Oryzomys [(*Oecomys*)] *guianae*: Ellerman, 1941:358; name combination.

Oryzomys [(*Oecomys*)] *tapajinus*: Ellerman, 1941:359; name combination.

Oryzomys (*Oecomys*) *concolor concolor*: Hershkovitz, 1960:546; part (*tapajinus* allocated as full synonym); not *concolor* Wagner.

Oryzomys concolor speciosus: Hershkovitz, 1960:553; part (*guianae* allocated as full synonym); not *speciosus* J. A. Allen and Chapman.

Oryzomys concolor roberti: Hershkovitz, 1960:559; name combination.

Oryzomys marmosurus guianae: Cabrera, 1961:405; name combination.

Oryzomys marmosurus tapajinus: Cabrera, 1961:406; name combination.

Oecomys roberti: Musser and Carleton, 1993:716; name combination (*guianae* and *tapajinus* allocated as synonyms without indication of rank).

DESCRIPTION: Moderately large species that possesses absolutely and relatively long tail ($\approx 123\%$ of HBL) and relatively short fur for its body size (5–7 mm over middle rump). Dorsal pelage texture soft, thought slightly harsh to touch. Upper parts bright in tone, tawny to fulvous brown, grading to ochraceous on flanks, although without obvious lateral line. Appearance of venter ranges from all white (hairs self-colored) to grayish white (hairs with gray bases and white tips), with varying degrees of intermediacy depending upon extent of gray-based hairs, or sometimes tinted with buffy or ochraceous overwash on chest and belly; dorsal-ventral pelage contrast sharp in individuals with mostly white under parts but only moderately defined in examples with grayish white or grayish buff venters. Tail wholly dark brown; caudal hairs so short that tail appears naked macroscopically, revealing fine scale rows; no tuft formed at tip. Pinnae relatively short and brown; tops of hindfeet white or tinged with ochraceous.

Chunky skull characterized by relatively short rostrum and wide interorbit. Supraorbital shelves distinctive but moderately developed compared with *O. trinitatis* and have fairly straight edges that do not diverge as strongly posteriorly; temporal ridges of low relief present, becoming poorly defined over parietals. Nasolacrimal capsules conspicuously bulge laterally and contribute to short-broad appearance of rostrum. Zygomatic arches converge little from braincase toward rostrum; zygomatic plates relatively narrow, and dorsal notches shallow. Incisive foramina relatively short, terminating well anterior to M1 roots and expanding widely over their middle section. Posterolateral palatal pits well expressed; mesopterygoid fossa broad, V- or U-shaped at anterior margin, and roof entirely osseous in some specimens, broken by slits in others. Tegmen tympani may touch rear edge of squamosal, but postglenoid foramen remains open, larger than tiny or absent subsquamosal fenestra (hamular process fused with the squamosal). Occurrence of alisphenoid struts variable, but typically absent; carotid circulatory plan complete (pattern 1 of Voss 1988). Ectotympanic bullae small, revealing much of medial periotic.

DISTRIBUTION: Southern Venezuela (Amazonas), Guyana, Surinam, northern and west-central Brazil, eastern Colombia, eastern Peru, and extreme eastern Bolivia; known elevational range sea level–800 m.

SELECTED LOCALITIES (Map 213): BOLIVIA: Pando, Remanso (Anderson 1997); Santa Cruz, 2.5 km NE of El Refugio, Parque Nacional Noel Kempff Mercado (Carleton et al. 2009). BRAZIL: Amazonas, Colocação Vira-Volta, left bank Rio Juruá (Patton et al. 2000),

Manacapuru, Rio Solimões (BM 1920.7.1.15), Sacado, right bank Rio Juruá (Patton et al. 2000); Pará, Campos do Ariramba, Igarapé Jaramacaru (MZUSP 69145), Capim (MZUSP 9896, 9897), Santa Rosa, Rio Jamanxim, upper Rio Tapajós (type locality of *Oecomys tapajinus* Thomas); Mato Grosso, Santa Ana do Chapada, Serra do Chapada, 30 mi NE of Cuiabá (type locality of *Rhipidomys roberti* Thomas), 264 km N of Xavantina, Serra do Roncador Base Camp (BM 81.412–81.417); Rondônia, Baão de Melgaço, Rio Comemoração, upper Rio Ji-Paraná (AMNH 37115, 37116, 37118). COLOMBIA: Caquetá, Tres Troncas, Río Caquetá (FMNH 72024). GUYANA: Demerara-Mahaica, Demerara, Supinaam River (type locality of *Oecomys guianae* Thomas); Upper Takutu–Upper Essequibo, Quarter Mile Landing, 5 km S of Annai (ROM 98125). PERU: Amazonas, Río Cenepa, vicinity of Huampami (MVZ 153528, 155005); Loreto, Boca Río Peruate (FMNH 88937); Madre de Dios, Itahuania, right bank Río Madre de Dios (FMNH 84303); Pasco, San Pablo (AMNH 231133); Puno, La Pampa, Limbani-Asterillos road (MCZ 39499). SURINAM: Paramaribo, Paramaribo (USNM 319968, 319969); Sipaliwini, Sipaliwini airstrip (CM 64562). VENEZUELA: Amazonas, Cerro Neblina, Base Camp (USNM 560822); Bolívar, Río Yuruani, 12 mi from mouth (AMNH 30726).

SUBSPECIES: Although broad in distribution, no evaluation of variation has been conducted to rigorously delimit infraspecific units; we provisionally treat *O. roberti* as monotypic.

NATURAL HISTORY: Patton et al. (2000) obtained samples of *O. roberti* primarily in várzea forest (88%) along the Rio Juruá, western Brazil, and rarely at the edges of second-growth forest; individuals were captured in equal numbers on the ground and in the canopy. Along the Rio

Map 213 Selected localities for *Oecomys roberti* (●). Contour line = 2,000 m.

Xingu, central Brazil, trap success was notable in ecotones of dense growth that proliferated around natural tree-falls within primary forest and in viney forest with low canopy (Carleton et al. 1986). Within the Cerrado biome of eastern Bolivia, examples of *O. roberti* were captured in semideciduous forest (Emmons et al. 2006). Litter size, as based on fetal counts and embryo scars, is only two or three (Patton et al. 2000).

REMARKS: Hershkovitz (1960) retained *roberti* as a subspecies of *O. concolor*, but submerged the otherwise dissimilar *mamorae* within his construct of *O. concolor roberti*.

Patton et al. (2000) reported the karyotype to consist of a high diploid count ($2n=80$) and intermediate number of banded chromosomes (FN=114).

Oecomys rutilus Anthony, 1921

Reddish *Oecomys*

SYNONYMS:

Oecomys rutilus Anthony, 1921a:4; type locality "Kartabo, [Cuyuni-Mazaruni,] British Guiana" [Guyana].

Oryzomys [(*Oecomys*)] *rutilus*: Ellerman, 1941:359; name combination.

Oryzomys bicolor bicolor: Hershkovitz, 1960:535; part (*rutilus* allocated as full synonym); not *bicolor* Tomes.

Oryzomys bicolor nitedulus: Cabrera, 1961:404; part (*rutilus* allocated as full synonym); not *nitedulus* Thomas.

DESCRIPTION: Smallest species of *Oecomys* so far recognized, suggesting dainty facsimile of *O. bicolor*. Pelage soft and dense, lax to touch, and moderately long compared with body size (6–8 mm over middle rump). Dorsal coat rich ochraceous tawny (nearly orange brown), and slightly paler along lower sides of head and body, bright buffy gray. Ventral pelage pure white, hairs white from root to tip, and sharply demarcated from dorsum. Tail only slightly longer than combined head and body (TL \approx 111% of HBL) and dark brown on all surfaces; tail hairs relatively long, typically concealing distal scale rows and forming conspicuous terminal tuft (5–11 mm per Voss et al. 2001).

Small skull delicately but compactly built with relatively short rostrum and narrow interorbit. Conspicuous supra-orbital ridges (narrowly ledge-like) outline interorbital and postorbital regions and sweep caudad to join distinct temporal ridges. Zygomatic arches converge slightly toward rostrum; zygomatic plates relatively narrow and dorsal notches shallow. Short and narrow incisive foramina terminate posteriorly about even with anterior faces of M1s. Rear of bony palate contains pair of prominent posterolateral palatal pits; mesopterygoid fossa narrow and U-shaped at anterior margin, and roof entirely osseous. Postglenoid foramen and subsquamosal fenestra spacious. Alisphenoid

Map 214 Selected localities for *Oecomys rutilus* (●). Contour line=2,000m.

struts typically present, and carotid circulatory plan primitive (pattern 1 of Voss 1988). Ectotympanic bullae small, exposing much of medial petiotic.

DISTRIBUTION: Extreme eastern Venezuela, Guyana, Surinam, and French Guiana, to Amazonas, Brazil; single elevational record at 60 m.

SELECTED LOCALITIES (Map 214; from Voss et al. 2001, except as noted): BRAZIL: Amazonas, 80 km N of Manaus. FRENCH GUIANA: Nouragues, Paracou. GUYANA: Cuyuni-Mazaruni, Kartabo, lower Essequibo (type locality of *Oecomys rutilus* Anthony). SURINAM: Paramaribo, Carolina Kreek. VENEZUELA: Bolívar, San Ignacio Yuruaní, 5.2 km NE via La Toma de Agua.

SUBSPECIES: *Oecomys rutilus* is provisionally regarded as monotypic.

NATURAL HISTORY: In French Guiana (Voss et al. 2001), nearly all examples of *O. rutilus* were captured in primary forest, one in roadside secondary growth; settings in primary vegetation included well-drained sites as well as swampy forest and along creeks; specimens issued about equally from terrestrial (pitfall lines) and arboreal (lianas, canopy platform) trapping stations. Adler et al. (2012) also captured this species most commonly on lianas, especially at lower heights in the forest at Paracou, French Guiana.

REMARKS: As so far documented, the geographic range of *O. rutilus* adheres to the Guiana subregion of Amazonia, along with those of *O. auyantepui* and *O. rex*.

Oecomys speciosus (J. A. Allen and Chapman, 1893)

Savanna *Oecomys*

SYNONYMS:

Oryzomys speciosus J. A. Allen and Chapman, 1893:212; type locality “Prinkestown, Trinidad,” Trinidad and Tobago.

Oryzomys trichurus J. A. Allen, 1899b:206; type locality “El Libano plantation, near Bonda (alt. 500 ft.), Santa Marta District,” Magdalena, Colombia.

Oecomys caicarae J. A. Allen, 1913c:603; type locality “Caicara, Rio Orinoco, [Bolívar,] Venezuela.”

Oecomys guianae caicarae: Tate, 1939:193; name combination.

Oryzomys [(*Oecomys*)] *caicarae*: Ellerman, 1941:357; name combination.

Oryzomys (*Oecomys*) *concolor concolor*: Hershkovitz, 1960: 546–547; part (*caicarae* and *trichurus* allocated as full synonyms); not *concolor* Wagner.

Oryzomys concolor speciosus: Hershkovitz, 1960:553; name combination.

Oryzomys marmosurus marmosurus: Cabrera, 1961:406; part (*caicarae* allocated as full synonym); not *marmosurus* Thomas.

Oryzomys trinitatis illectus: Cabrera, 1961:408; part (*trichurus* allocated as full synonym), not *illectus* Bangs.

Oecomys speciosus: Musser and Carleton, 1993:716; first use of current name combination (*caicarae* and *trichurus* allocated as synonyms without indication of rank).

DESCRIPTION: Medium-sized, orange-brown mouse with bright ochraceous sides and pure white venter. Larger than examples of *O. bicolor* or *O. auyantepui* but appreciably less robust than those of *O. concolor* or *O. trinitatis* (Table 1). Dorsal fur soft, dense, and medium in length (5–8 mm over middle rump). Dorsal coloration usually rich ochraceous tawny, grading to bright ochraceous orange along sides of body from nose to rump. Individual variation occurs, some specimens showing redder dorsal coat and others darker upper parts, approaching brownish tawny; in many examples, bright ochraceous hue confined to cheeks and attenuates as distinctive lateral line bordering ventral pelage. Venter typically pure white and contrasts sharply with dorsum. Feet buffy, ears dark brown. Tail relatively long ($\approx 118\%$ of HBL) and brown throughout; caudal hairs short over most of tail, lengthen toward tip to end in barely perceptible tuft.

Although medium in size, skull presents sturdy conformation and moderately long rostrum. Low supraorbital shelves extend posteriorly to merge with temporal ridges. Long and narrow incisive foramina extend between M1s, and bony palate projects beyond third molars to form moderately wide shelf. Large postglenoid fissure and small but obvious subsquamosal foramen penetrate lateral wall

of braincase. Alisphenoid struts typically absent; carotid circulatory plan primitive (pattern 1 of Voss 1988).

DISTRIBUTION: Northeastern Colombia, northern Venezuela, and Trinidad; known elevational range from sea level to 1,250 m; most site records below 400 m.

SELECTED LOCALITIES (Map 215): COLOMBIA: Cesar, Valledupar, Río Guaimaral (USNM 280521); Magdalena, El Libano plantation, near Bonda (type locality of *Oryzomys trichurus* J. A. Allen). TRINIDAD AND TOBAGO: Trinidad, Prinkestown (type locality of *Oryzomys speciosus* J. A. Allen and Chapman). VENEZUELA: Apure, Hato Cariben, 60 km NE of Puerto Paez, Río Cinaruco (USNM 374314–374316), Hato El Frio, 30 km W of El Samán (MHNLS 7923; USNM 448583); Bolívar, Caicara, Río Orinoco (type locality of *Oecomys caicarae* J. A. Allen), Hato San José, 20 km W La Paragua (USNM 406009); Falcón, Capatárida (USNM 442297–442300); Guárico, San José de Tiznados, 52 km NNW of Calabozo (USNM 545116–545119); Monagas, Hato Mato de Bejuco, 54 km SE of Maturín (USNM 442141–4421450); Sucre, near Hacienda Tunantal, 21 km E of Cumaná (USNM 405999), Ensenada Cauranta, 7 km N and 5 km E of Guira (USNM 409856–409860); Trujillo, Agua Santa, 23 km NW of Valera (USNM 371152, 371153); Yaracuy, 19 km NW of Urama, Km 40 (USNM 372514, 372515).

SUBSPECIES: Substantial variation in pelage color is apparent among the samples referred to *O. speciosus*, but whether this variation reflects broad geographic patterns that concord with any of the available junior synonyms as subspecies invites further study. Among Venezuelan populations, Linares (1998) recognized two subspecies, *O. s. speciosus* and *O. s. caicarae*, but we provisionally view *O. speciosus* as monotypic in lieu of studies across the entire distribution.

Map 215 Selected localities for *Oecomys speciosus* (●). Contour line = 2,000 m.

NATURAL HISTORY: Linares (1998) associated *O. speciosus* with palm and woodland savannas, semideciduous forest, and gallery forest.

REMARKS: Hershkovitz's (1960) concept of the subspecies *O. concolor speciosus* was an amalgam of four species (*O. speciosus* proper plus *O. auyantepui*, *O. roberti*, and *O. trinitatis*).

Oecomys superans Thomas, 1911

Large *Oecomys*

SYNONYMS:

Oecomys superans Thomas, 1911c:250; type locality "Canelos, Rio Bobonaza, [Pastaza,] Oriente of Ecuador. Alt. 2100'."

Oecomys palmeri Thomas, 1911c:251; type locality "Canelos, [Pastaza,] Oriente of Ecuador. Alt. 2100'."

Oecomys melleus Anthony, 1924b:4; type locality "Zamora, [Zamora-Chinchiipe,] eastern Ecuador, altitude about 3250 feet."

Oecomys superans: Gyldenstolpe, 1932a:42; name combination (*palmeri* allocated as synonym without indication of rank).

Oryzomys [(*Oecomys*)] *melleus*: Ellerman, 1941:358; name combination.

Oryzomys [(*Oecomys*)] *superans*: Ellerman, 1941:359; name combination (*palmeri* allocated as synonym without indication of rank).

Oryzomys (*Oecomys*) *superans*: Sanborn, 1951:21; name combination.

Oryzomys concolor superans: Hershkovitz, 1960:556; name combination (*melleus* and *palmeri* allocated as full synonyms, invalid as subspecies).

Oryzomys mamorae superans: Cabrera, 1961:405; part (*palmeri* allocated as full synonym).

Oecomys superans: Musser and Carleton, 1993:716; name combination (*melleus* and *palmeri* allocated as synonyms without indication of rank).

DESCRIPTION: As attested by the majority of dimensions measured, largest species of *Oecomys* (Table 1). Fur soft and fine in texture and moderately long (8–10 mm over middle rump); dorsal-ventral pelage transition moderately defined, usually without ochraceous lateral line. Overall, upper parts somber in tone, dark ochraceous brown, generally stronger concentration of blackish-brown over middle dorsum and paler toward sides. Under parts dull grayish white to dirty gray, tinged or washed with buff in some specimens whose venters appear dark grayish buff; individual hairs gray basally and tipped with buff. Tail moderately longer than combined head and body (TL ≈ 111% of HBL) and uniformly dark brown above and below; caudal hairs short and expose fine scale rows, without formation of terminal tuft

or pencil. Pinnae appear small and closely rounded for size of species.

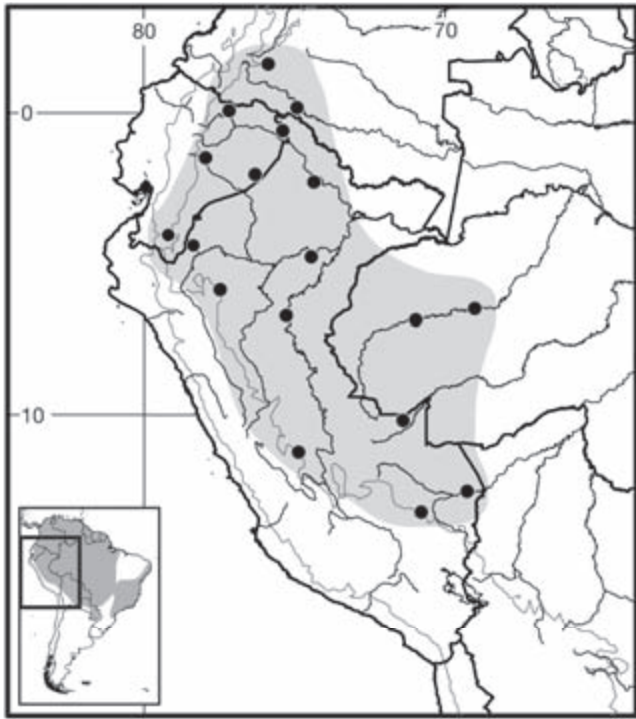

Skull large and stoutly built, with moderately long and broad rostrum and relatively narrow interorbit. Supraorbital ledges well developed, distinctly diverging to sweep caudad and join prominent temporal ridges. Zygomatic arches noticeably expand toward rear and strongly taper rostrally; zygomatic plates relatively broad and dorsal notches well defined. Incisive foramina relatively short and narrow, slightly oval in shape, their posterior margins situated well anterior to molar rows. Posterolateral-palatal pits are well expressed; the mesopterygoid fossa broad, V- or U-shaped at anterior border, roof entirely osseous in some specimens or broken by narrow slits in others. Postglenoid foramen small; subsquamosal fenestra usually tiny or absent (hamular process fused with squamosal). Alisphenoid struts typically absent, and carotid circulatory plan primitive (pattern 1 of Voss 1988). Tegmen tympani contacts squamosal but does not overlap its posterior margin. Ectotympanic bullae small, revealing much of medial periotic.

DISTRIBUTION: Lower Andean slopes and foothills in south-central Colombia, eastern Ecuador and Peru, and westernmost Brazil (Amazonas); known elevational range from sea level to 1,800 m; most localities below 400 m.

SELECTED LOCALITIES (Map 216): BRAZIL: Amazonas, Altamira, right bank Rio Juruá (Patton et al. 2000), Penedo, right bank Rio Juruá (Patton et al. 2000). COLOMBIA: Caquetá, Florencia, Río Bodoquera (FMNH 72013), Tres Troncas, La Tiqua, Río Caquetá (FMNH 72015, 72025). ECUADOR: Pastaza, Canelos, Río Bobonaza (type locality of *Oecomys superans* Thomas and *Oecomys palmeri* Thomas), Río Tigre (BM 54.473); Sucumbios, Santa Cecilia (KU 135117, 135150), Lagarto Yaco (MCZ 52609); Zamora-Chinchiipe, Zamora (type locality of *Oecomys melleus* Anthony). PERU: Amazonas, vicinity of Huampami, Río Cenepa (MVZ 155010–155013); Cusco, Quincemil, Río Marcapata (FMNH 68636; LSUMZ 19276); Huánuco, Tingo Maria (BM 27.11.1.131–27.11.1.137); Junín, Satipo (MCZ 39676); Loreto, Boca del Río Curaray (AMNH 71589–71591), Santa Elena, Río Samiria (FMNH 87195, 87196); Madre de Dios, Reserva Cuzco Amazonico, 14 km NE of Puerto Maldonado (Woodman et al. 1991); San Martín, Yurac Yacu (BM 27.1.1.117–27.1.1.121); Ucayali, Balta, Río Curanja (LSUMZ 12330–12332), Sarayacu, Río Ucayali (AMNH 76175, 76298, 76456).

SUBSPECIES: *Oecomys superans* is provisionally regarded as monotypic.

NATURAL HISTORY: Although generally associated with lowland tropical forest, little detailed habitat information is available for *O. superans*. Along the Rio Juruá, western Brazil, the few specimens were collected on the ground in highly disturbed secondary growth (Patton et al. 2000).

Map 216 Selected localities for *Oecomys superans* (●). Contour line=2,000 m.

REMARKS: Hershkovitz (1960) viewed *superans* as the largest and darkest of the five subspecies he identified within *O. concolor*. His morphological definition and distribution of the subspecies largely conform to our understanding of the species *O. superans*, including the recent documentation of the species in westernmost Brazil (Patton et al. 2000). The karyotype has been uniformly recorded as $2n=80$, $FN=108$ (A. L. Gardner and Patton 1976; Patton et al. 2000; A. F. B. Andrade and Bonvicino 2003).

The geographic ranges of *O. superans* and *O. roberti* overlap along the Andean foothills, where both have been trapped at the same localities, and the two are superficially similar and often misidentified in collections. *Oecomys roberti* is smaller in external and craniodental dimensions (Table 1), its ventral pelage is grayish white without any buffy overlay (although a few specimens from elsewhere in the range of *O. roberti* show a buffy tinge), and the incise foramina are relatively shorter and broader, more tear-dropped shaped.

Oecomys sydandersoni Carleton, Emmons, and Musser, 2009

Anderson's *Oecomys*

SYNONYMS:

Oecomys concolor: Musser and Carleton, 1993:716; part (provisional identification and range extension).

Oecomys sydandersoni Carleton, Emmons, and Musser, 2009:8; type locality "Bolivia, Departamento de Santa

Cruz, Provincia Velasco, El Refugio Huanchaca, 210 m; $14^{\circ}46'01''S/61^{\circ}02'02''W$."

DESCRIPTION: Medium-size for genus (e.g., larger than *O. bicolor* or *O. paricola*, smaller than *O. roberti* or *O. mamorae*). Pelage soft and fine in texture and moderately short (about 5–7 mm over middle rump). Dorsal color ochraceous brown to pale tawny, generally bright in tone with more grayish showing on head and flanks; ventral pelage pale to medium gray, with hairs of chin, throat, and inguinum entirely white to base in most specimens; dorsal-ventral pelage transition moderately defined, without an ochraceous lateral line. Tail only slightly longer than head and body ($TL \approx 106\%$ of HBL), brown to dark brown all around for most of length; short caudal hairs scarcely visible to unaided eye, revealing fine scale pattern, and rudimentary pencil expressed at tip.

Skull ruggedly built for its size, with short rostrum and relatively broad interorbit. Supraorbital shelves strongly convergent anteriorly, with free ledge approaching incipient bead. Zygomatic arches noticeably expand toward rear and strongly taper rostrally; zygomatic plates relatively broad and dorsal notches well defined. Medium-long incise foramina very broad toward rear, posterior ends obtuse (blunt) and anterior ends acute. Posterolateral-palatal pits well expressed; mesopterygoid fossa broad, bluntly U-shaped at anterior margin, and roof entirely osseous. Alisphenoid struts typically present, and carotid circulatory plan derived (pattern 3 of Voss 1988). Ectotympanic bullae small, revealing much of medial periotic.

DISTRIBUTION: Extreme eastern Bolivia, departments of Beni and Santa Cruz; single elevational record at 210 m.

SELECTED LOCALITIES (Map 217): BOLIVIA: Beni, 4 km above Costa Marques, Río Iténez (Carleton et al. 2009), Bahía de los Casara, 20 km W of Larangiera, Río Iténez (Carleton et al. 2009); Santa Cruz, El Refugio Huanchaca (type locality of *Oecomys sydandersoni* Carleton, Emmons, and Musser).

SUBSPECIES: *Oecomys sydandersoni* is monotypic.

NATURAL HISTORY: Most specimens have been captured in small clumps of woody vegetation surrounded by seasonally flooded grasslands, typically in traps placed above ground on vines, trunks, or branches within arm's reach (Carleton et al. 2009). One individual was captured in closed riverine forest, taken on a vine snaking through a shrub along the river's edge.

REMARKS: Specimens of *O. sydandersoni* were tentatively reported as *O. concolor* based on their superficial similarity (Musser and Carleton 1993). As in *O. concolor* and *O. mamorae*, *O. sydandersoni* possesses a derived carotid circulatory pattern (Carleton et al. 2009), a condition that may indicate closer relationship among the three relative to other species of *Oecomys*. The species has been collected

Map 217 Selected localities for *Oecomys sydandersoni* (●). Contour line = 2,000 m.

near to but not in syntopy with *O. bicolor*, *O. roberti*, and *O. trinitatis* in the Parque Nacional Noel Kempff Mercado, eastern Bolivia (Emmons et al. 2006; Carleton et al. 2009).

Oecomys trinitatis (J. A. Allen and Chapman, 1893)

Long-furred *Oecomys*

SYNONYMS:

- Oryzomys trinitatis frontalis*: Cabrera, 1961:408; name combination.
- Oryzomys trinitatis helvolus*: Cabrera, 1961:408; name combination (*vicencianus* allocated as full synonym, invalid as subspecies).
- Oryzomys trinitatis klagesi*: Cabrera, 1961:408; name combination.
- Oryzomys trinitatis trinitatis*: Cabrera, 1961:409; name combination (*fulviventor* and *palmarius* allocated as full synonyms, invalid as subspecies).
- O*[*ryzomys*]. *c*[*oncolor*]. *tectus*: Handley, 1966:781; name combination (*frontalis* indicated as full synonym, invalid as subspecies).
- Oecomys trinitatis*: Musser and Carleton, 1993:716–717; first use of current name combination (*frontalis*, *fulviventor*, *helvolus*, *klagesi*, *osgoodi*, *palmarius*, *splendens*, *subluteus*, *tectus*, and *vicencianus* allocated as synonyms without indication of rank).
- DESCRIPTION:** Medium-large species, similar in size to *O. roberti* and *O. concolor*. Dorsal fur soft and dense, palpably luxuriant and lustrous, and deep (10–13 mm over middle rump). Head and back dark tawny brown, commonly grading to brighter ochraceous-brown over cheeks and shoulders and along flanks; some individuals exhibit

Table 1. Size variation among *Oecomys* species, as indexed by select external and craniodental variables and roughly graded from smaller to larger.

Abbreviations: CLM, coronal length of maxillary tooththrow (M1–M3); HBL, length of head and body; HFL, length of hindfoot (including claw); IOB, least interorbital breadth; ONL, occipitonasal length; TL, length of tail; WT, weight; ZB, zygomatic breadth.

Notes: Sample statistics include the mean and range based on ± 1 standard deviation, which encompasses about 70% of observed cases; units of external and craniodental variables are in millimeters and mass in grams. Species samples were coarsely defined to convey broad limits of measurement variation as follows:

O. auyantepui—Amapá, Brazil, French Guiana, Guyana, and Surinam (N=26–48); *O. bicolor*—Amazonas and Madre de Dios, Peru (N=36–46); *O. cleberi*—south-central Brazil (N=14; R. G. Rocha et al. 2012); *O. catherinae*—Federal District and Minas Gerais, Brazil (N=23–27); *O. concolor*—Amazonas, Brazil (N=23–24); *O. flavicans*—Venezuela (N=7–55); *O. mamorae*—Beni and Santa Cruz, Bolivia (N=13–49); *O. paricola*—Para, Brazil (N=36–61); *O. phaeotis*—Peru (N=2–12); *O. rex*—Amapá, Brazil, French Guiana, Guyana, and Surinam (N=8–21); *O. roberti*—Amazonas, Mata Grosso, and Para, Brazil (N=87–104); *O. rutilus*—French Guiana and Guyana (N=2–16); *O. speciosus*—Venezuela (N=26–51); *O. superans*—Colombia, Ecuador, and Peru (N=20–86); *O. sydandersoni*—Beni and Santa Cruz, Bolivia (N=21–24); *O. trinitatis*—Venezuela (N=33–76). In general, sample sizes are larger for the craniodental variables, smaller for external measurements, and smallest for weight.

bright buffy orange dorsum; dorsal surfaces of forefeet and hindfeet dark brownish. Ventral pelage chromatically ranges from dark grayish white, through grayish white tinged with buff, to rich ochraceous gray. Demarcation between dorsal and ventral fur not well defined, occasionally marked by ochraceous lateral line in some specimens, whereas in others ochraceous tones wash along borders with grayish ventral fur. Tail longer than combined head and body (TL \approx 118% of HBL), dark brown and unicolor or slightly paler below; caudal hairs short, scalation thus visible to eye, and form slight pencil at tip.

Robust skull with relatively long rostrum, narrow interorbit, and strongly opisthodont upper incisors. Distinct supraorbital ridges or shelves delineate interorbital edges and strongly diverge caudad to join prominent temporal ridges. Zygomatic arches narrow toward rostrum but widen toward braincase; zygomatic plates broad and dorsal notches relatively deep. Incisive foramina moderately long and narrow to moderately broad, posterior margins situated anterior to molar rows. Large posterolateral palatal pits mark each side of bony palate beyond toothrows; mesopterygoid fossa broad, U-shaped at anterior margin, and its roof entirely osseous. Postglenoid foramen medium sized, but subsquamosal fenestra either closed (hamular process fused with squamosal) or very small in most specimens. Alisphenoid struts present in about 40% of sample, and carotid circulatory plan primitive (pattern 1 of Voss 1988). Tegmen tympani usually contacts rear edge of squamosal. Ectotympanic bullae small, revealing much of medial periotic.

DISTRIBUTION: Trinidad and Tobago, eastern, central and southern Venezuela, Guyana and Surinam, eastern Ecuador and Peru, northern and central Brazil; known elevational range from sea level to 2,150 m.

SELECTED LOCALITIES (Map 218): **BOLIVIA:** Santa Cruz, El Refugio, Parque Nacional Noel Kempff Mercado (Carleton et al. 2009). **BRAZIL:** Acre, opposite Igarapé Porongaba, left bank Rio Juruá (Patton et al. 2000); Amazonas, Villa Bella da Imperatriz, Boca Rio Andirá (AMNH 93532, 93533), Colocação Vira Volta, left bank Rio Juruá (Patton et al. 2000); Goiás, Annapolis (AMNH 134571, 134659, 134676); Mato Grosso, Humboldt Laboratory, Rio Roosevelt, Aripuanã (USNM 545275–545277), 264 km N of Xavantina, Serra do Roncador Base Camp (BM 81.418–81.420); Mato Grosso do Sul, Maracaju (AMNH 134904); Pará, Porto Jatobal, 73 km N and 45 km W of Marabá (MPEG 15360, 15361; USNM 521532). **COLOMBIA:** Cauca, Sabanetas (FMNH 90281); Córdoba, Socorre, upper Río Sinu (FMNH 69197–69199); Cundinamarca, western slope of Cordillera Oriental (type locality of *Oryzomys flavicans subluteus* Thomas); Meta, Villa Vicencio, about 50 mi SE of Bogotá (type locality of *Oryzomys helvolus* J. A. Allen and *Oryzomys vicencianus*

J. A. Allen). **GUYANA:** Upper Demerara-Berbice, Comackpea, Rio Cunerara (BM 6.1.1.14). **PERU:** Amazonas, Moyobamba (type locality of *Oecomys osgoodi* Thomas); Huánuco, Río Cayamba, Hacienda Exito (FMNH 24574, 24576); Loreto, San Jacinto (KU 158192). **SURINAM:** Para, Carolina Kreek (FMNH 95577–95579). **TRINIDAD AND TOBAGO:** Tobago, Pigeon Peak, Tobago Forest Preserve (USNM 538101); Trinidad, Mayaro (type locality of *Oecomys splendens* Hayman), Princetown (type locality of *Oryzomys trinitatis* J. A. Allen and Chapman). **VENEZUELA:** Amazonas, Cerro Neblina, Camp V (USNM 560648–560650); Aragua, Rancho Grande Biological Station, 13 km NW of Maracay (USNM 517572–517576); Bolívar, El Llagual, near Maripa, lower Río Caura (type locality of *Oryzomys klagesi* J. A. Allen), San Ignacio de Yuruaní (USNM 448577–448579); Sucre, Quebrada Secca (type locality of *Oryzomys palmarius* J. A. Allen and *Oryzomys fulviventer* J. A. Allen).

SUBSPECIES: *Oecomys trinitatis* is provisionally regarded as monotypic. In Venezuela, however, Linares (1998) retained *O. t. klagesi* along with *O. t. trinitatis* as recognizable subspecies.

NATURAL HISTORY: In Panama, Handley (1966) considered the species (reported as *Oryzomys concolor*) as semiarborescent and associated with tall grass and herbaceous growth in savannas and forest openings; another Panamanian example was obtained on a log in lowland forest characterized as Dry Tropical Forest (Fleming 1970). In Venezuela, Linares (1998) considered *O. trinitatis* an inhabitant of dense, evergreen forests with lush undergrowth. In western Brazil, specimens were taken in *terre firme* and at the edge of flooded forest (Patton et al. 2000).

Map 218 Selected localities for *Oecomys trinitatis* (●). Contour line = 2,000 m.

REMARKS: This nominal species forms the core of Hershkovitz's (1960) *O. concolor* in terms of distributional extent and the large number of synonyms included. Even after peeling away clearly diagnosable species (see accounts of *O. auyantepui*, *O. catherinae*, *O. concolor*, *O. flavicans*, *O. mamorae*, *O. roberti*, *O. speciosus*, and *O. superans*), based on morphological differences and/or evidence of sympatry, the residuum now comprising *O. trinitatis* remains a composite. For example, the relationship of the senior taxon *trinitatis*, described from Trinidad, to mainland forms, the status of trans-Andean populations (*tectus* and *frontalis*), and level of differentiation of populations to the north and south of the Amazon River will all require attention in unraveling the heterogeneity evident within *O. "trinitatis."*

Patton et al. (2000) reported a karyotype of $2n=58$, FN=96 for populations of *O. trinitatis* in western Amazonia.

Genus *Oligoryzomys* Bangs, 1900

Marcelo Weksler and Cibele R. Bonvicino

Members of the genus *Oligoryzomys*, commonly known as Colilargos or Pygmy Rice Rats, are found from north-eastern Mexico to extreme southern Chile and Argentina, and across an elevation from sea level to around 3,500 m. Species of the genus are present in lowland and montane forests (humid and dry), such as the Atlantic Forest, lowland Amazonian rainforest, and Andean cloud forest, open-vegetation habitats (grasslands and wetlands) such as the Cerrados, Pampas, Llanos, Pantanal, Chaco, and in drier environments such as Patagonia, Caatinga, and the Peruvian Pacific coast. We recognize 19 species of Colilargos for South America: *O. andinus*, *O. arenalis*, *O. brendae*, *O. chacoensis*, *O. delicatus*, *O. destructor*, *O. flavescens*, *O. fornesi*, *O. griseolus*, *O. longicaudatus*, *O. magellanicus*, *O. mottogrosae*, *O. messorius*, *O. microtis*, *O. moojeni*, *O. nigripes*, *O. rupestris*, *O. stramineus*, and *O. utiaritensis*. The genus contains four additional species extralimital to the continent, *O. costaricensis*, *O. vegetus*, and *O. fulvescens* in Central America, and *O. victus* from Saint Vincent Island and Martinique in the Lesser Antilles, now probably extinct (Musser and Carleton 2005; Hanson et al. 2011). An undescribed species, also extinct, is reported from Guadeloupe (Lorvelec et al. 2001). The earliest known fossils are from the Ensenadense (middle Pleistocene) in Argentina (Pardiñas et al. 2002).

Species of *Oligoryzomys* are very small (head and body ranges between 70 and 110 mm) cursorial mice. The dorsal pelage is coarsely or homogeneous yellowish to orangish-brown; the ventral pelage is paler (superficially whitish or pale yellow). The fur is soft, without subauricular patches (as in *Microryzomys*, with which *Oligoryzomys* species have been historically confused; see Carleton and Musser 1989).

The hindfeet lack well-developed natatory fringes and interdigital webs, and have short tufts of unguis hairs at bases of claws on digits II through V. The plantar surface is densely covered with distinct squamae distal to thenar pad (the heel is smooth); the hypothenar pad is large, and interdigital pads are small and fleshy (pads 1 and 4 displaced proximally relative to 2 and 3). The claw of digit I extends to the middle of the first phalanx of digit II, and the claw of digit V extends just beyond first interphalangeal joint of digit IV. The tail is usually longer than the combined head and body length, sparsely haired, and covered with more or less conspicuous epidermal scales; it lacks a long tuft of terminal hairs, and is weakly to distinctly bicolored (dark above, pale below). Four pairs of mammae are present in most species, one each in inguinal, abdominal, postaxial, and pectoral positions, except in *O. griseolus* with three pairs.

The skull has a delicate rostrum flanked by moderate zygomatic notches; the interorbital region is symmetrically constricted (hourglass or amphoral in shape), with rounded supra-orbital margins; the braincase is squared or rounded, without well-developed temporal, lambdoidal, or nuchal crests. The zygomatic plates lack an anterodorsal spinous processes, and their posterior margins lie anterior to the M1 alveolus. Jugals are absent or reduced to slivers of bone (maxillary and squamosal processes are in contact). The nasal bones have blunt posterior margins and do not extend posteriorly beyond the lacrimals, which are equally sutured to the maxillary and frontal bones. The posterior wall of the orbit is smooth. The frontosquamosal suture is colinear with the frontoparietal suture, and the parietals lack or have small lateral expansions. The bony palate between the molar rows is smooth and long, and the mesopterygoid fossa does not extend anteriorly between the third molars. The posterolateral palatal pits are variable in size, number, and morphology but are usually not recessed in fossae. The bony roof of the mesopterygoid fossa is perforated by very large sphenopalatine vacuities. The alisphenoid strut is absent (buccinator-masticatory foramen and accessory foramen ovale are confluent), and the alisphenoid canal has a large anterior opening. The stapedial foramen and the posterior opening of the alisphenoid canal are large, but the squamosoalisphenoid groove and the sphenofrontal foramen are absent (carotid circulatory pattern 2 of Voss 1988) in all species except *O. rupestris*, which either lack or have only a vestigial stapedial foramen (= pattern 3). The posterior suspensory process of the squamosal is absent. The postglenoid foramen is large and rounded, and the subsquamosal fenestra is always patent. The periotic is exposed posteromedially between the ectotympanic and the basioccipital, and usually extends anteriorly to the carotid canal. The mastoid is perforated by conspicuous posterodorsal fenestra. In the mandible, the capsular process is well developed in most adults, and the superior and inferior masseteric ridges converge anteriorly as

an open chevron below m1. The basihyal lacks the entoglossal process.

