recurves sharply and extends beyond the esophageal orifice (Carleton 1973). The caecum is large (68 mm in a Uruguayan specimen of *H. brasiliensis*). A gall bladder is absent (Voss 1991a).

Hooper and Musser (1964) described the anatomy of the glans penis, and both Massoia (1971a) and Díaz de Pascual and Péfaur (1982) the baculum. *Holochilus* has a single pair of preputial glands that reach anteriorly slightly beyond the ventral flexure of the penis; the medial ventral prostates are longer than the lateral ventral prostates; vesicular glands are lobed medially and along their greater curvatures, and the subterminal flexures are smooth (Voss and Linzey 1981).

In the first taxonomic revision and hypothesis of intergeneric relationships of *Holochilus*, Hershkovitz (1955b) included the genus among a group of dentally high-crowned sigmodontines with sigmoidal molars lacking well-developed mesolophs (e.g., with *Sigmodon*, *Neotomys*, and *Reithrodon*). Shortly thereafter, however, Hooper and Musser (1964) disaggregated these taxa, based on phallic morphology. More recent analyses of morphological and molecular characters strongly support *Holochilus* as a member of the tribe Oryzomyini (Voss and Carleton 1993; Stepan 1995; M. F. Smith and Patton 1999; Weksler 2006).

Hershkovitz (1955b) allocated 13 nominal forms to the genus, but recognized only two species, *H. brasiliensis* and *H. magnus*. The first species included 10 nominal forms as subspecies (*amazonicus*, *balnearum*, *berbicensis*, *brasiliensis*, *guianae*, *incarum*, *leucogaster*, *vulpinus*, *nanus*, and *venezuelae*) with *sciureus* and *chacarius* as junior synonyms of *H. brasiliensis brasiliensis*. This arrangement was sustained more on the basis of convenience than as a result of geographic variation (Hershkovitz 1955b:661). Massoia (1971, 1976, 1981b) was the first to validate *chacarius* and *sciureus* as full species, and Voss and Carleton

(1993) coined *Lundomys* to contain *H. magnus*, the sister-genus of *Holochilus* in some phylogenetic hypotheses (e.g., Weksler 2006). Subsequent studies have suggested a larger number of species, revealing either morphological differentiation among synonymized nominal forms (e.g., Marques 1988; Voss and Carleton 1993; Voglino et al. 2004) or extensive cytogenetic variation (e.g., T. R. O. Freitas, Mattevi, Oliveira et al. 1983; Aguilera and Pérez-Zapata 1989; Nachman and Myers 1989; Nachman 1992a, b). The latest taxonomic accounts (Musser and Carleton, 2005; Barreto and García-Rangel 2005) recognize at least three valid species (*H. brasiliensis*, *H. chacarius*, and *H. sciureus*) in the genus, which is clearly an underestimate.

Based on external, cranial, and dental features, Massoia (1981b) and Voss and Carleton (1993) recognized two morphological groups in *Holochilus*: the *brasiliensis* group, which included *darwini*, *leucogaster*, and *vulpinus*; and the *sciureus* group, containing *amazonicus*, *balnearum*, *berbicensis*, *chacarius*, *guianae*, *incarum*, *nanus*, and *venezuelae*.

The *brasiliensis* group comprises large animals with dense and luxurious fur, a tail about as long as the head and body or longer, no hypothenar pad on the plantar surface of the hindfoot, eight pairs of mammae, pronounced postorbital ridges, a long palate, distinct and subsquamosal fenestrae, masseteric crests that become closely approximated anteriorly to form a single crest that extends beyond the anterior root of m1 and approaches the mental foramen, somewhat medially flattened upper incisors with an indistinct labial bevel, and opposite or slightly alternating main molar cusps with the posterior faces of protoconid and hypoconid oriented 45° inward and typically persistence of mesoloph(id)-like structures. Axial skeletal elements in specimens referred to in the literature as *H. b. brasiliensis* and *H. b. vulpinus* have modal counts of 12 ribs, 19 thoracolumbar vertebrae, and 33–35 caudal vertebrae.

The *sciureus* group includes medium-sized animals with short and close fur, a tail shorter than the head and body, a very small hypothenar pad occasionally present, ether 8 or 10 pairs of mammae, weak to pronounced postorbital ridges, a mesopterygoid fossa extending to or slightly between the third molars, subsquamosal fenestrae that are often obscured by an expanded hamular process or by an internal crest or septum of the periotic, upper, and lower masseteric crests closely approximated anteriorly to form a single crest in some populations or coalescing at the level of the anterior root of m1 in others, laterally flattened upper incisors with a distinct labial bevel, lower incisors flattened laterally with a lingual bevel, and alternating main molar cusps with the posterior faces of both protoconid and hypoconid transversally oriented and mesoloph(id)-

like structures typically absent. Axial skeletal elements have modal counts of 12 ribs, 19 thoracolumbar vertebrae, and 29–32 caudal vertebrae (in *H. chacarius*).

Holochilus has a rich fossil record, especially in middle latitudes of southern South America, ranging from Middle Pleistocene to Holocene (Ameghino 1889; Voss and Carleton 1993; Pardiñas 1999a, 2004, 2008; P. E. Ortiz 2001; Teta et al. 2004; Pardiñas and Teta 2011b). Steppan (1996) described *Holochilus primigenus*, an extinct species known from Tarija, Bolivia. Although Steppan placed *primigenus* in *Holochilus*, he considered it transitional between *Lundomys* and *Holochilus*. Carleton and Olson (1999), Pardiñas (2008), and Pardiñas and Teta (2011b) questioned the generic assignment, and L. F. Machado et al. (2013) removed *primigenus* to their newly described *Reigomys*, as a member of a clade that included *Pseudoryzomys* and *Holochilus* along with the extinct *Noronhomys* and *Carletonomys*.

In this account, we recognize *H. brasiliensis*, *H. chacarius*, *H. sciureus*, *H. venezuelae*, *H. vulpinus*, and the recently described *H. lagigliaias* valid species. Despite extensive intrapopulation cytogenetic variability (Nachman 1992a), known karyotypes can be arranged into four groups with discrete ranges of autosomal fundamental and diploid numbers (FN/2n ratio). Species distinctions in the *brasiliensis* and *sciureus* groups are thus largely based on cytogenetic variation. Unnamed forms believed to constitute cytogenetically different species, such as the one with 2n=50, FN=58 karyotype and from Colombia (A. L. Gardner and Patton 1976), are not addressed in this account.

SYNONYMS:

- Mus*: Desmarest, 1819a:62; part (description of *brasiliensis*); not *Mus* Linnaeus.
- [*Mus*] *Holochilus* Brandt, 1835:428; as subgenus; type species *Holochilus sciureus* Wagner, designated under the plenary power of the International Commission (ICZN 2001:Opinion 1984).
- Holochyse* Lesson, 1842:137; incorrect subsequent spelling of *Holochilus* Brandt.
- Hesperomys* Wagner, 1843a:535; part; not *Hesperomys* Waterhouse.
- Holochilus* Schinz, 1845:192; incorrect subsequent spelling of *Holochilus* Brandt.
- Mus* (*Holochilus*): P. Gervais, 1854:411; as subgenus; *brasiliensis* included as species.
- Holochilomys* Brandt, 1855:304; proposed as a replacement name for *Holochilus* Brandt (see Remarks).
- Holocheilus* Coues, 1874:177; incorrect subsequent spelling of *Holochilus* Brandt.
- [*Hesperomys*] *Holochilus*: Burmeister, 1879:210; as subgenus; included *vulpinus* as species and *brasiliensis* as synonym.

Sigmodon: Winge, 1887:12; part; not *Sigmodon* Say and Ord.

Hesperomys (*Holochilus*): Ihering, 1894:19; part (listing of *brasiliensis*); name combination.

Hesperomys (*Nectomys*): Ihering, 1894:19; incorrect assignment of *sciureus* Wagner to *Nectomys* Peters.

REMARKS: Brandt (1835:428) erected *Holochilus* as a subgenus of *Mus*, and named two species for it to contain: *Mus* (*Holochilus*) *leucogaster* (on p. 428) and *Mus* (*Holochilus*) *anguya* (on p. 430), the latter a misspelling of *Mus angouya* Desmarest (a homonym of *Mus angouya* G. Fischer, which today equals *Sooretamys angouya*; see that account). The type species of Brandt's *Holochilus* was subsequently designated by Miller and Rehn (1902:89) as *Mus* (*Holochilus*) *leucogaster*. Wagner (1842c) described *Holochilus sciureus* and provided an expanded diagnosis of Brandt's genus while noting that the teeth of both *leucogaster* and *anguya* were unknown but were likely the same as in his *sciureus*.

As detailed by Voss and Abramson (1999:256–257), however, the holotype of Brandt's *Mus leucogaster* is an hystricomorphous rodent, not a myomorphous rat to which the name *Holochilus* has been connected since 1835 (e.g., Palmer 1904; Gyldenstolpe 1932; Hershkovitz 1955b; Cabrera 1961; Musser and Carleton 1993). Brandt (1855:304, 315), in his monographic description of the major variants of rodent jaw anatomy, recognized the crucial distinction between these jaw morphologies and realized that his *Mus leucogaster* had the hystricomorph condition. Further, in admitting his mistake concerning the identity of Desmarest's *Mus angouya* (a myomorph), Brandt (1855:304) proposed the name *H. langsdorffii* for the taxon that he had previously called *H. anguya*, and classified *Holochilus* in the subfamily Echinomyina of his suborder Hystricomorphi, along with *Loncheres*, *Echinomys*, *Nelomys*, and *Mesomys*, all now in the Echimyidae. And he proposed *Holochilomys*, which he placed in the family Myoides of his suborder Myomorphi, to contain the myomorphous species referred by others to his *Holochilus* (e.g., Wagner 1842a, b, c; 1843a; Burmeister 1854). Among subsequent authors, only Peters (1861) used the name *Holochilomys* as Brandt had intended (for a myomorphous rodent), but without bibliographic reference; consequently, Cabrera (1961:503), for example, gave Peters credit for the name and listed *Holochilomys* Peters, 1861 as a junior synonym of *Holochilus* Brandt, without comment.

Voss and Abramson (1999) examined the holotypes of Brandt's *leucogaster* and *langsdorffii*, noting that the former was a specimen of *Trinomys*, the genus of spiny rats occurring in the Atlantic Forest of coastal Brazil, while the latter was referable to a *Proechimys*, the spiny rats of Amazonia and Middle America. Voss and Abramson (1999) thus

petitioned the International Commission to conserve *Holochilus* Brandt for the myomorphous marsh rats and both *Proechimys* J. A. Allen, 1899 and *Trinomys* Thomas, 1921 for the hystricomorphous spiny rats, name associations that had stood in the literature for nearly a century or longer. In Opinion 1984, the International Commission (ICZN 2001) used its plenary power to designate *Holochilus sciureus* Wagner, 1842 as the type species of *Holochilus*, an action that maintained *Holochilus* as a name for the group of myomorphous rodents for which it had long been used. The name associations that follow from this action, beyond the fixation of Brandt's *Holochilus* to a sigmodontine rodent include: (1) Brandt's *anguya*, which was a misspelling of *angouya* Desmarest, is appropriately associated with the sigmodontine rodent now called *Sooretamys angouya* (see that account), and not with a species of *Holochilus* (contra Musser and Carleton 2005:1119, who inadvertently misspelled the name *anguyu*). (2) Brandt's *leucogaster* should be associated with the echimyid *Trinomys*, and not with the sigmodontine *Holochilus* where it is often listed in synonymies (e.g., Musser and Carleton 2005:1119), although *leucogaster* cannot be equated with any of the currently recognized species (see the *Trinomys* account). (3) Brandt's *langsdorffii* is correctly associated with another echimyid, the genus *Proechimys*, but also cannot be equated to an extant species (see the *Proechimys* account).

KEY TO THE SPECIES OF *HOLOCHILUS*:

1. Shorter tail (<150 mm, <23 caudal vertebrae); M3 hypoflexus and hypocone absent *Holochilus lagigliai*
- 1'. Longer tail (>150 mm, >25 caudal vertebrae); M3 hypoflexus and hypocone always present 2
2. Hindfoot shorter (<46 mm); hypothenar pad absent; tail shorter than head and body; upper and lower masseteric ridges usually coalesce at the level of the posterior root of m1; M1 with expanded paracones; mesoloph(id)-like structure absent on M1–M2 and m1–m2 3
- 2'. Hindfoot larger (>47 mm); hypothenar pad present; tail equal in length, or slightly longer, than head and body; upper and lower masseteric ridges usually coalesce at the level of the anterior root of m1; M1 with unexpanded paracones; mesoloph(id)-like structure present on M1–M2 and m1–m2 5
3. Lophs(ids) compressed with acute outer margins; distributed throughout the lowlands of lower Paraguay Basin in Brazil (Mato Grosso do Sul state), Argentina, and Paraguay; characterized by $2n=48-56$, $FN=57-63$ *Holochilus chacarius*
- 3'. Lophs(ids) compressed with strongly acute and more prismatic outer margins; range elsewhere than Paraguay Basin of Argentina, Brazil, and Paraguay; $2n=44-46$ or $55-56$, $FN=56$ 4

4. Restricted to Venezuela; $2n=44-46$ and $FN=56$ *Holochilus venezuelae*
- 4'. Distributed throughout the Amazon Basin and north-eastern Brazil; $2n=55-56$, $FN=56$ *Holochilus sciureus*
5. Size smaller (condyloincisive length 34.6–36.9 mm, length of upper molar rows 6.3–7.5 mm); distributed throughout the Atlantic forest and adjoining areas of southeastern and southern Brazil; $2n=40$, $FN=56$ *Holochilus brasiliensis*
- 5'. Size larger (condyloincisive length 36.3–45.9 mm, length of upper molar rows 7.3–8.1 mm); distributed in Uruguay and northeastern Argentina, $2n=35-39$, $FN=57-61$ *Holochilus vulpinus*

Holochilus brasiliensis (Desmarest, 1819)

Brazilian Marsh rat

SYNONYMS:

Mus brasiliensis Desmarest, 1819a:62; type locality “Brésil”; restricted to Lagoa Santa, Minas Gerais, by Hershkovitz (1955b:662), based on the itinerary of August St.-Hilaire.

Holochilus brasiliensis: Gray, 1843b:114; part (listing of *Mus brasiliensis* Desmarest); first use of current name combination.

Holochilomys brasiliensis: Hensel, 1872b:32; name combination.

Hesperomys [*Holochilus*] *brasiliensis*: Ihering, 1894:19; name combination.

Holochilus wagneri Moojen, 1952:65; type locality “Matas de Ipanema, São Paulo,” Brazil.

Holochilus brasiliensis brasiliensis: Hershkovitz, 1955b:662; name combination.

Holochilus brasiliensis nanus: Hershkovitz, 1955b:666; part, not *Holochilus nanus* Thomas.

DESCRIPTION: Intermediate in size relative to other species recognized herein, with head and body length 167–211 mm, tail length 183–214 mm, and hindfoot length between 51–56 mm (Bonvicino, Oliveira, and D’Andrea 2008). General coloration cinnamon above, becoming brightly orange on sides and pale orange on venter, with throat, chest, and inguinal region entirely white.

DISTRIBUTION: *Holochilus brasiliensis* occurs in southeastern and southern Brazil, from Espírito Santo state to coastal Rio Grande do Sul state, including the eastern border of Minas Gerais, and west into the Humid Chaco of Paraguay. Most sites are located in the Atlantic Forest ecoregion, including both coastal and interior localities. Distributional limits in relation to those of *H. vulpinus* are unclear in southern Brazil, with the southernmost locality vouchered by a karyotyped specimen caught in the swampy grasslands of Pelotas, in Rio Grande do Sul.

SELECTED LOCALITIES (Map 162): BRAZIL: Minas Gerais, Lagoa Santa (type locality of *Mus brasiliensis* Desmarest), Pirapora (MNRJ 4271), Viçosa (ROM 77592); Paraná, Castro (MHNCI 552); Rio Grande do Sul, Pelotas (T. R. O. Freitas, Mattevi, Oliveira et al. 1983); Rio de Janeiro, Carapebus (NUPEM 237), Maricá (MNRJ 28809), Silva Jardim (MNRJ 61802); São Paulo, Floresta Nacional Ipanema (“Ipanema,” type locality of *H. wagneri*), UHE de Ourinhos, Rio Ribeira (Tiepolo 2007).

SUBSPECIES: We treat *Holochilus brasiliensis* as monotypic.

NATURAL HISTORY: This species is nocturnal, amphibious, and herbivorous, with capture sites associated with riparian and swampy habitats in the Brazilian Atlantic Forest. Despite its infrequent capture in live-traps, it is a common prey item of the Barn Owl (*Tyto alba*) and small carnivores. Rocha-Mendes et al. (2010) recorded it in the diet of three felid species in Paraná (*Leopardus pardalis*, *L. tigrinus*, and *Puma yagouaroundi*). *Holochilus brasiliensis* has been documented in *ratadas* (rapid and extreme local population increases), along with other sigmodontines, in Paraná state, Brazil (Hershkovitz 1955b). It is a reservoir of *Schistosoma mansoni* in São Paulo (Dias et al. 1978).

REMARKS: Desmarest’s *Mus brasiliensis* was based on a specimen received by the Muséum National d’Histoire Naturelle in Paris from Aguste St.-Hilaire, and referred to as “le rat du Brésil.” Some nominal forms treated under *H. brasiliensis* (e.g., Musser and Carleton 2005:1119) have proven to belong to other rodent genera. For example, *Mus leucogaster* Brandt, 1835:428, once considered to be a junior synonym of *H. brasiliensis*, and once the type species of *Holochilus* (Miller and Rehn 1902), is actually a *Trinomys* (Voss and Abramson 1999). *Holochilus canellinus* Wagner and *Hesperomys leucogaster* Wagner are synonyms of *Sooretamys angouya*, and *Mus physodes* Brants is a synonym of *Euryoryzomys russatus* (see Musser et al. 1998 and the accounts for *Sooretamys* and *Euryoryzomys*). Our delimitation of *H. brasiliensis* is also considerably more restricted than those of recent taxonomic treatments of large *Holochilus* with mesoloph(id)-like structures on the molars (e.g., Musser and Carleton 2005). Several populations previously identified as *H. brasiliensis*, mainly in Argentina, Paraguay, and Uruguay, are herein considered to belong to *H. vulpinus*.

The karyotype is $2n=40$ and $FN=56$, with eight large to medium-sized and one small biarmed autosomes, and 10 small uniarmed autosomes. The X chromosome is a medium-sized acrocentric; the Y is a small biarmed chromosome (T. R. O. Freitas, Mattevi, Oliveira et al. 1983). This karyotype has been recorded in *H. brasiliensis* populations from southern (T. R. O. Freitas, Mattevi, Oliveira

Map 162 Selected localities for *Holochilus brasiliensis* (●). Contour line = 2,000 m.

et al. 1983) and southeastern Brazil (MNRJ 61802; P. R. Gonçalves et al., unpubl. data).

Holochilus chacarius Thomas, 1906

Chacoan Marsh Rat

SYNONYMS:

Holochilus chacarius Thomas, 1906c:447; type locality “Chaco 1 league N.W. of Concepcion, [Concepción,] Paraguay.”

Holochilus balnearum Thomas, 1906c:447; type locality “Bañado de S. Felipe, Tucuman [= Tucumán]. Alt. 435 m,” Argentina.

Holochilus brasiliensis vulpinus: Hershkovitz, 1955b:662; name combination; part, not *Mus vulpinus* Brants.

Holochilus brasiliensis balnearum: Hershkovitz, 1955b:665; name combination.

Holochilus brasiliensis chacarius: Massoia, 1971a:13; name combination.

Holochilus chacarius chacarius: Massoia, 1976b:12; name combination.

Holochilus chacarius balnearum: Massoia, 1976b:56; name combination.

DESCRIPTION: Small for genus, with head and body length 140–201 mm, tail length 148–183 mm, and hindfoot length 37–46 mm (Massoia 1976b; Bonvicino, Oliveira, and D’Andrea 2008). General coloration above reddish to cinnamon, intermixed with long black hairs; sides of body buffy, brightening to ochraceous buff along lower edge;

throat, chest, and inguinal regions entirely white but remainder of ventral surface buff or grayish, with hairs white basally; some individuals with venter entirely white.

DISTRIBUTION: *Holochilus chacarius* occupies lowlands of the Chaco ecoregion from western Brazil and Paraguay south into Argentina. The range in Argentina includes a narrow band in the provinces of Jujuy, Salta, Santiago del Estero, and Tucumán, and a second, wider region in the Humid Chaco from Formosa province south to northeastern Buenos Aires. Although S. Anderson (1997) failed to record this species from Bolivia, Pardiñas and Teta (2011b) recently referred specimens from Santa Cruz department to *H. chacarius*. Distributional relationships between *H. chacarius* and *H. sciureus* need clarification, especially in Bolivia. Pardiñas and Teta (2011b) summarized the fossil record.

SELECTED LOCALITIES (Map 163): ARGENTINA: Buenos Aires, San Pedro (Voglino et al. 2004); Chaco, Roque Saenz Peña (Massoia 1976b); Corrientes, Manantiales (Massoia 1976b); Entre Ríos, Gualaguay (Voglino et al. 2004), Strobel (P. Teta, unpubl. data); Formosa, Bañado La Estrella (P. Teta, unpubl. data); Jujuy, Ledesma (Massoia 1976b); Salta, El Talar (Massoia 1976b); Santa Fe, Jacinto L. Aráuz (Teta and Pardiñas 2010), Puerto Gaboto (Voglino et al. 2004); Tucumán, Concepción (Massoia 1976b). BOLIVIA: Santa Cruz, Bañados del Izozog (MNK 2038). BRAZIL: Mato Grosso do Sul, Corumbá (MNRJ [LBCE 5409]), Fazenda Rio Negro, Aquidauna (MNRJ [LBCE 4401]). PARAGUAY: Cordillera, 12 km N (by road) of Tobatí (A. L. Gardner and Patton 1976).

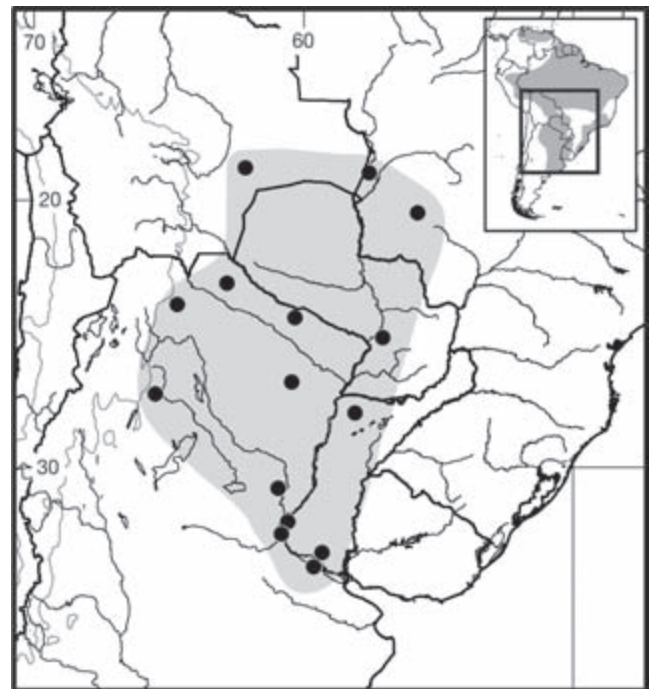

SUBSPECIES: Massoia (1976b) viewed *H. chacarius* as polytypic, with two subspecies: *H. c. balnearum* in southern Bolivia and northwestern Argentina in the lower Yungas, and *H. c. chacarius* in the Paraguayan Chaco and northeastern Argentina south to Buenos Aires province. These taxa can be differentiated by color and measurements as well as by several molecular markers (J. D. Hanson, unpubl. data).

NATURAL HISTORY: *Holochilus chacarius* inhabits swamps, flooded grasslands, and cultivated fields in open, mostly nonforested habitats; it swims, dives, and climbs well (Massoia 1976b). In the Paraguayan Chaco, *H. chacarius* was strongly associated with pasturelands, in areas with large amounts of litter and deep herbaceous ground cover (Yahnke 2006). Gestations under laboratory conditions last 27.8 ± 1 days, the mean number of embryos was 3.3 ± 1.2 , and sexual maturity was reached at the age of 60 days in both sexes (Piantanida 1993); the average number of embryos in western Paraguay was seven (range: 4–9). This species makes grass nests measuring 20–30 cm in diameter (weight = 25–95 g) in sugarcane and banana plantations, rice fields, or flooded grasslands, up to 1.4 m above the ground (Massoia 1976b). Nests found in north-

western Argentina were built on the ground in sugarcane plantations, with rounded living quarters constructed of interlaced strips and scraps of cane (Llanos 1944). This species also uses subterranean galleries, with one to three openings (Massoia 1971a). *Holochilus chacarius* is strictly herbivorous and can cause extensive damage to rice, banana, sugarcane, and other crops (Massoia 1974, 1976b). This species is a frequent prey item of the Barn Owl (*Tyto alba*) in northeastern Argentina (Voglino et al. 2004; Pardiñas, Teta, and Heinonen Fortabat 2005), and probably throughout its range.

REMARKS: Massoia (1971a, 1976b) and Pardiñas and Galliari (1998c) described external, cranial, and dental morphology. *Holochilus balnearum* Thomas has been considered a valid species (Reig 1986), a subspecies, or a junior synonym (at the subspecies level) of *H. chacarius* (Massoia 1976b; Musser and Carleton 2005).

The karyotype of *H. chacarius* is highly variable, with $2n$ ranging from 48 and 56 although the FN is more stable, varying between 57 and 60 (Vidal-Rioja et al. 1976; Nachman and Myers 1989; Nachman 1992a b). The karyotype described by Vidal et al. (1976), which was based on specimens from Salta province, is nearly identical to that of typical *H. sciureus*; however, specimens from the same general area, collected in Jujuy province, were recovered as sister to other *H. chacarius* as based on several gene sequences (J. D. Hanson et al., unpubl. data). Sequences

Map 163 Selected localities for *Holochilus chacarius* (●). Contour line = 2,000 m.

of the mtDNA ND3 gene of this species and of *H. vulpinus* differ by 18.9% (Kennedy and Nachman 1998).

Holochilus lagigliai Pardiñas, Teta, Voglino, and Fernández, 2013

Lagiglia's Marsh Rat

SYNONYM:

Holochilus lagigliai Pardiñas, Teta, Voglino, and Fernández, 2013; type locality not precisely known; the label of the holotype states only “El Nihuil–San Rafael–Mendoza–Argentina.” El Nihuil is a dam constructed in 1947 on the middle of the Río Atuel, at 35°04'S, 68°43'W, 1,300 m.

DESCRIPTION: Large, characterized by strikingly short tail, especially broad braincase, wide and anteriorly rounded zygomatic plates, bony palate without excrescences, M1 with subelliptical procingulum and persistent parastyle and protostyle, well-developed mesolophostyles on M1; M3 shorter than M2, and, uniquely for genus, with hypoflexus and hypocone absent.

DISTRIBUTION: *Holochilus lagigliai* is known only from the type locality and from Holocene fragments obtained at Gruta del Indio, both localities in Mendoza province, west-central Argentina.

SELECTED LOCALITIES (Map 164): ARGENTINA: Mendoza, EL Nihuil (type locality of *Holochilus lagigliai* Pardiñas, Teta, Voglino, and Fernández).

SUBSPECIES: *Holochilus lagigliai* is monotypic.

NATURAL HISTORY: No aspects of the natural history of *H. lagigliai* are known. The holotype was collected half a century ago nearby a dam (El Nihuil) along the Río Atuel at 1,300 m, the highest elevation recorded for the genus. The other three specimens referred to this species correspond to Holocene-aged mandibular remains from the Gruta del Indio archaeological site. *Holochilus lagigliai* is biogeographically isolated in the northwestern corner of Patagonia, with the nearest populations of living *Holochilus* about 500 km to the east (*H. brasiliensis* in Buenos Aires Province) and 850 km to the north (*H. chacarius* in Tucumán province; Massoia 1976). Along with other amphibious mammals, such as *Lutreolina crassicaudata*, *Hydrochoerus hydrochaeris*, and *Myocastor coypus*, *H. lagigliai* forms part of a group of subtropical mammals that have patchy records in Mendoza province. The conservation status of the species is unknown, as the southern corner of Mendoza province has been poorly prospected for mammals (Pardiñas et al. 2013).

REMARKS: The tail of *H. lagigliai* is strikingly short compared with other similarly sized marsh rats and may influence its swimming capacity. Amphibious rats use the tail to change direction during swimming and as a point of rest against the bottom surface (Sierra de Soriano 1969). Mor-

Map 164 Selected localities for *Holochilus lagigliai* (○) and *Holochilus vulpinus* (●). Contour line = 2,000 m.

phologically, *H. lagigliai* possesses a mosaic of traits present in species of the *sciureus* and *brasiliensis* groups, including a large cranium and molars, presence of a mesolophostyle, and small hindfeet and short tail. It does, however, share the unique M3 morphology with other members in the genus, with the hypoflexus and hypocone absent (Pardiñas et al. 2013).

Holochilus sciureus Wagner, 1842

Amazonian Marsh Rat

SYNONYMS:

Holochilus sciureus Wagner, 1842c:17; type locality “Rio Francisco [= Rio São Francisco] in Brasilien,” regarded to be in Minas Gerais, Brazil (Hershkovitz 1955b).

Hesperomys squamipes: Burmeister, 1854:165; part (listing of *sciureus*); not *Mus squamipes* Brants.

Mus (Holochilus) brasiliensis: P. Gervais, 1854:411; part (reference to “le rat du Brésil”); not *Mus brasiliensis* Desmarest.

Hesperomys (Nectomys) sciureus: Ihering, 1894:19; name combination but incorrect assignment of Wagner’s *sciureus* to the genus *Nectomys*.

Holochilus nanus Thomas, 1897c:495; type locality “Source [= Soure], Island of Marajó [= Ilha de Marajó], Mouth of the Amazon [= Rio Amazonas],” Pará, Brazil.

Holochilus guianae Thomas, 1901e:149; type locality “Kanuku Mountains, about 59° W. and 3° N., and on the savannahs near their base, at altitudes varying from 240 to 2000 feet,” Upper Takutu–Upper Essequibo, Guyana.

Holochilus amazonicus Osgood, 1915:188; type locality "Itacoatiara, Amazon River, [Amazonas,] Brazil."

Holochilus incarum Thomas, 1920h:227; type locality "Santa Ana," Cusco, Peru.

Holochilus sciureus berbicensis Morrison-Scott, 1937:20; type locality "Blairmont Plantation, Berbice, coastal British Guiana," Upper Demerara-Berbice, Guyana.

Holochilus brasiliensis nanus: Hershkovitz, 1955b:666; name combination.

Holochilus brasiliensis amazonicus: Hershkovitz, 1955b:667; name combination.

Holochilus brasiliensis incarum: Hershkovitz, 1955b:668; name combination.

Holochilus brasiliensis guianae: Hershkovitz, 1955b:668; name combination.

Holochilus brasiliensis berbicensis: Hershkovitz, 1955b:669; name combination.

Holochilus sciureus berbicensis: Barreto and García-Rangel, 2005:2; name combination.

Holochilus sciureus sciureus: Barreto and García-Rangel, 2005:2; name combination.

DESCRIPTION: Smallest species in genus, head and body length 123–193 mm, tail length 115–178 mm, and hindfoot 35–46 mm. General coloration above coarsely mixed brownish and rufous, darkest at midline and lighter and more ochraceous on sides; ventral surface whitish, washed with buff, hairs with narrow slate gray bases.

DISTRIBUTION: *Holochilus sciureus* occurs in the lowlands of the Guyanas, Bolivia, Peru, and Brazil. It may extend to northwestern Argentina (Vidal-Rioja et al. 1976; but see Remarks for *H. chacarius*).

SELECTED LOCALITIES (Map 165): **BOLIVIA:** Beni, Totaisal, 1 km SW Estación Biológica del Beni (S. Anderson 1997), Río Tijhamuchi (S. Anderson 1997); Santa Cruz, 3.5 km W of Estación El Pailón (S. Anderson 1997), San Rafael de Amboró (S. Anderson 1997), 9 km SE of Tita (MSB 55299). **BRAZIL:** Alagoas, Penedo (J. A. Oliveira et al. 2003); Amazonas, Altamira, right bank Rio Juruá (Patton et al. 2000), Itacoatiara (type locality of *Holochilus amazonicus* Osgood); Bahia, Bom Jesus da Lapa (MNRJ 4145); Ceará, Fortaleza (J. A. Oliveira et al. 2003), Ipu (J. A. Oliveira et al. 2003); Mato Grosso, Taiamã Island, Cáceres (T. R. O. Freitas, Mattevi, Oliveira et al. 1983); Minas Gerais, Jaíba (MNRJ 43825), Pirapora (MNRJ 4208); Pará, Soure, Ilha de Marajó (type locality of *Holochilus nanus* Thomas), Utinga (MNRJ 20928); Pernambuco, Bodocó (J. A. Oliveira et al. 2003), Pesqueira (J. A. Oliveira et al. 2003); Roraima, Caracará, Parque Nacional do Viruá (MNRJ [JAO 2059]). **GUYANA:** Mahaica-Berbice, Blairmont Plantation (type locality of *Holochilus sciureus berbicensis* Morrison-Scott); Potaro-Siparuni, Paramakatoi (USNM 565655); Upper Takutu–Upper Esse-

quibo, Kanuku Mountains (type locality of *Holochilus guianae* Thomas). **PERU:** Ayacucho, Hacienda Luisiana (A. L. Gardner and Patton 1976); Cusco, Santa Ana, upper Río Urubamba Valley (Thomas 1920h); Loreto, Genaro Herrera (Aniskin 1994); San Martín, Rioja (FMNH 19853); Ucayali, Yarinacocha (LSUMZ 16709). **SURINAM:** Sipaliwini, Sipaliwini airstrip (R. J. Baker et al. 1983).

SUBSPECIES: We regard *Holochilus sciureus* as being monotypic, although Barreto and García-Rangel (2005) recognized two subspecies (*H. s. sciureus* from the Orinoco Basin [including *venezuelae* J. A. Allen, herein regarded as a distinct species] and *H. s. berbicensis* from the Amazon Basin). This hypothesis needs to be evaluated by an adequate review of museum specimens.

NATURAL HISTORY: Barreto and García-Rangel (2005) summarized general characters, distribution, form and function, ontogeny and reproduction, ecology, behavior, and genetics in a treatment that also included *H. venezuelae*. *Holochilus sciureus* is found primarily in the Amazon drainage and in the savannas of Guyana (Twigg 1962; Barreto and García-Rangel 2005). It occurs in open areas, inundated grass patches along river banks, or in small agricultural plots close to river banks in lowland rainforest (Emmons and Feer 1997; Patton et al. 2000). It feeds mainly on leaves and seeds of savanna grasses but is also a major crop pest in sugarcane fields. In Guyana, it constructs spherical, dual-chambered nests, usually placed 0.5–1.5 m above the ground in sugarcane and rice fields. Sometimes, nests consist only of a mass of fine leaves placed in cracks in the soil, under dense grass or tussocks, or on the soil surface beneath dense litter (Twigg 1962, 1965).

Embryo counts for pregnant females ranged from one to eight in the coastal region of Guyana (Twigg 1965), and four to six in northeastern Brazil (Moojen 1952). In the Amazonian forests of western Brazil, Patton et al. (2000) caught males with scrotal testes and pregnant or lactating females in the months of August through November. In Bolivia, a lactating female was taken in March; nonpregnant females were recorded in May, September, and October (S. Anderson 1997). In Guyana, males with scrotal testes made up 70–98% of the population, and >27% of females were reproductively active (Twigg 1962). Litter size was affected by environmental variables and increased with the size and age of the females (Twigg 1965). In captivity, gestation lasted about 28–30 days, and the mean number of embryos was 3.1 (range: 1–6); males reached maturity at the age of 2–3 months and females within 2–5 months (Mello 1986). This species is a reservoir of *Leishmania (Viannia) brasiliensis* at Amajari, Pernambuco state, Brazil (Brandão-Filho et al. 2003).

REMARKS: Massoia (1981b) raised *sciureus* Wagner to species rank, distinguishing between this taxon

and members of the *brasiliensis* group of species. Our deductions about the concept of this species stem from the analysis of samples from northeastern Brazil (Bahia, Alagoas, Pernambuco, and Ceará states) and Amazonia, which appear to form a morphologically cohesive entity lacking mesoloph-like structures on M1–M2 and with upper and lower mandibular masseteric ridges fused at the level of the anterior portion of m1 in most specimens. In addition, Pardiñas and Galliari (1998c) and Pardiñas and Teta (2011b) found morphological differences between *H. sciureus* and *H. chacarius*, particularly in their respective lower dentitions, including the form of the lophs (compressed with acute outer margins in *H. chacarius* versus compressed with strongly acute outer margins and more prismatic in *H. sciureus*); form and size of the anteromedian fossetid (subcircular and large in *H. chacarius* versus transversally elongated and small in *H. sciureus*); and occlusal development of the metaflexid (scarcely developed, not reaching the midline of the tooth in *H. chacarius* versus well developed, freely connected with the protoflexid in subadults of *H. sciureus*; see also Percequillo 2006). Petter and Tostain (1981) described morphological variation in M3 for French Guiana specimens.

This species is characterized by $2n=55-56$ and $FN=56$, with a marked predominance of acrocentrics in the autosomal complement, as based on specimens from Argentina (Vidal-Rioja et al. 1976), Brazil (T. R. O. Freitas, Mattevi, Oliveira et al. 1983), Peru (A. L. Gardner and Patton 1976; Aniskin 1994), and Surinam (R. J. Baker et al. 1983). Karyotypes from specimens identified as *H. balnearum*

(= *H. chacarius* herein) from northwestern Argentina are nearly identical to those of *H. sciureus* (Vidal-Rioja et al. 1976; but see Remarks under *H. chacarius*), leaving some question as to whether *H. sciureus* may extend south of 20°S latitude.

Holochilus venezuelae J. A. Allen, 1904

Venezuelan Marsh Rat

SYNONYMS:

Holochilus venezuelae: J. A. Allen, 1904b:330; type locality “El Llagual [= El Yaguel], [Bolívar,] Venezuela.”

Holochilus brasiliensis venezuelae: Hershkovitz, 1955b: 670; name combination.

Holochilus sciureus: Voss and Carleton, 1993:12; part (*venezuelae* listed as synonym); not *Holochilus sciureus* Wagner.

DESCRIPTION: Second largest species, with head and body length 130–226 mm, tail length 124–194 mm, and hindfoot 36–48 mm (O. J. Linares 1998). General color reddish brown above, strongly streaked with black mid-dorsally, lighter and more fulvous on sides; and reddish fulvous on lower back and rump; venter buffy gray, hairs gray basally with yellowish white to deep buff tips; feet thinly haired, grayish flesh-colored; claws whitish with subapical dusky ring, and fringed with whitish hairs at base; tail dark brown, not appreciably bicolored, with short black bristles increasing in length and abundance apically; terminal fifth of tail well clothed with blackish bristly hairs that conceal underlying scales (J. A. Allen 1904b).

DISTRIBUTION: *Holochilus venezuelae* occurs in Venezuela, from the lower Orinoco Basin to Lago Maracaibo (Fuentes and Poleo 2005). The distributional limits of *H. venezuelae* in comparison with those of *H. sciureus* need clarification.

SELECTED LOCALITIES (Map 166): VENEZUELA: Bolívar, El Yagual (type locality of *Holochilus venezuelae* J. A. Allen); Guárico, Calabozo (Eiris and Barreto 2009); Portuguesa, Piritu (FLMNH 13323); Zulia, Misión Tokuko (USNM 448570).

SUBSPECIES: *Holochilus venezuelae* is monotypic.

NATURAL HISTORY: *Holochilus venezuelae* is considered an important agricultural pest in Venezuelan rice plantations, with densities measured between 5 and 713 rats/ha (Cartaya and Aguilera 1985). Its diet is mostly grasses, especially *Leptochloa scabra* and *Oryza sativa*, with small amounts of Cyperaceae, dicots, and invertebrates (A. M. G. Martino and Aguilera 1993). The mean home range size for 11 individuals inhabiting one rice field was 0.278 ha (Cartaya and Aguilera 1984). Eiris and Barreto (2009) examined home range, territoriality, individual movement, and dispersal. Gestation lasts about 29 days, and the mean number of embryos ranged between 5.8 (Venezuelan Lla-

Map 165 Selected localities for *Holochilus sciureus* (●). Contour line = 2,000 m.

nos) and 7.4 (Acarigua, Venezuela) (Agüero 1978; Cartaya 1983; Poleo and Mendoza 2001). The mass of pregnant females increased about 48% (Aguilera 1987). In Venezuelan savannas dominated by *Paspalum fasciculatum*, marsh rats account for 0.2–1.3% of all rodents captured. Ectoparasites found on *H. venezuelae* include mites and ticks (*Amblyomma ovale*, *Androlaelaps fahrenholzi*, *Eutrombicula alfreddugesi*, *E. batatas*, *Gigantolaelaps canestrinii*, *G. mattogrossensis*, and *Ornithonyssus bacoti*), lice (*Hoplopleura contigua* and *H. quadridentata*), and a flea (*Polygenis dunni*). Known endoparasites include the nematodes *Physaloptera* sp., *Stilestrongylus* sp., and *Strongyloides* sp. (Guerrero 1985).

REMARKS: *Holochilus venezuelae* has been considered a full species (Aguilera et al. 1993), a subspecies of *H. sciureus* (O. J. Linares 1998), or a junior synonym of *H. s. sciureus* (Barreto and García-Rangel 2005). This taxon, however, is characterized by a karyotype with $2n=44$, $FN=56$ (Aguilera and Pérez-Zapata 1989), and thus with a relatively higher $FN/2n$ ratio than *H. sciureus*. A. L. Gardner and Patton (1976) described a karyotype from Villavicencio, Colombia, with $2n=50$, $FN=58$, one outside the known karyotypic variation for *H. venezuelae* and *H. sciureus* and which may represent an undescribed form. Further morphological and molecular comparisons are needed to test the affinities between the Colombian form and *H. venezuelae*. If these two forms prove to be conspecific, the range of *H. venezuelae* will extend west-

Map 166 Selected localities for *Holochilus venezuelae* (●). Contour line = 2,000 m.

ward into the headwaters of the Meta-Orinoco fluvial system in Colombia.

Holochilus vulpinus (Brants, 1827)

Crafty Marsh Rat

SYNONYMS:

Mus vulpinus Brants, 1827:137; type locality “Brasil”; regarded as Rio Uruguay, southeastern Brazil, by Lichtenstein (1830; see Hershkovitz 1955b:660); restricted to Maldonado, Uruguay, by Cabrera (1961), but Cerqueira (1975) convincingly placed the type locality in Brazil, on the banks of Rio Uruguay, between Itaqui and Uruguay, Rio Grande do Sul.

Mus Braziliensis Waterhouse, 1839:58; type locality “Bahia Blanca,” Buenos Aires, Argentina; not *Mus brasiliensis* Desmarest (see Remarks).

Holochilus brasiliensis: Gray, 1843b:114; part (listing of *brasiliensis* Waterhouse); not *Mus brasiliensis* Desmarest.

H[olochilus]. vulpinus: Wagner, 1843a:554; first use of current name combination.

Hesperomys vulpinus: Burmeister, 1854:163; name combination.

Hesperomys [(Holochilus)] vulpinus: Burmeister, 1879:210; name combination.

Holochilus multannus Ameghino, 1889:117; type locality “río Luján cerca de la estación Olivera en la provincia de Buenos Aires,” Argentina.

Holochilus Darwini Thomas, 1897c:496; replacement name for *Mus brasiliensis* Waterhouse, which is preoccupied by *Mus brasiliensis* Desmarest.

Holochilus chrysogaster Cabrera, 1912:102; *nomen nudum*, erroneously attributed to Waterhouse.

Holochilus brasiliensis vulpinus: Hershkovitz, 1955b:662; name combination.

DESCRIPTION: Largest species in genus, with range in head and body length 141–238 mm, tail length 160–238 mm, and hindfoot 41–55 mm (Massoia 1976b; Bonvicino, Oliveira, and D’Andrea 2008). General coloration above deep orangish to reddish brown strongly intermixed with long, glistening blackish brown hairs; sides bright ochraceous buff; ventral surface entirely white (northern populations), with narrow band of grayish to orangish hairs, or golden yellowish with throat and chest covered by patches of entirely white hairs (Massoia 1976b).

DISTRIBUTION: *Holochilus vulpinus* ranges from Paraguay and east-central Argentina throughout Uruguay to Rio Grande do Sul state in Brazil (Massoia 1976b, 1981b; Marques 1988). Extralimital fossils, referred to *H. brasiliensis* by Pardiñas and Teta (2011b), suggest that this species had a wider distribution during the Late Holocene,

reaching the northern border of Patagonia and the hill systems of central Argentina.

SELECTED LOCALITIES (Map 164): ARGENTINA: Buenos Aires, Arroyo Brusquitas (Massoia 1976b), Arroyo Chasicó (Massoia 1976), Bahía Blanca (type locality of *Holochilus brasiliensis* Waterhouse), Estancia La Providencia (Teta, González-Fischer et al. 2010), Mar del Tuyú (Massoia 1976b), Marucha (Teta, González-Fischer et al. 2010), 20 km S of Pedro Luro on Hwy 3 (Formoso et al. 2010), Punta Lara (Massoia 1976); Chaco, Parque Nacional Chaco (Teta, González-Fischer et al. 2010); Córdoba, Marull (Jayat et al. 2006 [erroneously cited as for *H. chacarius*]); Misiones, Oberá, Escuela Provincial 639 “Rosario Vera Peñaloza,” Lote 92, Sección II de Campo Ramón (Massoia 1993); Santa Fe, Jacinto L. Aráuz (Teta and Pardiñas 2010). BRAZIL: Rio Grande do Sul, Itaqui (Tiepolo 2007). PARAGUAY: Estancia Yacaré (GD 071). URUGUAY: Montevideo, Parque Lecocq (E. M. González 1996).

SUBSPECIES: We regard *Holochilus vulpinus* as monotypic, but Massoia (1976b), based on morphometrics, treated *darwini* Thomas as a subspecies separate from a more northern nominal form.

NATURAL HISTORY: *Holochilus vulpinus* constructs spherical and unlined nests of leaves, sticks, and grasses that average 22–27 mm in diameter or excavates galleries at the water level. Nests are often in tangles of vines and terminal forks of tree branches, up to 2–3 m above the ground (Barlow 1969) or in hygrophilous vegetation such as the bulrushes *Schoenoplectus californicus* or *Scirpus giganteus* (Cyperaceae) as high as 40–50 cm above the water level (Massoia 1976b). In Buenos Aires province, Argentina, up to seven young individuals were found in each nest (Massoia 1976b). In Uruguay, males and females found in reproduction condition were caught in May and April; pregnant females had two to four embryos (Barlow 1969). Population densities in southeastern Buenos Aires reached 4.3 individuals/ha (range 0–12.5; Dalby 1975). In Uruguay, Barlow (1969) found 45 nests in an area of 50 ha. Plants, including aquatic, riparian, and cultivated species, comprise the diet. Barlow (1969) described the molt cycle in Uruguayan specimens. This species is infested by the mites *Laelops manguinhosi*, *Androlaelaps fahrenheitzi*, and *Gigantolaelaps wolffsohni*, and the fleas *Craneopsylla minerva*, *Polygenis* (N.) *atopus*, *P.* (N.) *frustratus*, *P.* (P.) *acodontis*, *P.* (P.) *platensis* (Nava et al. 2003; Navone et al. 2010), the mite *Notoedres muris* (Klompen and Nachman 1990), the digenean *Urotrema scabridum*, *Cladorchis pyriiformis*, and the nematode *Tapironema coronatum* (Durette-Desset et al. 1997).

REMARKS: Waterhouse (1839) described *Mus brasiliensis* based on a specimen collected by Charles Darwin

at Bahía Blanca, on the coast of Buenos Aires province, Argentina. Although Waterhouse equated his animal to A. Saint-Hilaire’s “*le rat du Brésil*,” which formed the basis for Desmarest’s earlier description of *Mus brasiliensis*, Waterhouse’s taxon is not the same species although his *Mus brasiliensis* is pre-occupied by Desmarest’s name. Thomas (1897c) recognized this problem and proposed *Holochilus darwini* as a replacement for Waterhouse’s *brasiliensis*.

Massoia (1971a, 1976b) and Pardiñas and Galliari (1998c) described external, cranial, and dental morphology of *H. vulpinus* but under the name of *H. brasiliensis*. Specimens from owl pellets in central and eastern Argentina and previously identified as *H. brasiliensis* (e.g., Formoso et al. 2010) probably represent *H. vulpinus*. Specimens of *H. vulpinus* exhibit larger dimensions than *H. brasiliensis*, especially in its cranial measurements, such as the condyloincisive length (36.3–45.9 mm in *H. vulpinus* and 34.6–36.9 mm in *H. brasiliensis*) and length of the upper molar series (7.3–8.1 mm in *H. vulpinus* and 6.3–7.5 mm in *H. brasiliensis*).

This species is characterized by $2n=35-39$ and $FN=57-61$ in Argentina and Paraguay (Nachman 1992a, b), with a higher proportion of biarmed autosomes than in *H. brasiliensis* from coastal Rio Grande do Sul (Riva et al. 1977; T. R. O. Freitas, Mattevi, Oliveira et al. 1983; Nachman 1992a,b). Better documentation of the morphological distinction between *H. brasiliensis* and *H. vulpinus* is needed to clarify the geographic distribution of both taxa in Uruguay, Paraguay, and Argentina. *Holochilus vulpinus* differs from *H. chacarius* by a genetic distance of 18.9% in sequence comparisons of the mtDNA ND3 gene (Kennedy and Nachman 1998).

Genus *Hylaeamys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

Species of *Hylaeamys*, previously known as the *capito* complex or *megacephalus* group of the genus *Oryzomys* (*sensu lato*), are widely distributed throughout cis-Andean South America, from Colombia south to Paraguay and east to coastal Brazil. In this large area, they inhabit lower slopes of the Andes, extending to an elevation of 1,000 m, Amazonian lowlands and floodplains, lowlands and highlands of the Atlantic Forest, and forested habitats in Cerrado and Chaco, among the drier biomes of the continent. There are no known records from the Caatinga or the central portion of the Brazilian Pantanal.

I recognize seven species of *Hylaeamys*: *H. acritus* Emmons and Patton, *H. laticeps* (Lund), *H. megacephalus*

(G. Fischer), *H. oniscus* (Thomas), *H. perenensis* (J. A. Allen), *H. tatei* (Musser, Carleton, Brothers, and Gardner), and *H. yunganus* (Thomas). I include *seuanezi* Weksler, Geise, and Cerqueira as a synonym of *H. laticeps*, but see Brennand et al. (2013) who characterized this taxon morphologically and chromosomally, and mapped its range, as a species distinct from other coastal Brazilian *Hylaeamys* (*laticeps*, *megacephalus*, and *oniscus*).

Morphological characters that diagnose the genus include a tail length equal or subequal to head and body length; short, teardrop-shaped incisive foramina; and carotid circulatory pattern 2 (*sensu* Voss 1988), a trait that is shared only with the genus *Oligoryzomys* among members of the Oryzomyini. The pelage is usually short and harsh, with viliform, setiform, and aristiform hairs homogeneous in texture and similar in length (aristiforms 9–14 mm). The dorsal color ranges from a dark grayish to a rich buffy brown; ventral color is uniformly gray. The tail is shorter than the head and body; its surface is usually darker than the ventral one, but the tail is not conspicuously bicolored. Hindfeet are long and narrow, with unequal tufts just reaching the tips of the claws; and with four interdigital pads and two plantar pads, the thenar and hypothenar (with polymorphism in the presence of the hypothenarin some samples of *H. yunganus*; see Musser et al. 1998:59, Table 7).

The skull is moderately to heavy built, 27.5–37.9 mm in greatest length. The rostrum has weakly projected nasolacrimal capsules; zygomatic notches are narrow and either shallow to moderately deep; the free dorsal margins of the zygomatic plates are reduced, with their anterior margins either straight or weakly concave. The zygomatic arches are slender and nearly parallel; the jugal is small. The interorbital region is slightly divergent posteriorly; supraorbital margins are squared or possess small dorsolateral projections, rarely strongly beaded. The braincase is elongate with a discrete temporal crest. Incisive foramina are short (3.5–5.8 mm long), and their lateral margins diverge posteriorly, making them teardrop in shape. The palate is long and wide, with small to large posterolateral palatal pits in shallow to deep palatine depressions; palatal excrescences are present in most specimens (Musser et al. 1998:74, Table 12). The anterior margin of the mesopterygoid fossa does not reach the level of the alveoli of the M3s; the roof of the fossa is either completely ossified or perforated only by small and narrow sphenopalatine vacuities on the presphenoid or at the presphenoid-basisphenoid suture. A modified cephalic arterial circulation is present (pattern 2 of Voss 1988), as indicated by absence of sphenofrontal foramina and squamosoalisphenoid grooves and presence of large stapedial foramina and a deep furrow in the posterolateral portion on the ventral surface of each

pterygoid plate. The buccinator-masticatory and accessory oval foramina are confluent, so an alisphenoid strut is absent in all specimens. Auditory bullae are small, stapedial processes are long and narrow, and bony tubes are short. The suspensory process of the squamosal is absent, and the tegmen tympani varies from small and triangular to large and squared, and does not extend anteriorly to overlap the squamosal; the postglenoid foramen is long and wide, and the subsquamosal fenestra is absent. The mandible is shallow; the posterior margin of the angular process is at the same vertical plane as that of the condyloid process; the coronoid process reaches the same height as the condyle; inferior and superior notches are shallow; and a capsular projection is absent.

Upper incisors are opisthodont. Molars are pentalo-phodont and moderately high-crowned; labial and lingual cusps are arranged in opposite pairs. Both labial and lingual flexi are moderately deep and narrow, overlapping on each molar at midplane. Musser et al. (1998) described and figured occlusal surfaces of *H. laticeps*, *H. megacephalus*, *H. oniscus*, *H. perenensis*, *H. tatei*, and *H. yunganus*. Young and a few adult specimens of *H. megacephalus* have m2s bisected by a long hypoflexid (Musser et al. 1998:79, Figs. 31 and 32). M1 has three main roots, anterior and posterior labial and lingual; M2 and M3 also have three main roots. Each lower molar has two roots, one each in anterior and posterior positions.

The axial skeleton is composed of 7 cervical, 12–13 thoracic, 6–7 lumbar, 4 sacral, and 27–30 caudal vertebrae; there is some variation in the number of ribs, but the modal count is 12. Hemal processes and hemal arches (rarely observed in *H. megacephalus*) are present at the junctions of the first and second and/or second and third caudal vertebrae.

The stomach is unilocular and hemiglandular, with a shallow angular notch. The glans penis is of the complex type (Hooper and Musser 1964), with a tridigitate and well-developed cartilaginous baculum. The three bacular mounds are visible in the terminal crater, and the basal portion of the bony baculum is wide and spatulate, barely concave. A single dorsal papilla and one urethral flap are present.

All species are very similar in external and cranial morphology, more easily differentiated by morphometric and karyological criteria and geographic ranges (see Percequillo 1998; Musser et al. 1998; Emmons and Patton 2005). Consequently, my Key employs all useful characters in the recognition of these species. Brennand et al. (2013) provided details of locality distribution and morphological comparisons among four species (*H. laticeps*, *H. megacephalus*, and *H. oniscus*, including the recognition of *H. seuanezi*) that occur in coastal Brazil.

SYNONYMS:

Mus: G. Fischer, 1814:71; part (description of *megacephalus*); not *Mus* Linnaeus.

H[esperomys].: Wagner, 1843a:542; part (listing of *cephalotes*); not *Hesperomys* Waterhouse.

Calomys: Fitzinger, 1867b:87; part (listing of *cephalotes*); not *Calomys* Waterhouse.

Oryzomys: Thomas, 1894b:354; part (listing of *laticeps*); not *Oryzomys* Baird.

Hylaeamys Weksler, Percequillo, and Voss, 2006:8; type species *Mus megacephalus* G. Fischer, by original designation.

REMARKS: The species-group taxa assigned to the genus *Hylaeamys* were profoundly affected by Hershkovitz's (1960, 1966a) revisionary acts in footnotes. I discussed the consequences of these acts in the Remarks section for the genus *Euryoryzomys*.

KEY TO THE SOUTH AMERICAN SPECIES

OF *HYLAEAMYS*:

1. Second upper molar with distinct medial mesofossette and short paraflexus 2
- 1'. Second upper molar without mesofossette and with long paraflexus 3
2. Pelage long (fur length 9–12 mm; Musser et al. 1998:101) and dense, uniformly dark brown; upper molar tooththrow long (5.5–5.7 mm) and wide (1.7–1.9 mm); incisive foramina short relative to greatest skull length (4.2–4.9 mm and 30.9–33.9 mm, respectively) *Hylaeamys tatei*
- 2'. Pelage short (fur length 6–10 mm) and less dense, from grayish brown to buffy brown; upper molar tooththrow short (3.9–5.5 mm); incisive foramina long relative to greatest skull length (3.9–5.8 mm and 27.5–35.3 mm, respectively); $2n=58-60$ and $FN=62-66$ in western populations (Brazil and Peru), and $2n=52-59$ and $FN=66-67$ in eastern samples (Surinam; see Musser et al. 1998:80–81, Table 13 for further details) *Hylaeamys yunganus*
3. Head and body (80–158 mm) and tail (90–138 mm) long; hypothenar pad large or very small; skull smaller and delicate (greatest length 27.2–34.9 mm); molar tooththrow shorter (3.7–5.2 mm) and molars narrower; sphenopalatine vacuities variably present; lower second molar without distinct entoflexid or entofossetid and with long hypoflexid nearly bisecting the molar in most specimens; $2n=54$ 4
- 3'. Head and body (81–174 mm) and tail (94–162 mm) long; hypothenar pad medium sized; skull large and robust (greatest length 29.5–37.9 mm); molar tooththrow longer (4.5–5.6 mm) and molars robust; roof of mesopterygoid fossa completely ossified in most specimens (>90% of

specimens from Rio Juruá, Amazonas and Acre states, and eastern Atlantic Forest, Brazil); lower second molar with distinct entoflexid or entofossetid and short hypoflexid in most specimens; $2n=48$ and 52 5

4. Head and body (80–158 mm) and tail (90–138 mm) shorter; hypothenar pads small; skull smaller (greatest length 27.2–34.9 mm) and delicate; molar tooththrow shorter (3.7–5.2 mm) and molars delicate; sphenopalatine vacuities small and narrow (vacuities present in 50–59% of Paraguayan specimens); multiple posterolateral palatal pits set in shallow to deep palatal notches; palatal excrescences present, from small projections to large bone struts fused to maxilla; $2n=54$ and $FN=62$ *Hylaeamys megacephalus*
- 4'. Head and body (131–152 mm) and tail shorter (110–130 mm); hypothenar pads large; skull smaller (greatest length 33.9–34.6 mm) and delicate; molar tooththrow shorter (4.7–5.2 mm) and molars delicate; roof of mesopterygoid fossa infrequently perforated by sphenopalatine vacuities (when present, very small and narrow); multiple posterolateral palatal pits set in shallow to deep palatal notches; palatal excrescences present as large bone struts fused to maxilla . . . *Hylaeamys acritus*
5. Head and body 81–169 mm and tail 94–162 mm; $2n=52$, $FN=62$ 6
- 5'. Head and body 122–174 mm and tail 100–157 mm; $2n=48$, $FN=60$; pelage sparser and coarser; dorsal color dark, grayish or blackish brown; skull larger (greatest length 31.8–37.6 mm); molars more robust (tooththrow length 4.6–5.5 mm) . . . *Hylaeamys laticeps*
6. Head and body (131–162 mm), tail (135–162 mm), and skull (33.7–37.6 mm) slightly larger; occurs in northeastern Brazil, north of Rio São Francisco *Hylaeamys oniscus*
- 6'. Head and body (81–169 mm), tail (94–154 mm), and skull (29.5–37.9 mm) smaller; occurs in Amazon Basin of Colombia, Ecuador, Peru, Bolivia, and western Brazil *Hylaeamys perenensis*

Hylaeamys acritus (Emmons and Patton, 2005)

Bolivian *Hylaeamys*

SYNONYMS:

Oryzomys capito: S. Anderson, 1997:399; part (listing of specimens from MNK); not *Mus capito* Olfers (= *Hylaeamys megacephalus* [G. Fischer]).

Oryzomys megacephalus: Musser, Carleton, Brothers, and Gardner, 1998:32; part; not *Mus capito* Olfers (= *Hylaeamys megacephalus* [G. Fischer]).

Oryzomys acritus Emmons and Patton, 2005:14; type locality “Bolivia: Departamento de Santa Cruz, Provincia Velasco, Parque Nacional Noel Kempff Mercado, El Refugio Huanchaca, an outpost with a few buildings

and an airstrip on private property, but within the park (14°42.553'S, 061°2.034'W [WGS 84]; elev. 170 m.)” [*Hylaeamys*] *acritus*: Weksler, Percequillo, and Voss, 2006: 14; first use of current name combination.

DESCRIPTION: Characterized externally by tail much shorter than head and body length (average about 81%); long dorsal (9–10 mm) and ventral hairs (3–4 mm); whitish venter; large and fleshy hypothenar pad; one ring of squamae on digit I of pes. Skull robust and with strongly developed palatal excrescences; very large foramen ovale; M2 with short paraflexus and single labial fossette (mesoflexus); m2 with short hypoflexid.

DISTRIBUTION: *Hylaeamys acritus* is an endemic species of northeastern Bolivia, limited to the west bank tributaries of the Río Iténez (= Río Guaporé in Brazil), in the departments of Santa Cruz and Beni.

SELECTED LOCALITIES (Map 167): BOLIVIA: Beni, Curicha (USNM 551653), San Joaquín, Monto Río Machupo (Emmons and Patton 2005); Santa Cruz, El Refugio Huanchaca, Parque Nacional Noel Kempff Mercado (type locality of *Oryzomys acritus* Emmons and Patton), Lago Caiman, Parque Nacional Noel Kempff Mercado (MNK 1949), Urubicha, Río Negro (MNK [NR 10]).

SUBSPECIES: *Hylaeamys acritus* is monotypic.

NATURAL HISTORY: All natural history data are from populations in Parque Nacional Noel Kempff Mer-

cado (Emmons and Patton 2005). There, individuals were captured on the ground in evergreen riverine (gallery) forests, deciduous and semideciduous *terra firme* forests, and seasonally flooded forests on the edge of seasonally flooded pampa. These forests are characterized by two physiognomies: a “seasonally deciduous emergent canopy, sparse understory and midstory varying in deciduousness depending both on the location and on the dryness of the particular year,” or liana forests, exhibiting “low canopies and dense lianas at all levels” (Emmons and Patton 2005:15). Elevational range is 170–700 m.

REMARKS: This recently recognized species is thoroughly diagnosed and described by Emmons and Patton 2005, who provided molecular and both metric and qualitative morphological characters in support of species status. Phenotypically, the most similar species is *H. megacephalus*, with which *H. acritus* shares similarities in body color, body and skull size, and molar topography. Despite these common features, *H. acritus* is the sister of *H. perenensis*, a western Amazonian *Hylaeamys* that is more closely related to the Atlantic Forest *H. laticeps* than to the eastern Amazonian-Cerrado *H. megacephalus*. *Hylaeamys acritus* is sympatric with *H. yunganus* (Emmons and Patton 2005).

Hylaeamys laticeps (Lund, 1840)

Atlantic Forest *Hylaeamys*

SYNONYMS:

Mus laticeps Lund, 1839a:233; *nomen nudum*.

Mus laticeps Lund, 1840b [1841c:279]; type locality “Rio das Velhas’s Floddal” (Lund 1841c:292, 294), Lagoa Santa, Minas Gerais (see also Musser et al. 1998).

Hesperomys laticeps: Burmeister, 1854:171; part (excluding *Hesperomys subflavus* Wagner [= *Cerradomys subflavus*]); name combination.

Calomys saltator Winge, 1887:48, plate I, Figs. 16 and 17; plate III, Fig. 7; renaming of *Mus laticeps* Lund.

Oryzomys laticeps: Thomas, 1894b:354; name combination.

[*Oryzomys* (*Oryzomys*)] *laticeps laticeps*: Tate, 1932e:18; part; name combination.

[*Oryzomys* (*Oryzomys*)] *saltator*: Tate, 1932e:18; name combination.

Oryzomys laticeps laticeps: Gyldenstolpe, 1932a:17; name combination.

Oryzomys oniscus: Moojen, 1952b:47; part; not *Oryzomys oniscus* Thomas (= *Hylaeamys oniscus*).

Oryzomys [(*Oryzomys*)] *capito laticeps*: Cabrera, 1961: 386; name combination.

Oryzomys capito: Hershkovitz, 1966a:137, footnote; part; not *Mus capito* Olfers (= *Hylaeamys megacephalus* [Fischer]).

Map 167 Selected localities for *Hylaeamys acritus* (○) and *Hylaeamys perenensis* (●). Contour line = 2,000 m.

Oryzomys seuanezi Weksler, Geise, and Cerqueira, 1999: 454; type locality “Fazenda União, Casimiro de Abreu municipality, Rio de Janeiro state (22°25’S, 42°02’W; 50 m.”

[*Hylaeamys*] *laticeps*: Weksler, Percequillo, and Voss, 2006: 14; first use of current name combination.

DESCRIPTION: Large, with head and body length 122–174 mm; tail short (100–157 mm); hindfeet robust, with fleshy hypothenar pads and sparse unguis tufts shorter than claws. Dorsal fur very short and harsh, colored buffy, yellowish, or grayish brown densely grizzled with dark brown; ventral fur shorter and predominantly grayish in color; tail bicolored, basally and uniformly colored distally; ears sparsely covered with reddish-brown hairs. Skull robust and large (greatest skull length 31.8–37.6 mm), with short, narrow, and teardrop-shaped incisive foramina (length 4.3–5.9 mm; width 2.1–2.9 mm); interorbital region diverges slightly posteriorly, with squared or weakly to moderately beaded supraorbital margins; palate with complex, multiple posterolateral palatal pits recessed in shallow palatine depressions and developed palatal excrescences. Toothrows robust (length 4.6–5.5 mm; M1 width 1.4–1.8 mm).

DISTRIBUTION: *Hylaeamys laticeps* is endemic to the eastern Brazilian Atlantic Forest. Known collecting localities are distributed along coastal lowland forests and eastern forested foothills of the Serra do Mar, from southern Bahia to northern Rio de Janeiro states. Consequently, the elevational range of this species is limited, extending from near sea level (Casimiro de Abreu, Rio de Janeiro, at 17 m) to approximately 100 m at Buerarema, Bahia, and about 300 m in Parque Estadual do Rio Doce, Minas Gerais.

SELECTED LOCALITIES (Map 168): BRAZIL: Bahia, Almada, Rio do Braço (MNRJ 9314); Espírito Santo, Linhares, Fazenda Santa Terezinha, 33 km NE of Linhares (UFMG MAS 4); Minas Gerais, Lagoa Santa (type locality of *Mus laticeps* Lund), Parque Estadual do Rio Doce (UFMG JRS 382); Rio de Janeiro, Casimiro de Abreu, Reserva Biológica de Poço das Antas (MNRJ 29406).

SUBSPECIES: I treat *Hylaeamys laticeps* as monotypic.

NATURAL HISTORY: This terrestrial species inhabits lowland evergreen forest and subtropical deciduous forest along the Atlantic coast, where it may be found in swampy, disturbed, and primary forests (G. A. B. Fonseca and Kierulff 1989; Stallings 1989), but most frequently in pristine habitats (Laemmert et al. 1946). In one southern Bahia community, *H. laticeps* was the most common small mammal, where it was encountered in forest fragments of all sizes as well as in the surrounding matrix, although it was more abundant in mature forests (Pardini 2004).

REMARKS: The southeastern Atlantic Forest populations of genus *Hylaeamys*, called *H. laticeps* by Musser et al. (1998), were only recently recognized as specifically distinct from other populations of this group, particularly those from the Cerrado (allocated to *H. megacephalus*) and northeastern Atlantic Forest in Brazil (*H. oniscus*; see Percequillo 1998; Musser et al. 1998; Weksler et al. 1999; Andrades-Miranda, Zanchin et al. 2002).

Throughout much of its recent history, the specific epithet *laticeps* Lund was not applied to any species, regarded only as a synonym of *H. megacephalus* (Musser and Carleton 1993; but see Hershkovitz 1960:544, footnote, who recognized *laticeps* but included in his concept a large number of names now allocated to species in five different genera). Musser et al. (1998), however, stated that *laticeps* Lund was the valid and available name that should be applied to the large Atlantic Forest *Hylaeamys* and regarded *oniscus* Thomas to be a junior synonym. Almost simultaneously, Weksler et al. (1999) proposed *Oryzomys seuanezi* for the morphologically and karyologically divergent populations from the southeastern Atlantic Forest (Weksler et al. 1999), regarding *Oryzomys oniscus* Thomas as a species restricted to northeastern Atlantic Forest. Here, I treat *seuanezi* Weksler, Geise, and Cerqueira as a junior synonym of *H. laticeps*, but I also regard *H. oniscus* as a valid species (see that account). Brennard et al. (2013)

Map 168 Selected localities for *Hylaeamys laticeps* (○) and *Hylaeamys oniscus* (●).

regarded *seuanezi* as a species distinct from other Atlantic Forest *Hylaeamys*, including *H. laticeps*, *H. megacephalus*, and *H. oniscus*.

Although most recent records would suggest that *H. laticeps* is a coastal Atlantic Forest dweller, the type locality at Lagoa Santa, Minas Gerais (where this species occurs in sympatry with *H. megacephalus*) is situated on the western slope of Serra do Espinhaço in a region mostly dominated by open vegetation of the Cerrado, although in a mosaic with patches of semideciduous forest. Lagoa Santa contrasts elevationally with most locality records for this species, because it is about 760 m above sea level.

Hylaeamys laticeps can be differentiated from *H. megacephalus* by its sparser and coarser pelage; dark, grayish or blackish brown dorsal body coloration; larger skull; more robust molars; larger and wider palatal excrescences; diploid number $2n=48$ and $FN=60$ (in contrast to $2n=54$ and $FN=62$ in *H. megacephalus*), and geographical distribution (while the former is restricted to eastern Brazilian Atlantic Forest, the latter has a more widespread range that extends from the Cerrado throughout eastern Amazonia).

Hylaeamys megacephalus (G. Fischer, 1814)

Azara's Hylaeamys

SYNONYMS:

Mus megacephalus G. Fischer, 1814:71; based on Azara's (1801, 1802) "rat second ou rat a grosse tête" and "del cola igual al cuerpo"; type locality "Paraguay east of the Río Paraguay, Departamento de Canendiyu [= Canindeyú], 13.3 km (by road) N Curuguaty (24°31'S/55°42'W, 255 m," based on neotype designation (Musser et al. 1998:251–2).

[*Hylaeamys*] *megacephalus*: Weksler, Percequillo, and Voss, 2006:14; first use of current name combination.

DESCRIPTION: Small to medium sized (head and body length 80–158 mm; mean 121.9 mm, $N=151$); tail shorter than head and body (range: 90–138 mm; mean 115.4 mm, $N=145$); hindfeet short with small plantar pads (especially hypothernar), and sparse ungual tufts shorter than claws. Dorsal fur short, dense, and slightly harsh, colored overall with ochraceous, yellowish, or orangish weakly to moderately ticked with dark brown; ventral fur shorter and predominantly gray, often with small white gular and inguinal patches; tail uniform in color or weakly to completely bicolored; ears sparsely covered with either entirely brown or banded hairs, brown basally but white or golden distally. Skull small and delicate (greatest length 27.2–34.8 mm); incisive foramina very short and broad, teardrop in shape (length 3.5–5.4 mm; width 1.9–3.1 mm); interorbital region diverges slightly posteriorly, with supraorbital margins rounded to weakly beaded; palate with complex and multiple posterolateral palatal pits recessed in shallow palatine depressions and with palatal excrescences varying from small projections to large struts fused to maxilla; short and narrow toothrows (length 3.7–5.2 mm; M1 width 1.1–1.6 mm).

DISTRIBUTION: *Hylaeamys megacephalus* has the largest known distribution of all congeners, occurring

throughout forested areas of the Cerrado and Chaco in central Paraguay, Cerrado and semideciduous forests in southeastern and central Brazil, and Amazonian forests of eastern Brazil, the Guianan region, and southern Venezuela, as well as forested areas in the Venezuelan Llanos; and on the coastal island of Trinidad. *Hylaeamys megacephalus* ranges in elevation from the Amazonian lowlands, such as Itaituba, Pará state, at 15 m, to the central Brazilian highlands, such as at Brasília, Distrito Federal, at 1,100 m.

SELECTED LOCALITIES (Map 169): **BRAZIL:** Amapá, Terezinha, Rio Amapari, Serra do Navio (MPEG 15024); Amazonas, Tambor, left bank Rio Jaú (INPA 2014); Ceará, Serra de Maranguape (UFC 74); Maranhão, Alto Parnaíba [= Alto Parnaíba] (FMNH 26447); Mato Grosso, Cidade Laboratório de Humboldt, Aripuanã (MPEG 12647), Juruena (MZUSP M 97.179); Mato Grosso do Sul, Fazenda Califórnia, Morraria do Sul, Bodoquena (MZUSP [APC 731]), Porto Faya (MZUSP 1700); Minas Gerais, Formoso, Parque Nacional Grande Sertão Veredas (MZUSP M 97.140); Pará, Bragança, Santa Maria, Tracuateua [= Tracuatena] (USNM 394180), Itaituba, Rio Tapajós (type locality of *Oryzomys Goeldi* Thomas); São Paulo, Fazenda Sete Lagoas, Mogi Guaçu (MZUSP 25759). **FRENCH GUIANA:** Cayenne, Paracou (Voss et al. 2001). **GUYANA:** Barima-Waini, Santa Cruz (ROM 98827). **PARAGUAY:** Caaguazú, 22.5 km N of Coronel Oviedo by road (UMMZ 124499); Canindeyú, 13.3 km by road N of Curuguaty (type locality of *Mus megacephalus* G. Fischer); San Pedro, Tacuati, Aca-Poi (USNM 293148). **SURINAM:** Saramacca, La Poule (FMNH 95623). **TRINIDAD AND TOBAGO:** Trinidad, Princetown (type locality of *Oryzomys velutinus* J. A. Allen and Chapman). **VENEZUELA:** Amazonas, Cerro Neblina Base Camp, left (west) bank Río Baria [= Río Mawarinuma] (USNM 559193), Tamatama, Río Orinoco (USNM 409873); Sucre, Campo Alegre (type locality of *Oryzomys modestus* J. A. Allen).

SUBSPECIES: As currently understood, *Hylaeamys megacephalus* is monotypic, although molecularly divergent samples from south of the Amazon River (from eastern Pará state, Brazil, to Paraguay), and those from north of the Amazon in central Brazil and the Guianan region (Patton et al. 2000; L. P. Costa 2003) may represent either valid infraspecific groups or require specific recognition.

NATURAL HISTORY: This species inhabits a range of biomes across its distribution but is always restricted to forested habitats (Mares et al. 1986; Ochoa et al. 1993). Specimens have been obtained in well-drained, swampy, or creekside primary forest as well as secondary forest. This species can also be common near human dwellings and rock outcrops (Handley 1976) and in overgrown orchards (Barnett and Cunha 1994). Sites of trap captures include

under fallen logs, under roots and buttresses of fallen trees, in tangled branches of fallen trees, at the base of buttressed trees, and in hollow logs (Voss et al. 2001). *Hylaeamys megacephalus* is a predominantly terrestrial species (Nitikman and Mares 1987; Voss et al. 2001) but can be scansorial (Marinho-Filho et al. 1998; Voss et al. 2001), with arboreal captures always in the lower forest strata (<2.0 m; Malcolm 1988, 1991).

In the gallery forests of the Cerrado, Mares and Ernest (1995) reported an increase in population density during the dry season, when densities reached 7.5 individuals/ha, whereas in central Brazilian Amazonia, Malcolm (1990) estimated densities at 0.404 individuals/ha. Pregnant females and reproductively active males have been observed in both dry (May and June) and wet (from September to November) seasons in Cerrado vegetation (Mares and Ernest 1995). In French Guiana, Henry (1994) recorded births and pregnant females year-round, with peaks coincident with the rainy season (April–May). Here, captive animals exhibited a gestation period of 26 days and litter sizes of one to six. Barnett and Cunha (1994) trapped pregnant females in December (dry season) in the transition between the Llanos and Amazon forest in Brazil.

REMARKS: Most of the nomenclatural issues involving this species have been clarified by Musser et al. (1998) and Percequillo (1998), especially the allocation of problematic names such as *Mus capito* Olfers, *Mus cephalotes* Desmarest, *Oryzomys velutinus* J. A. Allen and Chapman, *Oryzomys goeldi* Thomas, and *Oryzomys modestus* J. A. Allen, as well as the priority of *megacephalus* Fischer over that of *capito* Olfers. The names *megacephalus* (Fischer), *capito* (Olfers) and *cephalotes* (Desmarest; see also Desmarest 1804:24) were coined for the species Azara (1801, 1802) referred to as the “rat second ou rat a grosse tête” and “del cola igual al cuerpo” (respectively).

The concept of *H. megacephalus* as a widely distributed species throughout Amazonia as presented by Musser et al. (1998) in their revision of the complex has been modified by more recent analyses. Molecular sequence studies, for example, documented reciprocal monophyly for samples from eastern and western Amazonia, and to which the names *H. megacephalus* and *H. perenensis* are now applied, respectively (Patton et al. 2000; Voss et al. 2001; Bonvicino and Moreira 2001; L. P. Costa 2003; Musser and Carleton 2005). Morphometric, qualitative morphological, and karyological data also support this hypothesis. *Hylaeamys megacephalus* is smaller in size (head and body length 80–158 mm); has a smaller skull (greatest skull length 27.2–34.9 mm); has short, teardrop-shaped incisive foramina (length 3.4–5.4 mm); has a shorter maxillary toothrow (length 3.7–5.2 mm), and a karyotype with $2n=54$ and $FN=62$ (see account of *H. perenensis* for comparisons). However, even within this re-

Map 169 Selected localities for *Hylaeamys megacephalus* (●). Contour line = 2,000 m.

stricted concept of *H. megacephalus*, molecular clades separated by the Amazon River are reciprocally monophyletic, suggesting the possibility that further taxonomic divisions of this species may be warranted.

There are few records of this species from eastern coastal Brazil, except for those from Amapá, Maranhão, and Ceará states. The eastern edge of the range coincides with the limits of the Cerrado biome. There are no definitive records of this species in western Amazonia (see also Patton et al. 2000), and the western distributional limits of this common species remain unclear as well. Musser et al. (1998) suspected that contact between *H. perenensis* and *H. megacephalus* might be found along the lower Rio Tapajós, and also stated that more samples from this region should be examined to clearly evaluate the possibility that this river may represent the boundary between these forms. Given the degree of overall morphological similarity between *H. megacephalus* and *H. perenensis*, additional collections should provide for both karyotypic and molecular data. The karyotype of *H. megacephalus* consists of $2n = 54$, $FN = 62$ (Musser et al. 1998:Fig. 11); that of *H. perenensis* is $2n = 52$, $Fn = 62$ (see that account).

Hylaeamys oniscus (Thomas, 1904)
Northern Atlantic Forest *Hylaeamys*

SYNONYMS:

Oryzomys oniscus Thomas, 1904b:142; type locality “São Lourenço [= São Lourenço da Mata],” Pernambuco, Brazil.

[*Oryzomys* (*Oryzomys*)] *oniscus*: Tate, 1932e:18; name combination.

Oryzomys laticeps: Hershkovitz, 1960:544, footnote; part (*oniscus* Thomas listed as synonym); not *Mus laticeps* Lund (= *Hylaeamys laticeps*).

Oryzomys [(*Oryzomys*)] *capito oniscus*: Cabrera, 1961:387; name combination.

Oryzomys capito: Hershkovitz, 1966a:137, footnote; part; not *Mus capito* Olfers (= *Hylaeamys megacephalus* [G. Fischer]).

[*Hylaeamys*] *oniscus*: Weksler, Percequillo, and Voss, 2006:14; first use of current name combination.

DESCRIPTION: Large, head and body 140–162 mm (mean 147.2, $N = 8$); tail equal to or shorter than head and body (range: 135–162 mm; mean 146.8, $N = 8$); hindfeet robust, with fleshy and large plantar pads and sparse ungual tufts shorter than claws. Dorsal fur short and harsh, color overall yellowish to buffy heavily ticked with dark brown; ventral fur short and predominantly grayish; tail bicolored basally and uniformly colored distally; ears sparsely covered with reddish-brown hairs (more so dorsally) or yellowish (more so ventrally). Skull large and robust (skull length 33.7–37.6 mm); teardrop-shaped incisive foramina long and wide (length 4.9–5.8 mm; width 2.3–3.4 mm); slightly and posteriorly divergent interorbital region with squared to beaded supraorbital margins; palate with complex and multiple posterolateral palatal pits recessed in shallow to moderately deep palatine depressions, and palatal excrescences varying from small projections to large and robust bone struts fused to maxillae; and toothrows long and wide (length 4.9–5.3 mm; M1 width 1.4–1.6 mm).

DISTRIBUTION: *Hylaeamys oniscus* is endemic to the northeastern Atlantic Forest of Brazil, with all known localities north of the Rio São Francisco in the states of Alagoas, Pernambuco, and Paraíba (see Brennand et al. 2013).

SELECTED LOCALITIES (Map 168): BRAZIL: Alagoas, Fazenda do Prata, 13 km SSW of São Miguel dos Campos (MNRJ 30595), Fazenda Santa Justina, 6 km SSE of Matriz de Camaragibe (UFPB 978); Paraíba, Fazenda Pacatuba, 10 km NE of Sapé (UFPB 1931); Pernambuco, São Lourenço da Mata (type locality of *Oryzomys oniscus* Thomas).

SUBSPECIES: *Hylaeamys oniscus* is monotypic.

NATURAL HISTORY: No data are available on the natural history of *H. oniscus*, although all known localities are in typical coastal Atlantic rainforest.

REMARKS: *Hylaeamys oniscus* has been considered as either a valid taxon, as a species or subspecies, or as a synonym of *H. megacephalus*. More recently, this species was considered to be morphologically, morphometri-

cally (Musser et al. 1998), and karyologically (Andrades-Miranda, Zanchin et al. 2002) indistinguishable from the eastern populations of *H. laticeps* (as defined previously), and therefore as a junior synonym because *laticeps* Lund, 1840, has priority over *oniscus* Thomas, 1904. However, I regard *Hylaeamys oniscus* as a valid species, distinguishable from *H. laticeps* by its larger size (mean head and body length 147 mm versus 136 mm, respectively; mean greatest skull length 35.8 mm versus 34.3 mm; mean diastema length 9.8 mm versus 8.8 mm), by shorter tooththrows and narrower molars (mean maxillary tooththrow length 5.08 mm versus 5.14 mm; mean M1 width 1.45 mm versus 1.53 mm), and by a $2n=52$, $FN=62$ karyotype (specimens from the type locality; Maia 1990). Specimens with a karyotype of $2n=48$ and $FN=60-64$, and identified by Andrades-Miranda, Zanchin et al. (2002) as "*Oryzomys oniscus*," I assign to *Hylaeamys laticeps* (see account earlier).

Hylaeamys perenensis (J. A. Allen, 1901)

Western Amazonian *Hylaeamys*

SYNONYMS:

Oryzomys perenensis J. A. Allen, 1901c:406; type locality "Perené, Department of Junin, Peru; altitude 800 m," defined as "Valle Perené, Colonia del Perené; a coffee plantation at junction of ríos Paucartambo and Chanchamayo, 1000 m" (Stephens and Traylor 1983:161).

[*Oryzomys* (*Oryzomys*)] *perenensis*: E.-L. Trouessart, 1904: 419; name combination.

Oryzomys laticeps perenensis: Gyldenstolpe, 1932a:18; part; name combination.

Oryzomys [(*Oryzomys*)] *capito nitidus*: Cabrera, 1961:386; part; but neither *Mus capito* Olfers (= *Hylaeamys megacephalus* [G. Fischer]) nor *Hesperomys laticeps*, var. *nitidus* Thomas (= *Euryoryzomys nitidus*).

Oryzomys megacephalus: Musser, Carleton, Brothers, and Gardner, 1998:251; part (inclusion of samples from western Amazonia).

[*Hylaeamys*] *perenensis*: Weksler, Percequillo, and Voss, 2006:14; first use of current name combination.

DESCRIPTION: Medium sized (head and body length 81–169 mm; mean 135.7, $N=337$); tail shorter than head and body length (tail 94–154 mm; mean 122.9, $N=339$); hindfeet moderately robust, with medium-sized hypothenar pads. Coloration of dorsal pelage ochraceous buffy weakly to intensely ticked with dark brown or reddish brown; ventral pelage predominantly gray; dorsal surfaces of hindfeet grayish to whitish; ungual tufts short, whitish in color, but sparse; tail unicolored or only weakly bicolored. Skull large and robust (greatest length 29.5–37.9 mm); incisive foramina long, narrow, teardrop-shaped (length 3.6–6.0 mm;

width 1.5–2.9 mm); molars long and robust (maxillary tooththrow length 4.5–5.6 mm); roof of mesopterygoid fossa completely ossified (in more than 90% of specimens from Rio Juruá in Amazonas and Acre states, Brazil; Patton et al. 2000). Lower second molars with distinct entoflexid, entofossetid, and short hypoflexid in most specimens.

DISTRIBUTION: *Hylaeamys perenensis* ranges through lowland and lower montane rainforests of the western Amazon Basin, from eastern Colombia south through Ecuador and Peru to northeastern Bolivia, and extending into western Brazil. Extent of the range to the east is uncertain, but it is possibly bounded by the Río Putumayo in the north and the Rio Madeira–Rio Guaporé in the south. The Andean Cordillera forms the western limits of the range for *H. perenensis*; there are no known trans-Andean records. The species ranges in elevation from about 65 m (Lago Vai Quem Quer, Amazonas, Brazil) to 1,000 m (Mámbita, Cundinamarca, Colombia).

SELECTED LOCALITIES (Map 167): **BOLIVIA:** Pando, La Cruz (AMNH 262937). **BRAZIL:** Acre, Sena Madureira, km 8 on route BR 364 between Sena Madureira and Manuel Urbano (USNM 545295), Sobral, left bank Rio Juruá (MPEG 28312); Amazonas, Colocação Vira-Volta, left bank Rio Juruá (MVZ 190530), Seringal Condor, left bank Rio Juruá (MVZ 190485); Rondônia, Cachoeira Nazaré (MPEG 20811). **COLOMBIA:** Cundinamarca, Mámbita (AMNH 70526). **ECUADOR:** Orellana, San José Abajo (AMNH 68050); Pastaza, Sarayacu, Río Bobonaza (AMNH 67352); Zamora-Chinchi, Zamora (AMNH 36577). **PERU:** Amazonas, Huampami, Río Cenepa (Patton et al. 2000); Junín, Perené (type locality of *Oryzomys perenensis* J. A. Allen); Loreto, Reserva Nacional Allpahuayo-Mishana (Hice and Velazco 2012); Ucayali, Balta, Río Curanja (A. L. Gardner and Patton 1976, as *Oryzomys capito*).

SUBSPECIES: *Hylaeamys perenensis* is monotypic.

NATURAL HISTORY: *Hylaeamys perenensis* is found in seasonally inundated floodplain forests (*várzea*), non-flooded upland forests (*terra firme*), river beach grass, *Cecropia* stands, flooded and nonflooded grasslands, *Heliconia* thickets, active and abandoned garden plots, and second-growth forests (Woodman et al. 1995; Patton et al. 2000). Exclusively terrestrial, this species, where it occurs, may be the most abundant rodent both in *terra firme* and *várzea* forests, but has been trapped more commonly in *várzea* habitat (Patton et al. 2000). On the Rio Juruá in western Brazil, *H. perenensis* was reproductively active throughout the year "spanning both dry and rainy seasons" (Patton et al. 2000:153), where modal litter size was four, with embryo counts two to five. In Bolivia, the modal number was three embryos, also with a range of two to five (S. Anderson 1997).

REMARKS: *Hylaeamys perenensis* has been treated as a subspecies of what is now called *Hylaeamys laticeps* (Gyldenstolpe 1932; Ellerman 1941), as a synonym of *Euryoryzomys nitidus* (Cabrera 1961), or as part of *Hylaeamys megacephalus* (Musser and Carleton 1993). Musser et al. (1998) did demonstrate differences between *H. perenensis* and *H. megacephalus*, but adopted a conservative taxonomic posture and maintained both western (*H. perenensis*) and eastern Amazonian samples under the same species *H. megacephalus*. Their decision was based on the absence of evidence of a geographical barrier precluding gene flow between populations (Musser et al. 1998:41–42). However, Patton et al. (2000; see also L. P. Costa 2003) presented molecular evidence to sustain the morphological and karyological differentiation recognized by Musser et al. (1998), and I treat *H. perenensis* as a valid species based on these morphometric and molecular analyses.

Specimens of *H. perenensis* can be distinguished from those of *H. megacephalus* by their larger size, larger skull, longer teardrop-shaped incisive foramina, more robust molars, and a $2n=52$, $FN=62$ karyotype (A. L. Gardner and Patton 1976, as *Oryzomys capito*; Patton et al. 2000). Moreover, DNA sequences (Patton et al. 2000; L. P. Costa 2003; Emmons and Patton 2005) support a sister relationship between *H. perenensis* and *H. acritus*, which in turn are coupled to *H. laticeps* and then, finally, to *H. megacephalus*.

Hylaeamys tatei (Musser, Carleton, Brothers, and Gardner, 1998)

Tate's *Hylaeamys*

SYNONYMS:

Oryzomys tatei Musser, Carleton, Brothers, and Gardner, 1998:100; type locality “Palmera (01°25’S/78°12’W; . . .), at 4000 ft (1220 m), Provincia del Tungurahua, Ecuador.” [*Hylaeamys*] *tatei*: Weksler, Percequillo, and Voss, 2006:14; first use of current name combination.

DESCRIPTION: Large (mean head and body length 130.2 mm, range: 118–137 mm); pelage dark; incisive foramina short and narrow relative to size of cranium; toothrows long and wide; molars robust; coronoid process blunt and triangular in shape. Distinguishable from congeners by having long and deep mesoflexus on M1 and M2 (moderate wear forms either long medial mesofossette or small labial and long medial mesofossettes), and robust ectolophid on m1 and m2.

DISTRIBUTION: *Hylaeamys tatei* is known from only three, closely adjacent localities along the upper Río Pastaza on the eastern slope of the Ecuadorean Andes (Musser et al. 1998:106, Fig. 47).

SELECTED LOCALITIES (Map 170): ECUADOR: Tungurahua, Palmera (type locality of *Oryzomys tatei* Musser, Carleton, Brothers, and Gardner).

Map 170 Selected locality for *Hylaeamys tatei* (●). Contour line = 2,000 m.

SUBSPECIES: *Hylaeamys tatei* is monotypic.

NATURAL HISTORY: The region where all specimens of *H. tatei* were captured is characterized by a mosaic of “paramo or temperate plants” and “subtropical vegetation” (G. H. H. Tate notes cited in Musser et al. 1998:103), cultivated lands, second-growth forest, and primary forest (Rageot and Albuja 1994) between 1,159 and 1,524 m. Musser et al. (1998) also suggested that *H. tatei* could be a wet and cool premontane evergreen forest inhabitant of the eastern slopes of Ecuador and Peru, because four other broadly distributed species of this general habitat (*Nephelomys auriventer*, *Oreoryzomys balneator*, *Chilomys instans*, and *Akodon aerosus*) were collected with *H. tatei*.

REMARKS: *Hylaeamys tatei* is easily distinguished from congeners, but especially from *H. yunganus*, by its large body size and cranial dimensions, shorter incisive foramina (length 4.2–4.9 mm in *H. tatei*; length 3.9–5.8 mm in *H. yunganus*), and longer and wider maxillary tooththrow (length 5.5–5.7 mm and breadth 1.7–1.9 mm in *H. tatei*; length 3.9–5.5 mm and breadth 1.3–1.7 mm in *H. yunganus*).

Hylaeamys yunganus (Thomas, 1902)

Amazonian *Hylaeamys*

SYNONYMS:

Oryzomys yunganus Thomas, 1902b:130; type locality “Charuplaya, 1350 m,” stated by Thomas (1902b:126) as being “on the [Río] Securé, just north of 16 S,” Cochabamba, Bolivia.

[*Oryzomys* (*Oryzomys*)] *yunganus*: E.-L. Trouessart, 1904: 419; name combination.

Oryzomys [(*Oryzomys*)] *capito yunganus*: Cabrera, 1961: 387; name combination.

[*Hylaeamys*] *yunganus*: Weksler, Percequillo, and Voss, 2006:14; first use of current name combination.

DESCRIPTION: Moderate sized with tail equal to or shorter than head and body length (head and body length 115–149 mm; tail length 107–128 mm). Dorsal fur dense and velvety; hairs longer than sympatric *H. megacephalus* (mean sample length 7.1–8.4 mm versus 5.4–6.6 mm); upper parts dark brownish tawny to brownish black; under parts dark grayish white; tail monocolored or with ventral basal half either unpigmented or mottled; dorsal surfaces of front and hindfeet whitish; claws sparsely covered by unguis tufts; plantar surfaces of hindfeet lack hypothenar pads in some specimens; superciliary, genal, and mystacial vibrissae not exceptionally long, extending only to ears. Cranial size and shape similar to that of *H. megacephalus* and *H. perenensis*, but zygomatic plates much wider and lengths of bony palate, incisive foramina (4.3–5.6 mm), and molar rows (4.8–5.5 mm) each longer relative to occipito-nasal length. Posterior margins of dentary shallowly concave between condyloid and angular processes (compared with more deeply concave margins in *H. megacephalus* and *H. perenensis*). Molars chunky and wide (M1 width 1.5–1.6 mm); M2 with short paraflexus, labial and medial fossettes present; m2 with conspicuous entoflexid, short hypoflexid that extends only to medial plane of tooth, and single fossetid.