The upper incisors have smoothly rounded enamel bands, and the maxillary toothrows are parallel. The molars are bunodont, with labial flexi enclosed by a cingulum. The labial and lingual flexi of M1 and M2 do not (or shallowly) interpenetrate. The anterocone of M1 is divided into anterolabial and anterolingual conules by a distinct anteromedian flexus; the anteroloph is well developed and separated from the anterocone by a persistent anteroflexus; a protostyle is absent; mesolophs are present on all upper molars in most species, but absent in some specimens of *O. rupestris*; the paracone is connected by an enamel bridge to the anterior moiety of protocone; a median mure is connected to the protocone. The protoflexus of M2 is present in most species; a mesoflexus is present as a single internal fossette; the paracone is without an accessory loph. M3 has a posteroloph; hypoflexus is diminutive (tending to disappear with moderate to heavy wear) in some species, but persistent in others. An accessory labial root of M1 is absent. The anteroconid of m1 is usually without an anteromedian flexid; an anterolabial cingulum is present on all lower molars; the anterolophid is present on m1 but absent on m2 and m3; an ectolophid is absent on m1 and m2 in most species; the mesolophid is distinct on unworn m1 and m2 in most species, but reduced or absent in specimens of *O. mattogrossae*; the posteroflexid is present on m3. Accessory roots are absent for m1, but both m2 and m3 have one large anterior root and one large posterior root.

The stomach is unilocular-hemiglandular (Carleton 1973), and the glandular epithelium does not reach the corpus; the gall bladder is absent. The distal bacular cartilage of the glans penis is large and trifold, with a robust central digit; the nonspinous tissue on rim of the terminal crater does not conceal the bacular mounds.

SYNONYMS:

Mus: Olfers, 1818: 209; part (description of *nigripes*); not *Mus* Linnaeus.

Hesperomys: Waterhouse, 1839:74; part (description of *flavescens*).

Hesperomys (*Calomys*): Wagner, 1843a:528; part (listing of *flavescens* and *longicaudatus*); not *Hesperomys* Waterhouse.

Hesperomys (*Oryzomys*): Milne-Edwards, 1890:27; part (listing of *longicaudatus*); not *Hesperomys* Waterhouse.

Oryzomys: Thomas: 1894b:357; part (description of *stolzmanni*); not *Oryzomys* Baird.

Oligoryzomys Bangs, 1900a:94; type species *Oryzomys navus* Bangs (= *Oligoryzomys delicatus*), by original designation.

Oryzomys (*Oligoryzomys*): J. A. Allen, 1910b:100; name combination.

REMARKS: *Oligoryzomys* was variously considered as a full genus, subgenus, or synonym of *Oryzomys*, and its status as full genus was established only recently (Carleton and Musser 1989). Monophyly of *Oligoryzomys* is supported by phylogenetic analyses of allozymes (Dickerman and Yates 1995), mitochondrial and nuclear gene sequences (Myers et al. 1995; Weksler 2003; Agrellos et al. 2012), and morphological characters (Weksler 2006). The taxonomy of the genus, however, is in much disarray, and comprehensive studies on this widely distributed and specious genus are lacking. The taxonomic arrangement employed here is based on Carleton and Musser (1989), Musser and Carleton (1993, 2005), Bonvicino and Weksler (1998), Weksler and Bonvicino (2005), and Agrellos et al. (2012); it should be viewed as provisional. *Microakodontomys* was included as a junior synonym of *Oligoryzomys* by Weksler et al. (2006), but molecular and genetic data have indicated that this taxon might merit generic recognition (see account of *Microakodontomys transitorius* for additional information).

Carleton and Musser (1989) identified three undescribed species ("sp. A" from Caparaó, "sp. B" from Bolivian and Peruvian Andes, and "sp. C" from the Altiplano of southern Peru). The "sp. A" from Caparaó is identified here as *O. flavescens*, the other two cannot be allocated to any species, despite the karyological data from "sp. B" ($2n=68$, FN=74, A. L. Gardner and Patton 1976). Another undescribed species reported by Agrellos et al. (2012) from the Brazilian state of Amapá and French Guiana, is here considered as *O. messorius* (see that account).

KEY TO THE SOUTH AMERICAN SPECIES OF *OLIGORYZOMYS*:

1. Large opening of stapedial foramen (carotid circulation pattern 2) 2
- 1'. Small or vestigial opening of stapedial foramen (carotid circulation pattern 3); undivided anterocone; endemic to high elevations in central Brazil; $2n=44-46$, FN=52-53. *Oligoryzomys rupestris*
2. With eight mammae 3
- 2'. With six mammae; fur thick and long (length almost 1 cm); found only in the Táchira Andes of Venezuela, and Cordillera Oriental of easternmost Colombia *Oligoryzomys griseolus*
3. Tail shorter, equal or slightly longer than head and body length 4
- 3'. Tail considerably longer than head and body length. 5
4. Ventral color whitish; tail length approximately equal to head and body length; found only south of 45°S in Tierra del Fuego; $2n=54$, FN=56 *Oligoryzomys magellanicus*

- 4'. Ventral color whitish or buffy with perigenital and gular patches of pure white hairs; found in forested habitats in Amazonian basin; $2n=64$, FN=66 *Oligoryzomys microtis*
5. Limit between ventral and dorsal coloration well defined 6
- 5'. Limit between ventral and dorsal coloration scarcely defined or absent 13
6. Ventral coloration creamy or yellowish white 7
- 6'. Ventral coloration whitish 9
7. Tail clearly bicolored on proximal half 8
- 7'. Tail unicolored, slightly bicolored near the base; dorsal color reddish brown; found in the Andes at elevations between 600–3,350 m; $2n=60$, FN=76 *Oligoryzomys destructor*
8. Dorsal color pale ochraceous darkened by numerous fine dusky lines, head color grayish; found in Andes; $2n=60$, FN=70 *Oligoryzomys andinus*
- 8'. Dorsal color fawn-colored or pale rufous, head color similar to body color; distributed along eastern and western flanks of Andes in Chile and Argentina; $2n=56$, FN=66 *Oligoryzomys longicaudatus*
9. Orange or yellowish pectoral band present 10
- 9'. Pectoral band absent 11
10. Smaller zygomatic plate, darker overall dorsal coloration, head color similar to body color; found in eastern Brazil, Paraguay, Uruguay, and Argentina; $2n=62$, FN=82 *Oligoryzomys nigripes*
- 10'. Larger zygomatic plate, paler overall dorsal coloration, head color gray, especially in sides; endemic to central and northeastern Brazil; $2n=52$, FN=68 *Oligoryzomys stramineus*
11. Hair on skin and throat regions with gray base; distinctive tufts of orangish hairs anterior to the ears absent. 12
- 11'. Hair on skin and throat regions all white, including on the base; distinctive tufts of orangish hairs anterior to the ears present; occurs in northern Argentina, eastern Bolivia, southwestern Brazil, and Paraguay; $2n=58$, FN=74 *Oligoryzomys chacoensis*
12. Tail unicolored or slightly bicolored; $2n=72$, FN=76 *Oligoryzomys utiaritensis*
- 12'. Tail sharply bicolored; $2n=58$, FN=74 *Oligoryzomys brendae*
13. Dorsal coloration darker or orangish brown 14
- 13'. Dorsal coloration clay-colored; found only in hydro-morphic vegetation patches in arid and semiarid coastal plains of Peru *Oligoryzomys arenalis*
14. Dorsal coloration grayish, ventral coloration whitish with large gray basal band; found in montane regions of northernmost Brazil, southern Venezuela, and Guyana; $2n=66$, FN=74 *Oligoryzomys messorius*
- 14'. Dorsal coloration orangish brown or dark brown, ventral coloration buffy or cream 15
15. Smaller incisive foramen, never extending posteriorly beyond alveolar line of M1 16
- 15'. Longer incisive foramen, extending posteriorly beyond alveolar line of M1; $2n=64-66$, FN=66–68 *Oligoryzomys flavescens*
16. Very small size, head and body length <85 mm. 17
- 16'. Small size, head and body >84 mm; $2n=70$, FN=74 *Oligoryzomys moojeni*
17. Dorsal pelage strongly lined with dark hairs, general heterogeneous coloration, head color gray 18
- 17'. Dorsal pelage coloration homogeneous, head color similar to the body color, orange hair around the nose; sides lack guard hairs; distributed in northern South America, $2n=60$, FN=74 *Oligoryzomys delicatus*
18. Distributed in Brazil and Paraguay (and possibly Bolivia); $2n=62$, FN=64 *Oligoryzomys mottogrossae*
- 18'. Restricted to Formosa province, Argentina *Oligoryzomys fornesi*
- Oligoryzomys andinus* (Osgood, 1914)
- Andean Colilargo**
- SYNONYMS:
- Oryzomys andinus* Osgood, 1914b:156; type locality "Hacienda Llagueda [= Llaugueda, Stephens and Traylor 1983], upper Rio Chicama, [Libertad,] Peru. Altitude 6,000 ft."
- Oligoryzomys andinus*: Gyldenstolpe, 1932a:29; first use of current name combination.
- DESCRIPTION: Medium-sized mouse allied to *O. destructor* but with longer hindfoot and very long tail. Coloration of upper parts pale ochraceous darkened by numerous fine dusky lines; slight ochraceous lateral line present; face and head somewhat grayish; and under parts creamy white, sharply differentiated, hairs with slaty bases. Ears thinly haired with ochraceous basally and internally, brownish distally and externally. Dorsal surfaces of both forefeet and hindfeet white. Tail thinly clothed with very short hairs, brownish above, whitish below for proximal half, gradually becoming dusky toward tip. Skull similar in general form to that of *O. destructor* but relatively narrower with smaller teeth and bullae; incisive foramina compressed; braincase angled and truncate rather than rounded behind; and interorbital region at base of nasals slightly concave between sharply angled edges.
- DISTRIBUTION: *Oligoryzomys andinus* occurs on the dry Pacific slopes of the Peruvian Andes and the western margins of the Altiplano of Peru and Bolivia, between 1,700 and 4,000 m. An isolated population occurs in the eastern Peruvian Andes in Cusco department (Carleton and Musser 1989). The precise distributional limits of this species are unknown (Musser and Carleton 2005).

Map 219 Selected localities for *Oligoryzomys andinus* (●). Contour line=2,000 m.

SELECTED LOCALITIES (Map 219; from Carleton and Musser 1989, except as noted): BOLIVIA: Oruro, 1 km W of Huancaroma; Potosí, 31 km SW Acacio on road to Uncia (S. Anderson 1997), 3 km SE of Pocoata. PERU: Ancash, 1 km N and 12 km E of Pariacoto; Callon, 2 km S and 11 km W of Huarás; Cusco, 94 km W of Cuzco on road to Abancay; La Libertad, Hacienda Llaugueda (type locality of *Oryzomys andinus* Osgood); Lima, below Huaros, 6.3 mi W of Casapalca, Zarate, 6 km E of Pueblo San Bartolomé; Piura, Porculla Pass.

SUBSPECIES: *Oligoryzomys andinus* is monotypic.

NATURAL HISTORY: *Oligoryzomys andinus* is used as prey by the Barn Owl (*Tyto alba*) in Bolivia (S. Anderson 1997). No other aspect of ecology, behavior, reproductive biology, or other life history attributes is known.

REMARKS: Samples of this species used in morphometric (Olds and Anderson 1987:269) and allozyme analyses (Dickerman and Yates 1995:188) were misidentified as *Oryzomys longicaudatus* and *Oligoryzomys destructor*, respectively. The karyotype of *Oligoryzomys andinus* is characterized by $2n=60$ and $FN=70$ (A. L. Gardner and Patton 1976). The species was recorded sympatrically with *O. arenalis* in Lima department, Peru (Arana-Cardó and Ascorra 1994, in Musser and Carleton 2005).

Oligoryzomys arenalis Thomas, 1913

Sandy Colilargo

SYNONYMS:

Oryzomys arenalis Thomas, 1913c:571; type locality "Eten [= Etén]; sea-level," Lambayeque, Peru.

Oligoryzomys arenalis: Gyldenstolpe, 1932a:27; first use of current name combination.

DESCRIPTION: Smaller than any allied species. General dorsal color clay over underlying buffy, lined with dark brown; head slightly grayer and less buffy; sides buffy, with somewhat buffy line separating dorsal from ventral pelage; under surfaces creamy white, with slight buffy tint and with slaty bases to hairs; ear only slightly darker than dorsum; chin white; dorsal surfaces of forefeet and hindfeet white; tail long and bicolored, brown above and creamy white below. Skull similar to but smaller than that of *O. destructor*; zygomatic plates well developed and projecting forward; braincase not especially enlarged; interorbital space narrow, narrow part long and evenly curved, not especially divergent posteriorly, and supraorbital edges sharply square.

DISTRIBUTION: *Oligoryzomys arenalis* is found in the arid and semiarid coastal plains of Peru (Musser and Carleton 2005).

SELECTED LOCALITIES (Map 220): PERU: Arequipa, Atiquipa (Zeballos et al. 2000), Lomas, 7 km E of Matarani (MVZ 150165); Cajamarca, 35 mi WNW of

Map 220 Selected localities for *Oligoryzomys arenalis* (●). Contour line=2,000 m.

Cajamarca (MVZ 137918); La Libertad, Menocucho (FMNH 19422), Pacasmayo (Osgood 1914b), Trujillo (Osgood 1914b); Lambayeque, Etén (type locality of *Oryzomys arenalis* Thomas); Lima, Matucana (FMNH 53058); Piura, 15 km by road E of Canchaque (LSUMZ 19261), Faique, Los Potreros (FMNH 84442), Palambla (AMNH 63712), 33 road km SW of Huancabamba, W slope (LSUMZ 19256).

SUBSPECIES: *Oligoryzomys arenalis* is monotypic.

NATURAL HISTORY: *Oligoryzomys arenalis* is a rare species with an insectivorous-granivorous diet (Zeballos et al. 2000). This species is found in the dry coast of Peru in hydromorphic vegetation patches close to rivers and lagoons, at the edges of small swamps or irrigating ditches (Osgood 1914b), but it is not found in gallery forest (H. Zeballos, pers. comm.).

REMARKS: *Oligoryzomys arenalis* was recorded sympatrically with *O. andinus* in Lima department (Arana-Cardó and Ascorra 1994, in Musser and Carleton 2005).

Oligoryzomys brendae Massoia, 1998
San Javier's Colilargo

SYNONYM:

Oligoryzomys brendae Massoia, 1998:243; type locality "Cerro San Javier, Dpto. Tafí Viejo (aprox. 1000m. de altura)," Tucumán, Argentina.

DESCRIPTION: Size large for genus (mean head and body length 89.7 mm; tail length 126.0 mm; hindfoot length [with claw] 26.5 mm; condyloincisive length of skull 22.9 mm; maxillary toothrow length 3.9 mm); dorsal color orangish brown, somewhat grizzled in appearance; ventral hairs with gray bases and white to ochraceous tips; ears short (mean 18.2 mm in length), rounded, and dark brown; and tail longer than head and body (140% of length), sharply bicolored. Skull relatively robust with short, broad rostrum; well-expanded zygomatic arches; inflated and broad braincase; narrow and hourglass-shaped interorbital region with slightly defined supraorbital ridges; and relatively long incisive foramina extending anterior margins of M1s (emended diagnosis from Teta, Jayat et al. 2013).

DISTRIBUTION: *Oligoryzomys brendae* is found mainly in forested and highland grassland environments of the Yungas from northernmost Salta province southward to Catamarca province, Argentina, between 700 and 2,900 m. It extends farther to the south in La Rioja province where it is restricted to isolated humid ravines at the ecotone between the xeric Chaco Seco and Monte desert formations (Teta, Jayat et al. 2013).

SELECTED LOCALITIES (Map 221; from Teta, Jayat et al. 2013, except as noted): ARGENTINA: Catamarca, Las Chacritas, ca. 28 km NNW of Singuil, Las Juntas (MIC 203), Mogote Las Trampas, ca. 15 km NW of Chumbicha;

Jujuy, ca. 3 km S Bárcena, La Herradura, 12 km SW of El Fuerte, Quyeграда Alumbriojo, ca. 8 km NE of Santa Ana, Parque Nacional Calilegua; La Rioja, Pampa de la Viuda, km 19 Rte 73; Salta, El Corralito, ca. 25 km SW of Campo Quijano, 1.6 km W of Los Toldos, Metán (CML-PIDBA 986); Tucumán, Alberdi, ca. 10 km S of Hualinchay, Cerro San Javier (type locality of *O. brendae*).

SUBSPECIES: *Oligoryzomys brendae* is monotypic.

NATURAL HISTORY: Published information on the natural history of this species is lacking.

REMARKS: Recent phylogenetic analyses of mtDNA sequences (Gonzalez-Ittig et al. 2010; Palma et al. 2010; Teta, Jayat et al. 2013) suggested that *O. brendae* is a member of a *destructor* species group, and we recognize it as a valid species based on these data. Nevertheless, both the taxonomic status and geographic distribution of *brendae* needs to be re-evaluated in a comprehensive revision of *destructor* species group, particularly with respect to those southern Bolivian specimens from Potosi and Tarija departments assigned herein to *O. destructor* (see also Teta, Jayat et al. 2013). Palma et al. (2010) considered *brendae* as a *nomen nudum* because Massoia's work was published in a meeting presentation. However, we agree with Musser and Carleton (2005) that *brendae* is a valid name because the International Code of Zoological Nomenclature (ICZN 1985, 1999) does not exclude this type of publication as valid. Furthermore, although the description is very short, it contains all formal requirements, such as holotype and

Map 221 Selected localities for *Oligoryzomys brendae* (●). Contour line = 2,000 m.

type locality designations, and comparisons to other species. Selected localities are from Gonzalez-Irtig et al. (2010; specimens identified as *O. destructor*); Palma et al. (2010; specimens identified as *Oligoryzomys* sp.1), and Teta, Jayat et al. (2013), who recently reviewed this species. Specimens with a $2n=58$, FN=74 karyotype described by Espinosa and Reig (1991) as *Oligoryzomys* cf. *longicaudatus* belong to *O. brendae* (see Teta, Jayat et al. 2013).

Oligoryzomys chacoensis (Myers and Carleton, 1981)

Chacoan Colilargo

SYNONYMS:

Oryzomys (*Oligoryzomys*) *chacoensis* Myers and Carleton, 1981:19; type locality “419 km by road NW Villa Hayes (alongside the Trans Chaco Highway), Dept. Boquerón, Paraguay.”

Oligoryzomys chacoensis: Carleton and Musser, 1989: 72; first use of current name combination.

DESCRIPTION: Medium sized, distinguished from congeners by combination of whitish under parts, with hairs white to base on chin and throat, relatively long ears with hairs on inner surface with unusually short or absent dark basal bands, small but distinctive tufts of orange hairs anterior to ears, and karyotype with $2n=58$, FN=74.

DISTRIBUTION: *Oligoryzomys chacoensis* occurs in the Cerrado, Chaco, and semidry forests of northern Argentina, eastern Bolivia, southwestern Brazil, and Paraguay (Weksler and Bonvicino 2005).

SELECTED LOCALITIES (Map 222): ARGENTINA: Formosa, Riacho Pilagá (USNM 236243); Jujuy, San Salvador (INEVH [JY 1332]); Salta, Orán (INEVH [OR 22498]). BOLIVIA: Chuquisaca, Porvenir (AMNH 262120); Santa Cruz, 7km E and 3km N of Ingeniero Mora (AMNH 247769), San Ignacio de Velasco (USNM 391524); Tarija, Entre Rios (USNM 271412), Taringuiti (Weksler and Bonvicino 2005). BRAZIL: Mato Grosso, Cáceres (USNM 390126); Mato Grosso do Sul, Corumbá, 10km NE Urucum (USNM 390124). PARAGUAY: Alto Paraguay, Agua Dulce (Weksler and Bonvicino 2005); Boquerón, Fortín Guachalla (Weksler and Bonvicino 2005), Fortín Teniente Pratts Gil (Weksler and Bonvicino 2005), 419 km by road NW of Villa Hayes (type locality of *Oryzomys* [*Oligoryzomys*] *chacoensis* Myers and Carleton); Presidente Hayes, Estancia Laguna Porá (Weksler and Bonvicino 2005), 8 km NE of Juan de Zalar (UMMZ 134358), Puerto Pinasco (USNM 236293).

SUBSPECIES: *Oligoryzomys chacoensis* is monotypic.

NATURAL HISTORY: Specimens of *O. chacoensis* have been caught in bushes and low trees in the Paraguayan Chaco (Myers and Carleton 1981); the same authors reported an average of 4.6 embryos (range: 2–5) in 10 pregnant females from Paraguay, and suggested that reproduction occurred in January, February, July, with few births

Map 222 Selected localities for *Oligoryzomys chacoensis* (●). Contour line=2,000m.

in June (winter). S. Anderson (1997) reported two females with three embryos each, and one with five embryos, from Bolivia. Andean and Bermejo hantaviruses are associated with *O. chacoensis* (González Della Valle et al. 2002; Fulhorst et al. 2004).

REMARKS: Thomas (1925b:578) referred to specimens of this species as *Oryzomys* sp., *flavescens* group. The karyotype of *O. chacoensis* is characterized by $2n=58$, FN=74 (Myers and Carleton 1981). Two specimens from northeastern Brazil (USNM 528416, 304583) identified by Carleton and Musser (1989) as *O. chacoensis* are actually *O. stramineus* (see Bonvicino and Weksler 1998). The distribution of *O. chacoensis* given by Weksler and Bonvicino (2005) mistakenly included specimens from Tucumán and Jujuy provinces, Argentina, as *O. chacoensis* based on a wrong interpretation of karyotype provided by Espinosa and Reig (1991); these specimens are herein considered as *O. brendae* (see that account).

Oligoryzomys delicatus (J. A. Allen and Chapman, 1897)

Delicate Colilargo

SYNONYMS:

Oryzomys delicatus J. A. Allen and Chapman, 1897a:19; type locality “Caparo, Trinidad,” Trinidad and Tobago.

Oryzomys navus Bangs, 1899:9; type locality “Pueblo Viejo [= El Pueblito; Paynter 1997], Sierra Nevada de Santa Marta, [La Guajira,] Colombia. Altitude, 8000 feet.”

Oryzomys tenuipes J. A. Allen, 1904b:328; type locality “Merida (alt. 1630 m.), [Mérida,] Venezuela.”

Oryzomys (Oligoryzomys) munchiquensis J. A. Allen, 1912:85; type locality “La Florida (alt. 7700 ft.),” Cauca, Colombia.

Oligoryzomys navus navus: Gyldenstolpe, 1932a:27; name combination.

Oligoryzomys delicatus: Gyldenstolpe, 1932a:28; first use of current name combination.

Oligoryzomys tenuipes: Gyldenstolpe, 1932a:28; name combination.

Oligoryzomys munchiquensis: Gyldenstolpe, 1932a:28; name combination.

Oligoryzomys delicatulus Tate, 1939:191; incorrect subsequent spelling of *Oryzomys delicatus* J. A. Allen and Chapman.

Oryzomys delicatus navus: Cabrera, 1961:388; name combination.

Oryzomys delicatus tenuipes: Cabrera, 1961:389; name combination.

Oligoryzomys fulvescens: Carleton and Musser, 1989:70; part, specimens from northern South America.

DESCRIPTION: Small with yellowish brown fur above, darker and more rufous brown medially, mixed sparingly with blackish-tipped hairs; rump clear yellowish rufous; sides paler, yellowish buff; under parts clear buff; legs like adjoining parts of body; and dorsal surfaces of both forefeet and hindfeet yellowish white.

DISTRIBUTION: *Oligoryzomys delicatus* is distributed in South America throughout Colombia, northernmost Ecuador, northern Venezuela, and Trinidad and Tobago, and the coastal region of the Guianas. In Venezuela and the Guianas, the species is limited to coastal lowlands and llanos.

SELECTED LOCALITIES (Map 223): COLOMBIA: Cauca, Almaguer (AMNH 33860), Cocal (AMNH 32600); Cundinamarca, Paime (AMNH 71367); Huila, La Palma (AMNH 33858), near Villavieja (MVZ 113373); La Guajira, San Miguel (AMNH 38920); Magdalena, Palomino (AMNH 38917); Meta, 7 km NE of Villavicencio (AMNH 207936), Puerto López (ROM 90530); Quindio, Salento (AMNH 32925); Valle del Cauca, Pichindé (USNM 483980). ECUADOR: Napo, Santa Cecilia (KU 112879). SURINAM: Paramaribo, Paramaribo (USNM 319970). TRINIDAD AND TOBAGO: Trinidad, Caparo (type locality of *Oryzomys delicatus* J. A. Allen and Chapman), Nariva, Nariva Swamp (AMNH 189372). VENEZUELA: Apure, Hato El Frio (AMNH 257241); Aragua, Rancho Grande Biological Station (USNM 517581); Falcón, Río Socopo, 80 km NW Carora (USNM 442175); Guárico,

Hato Las Palmitas (USNM 442154); Lara, near El Tocuyo (USNM 495473); Mérida, Mérida (type locality of *Oryzomys tenuipes* J. A. Allen), Timotes (USNM 270814); Miranda, Río Chico (USNM 387881); Monagas, Hato Mata de Bejucó (USNM 442192), San Agustín (USNM 416707); Portuguesa, La Arenosa (AMNH 269143); Sucre, Cumaná, 2 km E (USNM 406024), Manacal (USNM 409911); Yaracuy, near Urama (USNM 374693); Vargas, Los Venados (USNM 371167); Zulia, near Cerro Azul (USNM 442176).

SUBSPECIES: Cabrera (1961) regarded three of the names we list above in the synonymy of *O. delicatus* as valid subspecies (*navus* Bangs and *tenuipes* J. A. Allen, in addition to the nominotypical form), with another considered a valid species (*munchiquensis* J. A. Allen). However, because none of these taxa have been evaluated, we believe it is premature to comment on the validity of any names as recognizable geographic races.

NATURAL HISTORY: *Oligoryzomys delicatus* was one of the most frequently captured rodents of the Llanos of Venezuela, being trapped in *Paspalum* savanna and lowland savanna (Utrera et al. 2000, as *O. fulvescens*). This species is a natural host of Maporal hantavirus in Venezuela (Bayard et al. 2004; Fulhorst et al. 2004; Hanson et al. 2011).

REMARKS: We recognize *O. delicatus* as a valid species distinct from *O. fulvescens* based on phylogenetic assessments of Rogers et al. (2009) and Hanson et al. (2011), which show that *Oligoryzomys* specimens from northern South America (i.e., *O. delicatus*) form a clade separate from *O. fulvescens* from Mexico and Honduras. Therefore, we considered most taxa from South America previously treated as junior synonyms of *O. fulvescens* (e.g., Musser and Carleton, 2005) as belonging to *O. delicatus*, with *O. fulvescens* restricted to Mexico and Central America. We note, however, that neither Hanson et al. (2011) nor we have examined relevant type material to support of

Map 223 Selected localities for *Oligoryzomys delicatus* (●). Contour line = 2,000 m.

this taxonomic arrangement. Karyotypes of *O. delicatus* are reported as $2n=62$, $FN=74$, 76 (Venezuela, Bolívar, as *Oryzomys* [*Oligoryzomys*] *longicaudatus*, variant 3, A. L. Gardner and Patton 1976) and $2n=60$, $FN=72$ (as *O. fulvescens* from Miranda, Venezuela [Kiblicky 1969] and Surinam [R. J. Baker et al. 1983]). We also recognize *O. messorius*, listed as a subspecies of *O. delicatus* by Cabrera (1961), as a valid species based on the distinct karyotype and morphology of specimens from Mt. Roraima and elsewhere in southern Guyana (see that account), and phylogenetic results (G. B. Miranda et al. 2009; Agrellos et al. 2012).

Oligoryzomys destructor (Tschudi, 1844)

Tschudi's Colilargo

SYNONYMS:

Hesperomys destructor Tschudi, 1844:182; type locality "im Oststriche" (= east region), Peru; restricted by Cabrera, 1961:390 to "las haciendas junto al río Chinchao, departamento de Huánuco, entre los 900 y los 1000 m de altitude" based on Hershkovitz (1940a:81).

Hesperomys melanostoma Tschudi, 1844:182; type locality "im Oststriche" (= east region), Peru; restricted by Cabrera, 1961:393 to "Departamento de Huánuco" based on Hershkovitz (1940a:81).

Oryzomys stolzmanni Thomas, 1894b:357; type locality "Huambo, [Amazonas,] N. Peru, 3700 feet."

Oryzomys destructor: E.-L. Trouessart, 1897:528; name combination.

Oryzomys melanostoma: E.-L. Trouessart, 1897:528; name combination.

Oryzomys stolzmanni maranonicus Osgood, 1914b:155; type locality "Hacienda Limon [= Hacienda Limón], near Balsas, Marañon River," upper Río Marañón, Cajamarca, Peru.

Oryzomys longicaudatus destructor: Thomas, 1928b:261; name combination.

Oryzomys (*Oligoryzomys*) *destructor*: Tate, 1932f:9; name combination.

Oryzomys (*Oligoryzomys*) *stolzmanni stolzmanni*: Tate 1932f:10; name combination.

Oligoryzomys stolzmanni: Gyldenstolpe, 1932a:28; name combination.

Oligoryzomys minutus maranonicus: Gyldenstolpe, 1932a:29; name combination.

Oryzomys (*Oligoryzomys*) *spodiurus* Hershkovitz, 1940a:79; type locality "Hacienda Chinipamba near Peñaherrera, Intag, in the subtropical forest of the western slope of the western cordillera of the Andes, Imbabura Province, Ecuador. Altitude, about 1500 meters."

Oryzomys (*Oligoryzomys*.) *longicaudatus destructor*: Hershkovitz, 1940a:81; name combination.

Oryzomys (*Oligoryzomys*.) *longicaudatus stolzmanni*: Hershkovitz, 1940a:81; name combination.

Oryzomys stolzmanni stolzmanni: Sanborn, 1950:2; name combination.

Oryzomys longicaudatus maranonicus: Cabrera, 1961:391; name combination.

Oryzomys longicaudatus stolzmanni: Cabrera, 1961:392; name combination.

Oryzomys spodiurus: Cabrera, 1961:395; name combination.

Oligoryzomys destructor: Carleton and Musser, 1989:73; first use of current name combination.

DESCRIPTION: Upper body reddish brown, interspersed with numerous black hairs and some gray with light tips; sides of body and outer part of hindlimbs reddish yellow; hair color behind ears lighter, while on head black hair more frequent; throat and chest whitish gray, while belly yellowish white; dorsal surfaces of feet covered by short silver-gray hair, with hairs of nail base very long; soles light brown, and nails are yellowish brown; tail brown and slightly shorter than the head and body length; internal ear surfaces with short, light brown hair, external surface covered with longer, blackish hairs; vibrissae black on basal-half and white toward tip; nose hair silver white.

DISTRIBUTION: *Oligoryzomys destructor* occurs in the Andes from southernmost Colombia to Bolivia, through Ecuador (on both eastern and western slopes) and Peru (eastern slopes and Amazonian drainage), over an elevational range from 600 to 3,350 m (Carleton and Musser 1989).

SELECTED LOCALITIES (Map 224): ARGENTINA: Jujuy, San Salvador (Rivera et al. 2007); Salta, Metán (Rivera et al. 2007); Tucumán, Monteros (OMNH 18656). BOLIVIA: Chuquisaca, Tola Orko (S. Anderson 1997); Cochabamba, Incachaca (S. Anderson 1997); La Paz, La Reserva (S. Anderson 1997), Ñequejahuira (S. Anderson 1997), Sorata (S. Anderson 1997), Ticunhuaya (S. Anderson 1997); Oruro, Poopo (S. Anderson 1997); Potosí, Tupiza (S. Anderson 1997); Santa Cruz, 1 km N and 8 km W of Comarapa (S. Anderson 1997), Vallegrande (S. Anderson 1997); Tarija, Tarija, 3 km SE of Cuyambuyo (S. Anderson 1997). COLOMBIA: Nariño, Ricaurte (AMNH 34233). ECUADOR: Chimborazo, Pallatanga (Carleton and Musser 1989); El Oro, Pinas (AMNH 61356); Loja, Puyango, Alamor (AMNH 61358); Pichincha, Gualea (AMNH 36297), Mojanda region (Carleton and Musser 1989), near Mount Illiniza (Carleton and Musser 1989); Zamora-Chinchi, Zamora (AMNH 60546). PERU: Amazonas, 6 road km SW of Lake Pomacochas (LSUMZ 19265), Uscho (AMNH 73197); Apurímac, 10 km SSE of Abancay (MVZ 115650); Ayacucho, Huanhuachayo (A. L. Gardner and Patton 1976); Cajamarca, Hacienda

Limón (type locality of *Oryzomys stolzmanni maranonicus* Osgood); Cusco, directly below Marcapata (LSUMZ 19252), Bosque Aputinye above Huyro (LSUMZ 19285); Huánuco, E slope Cordillera Carpish, Carretera Central (LSUMZ 14361), Río Chinchao (type locality of *Hesperomys destructor* Tschudi); Junín, near San Ramón, 22 mi E of Tarma (AMNH 231676), Perené (AMNH 61817); Puno, 3 mi N of Limbani (MVZ 116065), 11 km NNE of Ollachea (MVZ 172610), 14 km W of Yanahuaya (MVZ 173423).

SUBSPECIES: Several subspecies have been recognized in the literature (Hershkovitz 1940a; Cabrera 1961), but the validity of these must wait an appropriate evaluation of geographic variation based on adequate samples of museum specimens.

NATURAL HISTORY: Most Bolivian records of *O. destructor* are from the Yungas forests (S. Anderson 1997:394). Three pregnant females were recorded from Bolivia in May and April with three, four, and five embryos each (S. Anderson 1997). Recorded ectoparasites include

the mites *Gigantolaelaps wolffsohni*, *Laelaps paulistanensis*, and *Mysolaelaps microspinosus*, and the flea *Craneopsylla minerva* (Lareschi et al. 2003).

REMARKS: The karyotype of *O. destructor* is characterized by $2n=60$ and $FN=76$ (A. L. Gardner and Patton 1976, as *Oryzomys (Oligoryzomys) longicaudatus*, variant 4). Olds and Anderson (1987), in their review of *Oligoryzomys*, included specimens of this species under *O. longicaudatus*. Both the taxonomy and distributional limits are poorly understood (Musser and Carleton 2005:1140).

Oligoryzomys flavescens (Waterhouse, 1837)

Flavescent Colilargo

SYNONYMS:

Mus flavescens Waterhouse, 1837:19; type locality "Maldonado," Maldonado, Uruguay.

Hesperomys flavescens: Waterhouse, 1839:74; name combination.

H[esperomys]. (*Calomys flavescens*: Wagner, 1843a:530; name combination.

Oryzomys longicaudatus flavescens: E.-L. Trouessart, 1897:527; name combination.

Oryzomys flavescens: Thomas, 1926d:603; name combination.

Oryzomys flavescens: J. R. Contreras and Rosi, 1980a:157; first use of current name combination.

Oligoryzomys flavescens occidentalis J. R. Contreras and Rosi, 1980a: 158; type locality "Colonia Alto del Algarrobal, Departamento San Rafael, Provincia de Mendoza," Argentina.

Oligoryzomys flavescens antoniae Massoia, 1983; type locality "República Argentina, provincia de Misiones, departamento de Capital, arroyo Itaembé Mini, debajo del puente sobre la Ruta Nacional N° 12."

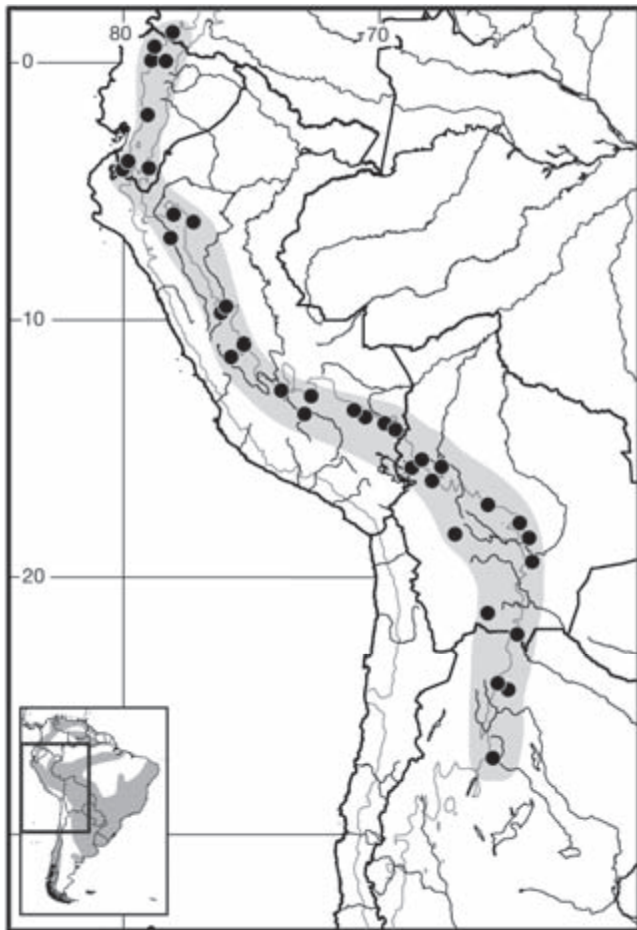

Oligoryzomys microtis: Carleton and Musser, 1989:71; part; not *Oryzomys (Oligoryzomys) microtis* J. A. Allen.

Oligoryzomys sp. A: Carleton and Musser, 1989:72; name combination.

DESCRIPTION: Small species characterized by dorsal color bright brownish-orange finely intermixed with dark hairs and lateral color of brighter orange. Skull with long incisive foramina that usually reach M1s, and short mesopterygoid fossa that does not reach M3s.

DISTRIBUTION: *Oligoryzomys flavescens* occurs in northern Argentina, eastern Paraguay, throughout Uruguay, and eastern Brazil, from sea level to about 1,800 m (Bonvicino et al. 1997).

SELECTED LOCALITIES (Map 225; from Weksler and Bonvicino 2005, except as noted): ARGENTINA: Buenos Aires, Balcarce, Berazategui, Diego Gaynor, Ezeiza, Punta Lara, General Lavalle, Monte Hermoso; Córdoba, Río Cuarto;

Map 224 Selected localities for *Oligoryzomys destructor* (●). Contour line = 2,000 m.

Jujuy, Maimará; Misiones, Arroyo Itaembé Mini (type locality of *Oligoryzomys flavescens antonia* Massoia); Tucumán, Concepción. BOLIVIA: Tarija, Tarija. BRAZIL: Bahia, Rio Una, 10km ESE of São José; Minas Gerais, Itamonte, Viçosa; Paraná, Piraquara, Ponta Grossa; Rio Grande do Sul, Esmeralda, Sapiranga, Taím, Tôrres; Santa Catarina, Itá (MNRJ [CRB 1932]); São Paulo, Americana, Caçapava, Casa Grande. PARAGUAY: Canendiyú, 6.3 km by road N of Curuguaty (Myers and Carleton 1981); Misiones, San Pablo; Presidente Hayes, La Golondrina. URUGUAY: Artigas, Artigas; Colonia, Colonia del Sacramento; Maldonado, Maldonado (type locality of *Mus flavescens* Waterhouse); Montevideo, Montevideo; Río Negro, Fray Bentos.

SUBSPECIES: Musser and Carleton (2005) regarded *Oligoryzomys flavescens* to be monotypic.

NATURAL HISTORY: *Oligoryzomys flavescens* is found in the Pampas, Chaco, Atlantic Forest (pristine and second-growth communities), and gallery forests in the Cerrado near the limits with Atlantic Forest. This species is also found along cropland borders in Argentina (M. Busch and Kravetz 1992). Population levels of *O. flavescens* dramatically increased during the flowering of *taquara-lixia* bamboo (*Merostachys skvortzovii*) in a possible *ratada* event (Galiano et al. 2007). Ectoparasites of *O. flavescens* include the mites *Gigantolaelaps wolffsohni*, *Laelaps paulistanensis*, and *Mysolaelaps microspinosus*, and the sucking louse *Hoplopleura travassosi* (Lareschi et al. 2003; Lareschi, 2010). This species is also the principal carrier of the Andean hantavirus in northern Argentina (Gonzalez Della Valle et al. 2002), and

Map 225 Selected localities for *Oligoryzomys flavescens* (●). Contour line=2,000 m

is a natural host of the Lechiguanas hantavirus in both Argentina and Uruguay (Fulhorst et al. 2004).

REMARKS: The basic chromosomal complement of *Oligoryzomys flavescens* is $2n=64$, $FN=66$, but its diploid and fundamental numbers are variable ($2n=64-67$, $FN=66-70$) due to the presence of acrocentric or metacentric supernumerary chromosomes (Espinosa and Reig 1991; Sbalqueiro et al. 1991). Myers and Carleton (1981) erroneously regarded their specimens with this karyotype to be *Oligoryzomys fornesi* (here recognized as *O. matogrossae*; see that account).

Oligoryzomys fornesi (Massoia, 1973)

Fornes's Colilargo

SYNONYM:

Oryzomys fornesi Massoia, 1973a:22; type locality "Ceibo 13, Nainneck, Departamento de Río Pilcomayo, provincia de Formosa, República Argentina."

DESCRIPTION: Another small species with small and pale ears covered on outer surface with ochre hairs, orangish brown or grayish brown dorsal pelage, with paler venter varying from pale ochre to yellowish white.

DISTRIBUTION: By current understanding, *O. fornesi* is limited to the vicinity of the type locality in Argentina.

SELECTED LOCALITIES (Map 226): ARGENTINA: Formosa, near Laguna Blanca (CEM 3436), Nainneck (type locality of *Oryzomys fornesi* Massoia).

Map 226 Selected localities for *Oligoryzomys fornesi* (●). Contour line=2,000 m.

SUBSPECIES: *Oligoryzomys fornesi* is monotypic.

NATURAL HISTORY: *Oligoryzomys fornesi* has been collected in open vegetation areas used as pasture for domestic livestock; numerous nests were found in banana trees (Massoia 1973a).

REMARKS: The taxonomic status of this species needs to be reassessed in relation to *O. mottogrossae*, with particular attention paid to study of the type specimen. See Remarks for *O. mottogrossae*.

Oligoryzomys griseolus (Osgood, 1912)

Grizzled Colilargo

SYNONYMS:

Oryzomys griseolus Osgood, 1912:49; type locality “Paramo de Tama, head of Tachira River, Venezuela. Alt. 6,000–7,000 ft.”

Oligoryzomys griseolus: Gyldenstolpe, 1932a:27; first use of current name combination.

Oryzomys delicatus griseolus: Cabrera, 1961:388; name combination.

DESCRIPTION: Overall ground color of upper parts pale clay, much duller than ochraceous or ochraceous buff of related forms, with abundant mixture of black-tipped hairs producing somewhat grizzled effect which is most pronounced on forehead and sides of face with fulvous minimized and gray predominates; small preauricular tuft of ochraceous-tipped hairs usually present; under parts mostly between clay color and ochraceous buff, almost or quite concealing slaty bases of hairs; middle of chin and throat white or whitish to bases of hairs; forefeet and hindfeet white above, with outer sides of tarsal joints dusky; tail bicolored, dusky above and dull whitish below. Only three pairs of mammae present. Skull with slender rostrum, well-developed zygomatic plates project forward farther than in related forms, and elongated incisive foramina that extend posteriorly beyond plane of M1s.

DISTRIBUTION: *Oligoryzomys griseolus* occurs in the Táchira Andes of westernmost Venezuela and in the Cordillera Oriental of easternmost Colombia (Musser and Carleton 2005).

SELECTED LOCALITIES (Map 227): VENEZUELA: Táchira, Buena Vista, 41 km SW of San Cristóbal (USNM 442155), Páramo de Tamá (type locality of *Oryzomys griseolus* Osgood), Buena Vista (USNM 442155).

SUBSPECIES: *Oligoryzomys griseolus* is monotypic.

NATURAL HISTORY: Specimens comprising the type series were collected in a small grassy swamp (Osgood 1912); others were found in lower montane very humid forest (Handley 1976).

REMARKS: No karyotypic data are available. Osgood (1912) and Musser and Carleton (2005) stated that *O. griseolus* sharply contrasts with *O. fulvescens* and resembles

Map 227 Selected localities for *Oligoryzomys griseolus* (●). Contour line = 2,000 m.

Central American *O. vegetus*, especially “in the extent of white on the throat and in the forwardly projecting zygomatic plate” (Osgood 1912:50). In the description of the species, Osgood (1912) stated that *O. griseolus* had six pairs of mammae, but all *Oligoryzomys* species examined to date have eight pairs (Steppan 1995; Weksler 2006); the only Oryzomyini taxa with six mammae are *Handleyomys* and *Scolomys* (Patton and da Silva 1995; Voss et al. 2002; Weksler 2006). A recent examination of the type series (B. D. Patterson, pers. comm.) confirms Musser and Carleton’s (2005) assignment of *griseolus* to the genus *Oligoryzomys*. Further examination is necessary to confirm Osgood’s mammae count. Although Musser and Carleton (2005) included the Cordillera Oriental of easternmost Colombia within the range of the species, we are unable to confirm the allocation of specimens from this region from our personal examination of specimens. Hence, possible records from Colombia are neither listed nor mapped as selected localities here.

Oligoryzomys longicaudatus (Bennett, 1832)

Long-tailed Colilargo

SYNONYMS:

Mus longicaudatus Bennett, 1832a:2; type locality: “Chiliæ”; restricted to Valparaíso, Chile by Osgood (1943b:143).

H[esperomys]. (*Calomys*) *longicaudatus*: Wagner, 1843a:529; name combination.

- Mus philippii* Landbeck, in Philippi, 1857:361; type locality "Valdivia," Chile.
- Hesperomys (Calomys) coppingeri* Thomas, 1881b:4; type locality "Cockle Cove, Trinidad Channel, Madre de Dios Island, W. Patagonia," Magallanes y Antártica Chilena; fixed by lectotype selection (Thomas 1927b:549).
- Oryzomys longicaudatus*: E.-L. Trouessart, 1897:527; name combination.
- Oryzomys coppingeri*: E.-L. Trouessart, 1897:529; name combination.
- Mus dumetorum* Philippi, 1900:14; type locality "provincia Valdivia," Chile.
- Mus exiguus* Philippi, 1900:19; type locality "Andibus provinciae Santiago," [= Andes of Santiago,] Chile."
- Mus commutatus* Philippi, 1900:25; type locality "Valdivia," Chile.
- Mus macrocercus* Philippi, 1900:30; type locality "provincia Colchagua," Chile.
- Mus nigribarnis* Philippi, 1900:31; type locality "Andibus de Talcaregüe," [= Talcaregue Andes,] Chile.
- Mus amblyrrhynchus* Philippi, 1900:36; type locality "provincia Valdivia," Chile.
- Mus melanizon* Philippi, 1900:39; type locality "Chile."
- Mus diminutivus* Philippi, 1900:43; type locality "Illapel et provincia O'Higgins," Chile.
- Mus agilis* Philippi, 1900:44; type locality "Illapel," Chile.
- Mus (Rhipidomys) araucanus* Philippi, 1900:46; type locality "Conceptione," [= Concepción,] Chile.
- Mus pernix* Philippi, 1900:48; type locality "La Ligua," Chile.
- Mus glaphyrus* Philippi, 1900:51; type locality "provincia Maule," Chile.
- Mus peteroanus* Philippi, 1900:56, type locality "Andibus de Peteroa," Peteroa, Curicá Province, Chile.
- Mus malaenus* Philippi, 1900:62; type locality "provincia Maule," Chile.
- Oryzomys magellanicus mizurus* Thomas, 1916b:186; type locality "Koslowsky Valley, 46°S., 71°W., Central Patagonia," Chubut, Argentina.
- Oryzomys longicaudatus pampanus* Massoia, 1973a:34; type locality "Estación Experimental Hilario Ascasubi (INTA), partido de Villarino, provincial de Buenos Aires, República Argentina."
- O[ryzomys]. l[ongicaudatus]. philippii*: M. H. Gallardo and Patterson, 1985:49; name combination.
- Oligoryzomys longicaudatus*: Carleton and Musser, 1989:74; first use of current name combination.

DESCRIPTION: Extremely long tail, nearly double length of head and body (head and body length of holotype given as 3 inches [76.2 mm], tail length 5½ inches [139.7 mm]). Fur soft, smooth, and luxuriant; hairs deep

ashy gray at base; those of the upper surface fawn-colored or pale rufous toward their points, tip frequently black; those of under surface tipped with white slightly tinged with fawn; face covered with short hairs of mingled fawn and black; lips nearly white; vibrissae extremely long, black at their base and silvery at tip; ears rounded and of moderate size, covered on inside with short hairs same color as those of face, and on outside with very short whitish hairs scarcely discernible on blackish skin; color of back mixed fawn and black, black disappearing on almost purely fawn-colored sides; front of forelegs and the outside of hind legs fawn-colored; tail scaly, furnished with numerous very short bristly hairs, brownish above and nearly white beneath; hairs of upper surface of tarsi short, very pale fawn approaching white; those of toes still more white; and lengthened bristles covering claws almost silvery.

DISTRIBUTION: *Oligoryzomys longicaudatus* occurs along the eastern and western flanks of the Andes in Chile and Argentina, from Tierra del Fuego to Atacama (Chile) and Tucumán (Argentina) in the north; isolated populations are reported from the lowland areas in the provinces of Buenos Aires, La Pampa, and Rio Negro.

SELECTED LOCALITIES (Map 228): ARGENTINA: Buenos Aires, Bahía San Blas (Palma, Rivera-Milla et al. 2005), Villarino, Estación Experimental INTA Hilario Ascasubi (type locality of *Oryzomys longicaudatus pampanus* Massoia); Chubut, Cushamen (LSUMZ 16882), Parque Nacional Los Alerces (MVZ 188421); La Pampa, Parque Nacional Lihue Calel (MVZ 182026); Neuquén, 2 km SE of La Rinconada (MVZ 163775), 5 km N of Las Coloradas (MVZ 159332); Río Negro, Chimpay (FMNH 50909), Choele Choel (FMNH 129276), Pichi Leufú (Rivera et al. 2007); Santa Cruz, 52 km WSW of El Calafate (MVZ 150983); Tierra del Fuego, Bahía Lapataia (Espinosa and Reig 1991). CHILE: Aysén, 20 km S of Chile Chico (FMNH 133384), Coyhaique (TTU 30185), Isla Gunther (FMNH 127745), Parque Nacional Queulat (FMNH 133358), Río Aysén (FMNH 22561); Araucanía, 7 km NNW of Los Álamos (MSU 6403), 1.7 km W of Paso Pino Hachado (MSU 6737), 11 km SE of Temuco (MSU 6739), Termas de San Luis (UMMZ 155906), 2 km NE of Tirúa (MSU 6708), 11 km N of Villa Ranquil (MSU 6402); Atacama, Ramadilla (FMNH 22660), 40 km E of Vallenar (TTU 30170); Biobío, Concepción (FMNH 22624), 13 km E of Recinto (FMNH 119489); Coquimbo, Conchalí (TTU 30180), Parque Nacional Fray Jorge (FMNH 133210), La Serena (FMNH 133211), Paihuano (FMNH 22644); Los Lagos, 2 km S of Bahía Mansa (FMNH 133313), Cuesta El Moraga (FMNH 133808), Isla Grande de Chiloé, Quellón (FMNH 22574), Parque Nacional Puyehue (FMNH 133264); Los Ríos, Valdivia (type locality of *Mus philippii* Landbeck); Magallanes y Antártica Chilena, Cockle Cove [= Caleta Cockle], Isla Madre

de Dios (type locality of *Hesperomys* [*Calomys*] *coppingeri* Thomas), Puerto del Hambre (Belmar-Lucero et al. 2009), Reserva Nacional Magallanes (Belmar-Lucero et al. 2009), San Martín (M. H. Gallardo and Palma 1990), Torres del Paine (Palma, Rivera-Milla et al. 2005); Maule, Pilén Alto (FMNH 22615); O'Higgins, Baños de Cauquenes (FMNH 22631); Santiago, La Parva (TTU 30183); Valparaíso, Valparaíso (type locality of *Mus longicaudatus* Bennett).

SUBSPECIES: We regard *Oligoryzomys longicaudatus* to be monotypic, although an adequate assessment of geographic trends for any character set that might indicate valid races has not been achieved to date.

Map 228 Selected localities for *Oligoryzomys longicaudatus* (●); the disjunct populations in eastern Argentina are mapped separately from the main distribution. Contour line = 2,000 m.

NATURAL HISTORY: Large-scale outbreaks (*ratadas*) of *O. longicaudatus* have been observed in both Chile (Gonzalez et al. 2000; Murúa et al. 1986) and Argentina (Sage et al. 2007), both associated with cyclical masting of the arborescent bamboo *Chusquea quil* and *C. culeou*, respectively. This species was found to select microsites with high foliage density and thick understory, which offer protection from horizontal view of predators (Gonzalez et al. 2000). *Oligoryzomys longicaudatus* have a single, limited reproduction period each year in Chile (Murúa et al. 1996). Ectoparasites of *O. longicaudatus* include the mites *Gigantolaelaps wolffsohni* and *Mysolaelaps microspinosus* (Lareschi et al. 2003). This species is also host to the nematode *Litomosoides pardinasi* (Notarnicola and Navone 2011) and to Andes hantavirus in the Chilean Andes and Oran hantavirus in Argentina (Belmar-Lucero et al. 2009; Fulhorst et al. 2004).

REMARKS: The karyotype of *O. longicaudatus* is $2n=56$, $FN=66$ (Espinosa and Reig 1991). M. H. Gallardo and Palma (1990) provided the morphological basis for the current classification of colilargos from Chile, including the lack of differentiation of previously identified *philippii* populations (e.g., Osgood 1943b). *Mus philippii* is usually assigned to Landbeck and Philippi (1858), but this species was actually described by Luis Landbeck within the article by Philippi (1857). Palma, Rivera-Milla et al. (2005) presented a phylogeographic study using mtDNA sequences of the species and discussed its relationship with *O. magellanicus*. Thomas (1916b:186) noted that his original designation of the type locality of *Hesperomys* (*Calomys*) *coppingeri* to the Straits of Magellan was incorrect, and that Cockle Cove (= Caleta Cockle) is “in the Trinidad Channel, at the north end of Madre de Dios Island, West Patagonia, in 50° S. lat.” Belmar-Lucero et al. (2009) showed that the distribution of *O. longicaudatus* extends into Tierra del Fuego, where it is sympatric with *O. magellanicus* (see also the account of this species).

Oligoryzomys magellanicus (Bennett, 1836)

Patagonian Colilargo

SYNONYMS:

Mus magellanicus Bennett, 1836:191; type locality “apud Portum Famine dictum, in fretu Magellanicus,” Port Famine [= Puerto del Hambre], Magallanes y Antártica Chilena, Chile.

Hesperomys (*Oryzomys*) *longicaudatus*: Milne-Edwards, 1890:27; part; not *Mus longicaudatus* Bennett.

Oryzomys magellanicus: J. A. Allen, 1905:47; name combination.

Oryzomys longicaudatus magellanicus: Gyldenstolpe, 1932a: 11; name combination.

Oryzomys (*Oligoryzomys*) *magellanicus magellanicus*: Tate, 1932f:10; name combination.

DESCRIPTION: Head and body length similar to tail length; dorsal color saturated with grayish buff; ventral color whitish; and dorsal surfaces of forefeet and hindfeet white, ears of moderate size, rounded, and hairy.

DISTRIBUTION: *Oligoryzomys magellanicus* is limited to the Patagonian region of Chile and Argentina, including Tierra del Fuego.

SELECTED LOCALITIES (Map 229): ARGENTINA: Terra del Fuego, Estancia Via Monte (Osgood 1932), Lago Fagnano (= Lago Cami; Osgood 1932), Lago Yehuín (= Lago Yerwin; Osgood 1932). CHILE: Magallanes y Antártica Chilena, Harrison Island (M. H. Gallardo and Patterson 1985), Puerto del Hambre (type locality of *Mus magellanicus* Bennett), Punta Arenas (M. H. Gallardo and Patterson 1985), Lago Sarmiento, Parque Nacional Torres del Paine (M. H. Gallardo and Palma 1990).

SUBSPECIES: *Oligoryzomys magellanicus* is monotypic.

NATURAL HISTORY: Osgood (1932) found this species to be fairly common at some localities on Tierra del Fuego, but in the vicinity of Punta Arenas and northward in western Patagonia it was found with difficulty and only in small numbers. It co-occurs with *Abrothrix olivacea* in forest communities but not with this species in the brush or open pampa.

REMARKS: *Oligoryzomys magellanicus* is characterized by $2n=54$, $FN=66$ (M. H. Gallardo and Patterson 1985). M. H. Gallardo and Palma (1990) described external, cranial, bacular, chromosomal, and allozyme characters that differentiate *O. magellanicus* from *O. longicaudatus*. Palma, Rivera-Milla et al. (2005) and Belmar-Lucero et al. (2009), however, showed, based on molecular and karyological characters, that specimens from southern Chile (including from Puerto Hambre, type locality of *O. magellanicus*) and Tierra del Fuego, in the range of *O. magellanicus* as proposed by M. H. Gallardo and Palma (1990), actually belong to *O. longicaudatus*. Palma, Rivera-Milla et al. (2005) also showed an outlier haplotype from Rio Penitente, which they regarded to be *O. magellanicus*. We recognize *O. magellanicus* as a valid species based on its distinctive short tail (same length as head and body, compared to the much longer tail of *O. longicaudatus*), its different karyotype, and the molecular results of Palma, Rivera-Milla et al. (2005). Our assessment is that *O. magellanicus* and *O. longicaudatus* are sympatric in southernmost Chile and Tierra del Fuego (based on molecular and karyological results), the first being rare (and thus not collected by Belmar-Lucero et al. 2009). Nevertheless, Palma et al. (2012) argued, based on their molecular data, that *O. magellanicus* is a subspecies of *O. longicaudatus*; the taxonomic and distributional limits of these species need re-evaluation, especially in a more integrative approach that combines molecular, karyotypic, and morphological data.

Map 229 Selected localities for *Oligoryzomys magellanicus* (O). Contour line=2,000 m.

Oligoryzomys mattogrossae (J. A. Allen, 1916)

Mato Grosso Colilargo

SYNONYMS:

Oryzomys (Oligoryzomys) mattogrossae J. A. Allen, 1916c: 528; type locality "Utiariry, [Rio Papagaio, 2,500 ft.] Mato Grosso [= Mato Grosso], Brazil."

Oligoryzomys mattogrossae: Gyldenstolpe, 1932a: 29; first use of current name combination.

Oryzomys [(Oligoryzomys)] mattogrossae: Ellerman, 1941: 355; name combination.

Oryzomys utiaritensis: Cabrera 1961:396; part; not *Oligoryzomys utiaritensis* J. A. Allen.

Oligoryzomys microtis: Carleton and Musser, 1989:71; part; not *Oryzomys (Oligoryzomys) microtis* J. A. Allen.

Oryzomys (Oligoryzomys) fornesi: Myers and Carleton, 1981:25; not *Oryzomys fornesi* Massoia.

Oligoryzomys fornesi: Bonvicino and Weksler, 1998:90; not *Oryzomys fornesi* Massoia.

DESCRIPTION: Characterized by rufous tone, especially on rump; under parts pale ochraceous buff instead of grayish white; tail relatively long.

DISTRIBUTION: *Oligoryzomys mattogrossae* occurs in the open-vegetation belt throughout Paraguay, and central and northeastern Brazil; this species also possibly occur in Bolivia (e.g., Santa Cruz specimens listed as *O. microtis* by Olds and Anderson [1987] and S. Anderson [1997]) and Argentina, but no voucher material was analyzed to confirm identification.

SELECTED LOCALITIES (Map 230): BRAZIL: Alagoas, Matriz de Camaragibe (UFPB 977); Bahia, Fazenda Sertão do Formoso, Jaborandi (MNRJ 62637); Distrito Federal, Brasília (UNB 279); Goiás, Aporé (LBCE 8579), Corumbá de Goiás (MNRJ 34440), Fazenda Vão dos Bois, Teresina de Goiás (MNRJ [CRB 674]), Mambaí (LBCE 10851), Serranópolis (LBCE 8509); Mato Grosso, Utiariri (type locality of *Oryzomys [(Oligoryzomys)] mattogrossae*

J. A. Allen); Mato Grosso do Sul, Cassilândia (LBCE 12111), Corumbá (LBCE 5718); Paraíba, Mamanguape (UFPB [MPS 72]); Pernambuco, Bom Conselho (UFPB-PMN 60), Buíque (UFPB 1893), Macaparana (UFPB [MPS 34]). PARAGUAY: Caaguazú, 24 km NNW of Carayaó, Estancia San Ignacio (UMMZ 133818), Canindeyú, 6.3 km NE by road of Curuguaty (UMMZ 124218).

SUBSPECIES: *Oligoryzomys mattogrossae* is monotypic.

NATURAL HISTORY: *Oligoryzomys mattogrossae* is an inhabitant of open-vegetation biomes such as the Cerrado, Caatinga, and Chaco, but can also be found in forest formations in the transition with Amazonian forest. It can occur in sympatry with *O. nigripes*, *O. stramineus* (see Weksler and Bonvicino 2005), *O. utiaritensis* (see J. A. Allen 1916c), and maybe with *O. flavescens* (see Myers and Carleton, 1981, and below). *Oligoryzomys mattogrossae* (specimens identified as *O. fornesi*) was the reservoir of Anajatuba hantavirus in the Brazilian state of Maranhão (E. S. T. Rosa et al. 2005).

REMARKS: *Oligoryzomys mattogrossae* was described by J. A. Allen (1916c) based on two specimens, the holotype from Utiariti and one paratype from “Guatsué” (not located by Painter and Traylor 1991, but presumably on middle Rio Papagaio), both in Mato Grosso state. Later, Cabrera (1961:396) considered this taxon a junior synonym of *O. utiaritensis*. However, morphologic and phylogenetic analyses (C. R. Bonvicino and M. Weksler, in prep.) showed that *O. mattogrossae* is an independent lineage; in particular, *O. mattogrossae* has a yellow-ochraceous ventral coloration that contrasts with the whitish venter of *O. utiaritensis* (as previously noted by Myers and Carleton 1981). Some authors (e.g., Carleton and Musser 1989) also considered *O. mattogrossae* a junior synonym of *O. microtis*, but these two species differ in a number of attributes, including distinct karyotypes ($2n=64$, FN=66 for *O. microtis*; A. L. Gardner and Patton 1976 [as *Oryzomys (Oligoryzomys) longicaudatus*, variant 2]; Aniskin 1994; Patton et al. 2000), nonsister status in molecular phylogenetic analyses (C. R. Bonvicino and M. Weksler, in prep.), and distinct habitats (*O. mattogrossae* is found mostly in open-vegetation biomes, whereas *O. microtis* is found only in the forested environments).

We recognize *Oligoryzomys mattogrossae* as a valid species based on the examination of the holotype and the discovery of a specimen from Sapezal (same municipality as Utiariti, type locality of *O. mattogrossae*) that shares the same traits of the holotype and that is a member of a well-supported clade within *Oligoryzomys*; specimens of this clade were previously referred to as *O. fornesi* (e.g., Weksler and Bonvicino 2005), a name that we restrict here to the type locality and vicinity (see that account). Therefore, the small body size and yellow belly of specimens, with $2n=62$, FN=64, found in the Cerrado and Caatinga domains, pre-

Map 230 Selected localities for *Oligoryzomys mattogrossae* (●). Contour line = 2,000 m.

viously identified by us (e.g., Bonvicino and Weksler 1998; Weksler and Bonvicino 2005) as *O. fornesi*, are here considered as *O. mattogrossae*. The karyotype of this species is frequently mistaken as a variant of the karyotype of *O. flavescens* ($2n=64-66$, FN=66-68; e.g., Myers and Carleton 1981; Sbalqueiro et al. 1991). However, *O. mattogrossae* ($2n=62$, FN=64) and *O. flavescens* ($2n=64-66$, FN=66-68) karyotypes are discontinuous because a $2n=63$ karyotype has not been reported. Furthermore, these two taxa appear to differ in morphological traits, such as the incisive foramen length (longer in *O. flavescens*). The $2n=62$, FN=64 karyotype has also been attributed to *O. elurus* (Svartman 1989; Andrades-Miranda, Oliveira, Lima-Rosa et al. 2001), but examination of the karyotyped specimens listed by these authors confirmed them as *O. mattogrossae*.

Oligoryzomys messorius (Thomas, 1901)

Hairy Colilargo

SYNONYMS:

Oryzomys navus messorius Thomas, 1901e:151; type locality “Kanuku Mountains, about 59° W. and 3° N., and on the savannas near their base, at altitudes varying from 240 to 2000 feet,” Upper Takutu–Upper Essequibo, Guyana.

Oligoryzomys navus messorius: Gyldenstolpe, 1932a:27; name combination.

Oryzomys delicatus messorius: Cabrera, 1961:388; name combination.

Oligoryzomys fulvescens: Carleton and Musser, 1989:70; part, specimens from northern South America.

DESCRIPTION: Color above grizzled grayish fawn, varying towards rufous; rump more rufous than back; face grayer; ears comparatively short, but little darker than general color of head, very different therefore to blackish ears of *O. fulvescens*; under surface dull whitish, with scarcely trace of buff, not sharply defined laterally, hairs all grayish basally; dorsal surfaces of hands and feet white. Tail short for group, thinly haired, brown above, lighter beneath; not sharply contrasted as in *O. fulvescens*.

DISTRIBUTION: *Oligoryzomys messorius* is distributed primarily in higher elevations of southern Venezuela, Guyana, Surinam, and northeastern Brazil.

SELECTED LOCALITIES (Map 231): BRAZIL: Amapá, Tartarugalzinho (MNRJ 35967); Roraima, Parque Nacional do Viruá (MNRJ 70475), Rio Cotinga, Limão (AMNH 75411). GUYANA: Upper Takutu–Upper Essequibo, near Awarawaunowa (ROM 38522), near Dadanawa (ROM 36021), Kanuku Mountains (type locality of *Oryzomys navus messorius* Thomas), Nappi Creek (ROM 31529), 5 km SE of Surama (ROM 103348). SURINAM: Sipaliwini, Sipaliwini airstrip (CMNH 76892). VENEZUELA: Amazonas, Pozón, 50 km NE of Puerto Ayacucho (ROM 107871); Bolívar, Auyán-Tepuí (AMNH 130883), Mount Roraima, Arabopo (AMNH 75662).

SUBSPECIES: *Oligoryzomys messorius* is monotypic.

NATURAL HISTORY: Nothing is known about the ecology, population biology, or behavior of this species.

REMARKS: We recognize *O. messorius* as a valid species distinct from *O. delicatus* based on morphological differences of specimens of both taxa in the AMNH and

Map 231 Selected localities for *Oligoryzomys messorius* (●). Contour line = 2,000 m.

MNRJ collections (M. Weksler and colleagues, unpubl. data), karyotypic data ($2n=66$, FN=74) of specimens identified as *Oligoryzomys* sp. by Andrades-Miranda, Oliveira, Lima-Rosa et al. (2001; see also R. J. Baker et al. 1983 for specimens from Surinam with $2n=66$), and the phylogenetic position relative to other species in the genus (G. B. Miranda et al. 2009; Agrellos et al. 2012). Based on our ongoing morphological, karyotypic, and molecular analyses, the specimen reported as *Oligoryzomys* cf. *messorius* by Andrades-Miranda, Oliveira, Lima-Rosa et al. (2001), with karyotype of $2n=56$, FN=58, is distinct from the concept of *O. messorius* we espouse herein.

Oligoryzomys microtis (J. A. Allen, 1916)

Small-eared Colilargo

SYNONYMS:

Oryzomys (*Oligoryzomys*) *microtis* J. A. Allen, 1916c:525; type locality “Lower Rio Solimoens [= Solimões] (fifty miles above mouth),” Amazonas, Brazil; restricted to Manacapuru, north bank of lower Rio Solimões, 70 km WSW Manaus (Voss et al. 2001:118–119, footnote).

Oryzomys chaparensis Osgood, 1916:205; type locality “Todos Santos, Chaparé River, [Cochabamba,] Bolivia. Altitude about 1200 feet.”

Oligoryzomys microtus Gyldenstolpe, 1932a:27; incorrect subsequent spelling of *Oryzomys* (*Oligoryzomys*) *microtis* J. A. Allen.

Oryzomys [(*Oligoryzomys*)] *microtis*: Ellerman, 1941:355; name combination.

Oligoryzomys microtis: Carleton and Musser, 1989:71; first use of current name combination.

DESCRIPTION: Similar in size and general coloration to *O. delicatus* but very much less rufous above and clearer white below, and with very much smaller ears. Upper parts dull yellowish brown, finely lined with black-tipped hairs; under parts white (in holotype, but faintly tinged with buff in some specimens); upper surfaces of feet thinly clothed with light buffy brown hairs; soles dark brown; tail shorter than head and body, brown, nearly naked, finely annulated, with tip not distinctly tufted; ears small, brownish, and nearly naked. Patton et al. (2000:Table 33) provided mean, standard error, and range for external and cranial measurements for large series of adults from Rio Juruá in western Amazonian Brazil; total length 168–233 mm, tail length 80–125 mm, hindfoot length 21–26, and ear length 11–15 mm; series as small-bodied, long-tailed, and short-haired mouse, yellowish brown above and grayish white below; skull with elongated braincase, broad but long rostrum, and hourglass-shaped interorbital region with squared edges.

DISTRIBUTION: *Oligoryzomys microtis* occurs broadly in the Amazon Basin of eastern Peru, northeastern

Bolivia, and western Brazil, extending eastward along the floodplain of the Rio Amazonas in Pará state.

SELECTED LOCALITIES (Map 232): **BOLIVIA:** Beni, El Triunfo (USNM 391298), La Penas (USNM 460741); Cochabamba, Todos Santos (type locality of *Oryzomys chaparensis* Osgood); La Paz, Mapiri (AMNH 72697); Pando, La Cruz (AMNH 262901), Pemanso (AMNH 262912), Río Nareuda (AMNH 248982); Santa Cruz, El Refugio (AMNH 268971). **BRAZIL:** Acre, Igarapé Porongaba, right bank Rio Juruá (Patton et al. 2000); Amazonas, Jainú, right bank Rio Juruá (Patton et al. 2000), Manacapuru, north bank Rio Solimões, 70 km WSW of Manaus (type locality of *Oryzomys* [*Oligoryzomys*] *microtis* J. A. Allen), Parintins (AMNH 92899), Rio Madeira, Rosarinho, Lago Miguel (AMNH 92705), Seringal Condor, left bank Rio Juruá (Patton et al. 2000); Pará, Belém (USNM 461069), Capim, 150 mi SE of Belém (AMNH 188964), Marabá, Serra do Norte (USNM 543345), Villarinho do Monte, Rio Xingu (AMNH 95984). **PERU:** Loreto, Jenaro Herrera (Aniskin 1994), Mishana Allpahuayo (Aniskin 1994); Madre de Dios, Río Manu, 57 km above mouth (USNM 559399), Río Tambopata, 30 km above mouth (USNM 530925); Pasco, ca. 10 km N of Puerto Bermudez (AMNH 245551); Ucayali, Balta, Río Curanja (LSUMZ 14360).

SUBSPECIES: We treat *Oligoryzomys microtis* as monotypic.

NATURAL HISTORY: *Oligoryzomys microtis* is a terrestrial inhabitant of edge habitats within the lowland rainforest of the Amazon Basin. Population genetic analyses of *O. microtis* from the Brazilian Amazon (Patton et al. 1996, 2000) showed weak isolation by distance occurring only over large geographical distances. Migration rates (Nm) were high, and most (about 80%) of haplotype variation was observed within local populations. Specimens of *O. microtis* captured in Bolivia and Peru were positive for the Río Mamoré hantavirus (Carroll et al. 2005; Powers et al. 1999; Richter et al. 2010).

Pregnant females were recorded in March, May, August, and September in Bolivia; the number of embryos vary from three to five (S. Anderson 1977). Along the Rio Juruá in the western Amazon of Brazil, individuals reached reproductive maturity quickly, some while still in juvenile pelage, pregnancy rates were high (with litter size, based on embryo counts, ranging from two to eight [modal number=4]), and reproduction was recorded throughout the dry season. They inhabit mainly seasonally flooded habitats along river margins (*várzea*) exposed during the dry season, but also occur in *terra firme* forest (Patton et al. 2000).

REMARKS: A. L. Gardner and Patton (1976) reported a karyotype of $2n=64$, $FN=66$ for specimens from eastern Peru (as *Oryzomys* [*Oligoryzomys*] *longicaudatus*, variant

Map 232 Selected localities for *Oligoryzomys microtis* (●). Contour line=2,000 m.

2). Aniskin and Volobouev (1999) and Patton et al. (2000) both reported the same karyotype from additional localities in the Peruvian and the western Brazilian Amazon, respectively. Other karyotypes are found in colilargos from the Brazilian Amazon within the geographic range of *O. microtis* (C. R. Bonvicino, unpubl. data), and it is likely that this is a karyotypically polytypic species.

Voss et al. (2001:118–119, footnote) discussed the location of the type locality, north of the Rio Solimões, and the lack of morphological differentiation between the type series and topotypes of *O. fulvescens*. *Oligoryzomys* species, however, are very similar to one another, and we cannot discard that such is the case for *O. microtis* and *O. fulvescens*. Additional morphological comparisons are necessary to resolve this problem, and we keep the name *microtis* in this account. This species needs an in-depth taxonomic assessment.

Oligoryzomys moojeni Weksler and Bonvicino, 2005

Moojen's Colilargo

SYNONYM:

Oligoryzomys moojeni Weksler and Bonvicino, 2005:116; type locality “Fazenda Fiandeira in ‘Morro do Chapéu’ region, in the lowest part of the Chapada dos Veadeiros National Park, 65 km SSW Cavalcante (14°04’S 47°45’W, altitude ranging from 550 to 740m), Goiás State, Brazil.”

DESCRIPTION: Medium sized, characterized by brown-orange dorsal pelage that does not contrast sharply with creamy ventral pelage, notably short incisive foramina, and second highest diploid number ($2n=70$) for genus.

Map 233 Selected localities for *Oligoryzomys moojeni* (●).

DISTRIBUTION: Central Brazil, in the Cerrado of Goiás and Tocantins states, at elevations below 800 m.

SELECTED LOCALITIES (Map 233; from Weksler and Bonvicino 2005, except as noted): BRAZIL: Goiás, Cavalcante, Colinas do Sul, Mimoso de Goiás, Minaçu, Uruaçu; Tocantins, Lajeado (J. F. S. Lima et al. 2003), Porto Nacional (J. F. S. Lima et al. 2003).

SUBSPECIES: *Oligoryzomys moojeni* is monotypic.

NATURAL HISTORY: *Oligoryzomys moojeni* occurs at elevations between 500 and 800 m in the Brazilian Cerrado, primarily in open vegetation formations such as *cerrado sensu stricto* and *campo úmido*, but also in open gallery forest (Weksler and Bonvicino 2005). Two pregnant females were captured at the type locality in August (dry season), each with three embryos.

REMARKS: The karyotype of *Oligoryzomys moojeni* is characterized by $2n=70$ and $FN=74-76$; variation in the autosomal fundamental number is due to a pericentric inversion affecting a medium chromosome pair (J. F. S. Lima et al. 2003). In their respective karyotypic analyses, Andrades-Miranda, Oliveira, Lima-Rosa et al. (2001), and F. J. S. Lima et al. (2003) referred to this species as *Oligoryzomys* sp.

Oligoryzomys nigripes (Olfers, 1818)

Black-footed Colilargo

SYNONYMS:

Mus nigripes Olfers, 1818:209; type locality fixed by neotype designation to “Ybycuí National Park, Department Paraguari, approximately 85 km SSE Atyrá, Paraguay” (Myers and Carleton 1981:14).

Mus longitarsus Rengger, 1830:232; type locality “Ufer des Paraguaystromes, nördlich von Villa-Real.”

Hesperomys eliurus Wagner, 1845a:147; type locality “Ytarare [= Itararé],” São Paulo, Brazil.

Hesperomys pygmaeus Wagner, 1845a:147; type locality “Ypanema” (= Floresta Nacional de Ipanema, 20 km NW Sorocaba, São Paulo, Brazil, 23°26'7"S 47°37'41"W, 701 m; L. P. Costa et al. 2003).

Hesperomys (Calomys) pygmaeus: Burmeister, 1854:173; name combination.

Oryzomys pygmaeus: E.-L. Trouessart, 1897:527; name combination.

Oryzomys nigripes: E.-L. Trouessart, 1897:528; name combination.

Oryzomys eliurus: E.-L. Trouessart, 1897:528; name combination.

Oryzomys longitarsus: E.-L. Trouessart, 1897:528; name combination.

Oryzomys delticola Thomas, 1917c:96; type locality “Isla Ella, in the delta of the Rio Parana, at the top of the La Plata Estuary,” Buenos Aires, Argentina.

Oryzomys (Oligoryzomys) delticola: Tate, 1932f:10; name combination.

Oryzomys (Oligoryzomys) longitarsus: Tate, 1932f:10; name combination.

Oryzomys (Oligoryzomys) nigripes: Tate, 1932f:10; name combination.

Oryzomys (Oligoryzomys) eliurus: Tate, 1932f:10; name combination.

Oryzomys (Oligoryzomys) pygmaeus: Tate, 1932f:10; name combination.

Oligoryzomys eliurus: Carleton and Musser, 1989:73; name combination.

Oligoryzomys nigripes: Carleton and Musser, 1989:73; first use of current name combination.

Oligoryzomys delticola: Carleton and Musser, 1989:75; name combination.

DESCRIPTION: Large, characterized by dark-brown to dark-yellowish dorsal pelage color, with sharply defined transition to whitish ventral coloration, and often with orange pectoral band; long ears; $2n=62$, $FN=78-82$ karyotype.

DISTRIBUTION: *Oligoryzomys nigripes* occurs in eastern Brazil (from Pernambuco in the north to Rio Grande do Sul in the south along the coast, and in the southern portion of the Cerrado in Minas Gerais and São Paulo states and the Distrito Federal), Paraguay (east of the Río Paraguay), Uruguay (Salto, Durazno, Colonia, and Maldonado departments), and Argentina (Buenos Aires, Misiones, and Chaco provinces).

SELECTED LOCALITIES (Map 234; from Weksler and Bonvicino 2005, except as noted): ARGENTINA: Buenos

Aires, Isla Ella, delta of Río Paraná (type locality of *Oryzomys delticola* Thomas); Chaco, Las Palmas; Misiones, Caraguatay. BRAZIL: Bahia, Rio Una, 10km ESE of São José; Distrito Federal, Brasília; Espírito Santo, Venda Nova; Goiás, Flores de Goiás; Minas Gerais, Fazenda Canoas, Juramento, Passos, Peirópolis; Paraíba, Pirauá; Pernambuco, Bom Conselho, Buíque; Rio de Janeiro, Itaguaí, Nova Friburgo; Rio Grande do Sul, Faxinal, Pontal do Morro Alto; Santa Catarina, Florianópolis, Itá; São Paulo, Araraquara, Guaratuba, Iguapé, Itapetininga, Pedreira. PARAGUAY: Amambay, 4km (by road) SW of Cerro Corá (Myers and Carleton 1981), 28km SW of Pedro Juan Caballero (Myers and Carleton 1981); Caaguazú, Sommerfield Colony; Canindeyú, 6.3km by road N of Curuguaty; Central, Asunción; Itapúa, Encarnación; Misiones, San Francisco. URUGUAY: Durazno, Durazno; Maldonado, Punta del Este; Salto, Salto.