DISTRIBUTION: *Hylaeamys yunganus* is widely distributed, with a range nearly concordant with the lowland Amazonian rainforest in Brazil, Bolivia, Peru, Ecuador, Colombia, Venezuela, Guyana, Surinam, and French Guiana (Musser et al. 1998:47, Fig. 15). Across this broad region, *H. yunganus* also occupies a wide elevational range, from sea level in French Guiana (Île de Cayenne) to nearly 2,000 m on the eastern Andean slopes of Peru (Yambrasbamba).

SELECTED LOCALITIES (Map 171): **BOLIVIA:** Cochabamba, Charuplaya (BM 2.1.1.39); Pando, Bella Vista, 10 km SSW of Mapiiri (BM 1.1.1.65); Santa Cruz, 4.5 km N and 1.5 km E of Cerro Amboró, Río Pitasama (AMNH 262079). **BRAZIL:** Amapá, Serra do Navio, Macapá (USNM 392065); Mato Grosso, Rio Saueniná (AMNH 37112), 264 km N of Xavantina, Serra do Roncador (BM 81.470); Pará, Agrovila da União, 18 km S and 19 km W of Altamira (USNM 521519); Rondônia, Rio Roosevelt, left bank upper Rio Aripuanã (AMNH 37113). **COLOMBIA:** Cundinamarca, Guaicáramo (AMNH 71328); Putumayo, Río Macaya, at Río Caquetá (FMNH 72067). **ECUADOR:** Napo, Volcán Sumaco (AMNH 68118); Zamora-Chinchiipe, Zamora (AMNH 47830). **French Guiana:** Île de Cayenne (MNHN 1986–322). **Guyana:** Barima-Waini,

Santa Cruz (ROM 98719). **PERU:** Amazonas, Yambrasbamba (BM 26.8.6.14); Huánuco, Chinchao (FMNH 23721); Puno, Río Inambari, probably near Oroya (BM 1.1.1.26); Ucayali, San José, on Río Santa Rosa (LSUMZ 16685). **SURINAM:** Marowijne, Powakka, ca. 50 km S of Paramaribo (CM 54048). **VENEZUELA:** Amazonas, Cerro Duida, Agüita Camp (AMNH 77314); Bolívar, Auyán-tepuí (AMNH 130906).

SUBSPECIES: Despite a wide geographic range and demonstrable variation (see Remarks), *Hylaeamys yunganus* currently regarded as monotypic.

NATURAL HISTORY: *Hylaeamys yunganus* inhabits flooded (*várzea*) and nonflooded (*terra firme*) forests (Musser et al. 1998; Patton et al. 2000; Voss et al. 2001). There is some apparent geographical variation in habitat preferences. In the western Amazon of Brazil, Patton et al. (2000) trapped specimens of *H. yunganus* in primary and secondary flooded and nonflooded forests as well as in abandoned and active garden plots and *Heliconia* thickets. In French Guiana, Voss et al. (2001) reported that the species was limited to primary forest, most frequently in moister sites such as swampy and creekside forest formations where specimens were captured under or beside logs, around the bases of trees, in dense undergrowth unsheltered by woody objects, in tangled dead branches, among fallen palm fronds, and among the stilt roots of standing trees. This difference in habitat utilization may involve competitive interactions with congeners, for in western Brazil, Patton et al. (2000) found *H. yunganus* more frequently associated with *terra firme* forests than was sympatric *H. perenensis* (see above). *Hylaeamys yunganus* has been captured only in traps set at ground level and never in lianas above the ground as has *H. megacephalus*. Capture data also suggest that this species is less abundant than sympatric *H. perenensis* or *H. megacephalus* in the western and eastern Amazon Basin, respectively (Patton et al. 2000; Voss et al. 2001).

Reproductively active males (those with scrotal testes) and females (pregnant, lactating, or postlactating) have been recorded throughout the year in the western Amazon; the modal litter size was two embryos (range: 1–4; Patton et al. 2000). When compared with the sympatric and syntopic *H. perenensis*, *H. yunganus* had smaller modal litter sizes, lower pregnancy rates, and apparently delayed parturition, on average. These features may be related to differences in abundance observed in the field among sympatric species of *Hylaeamys*.

REMARKS: *Hylaeamys yunganus* has been recognized as a valid form since its description (Thomas 1902b), being only provisionally treated as a subspecies of *Hylaeamys megacephalus* by Cabrera (1961). In external morphology, *H. yunganus* is very similar to sympatric

congeners, namely, *H. megacephalus* in eastern Amazonia and *H. perenensis* in western Amazonia. The most conspicuous external character distinguishing *H. yunganus* is the reduction in size or absence of the hypothenar pad on the hindfoot. However, given substantial individual variation of size and presence, this feature lacks utility as an absolutely diagnostic trait (Musser et al. 1998:63, Table 7). In cranial morphology, *H. yunganus* can be told readily from both *H. megacephalus* and *H. perenensis* by the presence of two enamel islands and a short paraflexus on M2, the most reliable character state that distinguishes these species.

Musser et al. (1998:269–271) discussed problems associated with the placement of the type locality. In Brazil, distributional records are widely scattered in the lowland forests of the Amazon Basin. In Bolivia, Peru, and Ecuador the species ranges from lowland rainforest to montane forests in the foothills of the Andes. In Colombia, all records are associated with the narrow area of lowland forest along the eastern base of the Andes, in the headwaters of left bank tributaries of the Río Orinoco. There are no known records of *H. yunganus* in eastern Colombia along the middle and lower reaches of Orinocan tributaries. All collecting sites in Venezuela are from the table mountains (*tepuis*) in the southern and eastern parts of the country.

Hylaeamys yunganus exhibits marked geographical variation in cranial dimensions, with samples from western Amazonia and from the Venezuelan *tepuis* having larger

skulls than those from eastern Amazonia and elsewhere in the Guianan region (Musser et al. 1998). This species is also characterized by chromosomal polymorphism both within and between western ($2n=58-60$; FN=62–66; A. L. Gardner and Patton 1976; Patton et al. 2000) and eastern populations ($2n=52-59$; FN=64–67; Musser et al. 1998). Whether these differences warrant taxonomic recognition must remain for future analyses.

Genus *Lundomys* Voss and Carleton, 1993

Robert S. Voss

The genus *Lundomys* contains a single species, *L. molitor*, which now occurs only in southern Brazil (Rio Grande do Sul) and Uruguay. Previously known as *Holochilus magnus* and thought to be a “sigmodont” (closely related to *Sigmodon*; Hershkovitz 1955b), this taxon was referred to the tribe Oryzomyini by Voss and Carleton (1993) on the basis of derived cranial and visceral characters. Recent phylogenetic analyses (e.g., Weksler 2003, 2006; Parada et al. 2013) unequivocally support the hypothesis that *Lundomys* and *Holochilus* are oryzomyines (not closely related to *Sigmodon*), although they are not consistently recovered as sister taxa (contra Pardiñas and Teta 2011b). Pleistocene and/or early Holocene fossils have been reported from central Brazil (Minas Gerais; Voss and Carleton 1993), Uruguay (Ubilla et al. 2004), and northern Argentina (Lezcano et al. 1992; Pardiñas and Lezcano 1995; Pardiñas and Deschamps 1996; Teta and Pardiñas 2006; Pardiñas and Teta 2011b). Except as noted otherwise here, this account is based on Voss and Carleton (1993), which should be consulted for additional details concerning morphological characters, taxonomy, distribution, and natural history.

Lundomys molitor is a large rat (mature adults probably weigh >300g) with long, dense, soft, yellowish-brown dorsal pelage and buffy under parts. The ears are small and well provided with short brownish or yellowish fur (not contrasting in color with the fur of the head). Mystacial, superciliary, genal, submental, interramal, and carpal vibrissae are present; the mystacial hairs are short and do not extend posteriorly behind the pinnae when laid back against the head. The manus is unremarkable, but the huge (58–68 mm) hindfoot has naked claws (not concealed by long tufts of unguis hairs), conspicuous interdigital webbing, and dense fringes of long silvery hairs along the plantar margins; the plantar surface is hairless and densely squamate, with one metatarsal and four very small interdigital pads (the hypothenar pad is absent); the claw of pedal digit V extends to the end of phalanx 1 of digit IV. There are eight mammae in inguinal, abdominal,

Map 171 Selected localities for *Hylaeamys yunganus* (●). Contour line=2,000 m.

postaxial, and pectoral pairs. The sparsely haired tail (with clearly visible epidermal scales) is unicolored and much longer than the combined length of head and body.

The skull in dorsal view has a blunt, massive rostrum flanked by deep zygomatic notches; the interorbital region is narrow with sharp (but not beaded) supraorbital margins; and the braincase lacks well-developed temporal crests. The zygomatic plates are very broad, with concave anterior margins and spinous anterodorsal processes; the jugals are present and consistently separate the maxillary and squamosal zygomatic processes; and there is a well-developed vertical ridge along the frontosquamosal suture in the back of the orbit. Incisive foramina are long, extending posteriorly to or between the first molar alveoli; the palatal bridge is long and narrow, with prominent posterolateral pits; the parapterygoid fossae are about as wide as the mesopterygoid fossa; and the roof of the mesopterygoid fossa is completely ossified (or perforated by very small sphenopalatine vacuities). Diagnostic features of the basicranium and ear region include the absence of an alisphenoid strut (the buccinator-masticatory foramen and the foramen ovale are confluent); a derived carotid arterial circulation (pattern 3 of Voss 1988); and a tegmen tympani that is not connected to a posterior suspensory process of the squamosal. The auditory bullae are globular, with short and narrow bony tubes, and although the petrosal is broadly exposed posteromedially between the ectotympanic and the basioccipital, it does not extend anteriorly to the carotid canal; above each auditory bulla, the lateral surface of the braincase is perforated by a large postglenoid foramen and a subequally sized subsquamosal fenestra. The coronoid process of the mandible is about level with the condyle; the tip of the angular process does not extend posteriorly much behind the condylar process; the superior and inferior masseteric crests converge anteriorly as an open chevron (not tightly compressed to form a single anterior ridge); and the capsular process is indistinct.

The upper incisors are opisthodont, with smoothly rounded (not faceted) yellow-orange enamel bands. The upper molars are bunodont (not planar), with rounded (rather than angular) labial and lingual cusp margins. The anterocone of M1 is weakly divided (when unworn) into subequal labial and lingual lobes by a shallow anteromedian flexus; an anteroloph is present but small on unworn M1 and well developed on M2 and M3; a shallow protoflexus is present on unworn M2. A small mesoloph is always present on M1 and M2, but it is never fused with a mesostyle on the labial cingulum; no mesoloph is present on M3. All upper molars have three roots. The anteroconid of m1 is entire (not divided by an anteromedian flexid), but it encloses a large enamel pit; minute anterolophids are present on all unworn lower molars; small mesolophs are present on m1 and m2

but not on m3; and discrete posterolophids are present and persistent on m1 and m2. The lower first molar has three or four roots, but m2 and m3 have two roots each.

The axial skeleton includes 12 ribs, 19 thoracolumbar vertebrae, 4 sacral vertebrae, and 35–36 caudal vertebrae. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. The entepicondylar foramen of the humerus is absent.

The stomach is unilocular and hemiglandular, and the gall bladder is absent. Other visceral and genital characters are unknown.

Hesperomys: Winge, 1887:14; part (description of *molitor*); not *Hesperomys* Waterhouse.

Holochilus: Hershkovitz, 1955b:657; part (description of *magnus*); not *Holochilus* Brandt.

Lundomys Voss and Carleton, 1993:5; type species *Hesperomys molitor* Winge, by original designation.

Lundomys molitor (Winge, 1887)

Lund's Water Rat

SYNONYMS:

Hesperomys molitor Winge, 1887:14; type locality given originally as “Lapa do Capão Secco [= Lapa do Capão Seco], da Escrivania [= Escrivânia] Nr. 5 og da Serra das Abelhas”; fixed by lectotype designation (Voss and Myers 1993) to “Lapa da Escrivania [= Escrivânia] Nr. 5, “a cave excavated by P. W. Lund near Lagoa Santa, Minas Gerais, Brazil.

Oryzomys molitor: E.-L. Trouessart, 1897:528; name combination.

Holochilus magnus Hershkovitz, 1955b:657; type locality “Paso de Averías, Río Cebollati, about 40 km south of Trienta y Tres [Lavalleja], eastern Uruguay.”

[*Calomys*] *molitor*: Hershkovitz, 1962:123; name combination.

Holochilus molitor: Massoia, 1980c:282; name combination.

Lundomys molitor: Voss and Carleton, 1993:5; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: All known Recent specimens of *Lundomys molitor* have been collected in Uruguay and in the adjacent Brazilian state of Rio Grande do Sul.

SELECTED LOCALITIES (Map 172): BRAZIL: Rio Grande do Sul, Tupanciretã (T. R. O. Freitas, Mattevi, Oliveira et al. 1983). URUGUAY: Canelones, Bañado de Tropa Vieja (AMNH 206363); Lavalleja, Paso Averías, Río Cebollati (type locality of *Holochilus magnus* Hershkovitz); Soriano, 3 km E of Cardona (AMNH 206368); Treinta y Tres, 8 km E of Treinta y Tres (FMNH 29260).

Map 172 Selected localities for *Lundomys molitor* (●).

SUBSPECIES: I treat *Lundomys molitor* as monotypic.

NATURAL HISTORY: *Lundomys molitor* has been collected in freshwater marshes and along streams bordered by grass and brush. Throughout its range, *L. molitor* is sympatric (and perhaps syntopic) with *Holochilus brasiliensis*, an externally similar semiaquatic species with which it was formerly confused (Hershkovitz 1955b). Scant information from several sources suggests that *L. molitor* is nocturnal, herbivorous, and builds spherical elevated nests supported by and constructed from reeds (Barlow 1969; Sierra de Soriano 1969; Voss and Carleton 1993).

REMARKS: Extralimital fossil remains of *Lundomys molitor* (from Argentina and central Brazil) have been interpreted as evidence for geographic range shifts correlated with Quaternary climatic fluctuations—northward into the tropics during cool episodes (Voss and Carleton 1993) and southward into temperate regions during warmer periods (Teta and Pardiñas 2006; Pardiñas and Teta 2011b).

Genus *Melanomys* Thomas, 1902

Marelo Weksler and Simone Lóss

Members of the genus *Melanomys*, generally known as dusky rice rats, are found in lowland or lower montane forested habitats in Central America from Honduras to Panama (Hall 1981; F. A. Reid 1997), and south to north-

western South America, in Colombia, Ecuador, Peru, and westernmost Venezuela. We recognize six species in the genus: *M. caliginosus*, *M. columbianus*, *M. robustulus*, *M. zunigae*, *M. chrysomelas*, and *M. idoneus*. The last two species are currently found only in Central America and not included in this account. The genus is poorly known, as the last review was that of J. A. Allen (1913b). The following morphological description is based on the analyses of specimens deposited in the AMNH and USNM collections, including most holotypes, but also includes information from J. A. Allen (1913b), Goldman (1918), Hooper and Musser (1964; glans penis), Carleton (1973; stomach), Voss and Linzey (1981; male accessory glands), Voss (1991a; gall bladder), Weksler (2006), and Lóss and Weksler (unpubl. data).

Melanomys are medium-sized (head and body length, 100–150 mm), vole-like rodents with dorsal pelage dark brown, and ventral pelage grayish or yellowish brown; the limits of dorsal and ventral colors are subtle or indistinct. The body pelage is short and close in coastal (lowland) populations, or long, dense, and soft in interior (mountain) forms. Pinnae are small and slightly hairy, not contrasting in color with the dorsal fur. The mystacial vibrissae are short and sparse, extending only to base of pinnae when laid back against cheek. The manus and pes are covered dorsally with short and dark hairs, and the manual claws are long and keeled. The hindfeet do not have natatory fringes or interdigital webs, and have short and sparse tufts of ungual hairs at bases of claws on digit II through digit V; the plantar surface is densely covered with distinct squamae distal to the thenar pad; the hypothenar pad is absent or vestigial, and the interdigital pads are small and fleshy, with pads 1 and 4 displaced proximally relative to 2 and 3. The claw of digit I extends to the middle of phalanx 1 of digit II, and claw of digit V extends to the middle of phalanx 1 of digit IV. The tail is unicolored and dark, sparsely haired, and covered with more or less conspicuous epidermal scales; it is much shorter than the combined length of head and body and does not have a tuft of terminal long hairs. The mammary complement consists of eight teats in inguinal, abdominal, postaxial, and pectoral pairs.

The skull has a robust rostrum flanked by moderate to deep zygomatic notches. The interorbital region is convergent anteriorly, with weakly beaded supraorbital margins. The braincase is rounded, without well-developed temporal crests; the lambdoidal and nuchal crests are weakly developed in older adults. The posterior margins of the zygomatic plates are situated anterior to the M1 alveoli in most specimens, but approximately even with M1 in others. The zygomatic plates lack anterodorsal spinous processes. Jugals are present, but they are very small (maxillary and

squamosal zygomatic processes often overlap in lateral view but rarely are in contact). Lacrimals have a longer maxillary than frontal suture. The frontosquamosal suture is placed either anterior to or continuous with the frontoparietal suture. Parietals have broad lateral expansions. The incisive foramina are short, not extending beyond the M1 alveoli, either with slightly posteriorly divergent or parallel margins. The bony palate between the molar rows is smooth and long; the mesopterygoid fossa penetrates anteriorly between maxillae but not between molar rows. Posterolateral palatal pits are variable in size, number, and morphology but are usually contained within deeply recessed fossae. The bony roof of mesopterygoid fossa is completely ossified or perforated by extremely reduced (slit-like) sphenopalatine vacuities. An alisphenoid strut is absent (buccinator-masticatory foramen and accessory foramen ovale are confluent). The alisphenoid canal has a large anterior opening. The stapedia foramen and posterior opening of the alisphenoid canal are small; a squamosoalisphenoid groove and sphenofrontal foramen are absent; and a secondary anastomosis crosses the dorsal surface of pterygoid plate (characters of carotid circulatory pattern 3 of Voss 1988). A posterior suspensory process of the squamosal is absent. The postglenoid foramen is large and rounded, and the subsquamosal fenestra is absent or vestigial. The periotic is exposed posteromedially between the ectotympanic and basioccipital, usually not extending anteriorly to the carotid canal; the mastoid usually is completely ossified, not fenestrated. A capsular process is present but not well developed in most fully adult specimens. The basihyal is without entoglossal process.

Upper incisors have smoothly rounded enamel bands. The maxillary toothrows are parallel; the molars are bunolophodont and with labial flexi enclosed by a cingulum. Labial and lingual flexi of M1 and M2 meet at the midline, with overlapping enamel. The anterocone of M1 is not divided into labial and lingual conules (anteromedian flexus absent), the anteroloph is fused with the anterocone labially, and an anteroflexus is present as a small fossette. M1 lacks a protostyle. Mesolophes are present on all upper molars, the paracone is connected by an enamel bridge to an anterior moiety of the protocone, and the median mure is not connected to the protocone. The protoflexus is absent from M2, but a mesoflexus is present, either as a single internal fossette or divided into labial and medial fossettes. The paracone of M2 lacks an accessory loph. M3 also lacks a posteroloph, but it possesses a diminutive hypoflexus (which tends to disappear with moderate to heavy wear). An accessory labial root of M1 is present. The anteroconid of m1 is usually without an anteromedian flexid. An anterolabial cingulum is present on all lower molars.

An anterolophid is present on m1 but absent on m2 and m3, an ectolophid is absent on m1 and m2, the mesolophid is distinct on unworn m1 and m2, and a posteroflexid is present on m3. Accessory lingual and labial roots are present on m1; m2 and m3 each have one large anterior root and one large posterior root.

The first rib has a double articulation. The humerus lacks an entepicondylar foramen, but has a supratrochlear foramen. There are 12 ribs. The fifth lumbar (17th thoracolumbar) vertebra has a vestigial anapophysis. A posterior spinous process is present on the hemal arch at the junction of the second and third caudal vertebrae.

The stomach is unilocular-hemiglandular, without extension of glandular epithelium into the corpus. The gall bladder is absent. One pair of preputial glands is present. The distal bacular cartilage of the glans penis is small and trifold (with a short and slender central digit); the non-spinous tissue on the rim of the terminal crater does not conceal the bacular mounds; the dorsal papillae are spineless; and the urethral processes are without subapical lobules.

SYNONYMS:

Hesperomys: Tomes, 1860b:263; part (description of *caliginosus*); not *Hesperomys* Waterhouse.

Hesperomys (Habrothrix): J. A. Allen, 1891b:210; part (listing of *caliginosus*); not *Hesperomys* Waterhouse nor *Habrothrix* Waterhouse.

Oryzomys: Thomas, 1894b:355; part (description of *phaeopus*); not *Oryzomys* Baird.

Akodon: E.-L. Trouessart, 1897:537; part (listing of *caliginosus*); not *Akodon* Meyen.

Oryzomys (Zygodontomys): Bangs, 1900a:95; part (listing of *obscurior* as subspecies of *phaeopus*); not *Oryzomys* Baird nor *Zygodontomys* J. A. Allen.

Oryzomys (Melanomys) Thomas, 1902f:248; type species of new subgenus *Oryzomys phaeopus* Thomas (= *Hesperomys caliginosus* Tomes).

Melanomys: J. A. Allen, 1913b:537; first use as generic designation.

REMARKS: The genus has no fossil record. *Melanomys* can be distinguished from other oryzomyine genera by the following combination of characters: dark dorsal coloration with minimal ventral countershading, tail shorter than head and body, reduction of ungual tufts, robust rostrum, lacrimals with longer maxillary than frontal sutures, long palate, carotid circulatory pattern 3 (Voss, 1988), and bunolophodont molars.

Monophyly of *Melanomys* is corroborated by cladistic analysis of morphological characters (Pine et al. 2012), an unsurprising result given the morphological distinctiveness of *Melanomys* within the Oryzomyini, but recent molecular phylogenetic analyses (Hanson and

Bradley 2008; Pine et al. 2012) recovered *Sigmodontomys alfari* within *Melanomys*, rendering the genus polyphyletic. Pine et al. (2012) proposed that incomplete lineage sorting of sequence haplotypes could be causing the non-monophyly of *Melanomys*. Herein, both *Melanomys* and *Sigmodontomys* are retained as separate genera, but additional analyses are required to confirm or reject this arrangement.

KEY TO THE SOUTH AMERICAN SPECIES
OF *MELANOMYS*:

1. Dorsal pelage dark brown, with tips slightly reddish or dark brown; nasals long (mean 12 mm) 2
- 1'. Dorsal pelage streaked with ochraceous and black, paler than in other species; nasals short (mean 11 mm); known only from the region of Sierra Nevada de Santa Marta in Colombia and westernmost Venezuela
. *Melanomys columbianus*
2. Incisive foramina short (3.7–5.6 mm) 3
- 2'. Incisive foramina long (5.6–6.6 mm); known only from the Lomas de Atocongo, Peru *Melanomys zunigae*
3. Dorsal color coppery brown; interorbital region and rostrum wide; size large *Melanomys robustulus*
- 3'. Dorsal color olivaceous; interorbital region and rostrum narrow; size smaller *Melanomys caliginosus*

Melanomys caliginosus (Tomes, 1860)

Dusky *Melanomys*

Oryzomys (Melanomys) caliginosus monticola: Cabrera, 1961:401; name combination.

Oryzomys (Melanomys) caliginosus buenavistae: Cabrera, 1961:401; name combination.

DESCRIPTION: Geographically variable species, but overall very dark dorsally, almost black flecked with ochraceous or reddish, with dark reddish-brown sides, and orange-brown under parts. Nominotypical form more brownish washed with pale yellow and finely lined with black, especially along midback; other geographic populations range from much darker with hairs tipped ochraceous brown to heavily washed with chestnut red. Most similar to *M. columbianus*, distinguished from it primarily by darker overall color and longer nasals.

DISTRIBUTION: *Melanomys caliginosus* ranges from west-central Colombia to southwestern Ecuador, from sea level to 2,300m. It is distributed mostly along the Andean Cordillera, but also in the lowland rainforest of the Pacific versant, including the Chocó (see Cadena et al. 1998), and in the Cauca Valley. Hanson and Bradley (2008) assigned Central American records ascribed to this species by previous workers (e.g., Hall 1981; Musser and Carleton 2005) to either *M. chrysomelas* or *M. idoneus*.

SELECTED LOCALITIES (Map 173): COLOMBIA: Antioquia, Bellavista (FMNH 70356), Concordia (type locality of *Oryzomys phaeopus obscurior* Thomas), Santa Bárbara, Río Urrao (FMNH 71836); Boyacá, Muzo (FMNH 71838); Caldas, Samana, Río Hondo (FMNH 71816); Cauca, Munchique (AMNH 32406); Huila, Andalucía (AMNH 33783), San Adolfo (FMNH 71823); Meta, Buenavista (type locality of *Melanomys buenavistae* J. A. Allen); Nariño, Candelilla (FMNH 89550); Tolima, Río Toche (type locality of *tolimensis*; AMNH 32976); Valle del Cauca, Río Frio (type locality of *Melanomys phaeopus vallicola* J. A. Allen), Zabaletas (USNM 507245). ECUADOR: Chimborazo, Pallatanga (type locality of *Oryzomys phaeopus* Thomas); El Oro, Salvias (AMNH 47766), Santa Rosa (AMNH 61296); Esmeraldas, Esmeraldas (type locality of *Hesperomys caliginosus* Tomes); Loja, Celica (USNM 461644), Guayas, Los Pozos (AMNH 67470); Manabí, Cuaque (AMNH 66338); Pichincha, Las Máquinas (AMNH 66326), San Tadeo (FMNH 53249); Santa Elena, Cerro Manglar Alto (AMNH 66352).

SUBSPECIES: *Melanomys caliginosus* is clearly polytypic, displaying extensive variation over its known range. The 10 names we currently treat as synonyms of *M. caliginosus* may represent either valid subspecies or even species,

but to date we have been unable to detect external or cranial features that consistently separate any into diagnosable units (Weksler and Lóss, unpubl. data). Thus, for the moment we see no value in trying to delineate infraspecific units.

NATURAL HISTORY: Cadena et al. (1998) trapped this species in virtually intact forest with many palms and epiphytes. They found a male with scrotal testes and a lactating and pregnant female during March. The pregnant female gave birth to two young a few hours after capture and proceeded to eat them over the following days. Previous studies describing the natural history of *M. caliginosus* actually refer to populations from Costa Rica and Panama that we recognize as *M. chrysomelas* and *M. idoneus*, respectively. We include this information here because the genus seems to be ecologically conservative. T. H. Fleming (1970) reported pregnant or lactating females in May, July, August, and November in Panama (= *M. idoneus*). A. L. Gardner (1983b) found pregnant or lactating females in February, March, and August in Costa Rica (= *M. chrysomelas*); 11 pregnant females from Costa Rica averaged 3.5 embryos (range: 1–6); one female had postpartum estrus. Laboratory specimens were eager to eat insects, and some specimens were captured

Map 173 Selected localities for *Melanomys caliginosus* (●); range in Panama from Hall (1981). Contour line = 2,000 m.

during the day in Costa Rica, around leaves and other debris associated with logs, buttress of large trees, and bases of banana foliage (A. L. Gardner 1983b).

REMARKS: Hanson and Bradley (2008) described extensive mitochondrial variation in what had been treated as *M. caliginosus*, which led them to recognize *M. chrysomelas*, *M. idoneus*, and *M. columbianus* as distinct species. We follow their arrangement based on our analyses of morphological and morphometric characters of specimens housed in the AMNH and USNM (Weksler and Lóss, unpubl. data). This complex of species is in need of revision.

Specimens from eastern Colombia (Norte de Santander and Arauca) in the Field Museum that are listed as *Melanomys caliginosus* in the FMNH database ([http:// http:// emuweb.fieldmuseum.org/mammals/Query.php](http://emuweb.fieldmuseum.org/mammals/Query.php)) are not included in our analysis. These localities are outliers to the defined range of the species, and we have not been able to examine them to verify this identification.

A. L. Gardner and Patton (1976) described the chromosomal complement of *M. caliginosus* (now *M. chrysomelas*) from Costa Rica as $2n=56$ and $FN=58$. The karyotype of *M. caliginosus*, as we restrict this species herein, is unknown.

Melanomys columbianus (J. A. Allen, 1899)

Colombian *Melanomys*

SYNONYMS:

Akodon columbianus J. A. Allen, 1899b:203; type locality "Manzanares (alt. 3000 ft), Santa Marta District, [Magdalena,] Colombia."

Melanomys columbianus: J. A. Allen, 1913b:550; first use of current name combination.

Oryzomys (*Melanomys*) *caliginosus columbianus*: Cabrera, 1961:400; name combination.

DESCRIPTION: Distinguished of *M. caliginosus* and *M. robustulus* by paler dorsal pelage, dark brown grizzled with strong yellowish brown varied with black, with tendency for black dorsal stripe. Venter uniform rusty brown, with rusty tips concealing grayish undertones; tail dusky, unicolorous, nearly naked, with scanty short hairs not concealing scale annuli. Rostrum broader than in *M. caliginosus*; otherwise, cranial measurements similar for two species.

DISTRIBUTION: Known only from the region of Sierra Nevada de Santa Marta, northern Colombia, and adjacent northwestern Venezuela, at elevations between 1,000 m and 2,500 m. Extensive collecting below 1,000 m in the Sierra Nevada de Santa Marta yielded no specimens (J. A. Allen 1913b).

SELECTED LOCALITIES (Map 174): COLOMBIA: La Guajira, Chirua (AMNH 36825); Magdalena, Don Diego (AMNH 23291), Manzanares (AMNH 15336). VENEZUELA: Mérida, La Azulita (FMNH 22159); Zulia, Misión Tukuko (USNM 448569).

SUBSPECIES: *Melanomys columbianus* is monotypic.

NATURAL HISTORY: There is no published information on any aspect of the ecology or behavior of this species.

REMARKS: In his original description, J. A. Allen (1912) regarded *M. columbianus* as a member of the genus *Akodon*, comparing it only to *Akodon venezuelensis* (now *Necromys venezuelensis*; see Musser and Carleton 2005) and *Akodon bogotensis*. A year later, in his revision of *Melanomys*, J. A. Allen (1913b) treated *columbianus* as a species of *Melanomys*. Cabrera (1961), however, placed it as a subspecies of *M. caliginosus* without comment. Hanson and Bradley (2008), based on sequences from the mtDNA cytochrome-*b* gene, recommended that *M. columbianus* be recognized as a distinct species, pending further morphological review. We regard this species as distinct from *M. caliginosus* based on as yet unpublished morphometric analyses (Weksler and Lóss, unpubl. data), geographic isolation from the other species, and a few qualitative characters (see above). The karyotype is unknown.

Map 174 Selected localities for *Melanomys columbianus* (●). Contour line = 2,000 m.

Melanomys robustulus Thomas, 1914

Robust Dark Rice Rat

SYNONYMS:

Melanomys robustulus Thomas, 1914d:243; type locality “Gualaquiza, Oriente of Ecuador [Morona-Santiago]. Alt. 250’.”

Oryzomys (Melanomys) robustulus: Tate, 1932f:12; name combination.

DESCRIPTION: Largest species in genus, with head and body length of holotype=122 mm. Skull large, heavily built, with large and convex braincase, broad interorbital region (6.8 mm for holotype), and overhanging supraorbital ledges. Distinguished from both *M. caliginosus* and *M. columbianus* by coppery brown rather than olivaceous dorsal color. Forefeet and hindfeet and tail uniformly black.

DISTRIBUTION: Southeastern Ecuador and northwestern Peru, in tropical lowland rainforest between elevations of 400 to 1,200 m.

SELECTED LOCALITIES (Map 175): ECUADOR: Morona-Santiago, Gualaquiza (type locality of *Melanomys robustulus* Thomas); Napo, San Javier (FMNH 29454); Pastaza, Montalvo (FMNH 41475), Río Pindo Yacu (FMNH 43228); PERU: Loreto, Boca del Río Curaray (AMNH 71555; see LeCroy and Sloss 2000:43 for position of this locality).

SUBSPECIES: *Melanomys robustulus* is monotypic.

NATURAL HISTORY: Little is known of this species. It has been reported as nocturnal and terrestrial (Tirira and Boada 2008).

Map 175 Selected localities for *Melanomys robustulus* (●). Contour line=2,000 m.

REMARKS: Thomas (1914d:243) regarded this species as more similar to *M. chrysomelas* from Central America than to the neighboring *M. caliginosus*. The karyotype is unknown.

Melanomys zunigae Sanborn, 1949

Zuniga's Dark Rice Rat

SYNONYMS:

Oryzomys (Melanomys) zunigae Sanborn, 1949d:2; type locality “Lomas de Atocongo, Department of Lima, Perú.”

Melanomys zunigae Musser and Carleton, 1993:708; first use of current name combination.

DESCRIPTION: Palest species in genus, with general dorsal color dark brown becoming paler on the sides; under parts paler brown mixed with grayish black but with pale tips; both forefeet and hindfeet brown rather than black; tail blackish brown above and slightly paler below. Skull distinguished from congeneric species by long incisive foramina that extend posteriorly to between first molars.

Map 176 Selected localities for *Melanomys zunigae* (●). Contour line=2,000 m.

DISTRIBUTION: This species is known only from the western coast of central Peru, between 600 and 800 m.

SELECTED LOCALITIES (Map 176): PERU: Lima, Cerro San Jerónimo (FMNH 65578), Lomas de Atocongo (type locality of *Oryzomys* [*Melanomys*] *zunigae* Sanborn).

SUBSPECIES: *Melanomys zunigae* is monotypic.

NATURAL HISTORY: This species is known only from the Lomas de Atocongo, a group of low lying hills close to Lima in west central Peru (Musser and Carleton 2005). This area is characterized by desert or dryland habitat, with mesic vegetation along streams and on hilltops as a product of sporadic precipitation from fog during the winter season (Mena et al. 2007). The species is terrestrial and probably nocturnal (Zeballos and Vivar 2008).

Melanomys zunigae is listed as Critically Endangered (Possibly Extinct) by the IUCN (2011) because it has not been seen despite extensive searching over the past 50 years, and because there is a continuing, severe decline in the extent and quality of any remaining habitat (Zeballos and Vivar 2008).

REMARKS: Sanborn (1949d) regarded *M. zunigae* as most closely related to populations of *M. caliginosus phaeopus* from western Ecuador. No phylogenetic analyses of any character set, however, are available comparing this species to any other in the genus. The karyotype is unknown.

Genus *Microakodontomys* Hershkovitz, 1993

Roberta Paresque and J. Delton Hanson

Microakodontomys is a monotypic genus (Hershkovitz 1993) with a restricted distribution in the Brazilian Cerrado biome. The single species is one of the smallest sigmodontines (mean head and body length = 35.3 ± 7.7 mm), with a long, conspicuously scaled tail that is much longer than head and body (mean 93 ± 6.1 mm). It has a relatively long and narrow hindfoot (mean 24 ± 0.8 mm) with small interdigital and hypothenar plantar tubercles and an elongate thenar tubercle. Digit I is much shorter than digits II–IV, which are about the same length, and digit V extends just to the base of the third phalanx of digit IV. Claws are thin, and moderately long with sparse pale unguis hairs.

Dorsally *Microakodontomys* is buffy-ochraceous tinged blackish in color; the venter is creamy. Tricolored hairs, dark brown at the base and black at the tip, with an intermediate and broad buffy band, define the dorsal coloration. Guard hairs on the dorsum are black, forming a dark dorsal strip compared with the fewer, shorter guard hairs on the flanks, which appear more ochraceous. The snout has a black band reaching from the tip to the corner of the eye where it becomes a black eye-ring. The mystacial vibrissae are relatively short, with the longest only extend-

ing to the ears. The proximal half of the tail is bicolored, and on the bicolored half of the tail the hair on the dorsal surface is black, whereas on the ventral surface the hair grades from completely ochraceous (proximal portion), to basally black with ochraceous tips (distal portion). The tip of the tail has a slight tuft.

The skull is small (greatest length 19.3–22.8 mm) with a moderately long, slender rostrum (the nasals are about 35% of the skull length). The lacrimals are slightly inflated, leading into a narrow interorbital region with a slight medial constriction and comparatively little posterior divergence. The zygomatic plates project slightly and partially overlap the capsule of the incisor root. The braincase is flat above and moderately curved behind, with the inflated portion of the supraoccipital bone dorsally visible and the interparietal long and wide. The incisive foramina are narrow and extend to the anterior margins of the M1s, whereas the large posterolateral pits border the palatal bridge, which extends beyond the posterior plane of the M3s. *Microakodontomys* lacks stapedia or sphenofrontal foramina and a squamosal-alisphenoid groove (i.e., it conforms to carotid circulatory pattern 3 of Voss 1988).

Microakodontomys is tetralophodont, with mesolophids and mesolophids absent in all molars. The brachydont upper molar row is short (3.1–3.4 mm) and tuberculate. The paraflexus in all upper molars is isolated from the margin, as is the metaflexus in the first and third upper molars. In M1, the anterocone has well-defined anterolabial and anterolingual conules; an anterior fossette is absent, as are the posterostyle and posteroloph. M3 is less than half the size of M2, but has an enlarged median fossette and is subtriangular in occlusal outline. The lower molars are subhypsodont; m1 and m2 has isolated mesoflexids and postereoflexids and lacks ectolophids; m1 is also missing an anterolophid and stylid; and m3 is subtrapezoidal in occlusal outline and has isolated lingual flexids. Upper incisors are opisthodont.

Nearly all cranial and dental information for this species was gleaned from Hershkovitz's (1993) description of the type specimen. Recent material has been collected from the Cerrado of Brazil and is discussed here.

SYNONYM:

Microakodontomys Hershkovitz, 1993:2; type species *Microakodontomys transitorius*, by original designation.

REMARKS: In his description, Hershkovitz (1993) discussed affinities of the genus based on size as well as on cranial measurements. He viewed this taxon as a derived member of the Sigmodontinae, suggesting it was intermediate between akodontines and oryzomyines: resembling *Akodon* in its molar pattern and certain cranial characteristics and *Oligoryzomys* or *Microryzomys* in overall cranial similarity. Although Hershkovitz (1993:4) ac-

knowledged the possibility that his new taxon was only a “well-differentiated species of *Oligoryzomys*,” he believed that based on dental characteristics, facial coloration, and tail length *Microakodontomys* was easily distinguishable from any other sigmodontine rodent. However, the lack of mesoloph and mesolophids in some specimens of *Oligoryzomys rupestris* as well as in *O. fornesi* and the general characteristics of small body, long tail, and long hindfeet have called into question the status of the *Microakodontomys*. Musser and Carleton (2005) recognized *Microakodontomys* but recommended additional studies to determine its relationships with *Oligoryzomys*. In contrast, Weksler et al. (2006) considered *M. transitorius* an aberrant form of *Oligoryzomys* and subsumed *Microakodontomys* within that genus.

During a recent collecting effort at the type locality of *M. transitorius*, R. Paresque and colleagues (unpubl. data) trapped four additional specimens and compared them with sympatric individuals of two *Oligoryzomys* species (*O. nigripes* and *O. fornesi*) to test whether *Microakodontomys* was a valid genus. Their parsimony analyses of DNA sequence data from *Microakodontomys* (including from the holotype) and other sigmodontine genera supported *Microakodontomys* as a valid genus within the Oryzomyini, and one with a closer relationship to *Sigmodontomys alfari*, *Melanomys caliginosus*, and *Oryzomys couesi* than to *Oligoryzomys*.

Microakodontomys transitorius Hershkovitz, 1993

Transitional Colilargo

SYNONYMS:

Microakodontomys transitorius Hershkovitz, 1993:2; type locality “Parque Nacional de Brasília [Distrito Federal], about 20 km NW of Brasília, D. F., [Brazil] about 1100 m.”

Oligoryzomys transitorius: Weksler, Percequillo, and Voss, 2006:4; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: This species has an extremely restricted distribution, known only from two sites in the Parque Nacional de Brasília in central Brazil.

SELECTED LOCALITIES (Map 177): BRAZIL: Distrito Federal, Parque Nacional de Brasília (type locality of *Microakodontomys transitorius* Hershkovitz).

SUBSPECIES: *Microakodontomys transitorius* is monotypic.

NATURAL HISTORY: *Microakodontomys transitorius* is found in edge habitat in the Cerrado biome of Brazil that is transitional between *campo limpo* (wet grassland) and *campo sujo* (grass and shrub assemblage). With its long tail and moderately long feet, this mouse is presumably adapted to both sylvan environs as well as more pastoral habitats

Map 177 Selected locality for *Microakodontomys transitorius* (●).

(Hershkovitz 1993). Additionally, its external morphology is similar to that of *Oligoryzomys fornesi* and *O. nigripes*, both of which are also found syntopically in edge habitats. The restricted distribution, combined with the low incidence of capture despite frequent collection efforts over the years, suggests that *M. transitorius* is a rare species.

REMARKS: The karyotype has $2n=38$, $FN=46$ (R. Paresque et al., unpubl. data). The autosomal complement includes 13 acrocentric pairs, gradually decreasing in size, and five pairs of small, biarmed chromosomes. The X chromosome is large submetacentric, and the Y chromosome is a small submetacentric.

Genus *Microryzomys* Thomas, 1917

Michael D. Carleton

Species of *Microryzomys* are small oryzomyines (10–15 g) that are externally recognizable by their soft, luxuriant fur and a tail notably longer than head and body. The hindfeet are short and slender, the plantar surface bears six fleshy pads (thenar and hypothenar pads are large), and the fifth digit (V) is nearly as long as the central three (II–IV). Females possess eight mammae, arranged in four pairs and anatomically positioned as in

other Oryzomyini (Carleton and Musser 1989; Voss and Carleton 1993).

The skull is delicately constructed, characterized by a short, attenuate rostrum, hourglass-shaped interorbit, and smooth, rounded braincase devoid of ridges. The zygomatic plate is conspicuously narrow and the dorsal notch rudimentary. The cranial wall above the otic capsule is perforated by a spacious subsquamosal fenestra and postglenoid foramen, which together delineate a narrow hamular process. For an oryzomyine, the bony palate is short, extending only slightly beyond the end of the third molars, and the posterolateral palatal pits are correspondingly small and simple; parapterygoid fossae are shallow and narrow. An alisphenoid strut is uniformly absent, the masticatory-buccinator foramen and foramen ovale accessorius being broadly confluent. The co-occurrence of certain cranial foramina and osseous grooves indicates a primitive cephalic arterial supply (Carleton and Musser 1989; pattern 1 of Voss 1988): large stapedia foramen, large posterior opening of the alisphenoid canal, and presence of an squamosoalisphenoid groove leading to the sphenofrontal foramen. The ectotympanic bulla is small, exposing a broad wedge of the periotic in ventral view, and the tegmen tympani does not overlap the squamosal (Voss 1993).

Species of *Microrizomys* possess diminutive, cuspidate molars with brachydont crowns and a pentalophodont occlusal pattern. The upper and lower third molars are noticeably smaller than the second molars. The anterocone(-id) is deeply bifurcated and wide, imparting a rectangular shape to the first molars; the well-developed mesoloph(id) reaches the buccal margin of the tooth; and an anteroloph(id) is usually present and distinct. Three roots anchor each upper molar; each lower molar has two. The upper incisors are narrow, asulcate, and typically orthodont. See Carleton and Musser (1989) and accounts herein for additional external, cranial, and dental descriptions and comparisons with *Oligoryzomys* and *Oryzomys sensu stricto*; see Musser and Carleton (2005) and Weksler et al. (2006) for contrasts with the externally similar Andean species *Oryzomys balneator* Thomas (1900), now placed in the newly described genus *Oreoryzomys* Weksler, Percequillo, and Voss (2006).

Stomach morphology conforms to the unilocular-hemiglandular plan, but glandular epithelium is more extensive over the lesser curvature than in *Oryzomys sensu stricto* (Carleton and Musser 1989). No gall bladder is present (Voss 1991a). A full complement of male accessory reproductive glands, including preputials, has been reported based on single examples of each species (Voss and Linzey 1981; Carleton and Musser 1989).

SYNONYMS:

Hesperomys: Tomes, 1860a:215; part (description of *minutus*); not *Hesperomys* Waterhouse.

Oryzomys: E.-L. Trouessart, 1897:527; part (listing of *minutus*); not *Oryzomys* Baird.

Oryzomys (*Microrizomys*) Thomas, 1917g:1; type species *Oryzomys minutus* (Tomes), by original designation.

Microrizomys: Thomas, 1926b:314; first usage as genus.

Oryzomys (*Oligoryzomys*): Thomas, 1926e:613; part (allocation of *Microrizomys* as full synonym, invalid as subgenus); not *Oligoryzomys* Bangs.

Oligoryzomys: Gyldenstolpe, 1932a:26; part (listing of *Microrizomys* as full synonym); not *Oligoryzomys* Bangs.

Thallomyscus Thomas, 1926e:612; type species *Oryzomys dryas* Thomas, by original designation.

Oryzomys (*Thallomyscus*): Tate, 1932f:5; name combination.

Oryzomys (*Microrizomys*): Osgood, 1933c:1; name combination (*Thallomyscus* allocated as full synonym, invalid as subgenus).

REMARKS: *Microrizomys* was originally designated as a subgenus of *Oryzomys* and subsequently retained as such (Osgood 1933c; Ellerman 1941; Cabrera 1961) or placed in synonymy with *Oligoryzomys* (Thomas 1926e; Gyldenstolpe 1932; Tate 1932f). The junior synonym *Thallomyscus* has been formally retained as a subgenus (Tate 1932f) or allocated as a full synonym (Osgood 1933c; Carleton and Musser 1989). *Microrizomys*, along with *Oligoryzomys*, was once considered to be a taxonomic grade that artificially united merely small-bodied species of *Oryzomys* (Goldman 1918; Tate 1932f; Hershkovitz 1944); however, Carleton and Musser (1989) consolidated discrete morphological traits that differentiate species of *Microrizomys* from both *Oligoryzomys* and typical *Oryzomys* and recast its diagnosis as genus. *Microrizomys* is a member of Oryzomyini (*sensu* Voss and Carleton 1993; Musser and Carleton 2005; Weksler 2003, 2006) and shares certain morphological traits with *Neacomys*, *Oligoryzomys*, and *Oreoryzomys* (Carleton and Musser 1989; Weksler 2006; Weksler et al. 2006). In phylogenetic interpretations using allozymic or mitochondrial sequence data, *Microrizomys* variously falls in a clade that includes *Neacomys* and *Oligoryzomys* (Dickerman and Yates 1995; Myers et al. 1995; Patton and da Silva 1995; M. F. Smith and Patton 1999). In taxonomically broad studies of oryzomyines (Weksler 2003, 2006; Weksler et al. 2006; Percequillo, Costa, and Weksler 2011; Pine et al. 2012), using morphology in combination with nuclear and/or mitochondrial genes, the genus emerges as sister to *Oreoryzomys*, usually in the cladistic hierarchy (*Neacomys* (*Oligoryzomys* (*Microrizomys* + *Oreoryzomys*))).