SUBSPECIES: *Oligoryzomys nigripes* is monotypic.

NATURAL HISTORY: *Oligoryzomys nigripes* had an average of 4.7 embryos (range: 4–6) in 21 pregnant females from the Brazilian states of Rio de Janeiro and São Paulo collected in September and November (C. R. Bonvicino, unpubl. data). Myers and Carleton (1981) reported an average of 3.57 embryos (range 2 to 5) in 32 pregnant females from Paraguay collected around June and August (with a hiatus in July). *Oligoryzomys nigripes* is the most habitat-generalist of all Brazilian *Oligoryzomys* species, occurring in primary and secondary vegetation in Atlantic Forest and Cerrado. It can be sympatric with *O. stramineus* (see Bonvicino and Weksler 1998), though the two species have never been caught in the same trapline. It can be syntopic with *O. flavescens* and *O. mottogrossae*. *Oligoryzomys nigripes* is more commonly trapped on the ground, but Myers and Carleton (1981) mentioned specimens collected in trees and suggested some arboreal activity. Püttker, Pardini et al. (2008) found the species at sites with a low canopy and a dense understory. In southern Brazil, population levels peaked in the cold and dry months and reached null values during the warmest months, with the population increase connected to greater availability of food resources, especially of grass seeds (Antunes et al. 2009). This colilargo can reach a density of 33 animals per hectare during population explosions (study population in Buenos Aires province, Argentina; Jaksic and Lima 2003). In the Rio de la Plata delta (and probably elsewhere), *O. nigripes* is prey of the Barn Owl (*Tyto alba*) and host to the ectoparasitic mites *Haemolaelaps glasgowi*, *Gigantolaelaps mottogrossensis*, *Laelaps paulistanensis*, and *Mysolaelaps microspinosus* (see Massoia and Fornes 1964b). The species is also host to the nematodes *Stilestrongylus lanfrediae* in Rio de Janeiro, Brazil (J. G. R. Souza et al. 2009) and *Syphacia kinsellai* in Misiones, Argentina (M. Robles and Navone 2007), and individuals are a reservoir for the Araucaria hantavirus (R. C. Oliveira et al. 2011).

Map 234 Selected localities for *Oligoryzomys nigripes* (●). Contour line = 2,000m.

REMARKS: The name *nigripes* was first given to Azara's (1801:98) *le rat à tarse noir* by Olfers (1818:209; see Desmarest 1819f; Hershkovitz 1959b; Myers and Carleton 1981). As no type specimen was selected in the original or in subsequent publications, Myers and Carleton (1981:14) designated a neotype from Ybycuí National Park, 85 km SSE Atyrá (which is approximately where Azara obtained his specimens), in the department of Paraguá, Paraguay.

Oligoryzomys nigripes has a diploid number of 62 chromosomes but a variable autosome fundamental number ranging from 79 to 82 due to pericentric inversions (Bonvicino, D'Andrea, and Borodin 2001). Because Bonvicino and Weksler (1998) and Weksler and Bonvicino (2005) were unable to separate samples of *O. nigripes* from those of *delticola* Thomas or *eliurus* Wagner on morphological and karyological grounds, we consider both *delticola* and *eliurus* as equivalent to *O. nigripes* herein. Recent analyses of mtDNA sequence data (D-loop and cytochrome-*b*) corroborate that *delticola* is best considered a synonym of *O. nigripes* (Francés and D'Elía 2006; Rivera et al. 2007). L. F. Machado et al. (2011) presented further characters that differentiate sympatric *O. nigripes* from *O. flavescens*.

Oligoryzomys rupestris Weksler and Bonvicino, 2005
Highlands Colilargo

SYNONYM:

Oligoryzomys rupestris Weksler and Bonvicino, 2005:119; type locality "Pouso Alto (14°01'S 47°31'W), in the

highest part of the Chapada dos Veadeiros National Park, at 1,500m altitude, 14km NNW of Alto Paraíso, Goiás State, Brazil.”

DESCRIPTION: Small sized, characterized by gray head that contrasts with lighter yellow-brownish dorsal body coloration; small tufts of whitish hairs anterior to base of pinna; reduced or absent stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen that characterizes carotid circulatory pattern 3 (*sensu* Voss 1988); and lowest known diploid number ($2n=44-46$) among species in the genus.

DISTRIBUTION: *Oligoryzomys rupestris* occurs in central Brazil, where it is known from only three localities, one each in Goiás, Minas Gerais, and Bahia states, at elevations above 1,000m.

SELECTED LOCALITIES (Map 235): BRAZIL: Bahia, Pico das Almas (MZUSP 29015); Goiás, Pouso Alto (type locality of *Oligoryzomys rupestris* Weksler and Bonvicino); Minas Gerais, Serra do Cipó (MZUSP 27423).

SUBSPECIES: *Oligoryzomys rupestris* is monotypic.

NATURAL HISTORY: This species occurs only in high-elevation areas characterized by *campos rupestre* vegetation in the Cerrado Biome (Weksler and Bonvicino 2005). No female was found pregnant in November (end of dry season) at the type locality (Bonvicino, Lemos, and Weksler 2005). No other natural history information is available.

REMARKS: *Oligoryzomys rupestris* has the lowest diploid number of all species in the genus, with $2n=44$ to 46 and an autosomal fundamental number varying from 52 to 53 (M. J. de J. Silva and Yonenaga-Yassuda 1997; as *Oligoryzomys* sp. 1 and sp. 2). The derived carotid circulation

pattern (pattern 3 of Voss 1988) of *O. rupestris* is unique among *Oligoryzomys* species.

Oligoryzomys stramineus Bonvicino and Weksler, 1998
Straw-colored Colilargo

SYNONYM:

Oligoryzomys stramineus Bonvicino and Weksler, 1998: 98; type locality “Fazenda Vão dos Bois (13°34'29"S 47°10'57"W, 424 m), Terezina de Goiás, Goiás State, Brazil, 24 km N of Terezina de Goiás, 15 km SW of Rio Paranaã, a tributary of the upper Rio Tocantins, road GO-118, km 275.”

DESCRIPTION: Large species characterized by pale dorsal color, with defined transition between lateral and whitish ventral pelage, long incisive foramina, broad zygomatic plates, and $2n=52$, FN=68–70 karyotype.

DISTRIBUTION: *Oligoryzomys stramineus* occurs in central and northeastern Brazil, from Goiás and Minas Gerais states in the south to Ceará, Piauí, Paraíba, and Pernambuco states in the north, in both Cerrado and Caatinga vegetational domains.

SELECTED LOCALITIES (Map 236): BRAZIL: Bahia, Caetitê (MNRJ 63416); Ceará, Russas (Fernandes et al. 2012), Santanopole (USNM 304583); Goiás, Fazenda Vão dos Bois, Teresina de Goiás (type locality of *Oligoryzomys stramineus* Bonvicino and Weksler), Mambai (Weksler and Bonvicino 2005); Minas Gerais, Fazenda Canoas, Juramento (Weksler and Bonvicino 2005); Paraíba, Pirauá (UFPB [LFS 49]); Pernambuco, Agrestina (UFPE [PMN 62]), Buíque (UNPE [PMN 147]), Correntes (Weksler and Bonvicino 2005), Exu (Weksler and Bonvicino 2005).

SUBSPECIES: *Oligoryzomys stramineus* is monotypic.

NATURAL HISTORY: *Oligoryzomys stramineus* is primarily found in gallery forests within the Cerrado. Young juveniles were collected in August, suggesting that reproduction occurred around June–July; one pregnant female was captured in September with four embryos (Weksler and Bonvicino 2005). This species is sympatric with *O. fornesi* (with both obtained in the same trapline) and *O. nigripes* (but never in the same trapline) at some localities in central Brazil (Weksler and Bonvicino 2005).

REMARKS: The karyotype of *Oligoryzomys stramineus* is characterized by $2n=52$, FN=68 to 69 (Furtado 1981; Maia et al. 1983; both as *Oligoryzomys* aff. *elivurus*). Differences in autosomal fundamental number are due to an inversion in a small acrocentric pair (Bonvicino and Weksler 1998). See remarks in the account for *Oligoryzomys chacoensis* for the confusion over the distributional range of that species due to misidentification with specimens of *O. stramineus* (e.g., Carleton and Musser 1989:72).

Map 235 Selected localities for *Oligoryzomys rupestris* (●). Contour line=2,000m.

Map 236 Selected localities for *Oligoryzomys stramineus* (●) and *Oligoryzomys utiaritensis* (○). Contour line=2,000m.

Oligoryzomys utiaritensis J. A. Allen, 1916

Utiariti Colilargo

SYNONYMS:

Oryzomys (*Oligoryzomys*) *utiaritensis* J. A. Allen, 1916c: 527; type locality “Utiarity [= Utiariti], Rio Papagaio, Matto Grosso, Brazil.”

Oligoryzomys utiaritensis: Gyldenstolpe, 1932a:29; first use of current name combination.

Oryzomys [(*Oligoryzomys*)] *utiaritensis*: Ellerman, 1941: 356; name combination.

Oligoryzomys eliurus: Carleton and Musser, 1989:73; part; not *Hesperomys eliurus* Wagner.

DESCRIPTION: Upper parts clay-colored, finely lined with black-tipped hairs over back, nearly pure clay-color on sides; front of head and nose darker and slightly grayish; under parts grayish white, hairs darker at base; upper surfaces of forefeet and hindfeet paler, about flesh color, soles dark brown; ears large, light brown, nearly naked; and tail longer than head and body, finely annulated, light brown, and nearly naked, apical portion with short, bristly grayish hairs. Agrellos et al. (2012) diagnosed *O. utiaritensis* by the following characters: grizzled yellowish-brown dorsal pelage contrasting with whitish ventral pelage and tail weakly bicolored; long incisive foramina with posterior borders reaching or almost reaching alveoli of first upper molars, but never extending posteriorly; highest diploid number for genus ($2n=72$); and three putative synapomorphies in mtDNA cytochrome-*b* and one in nuclear intron 7 of beta-fibrinogen gene sequences.

DISTRIBUTION: *Oligoryzomys utiaritensis* is distributed across the northwest of Mato Grosso and southwest of Pará states, an area that includes the Chapada dos Parecis, a massive plateau in northwestern Mato Grosso that marks the transition between the Cerrado and Amazonian domains in central Brazil.

SELECTED LOCALITIES (Map 236): BRAZIL: Pará, Castelo dos Sonhos, Altamira (MNRJ 75609); Mato Grosso, Campo Novo do Parecis (MNRJ 75616), Feliz Natal (MNRJ [SVS 819]), Peixoto de Azevedo (MNRJ 75600), Utiariti, Rio Papagaio (type locality of *Oryzomys* [*Oligoryzomys*] *utiaritensis* J. A. Allen).

SUBSPECIES: *Oligoryzomys utiaritensis* is monotypic.

NATURAL HISTORY: Specimens of *Oligoryzomys utiaritensis* were captured between 110 and 570m elevation, in secondary semideciduous forest at the limits of corn and soy plantations, in eucalypt plantations with herbaceous vegetation, and in very altered vegetation near plantations (Agrellos et al. 2012). This species is sympatric with *O. mattogrossae* at the type locality (J. A. Allen 1916c). Individuals serve as a reservoir of the Castelo dos Sonhos hantavirus (E. S. T. Rosa et al. 2011).

REMARKS: Recent karyotypic, morphologic, and molecular analyses (Agrellos et al. 2012) demonstrated that *O. utiaritensis* and *O. nigripes* (= *O. eliurus*; see the species account) were different species. *Oligoryzomys utiaritensis* had a karyotype with $2n=72$ and $FN=76$, unlike *O. nigripes* with $2n=62$, $FN=78-82$. Analyses of mtDNA and nucDNA markers indicated that *O. nigripes* and *O. utiaritensis* were not sister taxa.

Genus *Oreoryzomys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

Oreoryzomys balneator, the sole species in the genus, is endemic to high-elevation montane forests in Ecuador and northern Peru. It is currently known from very few specimens and localities.

Externally, *O. balneator* has a small body size, with head and body length ranging from 75–94 mm; the tail is longer than head and body (tail length 95–120 mm); hindfeet are narrow and delicate (length 23.5–27 mm); and ears are short and rounded. The dorsal pelage is dense and compact, with short hairs (aristiforms reaching 12 mm in length), and darkly colored, ochraceous densely grizzled with dark brown. The ventral pelage is shorter, sharply distinct from the dorsum and sides of the body in color, grayish to buffy gray. The tail is whitish along its basal half, with the distal half uniformly dark brown; the tail tip may be white in some specimens. Hindfeet are covered dorsally with short,

bicolored (brown proximally and white distally), and self-colored hairs (entire white); unguis tufts are short, and do not conceal the claws. Mystacial vibrissae are dense, thick, and long, surpassing the tip of ears when laid back.

The skull of *O. balneator* is very small and delicate (greatest length range: 22.2–25.7 mm). The rostrum is long and narrow, flanked by small and discrete nasolacrimal foramina, and has very shallow and narrow zygomatic notches. The zygomatic plates are narrow, with their anterior margins straight; zygomatic arches are slightly divergent posteriorly, and jugals are absent. The interorbital region is anteroposteriorly short and wide, with an hourglass shape; the anterior half has rounded supraorbital margins, and the posterior half shows squared margins. The braincase is rounded and globose, without temporal crests; in occipital view, the braincase is well rounded, and both the foramen magnum and occipital condyles are oriented more ventrally. Incisive foramina are short (length 2.8–3.8 mm), with convex lateral margins and rounded anterior and posterior margins. The palate is long and wide, with or without small and inconspicuous palatal excrescences; the posterolateral palatal pits are large and deep. The anterior border of mesopterygoid fossa is rounded; its roof is perforated by long and narrow sphenopalatine vacuities present at the presphenoid-basisphenoid suture. An alisphenoid strut is absent. The stapedial foramen, squamosoalisphenoid groove, and sphenofrontal foramen are present, configuring carotid circulatory pattern 1 (*sensu* Voss 1988). Both the subsquamosal fenestra and postglenoid foramen are large. Auditory bullae are small but globose, with long and flat bony tubes; the stapedial process is small; the tegmen tympani varies in size, and may or may not marginally overlap the squamosal.

The mandible is shallow; the coronoid process is very short and triangular, and positioned lower than the condyloid process, thus defining an extremely shallow superior notch. The angular process is shorter than the condyloid process, so the inferior notch is also shallow. A capsular process is well developed.

Upper incisors are orthodont. Molars are pentalphodont, although some specimens may have tetralophodont lower molars, with a reduced to absent mesolophid. Molars have low crowns with the main cusps arranged in opposite pairs. Labial and lingual flexi interpenetrate moderately at the median molar plane; the labial flexus is deep and wide, while the lingual flexus is relatively shorter. The anterocone of M1 is divided by a deep anteromedian flexus; the paracone is connected to the protocone by its medial portion, configuring a very long mesoflexus and thus a long and narrow mesoloph (the anteroloph is also very long); with wear, it forms a long mesofossette. M2 is similar in shape and occlusal details, except for the absence of anterocone, but the anteroloph is well developed. M3 is

smaller, but similar to the other teeth. A deep anteroflexid is present on m1 as is a long and narrow mesolophid (although this latter structure is absent in one specimen). The second lower molar exhibits individual variation in the presence of a mesolophid, conspicuous in most specimens, but others lack a noticeable trace, even in unworn molars.

SYNONYMS:

Oryzomys: Thomas, 1900c:273; part; not *Oryzomys* Baird. *Oreoryzomys* Weksler, Percequillo, and Voss, 2006:21; type species *Oryzomys balneator* Thomas, by original designation.

REMARKS: *Oreoryzomys* is recovered as the sister taxon to *Microryzomys* in phylogenetic analyses of oryzomyine rodents based on molecular and morphological data (Weksler 2003, 2006). In fact, the two genera are morphologically similar (as first observed by M. D. Carleton, pers. comm.); both share a deep anteromedian flexus on M1, a short, convexly shaped incisive foramina, type 1 carotid circulatory pattern, a rounded interorbital region hourglass in shape, a rounded brain case, and a posteroventral oriented foramen magnum.

Oreoryzomys balneator (Thomas, 1900)

Ecuadorean Oreoryzomys

SYNONYMS:

Oryzomys balneator Thomas, 1900c:273; type locality “Mirador,” Baños, Tungurahua, Ecuador.

Oryzomys ([*Oryzomys*]) *balneator*: E.-L. Trouessart, 1904:418; name combination.

Oryzomys balneator hesperus Anthony, 1924b:7; type locality “El Chiral, Western Andes, Provincia del Oro, Ecuador, elevation 5350 ft.”

Oryzomys balneator balneator: Gyldenstolpe, 1932a:13; name combination.

[*Oreoryzomys*] *balneator*: Weksler, Percequillo, and Voss, 2006:21; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: This species is known from a few localities on both western and eastern slopes of the Andes in Ecuador and northern Peru, at intermediate elevations (from 1,500 to 1,586 m).

SELECTED LOCALITIES (Map 237): ECUADOR: El Oro, El Chiral (*Oryzomys balneator hesperus* Anthony); Napo, Baeza (BM 15.7.12.9); Tungurahua, Mirador (type locality of *Oryzomys balneator*); Zamora-Chinchiipe, 4 km E of Sabanilla (USNM 513570). PERU: Cajamarca, 4 km W of Chaupe (AMNH 268144).

SUBSPECIES: I treat *Oreoryzomys balneator* as monotypic.

NATURAL HISTORY: This species occurs in Andean montane and cloud forest. According to Musser et al. (1998), Mirador, the type locality of *O. balneator*, has a

Map 237 Selected localities for *Oreoryzomys balneator* (●). Contour line = 2,000 m.

matrix of vegetation with sharp contrasts, including *páramo* mixed with temperate plants in the valleys interdigitating with extensive areas of subtropical forest. The climate is rainy, cold, and windy. There are no published details on the habitat where specimens were caught, but museum skin labels (BM) indicate that individuals were “trapped amidst the roots on a tree,” found “at old stump,” “among dead logs,” and “in woods,” suggesting that they are terrestrial. No other information on natural history is available.

REMARKS: The validity of *Oryzomys balneator hesperus* Anthony remains to be determined, pending examination of the type material. Until that definition has been achieved, I provisionally recognize Anthony’s name as a synonym of *Oreoryzomys balneator*. It is noteworthy that the type and only known locality of *hesperus* represents the single western slope site for *O. balneator*, which is otherwise distributed along the eastern Andean gradient.

Genus *Oryzomys* Baird, 1857

Alexandre R. Percequillo

Until very recently, the genus *Oryzomys* was one of the most taxonomically diverse of the many genera within the subfamily Sigmodontinae, comprising some 43 species distributed from the southern United States in North America to northern Argentina in South America (Musser and Carleton 2005). However, the extensive taxonomic rearrangement proposed by Weksler et al. (2006), based on morphological (Percequillo 1998, 2003; Weksler 2006) and

molecular analyses (Weksler 2003, 2006), restricted the genus *Oryzomys* in its taxonomic content and thus substantially narrowed its geographic range, especially in South America. Currently five species are attributed to this genus (Musser and Carleton 2005; Voss and Weksler 2009). Three of these (*O. antillarum*, *O. dimidiatus*, and *O. palustris*) are restricted to North and Central America (see Hall 1981; Weksler et al. 2006) and are not considered further here. Two species either extend into northwestern South America (*O. couesi*) or are limited to this continent (*O. gorgasi*).

The South American species of genus *Oryzomys* (based on Hall 1981; H. Sánchez et al. 2001) are medium-sized oryzomyine rats, with the tail ranging from shorter to longer than head and body length, with conspicuous epidermal scales, and with ventral caudal hairs longer than dorsal ones and a small pencil of terminal hairs. Hindfeet are long and narrow, with webs of skin connecting digits II, III, and IV, and a fringe of stiff and short hairs along the metatarsal margins; ungual tufts are sparse and short, and do not conceal the claws; plantar surfaces are covered with squamae, and the hypothenar pads are small and inconspicuous. Ears are small and rounded. The pelage is harsh and dense, usually short; dorsal pelage is grizzled grayish brown to ochraceous tawny, mixed with black; color of the sides is paler and with less black; ventral pelage is white to ochraceous buff. The tail is distinctly bicolored at its base or throughout most of its length.

The skull is strongly built although not very long. The rostrum is short and strong, with deep and wide zygomatic notches and well-projected and inflated nasolacrimal capsules. The interorbital region is broad and strongly divergent posteriorly with heavily beaded supraorbital margins or with well-developed supraorbital crests; temporal crests are well developed and collinear with the supraorbital margins. Incisive foramina are very long and narrow, with their posterior margins penetrating between the first molars; lateral margins are widest medially. The palate is long and wide (*sensu* Hershkovitz 1962); posterolateral palatal pits are complex, numerous, and recessed in deep and rounded depressions. The anterior border of the mesopterygoid fossa is rounded, and its roof is completely ossified without a trace of sphenopalatine vacuities (except in *O. palustris*, which has very large and wide vacuities). The stapedial foramen is minute or absent, and both the squamosoalisphenoid groove and sphenofrontal foramen are absent, configuring carotid circulatory pattern 3 (*sensu* Voss 1988). The buccinator-masticatory and accessory oval foramina are confluent, thus an alisphenoid strut is absent. The postglenoid foramen is narrow, and the subsquamosal fenestra is a small aperture in most species, due to a broad hamular process of the squamosal, obliterated in both South American species. The suspensory process of the squamosal is absent and the tegmen tympani is short,

and may or may not overlap the squamosal. Auditory bullae are small but globose, with a distinct dorsostapedial process that may or may not overlap the squamosal; bony tubes are abruptly constricted, and ectotympanic capsules are globose.

The mandible is strong, with or without the capsular projection of lower incisors; superior and inferior notches are shallow. Upper incisors are strongly opisthodont. Molars are pentalophodont, and brachydont; toothrows are parallel and appear smaller in relation to the remaining parts of the skull; main cusps are arranged in opposite pairs; and labial and lingual flexi interpenetrate only slightly at the median molar plane. Carleton and Musser (1989) described occlusal topology in detail. The first upper and lower molars have accessory roots.

SYNONYMS:

Mus: Harlan, 1837:385; part (description of *palustris*); not *Mus* Linnaeus.

[*Hesperomys*] *Oryzomys* Baird, 1857:458; as subgenus; type species *Mus palustris* Harlan, by monotypy.

Hesperomys: Alston, 1877:756; part (description of *couesi*); not *Hesperomys* Waterhouse.

Oryzomys: Coues, 1890:4165; elevation to generic rank.

Nectomys: Thomas, 1905a:586; part (description of *dimidiatus*); not *Nectomys* Peters.

Micronectomys: Hershkovitz, 1948:55; *nomen nudum*.

REMARKS: The number of species within the genus *Oryzomys* is in flux. Weksler et al. (2006:4, Table 1) recognized five (*O. antillarum* Thomas, *O. couesi* Alston, *O. dimidiatus* Thomas, *O. gorgasi* Hershkovitz, and *O. palustris* Harlan). Carleton and Arroyo-Cabrales (2009) reviewed the *couesi* complex from western Mexico, and recognized three other species in addition to *O. couesi* (*O. albiventer* Merriam, *O. nelsoni* Merriam, and *O. peninsulae* Thomas). Most recently, Hanson et al. (2010), based on molecular phylogenetic analysis of samples from throughout the North and Middle American range, increased this number by four. These authors split *O. texensis* J. A. Allen from *O. palustris* and *O. mexicanus* J. A. Allen from *O. couesi* while identifying two undescribed species from Costa Rica and Panama. To date, no samples from South America have been included in any molecular phylogenetic study.

KEY TO THE SOUTH AMERICAN SPECIES OF *ORYZOMYS*:

1. Rostrum long and slender; incisive foramina wider posteriorly; hamular process of squamosal slender, configuring a large subsquamosal fenestra *Oryzomys couesi*
- 1'. Rostrum stout and blunt; incisive foramina wider medially, tapering posteriorly; hamular process of squamosal broad, configuring a small subsquamosal fenestra *Oryzomys gorgasi*

Oryzomys palustris couesi: Hall, 1960:173; name combination.

Oryzomys [(*Oryzomys*)] *palustris couesi*: Hall, 1981:609; name combination.

DESCRIPTION: Large and robust skull, with short and wide rostrum; incisive foramina penetrate between procingula of first upper molars; posteriorly strongly divergent interorbital region with strongly beaded to shelved supraorbital margins; prominent posterolateral palatal pits recessed in medium to deep palatal depressions; and completely ossified roof of mesopterygoid fossa (see Weksler 2006). Hershkovitz (1987a) noted typical ochraceous orange color of body (dorsal, lateral, and ventral) throughout species’ range and entirely whitish mystacial facial region.

DISTRIBUTION: This species is widespread throughout North and Central America (Hall 1981; Musser and Carleton 2005), with only a single record from South America, in northwestern Colombia (Hershkovitz 1987a).

SELECTED LOCALITIES (Map 238): COLOMBIA: Córdoba, Montería (Hershkovitz 1987a).

SUBSPECIES: Substantial subspecies diversity is currently recognized within the North and Central American range of *O. couesi* (Hall 1981, as *Oryzomys palustris*).

NATURAL HISTORY: Nothing is known about the natural history of this species in South America, aside from the comment made by Hershkovitz (1987a) that the single specimen he obtained was collected in a rice field.

REMARKS: Long considered a subspecies of a very wide-ranging *Oryzomys palustris* (e.g., Hall 1960, 1981), *O. couesi* is now widely recognized as a valid species based on a number of morphological, karyotypic, and molecular geographic analyses (see summaries in Musser and Carleton 2005; Hanson et al. 2010). Hershkovitz (1971) regarded *O. couesi* as distinct from *O. gorgasi*, based on comparisons he made in the original description of the latter. H. Sánchez et al. (2001) also compared *O. couesi* to *O. gorgasi*, pointing out their differences. However, none of these authors directly compared the voucher of *O. couesi* (FMNH 127250) from Montería, Colombia, to the holotype or the Venezuelan series of *O. gorgasi*. Thus, there remains a remote possibility that only one species of *Ory-*

Map 238 Single known South American locality for *Oryzomys couesi* (●); range in Panama from Hall (1981). Contour line = 2,000 m.

zomys is present at South America. If this is correct, the appropriate name applied to the South American species would be *O. gorgasi* (see H. Sánchez et al. 2001).

The diploid number of the Colombian specimen is $2n = 56$ (Hershkovitz 1987a), the same as that recorded for specimens from Middle American localities (Haiduk et al. 1979; R. J. Baker et al. 1983; Burton et al. 1987).

Oryzomys gorgasi Hershkovitz, 1971

Gorgas’s Marsh Rice Rat

SYNONYMS:

Oryzomys gorgasi Hershkovitz, 1971:700; type locality “Loma Teguerre (7°54’N, 77°W), Departamento Antioquia, northwestern Colombia, between Río Atrato and mouth of a *caño* (channel) of the east bank *ciénaga* just below and opposite Sautatá (Chocó), Interoceanic Canal Survey Route 25 (Golfo de Urabá [*sic*] to Bahía Humboldt, via Ríos Atrato-Truandó); altitude, 1 meter above sea level.”

Oryzomys curasoeae McFarlane and Debrot, 2001:182; type locality “Fissure, 30 m below edge of north face of Tafelberg Santa Barbara, (UTM coordinates: 19–518570, 13–34570),” Curaçao, Caribbean Netherlands.

DESCRIPTION: Same external and craniodental traits typical of genus *Oryzomys*, as presented earlier. H. Sánchez et al. (2001:210) stated that *O. gorgasi* differed from other species (specifically *O. couesi*, *O. dimidiatus*, and *O. palustris*) by presence of stout and blunt rostrum, posteriorly tapering incisive foramina, absence of sphenopalatine vacuities, and broad hamular process of squamosal, which reduces subsquamosal fenestra to small opening. However, Weksler (2006) scored the roof of mesopterygoid fossa of *O. couesi* as completely ossified, the same condition as *O. gorgasi*, thus suggesting that this trait may be polymorphic in samples of *O. couesi*. Consistency in the lack of sphenopalatine vacuities and thus the utility of an unossified mesopterygoid fossa roof as diagnostic of *O. gorgasi* warrant further evaluation by examination of more extensive series of specimens of all species in the genus.

DISTRIBUTION: *Oryzomys gorgasi* is known from two localities in the trans-Andean portion of northern South America, one each in Colombia and Venezuela. This species is not known to extend into Panama, despite the close proximity of the single Colombian locality to that country. It is apparently extinct from Curaçao, off the northwestern Venezuelan coast.

SELECTED LOCALITIES (Map 239): **COLOMBIA:** Antioquia, Loma Teguerra (Hershkovitz 1971). **VENEZUELA:** Zulia, El Caimito, Refugio de Fauna Silvestre y Reserva de Pesca Ciénaga de Los Olivitos, 40 km NE of Maracaibo (H. Sánchez et al. 2001).

NATURAL HISTORY: In Colombia, the only known specimen was collected in the “swamp, or ciénaga, forests in the Río Atrato basin” (Hershkovitz 1971:701) “at least 60 km upriver from the gulf of Urubá in an area of high annual rainfall, . . . a freshwater swamp” (H. Sánchez et al. 2001:210). The series from Venezuela were obtained at El Caimito, a small coastal island covered by xerophytic vegetation and by mangroves along swampy lagoon margins (H. Sánchez et al. 2001). Here, the species was omnivorous, feeding on crustaceans, insects, seeds, and other plant tissues. Endoparasites observed included the onchocercid filarioid *Litomosoides sygmodontis* and the recitulariid genus *Pterygodermatites* (subgenus *Paucipectines*). Despite being common in Neotropical cricetids, neither oxyurid nor trychostrongylid nematode endoparasites were found in examined stomachs.

Oryzomys gorgasi is a species apparently uncommon in Venezuela, as considerable trapping effort at three localities near El Caimito has produced no other specimens (H. Sánchez et al. 2001). Instead, the black rat (*Rattus rattus*) was commonly captured, suggesting that this more aggressive exotic species may be competing with and displacing *O. gorgasi*. Similarly, Voss and Weksler (2009), based on paleontological (McFarlane and Debrot 2001) and ecologi-

cal data (H. Sánchez et al. 2001) for *O. gorgasi*, suggested that black rats were possibly responsible for the extinction of this species on the island of Curaçao.

REMARKS: Since its description by Hershkovitz (1971) and, at the time, only known from the holotype, *O. gorgasi* has been considered a valid species, closely related to *O. palustris* and *O. couesi* (Honacki et al. 1982; Musser and Carleton 1993). In 2001 H. Sánchez et al. reported on a series of specimens from the coastal mangroves of northwestern Venezuela, supplemented Hershkovitz’s description of *O. gorgasi*, and solidified its specific status relative to other species of *Oryzomys*. They noted, however, that the markedly wide rostrum of the holotype might be due to allometric growth of the facial region during captivity.

More recently, *Oryzomys curasoae*, an extinct species based on remains obtained from limestone fissures, was described from the continental shelf island of Curaçao off the northern Venezuelan coast (McFarlane and Debrot 2001). In the original description, these authors suggested that their species was close to *Oryzomys*, subgenus *Oecomys*, but refrained from addressing phylogenetic relationships. Subsequently, Voss and Weksler (2009), based on an extensive comparative analysis of several members of tribe Oryzomyini, constructed a phylogenetic hypothesis in which *O. curasoae* was nested with other species of *Oryzomys* (*sensu* Weksler et al. 2006), specifically as sister to *O. gorgasi*.

Map 239 Selected localities for *Oryzomys gorgasi* (●). Contour line = 2,000 m.

Because quantitative traits also highlight the similarity between these two forms, these authors considered both taxa as “strict synonyms,” with priority for the name *O. gorgasi*. They limited the name *curasoae* “solely to refer to the subfossil material from Curaçao” (Voss and Weksler 2009:5).

Musser and Carleton (2005) incorrectly gave the type locality of *O. curasoae* as “Venezuela, Curaçao Isl.” This island is, however, part of the Caribbean Netherlands, although on the continental shelf just north of the Venezuelan mainland (map, Fig. 1).

Genus *Pseudoryzomys* Hershkovitz, 1962

Robert S. Voss

The genus *Pseudoryzomys* contains a single species, *P. simplex*, which occurs in tropical and subtropical grassland habitats below 1,000 m elevation in Brazil, northern Argentina, western Paraguay, eastern Bolivia, and extreme southeastern Peru. Although Hershkovitz (1962), Reig (1984, 1986), and Braun (1993) classified *Pseudoryzomys* as a phyllotine, other morphological researchers have suggested that the genus is more closely related to oryzomyines (Olds and Anderson 1990; Voss and Myers 1991; Langguth and Neto 1993; Voss and Carleton 1993; Steppan 1995). Recent phylogenetic analyses (e.g., Weksler 2003, 2006; Percequillo, Weksler, and Costa 2011; Parada et al. 2013) unequivocally support the hypothesis that *Pseudoryzomys* is an oryzomyine closely related to *Holochilus*. Subfossil material of *Pseudoryzomys* is known from Brazilian cave deposits (Winge 1887)—some of which may date from the late Pleistocene—and from an archaeological site in Buenos Aires province, Argentina (Pardiñas 1995a). As far as known, the genus is not a member of any island fauna. Except as noted otherwise below, the following account is abstracted from Voss and Myers (1991), which should be consulted for additional details concerning taxonomy, morphology, and geographic distribution.

Pseudoryzomys simplex is a medium-sized (30–60 g; Pine and Wetzel 1976; J. R. Contreras and Berry 1982) sigmodontine with coarsely grizzled-brownish dorsal fur and gray-based yellowish or buffy ventral fur. The pinnae are small, covered with short hairs that are colored like the fur of the head, and do not appear naked. The hindfeet are long and narrow with the middle three digits (II–IV) much longer than the outer two (I and V); the heel is smooth and hairless, but the rest of the naked plantar surface is densely covered with small tubercles, among which one or two metatarsal pads (the hypothenar may be present or absent) and four very small interdigital pads can be distinguished. The tail, distinctly bicolored (dark above and pale below) is about as long as the combined length of the head and body; it is covered with short hairs, but the underlying

epidermal scales are clearly visible, and there is no terminal tuft of distinctly longer hairs. There are eight mammae in inguinal, abdominal, postaxial, and pectoral pairs.

The skull is distinctively proportioned in dorsal view, with a short rostrum, deep zygomatic notches, and a narrow interorbital region. The posterior supraorbital margins are anteriorly convergent and either sharp-edged or beaded; the zygomatic arches are widest across their squamosal roots and converge anteriorly. In lateral view, the zygomatic plates are very broad, with straight or concave anterior margins, and sometimes bearing blunt anterodorsal processes. The incisive foramina are narrow, parallel sided, and long, usually extending posteriorly to or between the anterocones of the first molars. The palate is smooth, without deep lateral gutters or median keels, and long (extending posteriorly well behind the third molars); prominent posterolateral palatal pits are present. The bony roof of the mesopterygoid fossa is perforated by large sphenopalatine vacuities; the parapterygoid fossae are shallow (not deeply excavated) and narrow (without expanded lateral margins). An alisphenoid strut separating the buccinator-masticatory foramen from the foramen ovale accessorius may be either present or absent. The carotid arterial pattern is derived (pattern 3 of Voss 1988). The auditory bullae are small, and the tegmen tympani does not overlap the squamosal. A very large postglenoid foramen and a smaller subsquamosal fenestra perforate the lateral surface of the braincase above the bulla on either side of the skull. The mandible is short and deep, with a large falciform coronoid process; the tip of the angular process is below or slightly behind the condyle. The lower incisor alveolus terminates in a well-developed capsular process below or just behind the base of the coronoid process.

The upper incisors are narrow, strongly opisthodont, and smooth (ungrooved), with yellow-orange enamel bands. The upper molar rows are parallel, and the teeth themselves are low-crowned and bunodont (even when unworn). The principal labial and lingual cusps of the upper molars are arranged in opposite pairs connected by transverse lophs. The anterocone of M1 is undivided, as is the anteroconid of m1. Small mesolophs are present on M1 and M2 but do not connect with mesostyles on the labial cingulum; mesolophs are absent on all of the lower molars. M1 and m1 each have four roots, but all the remaining molars have only three roots each.

Axial skeletal elements include 12 ribs, 19–20 thoracolumbar vertebrae, 3–4 sacral vertebrae, and 29 caudal vertebrae. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. Each ring-shaped hemal arch on the undersides of the caudal vertebrae has

a distinct spinous process on its posterior margin (Stepan 1995). The entepicondylar foramen of the humerus is absent.

The stomach is unilocular and hemiglandular, and the gall bladder is absent. One pair of preputial glands is present, but other male accessory secretory organs remain undescribed. The glans penis (illustrated by Langguth and Neto 1993) conforms to the complex bauplan, with a spinous exterior and a deep terminal crater containing three bacular mounds (supported by a tridigitate bacular cartilage), a dorsal papilla, and a bifurcate urethral flap.

The karyotype consists of 56 diploid chromosomes, all of which appear to be acrocentric; the fundamental number (FN) is 54.

SYNONYMS:

Hesperomys: Winge, 1887:11; part (description of *simplex*); not *Hesperomys* Waterhouse.

Oryzomys: E.-L. Trouessart, 1897:528; part (listing of *simplex*); not *Oryzomys* Baird.

Oecomys: Moojen, 1952b:55; part (listing of *simplex*); not *Oecomys* Thomas.

Pseudoryzomys Hershkovitz, 1959a:8; *nomen nudum* (see Pine and Wetzel 1976).

Calomys: Hershkovitz, 1962:123; part; (listing of *simplex*); not *Calomys* Waterhouse.

Pseudoryzomys Hershkovitz, 1962: 208; type species *Oryzomys wavrini* Thomas, by original designation.

REMARKS: Hershkovitz (1959a) originally proposed the name *Pseudoryzomys*, but the name was not made formally available until three years later, when Hershkovitz (1962) provided a generic diagnosis (Pine and Wetzel 1976).

Pseudoryzomys simplex (Winge, 1887)

False *Oryzomys*

SYNONYMS:

Hesperomys simplex Winge, 1887:11; type locality (fixed by lectotype selection; Voss and Myers, 1991) "Lapa da Escrivania [= Escrivânia] Nr. 5," a cave excavated by P. W. Lund near Lagoa Santa, Minas Gerais, Brazil.

Oryzomys simplex: E.-L. Trouessart, 1897:528; name combination.

Oryzomys wavrini Thomas, 1921b:177; type locality "Jesematathla [= Jesamatathla], west of Concepción," Presidente Hayes, Paraguay.

Oecomys simplex: Moojen, 1952b:55; name combination.

Pseudoryzomys wavrini: Hershkovitz, 1959a:8; name combination, but *Pseudoryzomys* a *nomen nudum* with this date (see Remarks, above).

Calomys simplex: Hershkovitz, 1962:123; name combination.

Pseudoryzomys wavrini: Hershkovitz, 1962:208; first valid use of this name combination.

Pseudoryzomys wavrini reigi Pine and Wetzel, 1976:649; type locality "Pampa de Meio, Río Itenez, Depto. Beni, Bolivia."

Pseudoryzomys simplex: Massoia, 1980c:282; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Pseudoryzomys simplex* is known from low-lying areas below 900m from northeastern Argentina, western Paraguay to eastern Bolivia and the Pampas del Heath in extreme southeastern Peru, and from there eastward through Brazil to the eastern margin of the Amazon Basin and the northeastern Atlantic coast. The species is largely confined to lowland areas with strongly seasonal rainfall, such as the grasslands and wetlands (*campo úmido*) found throughout the Chaco, Cerrado, and Caatinga domains (Voss and Myers 1991; L. G. Lessa and Talamoni 2000; F. F. Oliveira and Langguth 2004; Pardiñas, Cirignoli, and Galliari 2004; Bezerra et al. 2009; Prada and Percequillo 2013). Subfossils document a Holocene distribution that once extended southward to the Argentinean province of Buenos Aires (Pardiñas 1995a).

SELECTED LOCALITIES (Map 240): ARGENTINA: Chaco, Predisencia Roque Sáenz Peña (Prado and Percequillo 2013); Formosa, Estancia Guayacolec (Massoia, Heinonen Fortabat, and Diéguez 1997); Santa Fe, Pedro Gómez Cello (Pardiñas, Cirignoli, and Galliari 2004), Santa Margarita (Massoia et al. 1995b). BOLIVIA: Beni, Estación Biológica del Beni (AMNH 262048); Santa Cruz, Pampa de Meio, Río Iténez (Prado and Percequillo 2013), Parque Nacional Noel Kempff Mercado (Prado and Percequillo 2013), Santa Ana (Prado and Percequillo 2013). BRAZIL: Amapá, Fazenda Asa Branca, Tartarugalzinho (Prado and Percequillo 2013); Amazonas, Humaitá, Escola Agrotécnica (Prado and Percequillo 2013); Bahia, Mata do Zé Leandro (L. G. Pereira and Geise 2009); Goiás, Moro da Baleia, Alto Paraíso, Parque Nacional da Chapada dos Veadeiros (Prado and Percequillo 2013); Mato Grosso, Posta Leonardo (Prado and Percequillo 2013); Mato Grosso do Sul, Gruta São Miguel (Prado and Percequillo 2013), Rio Sucuriú (Prado and Percequillo 2013); Minas Gerais, Lagoa Santa (Voss and Myers 1991); Pernambuco, 40 km W of Recife (UMMZ 164995), Vila Feira Nova (Prado and Percequillo 2013); São Paulo, Estação Ecológica Jataí (L. G. Lessa and Talamoni 2000); Tocantins, Parque Nacional do Araguaia (Bezerra et al. 2009), Peixe (Prado and Percequillo 2013). PARAGUAY: Presidente Hayes, Fortín Juan de Zalazar (CONN 16487). PERU: Madre de Dios, Pampas del Heath (MUSM 11732).

SUBSPECIES: I treat *Pseudoryzomys simplex* as monotypic.

NATURAL HISTORY: All known collection localities for *Pseudoryzomys simplex* are from tropical and subtropical landscapes characterized by open vegetation (e.g., in the Cerrado, Chaco, and Pantanal biomes). The few specimens

Map 240 Selected localities for *Pseudoryzomys simplex* (●). Contour line = 2,000 m.

accompanied by explicit habitat information were captured on the ground in grassy habitats, usually seasonally flooded savannas, marshes, and river floodplains. For some reason, *P. simplex* is hard to trap, and most known specimens have been recovered from Barn Owl (*Tyto alba*) pellets (e.g., by Pardiñas, Cirignoli, and Galliari 2004; Teta, Pereira, Muschetto, and Fracassi 2009). Nothing has been recorded in the literature concerning diet, reproduction, or other natural history topics.

Genus *Scolomys* Anthony, 1924

James L. Patton

Described in 1924 by H. E. Anthony from the eastern slope of the Ecuadorean Andes, the genus *Scolomys* remained an enigmatic taxon for the next 60 years, known in the published literature only from the original series of six specimens collected by G. H. H. Tate that comprised the single, and during that time, only known species, *S. melanops* Anthony. Following in rapid succession, and based on surveys at several sites in the western Amazon Basin, Pacheco (1991) described a second species (*S. ucayalensis*) from northern Peru, Patton and da Silva (1994) described a third species (*S. juruaense*) from western Brazil, and Gómez-Laverde et al. (2004) recorded specimens from southern Colombia and reviewed the systematics of the genus. These latter authors extended the range of *S. melanops* from the upper Río Pastaza and the Río Napo in Ecuador southeast to include three localities in northern Peru to the left (= north) bank of

the Río Amazonas near Iquitos. They assigned newly collected specimens from the Río Caquetá and Río Rumiayaco to the Peruvian taxon *S. ucayalensis* Pacheco, and extended the range of this species to a second locality in northeastern Peru. Finally, they argued that *S. juruaense* Patton and da Silva was not specifically distinct from *S. ucayalensis*.

Species of *Scolomys* are small (head and body length range: 80–90 mm), short-tailed (tail length 55–77 mm), and short-eared (pinna height 15–17 mm) mice with a short and broad head and distinctly spiny fur both above and below (Patton and da Silva 1995; Gómez-Laverde et al. 2004). The body pelage is short and close, colored grizzled pale reddish-black to nearly totally black dorsally and gray ventrally. Dorsal hairs are of two types: long (averaging 12 mm), stout, flat, and broad (averaging 0.6 mm) spines with a medial trough on both surfaces, with the terminal one-third to one-quarter increasingly dark to the tip and proximal portion clear; and long, thin hairs equal in length to the spines and with tips reddish or blackish. Ventral hairs of both types are uniformly gray from base to tip. Mystacial, superciliary, genal, submental, interramal, and carpal vibrissae are present. Pinnae are small, appearing somewhat thickened and thus stiff, and, while appearing naked from a distance, are clothed externally and internally with short reddish-brown hairs. The manus has five large, fleshy plantar pads (two carpal and three interdigital), with toes pale in color. Digit I is reduced but has a small nail; digits II through V are long and well developed with short, stout, and curved claws. Hindfeet are rather short and broad, although the metatarsus is nearly twice as long as digit III; the heel is haired, and the naked sole begins at about one-quarter the length of the plantar surface (not including the digits). The outer digits are shorter than the middle three (with the claw of digit I extending to or just past the base of digit II and that of digit V extends to the proximal phalanx of digit IV). Conspicuous tufts of long, silvery hairs are present at dorsal base of each claw, extending past their tips, but the claw is visible from above. The claws are short, stout (about twice as long as deep) and strongly curved along their dorsal surface. There are five to six plantar pads, with the thenar and four interdigital pads large, fleshy, always present; the hypothenar pad is either absent or only weakly developed. The tail is shorter than head and body length, is sparsely haired, and lacks any terminal tuft or pencil or long hairs. There are 15–18 scale annuli per centimeter at midlength of the tail, with annual hairs broad, blackish, and 2.5–4 scale rows in length, but sparsely distributed so that the tail scales are conspicuous. Females possess only three pairs of mammae (one thoracic, one abdominal, and one inguinal), in contrast the four pairs typical of other genera of the tribe Oryzomyini.

The skull, in dorsal view, has a short and broad or tapering rostrum flanked by shallow, barely perceptible zygomatic notches, laterally expanded nasolacrimal capsules (especially so in *S. melanops*), a broad interorbital region hourglass in shape, and with well-developed beaded ledges overhanging the margins from the middle of the frontals and continuing along the posterior margins of the orbit onto the braincase just above the squamosoparietal suture as moderately developed temporal ridges. The braincase is distinctly rounded and globular, dominating the dorsal aspect of the skull (length of braincase is about one-half the length of the skull). Nasals are somewhat expanded and taper posteriorly to a median point that terminates well behind the premaxillofrontal sutures. The interparietal is large, one-half to one-third as deep as wide.

In lateral view, the nasals extend onto or just beyond the anterior curvature of the incisors. The zygomatic plates are narrow, vertical to slightly angled posteriorly from its base, and without a distinct, free dorsal edge (thus, the zygomatic notches are markedly shallow when viewed from above). The zygomatic arch is thin, with a reduced jugal. The postglenoid foramen is moderate to small, hamular processes of the squamosal are stout, the subsquamosal foramen is reduced to totally occluded, and the mastoid fenestra is very small to nonexistent. The tegmen tympani of the periotic either does not contact or abuts but does not overlap the squamosal. Tympanic bullae are small and inflated ventrally only to the level of the molar series.

In ventral view, the incisive foramina are moderate in size (occupying about 60% of the diastemal distance), distinctly teardrop in shape, and pointed anteriorly with diverging sides and expanded, rounded posterior margins. The premaxillary-vomerine septum is greatly swollen, nearly filling the entire cavity of the incisive foramina. The bony palate is long (*sensu* Hershkovitz 1962), without a median ridge or palatal excrescences, with only weakly evident lateral folds, but with large and complex posterolateral pits. The mesopterygoid fossa is wide with parallel sides and a rounded or squared anterior margin ending well behind the third upper molars. The bony roof of the fossa is complete or perforated only by barely perceptible sphenopalatine vacuities along the presphenoid. Parapterygoid fossae are well developed, with their lateral margins straight to slightly convex and strongly divergent toward the bullae, devoid of vacuities except for a small foramen ovale, and moderately excavated, not flat in appearance. An alisphenoid strut is absent, but only the foramen ovale is present laterally, without an anterior opening of the alisphenoid canal. A shallow trough indicating the passage of the masticatory-buccinator branch of the maxillary nerve is visible; it emanates from the anterior margin of the foramen ovale and obliquely crosses the alisphenoid onto the

squamosal. Facial circulation is apparently derived from the internal carotid artery (pattern 3, *sensu* Voss 1988), as indicated by a greatly reduced to absent stapedia foramen, no squamosoalisphenoid groove along the internolateral wall of the braincase, and no sphenofrontal foramen.

The mandible is short and stout, with a short coronoid process with a weakly to moderately curved posterior projection. A capsular process is weakly developed. Lower incisors are thin, elongate, and with enamel essentially devoid of pigment. Upper incisors are asulcate and faced with yellow to pale yellow enamel. These are small, deeper than wide, and proodont (in *S. melanops*) to orthodont (in *S. ucayalensis*).

Maxillary toothrows converge slightly posteriorly and are angled obliquely downward and outward at about 40°. Upper and lower molars are small and form a graded series with the third molar greatly simplified. Upper teeth are pentalophodont with their principal cusps arranged transversely and slightly obliquely. Labial and lingual reentrant folds do not interdigitate or contact, with the major labial folds of M1 and M2 (paraflexus and metaflexus) deep, extending at least two-thirds across the tooth, lingual folds reduced, with protoflexus only evident as a shallow lateral indentation in M1 and not visible at all in M2. The procingulum of M1 and m1 is well developed but not divided into separate anterolabial and anterolingual conules (no anterior medial flexus[id] present). An anteroflexus on M1 is absent, so the anteroloph is not separated from the labial anteroconule. The anteroloph of M2 is well developed. Distinct mesolophs are present and extend to the labial margin of all three molars. The posteroloph is well developed on M1 but barely perceptible on M2 and absent on M3. The paracone and metacone of M1 and M2 is tall and well developed, with the protocone and hypocone proportionately reduced in size and much lower in topography. Only the paracone and weakly developed protocone are present on M3.

The stomach is unilocular and hemiglandular. The male phallus (of *S. ucayalensis*, this structure has not been described for *S. melanops*) is cylindrical with an incomplete crater rim, terminally exposed urethral flaps, lateral mounds of distal baculum hidden by tissue of the crater rim, and an epidermis with widely spaced small spines.

SYNONYM:

Scolomys Anthony, 1924b:1; type species *Scolomys melanops*, by original designation.

REMARKS: *Scolomys* possesses each of the seven putative synapomorphies that diagnose the tribe Oryzomyini (Weksler 2006; see above), but of the remaining characters shared by most members of the tribe, *Scolomys* has only six rather than eight mammae in females (Patton and da Silva 1995) and acutely angled posterior nasal margins rather than rounded or squared ones (Weksler 2006).

Initial molecular sequence analyses of both mitochondrial and nuclear genes failed to support the placement of *Scolomys* as a member of the Oryzomyini (M. F. Smith and Patton 1999; D'Elía 2003). However, more taxon dense molecular analyses (L. F. García 1999; Weksler 2003), especially when combined with a cladistic analysis of morphological characters (Weksler 2006), firmly placed *Scolomys* within the Oryzomyini as the sister to *Zygodontomys* but near the base of the radiation. The apparent sister relationship between these two genera was unexpected, as noted by Weksler (2006:75): “*Scolomys* and *Zygodontomys* are two of the most distinctive clades of oryzomyines, and they are ecologically and morphologically dissimilar from one another. Whereas species of *Scolomys* are rainforest specialists (Patton and da Silva 1995; Gómez-Laverde et al. 2004), species of *Zygodontomys* are highly specialized for savannas and other open vegetation formations (Voss 1991a). The IRBP sequence divergence of both lineages was also high, suggesting an early split within oryzomyine evolution. Although the clade lacks IRBP synapomorphies, analyses using faster-evolving mitochondrial genes have also recovered the same grouping (L. F. García 1999). This suggests an early cladogenetic event between the *Scolomys* and *Zygodontomys* lineages after the appearance of the *Scolomys-Zygodontomys* ancestor.”

I follow Gómez-Laverde et al. (2004) and recognize two species in the genus.

KEY TO THE SPECIES OF SCOLOMYS:

1. Incisors proodont; rostrum short and blunt; nasolacrimal capsules expanded when viewed from above; zygomatic arches rounded; subsquamosal fenestra open; mandible short and deep; coronoid process short; hypothenar pad usually present; $2n=60$ *Scolomys melanops*
- 1'. Incisors orthodont; rostrum longer and more tapering; nasolacrimal capsules not expanded; zygomatic arches straight, converging anteriorly; subsquamosal fenestra occluded; mandible gracile, with elongated coronoid process; hypothenar pad reduced to absent; $2n=50$ *Scolomys ucayalensis*

Scolomys melanops Anthony, 1924

Gray Spiny Mouse

SYNONYM:

Scolomys melanops Anthony, 1924b:2; type locality “Mera, about 3800 feet elevation, eastern [Pastaza] Ecuador.”

DESCRIPTION: Karyologically and molecularly well differentiated from *S. ucayalensis*, although externally both species share same small body, short and nearly naked tail, distinctly spiny fur, and grizzled pale reddish-brown to dark reddish-black finely streaked with black color above and below (Anthony 1924; Patton and da Silva 1994; Gómez-

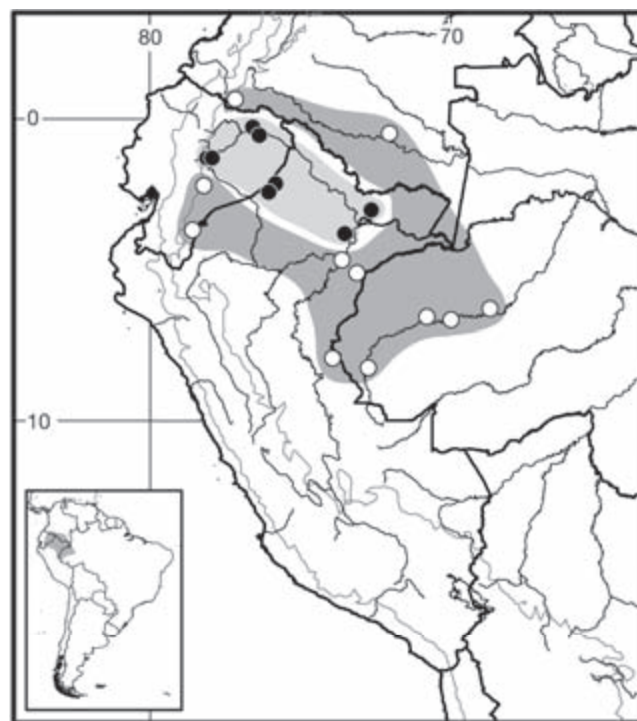

Laverde et al. 2004). Cranially, however, two species readily distinguished. *Scolomys melanops* with short, wide, and blunt rostrum; wide and rounded zygomatic arches circumscribing wide and short orbital openings; laterally expanded nasolacrimal capsules; an open subsquamosal fenestra; proodont upper incisors; and short and deep mandible with short coronoid process. Hypothenar pad on plantar surface of hindfoot also well developed.

DISTRIBUTION: *Scolomys melanops* is known from three localities in eastern Ecuador and four in northeastern Peru, all between the Río Pastaza and Río Napo and north of the Río Amazonas. Elevation ranges from about 150 m to 1200 m.

SELECTED LOCALITIES (Map 241): ECUADOR: Orellana, Parque Nacional Yasuní, 38 km S of Pompeya Sur (ROM 104537); Pastaza, Mera (type locality of *Scolomys melanops* Anthony), Puyo (YPM 823); Sucumbios, Limoncocha (USNM 513581). PERU: Loreto, Estación Biológica Allpahuayo (Hice 2001), Quebrada Orán, ca. 5 km N of Río Amazonas, 85 km NE of Iquitos (LSUMZ 27927), San Jacinto (KU 158212), 1.5 km N of Teniente Lopez (KU 158214).

SUBSPECIES: *Scolomys melanops* is monotypic.

NATURAL HISTORY: This species has been trapped in cultivated fields and at the edge of mature forest (Rageot and Albuja 1994) and in patches of remnant forest (Gómez-Laverde et al. 2004) in eastern Ecuador, and in

Map 241 Selected localities for *Scolomys melanops* (●) and *Scolomys ucayalensis* (○). Contour line = 2,000 m.

undisturbed forest as well as in selectively logged forest types at localities in northeastern Peru (Hice 2001; Hice and Velazco 2012). Except for two individuals caught on fallen logs, all others were on the ground, where the species was obtained on pitfall lines as commonly as in traps (Hice and Schmidly 2002). Hice (2001) recorded this species in all months of the wet season but never captured individuals in the four drier months of the year. She noted that reproductively active males were captured in March, October, and November, and pregnant females in March and April. The average litter size was 2.5 embryos. Anthony (1924b) reported pregnant females in March, with a litter size of three. Rengifo and Aquino (2012) described the nest, noting in particular the use of fiber taken from the palm *Lepidocaryum tenue*. Little else is known of the ecology or behavior of *S. melanops*.

REMARKS: Patton and da Silva (1995) described the karyotype of specimens from the Río Napo, Ecuador, with $2n=60$, $FN=78$, a large submetacentric X chromosome and large subtelocentric Y chromosome.

Scolomys ucayalensis Pacheco, 1991

Ucayali Spiny Mouse

SYNONYMS:

Scolomys ucayalensis Pacheco, 1991:1; type locality "Centro de Investigaciones 'Jenaro Herrera', 2.8 km E of Jenaro Herrera, department of Loreto, right bank of the Ucayali river; at 135 m elev.; 73°39'W, 04°52'S."

Scolomys juruaense Patton and da Silva, 1994:324; type locality "Seringal Condor, left bank Rio Juruá, Amazonas, Brazil 70°51'W, 6°45'S."

DESCRIPTION: Small mouse with short, nearly naked tail (83% of head and body length); short and broad head with distinctly pointed snout; short and relatively broad hindfeet; greatly reduced to absent hypothenar pad but well-developed thenar and interdigital pads; small and rounded ears; and dorsal color varying from grizzled pale reddish-brown to dark reddish-black finely streaked with black. Skull with rounded and inflated braincase; short and basally broad rostrum that tapers distally; narrowed and straight zygomatic arches; narrow but long orbital openings; subquamosal fenestra totally occluded by stout hamular process of squamosal; short and distally broad incisive foramina; and wide mesopterygoid fossa with parallel sides and squared, as opposed to rounded, anterior margin.

DISTRIBUTION: *Scolomys ucayalensis* occurs largely in lowland rainforest from extreme southern Colombia to northeastern Peru, western Brazil, and southern Ecuador, across an elevational range from 200 to 1,400 m. The distribution circumscribes that of its congener *S. melanops*, and the two are likely to be found in sympatry with additional collecting north of the Río Marañón-Río Amazonas axis.

SELECTED LOCALITIES (Map 241): BRAZIL: Acre, Sobral, left bank Rio Juruá (INPA 2485); Amazonas, Seringal Condor, left bank Rio Juruá (type locality of *Scolomys juruaense* Patton and da Silva), Penedo, right bank Rio Juruá (MVZ 183165), Barro Vermelho, left bank Rio Juruá (MVZ 183170). COLOMBIA: Amazonas, Corregimiento Puerto Santander, cerca de la Quebrada Bocaduché, margen sur Río Caquetá (ICN 16233); Nariño, cuenca alta del Río Rumiayaco (IAvH 6203). ECUADOR: Morona-Santiago, Domono (M. Brito and Arguero 2012); Zamora-Chinchipec, Alto Machinaza (M. Brito and Arguero 2012). PERU: Loreto, 2.8 km E of Jenaro Herrera (type locality of *Scolomys ucayalensis* Pacheco), Nuevo San Juan, Río Gálvez (AMNH 272668); Ucayali, Reserva Nacional Sierra del Divisor (H. Quintana et al. 2009).

SUBSPECIES: *Scolomys ucayalensis* is monotypic, with little expressed variation in mensural characters among the known samples (Gómez-Laverde et al. 2004).

NATURAL HISTORY: Pacheco (1991) obtained his two specimens at the type locality in dense undergrowth at the edge of primary forest artificially cut for regeneration studies, suggesting that this species naturally occurs in disturbed or secondary forest. Patton et al. (2000), however, collected their specimens along the Rio Juruá in western Brazil in undisturbed *terra firme* forest, though where there were often areas of local, natural disturbances (such as tree falls) and thus with a dense understory. There, pregnant females were captured from August through March, which spans both the wet and dry seasons. Embryo counts ranged from one to three. In contrast, the two Ecuadorean localities are both on the eastern Andean slope, one in mature subtropical rainforest dominated by the *cauchillo* tree (*Ficus* [Moraceae]) and the second in cloud forest with trees that reach 20 m in height and covered by bryophytes and bromeliads.

REMARKS: Gómez-Laverde et al. (2004), with the availability of much larger and geographically more expansive samples, showed that the presumptive distinctive characters differentiating *S. juruaense* to *S. ucayalensis* were primarily age related. Combined with very limited mitochondrial sequence divergence (about 1%), they argued that the two taxa were conspecific, a decision followed here. M. Brito and Arguero (2012) provided cranial measurements for the four known Ecuadorian specimens of *S. ucayalensis* and contrasted the morphological characteristics of this species with those of *M. melanops*.

Patton and da Silva (1995) described a karyotype of western Brazilian specimens as $2n=50$, $FN=68$, with a large acrocentric X chromosome and small acrocentric Y chromosome. These authors also figured and described the male phallus.

Genus *Sigmodontomys* J. A. Allen, 1897

Marcelo Weksler

Sigmodontomys is a monotypic genus found in lowland and lower montane trans-Andean forests in northwestern South America (Colombia, Venezuela, and Ecuador) and from Honduras to Panama in Central America. Until recently (e.g., Musser and Carleton 2005), *Sigmodontomys* included the two species *S. alfari* J. A. Allen, 1897 and *S. aphrastus* (W. P. Harris 1932), but phylogenetic analyses did not recover the two taxa as sister species (Weksler 2006; Pine et al. 2012), and *aphrastus* is now placed in its own genus: *Tanyuromys* Pine, Timm, and Weksler, 2012 (see *Tanyuromys* account). The following morphological description is based on AMNH and USMN specimens supplemented by information extracted from Hershkovitz (1944), Arata (1964; male accessory reproductive glands), Hooper and Musser (1964, glans penis), and Voss (1991a; gall bladder).

Sigmodontomys are medium-sized rodents, with moderate head and body size (range 120–152 mm). The tail is longer than the combined head and body length (length 149–190 mm), and the hindfeet are long and robust (length 34–37 mm). The body pelage is long, dense, and glossy; coloration of the upper parts ranges from dark ochraceous-orange to grizzled-yellowish brown, and the under parts from gray, white, or ochraceous, but hairs always with a dark gray base. The pinnae are small, slightly hairy, and dark, contrasting with paler dorsal coloration. The manus and pes are covered dorsally with short, dark hairs. Digits II–IV of the hindfeet are much longer than dI and dV (claw of dI reaches the medial portion of first phalanx of dII; claw of dV extends to interphalangeal joint of dIV). The plantar surface of the hindfoot is naked, densely covered with small epidermal tubercles distally, and has one or two small metatarsal pads (the thenar pad is always present, but the hypothenar pad is either absent or extremely reduced) and four very small interdigital pads. Small webs of skin are present between the digits II, III, and IV, but seldom extending more than about half the length of the first phalanx. Both forefeet and hindfeet have sparse ungual tufts covering but seldom extending beyond the tips of the claws (the tufts are absent on the hallux); the hindfeet lack natatory fringes. The tail is unicolored and sparsely haired, without a terminal pencil or tuft of distinctly longer hairs. Females have four pairs of mammae, one each in inguinal, abdominal, postaxial, and pectoral positions.

The skull is medium sized and robust. The rostrum is short and wide, and flanked by deep zygomatic notches. The nasals have squared or gently rounded posterior margins that extend posteriorly approximately to the same level as or slightly beyond the lacrimals; lacrimals usually have a longer maxillary than frontal suture. The interorbital margins converge anteriorly and possess strongly beaded

supraorbital edges; the braincase is squared and relatively narrow, with well-developed temporal, lambdoidal, and nuchal crests. The posterior wall of the orbit is smooth. The frontosquamosal suture is anterior to the frontoparietal suture (the dorsal facet of the frontal is in broad contact with the squamosal). The parietal has a broad lateral expansion, a large portion of which dips below the temporal ridge posteriorly. The zygomatic arches are rounded or slightly convergent anteriorly, widest across middle portion of the arch or more posteriorly. The zygomatic plates lack anterodorsal spinous processes, and their posterior margins lie level to the alveolus of M1. Incisive foramina are broad and short, terminating well anterior to the alveoli of the M1s. The palatal bridge lacks deep furrows or median ridges, and extends slightly behind the third molars; conspicuous posterolateral palatal pits are present. The bony roof of the mesopterygoid fossa is perforated by reduced and narrow sphenopalatine vacuities. The postglenoid foramen is large and rounded, but the subsquamosal fenestra is absent or vestigial. The mastoid is completely ossified, or has only a small perforation (mastoid fenestra absent). The mandible is robust, with a large falciform coronoid process slightly higher than the condyloid process, and a rounded angular process. The capsular process is developed, situated below or just posterior to the base of the coronoid process.

The upper incisors are ungrooved and opisthodont. The molars are pentalophodont and bunodont. Maxillary toothrows are parallel; the molar series is robust and long, ranging from 5.3–6 mm in length; the labial and lingual flexi of upper molars shallowly penetrate at molar midline; the labial and lingual flexi are arranged in opposite pairs. Labial cingula are present, obliterating the lateral view of labial folds. The anterocone of M1 is undivided (anteromedian flexus absent); the anteroloph is well developed and fused with the anterocone by a labial cingulum; a protocone is absent; an enamel bridge connects the paracone to the posterior portion of the protocone. M2 usually lacks a protoflexus and the mesoflexus is present as single fossette. M3 has a mesoloph, posteroloph, and shallow hypoflexus (that disappears with wear); the paracone and protocone are distinguishable on the molar surface, the hypocone is reduced, and the metacone is greatly reduced and completely fused with the posteroloph. The labial accessory root of M1 is present (four roots total).

Lower molars have the labial and lingual cusps in an opposite orientation. The anteroconid of m1 is undivided but contains a large internal fossetid; an anterolabial cingulum is developed in m1 but is absent on m2 and m3; an anterolophid is absent on m2, and the mesolophid is present in all lower molars; the ectolophid is absent, but an ectostylid is observed in the m1 of some specimens; the posteroflexid on m3 is large and persistent. There are four roots on m1, one

anterior, one posterior, one lingual (below the metaconid), and one labial (below the metaconid); both m2 and m3 possess three roots each (two anterior and one posterior).

The axial skeleton consists of 12 ribs and 7 cervical, 19 thoracolumbar, 4 sacral, and 33–36 caudal vertebrae. The hemal arch between the second and third caudal vertebrae rarely forms a posterior spinous process. The entepicondylar foramen is absent, and the supratrochlear is present. The trochlear process of the calcaneus is noticeably posterior to the articular facet.

The gall bladder is absent. The glans penis has a deep terminal crater with three bacular mounds containing a tridigitate distal cartilaginous apparatus, with the central digit more slender than lateral ones; the dorsal papilla exhibits one apical spine, and a spineless urethral process without lateral lobule. The preputial glands are large.

SYNONYMS:

Sigmodontomys J. A. Allen, 1897a:38; type species *Sigmodontomys alfari* J. A. Allen, by original designation.

Nectomys: Thomas, 1897f:547; part (description of *russulus*); not *Nectomys* Peters.

Oryzomys: J. A. Allen, 1908:635; part (description of *ochraceus*); not *Oryzomys* Baird.

Nectomys (*Sigmodontomys*): Hershkovitz, 1944:21; part (listing of *alfari*, *efficax*, *russulus*, and *esmeraldarum*); subgeneric designation.

Oryzomys (*Sigmodontomys*): A. L. Gardner and Patton, 1976:11; subgeneric designation.

REMARKS: Hershkovitz (1944, 1948b) included *Sigmodontomys* as a subgenus of *Nectomys*, and considered *Sigmodontomys alfari* as the single species, with four subspecies. Cabrera (1961) proposed a similar taxonomic arrangement, but A. L. Gardner and Patton (1976), on the basis of karyology and bacular morphology, considered *Sigmodontomys* to be a subgenus of *Oryzomys* (Baird 1857). Musser and Carleton (1993, 2005) regarded *Sigmodontomys* as a full genus, an arrangement corroborated by Weksler's (2003, 2006) phylogenetic analyses.

Cadena et al. (1998) reported a distinct species from Nariño in the Colombian Chocó as "*Sigmodontomys* sp.," but ongoing research (M. Pinto and M. Weksler, unpubl. data) suggests that this specimen belongs to a new taxon phylogenetically close to *Mindomys hammondi* (see Pine et al. 2012).

Bonvicino (1999) placed *Nectomys parvipes* (Petter 1979) in the genus *Sigmodontomys*, but following Voss et al. (2001: 94–95), I treat this taxon as a synonym of *Nectomys rattus* (see *Nectomys* account).

Recent molecular phylogenetic analyses (Hanson and Bradley 2008; Pine et al. 2012) recovered *Sigmodontomys alfari* as nested within *Melanomys*, rendering the latter taxon polyphyletic. Pine et al. (2012) suggested that the

non-monophyly of *Melanomys* was due to incomplete lineage sorting as their cladistic analysis of morphological characters corroborated the monophyly of this genus relative to other Oryzomyini. Herein, I retain both *Melanomys* and *Sigmodontomys* as separate genera, but additional analyses are required to confirm this arrangement.

Nectomys [(*Sigmodontomys*)] *alfari russulus*: Hershkovitz, 1944:77; name combination.

Nectomys [(*Sigmodontomys*)] *alfari esmeraldarum*: Hershkovitz, 1944:78; name combination.

Oryzomys (*Sigmodontomys*) *alfari*: A. L. Gardner and Patton, 1976:11; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Sigmodontomys alfari* is found throughout trans-Andean lowland and lower montane forests in Colombia, Venezuela, and Ecuador; most collecting localities range from sea level to 1,300 m; this species also

occurs in Central American lowland forests from Panama to Honduras.

SELECTED LOCALITIES (Map 242): COLOMBIA: Antioquia, La Tirana (USNM 499611), Valdivia (type locality of *Nectomys russulus* Thomas); Caldas, Samaná, Río Hondo (FMNH 71639); Cauca, Güengüé (AMNH 32183), Sabanetas (FMNH 90282); Chocó, Teresita, Río Truando (FMNH [B-185]); Córdoba; Socorré, upper Río Sinú (FMNH 69192); Nariño, Barbaças (type locality of *Oryzomys barbaças* J. A. Allen), Guayacana (FMNH 89563); Norte de Santander, San Calixto, Río Tarrá (USNM 279742); Valle del Cauca, Buenaventura, Palmares del Pacífico (USNM 483981), Virology Field Station, Río Raposo (USNM 334703). ECUADOR: Esmeraldas, Río Blanco, near Mindo (BM 34.9.10.214), San Javier (type locality of *Nectomys esmeraldorum* Gyldenstolpe); Guayas, Bucay (AMNH 61355). VENEZUELA: Zulia, Novito, 19 km WSW of Machiques (USNM 442251).

SUBSPECIES: I treat *Sigmodontomys alfari* as monotypic.

NATURAL HISTORY: In Panama, Handley (1966) recorded *Sigmodontomys alfari* as a common species, occurring in marshes, abandoned cane fields, and other for-

est openings. In Venezuela, Handley (1976) secured specimens on the ground under low bushes in a banana patch, both near streams and at dry sites. The species is said to be semiaquatic (F. A. Reid 1997; Lord 1999), but no factual report on its swimming ability was found; analysis of morphological characters (e.g., interdigital webbing reduced, natatory fringes absent), however, indicate that it has fewer semiaquatic adaptations than *Nectomys* (Thomas 1897f; Weksler 2006). Handley (1966) reported *S. alfari* at lower elevations in Panama, but Goodwin (1946: 402) stated that in Costa Rica, “[S.] *alfari* occupies higher regions”; most South American records of *S. alfari* are from localities between 200 and 1,300 m (Musser et al. 1998; McCain et al. 2007), but one locality (Sabanetas) is situated at 1,900 m (Musser et al. 1998). Recorded parasites include the flea *Polygenis roberti*, the chiggers *Crotiscus desdentatus*, *Eutrombicula goeldii*, and *Pseudoschoengastica bulbifera*, the laelapids mites *Echinolaelaps lowei* and *Gigantolaelaps* spp., the tick *Teratohrix higae*, and the nematodes *Hypocristata anguillula*, *Stilestrongylus barusi*, and *Syphacia alata* (Quentin 1969; Durette-Desset and Guerrero 2006; Digiani and Durette-Desset 2007; Goff 1981; Wenzel and Tipton 1966).

REMARKS: A. L. Gardner and Patton (1976) reported a $2n = 56$ FN = 54 karyotype for Costa Rican specimens.

Map 242 Selected localities for *Sigmodontomys alfari* (●); range in Panama from F. A. Reid (2009). Contour line = 2,000 m.

Genus *Sooretamys* Weksler, Percequillo, and Voss, 2006

Alexandre R. Percequillo

The only known species of this genus, *Sooretamys angouya*, is widely distributed in eastern South America, from the Brazilian Atlantic rainforest to the humid forests of eastern Argentina and Paraguay.

Sooretamys angouya is easily distinguished from other sympatric oryzomyines (such as *Euryoryzomys russatus*, *Hylaeamys laticeps*, *Hylaeamys megacephalus*, and *Nectomys squamipes*) by its larger size (head and body length 125–215 mm), a tail much longer than head and body (range: 160–240 mm), and nonwebbed, robust, and wide hindfeet (length 25–42 mm). The body pelage is soft, long, and very dense; wool hairs are thin, long, and wavy; cover hairs are longer and thicker on their distal half; and guard hairs are much longer, stiffer, and thicker over their distal third. The dorsal body color varies from buffy yellow grizzled with dark brown to buffy orange grizzled with black. Ventral color grades from a whitish or buff weakly grizzled with gray to an almost pure white, buff, or buffy yellow. The tail is covered with short hairs, which do not conceal large scales; tail scales and hairs are blackish or dark brown, and the tail is unicolored. Internal and external surfaces of ears are well

furred, with hairs entirely brown. Forefeet and hindfeet are covered above by short hairs, and the ungual tufts of the toes are dense and long, almost concealing the claws. Brown hairs typically cover the dorsal surface of the hindfeet although some specimens have only a dark brown line or diffuse patch along the length of the foot. Ungual tuft hairs are proximally brown but white at their tips. Mystacial vibrissae are very dense and long, surpassing the ears when laid back; the most dorsal vibrissae are dark brown with golden tips, and the most ventral are entirely white.

The skull of *Sooretamys* is unique among genera of the *Oryzomyini*, easily recognized by its larger size (skull length 35.6–44.3 mm); longer incisive foramina (length 7.3–9.5 mm) that reach the alveolus of M1 in many specimens; long and narrow interorbital region (breadth 4.9–6.0 mm), hourglass in shape, with squared supraorbital margins; and very robust molars (toothrow length 5.6–6.5 mm; M1 breadth 1.5–1.8 mm). The rostrum is long and wide, flanked by well-inflated capsular projections of the nasolacrimal foramen. The zygomatic plates are wide, with straight or concave free anterior margins well projected anteriorly. The zygomatic arches are expanded laterally and wider near their squamosal roots. The braincase has a rounded profile, with the temporal border squared but without crests or beads. The palate is long with deep and complex posterolateral pits; palatal excrescences are absent. The roof of the mesopterygoid fossa is perforated by long and wide sphenopalatine vacuities that expose the orbitosphenoid bone. The stapedial foramen is minute or absent and, with the lack of both a squamosoalisphenoid groove and sphenofrontal foramen, configures the derived carotid circulatory pattern 3 (*sensu* Voss 1988). The buccinator-masticatory and accessory oval foramina are confluent, so all specimens lack an alisphenoid strut. Both the postglenoid foramen and sub-squamosal fenestra are large apertures. Auditory bullae are large (breadth of one bulla range: 4.9–5.9 mm), with short stapedial processes and well-developed dorsostapedial processes overlapping the squamosal. The suspensory process of the squamosal is absent, and the tegmen tympani is short and may or may not overlap the squamosal.

The mandible has a low coronoid process, nearly triangular in shape and equal in height to the condyloid process; the angular process does not exceed the condyloid process. Both superior and inferior notches are shallow.

Upper incisors are opisthodont. Molars are pentalo-phodont and low-crowned with the main cusps arranged in opposite pairs, and with labial and lingual flexi interpenetrating only slightly at the median molar plane. On M1 and M2, the paracone is connected medially to the protocone, not to the median mure, defining a long and obliquely oriented parafossette that fuses to the metacone only with heavy wear. M1 has four roots, one anterior, one

posterior, and two accessory rootlets; M2 and M3 each has two roots.

The axial skeleton comprises 7 cervical, 12–13 thoracic, 6–7 lumbar, 4 sacral, and 31–36 caudal vertebrae. Hemal arches have a distinct median posterior process.

The stomach is unilocular and hemiglandular; the bordering fold between gastric and glandular epithelium is well developed and oriented at 45° to the right of stomach. The gall bladder is absent. The glans penis is complex (terminology of Hooper and Musser 1964). The proximal bony baculum has a wide and flattened basal portion and long and rounded apical portion. The cartilaginous terminal baculum is tridigitate and well developed, about half the length of the bony baculum; the central cartilaginous digit is longer than the laterals, with its distal apex extending past the glans body.

- [Sooretamys] angouya*: Weksler, Percequillo, and Voss, 2006:23; first use of current name combination.
- DESCRIPTION: As for the genus.
- DISTRIBUTION: *Sooretamys angouya* is distributed along the forested foothills and slopes of the Serra do Mar, Serra da Mantiqueira, and eastern hillsides of the Serra do Espinhaço (all in the Atlantic Forest), and coastal lowland forests (*restinga*) from Espírito Santo to Rio Grande do Sul states, Brazil, including some of the coastal islands in Santa Catarina and São Paulo states. To the west, this species reaches the Argentinean provinces of Misiones, Corrientes, and Entre Ríos, on the right (= east) bank of the Río Paraguay and the Argentinean provinces of Formosa and Chaco and the Paraguayan state of Presidente Hayes, on the left (= west) bank of the Río Paraguay.
- SELECTED LOCALITIES (Map 243): ARGENTINA: Corrientes, Santa Tecla, Rte 12, km 1287 (MLP 1.X.94.5); Entre Ríos, Isla Chapetón, Río Paraná (Teta, Pardiñas et al. 2007); Formosa, Estancia Guaycolec (Teta, Pardiñas et al. 2007). BRAZIL: Espírito Santo, Hotel Faz Monte Verde, 24 km SE of Venda Nova do Imigrante (UFPA 334); Rio São José (MZUSP 6210); Minas Gerais, Lagoa Santa (type locality of *Calomys rex* Winge), Passos (MNRJ 32745); Rio de Janeiro, Fazenda do Tenente, São João de Marcos (MNRJ 5768); Rio Grande do Sul, Capão do Leão, Mostardas (UFRGS 2114), Fazenda Aldo Pinto, São Nicolau (MPEG 23275), Tôrres (UFRGS 8); Santa Catarina, Florianópolis (UFRGS 2042); São Paulo, Iguapé (MZUSP 26799), Ilha do Mar Virado (MZUSP AUC 165), Rio Feio (MZUSP 1910), Teodoro Sampaio (MZUSP 25324). PARAGUAY: Amambay, 4 km by road SW of Cerro Corá (UMMZ 125457); Paraguari, Sapucay (type locality of *Oryzomys ratticeps paraganus* Thomas); Presidente Hayes, 24 km NW of Villa Hayes (UMMZ 133795).
- SUBSPECIES: I treat *Sooretamys angouya* as monotypic.
- NATURAL HISTORY: *Sooretamys angouya* is a scansorial species that can be captured both on the ground, on vines, and in trees (data from skin tags and collector field journals). Olmos (1992) reported that *S. angouya* is an aggressive species that, when caught in the same trap with another species, always killed and ate the individual, and that fights were commonplace when conspecifics were together. Olmos (1992:561) also reported that this species moved on the ground by meter-long leaps, and that individuals were good climbers of both trees and rock walls, as well good diggers, producing "extensive tunnels, even in hard, rocky ground."
- In the eastern part of its range, *S. angouya* inhabits mature and undisturbed portions of the Atlantic Forest, but is more commonly observed in secondary forests (Pardini

and Umetsu 2006). In westernmost regions (Formosa, Argentina, and Presidente Hayes, Paraguay), the species occurs in patches and remnants of semideciduous and gallery forests amid Chaco vegetation (G. D'Elia, pers. comm.).