Both forms of *Microrizomys* may prove to be species composites. Carleton and Musser (1989) drew attention to the strong morphometric differentiation of their isolated samples of *M. altissimus* in central Colombia and questioned

the apparent morphological homogeneity of both *M. altissimus* and *M. minutus* across the Huancabamba Depression in northwestern Peru. The high-elevation occurrence of the genus in different Andean cordilleras elegantly lends itself to a phylogeographic study using molecular data.

KEY TO THE SPECIES OF *MICRORYZOMYS*:

1. Pelage principally ochraceous-tawny; dorsal and ventral body fur faintly contrasted; tail basically unicolor and longer (usually >110 mm); dusky markings present on tops of forefeet and hindfeet; skull with shorter, ovate incisive foramina (usually terminating short of or even with the level of the M1s) and shorter toothrow (usually <3.0 mm); dentary with distinct incisor tubercle
 *Microrizomys minutus*
- 1'. Dorsal pelage more buffy, and under parts grayish buff; dorsum and venter clearly demarcated; tail bicolored and shorter (usually <110 mm); tops of forefeet and hindfeet whitish; skull with longer, narrower incisive foramina (usually penetrating between the M1s) and longer toothrows (usually >3.0 mm); dentary with inconspicuous incisor tubercle *Microrizomys altissimus*

Microrizomys altissimus (Osgood, 1933)

Páramo Colilargo

SYNONYMS:

- Oryzomys minutus*: Osgood, 1914b:158; part.
Oryzomys (Microrizomys) minutus altissimus Osgood, 1933c:5; type locality "La Quinua, mountains north of Cerro de Pasco, [Pasco,] Peru. Alt. 11,600 ft."
M[icrorizomys]. a[ltissimus]. altissimus: Hershkovitz, 1940a:81; name combination.
Microrizomys altissimus hylaeus Hershkovitz, 1940a:81; type locality "Atal, within the confines of the Hacienda Indújel del Vincula, near San Gabríel, Montúfar, Carchi Province, Ecuador. Altitude, about 2900 meters."
Microrizomys altissimus chotanus Hershkovitz, 1940a:82; type locality "southern slopes of the arid Chota Valley, parish of Pimanpiro, Imbabura Province, Ecuador. Altitude, about 2000 meters."
Oryzomys altissimus altissimus: Cabrera, 1961:397; name combination.
Oryzomys altissimus hylaeus: Cabrera, 1961:398; name combination.
Oryzomys altissimus chotanus: Cabrera, 1961:398; name combination.

DESCRIPTION: *Microrizomys altissimus* is characterized by more buff in the upper body fur and grayish buff in the under parts such that the dorsum and venter are clearly demarcated; grayish head, tail bicolor and usually shorter than 110 mm, and tops of forepaws and hindpaws whitish; hindfeet and metatarsal pads narrower; skull slightly

heavier with broader braincase; longer incisive foramina, and longer (usually greater than 3.0 mm), more robust toothrows; and incisor tubercle of dentary small (see Carleton and Musser 1989:68).

DISTRIBUTION: *Microrizomys altissimus* occurs in the high elevations of the central Andes, including the Cordillera Central of central Colombia; Cordilleras Occidental and Oriental of Ecuador; Cordilleras Occidental and Oriental of northern Peru, and southward to the vicinity of Junín in central Peru. Its known elevational range is from 2,000 to 4,300 m, but most occurrences are from 2,500 to 4,000 m.

SELECTED LOCALITIES (Map 178; from Carleton and Musser 1989, except as noted): COLOMBIA: Quindío, Finca La Cubierta, 6 km N of Salento-Cocora road; Tolima, Nevado de Ruiz. ECUADOR: Azuay, Bestión; Bolívar, Sinche; Cañar, Chical, Naupan Mountains; Carchi, Atal, near San Gabríel, Montúfar (type locality of *Microrizomys altissimus hylaeus* Hershkovitz); Napo, Antisana; Pichincha, Pichincha; Tungurahua, San Francisco. PERU: Amazonas, mountains E of Balsas; Ancash, Huaras, Quilcahuanca; Huánuco, Huánuco; Junín, Maraynioc, 45 km NE of Tarma; Libertad, mountains NE of Otuzco; Pasco, La Quinua, mountains N of Cerro de Pasco (type locality of *Oryzomys (Microrizomys) minutus altissimus* Osgood); Piura, Huancabamba.

SUBSPECIES: Carleton and Musser (1989) provisionally regarded *Microrizomys altissimus* as monotypic.

NATURAL HISTORY: *Microrizomys altissimus* inhabits grassy páramo and assorted subalpine wet forest ecotones, where it has been obtained in terrestrial settings (Voss 1978–1980 [in Carleton and Musser 1989]; Barnett 1999; Voss 2003). Most instances of sympatry with *M. minutus* have been documented where upper montane rainforest and páramo intermix, within an elevational belt of 2,500 to 3,500 m (Osgood 1933c; Carleton and Musser 1989; Barnett 1999). Its diet in Peruvian montane forest was characterized as omnivorous, including grass stems and seeds, insect larvae and adults, and fruits (Noblecilla and Pacheco 2012). Basic aspects of behavior, ecology, and reproduction require much illumination.

REMARKS: Osgood (1933c) originally diagnosed *altissimus* as a subspecies of *Oryzomys minutus*, but Hershkovitz (1940a) elevated it to species and created two additional subspecies. Cabrera (1961) recognized the two subspecies named by Hershkovitz (1940a) from Ecuador, but Carleton and Musser (1989) considered neither valid. Carleton and Musser (1989:21), however, noted the cranial morphometric distinctiveness of samples from Colombia, a separation that is not reflected in the distribution of the named subspecies. The karyotype is characterized as $2n=57$ and $FN=58$, based on a single female judged to be "a heterozygote for a Robertsonian translocation" (A. L. Gardner and Patton 1976).

Map 178 Selected localities for *Microrzomys altissimus* (●). Contour line = 2,000 m.

Microrzomys minutus (Tomes, 1860)

Montane Colilargo

SYNONYMS:

H[esperomys]. minutus Tomes, 1860a:215; type locality unknown, probably near Pallatanga, on the western slope of the Cordillera, Chimborazo, Ecuador (Carleton and Musser 1989:65).

Oryzomys minutus: E.-L. Trouessart, 1897:527; name combination.

Oryzomys dryas Thomas, 1898f:267; type locality "Pallatanga, [Chimborazo,] Ecuador."

Oryzomys dryas humilior Thomas, 1898f:268; type locality "Plains of Bogotá," Cundinamarca, Colombia.

Oryzomys (Oligoryzomys) dryas humilior: Bangs, 1900a:95; name combination.

Oryzomys (Oligoryzomys) fulvirostris J. A. Allen, 1912:86; type locality "Munchique (alt. 8325 ft)," Cauca, Colombia.

Oryzomys (Microrzomys) minutus fulvirostris: Osgood, 1933c:5; name combination.

Oryzomys (Microrzomys) minutus aurillus: Osgood, 1933c:4; name combination.

Microrzomys minutus: Hershkovitz, 1940a:83; name combination.

Microrzomys m[inutus]. humilior: Hershkovitz, 1940a:83; name combination.

Microrzomys m[inutus]. fulvirostris: Hershkovitz, 1940a:83; name combination.

Microrzomys m[inutus]. aurillus: Hershkovitz, 1940a:83; name combination.

DESCRIPTION: This species of *Microrzomys* is characterized by the prevalence of ochraceous-tawny pelage tones, faint or no contrast from the ventral body fur, tail basically unicolored and usually longer than 110 mm, and dusky markings on tops of the forefeet and hindfeet; hindfeet slightly wider, and plantar pads more robust; skull more delicate with narrower braincase, shorter and ovate incisive foramina, and shorter tooththrow (usually less than 3.0 mm); dentary with distinct tubercle (see Carleton and Musser 1989:65–66).

DISTRIBUTION: This species is known from middle to high elevations in the northern and central Andes, including the Caribbean Coastal Ranges and Mérida Andes of Venezuela; Sierra Nevada de Santa Marta, Cordilleras

Oriental, Central, and Occidental of Colombia; Cordilleras Oriental and Occidental of Ecuador; Cordillera Occidental of northwestern Peru and Cordillera Oriental and its eastern flanks in central Peru; into west-central Bolivia as far as westernmost Santa Cruz department. This range excludes the Altiplano region and coastal ranges of southwestern Peru. Known elevational occurrence is from 800 to 4,265 m, with over 80% of collecting localities between 2,000 and 3,500 m.

SELECTED LOCALITIES (Map 179; from Carleton and Musser 1989, except as noted): **BOLIVIA**: La Paz, 30 km N of Zongo; Santa Cruz, Siberia, 25 and 30 km W of Comarapa. **COLOMBIA**: Antioquia, Santa Bárbara, Río Urrao, Ventanas, Valdivia; Cauca, Cerro Munchique (type locality of *Oryzomys (Oligoryzomys) fulvirostris* J. A. Allen), Valle de la Papas; Cundinamarca, Guasca, Río Balcones; Magdalena, Macotama; Quindío, Salento. **ECUADOR**: Azuay, Molleturo, Bestión; Carchi, Montúfar, near San Gabriel; Chimboraza, Pallatanga (type locality of *Oryzomys dryas* Thomas); El Oro, Taraguachocha, Cordillera de Chilla; Napo, Baeza; Pichincha, Pacto. **PERU**: Amazonas, Cordillera Colán, NE of La Peca, Uchco, Tambo Almirante; Ayacucho, Puncu, 30 km NE of Tambo; Cajamarca, Taulís; Cusco, Marcapata, Torontoy (type locality of *Oryzomys (Microryzomys) aurillus* Thomas); Huánuco, below Carpish Pass, trail to Hacienda Paty; Junín, Acobamba, 45 km NE of Cerro de Pasco (incorrectly given as Pasco department), Yano Mayo, Río Tarma; Piura, Cerro Chinguela, 5 km NE of Zapalache; Puno, Agualani, 9 km N of Limbani (MVZ 171476). **VENEZUELA**: Mérida, Páramo Tambor; Miranda, Alto de Nuevo León, 33 km WSW of Caracas; Sucre, Cerro Negro, 10 km NW of Caripe; Tachira, Buena Vista, 41 km SW of San Cristóbal; Trujillo, Hacienda Misisí, 15 km E of Trujillo.

SUBSPECIES: Carleton and Musser (1989) treated *Microryzomys minutus* as monotypic.

NATURAL HISTORY: The species is found in various Andean moist forest environments, from lower montane and upper montane rainforest, through various subalpine forest and shrubby habitats, into the lower fringes of páramo (Osgood 1933c; Carleton and Musser 1989; Barnett 1999; Voss 2003). In Venezuela, *M. minutus* was most frequently encountered in upper montane rainforest (cloud forest as per Handley 1976), in both disturbed and pristine habitats (Cabello et al. 2006), and most collecting localities with known elevation fall within this vegetational zone (Carleton and Musser 1989). Cabello et al. (2006) considered the species to be the most abundant rodent in Venezuelan cloud forests. Diet in the Peruvian montane forest was characterized as omnivorous, including grass stems and seeds, insect larvae and adults, and fruits (No-

Map 179 Selected localities for *Microryzomys minutus* (●). Contour line = 2,000 m.

blecilla and Pacheco 2012). *Microryzomys minutus* has been collected usually on the ground (Handley 1976; Voss 1978–1980 [in Carleton and Musser 1989]; Cabello et al. 2006) like its congener *M. altissimus*, but Carleton and Musser (1989) suggested that the longer tail and larger plantar pads of *M. minutus* indicate greater scansorial or arboreal proclivities. Possible differences in climbing behavior, along with other natural history information, need detailed autecological study where the two species occur in syntopy.

REMARKS: *Microryzomys minutus* formerly included *altissimus* as a subspecies as described by Osgood (1933c), who also treated *aurillus*, *humilior*, and *fulvirostris* as valid subspecies. Carleton and Musser (1989) found no geographic units that they deemed diagnosable as subspecies. Diploid chromosomal count reported as $2n = 58$ (Kiblicky 1969).

Genus *Mindomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

Known only from a handful of specimens from the Ecuadorian Andes, *Mindomys* is a monotypic genus with its single species, *M. hammondi*, characterized by a distinctive morphology but uncertain phylogenetic relationships (Weksler 2006). The body size of all specimens is large (head and body length 173–293 mm), the tail is much longer than head and body (tail length 222–251 mm), and the hindfeet are robust (length 38–42 mm). The dorsal body pelage is long (aristiform length 14–16 mm), compact, dense, and harsh; aristiforms are extremely abundant. The dorsal body coloration varies from grayish to buffy yellow grizzled with brown; the ventral coloration is light buff densely grizzled with grayish, markedly gray grizzled with white in some specimens. Long hairs that partially conceal large scales cover the tail surface; these caudal hairs increase in length from the base to the tip of the tail. The tail scales and hairs are blackish or dark brown, and there is no dorsoventral countershading. Both external and internal surfaces of the ears are well furred with short, entirely brown hairs. The forefeet are robust and completely covered above by short brown hairs. The hindfeet are densely covered by short hairs above that are overall whitish or grayish, but brown basally and white apically. Ungual tufts are short and sparse but extend to the tips of the claws. The mystacial vibrissae are thick, very dense, long, and reach considerably past the ears when laid back; supraorbital vibrissae are very long, largely surpassing the tips of the pinnae.

The skull is very large and robust, ranging from 37.6–44.3 mm in length. The rostrum is long (nasal length 13.4–16.6 mm) and wide (rostral breadth 6.4–7.2 mm), with weakly projected nasolacrimal capsules. The zygomatic notches are narrow and very shallow; the free dorsal margins of the zygomatic plates are very reduced, with their anterior margins exhibiting straight profiles. The zygomatic arches are robust and convergent anteriorly; jugals are small. The interorbital region is wide (interorbital constriction 6.1–8.0 mm) and slightly divergent posteriorly; supraorbital margins are squared or have small dorsolateral projections. The braincase is elongate and has distinct temporal crests. Incisive foramina are medium to long (length 5.7–6.7 mm) and laterally convex, forming an elongated oval. The palate is long and wide, with small posterolateral palatal pits set in shallow palatine depressions; no palatal excrescences are present. The anterior margin of the mesopterygoid fossa may reach the alveoli of the M3s; its roof is completely ossified or has only small and nar-

row sphenopalatine vacuities in the presphenoid or at the presphenoid-basisphenoid suture. The stapedial foramen is large, and the squamosoalisphenoid groove and sphenofrontal foramen are present, features that define carotid circulatory pattern 1 (*sensu* Voss 1988). The buccinator-masticatory and accessory oval foramina are confluent, thus an alisphenoid strut is absent in all specimens. Auditory bullae are small, with a robust, long, and flattened stapedial process; the bony tubes are short and flat. The bullae are in close contact with the squamosal, resulting in a small and narrow postglenoid foramen; the subsquamosal fenestra is absent. The suspensory process of the squamosal is absent, and the tegmen tympani is short, overlapping the squamosal.

The mandible is deep and robust; the angular process surpasses the condyloid process posteriorly, and the coronoid process is shorter than the condyloid. Inferior and superior notches are shallow. A small but discrete capsular process is present in older specimens.

Upper incisors are opisthodont. The molars are pentalophodont and moderately high-crowned; cusps are compressed anteroposteriorly, high in profile, and with labial and lingual cusps arranged in opposite pairs. Both labial and lingual flexi are deep and narrow, overlapping at the molar midplane. Molars are extremely robust, with the upper series 6.1–6.8 mm in length. The paracone of M1 is connected medially to the protocone and is also linked to the mesoloph by an oblique paralophule, which defines a narrow and oblique medial fossette. M3 is long, with all main elements discernible on its occlusal surface, including the metacone and posteroloph.

SYNONYMS:

Nectomys: Thomas, 1913c:570; part (description of *hammondi*); not *Nectomys* Peters.

Oryzomys (*Macruroryzomys*) Hershkovitz, 1948b:56; type species *Nectomys hammondi* Thomas; *nomen nudum*.

[*Oryzomys*] (*Macruroryzomys*): Cabrera, 1961:410; name combination.

Oryzomys: Musser and Carleton, 1993:722 (listing of *hammondi*); part; not *Oryzomys* Baird.

Mindomys Weksler, Percequillo, and Voss, 2006: 16; type species *Nectomys hammondi* Thomas, by original designation.

REMARKS: The uniqueness of this species with respect to other oryzomyine rodents prompted Hershkovitz (1948b) to erect the genus-group name *Macruroryzomys* for *N. hammondi*. However, as Hershkovitz (1970b) later admitted and as reinforced by Pine and Wetzel (1976), *Macruroryzomys* is a *nomen nudum* since no characters were given for it. Hence, this distinctive taxon lacked a valid generic name until the descriptions of Weksler et al. (2006).

Mindomys hammondi (Thomas, 1913)

Hammond's Mindomys

SYNONYMS:

Nectomys hammondi Thomas, 1913c:570; type locality "Mindó, N.W. of Quito. Alt. 4213 ft.," Pichincha, Ecuador.

[*Oryzomys*] (*Macruroryzomys*) [*hammondi*]: Hershkovitz, 1948b:56; name combination.

Oryzomys hammondi: Musser and Carleton, 1993:722; name combination.

[*Mindomys*] *hammondi*: Weksler, Percequillo, and Voss, 2006:16; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Mindomys hammondi* is known from only three localities, all in the Ecuadorean Andes. Two of these are in the vicinity of Mindo on the western slope (elevation 1,260 to 1,330m) and other in the Amazonian lowlands (300–500m). The latter record, however, is problematic because it poses an unusual distributional pattern among Andean small mammals: no species that is distributed below 1,500m in the Ecuadorean Andes, as is *M. hammondi*, is known to occur on both the east and west slopes. Rather, species below this elevation occur either on one or the other side of the Andes (Weksler et al. 2006:16, footnote 5; see McCain et al. 2007:135 for further discussion).

SELECTED LOCALITIES (Map 180): ECUADOR: Pichincha, Mindo (type locality of *Nectomys hammondi*), Concepción (MCZ 52543).

SUBSPECIES: *Mindomys hammondi* is monotypic.

NATURAL HISTORY: No data other than those dealing with general habitat are available for this species. Voss (1988) provided good habitat descriptions for the Mindo region (where the most recent specimen of *M. hammondi* was captured), which is drained by the Mindo, Canchupi, and Saguambi rivers. This general area is covered by montane rainforest (cloud forest), except in river valleys in which the forest is similar to late successional lowland rainforest because these valleys were deforested some decades ago. The canopy is of moderate height (15 to 20m), and the trees are covered by abundant epiphytes (orchids, bromeliads, Aracea, and lianas) as well as by a thin moss layer. The most common emergents are palms and giant bamboo. The understory is dense and formed by woody dicots (mainly Piperaceae and Melastomataceae), Musaceae, Zingiberaceae, Cuclanthaceae, small Arecaceae and a giant *Equisetum*, this last commonly along riverbeds. The litter layer is formed by logs, branches, leaves, flowers, and fruits, and covers a thin humus layer. The small rivers in the Mindo region are shallow and sluggish, with muddy or sandy bottoms, and the larger rivers are deeper and faster, with sandy, gravel, or cobble-bottomed. During July, midwinter, the

Map 180 Selected localities for *Mindomys hammondi* (●). Contour line=2,000m.

minimum and maximum daily air temperatures average 14 and 22° C, respectively.

REMARKS: *Mindomys hammondi* has always been viewed as a valid species, regardless of the genus or subgenus to which it has been allocated (*Nectomys* [Thomas 1913], *Macruroryzomys* [Hershkovitz 1948b], or *Oryzomys sensu lato* [Musser and Carleton 1993]). In fact, the combination of external and cranial traits exhibited by this species clearly distinguishes it from all oryzomyine genera and species, notably its large size, short and harsh dark grayish pelage, long unicolored tail, large and robust skull and molars, narrow and slightly diverging but beaded interorbital region, and carotid circulatory pattern 1, among other features. Species of the genus *Nectomys* superficially resemble *M. hammondi* but are separable by cranial (carotid circulatory pattern; interorbital region) and dental traits (general molar occlusal pattern). While the phylogenetic position of *M. hammondi* within the Oryzomyini remains problematic (Weksler 2006), its status as a unique lineage led Weksler et al. (2006) to erect the genus *Mindomys*.

Genus *Neacomys* Thomas, 1900

Marcelo Weksler and Cibele R. Bonvicino

Members of the genus *Neacomys*, called bristly or spiny mice (e.g., Musser and Carleton 2005), occur throughout the Amazon Basin in Brazil, Colombia, Peru, Ecuador,

Bolivia, Venezuela, Guyana, Surinam, and French Guiana, and west of the Andes from easternmost Panama (Darién province) to Ecuador and Venezuela, where they are present in lowland, premontane, and lower montane rainforest below about 1,500 m elevation. Seven species are currently recognized from South America: *Neacomys dubosti*, *N. guianae*, *N. minutus*, *N. musseri*, *N. paracou*, *N. spinosus*, and *N. tenuipes*. An eighth species, *N. pictus*, is presently known only from easternmost Panama (see Hall 1981).

Species of *Neacomys* are small oryzomyines (head and body length 64–100 mm) with short and grooved spines in the coarsely grizzled yellowish-, reddish-, or grayish-brown dorsal fur and on the contrastingly pale or white ventral fur, with small ears, moderately long vibrissae, and sparsely haired tails as long as or slightly longer than the combined head and body length. The hindfeet are narrow and without interdigital webs; the three middle digits (II, III, and IV) are much longer than the outer two (I and V); the plantar surface is entirely naked (from heel to toes) and scaly, with six fleshy tubercles (thenar, hypothenar, and four interdigitals). Mammae number eight, positioned in inguinal, abdominal, postaxial, and pectoral pairs (not six as reported by Gyldenstolpe 1932 and Steppan 1995; see Weksler 2006).

The skull is delicate, with nasal bones blunt their posterior margins and extending posteriorly behind the lacrimals; lacrimals have subequal maxillary and frontal suture borders. The posterior wall of the orbit is smooth. The frontosquamosal suture is colinear with the frontoparietal suture. The parietals are mostly restricted to the dorsal surface of the skull. The zygomatic plates lack anterodorsal spinous processes, and their posterior borders lie anterior to the M1s. Jugals are present but small (the maxillary and squamosal zygomatic processes broadly overlap but are not in direct contact). Incisive foramina are short, not extending posteriorly to or between the M1 alveoli. The bony palate is smooth or weakly sculptured, and long (the mesopterygoid fossa does not penetrate anteriorly between maxillary bones). Posterolateral palatal pits are present but are not recessed in deep fossae. The bony roof of the mesopterygoid fossa is perforated by small sphenopalatine vacuities. An alisphenoid strut is almost always absent (buccinator-masticatory foramen and accessory foramen ovale are confluent); the alisphenoid canal has a large anterior opening; and the stapedia foramen is large (= carotid circulatory patterns 1 or 2 of Voss 1988). A posterior suspensory process of the squamosal is absent. The postglenoid foramen is large and rounded, and the subsquamosal fenestra is present. The petiotic is exposed posteromedially between the ectotympanic and basioccipital, extending anteriorly to the carotid canal. The capsular process is

present in most fully adult specimens; superior and inferior masseteric ridges join anteriorly at a point so as to form a chevron.

The upper incisors are opisthodont, with smoothly rounded enamel bands. The maxillary toothrows are parallel. Molars are bunodont and with labial flexi enclosed by a cingulum. The anterocone of M1 is divided into anterolabial and anterolingual conules by a distinct anteromedian flexus in some forms but undivided in others. The anteroloph is well developed and can be joined or not with the anterocone by a labial cingulum; a protostyle is absent; mesolophs are well developed on M1 and M2. An enamel bridge connects the paracone to the anterior moiety of the protocone. The protoflexus of M2 is present but poorly developed; the mesoflexus is present as a single internal fossette; the paracone lacks an accessory loph. M3 lacks a posteroloph and usually also a hypoflexus (the latter, if present, disappears with moderate to heavy wear). An accessory labial root of M1 may be present or absent. The anteroconid of m1 lacks an anteromedian flexid; an anterolabial cingulum is usually present on all lower molars (absent in m3 of some species); an anterolophid is present on m1 but absent (or weakly expressed) on m2 and m3; an ectolophid is absent on m1 and m2; a mesolophid is distinct on unworn m1 and m2; and a posteroflexid is well developed on m3. Lower molars each have two roots.

Axial skeletal elements have modal counts of 12 ribs, 19 thoracolumbar vertebrae, 4 sacral vertebrae, and 29–35 caudal vertebrae (Steppan 1995). The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and the first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. The humerus lacks an entepicondylar foramen.

The stomach is unilocular and hemiglandular (Carleton 1973; Weksler 2006), and the gall bladder is absent (Voss 1991a; Weksler 2006). Male accessory secretory organs consist of one pair each of preputial, bulbourethral, anterior and dorsal prostate, ampullary, and vesicular glands, and two pairs of dorsal prostate glands (Voss and Linzey 1981). The glans penis is complex, with a tridigitate bacular cartilage and a deep terminal crater containing three bacular mounds, one dorsal papilla, and a deeply bifurcated urethral flap (Hooper and Musser 1964; Weksler 2006).

SYNONYMS:

Hesperomys (Calomys): Thomas, 1882:105; part (description of *spinosus*); not *Hesperomys* Waterhouse or *Calomys* Waterhouse.

Hesperomys (Oryzomys): Thomas, 1884:448; part (listing of *spinosus*); not *Hesperomys* Waterhouse or *Oryzomys* Baird.

Oryzomys: E.-L. Trouessart, 1897:528; part (listing of *spinus*); not *Oryzomys* Baird.

Neacomys Thomas, 1900a:153; type species *Hesperomys (Calomys) spinosus* Thomas, by original designation.

REMARKS: Despite the recent description of several new species (Patton et al. 2000; Voss et al. 2001), considerable revisionary work is still needed for the genus. Patton et al. (2000), for example, detected three clades of highly divergent mtDNA haplotypes that probably correspond to yet unnamed small species, one from northern Peru and eastern Ecuador (referred to as *N. cf. minutus* by Tirira 2007; see also Hice and Velazco 2012), a second from the Imeri region between the Rio Solimões and Rio Negro in central Brazil, and a third on the lower Rio Xingu in eastern Brazil. *Neacomys spinosus* also may comprise more than one species across its wide range (Aniskin 1994; Patton et al. 2000). Most of the following account is based on Patton et al. (2000) and Voss et al. (2001), and should be viewed as provisional.

KEY TO THE SOUTH AMERICAN SPECIES OF *NEACOMYS*:

1. Stapedial foramen present, squamosoalisphenoid groove and sphenofrontal foramen absent (carotid circulatory pattern 2; Voss 1988) *Neacomys musseri*
- 1'. Stapedial foramen, squamosoalisphenoid groove, and sphenofrontal foramen present (carotid circulatory pattern 1; Voss 1988). 2
2. Anterocone divided by anteromedian flexus 3
- 2'. Anterocone undivided 4
3. Interorbital region hourglass in shape; supraorbital beads absent or weakly pronounced
. *Neacomys tenuipes*
- 3'. Interorbital region strongly convergent; supraorbital beads developed *Neacomys minutus*
4. Size large, total length of adults more than 165 mm
. *Neacomys spinosus*
- 4'. Size smaller, total length of adults less than 165 mm. . 5
5. Tail distinctly bicolored. *Neacomys guianae*
- 5'. Tail usually unicolored (rarely indistinctly bicolored at base). 6
6. Long outer digits of hindfeet, claw of fifth digit (dV) extends almost to end of first phalanx of dIV, claw of dI extends to middle of first phalanx of dIII; capsular part of auditory bullae narrow gradually to merge with bony tubes, bullae are more or less flask shaped
. *Neacomys dubosti*
- 6'. Very short outer digits of hindfeet, claw of dV extends ca. two-thirds length of first phalanx of dIV, claw of dI barely extends beyond base of first phalanx of dIII; bullae abruptly constricted anteromedially with sharper transition between a more globular tympanic capsule and narrower bony tubes *Neacomys paracou*

Neacomys dubosti Voss, Lunde, and Simmons, 2001

Dubost's Spiny Mouse

SYNONYM:

Neacomys dubosti Voss, Lunde, and Simmons, 2001:78; type locality "Paracou [= Domaine Experimental Paracou]," French Guiana.

DESCRIPTION: Small (head and body length from 64–81 mm), distinguished from other diminutive congeners by short (range: 70–85 mm) and usually unicolored tail; moderately short rostrum flanked by relatively shallow zygomatic notches; broad and strongly convergent interorbital region with highly developed; shelf-like supraorbital beads; broad and distinctly inflated braincase; short and convex-sided incisive foramina; carotid circulation pattern 1 (*sensu* Voss 1988); flask-shaped auditory bullae; M2 with undivided anterocone; mesoloph of M1 with more or less symmetrical connections to protocone and hypocone; and persistently tubercular molar cusps.

DISTRIBUTION: *Neacomys dubosti* occurs in French Guiana, northeastern Brazil, and southeastern Surinam. All localities are situated in lowland and premontane moist broadleaf forest in the Guianan subregion of Amazonia.

SELECTED LOCALITIES (Map 181; from Voss et al. 2001, except as noted): BRAZIL: Amapá, Serra do Navio; Pará, Monte Dourado (Cardoso 2011). FRENCH GUIANA: Cacao, Camopi, Iracoubo, Paracou (type locality of *Neacomys dubosti* Voss, Lunde, and Simmons), Piste de Saint Élie, Saül Trois Sauts. SURINAM: Sipaliwini, Oelmarie, Sipaliwini airstrip.

Map 181 Selected localities for *Neacomys dubosti* (●). Contour line = 2000 m.

SUBSPECIES: *Neacomys dubosti* is monotypic.

NATURAL HISTORY: Few data are available beyond the fact that the holotype of *N. dubosti* was taken in a pit-fall trap in creekside primary forest (Voss et al. 2001). This species occurs in sympatry with *N. paracou* in the center of French Guiana (Säul; Mauffrey et al. 2007), and in several other localities in French Guiana, Surinam, and Brazil (Catzeflis and Tilak 2009; Cardoso 2011). It also occurs in sympatry with *N. guianae* in the Nickerie district of Surinam (Voss et al. 2001).

REMARKS: The karyotype of Amapá specimens is $2n=62$ (Voss et al. 2001). Phylogeographic studies showed that *N. dubosti* has very little genetic variation, containing only half of the nucleotide diversity found in the co-distributed *N. paracou* (Catzeflis and Tilak 2009). The record from Pará state, Brazil was originally reported to be *N. guianae* (R. N. Leite 2006; see Cardoso 2011).

Neacomys guianae Thomas, 1905

Guianan Spiny Mouse

SYNONYM:

Neacomys guianae Thomas, 1905b:310; type locality “Demerara River, British Guyana. Alt. 120 feet,” probably Demerara-Mahaica, Guyana.

DESCRIPTION: Small, with head and body length 64–85 mm; tail about as long as head and body (range: 67–81 mm), distinctly bicolored in some specimens, and with small caudal scales; hindfoot with short outer digits (claw of digit V extends only about three-fourths length of first phalanx of digit IV, claw of dI extends to less than one-half length of first phalanx of digit II). Cranially, rostrum moderately long and flanked by shallow zygomatic notches; interorbital region narrow, hourglass in shape or weakly convergent anteriorly; zygomatic plates narrow; incisive foramina short; and bul-
lae flask shaped.

DISTRIBUTION: *Neacomys guianae* occurs in eastern Venezuela, Guyana, Surinam, and probably adjacent parts of northeastern Brazil, although confirmed specimens from this country are lacking. The record of this species from Monte Dourado, Pará state (R. N. Leite 2006) is a misidentified specimen of *N. dubosti* (Cardoso 2011). All localities are situated in lowland and premontane moist broadleaf forest in the Guianan subregion of Amazonia.

SELECTED LOCALITIES (Map 182; from Voss et al. 2001, except as noted): GUYANA: Cuyuni-Mazaruni, Kartabo; Demerara-Mahaica, Demerara River (type locality of *Neacomys guianae* Thomas). SURINAM: Sipaliwini, Sipaliwini airstrip, Tafelberg. VENEZUELA: Bolívar, 45 km NE of Icabarú.

SUBSPECIES: *Neacomys guianae* is monotypic.

Map 182 Selected localities for *Neacomys guianae* (●). Contour line=2000 m.

NATURAL HISTORY: *Neacomys guianae* occurs in sympatry with *N. dubosti* and *N. paracou* over much of the Guianan subregion (Voss et al. 2001).

REMARKS: Arenavirus Amaparí was isolated from *Neacomys* specimens collected in Serra do Navio and identified as *N. guianae* (F. P. Pinheiro et al. 1966; Cajimat et al. 2007; Charrel and de Lamballerie 2010); however only *N. paracou* and *N. dubosti* occur in this region (Voss et al. 2001). Specimens from Baramita (Barima-Waini region, Guyana) identified as *N. guianae* (Patton et al. 2000:Table 22) are actually *N. paracou* (Voss et al. 2001). Several other specimens identified as *N. guianae* in earlier publications (e.g., Carleton 1973; C. T. Carvalho 1962; Genoways et al. 1981; Hooper and Musser 1964; Husson 1978; Malcolm 1990; Voss and Emmons 1996; Patton et al. 2000; R. N. Leite 2006) are referable to *N. dubosti*, *N. paracou*, or *N. tenuipes* (see Voss et al. 2001; Cardoso 2011).

Neacomys minutus Patton, da Silva, and Malcolm, 2000

Minute Spiny Mouse

SYNONYM:

Neacomys minutus Patton, da Silva, and Malcolm, 2000: 105; type locality “Altamira, left bank Rio Juruá, Amazonas, Brazil, 06°35’S, 68°54’W.”

DESCRIPTION: Another diminutive species, with head and body length 65–76 mm; relatively long tail (tail length 70–84 mm); dark orange dorsal coloration strongly but finely streaked with black; short ears (13 mm or less);

small and delicate skull with short maxillary toothrow (<2.75 mm); primitive carotid arterial system (pattern 1 of Voss 1988), with squamosoalisphenoid groove and sphenofrontal foramen; teardrop-shaped incisive foramina; and weakly developed anteromedian flexus(id) on both upper and molar first molars.

DISTRIBUTION: *Neacomys minutus* is known from the lowland, moist broadleaf rainforest of the western Amazon Basin, from the central and lower sections of the Rio Juruá, Amazonas state, Brazil, and from the Río Gálvez, Loreto department, in northeastern Peru.

SELECTED LOCALITIES (Map 183; from Patton et al. 2000, except as noted): BRAZIL: Amazonas, Altamira, right bank Rio Juruá (type locality of *Neacomys minutus* Patton, da Silva, and Malcolm), Barro Vermelho, left bank Rio Juruá, Colocação Vira-Volta, left bank of Rio Juruá, Igarapé Nova Empresa, left bank Rio Juruá, Penedo, right bank Rio Juruá, Sacado, right bank Rio Juruá. PERU: Loreto, Nuevo San Juan, Río Gálvez (AMNH 272867).

SUBSPECIES: *Neacomys minutus* is monotypic.

NATURAL HISTORY: *Neacomys minutus* was caught both in upland (*terra firme*) and seasonally flooded (*várzea*) forest along the Rio Juruá (Patton et al. 2000). Pregnant females collected during dry and wet season, and litter size of three young. One lactating female was also pregnant, suggesting a postpartum estrus in this species. Reproductively active individuals of both sexes still in partial juvenile pelage but with completely erupted but unworn teeth suggest that breeding commences at an early age. This species is sympatric with *N. spinosus* and is apparently replaced by the very similar *N. musseri* in the headwaters of the Rio Juruá (Patton et al. 2000), but the two species are sympatric on the Río Gálvez in northeastern Peru (Catzeflis and Tilak 2009).

REMARKS: Substantial molecular divergence (8% in mtDNA cytochrome-*b* sequences) divide this species into upriver versus downriver clades along the Rio Juruá in western Brazil (Patton et al. 2000). Concordant nonoverlap in discriminate morphometric scores across the same clades and geography may signal species-level divergence in this taxon. If so, and as the holotype of *N. minutus* is a member of the upriver clade, populations from the lower Rio Juruá would lack an available name.

The karyotype of *N. minutus* is characterized by $2n=35-36$, $FN=40$, the uneven diploid number due to a Robertsonian fusion in the autosomal complement (Patton et al. 2000). Specimens of small *Neacomys* collected elsewhere in Peru, especially north of the Río Marañón, and in Ecuador are morphologically similar to *N. minutus* but are extremely divergent in mtDNA cytochrome-*b* sequences (Patton et al. 2000). These are best considered a separate and as yet undescribed species. Aniskin (1994) reported a karyotyped *Neacomys* sp. from Genaro [= Jenaro] Her-

Map 183 Selected localities for *Neacomys minutus* (●). Contour line = 2000 m.

ra, Peru, with $2n=30-32$ and $FN=38$, plus from 1 to 6 B chromosomes. This karyotype, although clearly different from those reported by Patton et al. (2000) for *N. minutus*, shows some resemblance, especially the morphology of the three largest acrocentric pairs. In addition, this *Neacomys* sp. has a large submetacentric that might be homologous to the heterozygous pair due to a centric fusion observed in some specimens of *N. minutus* (Patton et al. 2000).

Neacomys musseri Patton, da Silva, and Malcolm, 2000
Musser's Spiny Mouse

SYNONYM:

Neacomys musseri Patton, da Silva, and Malcolm, 2000:98; type locality "72 km NE Paucartambo (by road), at km 152, Manu Biosphere Reserve, Departamento de Cusco, Peru, 1460 m."

DESCRIPTION: Another small species, with head and body length 65–79 mm; tail only slightly longer (68–90 mm), slightly bicolored dark brown above, paler below, with scales visible but clothed in short hairs. Cranially similar to other small forms, but unique in having derived carotid pattern 2 (of Voss 1988), without squamosoalisphenoid groove and sphenofrontal foramen but with persistence of large stapedial foramen. M1 with deep anteromedian flexus that divides procingulum into two subequal conules, and incisive foramina evenly rounded rather than teardrop in shape.

DISTRIBUTION: *Neacomys musseri* is known from lowland and lower montane moist broadleaf forest in western Amazonia Brazil and eastern Peru. The recent record of *N. musseri* from San Fermín on the Río Tambopata in extreme eastern Puno department (Pacheco et al. 2012), Peru, suggests that the species might range into adjacent Bolivia.

SELECTED LOCALITIES (Map 184): BRAZIL: Acre, left bank Rio Juruá opposite Igarapé Porongaba (Patton et al. 2000). PERU: Cusco, 72 km NE of Paucartambo (type locality of *Neacomys musseri* Patton, da Silva, and Malcolm); Loreto, Nuevo San Juan, Río Gálvez (AMNH 272676); Madre de Dios, Quebrada Aguas Calientes, left bank Río Alto Madre de Dios, 2.75 km E of Shintuya (Solari et al. 2006); Puno, San Fermín (Pacheco et al. 2012).

SUBSPECIES: *Neacomys musseri* is monotypic.

NATURAL HISTORY: Patton et al. (2000) reported a pregnant subadult female with two embryos, collected on the ground in *várzea* habitat during the rainy season (February) in Brazil. Conversely, none of the specimens collected in Peru during the dry season (July) were in reproductive condition (Patton et al. 2000). *Neacomys musseri* is found in sympatry with *N. spinosus* (Patton et al. 2000; Solari et al. 2006) and with *N. minutus* in northeastern Peru (Catzeflis and Tilak 2009).

REMARKS: The karyotype of *N. musseri* is characterized by $2n=34$, FN=64 or 68 (Patton et al. 2000). This complement is similar in diploid number to that reported

by Aniskin (1994; see account for *N. minutus*), but differs markedly in the number of chromosome arms. Specimens that Woodman et al. (1991) referred to *N. tenuipes* from the Río Madre de Dios in southeastern Peru are likely this species. Because the range of *N. musseri* extends almost to the Bolivian border, the species may occur in that country.

Neacomys paracou Voss, Lunde, and Simmons, 2001

Paracou Spiny Mouse

SYNONYM:

Neacomys paracou Voss, Lunde, and Simmons, 2001:81; type locality type locality "Paracou [= Domaine Experimental Paracou]," French Guiana.

DESCRIPTION: Distinguished from other small-sized congeners by very short outer pedal digits (claw of dV extends only two-thirds length of phalanx 1 of dIV, claw of dI barely extends beyond base of phalanx 1 of dII); short and usually unicolored tail (sometimes weakly bicolored basally) with large scales; short rostrum flanked by relatively deep zygomatic notches; broad and usually strongly convergent interorbital region with well-developed and often shelf-like supraorbital beads; narrow and uninflated braincase; long and parallel-sided incisive foramina; carotid circulatory pattern 1 (of Voss 1988); globular auditory bullae; M1 with narrow and undivided anterocone, stout mesoloph often curving from and disproportionately connected to the hypocone; and principal molar cusps that wear quickly to enamel loops, not persistently tubercular.

DISTRIBUTION: *Neacomys paracou* occurs in French Guiana, Surinam, Guyana, eastern Venezuela (Bolívar state), and northern Brazil (Amapá, Amazonas, and Pará states). All localities are situated in lowland and premontane moist broadleaf forest in the Guianan subregion of Amazonia (Voss et al. 2001).

SELECTED LOCALITIES (Map 185; from Voss et al. 2001, except as noted): BRAZIL: Amapá, Serra do Navio; Amazonas, 80 km N of Manaus; Pará, Cachoeira Porteira. FRENCH GUIANA: Arataye, Cayenne, Mont St. Michel (Catzeflis and Tilak 2009), Paracou (type locality of *Neacomys paracou* Voss, Lunde, and Simmons). GUYANA: Barima-Waini, Baramita; Cuyuni-Mazaruni, Kartabo; Potaro-Siparuni, Kurupukari; Upper Takutu–Upper Essequibo, Nappi Creek. SURINAM: Marowijne, Perica; Para, Locksie Hattie; Sipaliwini, Oelemarie. VENEZUELA: Bolívar, San Ignacio de Yuruani.

SUBSPECIES: *Neacomys paracou* is monotypic.

NATURAL HISTORY: Voss et al. (2001) collected *N. paracou* in primary forest, either well drained or swampy, and in secondary vegetation, always at or near ground level. In Brazil, this is a rare species occurring mainly in primary forest (R. N. Leite 2006). *Neacomys paracou* occurs in sym-

Map 184 Selected localities for *Neacomys musseri* (●). Contour line = 2000 m.

Map 185 Selected localities for *Neacomys paracou* (●). Contour line = 2000 m.

patry with *N. dubosti* and *N. guianae* (Voss et al. 2001; R. N. Leite 2006).

REMARKS: Voss et al. (2001) recorded a karyotype with $2n=56$ for specimens from French Guiana and eastern Venezuela.

Neacomys spinosus (Thomas, 1882)

Large Spiny Mouse

SYNONYMS:

Hesperomys (Calomys) spinosus Thomas, 1882:105; type locality “Huambo—a plantation in the forest of the same name, to the east of Chachapoyas and Chirinoto, 3700 feet in altitude, on the banks of the river Huambo, a tributary of the Huallaga,” Amazonas, Peru.

Hesperomys (Oryzomys) spinosus: Thomas, 1884:448; name combination.

Oryzomys spinosus: E.-L. Trouessart, 1897:528; name combination.

N[eacomys]. s[pinosus]. typicus Thomas, 1900a:153; *nomen nudum*, in reference to the type species of *Neacomys*, *Oryzomys spinosus* Thomas.

Neacomys spinosus amoenus Thomas, 1904a:239; type locality “Santa Ana da Chapada, a village situated at an altitude of about 800 m., on the Serra do Chapada [= Chapada dos Guimarães], some thirty miles N.E. of Cuyabá,” Mato Grosso, Brazil.

Neacomys spinosus spinosus: Gyldenstolpe, 1932a:34; name combination.

Neacomys spinosus carcelini Hershkovitz, 1940c:1; type locality “Llunchi, an island on the northern side of the Río Napo, west of the mouth of the Río Jivino, latitude and longitude approximately $0^{\circ}37'S.$, $76^{\circ}46'W.$; parish of La Coca, Napo-Pastaza, Ecuador; altitude about 250 meters.”

DESCRIPTION: Largest species in genus, with head and body length 75–105 mm, almost nonoverlapping other species, and large skull, nearly 10% larger than that of other species. Specimens from eastern Ecuador to southern Peru and western Brazil rather uniform in body dimensions, but exhibit variation in darkness of dorsal pelage, from paler yellow-reddish brown mixed with black to darker reddish-brown. Thomas (1904a), in his description of *amoenus* from Mato Grosso state, Brazil, noted brighter ochraceous coloration in comparison with western Amazonian samples. Skull long with relatively narrow braincase, differing only in size but not proportions from other species compared by Patton et al. (2000). Carotid circulation pattern of primitive type, retaining well-developed squamosoalisphenoid groove and sphenofrontal foramen indicative of presence of supraorbital branch of stapedia artery (pattern 1 of Voss 1988). Maxillary tooththrow long, averaging >3 mm; molar occlusal morphology similar to that of other species except that procingulum of both M1 and m1 either entire, or only weakly divided into anterolabial and anterolingual conules by anteromedian flexus.

DISTRIBUTION: *Neacomys spinosus* is the most widely ranging species, occurring throughout the Amazon Basin from west-central Brazil to the Andean foothills and lowlands of southeastern Colombia, eastern Ecuador, eastern Peru, and northern and central Bolivia. It can be found commonly in both lowland evergreen rainforest and in midmontane forest on the eastern Andean slopes, to elevations of nearly 2,000 m.

SELECTED LOCALITIES (Map 186): BOLIVIA: Chuquisaca, 2 km E of Chuhuayaco (S. Anderson 1997); Cochabamba, El Palmar, Río Cochi Mayu (S. Anderson 1997); La Paz, 8 km from mouth of Río Madidi (S. Anderson 1997), Río Zongo (S. Anderson 1997); Pando, La Cruz (S. Anderson 1997); Santa Cruz, Estancia Cachuela Esperanza (S. Anderson 1997). BRAZIL: Acre, Sobral, left bank Rio Juruá (Patton et al. 2000); Amazonas, Penedo, right bank Rio Juruá (Patton et al. 2000), Seringal Condor, left bank Rio Juruá (Patton et al. 2000); Goiás, Baliza (UFPA [CRB 70]); Mato Grosso, Ponte Branca (UNB 1193), São José do Xingu (MNRJ [CRB 2794]); Pará, Castelo dos Sonhos (MNRJ [SVS/PA 282]). COLOMBIA: Meta, Finca El Buque, Villavicencio (A. L. Gardner and Patton 1976); Putumayo, Río Mecaya (FMNH 71792). ECUADOR: Orellana, Parque Nacional Yasuní (Patton et al. 2000);

Pastaza, Tinguino, ca. 130 km S of Coca (USNM 574567); Zamora-Chinchi, Zamora (AMNH 47795). PERU: Amazonas, Huambo (type locality of *Hesperomys (Calomys) spinosus* Thomas), Huampani, Río Cenepa (Patton et al. 2000); Ayacucho, Río Santa Rosa (A. L. Gardner and Patton 1976); Loreto, Reserva Nacional Allpahuayo-Mishana (Hice and Velazco 2012); Madre de Dios, Albergue Cusco Amazonica, Río Madre de Dios, ca. 12 km E of Puerto Maldonado (MVZ 157811), Cocha Cashu Biological Station (Solari et al. 2006); Puno, 11 km NNE of Ollachea (MVZ 172650); Ucayali, Balta, Río Curanja (A. L. Gardner and Patton 1976), Pucallpa (Aniskin 1994).