Females were reproductively active during October and November (Olmos 1992), with juveniles being trapped in June (dry season).

REMARKS: The taxonomic history of *S. angouya* is long and contorted, confounded especially by the several names proposed for the rat described by D. Felix de Azara (1801, 1802) as the “rat troisième ou rat angouya” and “del anguyá,” the specimens of which have been lost since the nineteenth century (see also Desmarest 1804, who referred to Azara’s “rat angouya”). Some authors have suggested that the epithet “angouya” should refer to a Paraguayan species of the genus *Cerradomys* (specifically *Cerradomys maracajuensis*; e.g., Avila-Pires 1960a; Myers et al. 1995; Percequillo 1998) or was best considered a *nomen dubium* (Weksler 1996). Musser et al. (1998), on the other hand, resolved the conundrum by defining a neotype for *Mus angouya* G. Fischer and associating it to the species then formerly known as *Oryzomys ratticeps* Hensel. This nomenclatural act brought stability to the taxon, although the official availability of G. Fischer’s names has not as yet been accepted by explicit action of the International Commission on Zoological Nomenclature (see Langguth 1966b; Sabrosky 1967; Musser et al. 1998).

Winge (1887) named as *Calomys rex* those specimens of *S. angouya* obtained by Peter W. Lund, preserved as fossil or subfossil material from the caves of Lagoa Santa, Minas Gerais. There are, however, no recent records of *S. angouya* from this region. The specimen Avila-Pires (1960b) recorded from the “Lagoa Santa region” actually came from Conceição do Mato Dentro, which is located nearly 110 km northeast of Lagoa Santa on the eastern slope of Serra do Espinhaço, a more humid area predominantly covered by forests. Today, the region of Lagoa Santa is covered mostly by Cerrado vegetation or is transitional between semideciduous forest and Cerrado. The same distributional pattern of typical forest-dwelling species registered in the caves of Lagoa Santa as fossils and subfossils is also observed for many other sigmodontine and echimyid genera, such as *Blarinomys breviceps*, *Bucepattersonius*, *Delomys* sp., *Euryoryzomys russatus*, and *Callistomys pictus* (Voss 1993; Emmons and Vucetich 1998; Voss and Carleton 1993; Musser et al. 1998; C. R. Silva et al. 2003; Pardiñas and Teta 2013a; see also Voss and Myers 1991 for a summary of the Lagoa Santa cave fauna).

C. O. da C. Vieira (1953:134) identified specimens of this species from São Paulo state, Brazil, as *Holochilus physodes physodes*, a name combination confusingly applied histori-

Map 243 Selected localities for *Sooretamys angouya* (●). Contour line = 2,000 m.

cally to both *Holochilus* and *Reithrodon* (see Musser et al. 1998:280–284, and accounts of those genera).

The karyotype of *S. angouya* is polymorphic, with diploid numbers ranging from 57–60 and fundamental numbers from 60–64 arms (E. J. C. Almeida 1980; Zanchin 1988; M. J. de J. Silva 1994; Geise 1995).

Genus *Tanyuromys* Pine, Timm, and Weksler, 2012

Marcelo Weksler

Tanyuromys is a monotypic genus found at a few mid-elevation forest sites in Costa Rica, Panama, and Ecuador. To date, only eight specimens are known for the genus, and thus our distributional and ecological knowledge of this taxon is quite sparse (e.g., we do not know whether the lack of collecting sites in Colombia is a sampling artifact or real). Until recently (Musser and Carleton 2005), *aphrastus* W. P. Harris was included in *Sigmodontomys*. Phylogenetic analyses (Weksler 2006; Pine et al. 2012), however, demonstrated that *aphrastus* was not closely related to *S. alfari* J. A. Allen, and Pine et al. (2012) thus erected *Tanyuromys* to contain *aphrastus*. The following morphological description is a synthesis of the recent work on this taxon by Weksler (2006), McCain et al. (2007), and Pine et al. (2012).

Tanyuromys are medium-sized rodents (adult head and body length range: 116–152 mm). The tail is much longer than the combined head and body length (length

176–235 mm), and the hindfeet are long and robust (length 35–40 mm). The dorsal pelage is long, thick, and soft. Coloration of the upper parts is grizzled dark brown with orange highlights, and that of the under parts is paler gray with pronounced ochraceous highlights but always with a dark gray base. The dorsoventral countershading is subtle, not as strong as in many other oryzomyines. The pinnae are small and sparsely to moderately covered with blackish, dark brown, or reddish-brown hairs both internally and externally. The mystacial and superciliary vibrissae are very long (extending posteriorly beyond caudal margins of the pinnae). The manus and pes have a sparse to moderate coverage of pale brown to dark brown hairs dorsally. Digits II–IV of the hindfeet are longer than dI and dV (claw of dI reaches the proximal portion of first phalanx of dII; claw of dV extends to the distal portion of second phalanx of dIV). The plantar surface of the hindfoot is naked, densely covered with small epidermal tubercles distally, and has one or two small metatarsal pads (the thenar pad is always present, but the hypothenar pad may be absent or extremely reduced) and four large and fleshy interdigital pads. The hindfeet lack well-developed natatory fringes and interdigital webs, and have sparse unguis tufts covering, but seldom extending beyond, the tips of claws (the tufts are absent on the hallux). The tail is unicolorous brown and sparsely haired, terminating in a short tuft of hairs but without a distinctly longer terminal pencil. Four pairs of mammae are present, one each in inguinal, abdominal, postaxial, and pectoral positions.

The skull is medium sized and robust. The rostrum is short and stout, and flanked by very shallow zygomatic notches. The nasals have acutely angled posterior margins extending posteriorly beyond the premaxillae and behind lacrimals, nearly reaching the interorbital constriction level; the lacrimals have longer maxillary than frontal sutures. The interorbital margins converge anteriorly and possess overhanging supraorbital edges; the braincase is rounded and broad, with well-developed temporal, lambdoidal, and nuchal crests. The frontosquamosal suture is anterior to the frontoparietal suture (the dorsal facet of the frontal is in broad contact with the squamosal). The parietal has a broad lateral expansion, a large portion dipping below the temporal ridge posteriorly. The zygomatic arches are convergent anteriorly, relatively unbowed, and widest at the squamosal root; the jugal is large, and the maxillary and squamosal zygomatic processes are widely separated, not overlapping in lateral view. The zygomatic plates lack anterodorsal spinous processes, and their posterior margins lie anterior to the alveoli of the M1s. The incisive foramina are short and terminate far anterior of the alveoli of the M1s. The palatal bridge lacks deep furrows or median ridges, extends only slightly behind the M3s, and is perforated by small

and simple posterolateral palatal pits. The bony roof of the mesopterygoid fossa is usually perforated by narrow sphenopalatine vacuities. The stapedia foramen and posterior opening of alisphenoid canal are very small, and the squamosalisphenoid groove and sphenofrontal foramen are absent, with secondary anastomosis of the internal carotid across the dorsal surface of the pterygoid plate (= carotid circulatory pattern 3 of Voss 1988). The postglenoid foramen is large and rounded, but the subsquamosal fenestra is absent or vestigial. The mastoid is completely ossified, or has only a small perforation (mastoid fenestra absent). The mandible is robust, with a large falciform coronoid process slightly higher than the condyloid process, and with a rounded angular process. The capsular process is usually absent, or present as a slight rounded elevation not protruding above the level of the coronoid-condylar notch. Superior and inferior masseteric ridges join anteriorly as a single crest below m1.

The upper incisors are ungrooved and opisthodont. The molars are pentalphodont and bunodont, with an apomorphic and complex occlusal pattern having extensive, deep, steep-sided flexi and fossettes (enamel islands) with irregular and jagged borders. The maxillary toothrows are mostly parallel, with a slight divergence posteriorly. The molar series is robust and long, ranging from 5.6–6.2 mm in length. Labial and lingual flexi of the upper molars are deeply interpenetrating; labial flexi are convoluted and enclosed by a cingulum. The anterocone of M1 is undivided, the anteroloph is well developed and fused with the anterocone by a labial cingulum, and the protostyle absent; an enamel bridge connects the paracone to the posterior portion of the protocone. The M2 protoflexus is usually absent, the mesoflexus is usually present as a single fossette. M3 has a mesoloph, posteroloph, and shallow hypoflexus (which disappears with wear); the paracone and protocone are distinguishable on the molar surface; and the hypocone is reduced, and the metacone is greatly reduced and completely fused with the posteroloph. The labial accessory root of M1 is present (four roots total).

On the lower molars, the labial and lingual cusps are opposite. The anteroconid of m1 is undivided but contains a large internal fossetid; the anterolabial cingulum and a small anterolophid are present on all lower molars, the latter disappearing with moderate to heavy wear. The mesolophid is present in all lower molars, and the ectolophid is absent. The posteroflexid on m3 is large and persistent. The first lower molar has four roots, one anterior, one posterior, one lingual (below the metaconid), and one labial (also below the metaconid).

The gall bladder is absent. The stomach is unilocular-hemiglandular with glandular epithelium extending into corpus.

SYNONYMS:

Oryzomys: W. P. Harris, 1932:5; part (description of *aphrastus*); not *Oryzomys* Baird.

Sigmodontomys: Musser and Carleton 1993:748; part (listing of *aphrastus*); not *Sigmodontomys* J. A. Allen.

Tanyuromys Pine, Timm, and Weksler, 2012:858; type species *Oryzomys aphastrus* W. P. Harris, by original designation.

REMARKS: Phylogenetic analyses (Weksler 2006; Pine et al. 2012) indicate that *Tanyuromys* is a member of an oryzomyine clade that also includes *Aegialomys*, *Nesoryzomys*, *Melanomys*, and *Sigmodontomys*, all trans-Andean taxa distributed in southern Central America and northern South America (especially west of the Andes), and the Galapagos Islands.

Tanyuromys aphastrus (W. P. Harris, 1932)

Long-tailed Montane Rat

SYNONYMS:

Oryzomys aphastrus W. P. Harris, 1932:5; type locality “Joaquin de Dota, Costa Rica. This locality is southeast of Santa Maria de Dota in the Pacific rain forest at an altitude of about 4,000 feet”; [= San Joaquín de Dota, Cordillera de Talamanca, San José, Costa Rica, 1,220 m; 09°35'N, 83°59'W].

Sigmodontomys aphastrus: Musser and Carleton 1993:748; name combination.

Tanyuromys aphastrus: Pine, Timm, and Weksler, 2012: 859; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Tanyuromys aphastrus* is known only from six middle-elevation (700–2,000 m) localities in north-central Costa Rica, western Panama, and northwestern Ecuador.

SELECTED LOCALITIES (Map 244; South American only): ECUADOR: Imbabura, 10 km E of Santa Rosa (QCAZ 10427); Pichincha; Guarumos (MCZ 50396), Mindo (UMMZ 155808).

SUBSPECIES: *Tanyuromys aphastrus* is monotypic.

NATURAL HISTORY: McCain et al. (2007) provided almost all known information about the natural history of this species, a synthesis of which is presented here. All eight known specimens were collected in traps set on the ground. In Costa Rica and Pichincha (Ecuador), specimens were taken in intact, mature montane forest; in Imbabura (Ecuador), one specimen “was collected in a mixed forest and tall-grass area within 10 m of a stream” (T. E. Lee et al. 2010:10); and in Panama, two specimens were captured “in disturbed, fairly open, relatively dry habitat, which included mixed grass, weeds, brush, oaks, and other trees” (R. H. Pine, pers. comm., cited in McCain et al. 2007:131). It is unclear from the few specimens available despite substantial trapping effort whether *T. aphastrus* occurs in very

Map 244 Selected localities for *Tanyuromys aphastrus* in South America (●). Contour line = 2,000 m.

low densities or is simply difficult to trap using standard methods.

Of the eight available specimens, three are females, and five are males. Six specimens are adults; one adult male caught at Monteverde, Costa Rica, had descended testes measuring 7×5 mm and another from Chiriquí, Panama, had testes measuring 5 mm in length. The remaining two specimens include a juvenile female caught in Monteverde Cloud Forest Reserve and a young adult male from Chiriquí. One species of tick (*Ixodes sinaloa*) was collected from an adult at Monteverde.

REMARKS: The karyotype of *Tanyuromys aphastrus* is unknown. *Tanyuromys* differs from all other extant Oryzomyini (*sensu* Weksler 2003; Weksler et al. 2006; Weksler and Percequillo 2011) in the degree of lophodonty and the complicated enamel folding pattern of flexi and flexids of the molars (Pine et al. 2012).

Genus *Transandinomys* Weksler, Percequillo, and Voss 2006

Michael D. Carleton

Transandinomys contains two species (*bolivaris* J. A. Allen, 1901; *talamancae* J. A. Allen, 1891) that inhabit lowland to premontane wet forests in Central America and northwestern South America. They are medium sized (head and body length ranges from 100 to 140 mm) and possess a nearly naked, finely scaled tail that is as long as to slightly longer than the head and body. Conformation of

the hindfoot indicates scampering, terrestrial habits: relatively long (about 26 to 32 mm) and narrow; digits I and V short relative to II–IV; ungual tufts ample; plantar pads six in number, 1 and 4 displaced proximally from 2 and 3, hypothenar small but discrete. The long arrays of cephalic vibrissae constitute the most definitive external trait, notably the sweeping superciliary vibrissae that extend posteriorly well behind the pinnae. Eight teats are present.

The cranium is moderate in build and size (occipitonasal length about 28 to 32 mm) and elongate in conformation, displaying a long, attenuate rostrum, nearly parallel-sided zygomatic arches, moderately incised zygomatic notch, and a rectangular, boxy braincase. Distinct supraorbital shelves with beaded edges mark the frontal borders and impart a cuneate shape to the interorbital constriction. The subsquamosal fenestra penetrates the posterior wall of the braincase as a narrow cleft, notably smaller than the companion postglenoid foramen. The incisive foramina are intermediate in length (i.e., not as long as in *Oryzomys* proper but longer than *Hylaeamys*), but do not extend between the alveoli of the M1s. The bony palate is narrow and long, as characteristic of most oryzomyines, and posterolateral palatal pits are well defined. The anterior border of the mesopterygoid fossa is evenly rounded, and sphenopalatine vacuities are consistently patent as short, narrow slits. The ectotympanic bulla is small, revealing a narrow posteromedial wedge of the periotic. The carotid arterial pattern of both species is complete (pattern 1 of Voss 1988: stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen present. Alisphenoid struts are absent).

The molar rows in both species of *Transandinomys* (coronal length of M1–3 range: 4.3–4.7 mm) are brachydont and cuspidate, the primary cusps positioned as opposite pairs, and the occlusal configuration is fundamentally pentalophodont (anterolophs, mesolophs, mesolophids present). The anterocone of the M1 is broad and undivided (anteromedian flexus absent). M2 has a long paraflexus and single median fossette, and the m2 has a long hypoflexid that crosses the midline of the tooth. The upper molars possess three roots (labial accessory root absent), and the lowers have two. The upper incisors are moderately robust, asulcate, and opisthodont.

Most taxonomic, nomenclatural, morphological, and distributional information on the component species is contained in the studies of Goldman (1918), Pine (1971), Musser and Williams (1985), and Musser et al. (1998), all as reported under *Oryzomys* in its formerly all-inclusive sense.

SYNONYMS:

Oryzomys: J. A. Allen, 1891a:193; part (description of *talamancae*); not *Oryzomys* Baird.

Transandinomys Weksler, Percequillo, and Voss 2006:25; type species *Oryzomys talamancae* J. A. Allen, by original designation.

REMARKS: No special relationship between *bolivaris* and *talamancae* was perceived in the early taxonomic literature on oryzomyine rodents. Goldman (1918) segregated the two into monotypic species groups, *talamancae* and *bombycinus* (= *bolivaris*), within the genus *Oryzomys sensu lato*. The identity of each was lost following Hershkovitz's (1960) precipitous allocation of forms believed to be synonymous with *Oryzomys capito*, a footnoted opinion formalized by Cabrera (1961) in his influential classification of South American mammals. Musser et al. (1998) differentiated *bolivaris* and *talamancae* in detail because of their close morphological resemblance and overlapping trans-Andean distributions, and compared the two to members of the *megacephalus* and *nitidus* complexes. In separate and combined analyses of morphological and molecular data, *Transandinomys talamancae* regularly emerged in a large oryzomyine clade that also included species of *Euryoryzomys*, *Handleyomys*, *Hylaeamys*, *Nephalemys*, and *Oecomys* (Weksler 2003, 2006; Percequillo, Weksler, and Costa 2011; Pine et al. 2012). See Weksler et al. (2006, especially Table 3) for morphological traits that discriminate these groups. As noted by those authors, the exceptionally long superciliary vibrissae offer the most persuasive synapomorphy for associating *bolivaris* with *talamancae* in a monophyletic genus.

KEY TO THE SPECIES OF *TRANSANDINOMYS*:

1. Dorsal pelage longer, dark brown and somber, under parts dark gray; mystacial and superciliary vibrissae extremely long (>45 mm); tail as long as head and body; supraorbital ridges well defined; parietal rarely contributes to the lateral braincase wall below the temporal ridge; incisive foramina long relative to bony palate, nearly reaching level of M1s *Transandinomys bolivaris*
- 1'. Dorsal pelage shorter, tawny and brightly colored, under parts bright whitish-gray; mystacial and superciliary vibrissae long (<40 mm); tail slightly longer than head and body; supraorbital ridges weak; parietal contributes substantially to the lateral braincase wall below the temporal ridge; incisive foramina short relative to bony palate, terminating conspicuously anterior to level of M1s *Transandinomys talamancae*

Transandinomys bolivaris (J. A. Allen, 1901)

Long-whiskered *Oryzomys*

SYNONYMS:

Oryzomys bolivaris J. A. Allen, 1901c:405; type locality "Porvenir, Bolivar, Ecuador, altitude 1800."

Oryzomys castaneus J. A. Allen, 1901c:406; type locality "San Javier, [Esmeraldas,] northern Ecuador, altitude 60 ft."

Oryzomys rivularis J. A. Allen, 1901c:407; type locality "Rio Verde, [Pichincha,] northern Ecuador, altitude 3200 ft."

Oryzomys bombycinus Goldman, 1912a:6; type locality “Cerro Azul (altitude 2500 feet), near the headwaters of the Chagres River, [Panamá,] Panama.”

Oryzomys nitidus alleni Goldman, 1915:128; type locality “Tuis (about 35 miles east of Cartago), [Cartago,] Costa Rica.”

Oryzomys bombycinus bombycinus: Goldman, 1918:77; name combination.

Oryzomys bombycinus alleni: Goldman, 1918:78; name combination.

[*Oryzomys* (*Oryzomys*)] *bolivaris*: Tate, 1932e:16; name combination.

[*Oryzomys* (*Oryzomys*)] *castaneus*: Tate, 1932e:16; name combination.

[*Oryzomys* (*Oryzomys*)] *rivularis*: Tate, 1932e:16; name combination.

Oryzomys bombycinus orinus Pearson, 1939:2; type locality “Mount Pirre, [Darién,] eastern Panama, at an altitude of 4700 feet along the Rio Limón.”

Oryzomys capito bolivaris: Cabrera, 1961:385; name combination.

Oryzomys capito castaneus: Cabrera, 1961:385; name combination (*rivularis* allocated as full synonym, invalid as subspecies).

Oryzomys talamancae: Musser and Williams, 1985:14; part (*castaneus* included as synonym).

Oryzomys bolivaris: Musser and Carleton (1993:720); name combination (*alleni*, *bombycinus*, *castaneus*, *orinus*, and *rivularis* allocated as synonyms without indication of rank).

[*Transandinomys*] *bolivaris*: Weksler, Percequillo, and Voss, 2006:25; name combination (*alleni*, *bombycinus*, *castaneus*, *orinus*, and *rivularis* listed as synonyms without indication of rank).

DESCRIPTION: Individuals remarkable for extraordinary length of superciliary and genal vibrissae (see the Key) and for luxuriant dark-brown fur, very soft in texture and long (about 9–11 mm over middle dorsum); ventral pelage dark gray but clearly demarcated from upper parts. Tail appears nearly naked and approximates head and body in length. Moderately elongate skull characterized by wider interorbit and more prominent supraorbital shelves with beaded edges; minimal or no projection of parietal onto lateral braincase wall; and moderately long incisive foramina that end just anterior to molar rows. Most easily confused with specimens of its congener *T. talamancae* or with those of “*Handleyomys*” *alfaroi*, particularly where they may occur in sympatry (see the Key; Musser et al. [1998:125–143] supplied detailed comparisons with both taxa).

DISTRIBUTION: *Transandinomys bolivaris* occurs at low to middle elevations from southeastern Honduras, through eastern Nicaragua, Costa Rica, and Panama, to western Colombia and west-central Ecuador (as far as

Manabí province), west of the Andes; elevational range in South America, about sea level to 1,800 m.

SELECTED LOCALITIES (Map 245; from Musser et al. 1998, except as noted): COLOMBIA: Cauca, Río Mechenque; Chocó, Condoto, mouth Río Condoto; Nariño, Barbacoas, on Río Telembí; Valle del Cauca, 6 km N of Buenaventura (USNM 554232). ECUADOR: Bolívar, Hacienda Porvenir, west of Hacienda Talahua (type locality of *Oryzomys bolivaris* J. A. Allen); Esmeraldas, San Javier (type locality of *Oryzomys castaneus* J. A. Allen); Manabí, Cerro de Pata de Pájaro; Pichincha, Gualea, Río Tulipe.

SUBSPECIES: I treat *Transandinomys bolivaris* as monotypic (see Musser et al. 1998:143–149).

NATURAL HISTORY: *Transandinomys bolivaris* is a denizen of lowland evergreen rainforest and lower montane rainforest (cloud forest), typically in regions of exceptional annual rainfall and rich floristic diversity (summary in Musser et al. 1998). The species is terrestrial, typically collected in very moist microenvironments within the forest (e.g., under logs, around the base of large trees, among mossy boulders along small forest streams, and in low terrain subject to flooding [Handley 1966; Pine 1971; Timm et al. 1989; González-M. and Alberico 1993]).

Map 245 Selected localities for *Transandinomys bolivaris* (●); range in Panama follows Musser et al. (1998). Contour line = 2,000 m.

REMARKS: Other names historically applied to this species include *bombycinus*, as reviewed by Pine (1971), and *rivularis*, as discussed by A. L. Gardner and Patton (1976). Musser and Carleton (1993) established the priority of *bolivaris*, and Musser et al. (1998) addressed the morphological definition, variation, geographic distribution, and synonymy of the species. Pine (1971) retained subspecies (under the name *bombycinus*), but Musser et al. (1998) judged intraspecific variation too insubstantial and population samples too small to critically delimit geographic races. The chromosome complement consists of $2n=58$, $FN=80$ (A. L. Gardner and Patton 1976; based on Costa Rican individuals reported as *bombycinus*).

Transandinomys talamancae (J. A. Allen, 1891)

Oryzomys talamancae: Musser and Williams, 1985:13; specific revision (*carrikeri*, *magdalenae*, *medius*, *mollipilosus*, *sylvaticus*, *panamensis*, and *villosus* allocated as synonyms without indication of rank).

[*Transandinomys*] *talamancae*: Weksler, Percequillo, and Voss, 2006:25; name combination (*carrikeri*, *magdalenae*, *medius*, *mollipilosus*, *sylvaticus*, *panamensis*, and *villosus* listed as synonyms without indication of rank).

DESCRIPTION: Resembles *T. bolivaris* in general size but with longer tail, distinctly longer than head and body, and smaller hindfoot. Fur more brightly colored (tawny over dorsum, tawny-buff on sides, and grayish-white on ventrum), shorter (7–9 mm over middle dorsum), and palpably coarser in texture. Superciliary and genal vibrissae long compared with most oryzomyines, but significantly shorter than those of *T. bolivaris* (see the Key). Skull with narrower interorbit and weaker supraorbital ridging; shorter incisive foramina that terminate appreciably in front of molar rows and correspondingly longer bony palate; and substantial contribution of parietal to lateral braincase wall. See Musser et al. (1998) for additional comparisons as well as diagnostic contrasts with larger *Hylaeamys megacephalus* and smaller "*Handleyomys*" *alfaroi*.

DISTRIBUTION: *Transandinomys talamancae* occupies low to middle elevations of northwestern Costa Rica, through Panama, to western and northern Colombia, northwestern Venezuela, western Ecuador, and extreme northwestern Peru; known elevational range in South America is from sea level to 1,385 m.

SELECTED LOCALITIES (Map 246; from Musser et al. 1998, except as noted): COLOMBIA: Antioquia,

24–26 km S and 21–22 km W of Zaragoza; Bolívar, San Juan Nepomuceno; Boyacá, Muzo, Río Cobaria Fatima; Caldas, Samaná; Cauca, Río Mencheque; Cesar, San Alberto; Chocó, Gorgas Memorial Laboratory, Teresita, Serranía de Baudó; Córdoba, Socorré; La Guajira, Las Marimondas; Magdalena, Cincinati (type locality of *Oryzomys mollipilosus* J. A. Allen and *Oryzomys villosus* J. A. Allen); Norte de Santander, Río Tarrá. ECUADOR: Chimborazo, Ríos Chimbo-Coco; El Oro, Salvias; Esmeraldas, 3 km W Majua; Santa Elena, Cerro de Manglaralto. PERU: Tumbes, Quebrada Los Naranjos, Zarumilla (Pacheco et al. 2009). VENEZUELA: Aragua, Rancho Grande; Miranda, Parque Nacional Guatopo; Yaracuy, Finca El Jaguar, 12 km NW of Aroa, Palmichal, 23 km N of Bejuma; Zulia, Hacienda El Tigre, 17 km N and 55 km W of Maracai; Vargas, San Julián, 8 mi E of La Guaira (type locality of *Oryzomys medius* W. Robinson and Lyon); Zulia, Misión Tukuko.

SUBSPECIES: I treat *Transandinomys talamancae* as monotypic.

NATURAL HISTORY: *Transandinomys talamancae* is a terrestrial oryzomyine that inhabits evergreen, semi-deciduous, and deciduous tropical forests, including both moist and dry associations and within primary or secondary growth (Handley 1966, 1976; T. H. Fleming 1971; O. J. Linares 1998; Musser et al. 1998; F. J. García, Delgado-Jaramillo et al. 2012). Knowledge of ecology, reproduction, population dynamics, and life history of the species is mostly derived from T. H. Fleming's (1971) long-term field study

of Panamanian populations (reported as *Oryzomys capito*). O. J. Linares (1998) reported its diet as granivorous and omnivorous.

REMARKS: Recognition of this distinctive species was long hampered by its association as a form of *Oryzomys "capito"* (Hershkovitz 1960; Cabrera 1961; Handley 1966, 1976). Musser and Williams (1985) distilled the taxonomy, morphological identity, and distribution of the species; Musser et al. (1998) amplified those topics and refined the specific contents. See Musser et al. (1998:275) for commentary on the ambiguous connotation of the type locality "Talamanca," whether a specific village, the eastern lowlands adjacent to the Cordillera Talamanca, or the Cordillera Talamanca itself. Substantial karyotypic variation in diploid ($2n=34, 36, 40, 54$) and fundamental numbers (FN=64, 66, 67) has been encountered in samples from Venezuela and Ecuador (Pérez-Zapata et al. 1986; Musser et al. 1998), unaccompanied by appreciable morphological differences. The possible taxonomic significance of this variation requires study.

Genus *Zygodontomys* J. A. Allen, 1897

Robert S. Voss

Zygodontomys is a genus of two species that occur in un-forested landscapes below about 1,300m elevation from southeastern Costa Rica throughout Panama to Colombia, Venezuela, the Guianas, and northern Brazil. Populations also occur on adjacent continental-shelf islands, including Isla Margarita, Trinidad, and Tobago, where they may occupy forest as well as nonforest habitats. *Zygodontomys* is known from skeletal material found in caves on the island of Aruba (Hooijer 1967), but it is not a member of the extant fauna of that island. Hershkovitz (1962) thought that *Zygodontomys* was a phyllotine, but morphological evidence that *Zygodontomys* belongs to the tribe Oryzomyini was discussed inter alia by Voss (1991a), Voss and Carleton (1993), and Steppan (1995). Subsequent phylogenetic analyses of sequence data from the nuclear IRBP gene strongly support the hypothesis that *Zygodontomys* is an oryzomyine (Weksler 2003, 2006). Except as noted otherwise here, the following account is based on Voss (1991a), which should be consulted for additional details about taxonomy, morphology, distribution, and natural history.

Species of *Zygodontomys* have grizzled-brownish dorsal pelage, short vibrissae (not extending behind the pinnae when laid back alongside the head), and relatively small ears and eyes. The hindfeet are short and narrow, with middle digits (II, III, and IV) that are much longer than the outer digits (I and V); distinctively long tufts of ungual hairs cover the claws dorsally, and the plantar surface is provided with two metatarsal and four interdigital pads.

Map 246 Selected localities for *Transandinomys talamancae* (●). For Central American records, see Musser et al. (1998). Contour line=2,000 m.

The tail is short, about three-quarters of the combined length of head and body, sparsely haired, and bicolored (dark above, pale below). Females have eight mammae in inguinal, abdominal, postaxial, and pectoral pairs.

The skull is unremarkable in dorsal view, with a moderately long rostrum flanked by well-developed zygomatic notches; the interorbital region is convergent and distinctly beaded, and the supraorbital bead on each side is continuous with a well-developed temporal crest on the dorsolateral surface of the braincase; the stout zygomatic arches are convergent (widest across the squamosal roots). In lateral view, the zygomatic plates are broad, with straight or convex anterior margins, but without anterodorsal spinous processes. The incisive foramina (in ventral view) are long and usually extend posteriorly to or between the first molar alveoli. The palatal bridge is broad and smooth, without conspicuous ridges, deep furrows, or a spine-like median posterior process; one or more prominent posterolateral palatal pits are present on each side behind M3. The mesopterygoid fossa does not extend anteriorly between the toothrows, and its bony roof is either complete or perforated by sphenopalatine vacuities; the flanking mesopterygoid fossae are narrow and not deeply excavated. An alisphenoid strut is absent (the buccinator-masticatory foramen and the foramen ovale are confluent). A large stapedial foramen is almost always present, but other osteological traces of the stapedial circulation are highly variable (most specimens exhibit either pattern 1 or pattern 2 of Voss 1988). The tegmen tympani does not overlap the posterior margin of the squamosal above the auditory bulla. The subsquamosal fenestra is usually present but often small; it is absent from occasional specimens in most large samples. The lower incisor root is contained in a small but usually distinct capsular process below the base of the coronoid process on the lateral surface of each mandible.

The upper incisors are smooth (never grooved), narrow, and opisthodont, with yellow-orange enamel bands. The upper molar rows are parallel, and the teeth themselves are bunodont with labial and lingual cusps arranged in opposite pairs; the anterocone of M1 is undivided, and mesolophids are absent from all of the upper teeth, each of which has only three roots. The anteroconid of m1 is likewise undivided, and mesolophids are correspondingly absent from all of the lower molars; m1 has two roots, m2 has three roots, and m3 has either two or three roots.

Modal counts axial skeletal elements include 12 ribs and 19 thoracolumbar, 4 sacral, and 24 to 26 caudal vertebrae. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and first thoracic vertebrae, and the second thoracic vertebra has a hypertrophied neural spine. The entepicondylar process of the humerus is absent.

The stomach is unilocular and hemiglandular (Carleton 1973), and the gall bladder is absent (see Remarks). Male accessory secretory organs consist of one pair each of preputial, bulbourethral, anterior and dorsal prostate, ampullary, and vesicular glands, and two pairs of lateral prostate glands (Voss and Linzey 1981). The glans penis is complex, with a tridigitate bacular cartilage and a deep terminal crater containing three bacular mounds, one dorsal papilla, and a bifurcate urethral flap (Hooper and Musser 1964).

REMARKS: Absence of a gall bladder in *Zygodontomys* was first reported by Voss (1991a), who dissected 22 specimens of *Z. brevicauda* from several localities scattered throughout the range of that species (no fluid-preserved specimens of *Z. brunneus* were available for dissection). A gall bladder is likewise absent in other oryzomyines, and this state optimizes as a tribal synapomorphy on phylogenetic trees (Steppan 1995; Weksler 2006). In a paper on the digestive adaptations of Venezuelan rodents, however, Domínguez-Bello and Robinson (1991) reported that a gall bladder was observed in two specimens identified by them as *Z. microtinus* (= *Z. brevicauda*, see below). Unfortunately, no voucher material was preserved in that study (M. G. Domínguez-Bello, in litt.), so the observations in question cannot be checked. (Fluid-preserved specimens dissected by Voss [1991a] are listed by museum catalog number in appendix 2 of that report.)

SYNONYMS:

- Oryzomys*: J. A. Allen and Chapman, 1893:215; part (description of *brevicauda*); not *Oryzomys* Baird.
Akodon: J. A. Allen and Chapman, 1897a:20; part (description of *frustrator*); not *Akodon* Meyen.
Zygodontomys J. A. Allen, 1897a:38; type species *Oryzomys cherriei* J. A. Allen, by original designation.
Oryzomys (*Micronectomys*): Hernández-Camacho, 1957: 223; part (description of *borreroi*); not *Oryzomys* Baird; *Micronectomys* Hershkovitz is a *nomen nudum* (Musser and Carleton 2005:1144).

KEY TO THE SPECIES OF ZYGODONTOMYS:

1. Length of hindfoot >27 mm, upper molar toothrow >4.6 mm, breadth of braincase (measured just above squamosal zygomatic roots) >12.2 mm; in side-by-side comparisons with sympatric *Z. brevicauda*, with slightly more hypsodont molars, more oblique mures and murids, less opisthodont upper incisors, shallower zygomatic notches, and less inflated nasolacrimal capsules *Zygodontomys brunneus*
- 1'. Measurements and qualitative characters overlapping those of *Z. brunneus* except in the upper Magdalena valley, where length of hindfoot <28 mm, upper molars <4.5 mm, and breadth of braincase <12.1 mm; with

slightly less hypsodont molars, less oblique mures and murids, more opisthodont upper incisors, deeper zygomatic notches, and more inflated nasolacrimal capsules
 *Zygodontomys brevicauda*

Zygodontomys microtinus thomasi: Reig, 1986:407; name combination.

Zygodontomys reigi Tranier, 1976:1202; type locality "aux environs de Cayenne," French Guiana.

DESCRIPTION: See the Key, and Voss (1991a) for thorough descriptions and illustrated characters.

DISTRIBUTION: As recognized herein, *Zygodontomys brevicauda* occurs in unforested habitats below about 1,300 m from southeastern Costa Rica throughout Panama to Colombia, Venezuela, the Guianas, and northern Brazil. This species is sympatric with *Z. brunneus* in the upper Magdalena valley of Colombia.

SELECTED LOCALITIES (Map 247): BRAZIL: Amapá, Tartarugalzinho (Mattevi et al. 2002); Amazonas, Castanhal (Bonvicino, Gonçalves et al. 2008), Igarapé Tucunaré (Bonvicino, Maroja et al. 2003), Serra do Aracá (Bonvicino, Gonçalves et al. 2008), Tabocal (AMNH 79401); Pará, Serra do Tumucumaque (USNM 392078); Roraima, Serra da Lua (FMNH 20051), Sunumú (Bonvicino, Gonçalves et al. 2008). COLOMBIA: Antioquia, Cisneros (Voss 1991a); Atlántico, Ciénaga de Guájaro (USNM 280383); Casanare, Finca Balmoral (UVM 3820); Chocó, Unguía (FMNH 70219); Córdoba, Montería (UVM 3452), Socorré (FMNH 69130); Huila, Valle de Suaza (USNM 541900), Villavieja (MVZ 113379); Magdalena, Bonda (type locality of *Oryzomys sanctaemartae* J. A. Allen); Meta, Puerto Lleras (Voss 1991a); Tolima, Chicoral (type locality of *Zygodontomys fraterculus*

J. A. Allen), El Triunfo (type locality of *Zygodontomys griseus* J. A. Allen); Vichada, Maipures (BM 99.9.11.39). FRENCH GUIANA: Cacao (MNHN 1980-244), Kourou (MNHN 1986-904). GUYANA: Demerara-Mahaica, Hyde Park (USNM 172939); Mahica-Berbice, Tauraculi (ROM 31476); Rupununi, Dadanawa (ROM 36096). SURINAM: Marowijne, Wiawia Bank (RMNH 21612); Paramaribo, Paramaribo (RMNH 21588). TRINIDAD AND TOBAGO: Tobago, Richmond (type locality of *Oryzomys brevicauda* J. A. Allen and Chapman); Trinidad, Princetown (type locality of *Zygodontomys brevicauda tobagi* Thomas). VENEZUELA: Amazonas, Esmeralda (AMNH 77316); Barinas, Santa Bárbara (Voss 1991a); Bolívar, Boca de Parguaza (Voss 1991a), Hato La Florida, 44 km ESE Caicara (USNM 406147), 55 km NE Icabarú (USNM 442423); Carabobo, Patanemo (MARNR 8191); Falcón, Mirimire (USNM 496830); Miranda, Río Chico (USNM 388026); Monagas, Isla Guara (Voss 1991a); Sucre, Cristobal Colón (AMNH 36188), Cumaná (USNM 406135); Táchira, Estación Experimental (Voss 1991a); Zulia, El Panorama, Río Aurare (Voss 1991a).

SUBSPECIES: See Remarks.

NATURAL HISTORY: On the Central and South American mainland, *Zygodontomys brevicauda* is invariably found in unforested lowland habitats such as savannas, shrublands, pastures, orchards, and grassy roadsides. Favored microhabitats usually include an herbaceous groundcover interspersed with woody plants growing in small thickets, usually on moist soils. It is among the commonest nonvolant mammals taken in anthropogenic landscapes (where it is sometimes an agricultural pest; A. M. G. Martino and Aguilera 1993), and its geographic range has doubtless increased with the widespread deforestation of northern South America. Other sigmodontines that are often collected syntopically with mainland populations of *Z. brevicauda* include *Sigmodon alstoni*, *S. hirsutus*, and one or more species of *Oligoryzomys*. Island populations of *Zygodontomys brevicauda* are ecologically distinctive because they inhabit closed-canopy rainforest, a habitat from which *Zygodontomys* is consistently absent on the Central and South American mainland.

Information from many sources (e.g., Enders 1935; Aldrich and Bole 1937; Ibáñez 1980; August 1981, 1984; O'Connell 1981, 1989; Vivas 1984; Vivas et al. 1986) indicates that *Zygodontomys brevicauda* is nocturnal, terrestrial, and omnivorous, differing in one or more of these traits from other commonly syntopic taxa such as *Sigmodon* (which is diurnal and herbivorous) and *Oligoryzomys* (scansorial). Reproductive studies (e.g., Aguilera 1985; Voss et al. 1992) have shown that *Z. brevicauda* is a spontaneous ovulator that gives birth to litters of 1 to 11 offspring (4 and 5 are modal litter sizes in most stud-

ies; Voss 1991a) after a gestation of about 25 days; there is a postpartum estrus, and implantation is not delayed by lactation. The neonates, which typically weigh 3–4 g each, are sparsely haired and appear naked; among other postnatal developmental events, the eyes open on day 6, the molars begin erupting on day 8, and the young are weaned by day 16. Females reach sexual maturity at about three to four weeks of age, males at six to eight weeks. Apparently, reproduction is continuous in wild populations, even those in conspicuously seasonal habitats (subject to seasonal cycles of flooding and draught; August 1981, 1984; O'Connell 1981, 1989; Vivas 1984). Due to its numerical abundance, *Z. brevicauda* is probably an important item in the diet of many sympatric predators; to date it has been recorded from vomitus, scats, or stomach contents of the Barn Owl (*Tyto alba*), Striped Owl (*Asio clamator*), White-tailed Kite (*Elanus leucurus*), Crab-eating Fox (*Cerdocyon thous*), and Jaguarundi (*Puma yagouaroundi*). Fifty-five species of arthropod ectoparasites have been collected from *Z. brevicauda* in Panama and Venezuela (Voss 1991a:Table 29).

Zygodontomys brevicauda is the primary reservoir of Guanarito virus, the etiologic agent of Venezuelan hemorrhagic fever (Fulhorst, Bowen et al. 1999; Fulhorst, Ksiazek et al. 1999; contra Tesh et al. 1993). Given the widespread geographic distribution of *Z. brevicauda*, it seems likely that this dangerous disease could break out sporadically throughout eastern Central America and northern South America, despite the fact that human cases have only been reported from Venezuela (Manziona et al. 1998).

REMARKS: As suggested by the many names and name combinations listed as synonyms above, this species exhibits geographic variation in size, coat color, and other morphological traits. Several geographic patterns of morphological variation are noteworthy: (1) trans-Andean populations (in Central America, Colombia, and northwestern Venezuela) differ from cis-Andean populations (in central, southern, and eastern Venezuela, and the Guianas) in frequencies of alternative carotid circulatory morphologies; (2) distinct sphenopalatine vacuities are usually present in specimens from Central America, Colombia, and Venezuela, but they are usually absent in specimens from coastal Guyana, Surinam, and French Guiana; and (3) insular populations (e.g., on Isla Cebaco, Trinidad, and Tobago) are consistently larger-bodied than adjacent mainland populations.

Voss (1991a) recognized three subspecies of *Zygodontomys brevicauda* based on the first and second patterns described here. These were diagnosed as follows: *Z. b. brevicauda* (including *frustrator*, *soldadoensis*, *stellae*, *thomasi*, and *tobagi*) usually has large sphenopalatine vacuities and a derived pattern of carotid circulation; *Z.*

b. cherriei (including *fraterculus*, *griseus*, *sanctaemartae*, *seorsus*, and *ventriosus*) usually has large sphenopalatine vacuities and the primitive pattern of carotid circulation; and *Z. b. microtinus* (including *reigi*) usually lacks distinct sphenopalatine vacuities and has a derived pattern of carotid circulation. Island gigantism was hypothesized to have evolved independently within each subspecies, and the notion that all large-bodied forms of *Zygodontomys* are closely related to one another (Tate, 1939) was rejected.

However, neither morphometric analyses (discussed by Voss 1991a) nor karyotypic data (Mattevi et al. 2002; Bonvicino, Maroja et al. 2003; Bonvicino, Gonçalves et al. 2008) corroborate this subspecies classification, whose heuristic value now seems questionable. Chromosomal complements with diploid numbers ranging from 84 to 88 and fundamental numbers varying from 116 to 118 have been reported for this species (A. L. Gardner and Patton 1976; Pérez-Zapata et al. 1984; Reig et al. 1990; Mattevi et al. 2002; Bonvicino et al. 2003, 2008). Three of these karyomorphs ($2n=86$, FN=96–98; $2n=84$, FN=96–98; and $2n=82$, FN=94), each from savanna systems along the southern margins of the species range in northern Brazil and French Guiana, were reported to form reciprocally monophyletic cytochrome-*b* haplotype groups that Bonvicino, Gonçalves et al. (2008) interpreted as distinct species. However, a subsequent analysis of cytochrome-*b* sequence data that included Bonvicino's (2008) sequences together with others from Central American and Venezuelan specimens (P. González et al. 2010) did not recover these karyomorphs as reciprocally monophyletic clades. The latter analysis additionally revealed surprisingly high levels of sequence divergence among some Central American populations and, overall, a lack of clear phylogeographic structure (P. González et al. 2010).

Clearly, a comprehensive assessment of geographic variation in morphology, karyotypes, and DNA sequences (ideally including one or more nuclear genes in addition to the single mitochondrial locus hitherto analyzed) is needed to make sense of these discrepant results. The effort involved in such an enterprise would be biogeographically rewarding because mainland populations of *Zygodontomys* are strongly associated with savannas and other nonforest lowland vegetation, the late Cenozoic history of which might be reconstructed from evolutionary analyses of the vertebrate fauna that inhabits it (Voss 1991a). Pending such an integrative analysis of morphological, karyotypic, and molecular variation, a conservative nomenclatural option is to recognize a monotypic *Z. brevicauda*, with the caveat that this might represent a complex of closely related but evolutionarily independent taxa.

Map 247 Selected localities for *Zygodontomys brevicauda* (●). For Central American records, see Voss (1991a). Contour line=2,000 m.

Zygodontomys brunneus Thomas, 1898

Colombian Cane Mouse

SYNONYMS:

Zygodontomys brunneus Thomas, 1898f:269; type locality “El Saibal, W. Cundinamarca,” Colombia.

Zygodontomys brevicauda brunneus: Gyldenstolpe, 1932a: 112; name combination.

Oryzomys (Micronectomys) borreroi Hernández-Camacho, 1957:223; type locality “Ladera norte del Cerro de San Pablo, hacienda Montebello, Municipio de Betulia, Valle del Río Chucurí, Departamento de Santander, Colombia.”

DESCRIPTION: For details, see Thomas (1898f), Voss (1991a), and the Key.

DISTRIBUTION: *Zygodontomys brunneus* inhabits the intermontane valleys of Colombia, including those of the upper Río Magdalena, the upper Río Cauca, the upper Río Patía, and the upper Río Dagua.

SELECTED LOCALITIES (Map 248): COLOMBIA: Antioquia, San Jerónimo, 35 km NE of Medellín (FMNH 70205); Boyacá, Muzo (FMNH 71258); Cundinamarca, Volcanes, Municipio de Caparrapí (USNM 282114); Huila, Andalucía (AMNH 33773); Nariño, Finca Arizona, 4.5 km S of Remolino (UV 3099); Santander, Hacienda Montebello, near Cerro San Pablo (type locality of *Oryzomys [Micronectomys] borreroi* Hernández-Camacho); Valle de Cauca, Atuncela (UV [Voss 1991a]), Hacienda Formosa (UV 3579).

NATURAL HISTORY: Nothing has been published about the natural history of *Zygodontomys brunneus*, which, however, probably resembles *Z. brevicauda* in most ecological and behavioral traits. Interspecific habitat divergence, if any, might be expected where these taxa are sympatric in the upper Magdalena valley.

Map 248 Selected localities for *Zygodontomys brunneus* (●); those in the Magdalena and Cauca valleys are mapped as disjunct. Contour line=2,000 m

REMARKS: The taxonomic status of populations in western Colombia (in the Cauca, Dagua, and Patía valleys) is uncertain and merits future research.

Tribe Phyllotini Vorontsov, 1959
Jorge Salazar-Bravo

The tribe Phyllotini includes 11 extant genera of small to medium-sized rodents widely distributed in south-central and southern South America, often associated with Andean, Patagonian, and Chacoan bioregions. The maximum species diversity for the tribe occurs in the Puna habitats of Bolivia, Peru, northern Chile, and northern Argentina, an area suggested to be the region of original differentiation (Reig 1986). Species boundaries, relationships among species, and the content of the tribe have been studied by Hershkovitz (1962), Pearson (1958), Pearson and Patton (1976), Olds and Anderson (1990), Braun (1993), Steppan (1993), Steppan (1995), M. F. Smith and Patton (1999), and Pardiñas et al. (2014); these authors should be consulted for further reference. What follows is a summary of the more recent taxonomic history of the phyllotines. Additional details can be found in Olds and Anderson (1990), Braun and Mares (1995), Steppan (1995), Pardiñas (1997), Steppan and Pardiñas (1998), M. F. Smith and

Patton (1999), S. Anderson and Yates (2000), Mares and Braun (2000b), P. E. Ortiz, Pardiñas, and Steppan (2000), Spotorno et al. (2001), Steppan et al. (2007), Steppan and Sullivan (2000), P. E. Ortiz, Jayat, and Steppan (2012), and Salazar-Bravo et al. (2013), who collectively documented the sometimes acrimonious debates regarding the taxonomy of the tribe.

Olds and Anderson (1990) were the first to use morphological characters to formally diagnose and summarize the contents of the tribe Phyllotini. They included 14 genera: *Andalgalomys*, *Andinomys*, *Auliscomys*, *Calomys*, *Chinchillula*, *Eligmodontia*, *Euneomys*, *Galenomys*, *Graomys*, *Irenomys*, *Neotomys*, *Phyllotis*, *Punomys*, and *Reithrodon*. In addition, they recognized and diagnosed a “*Reithrodon* group” that included *Euneomys* and *Neotomys* along with *Reithrodon*. Braun’s (1993) concept of the Phyllotini was rather similar to that of Olds and Anderson (1990), except that she also included *Pseudoryzomys*. Important taxonomic conclusions from her analyses included the description of a new genus (*Maresomys*) for *Auliscomys boliviensis*, and the resurrection of *Loxodontomys* for *Auliscomys micropus* and *Paralomys* for *Phyllotis gerbillus* and *P. amicus*. Almost simultaneously, Steppan (1993) presented a cladistic analysis of mostly discrete morphological characters for the suite of taxa within Olds and Anderson’s (1990) concept of the Phyllotini plus several outgroups. He concluded that *Punomys* should be removed from the tribe. In addition, his analyses did not support the distinction of *Andalgalomys* with respect to *Graomys*, suggested the paraphyly of both *Phyllotis* and *Calomys*, and also found strong support for a *Reithrodon* group composed of *Euneomys*, *Neotomys*, and *Reithrodon*. Pardiñas (1997), Steppan and Pardiñas (1998), and P. E. Ortiz, Pardiñas, and Steppan (2000) provided further support for an expanded *Reithrodon* group. In a subsequent analysis, Steppan (1995) confirmed the majority of his earlier conclusions with regard to the content of the Phyllotini. However, he removed *Pseudoryzomys* from the tribe and found no support for a monotypic *Maresomys*. He also defined three subtribes, the Phyllotina (*Phyllotis* s. s. + *Graomys* [including *Andalgalomys*]), the Reithrodonina (*Auliscomys* [including *Maresomys*], *Andinomys*, and *Reithrodon* groups), and the Calomyina including only *Calomys*. His phylogenetic analysis supported a nested set of subtribe relationships of (Phyllotina, Reithrodonina (Calomyina)). Both Mares and Braun (2000b) and Steppan and Sullivan (2000) agreed with retaining *Andalgalomys* at the generic level, although the latter authors made it clear that their decision was provisional pending a full resolution of the phylogeny of *Graomys*. This same period saw the description of two phyllotine genera, *Salinomys* (Braun and Mares 1995) and *Tapecomys* (S. Anderson and Yates 2000) as well as

the expansion of molecular studies to study the composition of the Phyllotini and that of other suprageneric groups within the Sigmodontinae. Most recently, *Calassomys* has been added as another new member of the tribe, a taxon that appears as the basal member in DNA sequence results (Pardiñas et al. 2014).

Two pioneering studies shed light on the composition of the Phyllotini. Engel et al. (1998) supported earlier claims based on DNA-DNA hybridization studies (Catzefflis et al. 1993) that *Sigmodon* was the sister group to the rest of the Sigmodontinae. These authors also posited that *Reithrodon* did not belong within the Phyllotini. Using a larger sampling of sigmodontine species and mtDNA cytochrome-*b* gene sequences, M. F. Smith and Patton (1999) supported the hypothesis that *Reithrodon* as well as *Irenomys* were best treated as Sigmodontinae *incertae sedis* as they did not cluster within the Phyllotini. Steppan, Adkins, and Anderson (2004) also supported the exclusion of *Reithrodon* from the Phyllotini based on both nuclear and mtDNA analyses. Their analysis consistently placed *Reithrodon* as sister to the remaining Oryzomalia, rather than within the Phyllotini. Steppan, Adkins, and Anderson (2004) also showed that *Andinomys* and *Irenomys* were sister taxa to a clade formed by *Calomys*, *Auliscomys*, and *Phyllotis*, although the sampling was not designed to test the composition of the Phyllotini. Additional molecular studies further showed that *Euneomys* often formed a sister-taxon relationship with *Irenomys* and that both were outside of the Phyllotini (D'Elía 2003; D'Elía et al. 2006a; D'Elía et al. 2006b). In a later analysis explicitly directed to the genus *Phyllotis* and its close relatives, Steppan et al. (2007) found no support for *Paralomys* and moved *Phyllotis wolffsohni* to *Tapecomys*. None of these molecular phylogenetic studies, however, were sufficiently taxon dense to test adequately either the generic composition of the tribe or the limits of genera that had been questioned in prior studies.

Salazar-Bravo et al. (2013), in an expanded taxon and gene sequence study, revised the contents of the Phyllotini using both mtDNA and nucDNA gene sequences. Their analyses supported the generic separation of *Andalgalomys* from *Graomys* and the exclusion of *Andinomys*, *Chinchillula*, *Neotomys*, and *Punomys* from the tribe. They found no support for a *Reithrodon* group as proposed by Olds and Anderson (1990). These results strongly suggested the occurrence of multiple instances of putative morphological convergence among distinct sigmodontine lineages—for example, between *Euneomys* and *Neotomys* relative to *Reithrodon* and between the Phyllotini (as they restricted the tribe) and other Andean taxa. Salazar-Bravo et al. (2013) also concluded that fossil forms such as *Panchomys*, *Tafimys*, and *Olimipicomys*, once associated with the *Reithrodon* group

sensu Olds and Anderson (1990), and by implication included within the tribe Phyllotini, required additional study to determine whether their affinities lie with *Reithrodon*, with *Euneomys*–*Neotomys*, or with another group, including a restricted Phyllotini.

Here, I follow Salazar-Bravo et al. (2013) and Pardiñas et al. (2014) and recognize 11 extant genera in the tribe Phyllotini: *Andalgalomys*, *Auliscomys*, *Calassomys*, *Calomys*, *Eligmodontia*, *Galenomys*, *Graomys*, *Loxodontomys*, *Phyllotis*, *Salinomys*, and *Tapecomys*. The oldest known sigmodontine, and phyllotine, is *Auliscomys formosus* from the Montehermosense of Argentina, which dates to between 5 and 4 mya (Pardiñas et al. 2002; Pardiñas and Tonni 1998). Whether or not fossil taxa (e.g., *Bensonomys*) from the late Miocene to early Pliocene of North America (Baskin 1978; Lindsay and Cazplewski 2011) are also referable to the Phyllotini is both controversial and a question beyond the scope of this volume. The description of *Pardinamys humahuauquensis* from late Pliocene deposits (between 3 and 2.5 mya) from the Uquia formation in central Jujuy province, Argentina (P. E. Ortiz, Jayat, and Steppan 2012), suggests an important radiation before the establishment of modern communities in the central Andean region. Another new fossil genus is currently being described (U. F. J. Pardiñas et al., in litt.).

Members of the tribe are ubiquitous in pastoral habitats and forest fringes throughout the southern half of South America, from the highlands of central Ecuador to the Straits of Magellan along the main axis of the Andes, and from the Pacific coast of Peru and Chile east through Patagonia to southeastern Brazil. *Calomys hummelincki*, the sole representative of the tribe north of the Amazon Basin, occurs in the savannas of northern Venezuela and north-eastern Colombia and some of the continental islands off the Venezuelan coast.

In general, members of the Phyllotini have a body and limbs adapted for terrestrial life with normal ambulatory, slightly saltatorial, or scansorial activity. Notable specializations for burrowing, climbing, or swimming are absent. Body size varies from very small (mass of 12 g in adult *Calomys laucha*) to the approximate average for sigmodontine rodents (about 100 g in *Graomys*, some populations of *Phyllotis*, and *Tapecomys* [Pearson 1951; Hershkovitz 1962; S. Anderson 1997]). The pelage is normally thick, fine, and soft to moderately coarse, but never hispid or spiny. Dorsal coloration contrasts sharply to moderately with the ventral color, with or without a delimiting lateral line. Tail length is variable, ranging from less than one-half of the combined head and body to about the same as or slightly longer than the head and body (generally no more than 1.4 times, except in *Salinomys*, which can reach 1.6 times that of the head and body [Braun and Mares

1995]). The tail is moderately to well haired along the entire length; it may be either bicolored or unicolored; and a terminal pencil is present in some taxa. The eyes are normal in size and may or may not be circumscribed by a pale eye-ring. Preauricular and/or postauricular pale patches are usually present; the pinnae are moderate to large in size, and always more than 60% of the hindfoot length. The hindfoot is not markedly broadened or elongated; it is well haired above, the heel beneath is hairy, and the plantar surface may be either bare or hairy. The pollex possesses a nail, all other digits have unspecialized claws (Pearson 1958; Hershkovitz 1962; Olds and Anderson 1990).

The skull is variable in both shape and form, and may appear either delicate or robust. The distal edge of the nasals varies from roughly square, rounded, or obtusely triangular, terminating from slightly in front to slightly behind the frontomaxillary suture, but never with a long pointed process extending deeply between frontals. Supraorbital edges are square, ridged, beaded, or produced as ledges, never evenly rounded. The interparietal is well developed, at least transversely, and has a distinct suture separating each of its borders from at least two-thirds of the width of parietal and occipital, respectively. The zygomatic arches are complete. The zygomatic notches are deep and broad; the zygomatic plates are broad, often wider than one-half of the least interorbital breadth, and their anterior borders are straight or slightly convex, but not deeply excised. The palate extends behind the posterior plane of last molars; its posterior border may be rounded or square, with or without a short median spine. Posterolateral palatine pits are often marked by distinct perforations. The mesopterygoid fossa is more or less U-shaped, and slightly divergent posteriorly. The parapterygoid fossa is shallow and often ovate in outline; its lateral wall is not parallel to the inner wall but gradually merges into dorsal surface and anterior wall. Incisive foramina are long, often narrow, pointed behind, and, with few individual exceptions, extend posteriorly to or behind the anterior plane of the M1s. The rostrum is not markedly tapered dorsoventrally from its base to tip. The anterior process of the premaxillary is projected slightly beyond the vertical plane of the incisors, but even if united with the anterolateral border of the nasals it never forms a well-developed tubular projection or trumpet. The premaxillomaxillary suture on the side of the rostrum is oriented essentially dorsoventrally, forming an angle of 90–135° (but never <90°) with the ventral edge of the rostrum as it passes around to the ventral side (Hershkovitz 1962; Steppan 1995). The inferred carotid circulatory pattern is primitive (*sensu* Voss 1988), with a functional stapedia foramen, sphenofrontal foramen, and squamosal groove all present (Steppan 1995).

The incisors are strong but never extremely broad, and orthodont to opisthodont. Their frontal surfaces are pigmented yellowish to dark orange and are usually asulcate, except in *Auliscomys* where fine striae (requiring magnification) may be present. Molars are well developed; the procingulum of M1 may or may not be divided; a mesoloph(id), enteroloph, and posteroflexus are absent; the mesostyle of M1 is often absent, except in *Calomys*; the parastyle of M1 and anteroflexus are present only in some species of *Calomys* and in *Loxodontomys*. The first upper molar has four roots, three along the main axis of the tooth and a large root laterally placed (except in *Auliscomys* where the fourth root is small, and *Loxodontomys* where there are two lateral roots); lower m1 has two medial and one lateral roots. The occlusal surface of M2 is square or broadly rectangular in outline, its width of the posterior half is approximately two-thirds or more than the greatest length of the tooth; it has two or three roots. M3 is one-half to three-fourths the length of M2, with two or three roots. The procingulum of m1 is not isolated from the cusps due to the confluence protoflexids and metaflexids; the hypoflexid, mesoflexid, and posteroflexid are well developed; and the mesoflexid of m3 is reduced or absent.

The axial skeleton is composed of 12 to 14 thoracic, 6 to 7 lumbar, and 17 to 36 caudal vertebrae (Steppan 1995). A gall bladder is present in all genera examined (Voss 1991a). Mammary range from 8 to 14 (Hershkovitz 1962; Olds 1988). Diploid numbers range from $2n=20$ in *Auliscomys boliviensis* to $2n=78$ in *Andalgalomys pearsoni* (Pearson and Patton 1976; Olds et al. 1987; see *Auliscomys* account).

KEY TO THE GENERA OF PHYLLOTINI (FROM PEARSON 1951; HERSHKOVITZ 1962):

1. Upper first and second molars lack mesolophs and mesostyles 2
- 1'. Upper first and second molars with persistent but vestigial mesolophs and mesostyles *Calassomys*
2. Size relatively small (toothrow length <4.3 mm); pelage countershaded, preauricular and postauricular patches present; ear, measured from notch, never longer than hindfoot; toes of hindfoot variable in length; upper incisors orthodont or opisthodont, their anterior surface never marked by vertical grooves or striae; molars with relatively low crowns; procingulum of M1 divided by anteromedian flexus; small mesostyle present or absent, when present usually fused with paracone; mammae 6 to 14 3
- 2'. Relative body size medium to large (often toothrow length >4.3 mm); pelage countershade weak or strong, with or without preauricular and/or postauricular patches; ears shorter or longer than hindfoot; upper

- incisors orthodont or opisthodont, with anterior surface smooth or striated; upper molars high or low crowned; procingulum of M1 divided or not, its occlusal surface flat in outline; mesostyle absent; mammae never more than eight 5
3. Soles with three middle postdigital tubercles more or less united, forming a thickly haired cushion; first postdigital tubercle small, naked; fifth postdigital tubercle reduced or absent; tarsal tubercle small, naked; fifth hind toe long, its tip, less claw, reaching distal end of first phalanx of fourth toe or beyond. *Eligmodontia*
- 3'. Soles with six well-defined, unfused, and naked plantar pads; fifth hind toe short, not including the claw—this toe barely reaches the first phalanx of fourth toe 4
4. Dorsal color grayish with venter fully white; tail >56% of body length; tail with tufted (or pencilled) tip; white or somewhat discolored area above eyes; skull with supra-orbital region posteriorly divergent but without sharp ridges; skull when seen on lateral view rather bowed and with the braincase inflated; karyotype $2n=18$ in females or $2n=19$ in males; currently known only from desert-salt marsh environment in the temperate Monte Desert and Monte-Chaco ecotonal areas of central west Argentina *Salinomys*
- 4'. Dorsal color often brownish or buffy, with distinct countershade and often an ochraceous delimiting line in between; ventral coloration either pale with white-tipped hairs or fully white, but tail less than 56% of total body length and no longer than 80 mm; skull often flat when seen on dorsal profile, braincase narrow, not inflated; bullae not particularly inflated, its anterior-posterior length (not including tube) less than the length of molar row; known chromosomal complements ranges between $2n=36$ to 66; widespread *Calomys*
5. Dorsal color brownish or grayish; tail long (>90 mm), coequal with head and body length, conspicuously bicolored; supraorbital region comparatively broad, sides posteriorly diverging from slightly behind angle of maxillofrontal suture; interorbital breadth at midfrontal plane greater than greatest width of rostrum; supraorbital edges square or beaded, with or without projecting ledges 6
- 5'. Dorsal color olive to buffy, hair long or short; tail as long as or shorter than head and body length; supraorbital region narrow, the sides either parallel or convergent from slightly behind angle of maxillofrontal suture to form constriction at approximately midfrontal plane; interorbital breadth at midfrontal plane equal to or, usually, less than greatest width of rostrum; supraorbital edges square, pinched, or, sometimes, weakly beaded 8
6. Dorsal color agouti brownish, venter gray to whitish with individual hairs gray-based with white tips; hindfeet brownish with dark dorsal hairs near the base of the toes; interorbital region with sharp edges, but not overhanging ledges; nasals long, extending caudad behind premaxillae; zygomatic plate relatively broad and without a zygomatic spine *Tapecomys*
- 6'. Dorsal color grayish to brown, venter white with hairs on chin and throat fully white to base; hindfeet whitish, no patch of dark hairs at base of toes; interorbital region markedly divergent posteriorly, with sharp overhanging edges; nasals short, very rarely extending caudad beyond premaxillae; zygomatic plate relatively narrow, with concave anterior border and well-developed zygomatic spine 7
7. Smaller (average head and body length <102 mm; range: 75–119 mm), with shorter hindfeet (length <25 mm); ventral pelage white, sharply demarcated from dorsal color; ear with subauricular white spot; teeth low-crowned, tending to form lophs; anterocone may be divided; alisphenoid strut absent *Andalgalomys*
- 7'. Larger (average head and body length >131 mm; range: 111–159 mm), with longer hindfeet (length >25 mm); ventral pelage gray; no conspicuous subauricular white spot; teeth high-crowned, tending not to form lophs; anterocone entire; alisphenoid strut present *Graomys*
8. Size medium (average head and body length 106 mm), body stout, tail short (range: 30–44 mm); dorsal color buffy; venter with throats and chests fully white, elsewhere gray-based; incisors slender; molars brachyodont; zygomatic plate nearly as wide as the least interorbital breadth, with the anterior border rounded, slanted backward; forefeet and hindfeet white above; plantar surface of hindfoot well haired and hypothenar pad absent; skull markedly vaulted middorsally *Galenomys*
- 8'. Body size variable, with tails measuring >44 mm and >25% of the total length; incisors broad; molars hypsodont or at least subhypsodont; plantar surface of hindfoot naked; six unfused plantar pads; skulls not markedly vaulted 9
9. Tail relatively short (36–46% of total length), body stocky built and size small to medium (head and body length <150 mm); both buffy or white preauricular and postauricular patches present; upper incisors with grooves near center of anterior face (requires magnification); interorbital region narrow (often narrower than the width of nasals); anteromedian flexus of M1 absent *Auliscomys*
- 9'. Tail length variable, body size variable; without white postauricular and/or preauricular patches; no grooves on the anterior surface of upper incisors (even under

magnification); interorbital region narrow but often not less than width of nasals; anteromedian flexus of M1 present but only as a shallow groove. 10
 10. Body robust with thick, lax, and lusterless pelage; dorsal color varies from gray to brownish; venter lighter, often washed with white or yellow; ears small, length from notch 20–50% smaller than hindfoot; fifth hind toe long, reaching to the end of the first phalanx of the fourth toe; tail short in relation to total length; molar toothrow posteriorly divergent; tympanic bullae relatively small (anteroposterior length, exclusive of tubes, is greater than or equal to alveolar length of molar row); upper incisors broad; M2 and M3 about same size, M3 in young adults with a complex pattern; lives in forests, meadows, and mesic brushy habitats in the Andean foothills of southern Chile and southwestern Argentina, from sea level to 3,000 m

. *Loxodontomys*
 10'. Body form variable, often robust with long and fine pelage; dorsal color variable, many species with much lighter venter; ears medium to large (many species with ears about as long as hindfoot); fifth hind toe short (tip, less claw, not reaching distal end of first phalanx of fourth toe); tail subequal in length to combined head and body; maxillary toothrows parallel or posteriorly convergent; tympanic bullae relatively large; M2 distinctly larger than M3; widespread in rocky and brushy habitats from sea level to nearly 5,000 m, from northern Ecuador to southern Patagonia. *Phyllotis*

REMARKS: Vorontsov (1959) erred in his original construction of the tribal name Phyllotiini because a family-group name is to be based on the stem of the type genus, which in the case of Latin or Greek roots is the genitive singular to which the appropriate suffix is to be added (ICZN 1999:Arts. 29 and 29.3.1). In this case, the type genus is *Phyllotis*, a compound Greek work derived from *phyll-* (Greek *phyllon*, meaning leaf) and *-ot* (Greek *ous*, genitive *otos*, the ear). The stem of the family-group name is thus Phyllot-, to which the suffix -ini, when added, would give Phyllotini as the correct spelling. Reig (1980) was apparently the first to use Phyllotini.

Genus *Andalgalomys* D. F. Williams and Mares, 1978

Janet K. Braun

The genus *Andalgalomys*, commonly known as Chaco mice, ranges from southeastern Bolivia to western Paraguay, and in a narrow band throughout four provinces in west-central Argentina. Three species currently are recognized, where they occur in arid and semiarid habitats below

about 1,000 m elevation. The following generic description is, except as noted, compiled from information presented by D. F. Williams and Mares (1978), Olds et al. (1987), Steppan (1995), and Mares and Braun (1996); data are not available for all characters for all species.

All three species of *Andalgalomys* are externally similar, with large ears, and whitish subauricular spots and postauricular patches. The dorsum is yellowish brown to brownish olive, and the venter is immaculate white. The tail is sparsely to moderately haired, bicolored, penicillate, and exceeds the combined length of the head and body. The hindfeet are unwebbed; the three middle digits (II, III, and IV) are longer than the outer two (I and V); the plantar surface is entirely naked (from heel to toes) with six tubercles (thenar, hypothenar, and four interdigitals).

The skull has a long, slender rostrum; relatively deep, open zygomatic notches (about equal to width of zygomatic plate); and posteriorly divergent, overhanging supraorbital margins. The zygomatic arches are only slightly convergent. Zygomatic plates have slightly concave anterior margins and moderately developed anterodorsal spinous processes. The incisive foramina are relatively long, extending to about the level of the anterior conules of M1. The palatines have large, slit-like foramina. Auditory bullae are inflated, and the bullar tubes are short and wide. Parapterygoid fossae are moderately broad and shallowly to moderately excavated. A vertical strut of the alisphenoid generally is absent. The mandible has an angular notch that does not extend anterior to the posterior edge of the capsular process. The coronoid process is small and delicate, and the angular process terminates anterior to the condyle. The lower incisor root is contained in a prominent capsular process posteroventral to the base of the coronoid process.

The molar rows are more or less parallel. The incisors are opisthodont and ungrooved. The molars are tetralophodont (lacking any trace of a mesoloph or mesolophid), brachydont, and the crowns tuberculate and slighted crested. Cusps are about opposite in arrangement. The anterocone of M1 generally has an anterior median fold and an anteromedian style; the postcingulum has a slight notch or fold. The anteroloph of M2 is small and directed nearly anteriorly. The major fold of m3 is deep, separating the metaconid-hypoconid from the protoconid-paraconid by a double enamel wall. M3, m2, and m3 have three roots.

There are 12 ribs plus 18–19 thoracolumbar and 31–33 caudal vertebrae. The second thoracic vertebra has a greatly elongated neural spine. The epicondylar foramen of the humerus is absent.

The gall bladder is present. Male accessory secretory organs consist of two pairs of preputial glands. The glans penis is complex, with a tridigitate bacular cartilage; bacular

mounds are simple and unmodified, with the lateral mounds longer than the medial mound; the urethral flap is bifurcate. G. B. Diaz and Ojeda (1999) reported indices of renal relative medullary area, ratio of medulla to cortex, and relative medullary thickness.

Fossil material of *Andalgalomys* has been reported from southern Mendoza province, Argentina from about 8,900 ybp (Neme et al. 2002).

SYNONYMS:

Graomys: Myers, 1977:1; part (description of *pearsoni*); not *Graomys* Thomas.

Andalgalomys D. F. Williams and Mares, 1978:197; type species *Andalgalomys olrogi* Williams and Mares, by original designation.

KEY TO THE SPECIES OF *ANDALGALOMYS*:

1. Dorsum yellowish brown; length of tail ≥ 124 mm; bullae greatly inflated, >6.4 mm in length, and >4.8 mm in depth, width of bullae >5.8 mm; m3 length >0.80 mm; length of interparietal usually <2.5 mm; known only from the isolated Bolsón de Pipanaco near Andalgalá, Catamarca Province, Argentina *Andalgalomys olrogi*
- 1'. Dorsum not yellowish brown; length of tail usually <125 mm; bullae only moderately inflated, measurements less than indicated above; m3 length <0.80 mm; length of interparietal usually >2.5 mm 2
2. Dorsum reddish brown; length of skull generally >29.0 mm; breadth of mesopterygoid fossae from 1.0–1.4 mm; rostrum generally longer and broader; palatilar length generally >13.0 mm; width of zygomatic plate >2.7 mm; length of mandible generally >15.0 mm; known from the Chaco of Bolivia and Paraguay *Andalgalomys pearsoni*
- 2'. Dorsum grayish brown; length of skull generally <29.0 mm; breadth of mesopterygoid fossae <1.0 mm; rostrum shorter and more slender; palatilar length generally <13.0 mm; width of zygomatic plate <2.9 mm; length of mandible generally <15.0 mm; known from the western Chaco and the Chaco-Monte Desert ecotone in central Argentina *Andalgalomys roigi*

Andalgalomys olrogi D. F. Williams and Mares, 1978

Olrog's Chaco Mouse

SYNONYM:

Andalgalomys olrogi D. F. Williams and Mares, 1978:203; type locality "West Bank Rio Amanao, about 15 km W (by road) Andalgalá, Catamarca Province, Argentina."

Graomys olrogi: Steppan, 1995:79; name combination.

G[raomys]. (Andalgalomys) olrogi: Steppan and Sullivan, 2000:267; name combination.

DESCRIPTION: Largest species in genus, with mean head and body length 96.3 mm (range: 86–113 mm) and hindfoot length 24.2 mm (range: 23–25 mm). Tail longest proportionally (130% of head and body length) and absolutely (mean 125 mm; range: 124–126 mm) among the three species. Overall dorsal color yellowish-brown, with small whitish subauricular and postauricular patches present; ventral surface and upper surfaces of both forefeet and hindfeet white. Tail terminates in moderate pencil. Body of glans penis shorter and proportionally broader and baculum much shorter than both structures of *A. pearsoni* (D. F. Williams and Mares 1978).

DISTRIBUTION: *Andalgalomys olrogi* is known only from a few adjacent localities in the Bolsón de Pipanaco, an isolated valley in the Monte Desert of northwestern Argentina at an elevation of about 1,000 m.

SELECTED LOCALITIES (Map 249): ARGENTINA: Catamarca, west bank of Río Amanao, about 15 km W (on Rte 62) of Andalgalá (type locality of *Andalgalomys olrogi* Williams and Mares).

SUBSPECIES: *Andalgalomys olrogi* is monotypic.

NATURAL HISTORY: *Andalgalomys olrogi* occurs in or near creosote brush (*Larrea*, Zygophyllaceae) flats found at the northern end of the Bolsón de Pipanaco (D. F. Williams and Mares 1978). Unpublished field notes indicate nocturnality and little to no reproductive activity during the winter and some activity during the summer.

Map 249 Selected localities for *Andalgalomys olrogi* (○) and *Andalgalomys roigi* (●). Contour line = 2,000 m.

REMARKS: The chromosome complement consists of a $2n=60$, $FN=116$, with all autosomes biarmed, a moderately large submetacentric X and small metacentric Y chromosome (D. F. Williams and Mares 1978).

Andalgalomys pearsoni (Myers, 1977)

Pearson's Chaco Mouse

SYNONYMS:

Graomys pearsoni Myers, 1977:1; type locality "410 km NW Villa Hayes by road, Departamento Boquerón, Paraguay."

Andalgalomys pearsoni: D. F. Williams and Mares, 1978: 210; first use of current name combination.

Andalgalomys pearsoni dorbignyi Olds, Anderson, and Yates, 1987:9; type locality "Bolivia: Department of Sant Cruz; 29.5 km W of Roboré, 475 m ($18^{\circ}19'S$, $60^{\circ}02'W$)."

Graomys pearsoni: Steppan, 1995:79; name combination.

Graomys pearsoni dorbignyi: S. Anderson, 1997:461; name combination.

G[raomys]. (*Andalgalomys*) *pearsoni*: Steppan and Sullivan, 2000:267; name combination.

DESCRIPTION: Medium sized (head and body length 86–113 mm) with elongated tail (110% head and body; range: 97–124 mm) and moderate hindfeet (22–25 mm). Dorsal coloration brown streaked with gray; fur on rump about 10 mm long and slate gray at base; hairs on venter white to their base; small postauricular buffy patch present; both forefeet and hindfeet white on top; tail bicolored, dorsal third brown, ventral two-thirds buffy, and sparsely covered with hair. Tail nonpenicillate, with terminal hairs extending <3 mm beyond tip. Skull with same general confirmation as all species in genus, but averages larger in most length (e.g., condylobasal, rostral, diastema, palatal, incisive foramina) and breadth (e.g., braincase, interorbital, rostral, nasal) dimensions than other species.

DISTRIBUTION: *Andalgalomys pearsoni* occurs in the Chaco of western Paraguay and southeastern Bolivia below 500 m.

SELECTED LOCALITIES (Map 250): BOLIVIA: Santa Cruz, 29.5 km W of Roboré (Olds et al. 1987). PARAGUAY: Boquerón, Loma Plata (MSB 80512), 410 km NW of Villa Hayes by road (type locality of *Graomys pearsoni* Myers), Teniente Enciso (UCONN 17562).

SUBSPECIES: Olds et al. (1987) described Bolivian samples as a subspecies (*A. p. dorbignyi*) separate from the nomotypical form from northern Paraguay, based primarily on larger size, more pronounced anterior zygomatic spines, broader mesopterygoid fossa, and different diploid number.

NATURAL HISTORY: *Andalgalomys pearsoni* is found in dry grasslands that occur as isolated microhabitats in the Chaco of western Paraguay (Myers 1977). In south-

Map 250 Selected localities for *Andalgalomys pearsoni* (●). Contour line = 2,000 m.

eastern Bolivia, it has been collected in "arid, scrubby, low, partly open vegetation" (Olds et al. 1987:9) at the edge of the Chaco. The diet may include some insects (Myers 1977). Limited data suggest that some reproductive activity occurs during the winter (Myers 1977). Goff and Whitaker (1984) summarized information on arthropod ectoparasites.

REMARKS: Myers (1977) compared *A. pearsoni* only with those species of *Graomys* Thomas. Mares and Braun (1996) provided more explicit comparisons among the three species of *Andalgalomys* currently recognized. The karyotype varies from a $2n=76$ in Bolivian populations (*A. p. dorbignyi*) to $2n=78$ in those from Paraguay (*A. p. pearsoni*), with the two cytotypes varying in autosomal count from 10 and 12 pairs of uniarmed and 28 or 27 pairs of biarmed chromosomes. Both X and Y chromosomes are acrocentric (Olds et al. 1987).

Andalgalomys roigi Mares and Braun, 1996

Roig's Chaco Mouse

SYNONYMS:

Andalgalomys roigi Mares and Braun, 1996:929; type locality "Argentina: San Luis Province: 8 km W La Botija, Pampa de Las Salinas, $36^{\circ}12'27''S$, $66^{\circ}39'35''W$. 510 m elevation."

G[raomys]. (*Andalgalomys*) *roigi*: Steppan and Sullivan, 2000:267; name combination.

DESCRIPTION: Similar in size to *A. pearsoni*, with head and body length 75–113 mm and hindfeet 21–25 mm, but tail proportionally longer (119% of head and body; range: 85–135 mm). Overall dorsal coloration light brownish olive, with banded hairs neutral gray at their base and cream buff tips; guard hairs dark gray basally with black tips; sides paler than dorsum, with lateral hairs lacking black tips; venter white to base and sharply demarcated from sides and back. Tail bicolored, brownish above and whitish below, and moderately penciled, with hairs extending about 5 mm beyond tip; basal two-thirds moderately haired, although scales remain visible to eye; distal one-third well haired, and scales not visible; tail hairs increase in length distally, giving darker appearance to tip than base. Both subauricular and postauricular patches as well as tops of forefeet and hindfeet white. Skull similar in shape to other two species but smallest in length and breadth dimensions.