SUBSPECIES: Cabrera (1960) recognized three subspecies: the nominotypical form from the Andean slopes and Amazon Basin of Peru, *N. s. amoenus* from southwestern Brazil, and *N. s. carceloni* from the Andean foothills and Amazon Basin of Colombia and Ecuador. The validity of these taxa, however, must await an analysis of character variation over the range of the species, something that has yet to be accomplished.

NATURAL HISTORY: In Peru, Hice and Velazco (2012) recorded pregnant females in June, November, and December, with an average litter size of 3.1 ($N=10$, range 2–4), suggesting year-round breeding, but perhaps with a peak at the beginning of the rainy season in December. On the Rio Juruá in Brazil, pregnant females were captured both in the wet (February and March) and dry (August and September) seasons, also suggesting year-round breeding (Patton et al. 2000). Here, embryo counts ranged from two to four. In Peru, individuals were frequently captured in secondary growth and cultivated land, only rarely in forested habitats (Hice and Velazco 2012). Along the Rio Juruá, specimens were collected in primary rainforest and secondary growth in both *terra firme* and *várzea* habitats (Patton et al. 2000). Bonvicino, Cerqueira, and Soares (1996) also encountered this species in conserved forested formations elsewhere in Brazil. *Neacomys spinosus* occurs in sympatry with one or more small species over much of its range in western Amazonia, specifically with both *N. minutus* and *N. musseri* in western Brazil and Peru, and with other as yet unnamed species in northern Peru and eastern Ecuador (Patton et al. 2000). Some recent publications still refer to *Neacomys spinosus* as the reservoir of the Rio Mamoré hantavirus (e.g., Bi et al. 2008), but the role of this species as a reservoir is questionable (Young et al. 1998). The only verified reservoir of this hantavirus is *Oligoryzomys microtis* (Richter et al. 2010). Gettinger and Gardner (2005) described the mite *Laelaps neacomydis* from the pelage of *Neacomys spinosus* collected in Bolivia.

REMARKS: A uniform karyotype with $2n=64$, $FN=68$ has been recorded for samples from eastern Colombia, throughout eastern Peru, and from western Brazil (A. L.

Map 186 Selected localities for *Neacomys spinosus* (●). Contour line=2000m.

Gardner and Patton 1976; Aniskin 1994; Patton et al. 2000).

The mtDNA cytochrome-*b* sequence data are geographically limited for such a widely distributed species, with about 2% divergence between samples from eastern Ecuador versus those from western Brazil (Patton et al. 2000). However, unpublished data (J. L. Patton) document substantial mtDNA cytochrome-*b* divergence (up to 8.5%) between a sample from the middle Andean slopes in southern Peru and specimens from eastern Ecuador, northern Peru, and western Brazil, perhaps signaling species-level divergence.

Neacomys tenuipes Thomas, 1900

Slender Foot Spiny Mouse

Neacomys spinosus tenuipes Thomas, 1900a:153; type locality “Guaquimay, near Bogotá,” Cundinamarca, Colombia.

Neacomys pusillus J. A. Allen, 1912:81; type locality “San José [near Barbacoas], Cauca, Colombia.”

Neacomys tenuipes: Lawrence, 1941b:425; first use of current name combination.

DESCRIPTION: Another small species, with head and body length 72–97 mm. Tail longer than head and body (about 115%, length 74–108 mm), contrasting with subequal tails of other small species; distinctly bicolored, at least near base, with small caudal scales. Hindfoot with long outer digits (claw of dV extending to end of first phalanx

of dIV, claw of dI to at least middle of first phalanx of dII). Skull with long rostrum flanked by shallow zygomatic notches; interorbital region narrow and either hourglass in shape or weakly convergent anteriorly; zygomatic plates narrow; incisive foramina short; and auditory bullae flask shaped. M1 approximately rectangular in occlusal view, with broad, often divided anterocone; labial and lingual cusps subequal and persistently tubercular; and slender mesoloph with symmetrical attachments to protocone and hypocone.

DISTRIBUTION: *Neacomys tenuipes* is distributed in western and north-central Colombia and in northern Venezuela. Tirira (2007) extended the distribution into northwestern Ecuador under the species name *N. pictus* but provided no specific localities. All known localities are situated in premontane or lower montane forests, between 400 and 1,750 m (Voss et al. 2001; Musser and Carleton 2005; Tirira 2007).

SELECTED LOCALITIES (Map 187; from Voss et al. 2001): **COLOMBIA:** Antioquia, 11 km S and 30 km E of Cisneros, Quebrada del Oro, Sonsón, 25 km S and 22 km W of Zaragoza; Boyacá, Muzo; Caldas, Samana; Cundinamarca, Paimé; Huila, Acevedo. **VENEZUELA:** Aragua, Rancho Grande; Falcón, Cerro Socopo; Vargas, Los Venados; Yaracuy, Minas de Aroa.

SUBSPECIES: We treat *Neacomys tenuipes* as monotypic.

NATURAL HISTORY: Virtually nothing is known about the ecology or behavior of *Neacomys tenuipes*, al-

though, like other species in the genus, it is assumed to be nocturnal, solitary, and terrestrial. This species is considered vulnerable in Ecuador (Tirira 2001). Laelapine mites are associated with *N. tenuipes* in Venezuela (Furman 1972a).

REMARKS: Specimens from eastern Ecuador allocated to this species by Lawrence (1941b) are not *N. tenuipes* but likely represent the unnamed small species east of the northern Andes that Patton et al. (2000) identified as *Neacomys* sp. Clade 3 and Tirira (2007) referred to as *N. cf. minutus*. Neither the karyotype nor any analysis of geographic variation, in morphology or molecular sequences, has been recorded for *N. tenuipes*.

Genus *Nectomys* Peters, 1861

Cibele R. Bonvicino and Marcelo Weksler

Commonly called water rats, members of the genus *Nectomys* are found in most lowland rainforest biomes in South America, and in the riverine (gallery) forests of open habitats, such as the Cerrado, Llanos, and other grasslands. We recognize five species: *N. apicalis*, *N. grandis*, *N. palmipes*, *N. rattus*, and *N. squamipes*, but this number will likely change in the future due to continuing taxonomic research on the genus (which needs comprehensive revision). These rats are endemic to South America, found in all countries (except Chile) and on the continental shelf islands of Trinidad and Margarita, from sea level to 2,200 m (Hershkovitz 1944). Pardiñas et al. (2002) recorded fossil *Nectomys* from Middle to Late Pleistocene deposits in Argentina and Recent deposits in both Argentina and Brazil.

All species of the genus *Nectomys* share similar integumental, cranial, and dental characters. Water rats are of large size (head and body length 150–254 mm) with partially webbed hindfeet and long tails (tail length 151–255 mm). The pelage is thick and long, with well-developed underfur and long guard hairs. The dorsal pelage is dark, varying from brownish gray to a paler gray; the lateral pelage is paler than the back, and the venter is whitish or ochraceous with a gray base. The hindfeet are large, long, and have interdigital webbing and natatory fringes along the medial margins of digits I and II and lateral margins of digits IV and V. The plantar surface is naked and densely set with epidermal squamae (the heel is smooth); the hypothenar pad may be absent or reduced, and the four interdigital pads are very small. The tail is longer than head and body length, naked in appearance (small triads of hair are visible under magnification), and unicolored. There are eight pairs of mammae, one each in inguinal, abdominal, postaxial, and pectoral positions.

Map 187 Selected localities for *Neacomys tenuipes* (●). Contour line = 2000 m.

The skull is robust, with a broad and short rostrum flanked by deep zygomatic notches; the interorbital margins converge anteriorly and possess strongly beaded supraorbital edges; the braincase is squared and relatively narrow, with well-developed temporal, lambdoidal, and nuchal crests. The zygomatic plates lack anterodorsal spinous processes, and their posterior margins lie level to the alveoli of the M1s. The nasal bones have sharply convergent posterior margins. The posterior wall of the orbit is smooth. The frontosquamosal suture is colinear with the frontoparietal suture, and the parietals have large lateral expansions. The bony palate between the molar rows is smooth and long, and the mesopterygoid fossa extends anteriorly between the maxillae but does not extend to the level of the third molars. Posterolateral palatal pits are recessed in deep fossae, and the bony roof of mesopterygoid fossa is completely ossified. An alisphenoid strut is absent (buccinator-masticatory foramen and accessory foramen ovale are confluent), and the alisphenoid canal has a large anterior opening. The stapedia foramen and the posterior opening of the alisphenoid canal are small, and the squamosoalisphenoid groove and sphenofrontal foramen are absent; a secondary anastomosis of the internal carotid crosses the dorsal surface of the pterygoid plate (= carotid circulatory pattern 3 of Voss 1988). The postglenoid foramen is large and rounded, but the subsquamosal fenestra is absent or vestigial. The mastoid is completely ossified or has only a small perforation. In the mandible, the capsular process is absent or poorly developed, and the superior and inferior masseteric ridges are conjoined anteriorly as a single crest below m1. The basihyal lacks the entoglossal process.

Hershkovitz (1944:19) characterized the molars as large, pentalophodont, and bunodont in occlusal configuration but with high crowns, low crests, their dentine exposed at an early stage of wear, and fully-rooted. The labial and lingual flexi of M1 and M2 approach the midline of the tooth but do not interpenetrate. The anterocone of M1 is not divided, and the anteroloph is well developed and connected to the anterocone by the labial cingulum. The protostyle is absent, and the paracone is usually connected to the posterior moiety of the protocone. There is no protoflexus on M2, but the mesoflexus is present as single internal fossette, as the mesoloph is connected to the paracone by a labial cingulum. M3 has a posteroloph. The m1 anteroconid lacks an anteromedian flexid, an anterolophid is present on m1 but absent from m2 and m3, and ectolophids are absent from m1 and m2. Both M1 and m1 have accessory roots, and m2 and m3 each has two roots.

The stomach is unilocular-hemiglandular, but the glandular epithelium is extensive and reaches the corpus (Hersh-

kovitz 1962; Carleton 1973). The distal bacular cartilage of the glans penis is large and trifold; the central digit is robust.

SYNONYMS:

Mus: Brants, 1827:138: part (description of *squamipes*); not *Mus* Linnaeus.

Nectomys Peters, 1861:151; type species *Mus squamipes* Brants, by subsequent designation (G. S. Miller 1912: 180).

Holochilus: Fitzinger, 1867b:90; part (listing of *squamipes*); not *Holochilus* Brandt.

Potamys Liais, 1872:505; type species *Potamys brasiliensis*, by original designation (= *N. squamipes*); a homonym of *Potamys* Larranhaga, 1823:83, a junior synonym of *Myocastor* (see Hershkovitz 1944:26; McKenna and Bell 1997:207).

Hesperomys: Hensel, 1872b:28; part (description of *rattus*); not *Hesperomys* Waterhouse.

Sigmodontomys: Bonvicino, 1999:254; not *Sigmodontomys* J. A. Allen.

REMARKS: Hershkovitz (1944, 1948b) divided *Nectomys* into two subgenera, *Nectomys* and *Sigmodontomys* J. A. Allen, and considered *Nectomys squamipes* (Brants) the single species of the subgenus *Nectomys*, and within which he recognized 17 subspecies. Cabrera (1961) proposed a similar taxonomic arrangement, but A. L. Gardner and Patton (1976), on the basis of karyology and bacular morphology, considered *Sigmodontomys* to be a subgenus of *Oryzomys* Baird, 1857, and postulated that *Nectomys* was polytypic. Musser and Carleton (1993) regarded *Sigmodontomys* as a full genus and included three species in *Nectomys* (*N. squamipes*, *N. palmipes*, and *N. parvipes*).

Bonvicino (1994) argued that chromosomal diversification played an important role in speciation of water rats; eight basic diploid numbers have been described for *Nectomys*, including $2n=16$, $2n=17$, $2n=34$, $2n=38$, $2n=40$, $2n=42$, $2n=52$, and $2n=56$ (Yonenaga 1972a; Yonenaga-Yassuda et al. 1976; A. L. Gardner and Patton 1976; T. R. O. Freitas 1980; Furtado 1981; Sbalqueiro, Mattevi, Freitas, and Oliveira 1982; Sbalqueiro et al. 1986, 1987; Bossle et al. 1988; Maia et al. 1984; Zanchin 1988; M. A. Barros et al. 1992; Bonvicino, D'Andrea et al. 1996; Gómez-Laverde et al. 1999; Patton et al. 2000; Bonvicino and Gardner 2001). Bonvicino (1994) proposed that *Nectomys* comprised 11 species, and placed *N. parvipes* as a species in the genus *Sigmodontomys* (see also Bonvicino 1999); we include *N. parvipes* as a synonym of *N. rattus* (see below).

Most recently, Musser and Carleton (2005) retained *Sigmodontomys* as a valid genus and recognized five species of *Nectomys* (*N. apicalis*, *N. magdalenae* [= *N. grandis*], *N. palmipes*, *N. rattus*, and *N. squamipes*). Weksler's

(2006) phylogenetic analysis corroborated the recognition of *Nectomys* and *Sigmodontomys* as different genera. Our taxonomic arrangement here follows that of Musser and Carleton (2005) but should be viewed as provisional. Notably, we consider the different karyotypes as diagnostic traits of subspecies in some cases, such as *N. grandis grandis* and *N. palmipes tatei*, differentiating them from *N. grandis magdalenae* and *N. palmipes palmipes*, respectively, to reinforce the need for further studies on these taxonomic entities. Furthermore, despite chromosome variation found across the geographic range of *N. apicalis*, we retained all karyomorphs in a single species due to ongoing phylogeographic analyses of mtDNA cytochrome-*b* sequences that document genetic cohesion throughout this distribution for the karyomorphs with $2n=38$, $2n=40$, and $2n=42$. Finally, the identity of the $2n=56$ cytotype from Surinam (R. J. Baker et al. 1983) also needs further study, as it likely belongs to an undescribed species.

KEY TO THE SPECIES OF *NECTOMYS*:

1. Interparietal deep (anteroposterior dimension) relative to its width (transverse dimension); exoccipital occupying most of the dorsolateral surface of occiput 2
- 1'. Interparietal much wider than deep; dorsolateral exposition of the exoccipital reduced 4
2. Dorsal color light brown; distributed in Trinidad and northeastern Venezuela; diploid number <20
. *Nectomys palmipes*
- 2'. Dorsal color brown; distributed in Colombia, Peru, Ecuador, Brazil, and probably Bolivia; diploid number >30 3
3. Dorsal color overall grayish-ochraceous without a dark middorsal band; distributed in northern Andean valleys of Colombia, in Cauca and Magdalena rivers basins; $2n=32$ and 34 *Nectomys grandis*
- 3'. Distinct dark middorsal band covering less than one third of dorsal breadth; distributed in western Amazonia (Ecuador, Peru, Brazil, and probably Bolivia); $2n=38-42$ *Nectomys apicalis*
4. Distributed in the basins of the Río Uruguay, Río Paraná, Río São Francisco, and in independent river basins south of São Lourenço da Mata, Pernambuco, in the Atlantic Forest of Brazil, Uruguay, and Argentina; $2n=56$ *Nectomys squamipes*
- 4'. Distributed in the Amazonian region of Colombia and Venezuela (upper and middle Río Orinoco Basin), eastern Ecuador, Peru (Ucayali Basin), and Brazil (parts of Amazon Basin, Río Paraguay Basin, and independent river basins of the Atlantic Forest north of São Lourenço da Mata, Pernambuco; $2n=52-54$
. *Nectomys rattus*

Nectomys apicalis Peters, 1861

Western Amazonian Water Rat

SYNONYMS:

Nectomys apicalis Peters, 1861:152; type locality "Guayaquil"; subsequently restricted to Tena, Napo-Pastaza Province, Ecuador (Hershkovitz 1944:26).

Nectomys fulvinus Thomas, 1897c:499; type locality "Believed to be Quito," Ecuador. Hershkovitz (1944:26-27), however, convincingly argued that "it is certain that [the type of] *fulvinus* was collected by Jameson somewhere east of the Andes during his excursion from Quito to the Río Napo."

Nectomys saturatus Thomas, 1897f:546; type locality "Ibarra, [Imbabura], N. Ecuador, alt. 2225 metres."

Nectomys garleppi Thomas, 1899a:41; type locality "Ocobamba, Cuzco," Peru; subsequently restricted to "a station somewhere in the tropical or subtropical zone of the Río Ocobamba Valley, department of Cuzco, Perú" by Hershkovitz (1944:59).

Nectomys garleppi Thomas, 1902b:129; incorrect subsequent spelling of *Nectomys garleppi* Thomas.

Nectomys squamipes napensis Hershkovitz, 1944:56-57; type locality "site 'San Francisco', left bank of Río Napo, above the mouth of the Río Challuacocha; latitude and longitude approximately $0^{\circ}47'S$, $76^{\circ}25'W$, Parish of La Coca, Napo-Pastaza Province, Ecuador; altitude, about 200 meters."

Nectomys squamipes garleppi: Hershkovitz, 1944:59; name combination.

Nectomys squamipes vallensis Hershkovitz, 1944:61; type locality "Santa Ana, a semiarid, tropical pocket in the Río Urubamba Valley, department of Cuzco, Peru, altitude 3480 feet."

Nectomys squamipes saturatus: Hershkovitz, 1948b:51; name combination.

DESCRIPTION: Dorsum ochraceous buff with mixture, rarely with heavy overlay, of cinnamon brown or dark brown; dark middorsal band narrowly defined (occasionally absent); coloration from nose to crown on head not markedly different from that of middorsal region of back; under parts pallid neutral gray moderately washed with ochraceous; inner surface of forelimbs from wrist to elbow usually brown with mixture of ochraceous; tail brown, keel entirely brown or mixed with gray to entirely gray; hindfoot usually with five plantar tubercles.

DISTRIBUTION: *Nectomys apicalis* occurs in eastern Ecuador, eastern Peru, and northwestern Brazil (southwestern Amazonas state), and is probably also found in western Bolivia and Acre state in Brazil.

SELECTED LOCALITIES (Map 188): BRAZIL: Amazonas, Barro Vermelho (MVZ 190374), Seringal Condor (INPA 3070/MVZ 193781). ECUADOR: Pastaza, Sarayacu

(AMNH 67327); Pichincha, Nanegal (AMNH 47009); Suncumbios, Limoncocha (USNM 513585); Zamora-Chinchi, 4 km ENE of Los Encuentros (USNM 513584). PERU: Amazonas, vicinity of Huampami, Río Cenepa (MVZ 153533); Ayacucho, Hacienda Luisiana, left bank of Río Apurimac (LSUMZ 16712); Cusco, Kiteni, Río Urubamba (MVZ 166700); Junín, 3 mi SW of San Ramón (AMNH 231190); Loreto, Boca del Río Curaray (AMNH 71594); Ucayali, Balta, Río Curanja (MVZ 136641), Lagarto, upper Río Ucayali (AMNH 76512).

SUBSPECIES: We regard *Nectomys apicalis* as monotypic. However, the degree to which the karyological variation found in this species ($2n=38$, 40, or 42) might map onto patterns of regional morphological discontinuity needs to be investigated.

NATURAL HISTORY: This species has not been studied in the field, so data on ecology or behavior are scarce. Patton et al. (2000) noted that individuals with $2n=42$ collected along the Río Juruá were trapped mainly along streams in undisturbed or second-growth forests, or in garden plots adjacent to such forest. Juveniles were collected between August and November, and adult females taken over the same months were either pregnant (three embryos; $N=1$) or lactating (three placental scars; $N=1$).

REMARKS: Diploid and autosomal fundamental numbers in this species are variable. Populations from Ecuador have $2n=40$, $FN=40$ (Bonvicino and Gardner 2001);

those from the Alto Marañón drainage in northern Peru (Patton et al. 2000), the headwaters of the Río Purus in Peru (A. L. Gardner and Patton 1976, as *N. squamipes* variant 2), and the Río Juruá in western Brazil (Patton et al. 2000) were $2n=42$, $FN=40-41$; those from southeastern Peru were $2n=38$, $FN=40$ (A. L. Gardner and Patton 1976, as *N. squamipes* variant 3). These karyotypes are easily derived from one another by centric fusion and pericentric inversions. Note that populations of *Nectomys rattus* ($2n=52$) are found along the central Río Ucayali, between those of *Nectomys apicalis* population with $2n=40$ and those with $2n=38$ (A. L. Gardner and Patton 1976, as *N. squamipes* variant 1). Unpublished analysis of molecular variation in these forms reveals a genetic cohesion across the range of the species, but the significance of the karyotypic variation in *N. apicalis* requires further study.

Nectomys grandis Thomas, 1897

Magdalena-Cauca Water Rat

SYNONYMS:

Nectomys grandis Thomas, 1897c:498; type locality "Concordia, Medellín, Colombia"; emended to "Concordia, western slope of the Río Cauca Valley, Medellín, Antioquia, Colombia; altitude 1790 meters" (Hershkovitz 1944:62).

Nectomys magdalenae Thomas, 1897c:499; type locality "W. Cundinamarca, in lowlands near Magdalena R.," Colombia.

Nectomys squamipes grandis: Hershkovitz, 1944:62; name combination.

Nectomys squamipes magdalenae: Hershkovitz, 1944:64; name combination.

DESCRIPTION: Dorsal pelage color overall coarsely mixed grayish ochraceous, with ochraceous tones predominant; dark middorsal stripe normally absent. Skull heavy with upper profile evenly convex throughout, and frontal and parietal regions markedly swollen; uniform convexity markedly different from frontally flattened skulls of other species. Nasals fairly broad, slightly compressed about their middle, pointed behind, but not markedly extended posteriorly; supraorbital ridges curve slightly as they diverge, continuous with temporal ridges; frontoparietal suture almost transverse; interparietal longer anteroposteriorly and narrower transversely than in other species; incisive foramina widely open, parallel sided, and evenly rounded at both ends; posterior palate with unusually large and deep lateral pits; palatal margin of mesopterygoid fossa squared.

DISTRIBUTION: *Nectomys grandis* is found throughout the Río Magdalena and the Río Cauca basins in north-central Colombia.

SELECTED LOCALITIES (Map 189): COLOMBIA: Antioquia, Bellavista (FMNH 70110), Concordia (type lo-

Map 188 Selected localities for *Nectomys apicalis* (●). Contour line = 2,000 m.

Map 189 Selected localities for *Nectomys g. grandis* (○) and *Nectomys g. magdalenae* (●). Contour line = 2,000 m.

cality of *Nectomys grandis* Thomas), La Pintada, S of Medellín (USNM 544410), San Jerónimo, about 35 km NW of Medellín (FMNH 70104); Cundinamarca, lowlands near Río Magdalena (type locality of *Nectomys magdalenae* Thomas); Huila, Andalucía (AMNH 33729), San Adolfo, Acevedo (FMNH 71640), San Agustín (AMNH 33736); Norte de Santander, Río de Oro, 91 km N of Tibú (AMNH 255816); Tolima, Río Chilí (AMNH 69174).

SUBSPECIES: *Nectomys grandis* includes two subspecies: *N. g. magdalenae*, characterized by $2n=34$ and autosomal FN=40 (Gómez-Laverde et al. 1999) and restricted to the Río Magdalena basin; and *N. g. grandis*, with $2n=32$ (M. L. Bueno, pers. comm.) and restricted to the Río Cauca Basin.

NATURAL HISTORY: No information is available on the ecology or behavior of this species.

REMARKS: We tentatively recognize *grandis* and *magdalenae* as subspecies due to their allopatric distributions and different karyotypes. Further studies with a broader sample are necessary to clarify this taxonomic arrangement.

Nectomys palmipes J. A. Allen and Chapman, 1893
Trinidad Water Rat

SYNONYMS:

Nectomys palmipes J. A. Allen and Chapman, 1893:209; type locality "Princetown [= Princes Town], Trinidad."

Nectomys squamipes tatei Hershkovitz, 1948b:52; type locality "San Antonio, about 15 km. east of Mount Turumiquire, Sucre [actually Monagas], northern Venezuela; altitude about 1,800 feet."

DESCRIPTION: Pelage soft, dense, and glossy; overall dorsal color pale yellowish brown but middorsally strongly blackish from nose to tail; sides grayish buffy brown, sparingly varied with black-tipped hairs; top of head, from muzzle to behind eyes, blackish varied with gray; under parts whitish with wash of pale buff and base grayish; line of demarcation between coloration of dorsal and ventral surfaces very indistinct; ears oval in shape, evenly rounded above, flesh colored at their base, dusky apically, and sparsely haired; lateral surfaces of limbs grayish brown; feet scaly, so thinly haired as to be nearly naked; palms and soles scaly; plantar surface of pes with five tubercles; tail slightly shorter than head and body, blackish, nearly unicolored, basal 10 mm or more heavily furred, distal part scantily clothed with short bristly hairs, which form very slight pencil at tip.

DISTRIBUTION: *Nectomys palmipes* occurs on the island of Trinidad, and in the Río Orinoco delta and other independent basins of northern Venezuela.

SELECTED LOCALITIES (Map 190): TRINIDAD AND TOBAGO: Trinidad, Bush Bush Forest (AMNH 185474), Las Cuevas, Maraba Bay (M. A. Barros et al. 1992), Princetown (type locality of *Nectomys palmipes* J. A. Allen and Chapman), Savanna Grande (FMNH 8772). VENEZUELA: Anzoátegui, Cueva del Agua (M. A. Barros et al. 1992); Delta Amacuro, La Horqueta, Tucupita (M. A. Barros et al. 1992); Monagas, Cachipo (M. A. Barros et al. 1992), Caripito (AMNH 142608), San Antonio, 15 km E of Mount Turumiquere (type locality of *Nectomys squamipes tatei* Hershkovitz); Sucre, Dos Ríos (M. A. Barros et al. 1992), Latal (AMNH 69900).

SUBSPECIES: *Nectomys palmipes* includes two subspecies: *N. p. palmipes* with $2n=17$ from Trinidad, and *N. p. tatei* with $2n=16$ from Venezuela.

NATURAL HISTORY: Like all other species of this genus, *N. palmipes* is adapted for semiaquatic existence. Jonkers et al. (1968) reported a Caraparu-like virus, which causes Venezuelan equine encephalitis, in *N. p. palmipes* from Trinidad. Known ectoparasites of *N. p. tatei* include the flea *Polygenis punni* (Tipton and Machado-Allison 1972). Endoparasites of *N. p. palmipes* include the nematode *Litomosoides taylori* (Guerrero et al. 2011).

REMARKS: The name *palmipes* was first used by J. A. Allen and Chapman (1893) to describe a rat from Trinidad, later reported in Sucre state, northern Venezuela (Pittier and Tate 1932), and with a distribution extending to other northern Venezuelan states. Hershkovitz (1948b), based on morphologic and biogeographic data,

designated the Venezuelan populations as *tatei* and those from Trinidad as *palmipes*. The allopatric distribution of the two forms, combined with morphometric and karyological analyses, indicate that they constitute two different subspecies.

Voss et al. (2001) compared *N. palmipes* with *N. squamipes* and *N. melanius* (treated as a synonym of *N. rattus* herein). Besides differences in karyotype, *N. palmipes* has nasal margins that abruptly taper behind the premaxillae, nasolacrimal capsules that are partially concealed in lateral view, a tegmen tympani that always has a large anterior process, and a deeper (relative to width) interparietal.

The diploid and autosomal fundamental numbers of *palmipes* are $2n=17$ and $FN=29$ (M. A. Barros et al. 1992); those for *tatei* are $2n=16$ and $FN=25-28$, with variation in fundamental number due to a pericentric inversion polymorphism in pairs 3 and 4 (M. A. Barros et al. 1992). These two karyotypes differ primarily in the morphology of chromosome pair 1. Both taxa share a pale dorsal and ventral coloration, one trait in which they differ from all other species of the genus. Hershkovitz (1944:66-67) referred to *N. p. tatei* as *N. squamipes* subspecies II.

Map 190 Selected localities for *Nectomys p. palmipes* (○) and *Nectomys p. tatei* (●).

Nectomys rattus Pelzeln, 1883

Common Water Rat

SYNONYMS:

Hesperomys rattus Pelzeln, 1883:73; type locality “Marabitanas [= Marabitanos],” upper Rio Negro, Amazonas, Brazil.

Nectomys squamipes mattensis Thomas, 1904a:238; type locality “Santa Ana da Chapada, a village situated at an altitude of about 800 m., on the Serra do Chapada, some thirty miles N.E. of Cuyabá,” Mato Grosso, Brazil.

Nectomys squamipes melanius Thomas, 1910b:185; “Lower Essequibo River, 12 miles from mouth. Alt. 40 feet,” probably Demerara-Mahaica, Guyana.

Nectomys squamipes pollens Hollister, 1914b:104; type locality “Sapucay [= Sapucaí], Paraguay”; Hershkovitz (1944:42) states that Sapucaí is “a station on the railroad line about halfway between Villa Rica and Asunción, in the region drained by the Tevicuarhy, a tributary of the lower Paraguay”; see Remarks.

Nectomys squamipes amazonicus Hershkovitz, 1944:47; type locality “Tauary, on the east bank of the lower Rio Tapajóz [= Tapajós] about fifteen kilometers below Aveiros, state of Pará, Brazil.”

Nectomys squamipes montanus Hershkovitz, 1944:57; type locality “Hacienda Exito, on the Río Cayumbá, a small stream which enters the Huallaga next below the Río Chinchao, department of Huanuco, Peru; altitude, 3000 feet.”

Nectomys squamipes tarrensis Hershkovitz, 1948b:51; type locality “Río Tarra, upper Río Catatumbo, department of Norte de Santander, Colombia; altitude, 250 meters.”

Nectomys melanius: Voss, Lunde, and Simmons, 2001:93; name combination.

Nectomys parvipes Petter, 1979:507; type locality “Cacao au bord de la rivière Comté (4°35'N, 52°28'W),” French Guiana.

Sigmodontomys parvipes Bonvicino, 1999:254; name combination.

DESCRIPTION: Color similar to *Rattus rattus*, but sides of body, chest, and upper half of abdomen pale with whitish tips; iris very dark brown; eye-ring blackish; nose purple-gray; incisors yellow-ochre; ear very rounded, blackish, with grayish skin color at root; top of tarsus grayish, with very few short hairs and thus appears almost naked; claws tan with whitish tips; forefeet with distinct rudiment of thumb with nail; and tail scaly but moderately haired (approximate translation of Pelzeln 1883:73).

DISTRIBUTION: *Nectomys rattus* occurs throughout riverine forests of eastern Colombia, Venezuela (Orinoco Basin), Peru (Ucayali Basin), Guyana, French Guiana, Paraguay, and Brazil (parts of the Amazon and Paraguay ba-

sins, and in several independent rivers basins of the northernmost Atlantic Forest).

SELECTED LOCALITIES (Map 191): BRAZIL: Amazonas, Estirão do Equador (MPEG 1685), Marabitanas (type locality of *Hesperomys rattus* Pelzeln); Goiás, Anápolis (MNRJ 1505), Posse (MNRJ 2150); Maranhão, Bacabal (MPEG [CZ 1346]); Mato Grosso, Tapirapoan (MNRJ 2079); Mato Grosso do Sul, Salobra (MZUSP 2010); Pará, Belém (MPEG 622), Cachoeira da Porteira, Rio Trombetas (MPEG 10084); Pernambuco, Exu (PMN 404; see Furtado 1981), São Lourenço da Mata (PMN 252; see Furtado 1981); Piauí, Lagoa Alegre (MPEG [CZ 1380]). COLOMBIA: Meta, Villavicencio (AMNH 136324); Norte de Santander, Río Tarra (USNM 279730). French Guiana: Awala-Yalimapo (T-4420), Kaw (T-4578). GUYANA: Essequibo Islands-West Demerara, lower Essequibo River, 12 mi above mouth (type locality of *Nectomys squamipes melanius* Thomas). PARAGUAY: Paraguari, Sapucaí (FMNH 18162). PERU: Loreto, Lagunas (FMNH 19648); Ucayali, Yarinacocha (LSUMZ 14371). VENEZUELA: Bolívar, 46 km S and 7 km E of Ciudad Bolívar (USNMN 406048), El Lagual [= El Yagual] (AMNH 16964), Auyan-Tepuí (AMNH 130731); Mérida, Fundo Vista Alegre, San Isidro de Bejuquero (M. A. Barros et al. 1992); Zulia, Misión Tokuko (USNM 448572).

SUBSPECIES: Despite the number of names applied to different geographic segments of a very large range (e.g., Hershkovitz 1944), we regard *Nectomys rattus* as monotypic. However, the taxonomic status of populations from Surinam (Brokopondo, Rudi Kappelvligveld and Marowijme, Olea Marie) with a $2n=56$ karyotype need to be reevaluated.

NATURAL HISTORY: In the Cerrado region of Brazil, *Nectomys rattus* is found primarily along streams in gallery forest (Paula 1983; Mares and Ernest 1995; Hannibal and Cáceres 2010; Talamoni and Dias 1999). Paula (1983) recorded a home range size of 2,200 m², and Mares and Ernest (1995) estimated population densities of two to six individuals per hectare. In Venezuela, this species was trapped in dry forest, moist forest, and wet forest, always on the ground and near watercourses (Handley 1976). Ectoparasites of this species include the flea *Polygenis tripus* (L. R. Guimarães 1972) and the tick *Amblyomma* sp. (E. K. Jones et al. 1972). *Nectomys rattus* is also infected by the trematode *Schistosoma mansoni*, with an ability to eliminate viable eggs to complete the transmission cycle of the parasite (A. C. Ribeiro et al. 1998), and can be a reservoir of the protozoan genus *Leishmania* (Lainson and Shaw 1969).

REMARKS: Thomas (1904a) included *Hesperomys rattus* Pelzeln (1883) in *Nectomys*. Subsequently, Hershkovitz (1944) excluded *Hesperomys rattus* (Pelzeln) from the genus *Nectomys*, although he did not examine the holotype

but rather based his decision only on Pelzeln's original description, which did not mention interdigital membranes. However, interdigital membranes are not readily apparent in young specimens of *Nectomys*, including the skin of the holotype of *N. rattus* (NMW 471 housed in the Naturhistorisches Museum Wien in Vienna). Examination of the holotype (Alfredo Langguth, pers. comm.) and of photographs confirmed that Pelzeln's type is a *Nectomys*.

Nectomys rattus includes forms previously described as *N. squamipes mattensis* Thomas (1904a), *N. s. amazonicus* Hershkovitz (1944), *N. s. montanus* Hershkovitz (1944), *N. s. tarrensis* Hershkovitz (1948b), *N. s. pollens* Hollister (1914b), and *N. s. melanius* Thomas (1910b). Voss et al. (2001) used the name *N. melanius* for the species of water rats in the Guianan region but included in their concept karyotypes ranging from $2n=52$ to 56. They also suggested that *rattus* Pelzeln could be a senior synonym of *melanius* Thomas pending an examination of the holotype. However, as construed herein, *N. rattus* has a $2n=52$, with this basic diploid number supplemented in some populations by the presence of up to two supernumerary chromosomes, giving a $2n=54$ (Bonvicino, D'Andrea et al. 1996). For the moment, the systematic significance of the numerical variability in diploid number reported by Voss et al. (2001) for Guianan specimens is unclear. Nevertheless, we regard *melanius* Thomas as a junior synonym of *rattus* Pelzeln based on: (1) our unpublished molecular analysis that grouped specimens from Guyana and French Guiana with those of *N. rattus* with $2n=52$; (2) the morphological assessment of Voss et al. (2001) that regarded water rats from the Guianas and Amazon Basin to be the same; and (3) the inclusion of a $2n=52$ karyotype among the French Guianan specimens reported by Voss et al. (2001).

Map 191 Selected localities for *Nectomys rattus* (●). Contour line=2,000 m.

Bonvicino (1999) treated *parvipes* Petter as a species of *Sigmodontomys*, but Voss et al. (2001:94–95), after examination of the holotype of *parvipes*, stated that “none of its qualitative characters diverge from the range of variation exhibited by other specimens of French Guiana *Nectomys* with substantially larger measurements.” We concur, based on our examination of photographs of Petter’s holotype, and include *parvipes* Petter as junior synonym of *N. rattus*.

Nectomys squamipes Brants, 1827

Atlantic Water Rat

SYNONYMS:

M[us]. squamipes Brants, 1827:138; type locality “Brasilien”; subsequently restricted to São Sebastião, São Paulo State, Brazil (Hershkovitz 1944).

Mus aquaticus Lund, 1839a:233; *nomen nudum*.

M[us]. aquaticus Lund, 1840a [1841b:240]; type locality “Rio das Velhas’s Floddal” (Lund 1841b:264, 266), Lagoa Santa, Minas Gerais, Brazil.

H[esperomys]. squamipes: Wagner, 1843a:540; name combination.

Hesperomys (Holochilus) robustus Burmeister, 1854:164; type locality “Brazil”; see Hershkovitz (1944) for remarks about type locality.

Hesperomys (Holochilus) aquaticus: Burmeister, 1855a:6; name combination.

Nectomys squamipes: Peters, 1861:152; first use of current name combination.

Potamys brasiliensis Liais, 1872:507; renaming of *Mus aquaticus* Lund.

Hesperomys (Nectomys) squamipes: Ihering, 1893:14; name combination.

Nectomys squamipes squamipes: Gyldenstolpe, 1932a:66; name combination.

Nectomys squamipes aquaticus: Hershkovitz, 1944:40; name combination.

Nectomys squamipes olivaceus Hershkovitz, 1944:41; type locality “five miles north of Therezopolis [= Teresópolis], Rio de Janeiro, Brazil.”

DESCRIPTION: Color of back ochraceous orange mixed with brown; underfur, basal parts of cover hairs, and guard hairs neutral gray; rump colored like back but with tips of guard hairs frequently gray rather than ochraceous; upper parts of sides like back but with less dark brown, lower halves nearly uniformly ochraceous; hairs of chest and belly neutral gray basally, paling subterminally to gray, tips ochraceous orange; head from nose to crown cinnamon brown or dark brown, lightly mixed with ochraceous; narrow orbital ring present but poorly defined; cheeks colored like sides; area around mouth, chin, throat, and ventral surface of forelegs and hindlegs pallid neutral gray to nearly white with faint to medium-heavy ochraceous wash;

ears brown, thinly haired externally, and nearly naked internally; vibrissae black at their base, terminally black, brown, or gray; forefeet and hindfeet covered thinly above with white to brown hairs; brown plantar surfaces naked; hindfoot fringed with white; tail uniformly brown except for scattering of gray keel hairs, especially over terminal one-fourth, in some specimens.

DISTRIBUTION: *Nectomys squamipes* occurs in the São Francisco, Paraíba do Sul, and Paraná river basins of eastern Brazil (from Pernambuco state in the north to Rio Grande do Sul in the south), and in the Cerrado gallery forests bordering the Atlantic Forest in the Brazilian states of Minas Gerais, São Paulo, and Mato Grosso do Sul, Misiones in Argentina, and probably in Uruguay, although no specimens are known from that country.

SELECTED LOCALITIES (Map 192): ARGENTINA: Misiones, Caragatay (FMNH 26734). BRAZIL: Alagoas, Quebrângulo (MNRJ 12408); Bahia, Prado (UFPB [AL 1319]), Valença (UFPB [AL 3467]); Mato Grosso do Sul, Maracaju (MNRJ 3827); Minas Gerais, Araguari (MNRJ 7520), Barra do Paraopeba, Rio Extrema (MNRJ 2058), Conceição do Mato Dentro (MNRJ 13349); Pernambuco, São Lourenço da Mata (PMN 299, see Furtado 1981); Rio Grande do Sul, Sapiranga (UFRGS [LF 80]); Santa Catarina, Florianópolis (UFRGS [LF 2003]); São Paulo, Ilha de São Sebastião (type locality of *Mus squamipes* Brants), Itapura (MZUSP 10184); Sergipe, Cristinápolis (MNRJ 30574).

SUBSPECIES: We regard *N. squamipes* as monotypic.

NATURAL HISTORY: *Nectomys squamipes* inhabits primary forest vegetation near streams (Briani et al. 2001; Prevedello et al. 2010). Atlantic water rats are nocturnal and omnivorous, feeding on fungi, invertebrates, leaves, fruit, and small vertebrates (Crespo 1982b). D’Andrea et al. (1996) recorded population densities between 1.2 and 3.4 individuals per hectare with home range sizes between 2.2 to 12.0 per hectare. Litter sizes ranged from one to seven (mode=4 and 5), the gestation period was 30 days, and the minimum age to weaning was between 20 and 25 days. On Ilha do Cardoso (São Paulo state), *N. squamipes* reproduced seasonally and where survival rate was tied to fruit availability (Bergallo and Magnusson 1999), but at Sumidouro (Rio de Janeiro state), *N. squamipes* reproduced throughout the year but mostly during rainy periods, and survivorship increased with the effects of the dry periods (Bonecker et al. 2009). Briani et al. (2001) studied *N. squamipes* nests and found them to be egg shaped, about 15 cm long and 10 cm wide, without any apparent entrance, and composed of dry leaves and grass.

Endoparasites of *N. squamipes* include the trematodes *Schistosoma mansoni* (see A. V. Martins et al. 1955) and *Canaania obese* (see Maldonado et al. 2010) and the nematodes *Aspidorera raillicti*, *Physaloptera getula* (see Vicente

et al. 1982), and *Syphacia venteli* (see M. Robles and Navone 2010). The species is highly susceptible to infection by *Schistosoma mansoni* and is able to maintain the transmission cycle of this parasite (Maldonado Jr. et al. 1994; Gentile et al. 2006). Ectoparasites include the flea *Polygenis pradoi* (Botelho and Linardi 1980), and the mites *Eubrachylaelaps rotundus*, *Gigantolaelaps goyanensis*, *Laelaps manguinhosi*, and *Laelaps mazzai* (Botelho et al. 1981). *Nectomys squamipes* preyed upon by the Barn Owl (*Tyto alba*; R. P. Martins et al. 1980).

REMARKS: Hershkovitz (1944:65–66) included all names applicable to *Nectomys* in his highly polytypic *N. squamipes*, but we restrict this name only to those populations throughout the Atlantic Forest of coastal Brazil. Bonvicino, D'Andrea et al. (1996) substantiated the species-level status of the Amazonian *N. rattus* and *N. squamipes* through experimental hybrid crosses that produced sterile males with abnormal spermatogenesis, thus indicating that the two represent independent genetic lineages. Moreover, karyological data confirmed that both species occur in sympatry in Pernambuco state where no natural hybrids have been found through karyotyping (Furtado 1981).

The diploid and autosomal fundamental numbers ($2n=56$, $FN=56$) in this species are variable due to the presence of up to three supernumerary chromosomes (Bonvicino 1994). The upper toothrow of *N. squamipes* is significantly shorter than that of *N. rattus*, *N. apicalis*, *N. grandis*, or *N. palmipes* (Bonvicino 1994).

Map 192 Selected localities for *Nectomys squamipes* (●). Contour line = 2,000 m.

Genus *Nephelomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

Species of the genus *Nephelomys* in South America occur along the Andes from Bolivia to Colombia and in the coastal ranges of Venezuela, extending northward into the cordilleras of Panama and Costa Rica in Central America. These rats are found in montane cloud and elfin forests, and wooded páramo, across an elevational range from 900–3,500 m. Although there are no records of *Nephelomys* on the western dry western slopes of the Andes in Peru or southwestern Ecuador, more northern species may be present on both versants.

The genus has not been revised, and many nominal taxa are known primarily from their original descriptions. I have, however, examined most material in major museum collections and herein provisionally recognize 13 species: *N. albigularis*, *N. auriventer*, *N. caracolus*, *N. childi*, *N. devius*, *N. keaysi*, *N. levipes*, *N. maculiventer*, *N. meridensis*, *N. moerex*, *N. nimbosus*, *N. pectoralis*, and *N. pirrensis*. Two species are restricted to Central America (*N. devius* and *N. pirrensis*), although Voss (2014) provided a record from the Serranía de Darién on the Colombian side of the international border with Panama that most likely represents *N. pirrensis*. For details of these two species, see also Goldman (1913, 1918, 1920), Hall (1981), and F. A. Reid (2009).

Externally, species of this genus are defined by a tail longer than head and body length; long and dense mystacial vibrissae, surpassing the ears when laid backward; and long and narrow hindfeet, with the dorsal surfaces weakly furred and the ventral surfaces naked and with well-developed interdigital and plantar (thenar and hypothenar) pads. The pelage is soft and dense, varying from long to very long; the ventral pelage may have patches of self-colored hairs in the gular, thoracic, abdominal, and inguinal regions that vary in size and position depending upon the species; the ventral pelage coloration varies from grizzled white to rich buffy ochraceous tones.

The skull is very distinctive in comparison to those of other oryzomyine genera. In dorsal view, the rostrum is long and robust; the nasolacrimal capsules project weakly; the zygomatic notches are usually shallow and wide; and the interorbital region is hourglass in shape, with dorsolateral margins diverging or converging posteriorly and with the supraorbital border varying from rounded, squared, beaded, or strongly beaded. Incisive foramina may be short, medium, or long, with their lateral margins widest posteriorly (short to long teardrop shape) or widest medially (egg shaped). The palate is typically long and wide (*sensu* Hershkovitz 1962); in some species, the anterior margin of the mesopterygoid fossa reaches the alveoli or the hypoflexus of

the M3s, resulting in a shorter palate. Posterolateral palatal pits are located in shallow to very deep palatal depressions and range from simple at the palatal level to complex. An enlarged stapedial foramen, squamosoalisphenoid groove, and sphenofrontal foramen are present, configuring pattern 1 of the carotid circulatory system (*sensu* Voss 1988). An alisphenoid strut, separating the buccinator-masticator and accessory oval foramina, is present in some species. Auditory bullae are large and triangular in shape. The tegmen tympani is weakly developed, only rarely in contact with the squamosal in individuals of some species.

The mandible has a small and weakly falciform coronoid process, and the angular process extends posteriorly past the condyloid process. The capsular process is inconspicuous in most species and is frequently absent.

The molars are pentalophodont and hypsodont, with the main cusps arranged in opposite pairs. These cusps are connected transversely by lophids and anteroposteriorly by muresids. M1 and m1 both have a deep anteromedian flexus and flexid, respectively.

The glans penis is complex, with a tridigitate and well-developed cartilaginous baculum; there is a single dorsal papilla, one short and bifurcate urethral flap, and three bacular mounds visible in the terminal crater (Hooper and Musser 1964). Male accessory glands consist of one pair each of ventral prostate, ampullary, vesicular, and bulbo-urethral glands, and one pair each of medial and lateral prostate glands; preputial glands are absent (Voss and Linzey 1981). The stomach is unilocular-hemiglandular (Carleton 1973).

SYNONYMS:

- Hesperomys*: Tomes, 1860b:264; part (description of *albigularis*); not *Hesperomys* Waterhouse.
Hesperomys (*Calomys*): Thomas, 1882:103; part (listing of *albigularis*); not *Calomys* Waterhouse.
Hesperomys [*Oryzomys*]: Thomas, 1884:448; part (listing of *albigularis*); not *Oryzomys* Baird.
Oryzomys: E.-L. Trouessart, 1897:524; part (listing of *albigularis* and *meridensis*); not *Oryzomys* Baird.
Zygodontomys: Gyldenstolpe, 1932a:114; part (listing of *obtusirostris*); not *Zygodontomys* J. A. Allen.
Nephelomys Weksler, Percequillo, and Voss, 2006:18; type species *Hesperomys albigularis* Tomes, by original designation.

REMARKS: Several species-group nominal taxa historically and currently included in the genus *Nephelomys* (namely, *devius* Bangs, *meridensis* Thomas, *pirrensis* Goldman, *childi* Thomas, *o'connelli* [sic] J. A. Allen, *pectoralis* J. A. Allen, *maculiventer* J. A. Allen, *auriventer* Thomas, *keaysi* J. A. Allen, *obtusirostris* J. A. Allen, and *levipes* Thomas) were listed as synonyms of *Oryzomys albigularis* (= *N. albigularis*) in Hershkovitz's (1944:72) unfortunate footnote revision. Later, in another footnote, Hershkovitz

(1960:544) inadvertently listed *caracolus* Thomas, another name historically associated with *Oryzomys albigularis*, among synonyms of "*Oryzomys laticeps*" (now in *Hylaeamys*; see also that account) but subsequently corrected his error (Hershkovitz 1966a:137, footnote 11) by treating *caracolus* along with *devius* and *villosus* J. A. Allen (see Musser and Williams 1985) as "additional representatives" of *O. albigularis*. In my opinion, Hershkovitz's (1966a) concept of *Oryzomys* (= *Nephelomys*) *albigularis* is the same he developed previously (Hershkovitz 1944), with the only changes being the addition of other species-group names. These "additional representatives" were listed as junior synonyms without being given a taxonomic categorical rank. However, Hershkovitz (1966a) did recognize two taxa as distinct subspecies of *O. albigularis* (*meridensis* Thomas and *caracolus* Thomas).

From the 1940s through the 1960s, Hershkovitz treated several nominal taxa (now in the genera *Euryoryzomys*, *Hylaeamys*, *Nephelomys*, and *Transandinomys*) in synonymy with a small number of species-group names without the benefit of morphological diagnoses or apparently the examination of name-bearing types or other specimens. Unfortunately, Cabrera (1961) and others followed these nomenclatural acts, actions that have obscured the current application of many species-group names.

Species limits in the genus are poorly understood, and, as noted earlier, many named forms have been regarded as either synonyms or valid subspecies of a widespread *Nephelomys albigularis*. However, I have found both the frequency and extent of the white ventral patches to be valuable diagnostic features for species recognition in *Nephelomys*, contrary to past opinion (J. A. Allen 1904c; Osgood 1912, 1913, 1914b; Eisenberg 1989). Once segregated on this basis and by the limited karyotypic data, the 11 species I recognize herein are diagnosable by additional external and craniodental characters. My current hypothesis of species limits must await more thorough geographic sampling as well as more extensive morphological, karyotypic, and molecular analyses.

KEY TO THE SOUTH AMERICAN SPECIES OF NEPHELOMYS:

1. Ventral patches of self-colored white hairs absent . . . 2
- 1'. Ventral patches of self-colored white hairs present on variable frequencies 5
2. Alisphenoid strut present in >75% of specimens; interorbital region hourglass in shape, with rounded or weakly beaded supraorbital margins; ventral pelage grayish to grayish yellow. 3
- 2'. Alisphenoid strut present in <25% of specimens; skull robust and long (mean length 37.9 mm; range: 36.2–39.8 mm); incisive foramina very long (mean length

- 6.26 mm; range: 5.6–6.7 mm), teardrop in shape; interorbital region with strongly beaded supraorbital margins, diverging posteriorly; coloration of ventral pelage strongly ochraceous yellow; $2n=70$, FN=84
 *Nephelomys auriventer*
3. Alisphenoid strut small and delicate, a dorsoventrally oriented bony bar, defining the oval accessory and the buccinator-masticatory foramina 4
- 3'. Alisphenoid strut very robust, varying from a wide bar oriented anteroposteriorly (defining the oval accessory and the buccinator-masticatory foramina) to an almost complete alisphenoid bony wall, with small individual foramina for the nerves and vessels; incise foramina very short (mean length 4.56 mm; range: 4.1–5.1 mm), teardrop in shape *Nephelomys moerex*
4. Incisive foramina long (mean length 6.0 mm; range: 5.2–7.2 mm) with lateral margins widest medially; posterior margins of incisive foramina close to alveoli of M1s; palate short (mean length 6.6 mm; range: 5.9–8.1 mm), with anterior margin of mesopterygoid fossa frequently slightly penetrating between toothrows; posterolateral palatal pits elongated and situated in oblique, narrow and deep palatal fossae; $2n=76$ and FN=88
 *Nephelomys levipes*
- 4'. Incisive foramina short (mean length 5.4 mm; range: 4.1–6.5 mm) with lateral margins widest posteriorly; posterior margins of incisive foramina more distant from alveoli of M1s; palate long (mean length 7.5 mm; range: 6.7–8.7 mm), with anterior margin of mesopterygoid fossa rarely penetrating between toothrows; posterolateral palatal pits situated in more rounded and deep palatal fossae; $2n=80$ and FN=92 to 94
 *Nephelomys keaysi*
5. Ventral pelage grayish or whitish washed with gray; white patches in gular, pectoral, and/or inguinal regions 6
- 5'. Ventral pelage ochraceous yellow with a golden tone, with very small white gular patches; incisive foramina short (mean length 5.0 mm; range 4.6–5.1 mm), with lateral margins slightly rounded in outline; alisphenoid strut present in about 30% of specimens; posterolateral palatal pits small to large, in shallow palatal fossae; interorbital region hourglass in shape, with supraorbital margins rounded or squared. . . *Nephelomys nimbosus*
6. Ventral white patches present in moderate to high frequencies (>50%) 7
- 6'. Ventral white patches present in low frequencies (ca. 12%); posterolateral palatal pits small and numerous, situated in shallow or moderately deep palatal fossae. *Nephelomys childi*
7. Ventral white patches large and wide, occupying a large area on gular and pectoral regions 8
- 7'. Ventral white patches small and narrow, restricted to the gular and pectoral regions in about 60% of specimens; incise foramina long (mean length 6.1 mm; range: 5.3–6.9 mm) and narrow, with nearly parallel lateral margins; interorbital region divergent posteriorly, with supraorbital margins beaded to strongly beaded; posterolateral palatal pits small, varying in depth from palatal level or in shallow palatal fossae; $2n=66$, FN=90 *Nephelomys caracolus*
8. Ventral white patches large, present in more than 90% of specimens; alisphenoid strut absent 9
- 8'. Ventral white patches present in about 50% of specimens; delicate alisphenoid strut present in >60% of specimens; interorbital region convergent posteriorly, with rounded supraorbital margins in its anterior portion and squared margins in posterior portion
 *Nephelomys albigularis*
9. Posterolateral palatal pits vary from few to many, deep, and situated in shallow to moderately deep palatal fossae 10
- 9'. Posterolateral palatal pits numerous and deep, situated in sharply delimited, very deep and complex palatal fossae; white ventral patches very large, occupying gular and pectoral regions, rarely inguinal region; $2n=66$, FN=94. *Nephelomys pectoralis*
10. White ventral patches extremely long and wide, occupying gular and pectoral regions, reaching middle of abdomen or, more frequently, inguinal region (very few specimens have venter entirely white); few posterolateral pits, placed at palatal level or in shallow palatal fossae; shorter rostrum (mean nasal length 12.1 mm; range 10.85–13.65 mm); $2n=66$, FN=112
 *Nephelomys maculiventer*
- 10'. White ventral patches very large, occupying gular and pectoral regions; numerous posterolateral palatal pits, situated in shallow to deep palatal fossae; longer rostrum (mean nasal length 13.01 mm; range: 11.78–14.3 mm); $2n=66$, FN=104 *Nephelomys meridensis*
- Nephelomys albigularis* (Tomes, 1860)
- White-throated *Nephelomys***
- SYNONYMS:
- Hesperomys albigularis* Tomes, 1860b:264; type locality: “taken en camino [*sic*] on my return from Pallatanga”; restricted to “Pallatanga, [Chimborazo,] Ecuador” (Tate 1939:189).
- Hesperomys (Calomys) albigularis*: Thomas, 1882:103; name combination.
- [*Hesperomys (Oryzomys)*] *albigularis*: Thomas, 1884:448; name combination.
- [*Oryzomys*] *albigularis*: E.-L. Trouessart, 1897:524; name combination.

[*Oryzomys (Oryzomys)*] *albigularis*: E.-L. Trouessart, 1904: 417; name combination.

[*Oryzomys (Oryzomys)*] *albigularis albigularis*: Tate, 1932e: 16; name combination.

Oryzomys albigularis albigularis: Gyldenstolpe, 1932a:14; name combination.

[*Nephelomys*] *albigularis*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Recognized by combination of following traits: medium body size (head and body length 102–162 mm) with tail longer than head and body (138–184 mm); tail bicolored or weakly bicolored (few specimens with unicolored tails); long, dense and soft dorsal fur, ranging from buffy orange grizzled with dark brown to ochraceous intensely grizzled with dark brown; whitish or yellowish ventral pelage, with or without small patches of self-colored hairs in gular region (rarely in pectoral region); skull with long incisive foramina, nearly parallel lateral margins widening posteriorly; posterolateral palatal pits small and numerous, on level of palate or situated in moderately deep palatal fossae; alisphenoid strut variably present; interorbital region hourglass in shape or convergent posteriorly, with supraorbital margins rounded or slightly squared; sphenopalatine vacuities small and variably present.

DISTRIBUTION: *Nephelomys albigularis* occurs on the eastern and western slopes of the Andean Cordillera Oriental, from northwestern Peru to central Ecuador. The species is present on both sides of the arid Huancabamba Depression, and in isolated forested patches in this area. The elevational range is from 900 m (Hacienda Éxito, Huánuco, Peru) to 3,100 m (Taraguacocha, Cordillera de Chilla, El Oro, Ecuador).

The southernmost record of this species is Hacienda Éxito, in Huánuco department, Peru, at about 900 m. This site is located at the left margin of Río Cayumba, a left margin tributary of the Río Huallaga, which drains the upper elevations of the Cordillera Oriental. Farther to the north in Peru, most samples are distributed along the eastern slope of the Cordillera Oriental (in the upper Río Huallaga drainage) or on both banks of rivers (e.g., Río Cutervo, Río Utcubamba, and Río Huancabamba, all tributaries of the Río Marañón) between the central and eastern Andean cordilleras. Only specimens from Taulis (Cajamarca) and Seques (Lambayeque) represent unequivocal records of this species on the western slope in northern Peru. All remaining localities in the Cordillera Occidental, such as Cutervo (on the Río Chatano) and Tambo (on the Río Huancabamba), are in drainages of the Amazon Basin.

North of the Huancabamba Depression, in Ecuador, records of *N. albigularis* are predominantly from the western slopes of Cordillera Occidental. The species is known

from only two localities on the eastern slopes that drain to the Amazon Basin, near Loja in the headwaters of the Río Zamora (a Río Marañón tributary) and Mazán (in the inter-Andean Cuenca basin). The northernmost record of this species is Carmen, in Bolívar province, central Ecuador.

SELECTED LOCALITIES (Map 193): ECUADOR: Azuay, Mazán (BM 84.306), Molleturo (AMNH 61898); Bolívar, Carmen, near Sinchic (AMNH 66944); Cañar, Chical (AMNH 63333); Chimborazo, Pallatanga (type locality of *Hesperomys albigularis* Tomes); El Oro, El Chiral (AMNH 46481); Loja, Celica (AMNH 47813), 8 km W of Loja (UMMZ 164889). PERU: Amazonas, Uscho, about 50 km E Chachapoyas (FMNH 19698); Cajamarca, Taulis (AMNH 73135); Huánuco, Hacienda Éxito, Río Cayumba (FMNH 24771); La Libertad, Utcubamba, on trail to Ongón (LSUMZ 24790); Piura, Cerro Chinguela, ca. 5 km NE of Zapalache (LSUMZ 26992).

SUBSPECIES: *Nephelomys albigularis* is monotypic.

NATURAL HISTORY: Throughout its latitudinal and elevational range, *N. albigularis* inhabits the humid slopes of the Peruvian and Ecuadorean Andes (Chapman 1926), generally in montane and cloud/elfin forests. Barnett (1999) trapped *N. albigularis* in both primary and secondary cloud forests between 2,400 m and 2,700 m in Ecuador. Over a five-year period from June to October, he observed no pregnant females and captured one lactating female; of 16 males trapped, only four were in breeding condition (Barnett 1999). In northern Peru, *N. albigularis* inhabits very humid forests from 1,525 to 2,440 m, dwelling under logs, roots, and debris. Females captured in Amazonas, Peru, during August showed no evidence of embryos, although one lactating female was collected (data from museum tags).

REMARKS: *Nephelomys albigularis* was previously considered to be widely distributed, occurring from northwestern Peru to northern Colombia, northwestern Venezuela, and eastern Panama (Eisenberg 1989; Corbet and Hill 1991; Musser and Carleton 1993; Eisenberg and Redford 1999). This concept included populations that exhibit substantial karyological variation and morphological differences in external features such as the presence and extension of ventral white patches and also in several skull characters. Herein, I recognize these morphologically and chromosomally distinct geographic units as separate species (see following accounts).

My more restricted concept of *N. albigularis* includes samples that share the following morphological traits: medium frequency (50%) of gular and/or pectoral white patches; bicolored tail present in >70% of specimens; interorbital region hourglass in shape, with dorsolateral margins converging posteriorly; supraorbital margins rounded or only slightly beaded; incisive foramina long,

Map 193 Selected localities for *Nephelomys albigularis* (●). Contour line = 2,000 m.

wide, and teardrop in shape; palate long and ornate, with shallow to deep posterolateral palatal pits at the palatal level or in deep palatal notches; and alisphenoid strut present in >60% of examined specimens.

Nephelomys auriventer (Thomas, 1899)

Greater Golden-bellied *Nephelomys*

SYNONYMS:

Oryzomys auriventer Thomas, 1899d:379; type locality “Mirador, below Baños, on the Upper River Pastaza [= Río Pastaza], E Ecuador [= Tungurahua, Ecuador]. Altitude 1500 m.”

Oryzomys (*Oryzomys*) *auriventer auriventer*: Tate, 1932e: 16; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72, footnote; name combination; part; not *Hesperomys albigularis* Tomes, 1860 (= *Nephelomys albigularis* [Tomes]).

Oryzomys albigularis auriventer: Cabrera, 1961:381; name combination.

[*Nephelomys*] *auriventer*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Body long and robust (head and body length 140–173 mm), tail very long (range: 160–191 mm). Dorsal pelage short and harsh, colored orange yellow to orange golden densely grizzled with brown; ventral pelage light yellowish to intensely golden; white gular patches absent (except for one specimen from Peru with a small patch); tail uniformly colored or weakly bicolored. Skull long and robust (greatest length 36.2–39.9 mm); incisive foramina long and wide posteriorly (teardrop in shape); interorbital region slightly to strongly convergent anteriorly, with sharply angled supraorbital margins; palate long, with large and complex posterolateral palatal pits recessed in shallow fossae; alisphenoid strut rarely present; medial lacerate foramen narrow, and postglenoid foramen small and narrow.

DISTRIBUTION: *Nephelomys auriventer* is known from three closely adjacent localities in the upper Río Pastaza drainage of the Cordillera Oriental of Ecuador and from one locality in the Apurímac drainage in the Cordillera Oriental of Peru, at elevations between 1,140 m (Mera) to 1,660 m (Huanhuachayo).

SELECTED LOCALITIES (Map 194): ECUADOR: Pastaza, Mera (AMNH 67351), Tungurahua: Mirador (type locality of *Oryzomys auriventer* Thomas). PERU: Ayacucho, Huanhuachayo (LSUMZ 16667).

SUBSPECIES: *Nephelomys auriventer* is monotypic.

NATURAL HISTORY: The few collecting localities for *N. auriventer* are characterized by “paramo or temperate plants” and “subtropical vegetation” (G. H. H. Tate notes cited in Musser et al. 1998:103), cultivated lands, second-growth forest, and primary forest (Rageot and Albuja 1994).

REMARKS: Known from fewer than 20 specimens, *N. auriventer* is readily distinguished from congeners by the following combination of characters: ochraceous yellow to nearly golden ventral pelage color; large size (mean skull length 37.9 mm; range: 36.2–39.8 mm); robust molar series (mean length 6.22 mm; range: 6.03–6.5 mm); strongly beaded supraorbital ridges; and extremely narrow lacerate foramen and medium foramen postglenoid. A. L. Gardner and Patton (1976) reported karyotypic data from a Peruvian specimen with $2n = 70$ and $FN = 84$; although there is no karyological information available for Ecuadorean specimens, these share the same unique combination of morphological traits as the Peruvian specimen.

The considerable distributional hiatus (about 1,300 km) between Ecuadorean and Peruvian localities may be due to a truly disjunct range or to a sampling artifact. Few recent collecting efforts have been made across the wide region between these distributional end points since the Godman-Thomas expeditions of 1926 and 1927 (see, for example, Thomas 1926b,e,g, 1927a,f; Thomas and Leger 1926a).

Map 194 Selected localities for *Nephelomys auriventer* (●). Contour line = 2,000 m.

Nephelomys caracolus (Thomas, 1914)

Coastal Cordilleran *Nephelomys*

SYNONYMS:

Oryzomys caracolus Thomas, 1914d:242; type locality “Galiparé [= Galipán or Pichacho de Galipán], Cerro del Ávila, near Caracas. Alt. 6000’,” Vargas, Venezuela.

Oryzomys (Oecomys) caracolus: Tate, 1939:190; name combination.

Oryzomys laticeps: Hershkovitz, 1960:544, footnote; part; not *Mus laticeps* Lund (= *Hylaeamys laticeps* [Lund]).

Oryzomys capito velutinus: Cabrera, 1961: 387; part; not *Oryzomys velutinus* J. A. Allen and Chapman (= *Hylaeamys megacephalus* [G. Fischer])

Oryzomys albigularis caracolus: Hershkovitz, 1966a:137, footnote; name combination.

[*Nephelomys*] *caracolus*: Weksler, Percequillo, and Voss, 2006:8; first use of current name combination.

DESCRIPTION: Medium body size (head and body length 120–165 mm) and tail longer than head and body combined (tail length 144–176 mm). Dorsal pelage long and dense, yellowish intensely grizzled with brown in color; ventral pelage grayish to whitish, with narrow white pectoral patches variably present (in some specimens patches especially long, extending to gular region). Skull of medium size (greatest length 31.1–38.4 mm); incisive foramina long and

narrow, with acutely pointed anterior and posterior margins; palate with few, small posterolateral palatal pits at palate level or recessed in very shallow fossae, lacking palatine crests or excrescences; interorbital region divergent posteriorly, with supraorbital margins strongly angled and beaded.

DISTRIBUTION: *Nephelomys caracolus* is distributed throughout the Venezuelan Cordillera de la Costa, in Aragua, Carabobo, and Miranda states as well as in the Distrito Federal. Most records are associated with the Caribbean (or northern) slope; only a few samples are from the southern slope. Elevation ranges from 1,050 to 2,300 m. See R. P. Anderson and Raza (2010), who modeled the climatic niche and potential distribution of the species.

SELECTED LOCALITIES (Map 195): VENEZUELA: Aragua, Rancho Grande, Estación Biológica de Rancho Grande, 13 km NW of Maracay (USNM 405988); Carabobo, La Cumbre de Valencia (AMNH 31541); Miranda, Curupao, 19 km E of Caracas (AMNH 135170), Hacienda Las Planadas (R. P. Anderson and Raza 2010); Vargas, Galiparé [= Galipán], Cerro de Ávila (type locality of *Oryzomys caracolus* Thomas).

SUBSPECIES: *Nephelomys caracolus* is monotypic.

NATURAL HISTORY: This species has been captured in mature and disturbed humid evergreen and cloud forests with a rich subcanopy of ferns and vines and covered with abundant moss and epiphytes (Handley 1976). Specimens have also been taken in drier evergreen and cloud forests, with limited epiphytic cover, on the inland slopes of the Cordillera de la Costa (Handley 1976). O. J. Linares (1998) summarized the natural history of “*Oryzomys albigularis*” in Venezuela, but his concept included specimens and localities now assigned to both *N. caracolus* and *N. meridensis*.

REMARKS: *Nephelomys caracolus* has been listed as a species of the genus *Oecomys* (Tate 1939), as a synonym of *Hylaeamys megacephalus* (= *Oryzomys capito*, *sensu* Hershkovitz 1960; or *Oryzomys capito velutinus*, see Cabrera 1961), and as a synonym or subspecies of *Oryzomys* (= *Nephelomys*) *albigularis* (Hooper and Musser 1964; Musser and Carleton 1993; Handley 1976; Hershkovitz 1966a). Tate (1947:66) included some specimens of this species in his concept of *Oryzomys* [= *Nephelomys*] *meridensis*. More recently, Aguilera, Pérez-Zapata, and Martino (1995) and Márquez et al. (2000) established the species validity of *N. caracolus* based on karyological ($2n=66$, $FN=90$) and morphometric data, respectively. This species is morphologically distinct from other Venezuelan populations, treated here as *N. meridensis*, by the following combination of characters: lower frequency of ventral patches of self-colored white hairs, which are smaller and restricted to the gular region; interorbital region divergent posteriorly, with supraorbital margins beaded; incisive foramina longer with lateral margins wider medially (convex); and postero-

Map 195 Selected localities for *Nephelomys caracolus* (●) and *Nephelomys meridensis* (○). Contour line = 2,000 m.

lateral palatal pits smaller and placed at the palatal level or in shallow palatal notches.

Nephelomys childi (Thomas, 1895)

Child's Nephelomys

SYNONYMS:

Oryzomys childi Thomas, 1895b:59; type locality "Bogotá," Cundinamarca, Colombia."

Oryzomys meridensis: Bangs, 1900a:93; part; *childi* Thomas given as a synonym of *Oryzomys meridensis* Thomas.

Oryzomys. *Childi*: Thomas, 1901b:188; name combination.

[*Oryzomys* (*Oryzomys*)] *childi*: E.-L. Trouessart, 1904:419; name combination.

Oryzomys o'connelli J. A. Allen, 1913c:597; type locality "Buenavista (altitude 4500 feet), about 50 miles south-east of Bogotá," Meta, Colombia.

[*Oryzomys* (*Oryzomys*)] *o'connelli*: Tate, 1932e:17; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72 footnote; part; not *Hesperomys albigularis* Tomes, 1860 (= *Nephelomys albigularis* [Tomes]).

Oryzomys albigularis childi: Cabrera, 1961:381; name combination.

Oryzomys albigularis o'connelli: Cabrera, 1961:82; name combination.

[*Oryzomys*] *oconnelli*: Márquez, Aguilera, and Corti, 2000:85; corrected spelling of species epithet (ICZN 1999:Art.32.5.2.3).

[*Nephelomys*] *childi*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Distinguished from congeners by following traits: medium body size (head and body length

120–184 mm); tail longer than head and body (tail length 110–194 mm); dorsal pelage varying in length and texture geographically, with some samples presenting dense and shorter fur and other exhibiting very dense and longer hairs; ventral pelage of few individuals with small white patches in gular region. Skull with interorbital region hour-glass in shape or convergent posteriorly, with supraorbital margins rounded; rounded braincase, with discrete temporal border; long incisive foramina, with lateral margins wider posteriorly (teardrop in shape); palate with numerous posterolateral palatal pits recessed in shallow to moderately deep fossae; and developed palatal excrescences situated on palatine level or on palatine crests.

DISTRIBUTION: *Nephelomys childi* is endemic to Colombia, occurring in all three cordilleras of the northern Andes. In the Cordillera Oriental, this species is distributed on both the eastern and western forested slopes from the headwaters of Río Magdalena (Huila department), in the Sierra de Macarena (Meta department), and in the plains of Bogotá (Cundinamarca department). In the Cordillera Central, isolated populations occur in upper Cauca and Magdalena drainages (Huila and Cauca departments, respectively) and on the eastern slope in the departments of Antioquia, Caldas, Quindío, and Tolima. The only known populations of *N. childi* in the Cordillera Occidental are isolated on the extreme northwestern slope at Santa Barbara and Guapantal (Antioquia department). Elevational range is 1,140 to 3,400 m.

SELECTED LOCALITIES (Map 196): COLOMBIA: Antioquia, San Pedro (FMNH 72101), Santa Barbara, RíoUrroa (FMNH 71882); Cauca, Almaguer (BM 13.5.27.42); Cundinamarca, Anolaima (BM 99.10.3.23), Guasca, Río Balcones (FMNH 71896), Paima (AMNH 71340); Huila, Andalucía, eastern Andes (AMNH 33755); Meta, Buenavista (type locality of *Oryzomys oconnelli* J. A. Allen), Macarena Mt. (AMNH 142160); Tolima, El Éden, E Quindío Andes (AMNH 32983).

SUBSPECIES: *Nephelomys childi* is monotypic.

NATURAL HISTORY: Data on ecology or other aspects of the natural history of *N. childi* are lacking.

REMARKS: The holotypes and topotypes of *N. childi* and *N. oconnelli* are extremely similar in external and cranial traits, and, as a result, I regard these taxa as conspecific. Previous authors have considered *N. childi* a synonym of *Nephelomys meridensis* based on the presence and size of ventral white patches (Bangs 1900a; Thomas 1901b; Osgood 1914b) or as a synonym (Hershkovitz 1944) or subspecies (Cabrera 1961) of *N. albigularis*. Furthermore, many specimens referable to *N. childi* have been erroneously identified as *N. auriventer* (J. A. Allen 1916b; Cervero Díaz et al. 1986) or *N. pectoralis* (J. A. Allen 1916b; Anthony 1923a).

Map 196 Selected localities for *Nephelomys childi* (●). Contour line = 2,000 m.

This species can be readily recognized from its Colombian congeners *N. pectoralis* and *N. maculiventer* by the combination of a low frequency of small ventral white patches (about 12%) and shallow and small posterolateral palatal pits placed in shallow to moderately deep palatal fossae.

Nephelomys keaysi (J. A. Allen, 1900)

Keays's *Nephelomys*

SYNONYMS:

Oryzomys keaysi J. A. Allen, 1900a:225; type locality "Juliaca, Peru, altitude 6000 ft," corrected to "Inca Mines [= Santo Domingo Mine], about 200 miles northeast of Juliaca, on the east side of the Andes, on the Inambari River [= Río Inambari]," Puno, Peru, by J. A. Allen (1901b:41).

Oryzomys obtusirostris J. A. Allen, 1900a:225; type locality "Juliaca, Peru, altitude 6000 ft"; corrected to "Inca Mines [= Santo Domingo Mine], about 200 miles northeast of Juliaca, on the east side of the Andes, on the Inambari River [= Río Inambari]," Puno, Peru, by J. A. Allen (1901b:41).

Oryzomys (Oligoryzomys) obtusirostris: Thomas, 1901b:188; name combination.

[*Oryzomys (Oryzomys)*] *keaysi*: E.-L. Trouessart, 1904:419; name combination.

[*Oryzomys (Oryzomys)*] *obtusirostris*: E.-L. Trouessart, 1904:419; name combination.

Zygodontomys obtusirostris: Gyldenstolpe, 1932a:114; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72, footnote; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]).

Oryzomys albigularis keaysi: Cabrera, 1961:381; name combination.

[*Nephelomys*] *keaysi*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Medium sized (head and body length 125–165 mm); tail much longer than head and body (length 146–207), not bicolored in most specimens; dorsal pelage dense, long, and lax, colored ochraceous to buffy ochraceous intensely grizzled with brown; ventral pelage grayish, whitish, or rarely yellowish, without white pectoral or gular patches; interorbital region of skull slightly to strongly divergent posteriorly, with supraorbital margins squared to strongly beaded; incisive foramina long, with lateral margins wider posteriorly and posterior margins not reaching M1s; palate long, with large posterolateral pits at palate level or recessed in shallow and narrow fossae; palatal excrescences small and delicate; alisphenoid strut present in most specimens.

DISTRIBUTION: *Nephelomys keaysi* occurs on the forested eastern slopes of the Andes in central Peru (Santa Cruz, Pasco) south to central Bolivia (Chaparé, Cochabamba), at elevations between 1,000–2,600 m; most records are from 1,200–1,500 m.

SELECTED LOCALITIES (Map 197): BOLIVIA: Cochabamba, Chaparé (BM 34.9.2.128); Yungas (AMNH 38557); La Paz, Pitiguaya, Río Unduavi (AMNH 72647). PERU: Ayacucho, Yuraccyacu (LSUMZ 15693); Cusco, Machu Picchu, San Miguel Bridge (BM 22.1.1.28), Marcapata, Camante (FMNH 68628), 72 km NE of Paucartambo (MVZ 166682); Junín, Acobamba, 45 mi NE of Cerro de Pasco (BM 27.11.1.91), Satipo, Cordillera de Vilcabamba (USNM 582120); Pasco, Santa Cruz, ca. 9 km SSE of Oxapampa (LSUMZ 25894); Puno, Sagrario (FMNH 52705), Inca Mines (type locality of *Oryzomys keaysi* J. A. Allen and *Oryzomys obtusirostris* J. A. Allen).

SUBSPECIES: *Nephelomys keaysi* is monotypic.

NATURAL HISTORY: *Nephelomys keaysi* inhabits montane and cloud forests (Patton et al. 1990). Pregnant females were captured in November, with three embryos, at Santa Cruz, Peru, and females with uterine scars (four to five) were observed in July, east of Paucartambo, Peru. Stomachs of specimens from Bosque Aputinye, Cusco, Peru contained arthropods and vegetable matter (diet and reproductive data from museum tags and field notes).

REMARKS: *Nephelomys keaysi* was resurrected from the synonymy of *N. albigularis* on the basis of karyo-

logical (A. L. Gardner and Patton 1976) and molecular studies (Patton et al. 1990; see also Musser and Carleton 1993). The karyotype of *N. keaysi* is $2n=80$, $FN=92-94$, based on specimens from localities in Junín, Ayacucho, and Cusco departments, Peru (A. L. Gardner and Patton 1976, “*Oryzomys albigularis* variant 3”; J. L. Patton, pers. comm.).

The separate specific status of *N. keaysi* and *N. levipes*, which replace one another on the elevational gradient in southeastern Peru, was demonstrated by karyological (J. L. Patton, pers. comm.) and allozyme analyses (Patton 1986; Patton et al. 1990). Morphologically, *N. keaysi* differs from *N. albigularis* by absence of self-colored ventral patches, divergent interorbital margins with sharp or beaded supraorbital margins, and higher frequency of an alisphenoid strut. For comparisons with *N. levipes*, see Remarks under that species.

Nephelomys obtusirostris, here recognized as a synonym of *N. keaysi*, has been previously assigned to the *longicaudatus-stolzmanni* group of *Oryzomys* (= genus *Oligoryzomys*; Thomas 1901b) or to *Zygodontomys* (Gyldenstolpe 1932; Ellerman 1941). However, Tate (1939) correctly noted that the holotype of *Oryzomys obtusirostris* J. A. Allen was a young specimen of *Nephelomys keaysi*, with immature pelage and unerupted third upper molars.

Nephelomys keaysi is parapatric to *N. levipes* throughout much of its distribution (see account) and with *N. auriventer* at Huanhuachayo, Ayacucho, Peru (see account).

Map 197 Selected localities for *Nephelomys keaysi* (●). Contour line = 2,000 m.

Nephelomys levipes (Thomas, 1902)

Nimble-footed *Nephelomys*

SYNONYMS:

Oryzomys levipes Thomas, 1902b:129; type locality “Limbane [= Limbani], 2,000 m,” Puno, Peru.

[*Oryzomys* (*Oryzomys*)] *levipes*: E.-L. Trouessart, 1904:419; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72 footnote; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]).

Oryzomys [(*Oryzomys*)] *albigularis keaysi*: Cabrera, 1961:381; part; not *Oryzomys keaysi* J. A. Allen (= *Nephelomys keaysi* [J. A. Allen]); name combination.

[*Nephelomys*] *levipes*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Medium sized (head and body length 113–161 mm); tail longer than head and body (length 143–185 mm). Dorsal pelage very dense, very long, and lax, colored from yellowish to ochraceous grizzled with brown; ventral pelage shorter and predominantly yellowish, without patches of self-colored hairs; tail frequently weakly to strongly bicolored, rarely unicolored. Skull length 33.5–39.8 mm; interorbital region slightly to strongly divergent posteriorly, with squared to beaded supraorbital margins; incisive foramina long, wider in middle, with posterior margins almost reaching M1 alveoli; palate short, with anterior border of mesopterygoid fossa reaching alveoli or even M3 hypocones; posterolateral palatal pits deep, recessed at moderately deep to deep oblique and lateral fossa positioned at maxillopalatine suture; palate with small excrescences; sphenopalatine vacuities long and wide; alisphenoid strut present in all examined specimens.

DISTRIBUTION: *Nephelomys levipes* inhabits cloud and elfin forests on the eastern slopes of the Andes in northwestern Bolivia and southwestern Peru, at elevations from 1,800 to 3,200 m. This species replaces *N. keaysi* at higher elevations on the eastern Andean slope.

SELECTED LOCALITIES (Map 198): BOLIVIA: La Paz, Cocopunco (AMNH 72118); 15 km (by road) NE of Unduavi (UMMZ 156180); Santa Cruz, Serranía Siberia, 11 km NW by road of Torrecillas (AMNH 264192). PERU: Cusco, 32 km NE of Paucartambo (MVZ 166679); Puno, Limbani (type locality of *Oryzomys levipes* Thomas), 11 km NNE of Ollachea (MVZ 172637), 14 km W of Yanahuaya (MVZ 172639).

SUBSPECIES: *Nephelomys levipes* is monotypic.

NATURAL HISTORY: *Nephelomys levipes* is predominantly terrestrial but has also been captured in trees. Notes on specimen tags state that the species dwells in “humid, dark, mossy forest,” “high forest,” on “steep slopes,” and in “gorges near streams.” Pregnant females with one or three embryos were collected in July and with two, four, or

Map 198 Selected localities for *Nephelomys levipes* (●). Contour line = 2,000 m.

five embryos during June–August at localities in Puno and Cusco departments, Peru, respectively (specimen labels and field notes).

REMARKS: *Nephelomys levipes* has been considered a junior synonym of either *N. keaysi* (Gyldenstolpe 1932; Cabrera 1961) or *N. albigularis* (Hershkovitz 1944, 1966a; Corbet and Hill 1991). The molecular data of Patton et al. (1990), however, support *N. levipes* as specifically distinct from both *N. keaysi* and *N. albigularis*, an arrangement followed by subsequent authors (Musser and Carleton 1993, 2005; Eisenberg and Redford 1999). *Nephelomys levipes* can be differentiated from *N. keaysi* by a denser and longer dorsal pelage; longer incisive foramen, with lateral margins wider medially; posterolateral palatal pits situated in deeper and narrower palatal slits; and a higher frequency in the presence of an ectolophid on m1. The two species also differ in karyotype, with a $2n=76$ and $FN=88$ for *N. levipes* and $2n=80$, $FN=92$ to 94 in *N. keaysi* (“*Oryzomys albigularis* variant 3” of A. L. Gardner and Patton 1976; J. L. Patton, pers. comm.).

Nephelomys maculiventer (J. A. Allen, 1899)

Santa Marta *Nephelomys*

SYNONYMS:

Oryzomys maculiventer J. A. Allen, 1899b:204; type locality: “Sierra El Libano (alt. 6000 ft.), Santa Marta District,” Magdalena, Colombia.

Oryzomys meridensis: Bangs, 1900a:92; part; *maculiventer* listed as a synonym of *Oryzomys meridensis* Thomas.

[*Oryzomys* (*Oryzomys*)] *maculiventer*: E.-L. Trouessart, 1904:418; name combination.

Oryzomys meridensis maculiventer: Osgood, 1912:49; name combination.

Oryzomys albigularis maculiventer: Osgood, 1914b:159; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72 footnote; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]).

[*Nephelomys*] *maculiventer*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Medium to large body size (head and body length 127–180 mm); tail longer than head and body (length 148–194); long, dense, and lax dorsal pelage; ventral pelage with patches of self-colored hairs present in almost all examined specimens, with large patches in gular, pectoral (including ventral surface of forelimbs), abdominal, and inguinal areas; tail usually unicolored, rarely weakly bicolored; small and delicate skull (greatest skull length 32.7–35.9 mm); interorbital region hourglass in shape or slightly convergent posteriorly, with rounded supraorbital margins; short incisive foramina, wider posteriorly (teardrop in shape); long palate, with few but deep posterolateral pits either recessed in shallow fossae or at palate level.

DISTRIBUTION: All known localities of *N. maculiventer* are from the slopes of Sierra Nevada de Santa Marta and Serranía de Perijá, in northern Colombia, where this species ranges from 900–2,600 m in montane and cloud forests.

SELECTED LOCALITIES (Map 199): COLUMBIA: Cesar, Villeneuve, Sierra Negra (USNM 280641); La Guajira, San Miguel (AMNH 3894); Magdalena, Sierra El Libano (type locality of *Oryzomys maculiventer* J. A. Allen).

SUBSPECIES: *Nephelomys maculiventer* is monotypic.

NATURAL HISTORY: Nothing is known about the ecology, population biology, or other aspects of the natural history of this species.

REMARKS: A. L. Gardner and Patton (1976) regarded the population of *Nephelomys* from the Sierra Nevada de Santa Marta as a subspecies of *N. albigularis* based on karyological and morphological evidence. Subsequent authors (Musser and Williams 1985; Musser and Carleton 1993, 2005) treated *maculiventer* simply as a synonym of *N. albigularis*. The specimens from Santa Marta, however, are sharply differentiated morphologically from other species in the genus and have a different karyotype ($2n=66$, $FN=112$; “*Oryzomys albigularis* variant 1” of A. L. Gardner and Patton 1976). As a result, I recognize *N. maculiventer* as a valid species. Among the morphological features that diagnose this species are large ventral patches of self-colored hairs in most specimens and a skull with simple and few posterolateral palatal pits situated at the palatal level or in shallow palatal fossae.

Map 199 Selected localities for *Nephelomys maculiventer* (○) and *Nephelomys pectoralis* (●). Contour line = 2,000 m.

Nephelomys meridensis (Thomas, 1894)

Mérida Nephelomys

SYNONYMS:

Oryzomys meridensis Thomas, 1894b:351; type locality “Merida, Venezuela,” Mérida, Venezuela.

[*Oryzomys* (*Oryzomys*)] *meridensis*: E.-L. Trouessart, 1904:418; name combination.

[*Oryzomys* (*albigularis*)] *meridensis*: Osgood, 1914b:159; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72 footnote; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]).

O[*ryzomys*]. *albigularis meridensis*: Hershkovitz, 1966a:137, footnote; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]); name combination.

Oryzomys [(*Oryzomys*)] *albigularis*: Eisenberg, 1989:351; part.

[*Nephelomys*] *meridensis*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Medium body size (head and body length 135–160 mm); long tail that exceeds head and body (length 170–172 mm), typically unicolored but rarely weakly bicolored; dorsal pelage dense, lax, and very long; ventral pelage with large pectoral patches of self-colored hairs (gular, axillary, and inguinal patches rarely pres-

ent). Skull of medium size (greatest length 32.4–37 mm); interorbital region slightly convergent posteriorly or symmetrically constricted (hourglass in shape), with rounded or slightly beaded supraorbital margins posteriorly; palate with multiple and deep posterolateral palatal pits recessed in shallow depressions; palatine crest present, with small to very large palatal excrescences (if large, may be fused to maxilla).

DISTRIBUTION: This species occurs on forested slopes from the northeastern Cordillera Oriental of Colombia in Boyacá department, through the Páramo de Tamá on the Colombian-Venezuelan border, to the northern portion of the Sierra de Mérida, in Trujillo state, Venezuela, at elevations from 1,100 to 4,000 m. See R. P. Anderson and Raza (2010), who modeled the climatic niche and potential distribution of the species.

SELECTED LOCALITIES (Map 195): **COLUMBIA:** Boyacá, La Primavera (FMNH 92408); Norte de Santander, Páramo de Tamá (FMNH 18648). **VENEZUELA:** Mérida, Montes de Los Nevados (AMNH 33163), Páramo Tambor (BM 29.3.17.55); Táchira, Táchira (FMNH 7044); Trujillo, Hacienda Misisí, 14 km E of Trujillo (USNM 374310).

SUBSPECIES: *Nephelomys meridensis* is monotypic.

NATURAL HISTORY: Osgood (1912) secured specimens in ground litter and under logs and roots in the dense, cold, forested areas of the Páramo de Tamá, on the Venezuelan/Colombian border.

REMARKS: *Nephelomys meridensis* was recognized as a valid taxon throughout much of its history, either as a species (E.-L. Trouessart 1904; Goldman 1918; Gyldenstolpe 1932; Tate 1939; Ellerman 1941; Aguilera, Pérez-Zapata, and Martino 1995; Soriano and Ochoa 1997; Márquez et al. 2000; Musser and Carleton 2005) or subspecies (Osgood 1914b; Cabrera 1961; Hershkovitz 1966a; O. J. Linares 1998; Rivas and Péfaur 1999a). Other authorities simply included this name in the synonymy of *N. albigularis* (Hershkovitz 1944; Handley 1976; Péfaur and Díaz de Pascual 1985; Eisenberg 1989; Corbet and Hill 1991; Musser and Carleton 1993; Rivas and Péfaur 1999b).

Aguilera, Pérez-Zapata, and Martino (1995) and Márquez et al. (2000) separated populations from the Mérida Andes (= *N. meridensis*; $2n=66$, FN=104) from those from the Cordillera de la Costa (= *N. caracolus*; $2n=66$, FN=90) of Venezuela on karyological and morphometric grounds, respectively. These authors, as well as Percequillo (2003), also distinguished samples from the Páramo de Tamá on the Colombian/Venezuelan border ($2n=66$, FN=92) from those of the Mérida Andes. Morphologically, specimens from Mérida and the Páramo de Tamá are quite similar in the extent of their ventral white patches and in cranial traits, differing only slightly in the morphology of posterolateral palatal pits, which are

deeper on *N. meridensis*. The specimens from the Páramo de Tamá are included in my concept of *N. meridensis* until the validity of this decision is rejected by subsequent analyses. If differences between specimens from the Páramo de Tamá and the Mérida Andes prove to warrant taxonomic recognition, a new name will have to be erected for the former because none is currently available.

Nephelomys moerex (Thomas, 1914)

Gray-bellied *Nephelomys*

SYNONYMS:

Oryzomys albigularis moerex Thomas, 1914d:241; type locality “Mindó, N. W. of Quito. Alt. 4200’,” Pichincha, Ecuador.

[*Oryzomys*] *albigularis maerex* Anthony, 1926a:4; incorrect subsequent spelling of *moerex* Thomas.

[*Oryzomys*] *moerex*: Tate, 1939:189; name combination.

Oryzomys albigularis: Boyce et al., 1982:435; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]).

[*Nephelomys*] *moerex*: Weksler, Percequillo, and Voss, 2006: 18; first use of current name combination.

DESCRIPTION: Small to medium body (head and body length 114–160); tail longer than head and body (length 139–169 mm) and usually bicolored; dorsal pelage dense, lax, and short, overall colored ochraceous brown finely grizzled with dark brown; ventral pelage grayish, without patches of self-colored hairs. Skull with slightly convergent posteriorly or symmetrically constricted (hour-glass in shape) interorbital region, with rounded or squared supraorbital margins; incisive foramina very short (length 4.1–5.1 mm; mean 4.6 mm), with sides widest medially; alisphenoid strut present in high frequency but ranges from narrow strut oriented parallel to lateral border of parapterygoid plate to wide bone covering almost completely ovale accessorius and buccinator-masticatory foramina.

DISTRIBUTION: *Nephelomys moerex* is endemic to Ecuador, with all known localities from a small area on the northwestern and southwestern faces of Volcán Pichincha and the Mindo river drainage, at elevations from 1,200 to 2,800 m.

SELECTED LOCALITIES (Map 200): ECUADOR: Pichincha, Las Máquinas, San [= Santo] Domingo trail (AMNH 64702), Río Tulipe, Guala (FMNH 94979).

SUBSPECIES: *Nephelomys moerex* is monotypic.

NATURAL HISTORY: No data on natural history are available.

REMARKS: Thomas (1914d) originally described *moerex* as a subspecies of *N. albigularis*, a treatment followed by many subsequent authors (Anthony 1926a; Gyldenstolpe 1932; Ellerman 1941; Cabrera 1961). Others, however, regarded *moerex* as a full species (e.g., Tate 1939). Nevertheless, the name *moerex* was, until recently (Percequillo

Map 200 Selected localities for *Nephelomys moerex* (●) and *Nephelomys nimbosus* (○). Contour line=2,000 m.

2003), lost in the synonymy of *N. albigularis* (Hershkovitz 1966a; Boyce et al. 1982; Corbett and Hill 1991; Musser and Carleton 1993, 2005).

Known from only a few specimens (about three dozen deposited in the BM, AMNH, MCZ, and UMMZ collections), *N. moerex* is considerably different from typical *N. albigularis* or any other nominal form of the genus, and thus I recognize it here as a valid species (see also Percequillo 2003). This species is diagnosed by the combination of absence of white ventral patches (in all but one specimen), very short and oval incisive foramina, and, most conspicuously, presence of a robust and obliquely oriented alisphenoid strut in all specimens (in some specimens the strut almost obliterates the alisphenoid wall, leaving only small foramina for the passage of nerves and vessels).

Nephelomys nimbosus (Anthony, 1926)

Lesser Golden-bellied *Nephelomys*

SYNONYMS:

Oryzomys auriventer nimbosus Anthony, 1926a:4; type locality “San Antonio, on Rio Ulva, northeastern slope of Tunguragua, [Tunguruhua,] Ecuador, altitude 6700 feet.”

[*Oryzomys* (*Oryzomys*)] *auriventer nimbosus*: Tate, 1932e: 16; name combination.

[*Oryzomys*] *nimbosus*: Tate, 1939:189; name combination.

Oryzomys [(*Oryzomys*)] *albigularis nimbosus*: Cabrera, 1961:382; part; name combination.

[*Oryzomys*]. *albigularis*: Corbet and Hill, 1991:151; part; not *Hesperomys albigularis* Tomes (= *Nephelomys albigularis* [Tomes]); name combination.

Oryzomys auriventer: Musser and Carleton, 1993:720; part; not *Oryzomys auriventer* Thomas (= *Nephelomys auriventer* [Thomas]); name combination.

[*Nephelomys*] *nimbosus*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Small species, with head and body length 122–144 mm, and tail length 147–170 mm. Dorsal pelage very dense and very long, colored yellow orange to golden orange densely grizzled with brown; ventral pelage pale ochraceous yellow to intensely golden, with small white gular patches in most specimens. Skull small and delicate, length 31.5–35.4 mm; interorbital region narrow and either convergent posteriorly or amphoral in shape, with rounded or slightly squared supraorbital margins; incisive foramina short and widest posteriorly (teardrop in shape; mean length 4.98 mm; range: 4.6–5.1 mm); palate with small and simple posterolateral palatal pits located at palatal level or recessed in shallow depressions; alisphenoid strut found in about 30% of specimens.

DISTRIBUTION: *Nephelomys nimbosus* is endemic to Ecuador, with the four known collecting localities on the eastern Andean slope in Napo and Tungurahua provinces, at elevations from 2,000–2,440 m. Along the Río Pastaza drainage, this species is parapatric to *N. auriventer*, replacing it at higher elevations.

SELECTED LOCALITIES (Map 200): ECUADOR: Napo, Baeza (AMNH 63840), Chaco, Rio Oyacachi (AMNH 66807); Tungurahua, San Antonio (type locality of *Oryzomys auriventer nimbosus* Anthony), San Francisco, E of Ambato (AMNH 67354).

SUBSPECIES: *Nephelomys nimbosus* is monotypic.

NATURAL HISTORY: There is no published information on the natural history of *N. nimbosus*.

REMARKS: Anthony's *nimbosus* was considered either a subspecies of *N. auriventer* or of *N. albigularis*, or a synonym of the latter, since its description until Weksler et al. (2006) treated it as a species. Specimens of *N. nimbosus* are rare in museum collections, with fewer than 15 known, and few specialists have examined them. Based on my examination of the available material, I recognize *N. nimbosus* as a valid species because it can be distinguished from *N. auriventer* and other species of the genus by the combination of the characters mentioned above.

Nephelomys pectoralis (J. A. Allen, 1912)

Western Colombian *Nephelomys*

SYNONYMS:

Oryzomys pectoralis J. A. Allen, 1912:83; type locality "crest of Western Andes (alt. 10, 340 ft.), 40 miles west of Popayán, Cauca, Colombia."

[*Oryzomys albigularis*] *meridensis*: Osgood, 1914b:159; part; not *meridensis* Thomas.

[*Oryzomys (Oryzomys)*] *pectoralis*: Tate, 1932e:17; name combination.

[*Oryzomys*] *albigularis*: Hershkovitz, 1944:72 footnote; part; not *albigularis* Tomes.

Oryzomys [(Oryzomys)] albigularis pectoralis: Cabrera, 1961:382; part; name combination.

[*Nephelomys*] *pectoralis*: Weksler, Percequillo, and Voss, 2006:18; first use of current name combination.

DESCRIPTION: Differentiated from congeners from Colombia or generally northern Andes by medium head and body (length 124–180 mm); tail longer than head and body (length 110–196); long, dense, and lax dorsal pelage, colored yellowish to ochraceous grizzled with brown; ventral pelage grayish, with large and conspicuous white gular and pectoral patches that rarely reach abdominal region; and usually unicolored tail. Distinguishing cranial characteristics include medium-sized skull (greatest length 32.0–37.5 mm); robust and long rostrum; interorbital region hourglass in shape or posteriorly convergent, with slightly squared posteriorly supraorbital margins; incisive foramina short, with lateral margins widest posteriorly (teardrop in shape); numerous and complex posterolateral palatal pits recessed in very deep and well-defined depressions; roof of mesopterygoid fossa frequently ossified so that sphenopalatine vacuities, when present, small and narrow.

DISTRIBUTION: *Nephelomys pectoralis* is endemic to Colombia, occurring in all three Andean cordilleras. It is restricted to the western slope of the Cordillera Oriental, occurs along the length of the Cordillera Central, and is present on the forested western slope and upper regions of the eastern slope of the Cordillera Occidental.

SELECTED LOCALITIES (Map 199): COLUMBIA: Antioquia, La Bodega, N side Río Negrito (USNM 293778), Ventanas, Valdívía (FMNH 70417); Cauca, Cocal (AMNH 32539), Río Mechengue (FMNH 90217); Cundinamarca, Cuchillas del Carnicero, near Bogotá (BM 99.10.3.16); Quindío, El Roble (AMNH 32985); Valle del Cauca, Las Lomitas (AMNH 32200), Miraflores, near Palmira (AMNH 32185).

SUBSPECIES: *Nephelomys pectoralis* is monotypic.

NATURAL HISTORY: No details have been published.

REMARKS: The validity of the name *pectoralis* has been questioned throughout its history (Osgood 1914b; Hershkovitz 1944; Musser and Carleton 1993), although Cabrera (1961) listed it as a subspecies of *N. albigularis*. Specimens from Valle del Cauca (Peñas Blancas, Río Pichindé) have a $2n=66$, $FN=94$ karyotype (A. L. Gardner and Patton 1976, as "*Oryzomys albigularis* variant 2"), which differs from those of all other forms of *Nephelomys*. The limited geographic representation by specimens and lack of karyotypic data from topotypes, however, precluded these authors from associating this karyotype with the name *pectoralis*.

Nevertheless, my examination of these specimens and others from the Andes of Colombia supports the hypothesis that *N. pectoralis* should be distinguished from other members of the genus, and I recognize it as a valid species. Among its distinctive features are large and wide white ventral patches, numerous and deep posterolateral pits placed in deep palatal fossae, the low frequency of small sphenopalatine vacuities, and a karyotype of $2n=66$ and $FN=94$ (A. L. Gardner and Patton 1976).

Genus *Nesoryzomys* Heller, 1904

Robert C. Dowler

Members of the genus *Nesoryzomys* are restricted to the Galápagos Islands, Ecuador, with Recent species known from only four of the major islands in the archipelago: Isla Baltra, Isla Fernandina, Isla Santa Cruz, and Isla Santiago. Undescribed species, known from fragmentary subfossil remains, have been reported from Isla Isabela and Isla Rábida (Steadman and Zousmer 1988). Of the five described species, two are now considered extinct. Much of the following account is based on Weksler's (2006) morphological analysis.

The five species of *Nesoryzomys* fall in two size classes. The smaller species (*N. darwini* and *N. fernandinae*) have total lengths of about 200 mm and masses about 32 g, whereas the larger (*N. indefessus*, *N. narboroughi*, and *N. swarthi*) are all greater than 250 mm in total length and have masses around 100 g. The ears are medium-sized, well haired proximally and less so distally. Mystacial vibrissae are long, with the longest projecting posterior to the ears. The tail is shorter than the head and body and well haired, with scales rarely visible. Fur is medium-length and color varies among species, usually medium brown or dark brown approaching black. The ventral pelage is paler than that of the dorsum. A white subauricular patch is usually present. Both manus and pes have ungual tufts. The plantar surfaces of the hindfeet are naked with thenar, hypothenar, and four interdigital pads present. There are eight mammae.

The skull is elongate with a long rostrum and a very narrow, symmetrical interorbital region that has little, if any, supraorbital bead. The nasals are short, terminating bluntly even with the maxillary-frontal-lacrimal junction. The zygomatic plates are broad with distinct zygomatic notches. The zygomatic arches converge slightly anteriorly with the widest portion at the squamosal root. The lacrimal is primarily in contact with the maxillary and has relatively little contact with the frontal. The incisive foramina are long, with the posterior margins at same level as or posterior to the anterior margins of the M1s. The palate is flat with posterolateral palatal pits. There are large sphenopalatine vacuities that reach the basisphenoid. The

anterior alisphenoid canal is large, and an alisphenoid strut is absent. The carotid circulation is the derived pattern 3 (*sensu* Voss 1988), with a small stapedial foramen and both squamosoalisphenoid groove and sphenofrontal foramen absent. The ectotympanic bullae are large, covering most of the periotic bone viewed ventrally. The mandible has a sharply curved coronoid process equal in height to the condyle. The posterior border of the angular process lies directly below the tip of the condyle. The mandible has an obvious capsular process.

The molars are brachydont and bunodont, with lateral elements higher than central ones. The anterocone of M1 is divided into labial and lingual conules. All upper molars have mesoloph, and a mesoloph is present on m1 and m2. The M2 lacks a protoflexus. A posteroloph is present on M3. Both M1 and m1 have four roots.

The axial skeleton has 12 ribs. The first rib has a dual articulation with the seventh cervical and first thoracic vertebrae. A supratrochlear foramen is present in the humerus. The stomach is unilocular and hemiglandular (Patton and Hafner 1983), and a gall bladder is absent. Male accessory reproductive glands include a single pair of preputial glands, a pair of bulbourethral glands, and one pair of ampullary and vesicular glands. There is a single pair of dorsal prostate glands (Patton and Hafner 1983). The glans penis is elongate with a very shallow terminal crater. The osseous baculum is long and slender with a very small tridigitate cartilaginous apparatus (Patton and Hafner 1983).

SYNONYMS:

Oryzomys: Thomas, 1899c:280; part (description of *indefessus*); not *Oryzomys* Baird.

Nesoryzomys Heller, 1904:241; type species *Oryzomys indefessus* Thomas, by original designation.

[*Oryzomys*] (*Nesoryzomys*): Ellerman, 1941:343; usage as subgenus.

REMARKS: Patton and Hafner (1983) reviewed soft and craniodental characters in *Nesoryzomys* relative to those of other subgenera (now genera) of "*Oryzomys*" (*sensu lato*) and supported the generic status originally proposed by Heller. This opinion has been followed in recent reviews (e.g., Musser and Carleton 1993, 2005). The genus *Aegialomys* is considered sister to *Nesoryzomys* based on both molecular and morphological phylogenetic analyses (Patton and Hafner 1983; Weksler 2003, 2006; Pine et al. 2012). Patton and Hafner (1983) also suggested that all large forms of *Nesoryzomys* (*indefessus*, *narboroughi*, and *swarthi*) could be considered subspecies of one species, with *N. indefessus* having priority. Musser and Carleton (2005) concurred for *N. narboroughi* and *N. indefessus*, but retained *N. swarthi* as a distinct species based on craniodental features presented in the original description of *N. swarthi* (Orr 1938). Recent molecular studies (Weksler

2003) verified the divergence of *N. swarthi* and *N. narboroughi*. Additional molecular and chromosomal studies under way by the author further support the recognition of different species on separate islands and argue for a conservative retention of the original names for all *Nesoryzomys*.

KEY TO THE SPECIES OF *NESORYZOMYS*:

1. Hindfeet dark; adult skull length usually less than 36 mm; premaxillae short, terminating anterior to posterior margins of nasals 2
- 1'. Hindfeet white, adult skull length usually greater than 36 mm; premaxillae longer, terminating at the level of posterior margins of nasals. 3
2. Pelage dark brown with few yellow-tipped hairs; dorsal hairs of hindfoot brown; interparietal about half as wide as posterior margin of squamosal.
. *Nesoryzomys darwini*
- 2'. Pelage brown suffused with yellow-tipped hairs; dorsal hairs of hindfoot silver; interparietal wider than half the width of the posterior margin of squamosal
. *Nesoryzomys fernandinae*
3. Pelage dark brown to black; subsquamosal fenestra absent. *Nesoryzomys narboroughi*
- 3'. Pelage cinnamon brown; subsquamosal fenestra present 4
4. Posterior margins of the incisive foramina in adults projecting well between M1s; mastoid usually completely ossified; palate long with mesopterygoid fossa extending to posterior margin of maxillae; length of tail <122 mm *Nesoryzomys indefessus*
- 4'. Posterior margin of incisive foramina in adults at anterior margin of first molars; mastoid usually not fully ossified but having distinct fenestra; palate shorter with mesopterygoid fossa extending between maxillae; length of tail >122 mm *Nesoryzomys swarthi*

Nesoryzomys darwini Osgood, 1929

Darwin's *Nesoryzomys*

SYNONYMS:

Nesoryzomys darwini Osgood, 1929: 23; type locality "Academy Bay, Indefatigable Island [= Isla Santa Cruz], Galapagos Islands," Ecuador.

Oryzomys [(*Nesoryzomys*)] *darwini*: Ellerman, 1941:359; name combination.

DESCRIPTION: One of two small species in genus, total length 204–222 mm; tail shorter than head and body (70–80%); dorsal color reddish brown streaked with black but providing overall bright fulvous tone; sides slightly paler than back; and under parts rufous with gray-based hairs. Skull slender and without sharp ridges or angles. Distinguished from sympatric *N. indefessus* by much smaller size and cinnamon-brown overall color.

Map 201 Selected localities for *Nesoryzomys darwini* (●) and *Nesoryzomys fernandinae* (○).

DISTRIBUTION: *Nesoryzomys darwini* was known only from the island of Santa Cruz, Galapagos Islands, Ecuador; it is now considered extinct (Clark 1984; Dexter et al. 2004).

SELECTED LOCALITIES (Map 201): ECUADOR: Galapagos, Isla Santa Cruz (= Indefatigable Island), Academy Bay (type locality of *Nesoryzomys darwini* Osgood), Conway Bay (Osgood 1929), Fortuna, near Bellavista (AMNH 99922).

SUBSPECIES: *Nesoryzomys darwini* is monotypic.

NATURAL HISTORY: This species is presumed extinct, with the last specimens known collected in April 1930 (Patton and Hafner 1983). The species likely occurred across most of the island of Santa Cruz as the few specimens are from two coastal sites and two upland sites at 800 and 1,200 feet elevation, respectively. Nothing has been reported on the natural history of this species, although Osgood (1929) commented that it was much less numerous than sympatric *N. indefessus* based on trapping records of the specimens in the type series.

Nesoryzomys fernandinae Hutterer and Hirsch, 1979

Small *Fernandina Nesoryzomys*

SYNONYM:

Nesoryzomys fernandinae Hutterer and Hirsch, 1979:278; type locality "Insel [= Isla] Fernandina, 300m, Galapagos, Ecuador."

DESCRIPTION: Second small species, with alveolar length in type series 4.9–5.6 mm, overlapping only minimally with that of *N. darwini* at lower end of distribution and *N. narboroughi* at the upper end (see Hutterer and Hirsch 1979). Distinguished from its sympatric congener *N. narboroughi* by

smaller size (mass averaging 32.3 g versus 77.5 g, respectively) and darker brown dorsal pelage with dark feet, rather than paler grayish black and white feet (Dowler et al. 2000).

DISTRIBUTION: *Nesoryzomys fernandinae* is known only from the island of Fernandina, Galápagos Islands, Ecuador. All specimen records are from the western half of the island.

SELECTED LOCALITIES (Map 201): ECUADOR: Galápagos, Isla Fernandina (type locality of *Nesoryzomys fernandinae* Hutterer and Hirsch), Cabo Douglas (Dowler et al. 2000), caldera rim (Dowler et al. 2000).

SUBSPECIES: *Nesoryzomys fernandinae* is monotypic.

NATURAL HISTORY: *Nesoryzomys fernandinae* has been collected at coastal sites with saltbush (*Cryptocarpus pyriformis* [Nyctaginaceae] up to the highest elevation on Fernandina at approximately 1,360 m. At the higher areas, habitat is dominated by large *Scalesia microcephala* (Asteraceae), *Darwiniothamnus tenuifolius* (Asteraceae), and mixed grasses. This species occurs sympatrically with *N. narboroughi*, but it is rare at coastal sites and much more common at high elevations where vegetation is dense (Dowler and Carroll 1996). This species has not been collected in areas dominated by mangroves, where *N. narboroughi* may be abundant. Specimens taken in July and August were not in reproductive condition.

Nesoryzomys indefessus (Thomas, 1899)

Santa Cruz Nesoryzomys

SYNONYMS:

Oryzomys indefessus Thomas, 1899c:280; type locality “Indefatigable Island [= Isla Santa Cruz],” Galápagos Islands, Ecuador.

Nesoryzomys indefessus: Heller, 1904:241; name combination.

Oryzomys [(*Nesoryzomys*)] *indefessus*: Ellerman, 1941:359; name combination.

DESCRIPTION: Large bodied, with total length 260–297 mm; tail length 108–117 mm; Orr 1938); palest species in genus in dorsal color tones (Patton and Hafner 1983). Orr (1938) noted that the skull was virtually indistinguishable from that of *N. narboroughi*, although the two are slightly separable in multivariate discriminate space based on craniodental measurements (Patton and Hafner 1983).

DISTRIBUTION: *Nesoryzomys indefessus* was known only from the islands of Santa Cruz and Baltra, Galápagos Islands, Ecuador, but is now considered extinct (Clark 1984; Dexter et al. 2004).

SELECTED LOCALITIES (Map 202): ECUADOR: Galápagos, Isla Santa Cruz (= Indefatigable Island), Academy Bay (Patton and Hafner 1983), Conway Bay (Patton and Hafner 1983), Isla Baltra (= South Seymour Island; Patton and Hafner 1983).

Map 202 Selected localities for *Nesoryzomys indefessus* (●), *Nesoryzomys narboroughi* (▲), and *Nesoryzomys swarthi* (○).

SUBSPECIES: *Nesoryzomys indefessus* is monotypic.

NATURAL HISTORY: This species is presumed extinct, with the last specimens collected in 1941 on the island of Baltra. On Santa Cruz, A. Rambech, an early settler, reported native rats to be abundant from the coast to the wet summit in the late 1920s before the introduction of *Rattus rattus*. Collections by J. P. Chapin in March of 1935 at Conway Bay revealed only *Rattus rattus* (Clark 1984). Feral cats also may have played a role in the extinction of this species (Dexter et al. 2004). The species likely was common on both Santa Cruz and Baltra based on the number of specimens in collections. Recent surveys on both islands have failed to document an extant population (Patton and Hafner 1983; Dowler et al. 2000; Dexter et al. 2004). Heller (1904) reported that individuals inhabited burrows or rock crevices beneath bushes and was nocturnal.

Nesoryzomys narboroughi Heller, 1904

Large Fernandina Nesoryzomys

SYNONYMS:

Nesoryzomys narboroughi Heller, 1904:242; type locality “Mangrove Point, Narborough Island [= Isla Fernandina],” Galápagos Islands, Ecuador.

Oryzomys [(*Nesoryzomys*)] *narboroughi*: Ellerman, 1941:359; name combination.

Nesoryzomys indefessus: Patton and Hafner, 1983:562; part (*narboroughi* assigned as synonym); name combination.

DESCRIPTION: Large, with total length 264–300 mm; tail length 127–140 mm; Orr 1938); darkest color tones of

any species in genus (Patton and Hafner 1983). Readily separable from sympatric *N. fernandinae* by both size and overall color, as noted in that account.

DISTRIBUTION: *Nesoryzomys narboroughi* is known only from the island of Fernandina, Galápagos Islands, Ecuador. It occurs at every locality that has been sampled on the island, from the coast to the summit of the caldera.

SELECTED LOCALITIES (Map 202): ECUADOR: Galápagos, Isla Fernandina (= Narborough Island), Cabo Douglas (Dowler et al. 2000), caldera rim (Dowler et al. 2000), Mangrove Point (type locality of *Nesoryzomys narboroughi* Heller), Punta Espinosa (Patton and Hafner 1983).

SUBSPECIES: *Nesoryzomys narboroughi* is monotypic.

NATURAL HISTORY: *Nesoryzomys narboroughi* is common in all vegetated habitats on the island of Fernandina, including coastal sites with saltbush (*Cryptocarpus pyrifolius* [Nyctaginaceae]) and mangrove up to high elevations where *Scalesia microcephala* (Asteraceae), *Darwiniothamnus tenuifolius* (Asteraceae), and mixed grasses dominate. *Nesoryzomys narboroughi* occurs sympatrically with the smaller species *N. fernandinae*, but it is far more common at coastal sites and less common at high elevations. Population density in a saltbush community at Cabo Douglas was estimated at 100 per hectare, though the actual population at this site was restricted to relatively small habitat patches (Dowler and Carroll 1996). This species is nocturnal, though occasionally individuals may be active during daylight hours. These rodents show little fear of humans and may damage tents of researchers by gnawing. They probably have a catholic diet composed of both vegetation and invertebrates. Heller (1904) reported red material in the stomach that likely represented remains of crabs (*Grapsus grapsus*). Both the Galápagos Hawk (*Buteo galapagoensis*) and the Barn Owl (*Tyto alba*) prey on *N. narboroughi*.

REMARKS: I consider *Nesoryzomys narboroughi* to be a species separate from *N. indefessus*, contra Patton and Hafner (1983). The karyotype is $2n=32$, $FN=50$, with acrocentric X and Y chromosomes (A. L. Gardner and Patton 1976).

Nesoryzomys swarathi Orr, 1938

Santiago Nesoryzomys, Swarth's Nesoryzomys

SYNONYMS:

Nesoryzomys swarathi Orr, 1938:304; type locality "Sullivan [= Sullivan] Bay, James Island [= Isla Santiago]", Galápagos Islands, Ecuador.

O[ryzomys].(Nesoryzomys) swarathi: Corbet and Hill, 1980: 144; name combination.

Nesoryzomys indefessus: Patton and Hafner, 1983:562; part (*swarathi* assigned as subspecies); name combination.

DESCRIPTION: Largest species (total length 310–317 mm; tail length 124–140 mm; Orr 1938), but only slightly more so than *N. narboroughi*. Most similar in body

size, length of tail, and hindfoot to *N. narboroughi* but indistinguishable from *N. indefessus* in color tones. Patton and Hafner (1983), using colorimetry, verified the similarity in color tones between *N. swarathi* and *N. indefessus* and also demonstrated complete cranial separation between it and other large species.

DISTRIBUTION: *Nesoryzomys swarathi* is known only from the island of Santiago, Galápagos Islands, Ecuador. Specimens exist from only James Bay, Sullivan Bay, and La Bomba on the north coast (Dowler et al. 2000). Recent surveys revealed a population restricted to a 14-km stretch of north-central coastline centered on La Bomba (D. B. Harris et al. 2006); these surveys have failed to record the species at the other two historical localities.

SELECTED LOCALITIES (Map 202): ECUADOR: Galápagos, Isla Santiago (= James Island), La Bomba (Dowler et al. 2000; D. B. Harris et al. 2006), Sullivan Bay (type locality of *Nesoryzomys swarathi* Orr), James Bay (Peterson 1966).

SUBSPECIES: *Nesoryzomys swarathi* is monotypic.

NATURAL HISTORY: *Nesoryzomys swarathi* is currently restricted to mature cactus thorn-scrub dominated by the cactus *Opuntia galapageia* and tree species *Bursera graveolens* (Burseraceae) and *Croton scouleri* (Euphorbiaceae). The abundance of this species at La Bomba was positively correlated with cactus density, the proportion of mature cacti, and the presence of the shrub species *Lantana peduncularis* (Verbenaceae) (D. B. Harris et al. 2006). D. B. Harris and Macdonald (2007) reported median home ranges (minimum convex polygon) to be 1.76 ha for males and 0.68 for females. This *Nesoryzomys* is the only one to be found sympatrically with the invasive rodent species *Rattus rattus* and *Mus musculus*. *Nesoryzomys swarathi* is usually nocturnal with peak activities between 20:00 and 03:00 hours; however, in areas where high populations of *R. rattus* occur, activity may extend to crepuscular periods (D. B. Harris et al. 2006). Reproduction coincides with the rainy season from December through May and two litters of two to four young may be produced annually. Annual survival rates for *N. swarathi* are high (23.2%) relative to most continental oryzomyine species (D. B. Harris and Macdonald 2007).

REMARKS: As noted previously, this species was regarded as an insular race of *Nesoryzomys narboroughi* by Patton and Hafner (1983) but as a valid species by Musser and Carleton (1993, 2005), a decision with which I concur.

Genus *Oecomys* Thomas, 1906

Michael D. Carleton and Guy G. Musser

Oecomys is a moderately speciose genus of Sigmodontinae, containing at least 16 valid species according to current understanding (Musser and Carleton 2005; Carleton et al.

2009). The generic distribution generally adheres to tropical lowland rainforest, where the greatest species diversity is concentrated in the broad reaches of the Amazon Basin, including lower Atlantic-facing slopes of the Andean cordilleras. Marginal occurrences are found to the north of Amazonia, in coastal forests of northern Venezuela and trans-Andean forest of southernmost Central America, and to the south, in the Atlantic Forest of southeastern Brazil. The genus has been recorded from the Chaco in northern Argentina, but the species allocation of these records remains uncertain (see account for *O. mamorae*).

Species of *Oecomys* are small to medium-sized oryzomyines (average weights from 15–20 g in *O. rutilus* to 80–90 g in *O. superans*), externally characterized by soft fur, short and broad hindfeet with relatively long toes, and a tail moderately longer than the head and body (tail length about 110–120% of head and body length). The short, wide hindfoot bears thick, bright-white ungual tufts on digits II–V; pedal digit V is nearly as long as digits II–IV; and the plantar surface is smooth with six large, closely positioned pads, including a well-defined hypothenar pad. The tail in most species is basically unicolored, medium to dark brown above and below, or slightly paler underneath in some but never distinctly bicolored; caudal hairs are short, scarcely visible to the unaided eye and not obscuring the fine scale pattern; a rudimentary pencil or tuft of hairs is expressed at the tail tip in several species. The fur is soft, never spinose, and short to moderately long in length. Dorsal coloration varies from grayish brown to tawny to reddish brown, dull to bright in tone; ventral pelage color ranges from pure white to dark gray. Females possess eight mammae, including the pectoral pair, anatomically positioned as in most oryzomyines (Voss and Carleton 1993; Weksler 2006).

The skull is moderately robust and features a short and broad rostrum, a broad interorbital region, and slender zygomatic plate with a shallow or indistinct dorsal notch. The supraorbital edges are ridged or beaded, convergent anteriorly and notably divergent posteriorly (interorbital constriction cuneate), and extend across the parietals as temporal ridges in older individuals. A posteroventral flange of the parietal extends onto the lateral wall of the braincase; the interparietal is large, nearly as wide as the posterior border of the frontals. The incisive foramina are moderately long and generally wide, and in most species posteriorly terminate in front of the first molars or even with them. The bony palate is flat, long, and wide in conformation (*sensu* Hershkovitz 1962), and projects slightly or distinctly beyond the end of the third molars; posterolateral palatal pits are uniformly present but vary in development; parapterygoid fossae are moderately excavated above the plane of the bony palate; the roof of the mesopterygoid fossa is solid (sphenopalatine vacuities absent) or weakly perforated (va-

cuities present as narrow slits). The ectotympanic bullae are small and expose a broad wedge of the periotic in all species except *O. mamorae*, in which the broader ectotympanic capsule conceals more of the periotic; the tegmen tympani is reduced (see Voss 1993:18), occasionally touching but not overlapping the squamosal in all species except *O. rex*. Members of *Oecomys* possess different carotid circulatory patterns: complete in most species (stapedial foramen present, and large, posterior opening of alisphenoid canal large, and squamosal-alisphenoid groove leading to sphenofrontal foramen present; character state 0 of Carleton [1980] or pattern 1 per Voss [1988]); or derived in a few (stapedial foramen absent, or minute, squamosal-alisphenoid groove and sphenofrontal foramen absent; character state 3 of Carleton [1980] or pattern 3 per Voss [1988]; also see those different patterns as illustrated for oryzomyines by Carleton and Musser 1989). The occurrence of alisphenoid struts is variable in the genus, but they tend to be consistently present or absent (buccinator-masticatory and accessory oval foramina confluent) in a particular species. The hamular process of the squamosal is generally short and wide, the subsquamosal fenestra small or absent; a postglenoid foramen is uniformly present and moderately developed in most species. No significant sexual dimorphism is evident in craniodental measurements of those species that have been analyzed (*O. bicolor*, *O. catherinae*, *O. roberti*, *O. sydandersoni*—Patton et al. 2000; Carleton et al. 2009; Asfora et al. 2011). Explanation and/or illustration of the above characters and additional morphological description of *Oecomys* are provided by Hershkovitz (1960), Carleton and Musser (1989), Patton et al. (2000), Voss et al. (2001), Weksler (2006), and Carleton et al. (2009).

Most members of *Oecomys* possess opisthodont upper incisors, nearly orthodont in some species, and their maxillary toothrows are parallel. Molars are brachydont and cuspidate, the major lingual and labial cusps positioned oppositely; three roots anchor the upper molars and two roots the lowers. Labial and lingual flexi are broadly open and meet approximately at the tooth's midline, not interpenetrating. The M1 bears a broad anterocone with anterolingual and anterolabial conules joined medially, not cleft by an anteromedian fold; the conules are distinct in juveniles and young adults but lose definition with wear. A discrete anteroloph is present on M1 and a well-formed mesoloph on M1–2; the M3 retains an irregularly formed mesoloph and weak posteroloph. A mesolophid is consistently present on m1–2, but an ectolophid is variably developed, absent in most species. Hershkovitz (1960) and Weksler (2006) provide additional dental descriptions and character state definitions of *Oecomys*.

Few species of *Oecomys* have been surveyed for soft anatomical traits of the alimentary canal and reproductive

tract. Those that have been studied exhibit a complex glans penis, with a large medial bacular mound and smaller lateral bacular mounds; have a complete assortment of male accessory reproductive glands, including one pair of preputial glands; possess a unilocular-hemiglandular gastric morphology; and lack the gall bladder (Hooper and Musser 1964; Carleton 1973; Voss and Linzey 1981; Voss and Carleton 1993; Weksler 2006).

No long-term, autecological study is available for any species of *Oecomys*. Furthermore, correspondence of past natural history and ecological reports on *O. "bicolor"* or *O. "concolor,"* sensu Hershkovitz (1960), to a currently recognized species must be cautiously interpreted. In general, species are nocturnal, and individuals are typically associated with tropical lowland rainforest and numerous microhabitats in that broad classification, whether primary or secondary. Hershkovitz (1960) viewed *Oecomys* as the oryzomyine most specialized for arboreal life, a characterization sustained by collecting surveys, canopy-trapping, and nocturnal head-lamp observations, all of which attest to the superior scansorial abilities of its members (Handley 1976; Malcolm 1991; Patton et al. 2000; Voss et al. 2001). Linares (1998) characterized all species of Venezuelan *Oecomys* as frugivorous and granivorous; Voss et al. (2001) provisionally assigned *Oecomys* to the arboreal granivore/frugivore guild, but admitted that no detailed dietary investigations have been published to support their conjecture.

Species of *Oecomys* and the thomasomyine *Rhipidomys* superficially resemble one another and may be difficult to distinguish in the field where similar-sized members of the two genera co-occur. Several external differences serve to separate adults of the two genera in most instances, notably coloration of the dorsal surface of the hindfeet (darker over the metatarsum in *Rhipidomys*), length of the tail pencil (caudal pilosity and terminal pencil more strongly expressed in *Rhipidomys*), and number of mammae (three pairs in *Rhipidomys*, which lacks the pectoral pair found in *Oecomys*) (Thomas 1917d; Voss 1993; Patton et al. 2000; Voss et al. 2001).

SYNONYMS:

Mus: Pictet and Pictet, 1844:64; part (description of *cinna-momeus*); not *Mus* Linnaeus.

Hesperomys: Wagner 1845a:147; part (description of *concolor*); not *Hesperomys* Waterhouse.

Oryzomys: J. A. Allen and Chapman, 1893:212; part (descriptions of *speciosus* and *trinitatis*); not *Oryzomys* Baird.

Rhipidomys: E.-L. Trouessart, 1897:520; part (listing of *bicolor*); not *Rhipidomys* Tschudi.

Oryzomys (Oecomys) Thomas, 1906c:444; type species *Rhipidomys benevolens* Thomas, 1901 [= *Hesperomys bicolor* Tomes, 1860], by original designation.

Oecomys: Thomas, 1909:379; first usage as genus.

REMARKS: Thomas (1906c) erected *Oecomys*, as a subgenus, to segregate arboreal, pencil-tailed oryzomyines with a long palate from species of *Rhipidomys*, the externally similar genus under which many *Oecomys* taxa were first described. *Oecomys* was afterward treated as a valid genus by some systematists (Thomas 1909, 1917d; Gyldenstolpe 1932), but most regarded it as a subgenus of *Oryzomys* (Goldman 1918; Ellerman 1941; Hershkovitz 1960; Cabrera 1961; Hall 1981; Honacki et al. 1982; Corbet and Hill 1986). The karyotypic study of A. L. Gardner and Patton (1976) was pivotal in establishing the modern usage of *Oecomys* as a monophyletic genus (Carleton and Musser 1984; Reig 1984; Voss and Carleton 1993; Musser and Carleton 1993, 2005), a rank vindicated by broad phylogenetic evaluations of Sigmodontinae or Oryzomyini (M. F. Smith and Patton 1999; A. F. B. Andrade and Bonvicino 2003; D'Elía 2003a; Weksler 2003, 2006; Percequillo, Weksler, and Costa 2011; Pine et al. 2012). Within Oryzomyini, *Oecomys* belongs to a large clade that includes other genera that co-occur with it in lowland rainforest (*Euryoryzomys*, *Hylaeamys*, *Transandinomys*) and some that inhabit Andean montane forest (*Handleyomys*, *Nephelomys*).

Hershkovitz's (1960) revision consolidated the taxonomic contents of *Oecomys* but swept some 25 species and immense morphological variety into just two polytypic species, *O. bicolor* and *O. concolor*. His gross underestimation of specific diversity has been exposed by regional field studies in which three to five species of *Oecomys* have been documented in sympatry (Carleton et al. 1986, 2009; Woodman et al. 1991; Patton et al. 2000; Voss et al. 2001). Morphological definitions and distributional limits of the species recognized herein conform to the taxonomy presented in Musser and Carleton (1993, 2005), as based on the authors' personal examination of some 1,600 museum specimens and of all type specimens except that of *O. cleberi* Locks (1981). Identification of valid species and refinement of their distributions still require much systematic research and basic biological inventory. The treatment of all species as monotypic is a pro forma concession to this imperfect understanding of *Oecomys* systematics.

Species of *Oecomys* may be distinguished based on unique combinations of morphological traits, the most important of which include size; pelage color, especially distinctiveness of the dorsal-ventral contrast; fur texture and length; relative length of tail and development of a modest caudal pencil or tuft; pronouncement of supra-orbital and temporal ridging; relative width of the zygomatic plate and expression of the dorsal notch; length and shape of the incisive foramina; presence and size of the subsquamosal and postglenoid foramina; condition of

the tegmen tympani; presence or absence of alisphenoid struts; and the carotid arterial pattern. Chromosomal differences promise to be a useful tool for discriminating species, but many more forms need to be surveyed (A. L. Gardner and Patton 1976; Patton et al. 2000; Andrades-Miranda, Oliveira, Zanchin et al. 2001; A. F. B. Andrade and Bonvicino 2003; Langguth et al. 2005; C. C. Rosa et al. 2012). Descriptions in the species accounts do not repeat traits that are generally characteristic of the genus, as reviewed earlier. “Smaller than” and “larger than” comparative statements in the following descriptions reflect the ordering of select external and cranial dimensions (Table 1).

KEY TO THE SPECIES OF *OECOMYS* (VARIABLE ABBREVIATIONS: CLM, CORONAL LENGTH OF MAXILLARY TOOTHROW, M1–M3; HBL, LENGTH OF HEAD AND BODY; HFL, LENGTH OF HIND FOOT INCLUDING CLAW; IOB, LEAST INTERORBITAL BREADTH; ONL, OCCIPITONASAL LENGTH; TL, LENGTH OF TAIL; ALSO SEE TABLE 1):

1. Carotid circulatory pattern derived (sphenofrontal foramen and squamosoalisphenoid groove absent, stapedia foramen minute or absent) 2
- 1'. Carotid circulatory pattern complete (sphenofrontal foramen and squamosoalisphenoid groove present, stapedia foramen small but present) 4
2. Dorsal pelage predominantly gray to grayish buff, with a buffy to ochraceous lateral stripe; pelage moderately long for the genus ($\approx 7\text{--}9$ mm over middle rump); alisphenoid struts typically absent; interorbit narrower ($\text{IOB} \leq 5.1$ mm), supraorbital shelves weakly defined for the genus; palatal bridge short, terminating about the level of the posterior M3s, posterolateral palatal pits simple. *Oecomys mamorae*
- 2'. Dorsal pelage ochraceous brown to rufous brown, without distinct lateral stripe; pelage shorter ($\leq 5\text{--}7$ mm over middle rump); alisphenoid struts typically present; interorbit broader ($\text{IOB} \geq 5.1$ mm), supraorbital shelves moderately developed as per genus; palatal bridge long, projecting notably beyond M3s, posterolateral palatal pits pronounced 3
3. Size larger (HFL $\approx 26\text{--}30$ mm, ONL $\approx 31\text{--}34$ mm, CLM $\approx 4.8\text{--}5.2$ mm); tail notably longer than head and body; dorsal pelage more uniformly rufous brown and darker in tone, shorter in length ($4\text{--}5$ mm over middle rump); ventral pelage usually dull white, dorsal-ventral contrast more apparent; incisive foramina evenly curving, widest near their middle with the anterior and posterior ends acutely pointed *Oecomys concolor*
- 3'. Size smaller (HFL $\approx 22\text{--}26$ mm, ONL $\approx 28\text{--}31$ mm, CLM $\approx 4.4\text{--}4.8$ mm); tail slightly longer than head and body; dorsal pelage ochraceous brown to pale tawny generally bright in tone and showing more grayish over forequarters, slightly longer ($5\text{--}7$ mm over middle rump); ventral pelage grayish; incisive foramina noticeably widest toward the rear, the posterior ends blunt and anterior ends sharp. *Oecomys sydandersoni*
4. Size large (HFL $\approx 27\text{--}29$ mm, ONL $\approx 33\text{--}35$ mm, CLM $\approx 5.1\text{--}5.5$ mm); pelage thick, long, and richly luxuriant; interorbital region wide ($\text{IOB} \geq 6$ mm), with conspicuous supraorbital shelves and distinct postorbital processes; tegmen tympani well developed, securely overlapping squamosal *Oecomys rex*
- 4'. Size small to large; pelage short to long, coarse to soft in texture; interorbital region narrower (IOB usually ≤ 6 mm), supraorbital shelves moderate to strongly developed, without postorbital processes; tegmen tympani reduced, sometimes contacting but not overlapping squamosal, postglenoid foramen medium to large 5
5. Size small (HFL $\approx 18\text{--}23$ mm, ONL $\approx 23\text{--}28$ mm, CLM $\approx 3.2\text{--}4.0$); underparts typically all white, bright in tone, dorsal-ventral pelage contrast well defined; tail relatively short (TL $\approx 105\text{--}110\%$ of HBL), caudal hairs long, obscuring distal scale rows and forming a penicillate or tufted tip 6
- 5'. Size medium to large (HFL usually ≥ 23 mm, ONL usually ≥ 27 mm, CLM ≥ 4.0); under parts variable, dull white to some shade of grayish white, dorsal-ventral contrast variably delineated 7
6. Cranium and tooththrow diminutive (ONL ≤ 25.0 mm, CLM $\approx 3.2\text{--}3.4$ mm); dorsal pelage moderately long for body size ($6\text{--}8$ mm over the middle rump); terminal tail tuft longer, better developed; alisphenoid struts usually present *Oecomys rutilus*
- 6'. Cranium and tooththrow more robust (ONL ≥ 25.0 mm, CLM $\approx 3.6\text{--}4.0$ mm); dorsal pelage short for body size ($3\text{--}6$ mm over the middle rump); terminal tail tuft shorter, less conspicuous; alisphenoid struts usually absent. *Oecomys bicolor/Oecomys cleberi*
7. Size medium (HFL $\approx 22\text{--}26$ mm, ONL $\approx 27\text{--}31$ mm, CLM $\approx 4.0\text{--}4.6$) 8
- 7'. Size medium large to large (HFL $\approx 26\text{--}31$ mm, ONL $\approx 30\text{--}37$ mm, CLM $\approx 4.6\text{--}5.6$) 11
8. Dorsal pelage soft, dense, and long ($9\text{--}12$ mm over middle rump), caudal hairs long, obscuring scale pattern and forming a conspicuous terminal tuft 9
- 8'. Dorsal pelage shorter ($5\text{--}8$ mm over the middle rump), texture coarser; under parts typically pure white, sharply contrasting with bright orange-brown dorsum and ochraceous flanks; tail absolutely and relatively long (TL $\approx 118\%$ of HBL), with short caudal hairs and indistinct terminal pencil *Oecomys speciosus*

9. Tail relatively short (TL \approx 107% of HBL); alisphenoid struts typically present; subsquamosal fenestra occluded. *Oecomys auyantepui*
- 9'. Alisphenoid struts typically absent; subsquamosal fenestra open. 10
10. Under parts typically grayish white; tail absolutely and relatively long (TL \approx 117% of HBL).
. *Oecomys paricola*
- 10'. Under parts typically dull white; tail relatively short (TL \approx 105% of HBL) *Oecomys phaeotis*
11. Dorsal pelage shorter (5–10 mm over middle rump) and moderately soft 12
- 11'. Dorsal pelage longer (10–14 mm over middle rump), very dense and palpably soft to touch.
. *Oecomys trinitatis* complex
12. Size large (HFL \geq 28 mm, ONL \geq 34 mm, CLM \geq 5.2 mm), dorsal pelage medium in length (8–10 mm over middle rump), pelage somber in tone with dark grayish venter, tail moderately longer than head and body (TL \approx 118% of HBL). *Oecomys superans*
- 12' Size medium large (HFL \leq 28 mm, ONL \leq 34 mm, CLM \leq 5.1 mm), dorsal pelage short (5–7 mm over middle rump), pelage brighter in tone with white to grayish white venter, tail notably longer than head and body (TL \approx 123% of HBL)
. *Oecomys roberti*
13. Size medium large (HFL \approx 25–27 mm, ONL \approx 30–32 mm, CLM \approx 4.6–4.8 mm), confined to lower elevations in mountains of northeastern Colombia and northern Venezuela *Oecomys flavicans*
- 13'. Size medium large (HFL \approx 26–29 mm, ONL \approx 31–33 mm, CLM \approx 4.8–5.2 mm), distribution in greater Amazonia and trans-Andean forests of lower Central America and northwestern South America.
. *Oecomys trinitatis*
- 13''. Size large (HFL \approx 28–30 mm, ONL \approx 32–34 mm, CLM \approx 5.0–5.2 mm), confined to Atlantic Forest region of southeastern Brazil. *Oecomys catherinae*

Oecomys auyantepui Tate, 1939

Guianan *Oecomys*

SYNONYMS:

- Oecomys auyantepui* Tate, 1939:193; type locality “south slopes of Mt. Auyan-tepui, Caroni River, [Bolívar,] Venezuela, 3500 feet.”
- Oryzomys auyantepui*: Goodwin, 1953:302; name combination.
- Oryzomys concolor speciosus*: Hershkovitz, 1960:553; part (*auyantepui* allocated as full synonym, invalid as subspecies).
- Oryzomys trinitatis auyantepui*: Cabrera, 1961:407; name combination.

Oecomys paricola: Musser and Carleton, 1993:716; part (*auyantepui* allocated as synonym without indication of rank).

DESCRIPTION: Similar in body size to *O. paricola* and *O. phaeotis* (Table 1), larger than *O. rutilus* and *O. bicolor*, the two smallest-bodied species in genus, and appreciably smaller than all other congeners. Luxuriant pelage soft, dense, and long (10–12 mm over middle rump), with demarcation between dorsal and ventral pelage sharp. Dorsal fur rich ochraceous tawny (nearly orange brown) in most specimens, but darker—brownish tawny—in others; tops of hind feet dark brown to tip of digits. Ventral pelage typically grayish white (hairs with gray bases and white tips), or uncommonly with rich ochraceous overwash of gray bases; in some specimens, chin and throat pure white, in others white strip extends along midline from throat to groin. Tail only slightly longer than combined head and body (TL \approx 106% of HBL) and dark brown on all surfaces; caudal hairs long, typically obscuring distal scale rows and forming conspicuous tuft at tip (6–10 mm long per Voss et al. 2001).

Skull small and compact, with relatively short rostrum and narrow interorbit. Conspicuous supraorbital ridges outline interorbital and postorbital regions and sweep caudad to join distinct temporal beading. Zygomatic arches narrower rostrally and wider toward braincase; zygomatic plates relatively narrow and dorsal notches shallow. Incisive foramina moderately long and broad, their posterior margins situated about even with anterior rim of first molars. Pair of prominent posterolateral palatal pits and smaller foramina adorn bony palate behind molars. Mesopterygoid fossa wide and U-shaped at anterior margin, its roof entirely osseous. Strong alisphenoid struts present (Voss et al. 2001), and carotid circulatory plan primitive (pattern 1 of Voss 1988). Posterolateral wall of braincase bears postglenoid foramen but no subsquamosal fenestra. Ectotympanic bullae small, in ventral view exposing much of medial periotic.

DISTRIBUTION: Southeastern Venezuela (Bolívar), the Guianas, and north-central Brazil (Amazonas, Amapá)—the Guiana subregion of Amazonia; known elevational range from sea level to about 1,100 m.

SELECTED LOCALITIES (Map 203; from Voss et al. 2001, except as noted): BRAZIL: Amapá, Serra do Navio; Amazonas, 80 km N of Manaus. FRENCH GUIANA: Paracou; Trois Sauts. GUYANA: Cuyuni-Mazaruni, Kartabo, Cuyuni River; Upper Takutu–Upper Essequibo, 5 km SE of Surama. SURINAM: Sipaliwini, Avanavero Falls, Kabalebo River (RMNH 21733); Brokopondo, Brownsberg Nature Park, 7 km S and 18.5 km W of Afobakka (CM 54055). VENEZUELA: Bolívar, Auyan-tepui, south slope, Río Caroni (type locality of *Oecomys auyantepui* Tate).

Map 203 Selected localities for *Oecomys auyantepui* (●). Contour line=2,000 m.

SUBSPECIES: In resurrecting *O. auyantepui* to species, Voss et al. (2001) provided no evidence for definable subspecies; we provisionally regard the species as monotypic.

NATURAL HISTORY: At the type locality in Venezuela (Auyantepui, 3500 ft), Tate (1939) merely noted the habitat as humid forest. In French Guiana, specimens were obtained in primary lowland forest, both in well-drained sites and in creekside or swampy settings, mostly in arboreal trap-sets (lianas, canopy platforms) but rarely on the ground (Voss et al. 2001).

REMARKS: Populations of *auyantepui* are clearly distinct from those of *O. concolor* or *O. trinitatis*, the species under which it was earlier synonymized (Cabrera 1961; Hershkovitz 1960), and the taxon was returned to specific status by Voss et al. (2001). However, its level of relationship and nomenclatural status with regard to *O. paricola* (a synonym per Musser and Carleton 1993) and to *O. phaeotis* require further investigation. The geographic range of *O. auyantepui*, as so far known, is limited to the Guiana subregion of Amazonia, its distribution congruent with the ranges of *O. rex* and *O. rutilus*.

Oecomys bicolor (Tomes, 1860)

White-bellied Oecomys

SYNONYMS:

Hesperomys bicolor Tomes, 1860a:217; type locality "Gualaquiza," Rio Gualaquiza, 885 m, Morona-Santiago, Ecuador.

Hesperomys (Rhipidomys) bicolor: Thomas, 1884:448; name combination (tentative subgeneric referral of species).

Rhipidomys bicolor: E.-L. Trouessart, 1897:520; name combination.

Rhipidomys dryas Thomas, 1900c:271; type locality "Paramba, [Imbabura,] N. Ecuador. Alt. 1100 m."

Rhipidomys benevolens Thomas, 1901d:369; type locality "Chimate, Upper Beni River, [La Paz,] Bolivia, 68° W., 15° S.; alt. 700 m."

Rhipidomys rosilla Thomas, 1904d:35; type locality "La Union, Lower Orinoco," Bolívar, Venezuela.

[*Oryzomys (Oecomys) bicolor*: Thomas, 1906c:445; name combination.

Oryzomys (Oecomys) benevolens: Thomas, 1906c:445; name combination.

Oryzomys (Oecomys) dryas: Thomas, 1906c:445; name combination.

[*Oryzomys (Oecomys) rosilla*: Thomas, 1906c:445; name combination.

Oecomys nitedulus Thomas, 1910d:505; type locality "Lower Essequibo, 13 miles from mouth," Essequibo Islands-West Demerara, Guyana.

Oecomys bicolor: Osgood, 1914b:161; first use of current name combination.

Oecomys milleri J. A. Allen, 1916c:523; type locality "Barão Malgaço [Barão de Malgaço], Matto Grosso [now Rondônia], Brazil."

Oecomys florenciae J. A. Allen, 1916c:524; type locality "Florencia (altitude 675 feet), Rio Caquetá drainage, [Caquetá,] southwestern Colombia."

Oecomys trabeatus G. M. Allen and Barbour, 1923:262; type locality "Rio Jesusito, [Darién,] eastern Panama."

Oecomys bicolor: Gyldenstolpe, 1932a:39; name combination (*dryas* allocated as full synonym without indication of rank).

Oecomys rosilla: Gyldenstolpe, 1932a:39; name combination.

Oecomys benevolens: Gyldenstolpe, 1932a:40; name combination.

Oecomys andersi Goldman, 1933:525; type locality "Barro Colorado Island, Canal Zone [now Panamá province], Panama."

Oecomys phelpsi Tate, 1939:194; type locality "south slope Mt. Auyan-tepui, 3500 feet," Bolívar, Venezuela.

Oryzomys [(Oecomys)] benevolens: Ellerman, 1941:357; name combination.

Oryzomys [(Oecomys)] florenciae: Ellerman, 1941:358; name combination.

Oryzomys [(Oecomys)] milleri: Ellerman, 1941:358; name combination.

Oryzomys [(Oecomys)] nitedulus: Ellerman, 1941:358; name combination.

Oryzomys [(*Oecomys*)] *rosilla*: Ellerman, 1941:359; name combination.

Akodon (*Chalcomys*) *aerosus*: Tate, 1945:316; part (restriction of type specimen, *phelpsi* allocated as synonym).

Oryzomys (*Oecomys*) *bicolor trabeatus*: Hershkovitz, 1960:533; name combination (*endersi* allocated as full synonym, invalid as subspecies).

Oryzomys (*Oecomys*) *bicolor occidentalis* Hershkovitz, 1960:533; replacement name for *Rhipidomys dryas* Thomas, 1900, preoccupied by *Oryzomys dryas* Thomas (now = *Microrizomys minutus*).

Oryzomys bicolor bicolor: Hershkovitz, 1960:535 name combination (*florenciae*, *milleri*, *nitedulus*, and *rosilla* allocated as full synonyms, invalid as subspecies).

Oryzomys bicolor phaeotis: Hershkovitz, 1960:540; part (*benevolens* allocated as full synonym, invalid as subspecies).

Oryzomys bicolor bicolor: Cabrera, 1961:403; name combination (*dryas* allocated as full synonym, invalid as subspecies).

Oryzomys bicolor benevolens: Cabrera, 1961:403; name combination.

Oryzomys bicolor florenciae: Cabrera, 1961:403; name combination.

Oryzomys bicolor milleri: Cabrera, 1961:403; name combination.

Oryzomys bicolor nitedulus: Cabrera, 1961:404; name combination.

Oryzomys bicolor rosilla: Cabrera, 1961:404; name combination.

Oryzomys marmosurus guianae: Cabrera, 1961:405; part (*phelpsi* questionably listed as synonym).

Oecomys bicolor: Musser and Patton, 1989:6; name combination (restriction of type specimen, provisional allocation of *phelpsi* as synonym without indication of rank).

Oecomys bicolor: Musser and Carleton, 1993:716; name combination (*benevolens*, *dryas* [of Thomas, 1900], *endersi*, *florenciae*, *milleri*, *nitedulus*, *occidentalis*, *rosilla*, and *trabeatus* listed as synonyms without indication of rank).

DESCRIPTION: Recognizable chiefly by small size (averaging only larger than *O. rutilus*), combined with white under parts and relatively short tail (TL \approx 105–110% of HBL) that bears moderate terminal tuft. Pelage dense and felt-like, somewhat crisp to touch, and short compared with body size (3–6 mm over middle rump); demarcation between dorsal and ventral pelage sharp. Dorsal fur ranges from rich ochraceous tawny (nearly orange brown) to rufous brown, finely mixed with dark brown over middle dorsum and becoming slightly paler along lower sides of head and body, a bright buffy gray. Darker dorsum sharply set off from bright ventral pelage, which is uniformly white

(hairs self-colored) in the majority of specimens examined; variations include ventral hairs with white bases and buff to ochraceous tips, imparting pale wash to white ground color, or white over belly and chest with varying suffusion of gray-based hairs toward sides. Short tail all brown, and caudal hairs notably long for small size of species, typically obscuring scale rows and forming short but discrete tuft at tip (hairs extend 5–7 mm beyond tip).

Skull stoutly built for its compact size, with short rostrum, narrow interorbit with finely beaded supraorbital ledges, and relatively inflated braincase. Temporal ridges weakly defined and become obsolete over posterior braincase. The zygomatic arches slightly narrower rostrally and slightly wider toward braincase; zygomatic plates narrow and dorsal notches shallow. Incisive foramina relatively long and narrow, their posterior margins situated about even with anterior margin of first molars. Pair of prominent posterolateral palatal pits adorns bony palate; mesopterygoid fossa wide and U-shaped at anterior margin; roof entirely osseous. Postglenoid foramen and subsquamosal fenestra present and spacious. Alisphenoid struts commonly absent, but occurrence highly variable within species as currently defined; carotid circulatory plan complete (pattern 1 of Voss 1988). Ectotympanic bullae small, exposing much of medial periotic.

DISTRIBUTION: Lowlands of trans-Andean rainforests (eastern Panama to western Ecuador) and greater Amazonia (eastern Colombia and central Venezuela, through the Guianas, eastern Peru and Ecuador, to eastern Bolivia and south-central Brazil); known elevational range from sea level to 1,537 m, most locality records falling between sea level and 800 m.

SELECTED LOCALITIES (Map 204): BOLIVIA: Beni, Las Peñas (Anderson 1997); La Paz, Chimate (type locality of *Rhipidomys benevolens* Thomas); Santa Cruz, Ayacucho (Anderson 1997), 2.5 km NE of El Refugio, Parque Nacional Noel Kempff Mercado (Carleton et al. 2009). BRAZIL: Acre, Nova Vida, right bank Rio Juruá (Patton et al. 2000); Amapá, Serra do Navio (Voss et al. 2001); Amazonas, Colocação Vira-Volta, left bank Rio Juruá (Patton et al. 2000); Distrito Federal, 20 km S of Brasília (OMNH 17482, 17483); Mato Grosso, 264 km N of Xavantina, Serra do Roncador Base Camp (BM 81.385–81.388); Mato Grosso do Sul, Urucum de Corumbá (FMNH 26806); Pará, Capim (AMNH 188963), Gonotire, Rio Fresco at confluence with Rio Xingu (MZUSP 1298, 1301); Rondônia, Barão de Malgaço (type locality of *Oecomys milleri* J. A. Allen). COLOMBIA: Amazonas, Río Apaporis, Ina Gaje, Río Pacoa (FMNH 57237, 57239); Boyacá, Arauca, Río Covaria (FMNH 92524); Caquetá, Florencia, Río Bodoquera (type locality of *Oecomys florenciae* J. A. Allen). ECUADOR: Imbabura, Paramba, Río Mira (type locality of *Oryzomys* (*Oecomys*) *bicolor occidentalis* Hershkovitz, replacement

name for *Rhipidomys dryas* Thomas); Morona-Santiago, Gualaquiza (type locality of *Hesperomys bicolor* Tomes); Sucumbios, Santa Cecilia (KU 135116, 135153). FRENCH GUIANA: Nouragues (Voss et al. 2001). GUYANA: Essequibo Islands-West Demerara, 13 mi from mouth of Lower Essequibo (type locality of *Oecomys nitedulus* Thomas); Upper Takutu–Upper Essequibo, 5 km SE of Surama (Voss et al. 2001). PERU: Junín, Chanchamayo (BM 5.11.2.16, FMNH 29453); Loreto, San Jacinto (KU 158191), Boca Río Peruate, Río Amazonas (FMNH 88940–88943); Madre de Dios, Reserva Cuzco Amazonico, 14 km E of Puerto Maldonado (KU 144302–144304); San Martín, Yurac Yacu (BM 27.1.1.122–27.1.1.124). SURINAM: Sipaliwini, Oelemarie (CM 76862–76866); Paramaribo, Paramaribo (USNM 319963–319967). VENEZUELA: Amazonas, Tamatama, Río Orinoco (Handley 1976); Aragua, Estación Biológica Rancho Grande (AMNH 144851, KU 135127); Bolívar, La Unión (type locality of *Rhipidomys rosilla* Thomas), south slope Auyán-tepuí (type locality of *Oecomys phelpsi* Tate).

SUBSPECIES: As here defined, *O. bicolor* encompasses many junior synonyms and appreciable size and color variation. Whether such variation represents definable geographic races or the presence of additional valid species requires further investigation. In lieu of such studies, we provisionally treat *O. bicolor* as monotypic. Linares (1998) retained four subspecies for Venezuelan populations (*O. b. bicolor*, *O. b. nitedulus*, *O. b. phelpsi*, *O. b. rosilla*).

NATURAL HISTORY: *Oecomys bicolor* inhabits tropical evergreen forest, both primary and secondary and in seasonally inundated vegetation (várzea) and unflooded, upland forest (terra firme) (Handley 1966; Carleton et al. 1986; Patton et al. 2000). Along the Rio Juruá, western Brazil, Patton et al. (2000) collected most specimens of *O. bicolor* in undisturbed várzea forest but some in terra firme; a majority were captured in canopy traps (74%), some in traps placed in viny tangles about 2 m above ground and very few in ground sets. Pregnant females (litter size mode = 2, range: 1–4) have been recorded throughout the dry season and beginning of the rainy season (August–February; Patton et al. 2000). Perhaps more than any other *Oecomys*, individuals of *O. bicolor* have been documented from commensal settings, such as orchards, overgrown fields, and rustic dwellings (Hershkovitz 1960; Hutterer et al. 1995; Emmons et al. 2006).

REMARKS: Of the species-group taxa that Hershkovitz (1960) associated under his polytypic view of *O. bicolor*, three have been resurrected to species (*O. paricola*, *O. phaeotis*, *O. rutilus*—see Musser and Carleton 1993, 2005; Voss et al. 2001). The contents presented here also may be a complex of species. The status of taxa described from the Trans-Andean region (*trabeatus*, *endersi*, and

Map 204 Selected localities for *Oecomys bicolor* (●). Contour line = 2,000 m.

occidentalis) in particular warrant attention. As recorded by Hershkovitz (1960) and affirmed by our own museum research, a wide geographic hiatus separates these trans-Andean forms, described from Panama and northwestern Ecuador, from the core distribution of *O. bicolor* in Amazonia (Map 204), in spite of ample inventory in northern Colombia and northwestern Venezuela where other *Oecomys* have been recovered (e.g., *O. flavicans*, *O. speciosus*). In addition, Patton et al. (2000) identified a small, white-bellied form in sympatry with *O. bicolor* in western Brazil; the status of this indeterminate form invites resolution.

The karyotype has a diploid number of 80, with a high proportion of biarmed chromosomes (FN = 140; A. L. Gardner and Patton 1976; Patton et al. 2000).

Oecomys catherinae Thomas, 1909

Atlantic Forest *Oecomys*

SYNONYMS:

Mus cinnamomeus Pictet and Pictet, 1844:64; type locality, Brazil, Bahia (name preoccupied by *Mus cinnamomeus* Lichtenstein, 1830, a *Trinomys* [Echimyidae]).

Oecomys catherinae Thomas, 1909:234; type locality “Joinville, Santa Catherina [Santa Catarina], S. Brazil.”

Oryzomys [(*Oecomys*)] *catherinae*: Ellerman, 1941:357; name combination.

Oecomys cinnamomeus: Moojen, 1952b:53; name combination.

Oryzomys subflavus: Hershkovitz, 1960:543; part (*catherinae* allocated as full synonym); not *subflavus* Wagner.

Oryzomys concolor bahiensis Hershkovitz, 1960:561; type locality “Fazenda Almada, Ilhéus, Bahía, Brazil.”

Oryzomys catherinae catherinae: Cabrera, 1961:404; name combination.

Oecomys trinitatis: Musser and Carleton, 1993:717; part (*bahiensis*, *catherinae*, and *cinnamomeus* listed as synonyms without indication of rank); not *trinitatis* J. A. Allen and Chapman.

Oecomys catherinae: Musser and Carleton, 2005:1137 (*bahiensis* and *cinnamomeus* listed as synonyms without indication of rank).

DESCRIPTION: Specimens suggest slightly larger version of *O. trinitatis*. Dorsal pelage lush and thick (12–14 mm), sleek in texture, brownish-orange to tawny chestnut in color, and bright in tone. General impression of under parts dark grayish-white, ventral hairs with dark to slate gray bases, usually tipped with white; variations include streaks or patches of buffy-tipped hairs on chest and/or abdomen and creamy hairs confined to throat. Demarcation between dorsum and ventrum weakly defined. Tail dusky brown all around for most of length, paler beneath toward base; caudal hairs short, revealing the fine scale rows and not forming discrete tuft.

Robust skull features relatively long and narrow rostrum, pronounced supraorbital shelves with free edge reflected dorsally, and conspicuous temporal ridges that extend across braincase to occiput. Postglenoid foramen small, and subsquamosal fenestra tiny or absent. Incisive foramina relatively narrow and long, reaching level of anterior roots of upper first molars. Roof of mesopterygoid fossa usually fully ossified, sphenopalatine vacuities absent or minute. Alisphenoid struts commonly absent; carotid circulatory plan complete (pattern 1 of Voss 1988). Ectotympanic bullae small, exposing much of medial periotic.

DISTRIBUTION: Atlantic coast forests in southeastern Brazil (Paraíba southward to northern Santa Catarina) and along riverine forest into south-central Brazil (Goiás, Federal District, Mato Grosso do Sul) (see Fig. 3 in Asfora et al. 2011); known elevational range sea level to 700 m.

SELECTED LOCALITIES (Map 205; from Asfora et al. 2011, except as noted): BRAZIL: Paraíba, Mamanaguape; Alagoas, Ibateguara; Bahía, Fazenda Almada, Ilhéus (type locality of *Oryzomys concolor bahiensis* Hershkovitz); Goiás, Barra do Rio São Domingos (MZUSP 4012, 4020), Minaçu; Distrito Federal, 20 km S of Brasília (OMNH 17487, 17488); Goiás, Caldas Nova; Espírito Santo, Águia Branca; Minas Gerais, Pirapitanga; Espírito Santo, Viana; Mato Grosso do Sul, Brasilândia; Rio de Janeiro, Cambuci, Mangaratiba; São Paulo, Parque Estadual Intervales; Santa Catarina, Joinville (type locality of *Oecomys catherinae* Thomas).

SUBSPECIES: Although *bahiensis* Hershkovitz has been recognized as a subspecies, knowledge of intraspecific variation is too poor to defend usage of subspecies at this stage of understanding; *O. catherinae* is provisionally regarded as monotypic (also see Asfora et al. 2011).

Map 205 Selected localities for *Oecomys catherinae* (●).

NATURAL HISTORY: Asfora et al. (2011) recorded the species as occurring in dense rainforest, open rainforest, and semideciduous forest in a savanna-forest mosaic (i.e., gallery forest settings in the Cerrado biome).

REMARKS: Hershkovitz (1960) erected his new subspecies *Oryzomys concolor bahiensis* because he viewed *Oecomys catherinae* Thomas (1909) as well as *Oecomys rex* Thomas (1910) as a synonym of *Oryzomys subflavus* (now *Cerradomys subflavus sensu* Weksler et al. 2006). With correction of this misidentification (Musser and Carleton 2005) and because *Mus cinnamomeus* Pictet and Pictet is a junior homonym, *O. catherinae* assumes priority for Atlantic Forest populations.

Samples of *O. catherinae* from the Atlantic Forest and Cerrado riparian formations are closely related to, but genetically well differentiated from, samples of *O. trinitatis* in the Amazon Basin (L. P. Costa 2003). The karyotype uniformly consists of $2n=60$ and displays minor variation in the number of autosomal arms ($FN=62/64$) as based on broad geographic survey of chromosomal numbers (Asfora et al. 2011).

Oecomys cleberi Locks, 1981

Cleber's Oecomys

SYNONYM:

Oecomys cleberi Locks, 1981:1; type locality "Fazenda Agua Limpa, da Universidade de Brasília, Distrito Federal, Brasil. Longitude: 45°54'W. Latitude: 15°57'S."

DESCRIPTION: Small species, slightly larger than examples of *O. bicolor* and slightly smaller than those of *O. paricola* (Table 1). In general appearance, it recalls *O. bicolor*, having pure white to pale cream under parts sharply contrasted to orange-brown upper parts and relatively short tail with modest terminal tuft. Cranial architecture also resembles *O. bicolor*, including possession of primitive carotid circulatory plan (pattern 1 of Voss 1988); alisphenoid struts usually absent. R. G. Rocha et al. (2012) provide additional description and comparisons with *O. paricola* and *O. roberti*, other species that cohabit Cerrado of south-central Brazil.

DISTRIBUTION: Known from the southern Cerrado biome of Brazil based on four localities documented to date.

SELECTED LOCALITIES (Map 206; from R. G. Rocha et al. 2012, except as noted): BRAZIL: Mato Grosso, Fazenda São Luís, 30km N of Barra do Garças; Distrito Federal, Fazenda Água Limpa, Universidade Federal de Brasília (type locality of *Oecomys cleberi* Locks); Minas Gerais, Fazenda Cafundó, 13km NE of Nova Ponte; Mato Grosso do Sul, Fazenda Maringá, 54km of Dourados.

SUBSPECIES: Based on the few specimens (15) and few localities (4) so far known, *O. cleberi* is regarded as monotypic (R. G. Rocha et al. 2012).

NATURAL HISTORY: Locks (1981) reported the habitat as riparian forest.

Map 206 Selected localities for *Oecomys cleberi* (●).

REMARKS: Locks (1981) critically contrasted her new form to *O. bicolor* and *O. milleri* (here considered another synonym of *O. bicolor*). Morphological evidence and analysis of mtDNA cytochrome-*b* sequences affiliate *O. cleberi* and *O. bicolor* as cognate species, the former apparently endemic to the Cerrado and a vicariant relative to the latter distributed across greater Amazonia (R. G. Rocha et al. 2012). R. G. Rocha et al. (2012) cautioned that past reports of *O. bicolor* from Cerrado localities might instead represent *O. cleberi*. Morphological discrimination of the two species and the distributional extent of *O. cleberi* require further study.

Oecomys concolor (Wagner, 1845)

Natterer's Oecomys

SYNONYMS:

Hesperomys concolor Wagner, 1845a:147; type locality "Flusse Curicuriari im nordwestlichen Brasilien" [= Brazil, Amazonas, Rio Curicuriari, a tributary of the upper Rio Negro, below São Gabriel (da Cachoeira), fide Hershkovitz 1960; also see Carleton et al. 2009:24].

Rhipidomys marmosurus Thomas, 1899d:378; type locality "Maipures, Upper Orinoco," Vichada, Colombia.

[*Oryzomys* (*Oecomys*)] *marmosurus*: Thomas, 1906c:445; name combination.

O[*ecomys*]. *marmosurus*: Thomas, 1910b:187; name combination.

[*Oryzomys* (*Orzyomys*)] *concolor*: Tate, 1932e:3; name combination, taxonomic history.

Oryzomys [(*Oecomys*)] *marmosurus*: Ellerman, 1941:358; name combination.

Oryzomys (*Oecomys*) *concolor concolor*: Hershkovitz, 1960: 545–546; name combination (*marmosurus* allocated as full synonym, invalid as subspecies).

Oecomys concolor: A. L. Gardner and Patton, 1976:13; first use of current name combination.

Oecomys concolor: Musser and Carleton, 1993:716; name combination (*marmosurus* listed as synonym without indication of rank).

DESCRIPTION: Characterized by combination of medium-large size, relatively long tail (TL ≈ 118% of HBL), and short pelage (5–7 mm over middle rump). Dorsal pelage varies from dull fulvous brown to brighter ochraceous-tawny, especially over shoulders and cheeks. Venter also varies, wholly dull white in most specimens, or some with strong overwash of buff-tipped to ochraceous-tipped hairs, or some with small to broad expanses of gray over middle abdomen; dorsal-ventral pelage contrast weakly defined in the last two conditions. Pinnae dark brown, usually contrasting with adjacent upper parts. Tail brown to dark brown all around for most of length, mottled beneath near base; short caudal hairs expose scale rows for most of tail length, without formation of terminal pencil.

Skull with moderately prominent supraorbital ridges, with distinct interorbital constriction and posteriorly diverging supraorbital shelves (cuneate shape). Incisive foramina relatively narrow, their anterior and posterior ends acute, gently curving along lateral edges and widest near middle. Bony palate noticeably projecting beyond posterior margins of M3s, as in most oryzomyines; posterolateral palatal pits well developed, typically consisting of one large pit with interior perforations plus one or two supernumerary foramina. Alisphenoid struts typically present (Carleton et al. 2009), and carotid circulatory plan derived (pattern 3 of Voss 1988).

DISTRIBUTION: Lowland rainforest to the north of the Rios Amazonas-Solimões in northwestern Brazil and to the south of the Río Orinoco in eastern Colombia and southern Venezuela; known elevational range sea level to 400 m.

SELECTED LOCALITIES (Map 207; from Carleton et al. 2009, except as noted): **BRAZIL:** Amazonas, Ilha das Onças, left bank Rio Negro, Macaco, left bank Rio Jaú, Rio Curicuriari below São Gabriel da Cachoeira (type locality of *Hesperomys concolor* Wagner), Rio Uaupés, opposite Tahuapunta, Yavanari, right bank Rio Negro; Roraima, Rio Uraricoera. **COLOMBIA:** Meta, Los Micos, 18 km SW of San Juan de Arama; Vichada, Maipures, middle Río Orinoco (type locality of *Rhipidomys marmosurus* Thomas). **VENEZUELA:** Amazonas, Belén, Río Cunucunuma, Boca Mavaca, 68 km SE of Esmeralda, 12 mi W of Río Jawasu, left bank Río Casiquiare, San Juan, Río Manapiare, Tamatama, Río Orinoco; Apure, Hato Caribén, 60 km NE of Puerto Páez, Río Cinaruco.

SUBSPECIES: Carleton et al. (2009) provided no evidence for subspecific divisions within *O. concolor*.

REMARKS: The epithet *concolor* Wagner (1845a) was a forgotten name in oryzomyine taxonomy until Tate (1932e) tentatively identified it as a species of *Oryzomys* and Hershkovitz (1960) recognized it as a member of *Oecomys*. The highly variable morphology and pantropical range of *O. concolor* as defined by Hershkovitz reflected its composite nature, which embraced entirely or partly at least nine valid species among his synonyms (*O. auyantepui*, *O. catherinae*, *O. concolor*, *O. flavicans*, *O. mamorae*, *O. roberti*, *O. speciosus*, *O. superans*, *O. trinitatis*, as per Musser and Carleton, 2005). Among species of *Oecomys*, the derived circulatory plan of *O. concolor* is shared only with *O. mamorae* and *O. sydandersoni* and offers a morphological basis to hypothesize their closer relationship (Weksler 2006; Carleton et al. 2009). The geographic occurrence of *O. concolor* proper is confined to the Rio Negro West subregion of northern Amazonia, an area of endemism delineated from phylogeographic and distributional studies of neotropical birds (Cracraft and Prum 1988; Stotz et al. 1996).

Map 207 Selected localities for *Oecomys concolor* (●). Contour line = 2,000 m.

Oecomys flavicans (Thomas, 1894)

Tawny Oecomys

SYNONYMS:

Oryzomys flavicans Thomas, 1894b:351; type locality “Mérida, [Mérida,] Venezuela.”

Oryzomys flavicans illectus Bangs, 1898:164; type locality “Pueblo Viejo, [Sierra Nevada de Santa Marta, Magdalena,] Colombia, altitude 8000 ft.”

Oecomys mincae J. A. Allen, 1913c:603; type locality “Minca (altitude 2000 feet), Santa Marta region, [Magdalena,] Colombia.”

Oryzomys flavicans flavicans: Gyldenstolpe, 1932a:22; name combination.

Oecomys illectus: Gyldenstolpe, 1932a:42; name combination, elevation to species.

Oryzomys [(*Oecomys*)] *mincae*: Ellerman, 1941:358; name combination.

O[*ryzomys*] *flavicans*: Goodwin, 1953:310; spelling lapsus for *flavicans*.

Oryzomys (*Oecomys*) *concolor concolor*: Hershkovitz, 1960:545–547; name combination (*flavicans*, *illectus*, and *mincae* allocated as full synonyms, invalid as subspecies).

Oryzomys trinitatis flavicans: Cabrera, 1961:407; name combination.

Oryzomys trinitatis illectus: Cabrera, 1961:408; name combination.

Oecomys flavicans: Musser and Carleton, 1993:716; first use of current name combination (*illectus* and *mincae* allocated as synonyms without indication of rank).

DESCRIPTION: Medium large in body size (e.g., larger than *O. paricola* and *O. speciosus* but smaller than *O. trinitatis* and *O. superans*). Dorsal pelage soft, dense, and moderately long (8–10 mm over middle rump); head

and back bright ochraceous tawny that transforms to rich ochraceous lateral line along sides of body. Ventral pelage typically dull white spattered with buff in some individuals, with encroachment of basally gray hairs over middle abdomen; demarcation between bright lateral line and whitish venter sharp, with ochraceous tones wash along borders of ventral fur in some specimens. Tail longer than combined head and body (tail length \approx 115% of head and body length), brown on top, sides and all around distal one-fourth but pale brown below; caudal hairs short, revealing scale rows, without formation of tuft at tip.

Skull chunky, with relatively short rostrum and narrow interorbit. Distinct supraorbital ridges outline interorbital and postorbital margins and sweep caudad to join prominent temporal ridges. Zygomatic arches converge little toward rostrum; zygomatic plates broad and dorsal notches moderately incised. Incisive foramina moderately long and impressively broad, their posterior margins situated anterior to molar rows. A pair of large posterolateral palatal pits marks each side of bony palate behind toothrows; mesopterygoid fossa broad, U-shaped at anterior margin, with roof entirely osseous. Postglenoid foramen moderately large but subsquamosal fenestra typically closed (hamular process fused with squamosal). Alisphenoid struts typically present (ca. 70% of sample), and carotid circulatory plan primitive (pattern 1 of Voss 1988). Ectotympanic bullae small, revealing much of medial petiotic.

DISTRIBUTION: *Oecomys flavicans* occurs across northeastern Colombia and northern Venezuela; known elevation range from sea level to 2,000 m.

SELECTED LOCALITIES (Map 208): **COLOMBIA:** Cesar, Colonia Agrícola de Caracolicito (USNM 280595), Pueblo Viejo, Sierra Nevada de Santa Marta (type locality of *Oryzomys flavicans illectus* Bangs); Huila, 5 km N of Villavieja (MVZ 113378); Magdalena, Minca, Santa Marta region (type locality of *Oecomys mincae* J. A. Allen); Norte de Santander, San Calixto, Río Tarrá (USNM 280593, 280594). **VENEZUELA:** Aragua, Camp Rafael Rangel (USNM 317713–317715); Carabobo, El Trompillo (BM 14.9.1.43–14.9.1.45), San Esteban, near Venezuela Hills (BM 11.5.25.145); Mérida, Mérida (type locality of *Oryzomys flavicans* Thomas); Miranda, Hacienda La Guapa, 6 km S of Río Chico (USNM 387867); Portuguesa, La Hoyada, near Guanarito (AMNH 266915, 266916); Trujillo, Isnotú, 10 km WNW of Valera (USNM 371165); Zulia, Misión Tukuko (USNM 448580–448582).

SUBSPECIES: *Oecomys flavicans* is provisionally regarded as monotypic.

NATURAL HISTORY: Linares (1998) recorded *O. flavicans* as an inhabitant of dense, multistrata forest with abundant bromeliads, lianas, and epiphytes, in both sub-

Map 208 Selected localities for *Oecomys flavicans* (●). Contour line = 2,000 m.

montane and montane zones; it is occasionally numerous in agricultural settings such as cafetales.

REMARKS: Cabrera (1961) arranged *flavicans* as a subspecies of *trinitatis*, but the two forms occur in sympatry or altitudinal parapatry in the coastal ranges of northern Venezuela. Morphological differences between the two are slight: specimens of *O. flavicans* typically have a brighter tawny dorsum and flanks (usually darker brown in *O. trinitatis*), with a whitish venter (usually some shade of gray in *O. trinitatis*), and average smaller in external and cranial dimensions (Table 1), in particular length of the molar row (CLM usually $<$ 5 mm in *O. flavicans*; CLM usually \geq 5 mm in *O. trinitatis*).

Oecomys mamorae (Thomas, 1906)

Mamore Oecomys

SYNONYMS:

Oryzomys (*Oecomys*) *mamorae* Thomas, 1906c: 445; type locality “Mosetenes, Upper Mamoré, Yungas, [Cochabamba,] Bolivia”; but see Remarks.

Oecomys mamorae: Osgood, 1916b:206; first use of current name combination.

Oryzomys [(*Oecomys*)] *mamorae*: Ellerman, 1941:358; name combination.

Oryzomys mamorae mamorae: Cabrera, 1961:405; name combination.

Oryzomys concolor roberti: Hershkovitz, 1960:559; part (*mamorae* allocated as full synonym, invalid as subspecies).

Oecomys concolor roberti: S. Anderson, 1985:12; part (*mamorae* listed as full synonym, invalid as subspecies).

DESCRIPTION: Combination of medium-large size, absolutely and relatively long tail (Table 1), and moderately long pelage (7–9 mm) characterizes examples of *O. mamorae*. Dorsal pelage generally medium buffy brown,

dominated by gray hues in some series that range from gray to grayish buff; ventrum appears dull white from chin to inguen in most specimens, although some individuals exhibit encroachment of gray-based hairs over middle abdomen. Dorsal-ventral pelage contrast tends to be sharply marked, in most specimens accentuated by buff to bright ochraceous lateral strip that demarcates upper and under parts. Long tail ($\approx 115\text{--}118\%$ of head and body length) brown to dusky brown for most of its length, proximal section slightly paler beneath; short caudal hairs weakly obscure scale rows, without expression of terminal pencil.

Within the genus, cranium exhibits weakest expression of supraorbital ridging, which is confined more to rear of orbit and weakly diverges posteriorly. Interorbital shape thus appears more amphoral and its span narrow compared with constriction observed in other large-bodied species. Zygomatic plates broad for genus, with dorsal notches clearly incised. Incisive foramina relatively long, more nearly parallel sided, and relatively narrow without pronounced outward bowing. Rear termination of hard palate more or less even with caudal margins of M3s; perhaps in correlation with shorter palate, pit construction simpler, usually consisting of single opening. Alisphenoid struts typically absent and carotid circulatory plan derived (pattern 3 of Voss 1988; Carleton et al. 2009). Development of auditory bullae is exceptional for the genus: ectotympanic shell slightly more inflated, and less of posteromedial periotic exposed.

DISTRIBUTION: Subhumid and gallery forests in savanna and Chaco zones of central and eastern Bolivia, contiguous west-central Brazil, and northern and eastern Paraguay. The known elevational range is from sea level to 2,100 m, with most localities between 200–500 m.

SELECTED LOCALITIES (Map 209; from Carleton et al. 2009, except as noted): **BOLIVIA:** Beni, Baures, Puerto Salinas, Río Beni, Río Mamoré, Río Tijamuchi; Chuquisaca, Ticucha, Río Capirenda, Tola Orko, 40 km from Padilla; Cochabamba, Mosestenes, upper Río Mamoré (type locality of *Oryzomys* (*Oecomys*) *mamorae* Thomas); La Paz, 1 mi W of Puerto Linares; Santa Cruz, Camiri, 5 km S of Choreti, Punta Rieles, Santa Ana. **BRAZIL:** Mato Grosso, Caiçara; Mato Grosso do Sul, Urucum de Corumbá. **PARAGUAY:** Amambay, Colonia Sargento Duré, 3 km E of Río Apa; Chaco, Cerro León, 50 km WNW of Fortín Madre-jón; Misiones, 40 km S of San Ignacio.

NATURAL HISTORY: A specimen from the Chaco of Paraguay was captured on the ground in thorn forest (Myers and Wetzel 1979, reported as *Oryzomys concolor roberti*).

SUBSPECIES: Carleton et al. (2009) offered no data that indicate geographic variation, but the possibility of recognizable subspecies should be revisited with the fresh redefinition of *O. mamorae*; we provisionally regard it as monotypic.

REMARKS: Systematists recognized this distinctive species as valid until Hershkovitz (1960) confused matters by treating it as a full synonym of *Oryzomys concolor roberti*. The ranges of *O. mamorae* and *O. roberti* approach one another in eastern Bolivia, where they are strikingly different in external and cranial morphology, but sympatry has yet to be documented (Carleton et al. 2009). Specimens of *Oecomys* have been recovered from owl pellets in north-eastern Argentina, from the provinces of Chaco (Massoia and Fornes 1965b, as *O. concolor*) and Formosa (Pardiñas and Ramírez-Llorens 2005, as *O. sp.*). By geographic proximity, these samples are plausibly referable to *O. mamorae*, but critical review of variation within nominal *O. mamorae* and comparisons with the Argentinean populations are required to verify their specific assignment.

Ulyses Pardiñas (pers. comm.) kindly informed me that the type locality “Mosestenes” actually refers to an indigenous people distributed principally within the Yungas of central Bolivia, not a specific placename. The origin of the type specimen from somewhere within Cochabamba department, specifically the Cordillera de Mosestenes (Anderson 1997; Carleton et al. 2009), has been presumed since Hershkovitz’s (1960) interpretation of the locality, which regional placement plausibly followed Thomas’s (1906c) approximation of Mosestenes as the “Upper Mamoré.” However, the collector, Italian naturalist Luigi Balzan, also descended the Río Beni, La Paz department, and had visited Mosestenes settlements along that river (Balzan 1893,

Map 209 Selected localities for *Oecomys mamorae* (●). Contour line = 2,000 m.

2008), an area where the type may conceivably have been collected. Additional archival research is required to justify formal amendment of the type locality.

Oecomys paricola (Thomas, 1904)

Brazilian *Oecomys*

SYNONYMS:

Rhipidomys paricola Thomas, 1904e:194; type locality “Igarapé-Assu, near Pará, [Para, Brazil]. Alt. 50 m.”

[*Oryzomys* (*Oecomys*)] *paricola*: Thomas, 1906c:445; name combination.

Oecomys paricola: Gyldenstolpe, 1932a:39; first use of current name combination.

Oryzomys [(*Oecomys*)] *paricola*: Ellerman, 1941:358; name combination.

Oryzomys bicolor bicolor: Hershkovitz, 1960:535; part (*paricola* allocated as full synonym).

Oryzomys bicolor paricola: Cabrera, 1961:404; name combination.

DESCRIPTION: Like *O. auyantepui* and *O. phaeotis*, dorsal coat of *O. paricola* thick, silky in texture, and long (8–10 mm) for size of body. Dorsal color ranges from ochraceous brown to rich dark brownish red; flanks tend to be paler and faint ochraceous line may occur between upper and under parts. Venter generally dull grayish white, showing more white on throat, neck, and chest in some specimens, or having strong buffy wash across belly and chest in others. Tail dark brown over its circumference; caudal hairs lengthen over distal half of tail, obscuring scale rows and forming modest terminal pencil.

Skull resembles that of *O. auyantepui*—stockily built with blunt rostrum, well-defined supraorbital ridges, and typical cuneate interorbital constriction. Zygomatic arches converge anteriorly from their widest expanse toward braincase, and zygomatic plates relatively narrow with shallow dorsal notches. Moderately long and wide incisive foramina terminate anterior to front rims of M1s in most specimens, or extend even with anterior borders in some. Mesopterygoid fossa short and wide, with U-shaped anterior margin; roof either entirely osseous or perforated by short, narrow sphenopalatine vacuities. In contrast to *O. auyantepui*, cranium of *O. paricola* typically lacks alisphenoid struts and retains short, narrow subsquamosal fenestrae. Carotid circulatory pattern primitive (pattern 1 of Voss 1988), and ectotympanic bullae small, as typical of genus.

DISTRIBUTION: Central Brazil, south of the Amazon River, and northeastern Peru; range limits uncertain.

SELECTED LOCALITIES (Map 210): BRAZIL: Pará, 52 km SSW of Altamira, right bank Rio Xingu (USNM 549531, 549532), Capim (AMNH 203391, 203392, 203394), Igarapé-Assu, near Pará (type locality of *Rhipidomys paricola* Thomas), Km 217, BR 165, Santarem to

Map 210 Selected localities for *Oecomys paricola* (●). Contour line = 2,000 m.

Cuiabá (USNM 544601), Porto Jatobal, 73 km N and 45 km W of Marabá (USNM 521453, 521528); Mato Grosso, 264 km N of Xavantina, Serra do Roncador Base Camp (BM 81.380, 81.595, 86.1127); Mato Grosso do Sul, Maracaju (AMNH 134510, 134511). PERU: Loreto, Estación Biológica Allpahuayo, 25 km SW of Iquitos, on Iquitos-Nauta Highway (TTU [CLH 2348, 2846]), San Jacinto (KU 158190).

SUBSPECIES: *Oecomys paricola* is provisionally regarded as monotypic.

NATURAL HISTORY: Carleton et al. (1986) recorded *O. paricola* from primary lowland forest along the Rio Xingu, central Brazil.

REMARKS: The geographic range of *O. paricola* (south of the Amazon River) is allopatric to that of *O. auyantepui* (north of the Amazon River) and to that of *O. phaeotis* (western Amazonia); the status of the three as valid species needs verification.

Chromosomal variation ($2n=68, 70$; FN=72, 76) has been reported for geographically close populations of *O. paricola* located at the mouth of the Amazon River (C. C. Rosa et al. 2012); the authors suspected the existence of cryptic species, although accompanying morphological or molecular differentiation was not demonstrable.

Oecomys phaeotis (Thomas, 1901)

Dusky *Oecomys*

SYNONYMS:

Rhipidomys phaeotis Thomas, 1901b:181; type locality “Segrario, 13°5'S., 70°5'W., Upper Inambari, [Puno,] S.E. Peru. Alt. 1000 m.”

[*Oryzomys* (*Oecomys*)] *phaeotis*: Thomas, 1906c:445; name combination.

Oecomys phaeotis: Gyldenstolpe, 1932a:40; first use of current name combination.

Oryzomys [(*Oecomys*)] *phaeotis*: Ellerman, 1941:358; name combination.

Oryzomys bicolor phaeotis: Hershkovitz, 1960:540; name combination.

DESCRIPTION: Medium-sized species—larger than *O. bicolor*, about same as *O. auyantepui* and *O. paricola*, and smaller than all other species (Table 1). Pelage luxuriant: soft, dense, and long (10–12 mm over middle rump). Dorsal fur rich tawny brown in most specimens, darker along top of head and back than on sides. Ventral pelage typically dull white (hairs white from tips to roots); demarcation between dorsal and ventral pelage coloration sharp and usually accentuated by bright ochraceous strip. Tail longer than combined head and body ($\approx 110\%$ of HBL) and dark brown on all surfaces; caudal hairs relatively long, typically obscuring scale rows and forming noticeable tuft at tip (6–8 mm).

Skull compactly built, with relatively short rostrum and narrow interorbit. Conspicuous supraorbital ridges outline interorbital and postorbital regions and sweep caudad to join distinct temporal beading. Zygomatic arches narrower rostrally and wider toward braincase; zygomatic plates relatively narrow and dorsal notches shallow. Incisive foramina moderately long and broad, with posterior margins situated about even with anterior faces of M1s or extend just beyond them. A pair of prominent posterolateral palatal pits and smaller vascular perforations adorn bony palate behind molars; mesopterygoid fossa wide and U-shaped at anterior margin, its roof entirely osseous. Postglenoid foramen and subsquamosal fenestra large. Alisphenoid struts typically absent (present in 1 of 7 specimens), and carotid circulatory plan primitive (pattern 1 of Voss 1988). Ectotympanic bullae small, exposing much of medial periotic.

DISTRIBUTION: Eastern Andean slopes from Peru to northern Bolivia; limits unresolved.

SELECTED LOCALITIES (Map 211): **BOLIVIA:** Cochabamba, Alto Palmar, Chaparé (AMNH 119406). **PERU:** Cusco, Hacienda Villa Carmen, Cosñipata (FMNH 84314); Junín, 10 km WSW of San Ramón (MVZ 172649); Loreto, Quebrada Oran, 5 km N of Río Amazonas, 85 km NE of Iquitos (LSUMZ 27975); Puno, Segrario, upper Río Inambari (type locality of *Rhipidomys phaeotis* Thomas).

SUBSPECIES: Too few specimens of *O. phaeotis* exist to allow rigorous analysis of intraspecific variation and delineation of subspecies.

NATURAL HISTORY: There is no published information on the ecology or behavior of this species. Most collecting localities appear to be in lower montane forest.

REMARKS: See comments in accounts of *O. auyantepui* and *O. paricola*.

Oecomys rex Thomas, 1910

Regal Oecomys

SYNONYMS:

Oecomys rex Thomas, 1910d:504; type locality “R. Supinaam [= Supenaam], Lower Essequibo, Demerara [= Georgetown],” Demerara-Mahaica, Guyana.

Oryzomys [(*Oecomys*)] *rex*: Ellerman, 1941:359; name combination.

Oryzomys subflavus regalis Hershkovitz, 1960:543; unnecessary replacement name for *Oecomys rex* Thomas, 1910, mistakenly viewed as a junior synonym of *Oryzomys subflavus* [= *Cerradomys subflavus* (Wagner)].

Oryzomys catherinae rex: Cabrera, 1961:405; name combination.

DESCRIPTION: Large, morphologically distinctive species that exhibits several features whose expression is unique within genus. In size, *O. rex* is surpassed only by individuals of *O. superans* and approximates those of *O. catherinae* (Table 1). Dorsal pelage thick and long (10–12 mm), its texture very fine and more luxurious than that characteristic of long-furred *O. trinitatis*. Upper parts generally dark in tone, ranging from dull ochraceous brown to deep chestnut, finely intermixed with black-tipped hairs over middle dorsum and grading to brighter on flanks. Ventral pelage uniformly dark grayish white (hairs with gray bases and white tips) in most specimens, although some display overwash of buff to ochraceous on belly and dingy white on gular and inguinal regions. Tail brown all around,

caudal hairs short and inconspicuous without formation of terminal pencil or tuft. Tops of forefeet and hindfeet fuscous brown, becoming dingy white over phalanges.

Robust skull bears exaggerated supraorbital shelves and strong temporal ridges that extend across braincase and reach supraoccipital. An angular postorbital process at lateral union of frontal and parietal accentuates orbital-temporal ridging, and flaring supraorbital ridges account for extreme width of interorbit (Table 1). Nasolacrimal opening slit-like, capsules more nearly flat than bulging; rostrum consequently appears narrow relative to cranial size. Unlike other species of *Oecomys*, tegmen tympani well developed, adnate to squamosal and essentially occluding postglenoid foramen; subsquamosal fenestra absent or persists as short, narrow slit. Incisive foramina terminate noticeably anterior to M1s, except subequal with the anterior roots in old individuals. Carotid circulatory plan complete (pattern 1 of Voss 1988).

DISTRIBUTION: Southeastern Venezuela (Bolívar), the Guianas, and northeastern Brazil (Amapá, Amazonas); no elevational records.

SELECTED LOCALITIES (Map 212): BRAZIL: Amapá, Rio Amapari de Macapá (MPEG 6704, 6725), Serra do Navio, Rio Amapari (USNM 394254–394256); Amazonas, Fazenda Dimona, 80 km N of Manaus (INPA [JRM 2107]). FRENCH GUIANA: Riviere Approuague (MNHN 1983.389, 1983.390), Trois Sauts (MNHN 1982.621, 1983.391). GUYANA: Demerara-Mahaica,

Map 212 Selected localities for *Oecomys rex* (●). Contour line=2,000 m.

Demerara, Supinaam River (type locality of *Oecomys rex* Thomas); Potaro-Siparuni, 40 km NE of Surama (ROM 98033). SURINAM: Marowijne, 3 km SW of Albina (CM 76867); Sipaliwini, Avanavero (CM 68459). VENEZUELA: Bolívar, Serranía Imataca (MHNLS [JO 562]).

SUBSPECIES: *Oecomys rex* is provisionally regarded as monotypic.

NATURAL HISTORY: In southeastern Venezuela, Linares (1998) associated *O. rex* with humid, evergreen forest that harbors a lush undergrowth of bromeliads, epiphytes, and lianas.

REMARKS: Like *O. auyantepui* and *O. rutilus*, the geographic range of *O. rex* adheres to the Guiana subregion of Amazonia.

Oecomys roberti (Thomas, 1904)

Robert's *Oecomys*

SYNONYMS:

Rhipidomys roberti Thomas, 1904a:237; type locality "Santa Ana de Chapada, a village situated at an altitude of about 800 m, on the Serra do Chapada, some thirty miles N.E. of Cuyabá [Cuiabá]," Mato Grosso, Brazil.

[*Oryzomys* (*Oecomys*)] *roberti*: Thomas, 1906c:445; name combination.