DISTRIBUTION: *Andalgalomys roigi* is known from the Chaco and Chaco-Monte ecotone of west-central Argentina at elevations between about 300–1,000 m.

SELECTED LOCALITIES (Map 249): ARGENTINA: Catamarca, Chumbicha, 0.5 km E of Rte 38 along Rte 60 (CML 3693); La Rioja, Salar La Antigua, 45 km NE of Chamental (R. A. Ojeda et al. 2001), 26 km SW of Quimilo (OMNH 30016); Mendoza, Reserva Ñacuñán (Borghi and Eguaras 2000); San Luis, Pampa de las Salinas, 1.3 km N and 7.4 km W of La Botija (OMNH 23794), Parque Provincial Sierra de las Quijadas, 6 km W of Hualtaran (OMNH 23795), Lomas Blancas (D. Castro, Gonzales, and Vidal 1998).

SUBSPECIES: *Andalgalomys roigi* is monotypic.

NATURAL HISTORY: *Andalgalomys roigi* has been collected in arid and semiarid habitats in the narrow ecotone between the Monte Desert and Chaco that extends from Catamarca to Mendoza province. Specimens have been trapped most commonly in low thorn scrub vegetation bordering salt flats (Mares and Braun 1996; R. A. Ojeda et al. 2001). Molting has been reported to occur in the months of May and July (Mares and Braun 1996). Reproductive activity (including young/juvenile individuals) occurs in March, May, and November (Mares and Braun 1996; unpubl. data). Unpublished field notes suggest that this species is nocturnal. D. Castro, Gonzales, and Vidal (1998) and Borghi and Eguaras (2000) summarized information on arthropod ectoparasites. Mares and Braun (1998) documented mammalian associates at three localities where this species was caught.

REMARKS: The chromosome complement consists of a $2n=60$, FN=116, with both all autosomes and both X and Y chromosomes biarmed. This karyotype is similar to that of *A. olrogi* but differs from that of *A. pearsoni* in both diploid and fundamental numbers.

Genus *Auliscomys* Osgood, 1915

Jorge Salazar-Bravo

Members of the genus *Auliscomys* range from just north of 8°S (La Libertad in central Peru) southward through the Altiplano of Peru and Bolivia to northern Argentina and Chile, occurring in various highland habitats at localities ranging between 3,500 and above 5,000 m, where they occupy rock slides, *Polylepis* woodlands, and both bunchgrass and shrub dominated communities. This account is based on information extracted primarily from Gyldenstolpe (1932), Osgood (1947), Pearson (1951, 1958), Hershkovitz (1962), and Braun (1993), who should be consulted for further reference.

Species of the genus *Auliscomys* are small to medium-sized rats (head and body size <150 mm [Pearson 1958]) with long, lax fur, stout bodies, and tails either as long as or shorter than head and body length. The tail is well haired, bicolored, and lacks a tuft or pencil of hairs at the tip. Dorsal coloration varies among and within species, from uniformly grayish in *A. boliviensis* to rich brown in *A. pictus* to buffy yellow mixed with black in *A. sublimis*. Fur on the underparts is overall gray in tone with hair tips gray, dirty white, or pure white. Ears vary from small to large, between 21 and 23 mm in *A. pictus* and *A. sublimis* to 30 mm in *A. boliviensis*, often with buffy or white postauricular patches. Feet are stout, generally heavily fringed; digit V of the pes is long, reaching to the end of the first phalanx of digit IV (Gyldenstolpe 1932). Palms and soles are naked with six large, low pads. There are four pairs of mammae.

A narrow interorbital region (often narrower than the width of their nasals), with smooth and rounded supraorbital margins that lack ridges or beads, and widely expanded zygomatic arches, characterize the skull of *Auliscomys*. The margins of the supraorbital region diverge anteriorly; the nasals are short, barely extending beyond the maxillofrontal suture at its contact with the lacrimal bone (Steppan 1995); lacrimals are well developed; zygomatic notches are deep and with the anterodorsal margins of the zygomatic plates smoothly rounded (no zygomatic spines); the anterior margin of the orbit is positioned approximately even with the alveolus of M1. Incisive foramina are long, projecting distally between the M1s; the mesopterygoid fossa is narrow (much narrower than the parapterygoid fossae) and does not penetrate anteriorly between the M3s; parapterygoid fossae are broad and posteriorly divergent; the foramen ovale is small (except in some populations of *A. sublimis*); sphenopalatine vacuities are well developed; the carotid circulation is type 1 of Voss (1988), where the stapedia foramen and the posterior opening of the alisphenoid canal are large and the

squamosal-alisphenoid groove and the sphenofrontal foramen are present. The internal carotid canal is bounded by both the auditory bullae and the occipital bone. A capsular process is noticeably indistinct.

Upper incisors are orthodont with fine striae or shallow grooves, and with enamel colored whitish yellow to deep orange (see below). Molar rows are parallel. The molars are moderately low-crowned, robust, with main cusps alternating along the longitudinal plane but seldom reaching the midline. The anterocone of M1 is narrow and, except in *A. pictus*, undivided. A small labial root of M1 is set medially. Both M1 and M2 lack a mesostyle, and all three upper teeth lack parastyles. An anteromedian flexid in m1–3 is weakly developed and lost with wear, a posterolophid of m1 is distinct at all wear classes, the procingulum of M2 is moderately to well developed, and m3 has a highly reduced mesoflexid.

SYNONYMS:

Hesperomys: Waterhouse, 1846:9; part (description of *boliviensis*); not *Hesperomys* Waterhouse.

Rheithrodon Thomas, 1884:457; part (description of *pictus*); not *Reithrodon* Waterhouse, and incorrect subsequent spelling of *Reithrodon* Waterhouse.

Rhithrodon Thomas, 1893a:337; part (listing of *pictus*); not *Reithrodon* Waterhouse, and incorrect subsequent spelling of *Reithrodon* Waterhouse.

Phyllotis: E.-L. Trouessart, 1897:534; part (listing of *boliviensis*); not *Phyllotis* Waterhouse.

Euneomys: Thomas, 1901f:254; part (listing of *pictus*); not *Euneomys* Coues.

Auliscomys Osgood, 1915:190; as subgenus of *Phyllotis*, type species *Reithrodon pictus* Thomas, by original designation.

Euneomys (Auliscomys): Thomas, 1916a:141; name combination as a valid subgenus.

Maresomys Braun, 1993:40; type species *Hesperomys boliviensis* Waterhouse, by original designation.

Auliscomys (Maresomys): S. Anderson, 1997:443; name combination.

REMARKS: Originally diagnosed as a subgenus of *Phyllotis* (Osgood 1915), members of *Auliscomys* were subsequently recognized either at that rank (Osgood 1947; Pearson 1958) or as a full genus (Thomas 1926b; Gyldenstolpe 1932; Musser and Carleton 2005). The monophyly of *Auliscomys* is supported by karyotypic (Couve Montane 1975; Pearson and Patton 1976), morphological (Braun 1993; Steppan 1993, 1995), and molecular analyses (Salazar-Bravo et al. 2013). Some molecular data indicate that *Auliscomys* and *Galenomys* share a most recent common ancestor (e.g., Steppan et al. 2007; Salazar-Bravo et al. 2013). *Maresomys* was described by Braun (1993) to include *A. boliviensis* based a presumptive sister-taxon relationship

between *boliviensis* and *Galenomys garleppi*. However, this hypothesis did not receive support from other morphological (Steppan 1995; Steppan and Sullivan 2000) or molecular analyses (Salazar-Bravo et al. 2013). Therefore, I follow Steppan and colleagues and treat *Maresomys* as a synonym of *Auliscomys*. Anderson (1997) included *Maresomys* as a subgenus of *Auliscomys*.

Three recent species are currently recognized: *Auliscomys pictus*, *A. sublimis*, and *A. boliviensis*. *Auliscomys formosus*, a fossil form from the Montehermosan age deposits (ca. 5–4 mya) of Buenos Aires province, Argentina, is currently the oldest known sigmodontine fossil in South America (Pardiñas and Tonni 1998). Two other fossil forms associated with the genus (*Auliscomys fuscus* and *Auliscomys osvaldoreigi*) are apparently better arranged under the extinct genera *Olimpicomys* and *Panchomys*, respectively (Teta, Pardiñas et al. 2009). Some authors (e.g., Simonetti and Spotorno 1980; L. I. Walker and Spotorno 1992) assigned *Loxodontomys micropus* to *Auliscomys*, a hypothesis rejected by cladistic analyses of morphology (Braun 1993; Steppan 1993, 1995; Spotorno, Cofre et al. 1998; Steppan and Sullivan 2000). Furthermore, analyses of combined mtDNA and nucDNA sequences have failed to support a close relationship between *Auliscomys* and *Loxodontomys*, regardless of the method of analysis (Salazar-Bravo et al. 2013).

KEY TO THE SPECIES OF *AULISCOMYS*:

1. Tail shorter than 70 mm; upper incisors sometimes faintly grooved, somewhat proodont, and white to pale yellow. *Auliscomys sublimis*
- 1'. Tail longer than 70 mm; upper incisors slightly yellow 2
2. Upper incisors with longitudinal grooves, yellow or orange, not proodont; head plus body shorter than 125 mm; ear length from notch shorter than 25 mm; soles of feet pale *Auliscomys pictus*
- 2'. Upper incisors without longitudinal grooves, pale yellow, distinctly proodont; head plus body of adults longer than 125; ear length from notch longer than 25 mm, well clothed with hair and with tuft of long hair at base; soles of hindfeet blackish *Auliscomys boliviensis*

Auliscomys boliviensis (Waterhouse, 1846)

Bolivian Pericote, Achulla, Achohalla, Pericote Orejón Boliviano

SYNONYMS:

Phyllotis (*Auliscomys*) *boliviensis flavidior*: Sanborn, 1950:9; name combination.

Phyllotis boliviensis boliviensis: Pearson, 1958:452; name combination.

Auliscomys (*Maresomys*) *boliviensis*: Braun, 1993:40; name combination.

DESCRIPTION: Pale, long-eared species (ear length often >25 mm), with tail shorter than head and body (57 to 95%) and hindfeet with blackish soles (Pearson 1958). Considerable variation in head and body length, with some populations in southern Bolivia averaging 125 mm and others 112 mm. In general, stout-bodied with long and soft fur; upper surface of head and body with coarse mixture of gray, brown, and buff or ochraceous, sides paler, and muzzle whitish; ochraceous lateral line not always well developed; under parts whitish or pale gray, more or less washed with buff, and with ochraceous pectoral streak sometimes present (Hershkovitz 1962). Dorsal surface of tail often ochraceous with terminal portion darker, underside whitish becoming ochraceous terminally; tail not tufted at tip. Hindfeet comparatively larger than in congeners, with silvery-white, gray, or buff dorsal surfaces, sometimes with ochraceous metatarsal patch; soles coarsely scutellated, naked, and blackish. Ears long (>25 mm), covered internally with short yellow hairs and externally with much longer, rusty yellow hairs. Prominent ochraceous and white preauricular and buffy cream to whitish postauricular ear patches present.

Skull with strongly bowed zygomatic arches, very narrow interorbital region, and deep and broad zygomatic

notches. Skull with interorbital region anteriorly divergent, narrowest point located behind orbit; rostrum wider than interorbital region (Steppan 1995); braincase not globular but squared in profile; tympanic bullae large and thin walled. Hershkovitz (1962) indicated that anteroposterior length of tympanic bullae minus their tubes is subequal to alveolar length of molar row. Incisive foramina long and broad, posteriorly reaching almost to protocones of M1s; foramina widest at, or near to, premaxillomaxillary suture and taper slightly posteriorly. Dorsal edge of mesopterygoid fossae squared (in most individuals) and does not reach M3 alveolus. Parapterygoid fossae diverge dorsally, much broader than mesopterygoid fossa. Sphenopalatine vacuities well developed. Most adult specimens exhibit well-developed lacrimals.

Upper incisors distinctly proodont, ungrooved (or if present, sulci only faint, shallow striae usually not visible to unaided eye), and with pale yellow enamel. Molar rows parallel sided or slightly bowed. Molars details similar to those of *A. pictus*, but cusps not flexed forward, protoflexus of M2 more reduced, anterior cingulum of M3 and vestige of mesoloph larger, and protoflexid of m1 obsolete (Hershkovitz 1962). A persistent parastyle present on M2 (Mann 1978).

Vertebral column with 13 thoracic, 6 lumbar, and between 25 and 27 caudal elements (Steppan 1995). Spotorno (1987) provided anatomical details of male phallus and baculum. In comparison with both *A. pictus* and *A. sublimis*, glans of *A. boliviensis* with short rather than long urethral process, and baculum without basal median notch. Caecum coiled and long, followed by complex colon (Mann 1978).

DISTRIBUTION: *Auliscomys boliviensis* occurs across the Altiplano of southern Peru, northern Chile, and west-central Bolivia, between 3,500 and 5,000 m.

SELECTED LOCALITIES (Map 251): BOLIVIA: Chuquisaca, Sucre (Hershkovitz 1962); Oruro, 7 km S and 4 km E of Cruce Ventilla (MSB 57101), Estancia Agua Rica, 22 km S and 40 km SE of Sajama (MSB 57102), Livichuco (BM 1902.2.2.16); Potosí, Potosí (Hershkovitz 1962). CHILE: Arica y Parinacota, Guallatiri (Pine et al. 1979), 6 mi E of Putre (USNM 541735). PERU: Arequipa, Huancarama, Orcopampa (MUSA 512), Huaylarco, 54 mi ENE of Arequipa (MVZ 115892), San Ignacio (MCZ 39494), San Juan de Tarucani (MUSA 1403); Moquegua, Caccachara (MCZ 42922); Puno, Pampa de Ancomarca, 123 km S of Ilave (MVZ 115896); Tacna, Lago Suche (MVZ 115893), 13 km NE of Tarata (MVZ 141600).

SUBSPECIES: Both Pearson (1958) and Hershkovitz (1962) recognized two subspecies, *Auliscomys boliviensis boliviensis* in central Bolivia and northern Chile and *Auliscomys boliviensis flavidior* in southwestern Peru. However,

Pearson (1958:452) noted that “the boundary between the two subspecies could be drawn almost anywhere” because the differences between the two are so slight and abundant intermediates exist.

NATURAL HISTORY: The species occurs in the Altiplano, usually in open country with sparse vegetation; it has been observed living among boulder-strewn slopes among yareta (*Azorella compacta* [Apiaceae]), stone walls, and even within abandoned tuco-tucos (*Ctenomys*) burrows (Pearson 1951). In Bolivia, it was found occupying active burrows of *Ctenomys opimus* and sharing burrows with *Galea musteloides*. In northern Chile, it was trapped in tola (*Parastrephia lepidophylla* [Asteraceae]) dominated flatlands (Mann 1978). Individuals are diurnal (Pearson 1951; Mann 1978); although they are not reported to be gregarious, at one locality in Oruro, Bolivia (7 km S and 4 km E Cruce Ventilla), 7 and 10 individuals occupied a small (150 m²) area within active tuco-tuco burrows; these rodents would stick their heads up from inside the burrows as people approached (J. Salazar-Bravo, pers. comm.). They are reported to be fairly tame and can be handled and fed readily (Mann 1945); they interact with vizcachas, a species of much larger size, and cue in to its alarm calls (Pearson 1951). They are reported to feed on a variety of foods, including lichens, forbs, and other vegetation (S. I. Silva 2005). Bozinovic and Rosenmann (1988a) reported basal metabolic rate and thermal conductance values.

Males of different populations apparently enter reproductive activity at different times of the summer, some in September and others in early December (Pearson 1951). Pregnant females with three to four embryos were recorded in October and December in southern Peru. Reported ectoparasites and endoparasites for the species include a flea of the genus *Cleophsylla* as well as lice (*Hoplopleura affinis*), mites (*Atricholaelaps glasgowi*), two species of chiggers in the genus *Trombicula*, and nematodes of the genus *Stilestrongylus* (Colombetti et al. 2008; Diaw 1976; Pearson 1951). The tapeworm *Taenia talicei* was found in two of eight Bolivian animals examined (Scott L. Gardner, pers. comm.).

REMARKS: The record for this species from La Cumbre (La Paz, Bolivia) by Mercado and Miralles (1991) was based on a misidentified specimen of *Punomys* (Salazar-Bravo et al. 2011).

Auliscomys boliviensis has a diploid number of $2n=22$ and $FN=30$ in Peru and northern Chile (Couve Montane 1975; Pearson and Patton 1976; L. I. Walker and Spotorno 1992). In contrast, two males and a female from Oruro, Bolivia, had a diploid number of $2n=20$ (Peurach 1994). The question of whether these regional karyotypic differences might support the current subspecies allocations or even reflect species-level boundaries underscores the need for further taxonomic work.

Auliscomys pictus (Thomas, 1884)
Colorful Pericote, Hucucha Guanaco,
Ratón Orejón Pintado

SYNONYMS:

Rheithrodon [*sic*] *pictus* Thomas, 1884:457, plates 19–21; type locality “Junín,” given as “Junín, 13,700 feet, Department of Junín, Peru” by Pearson (1958).

Rhithrodon [*sic*] *pictus*: Thomas, 1893a:337.

E[uneomys]. pictus: Thomas, 1901f:254; name combination.
P[hyllois]. (Auliscomys) pictus: Osgood, 1915:191; name combination.

Phyllotis (Auliscomys) decoloratus Osgood, 1915:191; type locality “Tirapata, Dept. Puno, Peru.”

Auliscomys pictus: Thomas, 1926b:316; first use of current name combination.

Phyllotis (Auliscomys) pictus: Pearson, 1958:448; name combination.

Phyllotis pictus: Hershkovitz, 1962:404; name combination.

DESCRIPTION: Medium sized with head and body length 100–133 mm; back and sides of trunk brownish; rump, outer sides of thigh, and base of tail tawny to ochraceous. Head and shoulders often grizzled, and lateral line, when present, ochraceous. Under parts gray to dirty white with dark basal portion of hairs showing through; small ochraceous pectoral streak present in some populations (Hershkovitz 1962). Tail bicolored, typically more than 68 mm long but <91% of head and body length; never conspicuously tufted. Ears <27 mm, with inner posterior surface ochraceous and pale postauricular tufts usually

present. Hindfeet short (average 25.8 mm near Lake Titicaca in south to 27 mm in Junín department in north [Pearson 1958]), with upper surfaces gray, lightly washed with ochraceous; soles finely scutellated.

Skull characterized by very narrow interorbital region, with sides either concave or parallel sided, and with squared but never ridged or beaded edges; rostrum short and wide; zygomatic arches moderately expanded; interparietal well developed; posterolateral palatal pits present; and bullae rather noninflated with anteroposterior length, not including bony tubes, shorter than alveolar length of molar row (Hershkovitz 1962).

Upper incisors grooved, moderately heavy, and orthodont. Molar rows parallel sided or slightly divergent posteriorly. Both upper and lower first molars with four roots; all cheek teeth subhypodont with cusps more or less ovate in outline (Hershkovitz 1962). Procingulum of M1 divided in young individuals; old individuals or heavily worn M1s ovate in outline. Procingulum of M2 well developed, with well-developed paraflexus and obsolete protoflexus. Vestigial mesoloph often present in M1–2. Posteroloph of m2 relatively well developed but weakly developed in m3; m2 with persistent protoflexus even in well-worn tooth; occlusal pattern of m3 sigmoid in shape.

Axial skeleton with mode of 13 thoracic and six lumbar vertebrae and between 22 and 26 caudal vertebrae (Steppan 1995). Gall bladder present (Voss 1991a); Dorst (1973b) described stomach structure; and Hooper and Musser (1964) detailed anatomy phallus and baculum.

Color and size noticeably variable throughout range. Larger individuals (ca. 10% longer in head and body and 4% longer in greatest length of the skull) occur in northern portion of range near type locality relative to specimens from Bolivian-Peruvian border. In general, animals from more humid drainage systems (e.g., populations on eastern escarpment of Altiplano from above Limbani, Puno, Peru) with longer-tailed and darker color tones than those from drier regions of Titicaca drainage (Pearson 1958).

DISTRIBUTION: *Auliscomys pictus* occurs throughout the highlands of Bolivia and Peru, very likely extending into extreme northern Chile, although there are no confirmed records from that country. Known localities range from La Libertad department in central Peru to La Paz department in Bolivia, at elevations from 2,590 to 4,820 m (Pearson 1958; Hershkovitz 1962; S. Anderson 1997).

SELECTED LOCALITIES (Map 252): **BOLIVIA:** La Paz, Limani (CBF 851), Pongo (AMNH 72727), Quiswarani (CBF 6431). **PERU:** Ancash, 1 km N and 12 km E of Pariacoto (MVZ 138126); Arequipa, Tocra Pampa, Cayloma (MUSA 881); Ayacucho, Tucumachay Cave (UMMZ

122625), 15 mi WNW of Puquio (MVZ 138133); Cusco, 55.5 km by road N of Calca (UMMZ 160541); La Libertad, 10 mi WNW of Santiago de Chuco (MVZ 138142); Lima, Pacomanta, km 120 on Lima to Huarochirí highway (KU 143594); Pasco: Chipa (AMNH 60580); Puno, 1 mi S of Limbani (MVZ 116150), Santa Rosa (MCZ 42806).

SUBSPECIES: *Auliscomys pictus* is monotypic. Neither Pearson (1958) nor Hershkovitz (1962), in their respective reviews of this species, recognized formal geographic units despite recording variation in size and color across the species's range.

NATURAL HISTORY: *Auliscomys pictus* has been trapped in relatively mesic habitats in the Altiplano containing an abundance of grasses (mostly *Stipa ichu*) and other herbaceous vegetation at high elevations (Pizzimenti and DeSalle 1980) and also in stone walls and places far from water (Pearson 1951). Animals were active day and night (Pearson 1951). In southern Peru, the species used a wide range of food items (Pizzimenti and DeSalle 1980), including both plant material from forbs (93% of diet) and insects (7%). A report from Chile stating that this species feeds on mushrooms, seeds, and fruits is likely incorrect and probably refers to *Loxodontomys micropus* (S. I. Silva 2005).

Pearson (1951) reported that breeding commenced between September and December in southern Peru. Hershkovitz (1962) noted a pregnant female with five embryos from Cusco department taken in April; females, some with up to five embryos and six uterine scars were trapped in January in Arequipa (H. Zeballos, pers. comm.). S. Anderson (1997) reported a female with three embryos in January from La Paz, Bolivia.

Together with *Auliscomys sublimis*, *Auliscomys pictus* composed more than 30% of the diet of owls at Pairumani, Peru (Pearson 1951), and remains of this species were reported in the scats of Culpeo (*Lycalopex culpaeus*) near La Paz, Bolivia (Mercado and Miralles 1991), and the highlands of Abiseo National Park in Peru (Romo 1995). Pearson (1951) mentioned that the ears of *Auliscomys pictus* are often “nibbled” away as a result of infestation by orange mites, and Sarmiento et al. (1999) recorded two genera of nematodes (*Parastrongylus* and *Trichuris*) for the species. Red blood cell volumes and hemoglobin concentrations were within the range of variation of other rodents at both high and low elevations (Morrison et al. 1963).

REMARKS: *Auliscomys decoloratus* was described as a distinct species (Osgood 1915) based on the small size and pale coloration of an individual from Tirapata in southern Peru. Subsequent reviewers (Sanborn 1950; Pearson 1958; Hershkovitz 1962) have consistently regarded *decoloratus* as a synonym of *A. pictus*, and unworthy of even subspecific recognition.

Map 252 Selected localities for *Auliscomys pictus* (●). Contour line = 2,000 m.

Pearson (1972) and Peurach (1994) described a karyotype with $2n=28$, $FN=30$ from Peruvian and Bolivian localities, respectively.

Phyllotis sublimis sublimis: Pearson, 1958:447; name combination.

Phyllotis sublimis leucurus: Pearson, 1958:448; name combination.

DESCRIPTION: Fluffy-furred, short-tailed species with widely bowed zygomatic arches, pinched interorbital region, and small bullae typical of genus (Pearson 1958). Adult body size (head and body length) averages 110 mm (Pearson 1951). Dorsal pelage long, extremely soft, and fine. Overall dorsal color buffy yellow mixed with some black hairs; head pelage somewhat more grizzled than rest of body; no eye-ring present; sides of body paler turning to white on cheeks; although lateral line usually indistinct, under parts sharply defined whitish to pale gray with base of fur often plumbeous; upper surfaces of forefeet and hindfeet silvery white; hindfeet naked below except on heel. Tail length always <68 mm; tail itself covered with fine white hair, often distinctly bicolored, but lacking tuft at tip. Ears are short (average 22.2 mm) and covered with fine yellowish hair inside; distinct postauricular patches often present.

Skull quite similar to that of *A. pictus*. Interorbital region narrow, parallel sided in middle, divergent anteriorly, and with rounded margins; zygomatic arches evenly bowed, which in combination with globular braincase give skull more "rounded" profile than other species of highland phyllotines; rostrum narrower than in *A. pictus*; interparietal small; bullae only slightly smaller than those of *A. pictus* and pear rather than flask shaped; foramen ovale about size of M3 and in many specimens completely unobstructed.

Upper incisors orthodont with enamel colored pale yellow to almost white and with anterior faces marked by faint, shallow grooves (sometimes hard to see by unaided eye). Molar rows parallel. Molars hypsodont, cusps subovate in outline, with flexi from opposite sides not reaching midline (Hershkovitz 1962). Procingulum of M1 broad but undivided; metaloph and paraloph well developed; base of mesoflexus and hypoflexus not alternating, which defines an almost straight median mure. M1 with 4 roots. M2 with small procingulum and weakly developed paraflexus and protoflexus, both becoming lost with moderately wear. Vestige of mesoloph sometimes present on M1–2. Overall, outline of M2 sigmoid when worn. Procingulum of m1 weakly divided by anteromedian flexid, which becomes lost in worn teeth; m1 with 3 roots; and base of the protoflexid opposes that of metaflexid, forming a short anterior murid in medial position (Hershkovitz 1962).

Steppan (1995) reported 13 thoracic, 6 lumbar, and between 24 and 25 caudal vertebrae. Phallus and baculum similar to *A. pictus* (Spotorno 1987).

Both Pearson (1958) and Hershkovitz (1962) called attention to large variability within and among samples, especially in skull size, head and body length, and dorsal and ventral coloration. Specimens from the more humid eastern Andean slope are darker than those from comparatively dry Altiplano of southern Peru (Pearson 1962).

DISTRIBUTION: *Auliscomys sublimis* occurs in the Altiplano highlands from southern Peru through west-central Bolivia and northern Chile to northern Argentina, between 3,200 to above 5,000 m.

SELECTED LOCALITIES (Map 253): ARGENTINA: Jujuy, ca. 3 km S of Guairazul (PEO-e 301); Salta, 3 km E of La Poma (PEO-e 234). BOLIVIA: Cochabamba, 9.5 km by road SE of Rodeo, then 2.5 km on road to ENTTEL antenna (AMNH 260915); La Paz, 20 mi S of La Paz (MVZ 120168), Ulla-Ulla (MSB 75283); Potosi, Lipez (BM 26.6.12). CHILE: Antofagasta, Toconce, 60 mi ENE of Calama (MVZ 116793); Arica y Parinacota, Choqueimpie, 114 km NE of Arica (LCM 1194). PERU: Arequipa, 5 km W of Cailloma (MVZ 174013), Salinas, 4,316 m (MUSA 1141), Tocra Pampa (MUSA 1140); Puno, 8 mi SSW of Limbani (MVZ 114735); Ayacucho, 15 mi WNW of Puquio (MVZ 138143); Tacna, Pampa de Titire, 29 km NE of Tarata (MVZ 115914).

SUBSPECIES: Pearson (1958) recognized two subspecies, the nominotypical form from southern Peru south through northern Chile and north-central Bolivia, and *A. s. leucurus* from extreme southern Bolivia, adjacent Antofagasta, Chile, and northernmost Argentina. The southern race differs primarily in absolutely and proportionally longer tooththrows and grayer venters. Pearson (1951) also noted that specimens from the more humid eastern Andean slopes in southern Peru were noticeably darker than those from the drier Altiplano, but did not recommend a formal distinction from typical *A. s. sublimis*. Hershkovitz (1962:430), while also delineating two subspecies, argued that “differences in molar row length and color of underparts between northern and southern populations of the species are not significantly greater than differences between local populations in Arequipa Department, Peru.” S. Anderson (1997) retained Pearson’s subspecific division for Bolivian populations.

NATURAL HISTORY: *Auliscomys sublimis* reaches record elevations of up to 5,500 m (Thomas 1900h; Pearson 1958). Reported as “one of the commonest mice of the Altiplano of southern Peru” (Pearson 1951), this species is often present in areas with abundant vegetative cover, in pastures, rocky outcrops, and *Stipa*-dominated scrublands, or among boulders and yareta (*Azorella compacta*

[Apiaceae]). It may also be found in high-elevation meadows (called *bofedales*), where it excavates its own burrows or occupies old tuco-tuco or guinea pig burrows (Mercado and Miralles 1991). Pearson (1951) and Hershkovitz (1962) suggested that the species might aestivate, but no direct evidence has been reported. Pizzimenti and DeSalle (1980) argued that *A. sublimis* was omnivorous, as the diet included 0–79% insects, but Mercado and Miralles (1991) found the species to be a specialized herbivore. Pearson (1951) described the habits as gregarious and nocturnal. Some females were sexually precocious (Pearson 1958), and females with up to five embryos were found in Arequipa department in Peru (H. Zeballos, pers. comm.). Pearson (1951) recorded scrotal males at the end of July in southern Peru (Pearson 1951), and a young individual was trapped in May at Sierra de Tilcara, Argentina (M. M. Díaz and Barquez 2007).

Together with *Auliscomys pictus*, *Auliscomys sublimis* comprised more than 30% (by volume) of the prey of owls in southern Peru (Pearson 1951), and it was reported to be the dominant species from owl pellet samples in Jujuy, northern Argentina (Jayat, Ortiz, Pacheco, and González 2011). P. E. Ortiz, Cirignoli et al. (2000) recovered the remains of at least 10 individuals in pellets of the Short-eared Owl (*Asio flammeus*). The species was present in the diet

Map 253 Selected localities for *Auliscomys sublimis* (●). Contour line = 2,000 m.

of both the Andean cat (*Leopardus jacobitus*) and Pampas cat (*L. colocolo*) in Bolivia (L. Villalba, pers. comm.).

REMARKS: Teta and Ortiz (2002) reported Holocene records from archaeological sites in Jujuy, Argentina. Mitochondrial and nuclear sequence analyses support a sister relationship between *A. sublimis* and *A. pictus* (Steppan et al. 2007; Salazar-Bravo et al. 2013). Pearson (1972) described a karyotype with $2n=28$, FN=30, identical to that of *A. pictus*.

Genus *Calassomys* Pardiñas, Lessa, Salazar-Bravo, and Câmara, 2014

Ulyses F. J. Pardiñas and James L. Patton

This recently described genus has the smallest geographic range of any within the tribe Phyllotini, as the single species (*C. apicalis*) is known from only three, closely adjacent localities in the Cerrado ecoregion of Minas Gerais state, Brazil. Although the general external morphology, especially the abundant and long mystacial vibrissae combined with its long tail, resembles some medium-sized oryzo-myine and thomatomyine genera, details of the skull and molars clearly link *Calassomys* with other phyllotines. Morphological attributes suggest an affinity with *Calomys*, but molecular sequence data place *Calassomys* basal to all other members of the tribe. Pardiñas et al. (2014) provide detailed comparisons to *Calomys* and several nonphyllotine genera (*Delomys*, *Wiedomys*, *Zygodontomys*, and *Necromys*) with which *Calassomys* shares some features.

The single species is medium sized (head and body length ranges from 103–125 mm) with a long (tail length 130–158 mm; >125% of head and body length) and bicolored tail, brown above and white below but with the terminal 25–50 mm completely white and ending in a sparse apical tuft 5–6 mm in length. The tail is covered by sets of three delicate hairs per scale, each dorsal hair covering two scale rows. Ears are moderately large, rounded, and partially naked, covered on both surfaces by short and delicate brown hairs but with concha and tragus strikingly yellow. Ear length (from notch) averages >18.2 mm. Dorsal fur is characterized by dark gray base and brown-ochraceous overtones; guard hairs are long (ca. 15 mm) and soft. Ventral hairs have gray bases and white tips; the muzzle and cheeks are whitish gray. Mystacial vibrissae are long, surpassing the ears when laid back alongside the head. A conspicuous black ring surrounds eyes. Forefeet are covered dorsally by short, whitish hairs; digits II and dIV are subequal in size, and dII and dV are shorter, with dII clearly longer than dV; dI is vestigial but has a small nail; dII–V possess inconspicuous claws (about 1.8 mm long), dorsally

covered by whitish ungual hairs. The ventral surface of the forefeet is naked and unpigmented, with two carpal and three interdigital large and fleshy pads. The hindfeet are covered dorsally by whitish hairs; the plantar surface is naked and unpigmented, slightly squamated, and has four large, nearly ovate interdigital pads plus a hypothenar pad subequal in size to the first interdigital and located intermediate between the first interdigital and thenar pad; the thenar pad is enlarged and narrow. Long hairs on the sides of the heel partially cover the calcaneal area.

The skull is domed in lateral profile with the braincase generally dominating the dorsal aspect. The rostrum is long and moderately broad, its sides tapering gradually but with the premaxillary bones visible for almost their entire length along the nasal margins. The nasals are parallel sided and broad, projecting anteriorly to form an incipient rostral tube or “trumpet,” completely obscuring the upper incisors in dorsal view. Lacrimals are large. The interorbital region is wide and dorsally flat, with the constriction placed immediately posterior to inconspicuous frontal sinuses; margins of the frontal bones are sharp and posteriorly divergent but do not form supraorbital shelves. The coronal suture is V-shaped. The braincase is large and round, and lacks both temporal and lambdoidal ridges; the suture between the parietals and squamosals is concealed by a slightly developed bony ridge in adult specimens. The zygomatic plates are narrow and high, with a moderate forward extension forming a free anterodorsal margin and defining shallow zygomatic notches. The zygomatic arches are delicate; their midpoints dip ventrally to remain visible above the level of the orbital floor. A short jugal distinctly separates maxillary and squamosal portions of the arch. Parietals lack extensions in lateral view. The hamular process of the squamosal is long, thick, and has an unexpanded posterior end; the subsquamosal fenestra is reduced with respect to the postglenoid foramen. Incisive foramina are wide and long, compressed anteriorly, with the posterior ends rounded and extending slightly past the anterior roots of M1s; the premaxillary process occupies about three-fourths the length of the foramina. The palate is wide and short, with diminutive posterolateral palatal pits placed on the sides of the mesopterygoid fossa. That fossa is especially wide, with its anterior border reaching the posterior face of M3s; the anterior portion is slightly lyre-shaped due to the presence of a median palatine process. Sphenopalatine vacuities on the roof of the mesopterygoid fossa are typically present as narrow slits. Pterygoids are short, small, and parallel; the parapterygoid plates are flat and reduced in size with respect to the mesopterygoid fossa. Auditory bullae are medium in size, flat in profile, and subtriangular in outline, with a short and wide bony tube. The carotid circulation is primitive, or pattern 1 (*sensu* Voss

1988), characterized by a large stapedial foramen and posterior opening of alisphenoid canal, squamosal-alisphenoid groove, and sphenofrontal foramen.

The mandible is enlarged with the ascendant portion subtriangular in outline. The anterior point of the diastema is located slightly below the alveolar plane; the posterior face of the diastema is smooth; and the mental foramen is moderately visible in labial view. The masseteric crest is evident, with its upper and lower ridges meeting to produce a thick edge running from the plane defined by the posterior face of m1 to slightly above the level of the mental foramen. The capsular projection is conspicuous, lying near the base of the coronoid process, which is reduced and slightly inflected backward. The condyloid process is wide and short; the angular process is short. The lunar notch is scarcely developed. The mandibular foramen is compressed and located above the mylohyoid line; the retromolar fossa is moderately enlarged.

Upper incisors are faced with bright orange enamel; they are opisthodont, smooth, and narrow, with juxtaposed tips showing a straight cutting edge; the dentine fissure is a long, straight slit (see Steppan 1995). Upper molars are crested, with their labial cusps higher than lingual ones, markedly opposite in pattern, brachyodont, and small with respect to the skull. M1 is trilophodont, subrectangular in outline, with a well-developed procingulum usually without an anteromedian flexus; mures are longitudinally oriented; the hypoflexus and protoflexus are transverse; protocones and hypocones are subequal in size; minute mesolophids are consistently present; and both parastyle and mesostyles are usually present as thickenings of the labial cingula. The anteroloph and mesoloph exhibit a tendency to coalesce with the paracone and metacone, respectively. The hypoflexus is wide and posteriorly directed. M2 is square in outline and bilophodont; the anteroloph is reduced or absent; a mesoloph is typically present; and a wide mesoflexus is opposite the hypoflexus. M3 is cylindroform and moderately reduced in size with respect to M2; the hypoflexus is vestigial, but the mesoflexus persists as a small fossette. M1 and M2 appear to have three roots, and M3 one or two. Lower molars are also crested, transversally compressed, with the main cusps moderately alternating and both mesolophids and mesostyles absent. The trilophodont m1 has a well-developed and fan-shaped procingulum, also usually without an anteromedian flexid; the mesoflexid is especially wide; protoconid and hypoconid areas are subtriangular in outline; the entoconid is enlarged and bulbous; and the posterolophid is reduced. The m2 is bilophodont, with a reduced posterolophid. And m3 is subtriangular in outline, sigmoid, and has a reduced mesoflexid. All lower molars lack mesolophids.

The axial skeleton consists of 12 thoracic ribs and 12 thoracic, 7 lumbar, and 30 caudal vertebrae. The neural spine of the second cervical vertebra is enlarged, has a distinctive knob, and does not overlap with the third cervical vertebra. The neural spine of the second thoracic vertebra is conspicuously enlarged, twice or more so than the adjacent spines. Hemal arches are absent from the caudal vertebral, but hemal processes are present, starting between the second and third caudal vertebrae, becoming more pronounced between the fourth and fifth, then decreasing in size until they disappear. The humerus lacks the entepicondylar foramen, and the supratrochlear fossa is perforated.

Little information is available on soft anatomy. There are two diastemal and five interdental palatal rugae. A gall bladder is present, and the stomach is unilocular-hemiglandular (see Carleton 1973), with the antrum slightly smaller than the corpus. The bordering fold crosses the lesser curvature at the apex of the incisura angularis and the greater curvature at a locus opposite the incisura angularis; the glandular epithelium extends past the esophageal orifice and protrudes as a wide bulge into the corpus.

SYNONYM:

Calassomys Pardiñas, Lessa, Salazar-Bravo, and Câmara, 2014:202; type species *Calassomys apicalis*, by original designation.

REMARKS: *Calassomys* appears as basal to all other extant genera of phyllotines in phylogenetic analyses of mtDNA and nucDNA sequences (Pardiñas et al. 2014), a position consistent with the persistence of vestigial mesolophids and mesostyles on both M1 and M2, unique features among the Phyllotini. This phylogenetic hypothesis suggests that the ancestor of the phyllotine crown group ranged outside of the Andes, the area usually credited as the ancestral home of the tribe (Reig 1986).

Calassomys apicalis Pardiñas, Lessa, Salazar-Bravo, and Câmara, 2014

Calaça's White-tailed Mouse

SYNONYM:

Calassomys apicalis Pardiñas, Lessa, Salazar-Bravo, and Câmara, 2014:203; type locality "Brazil, Minas Gerais, Sempre Vivas National Park, 3.25 km by road NW Macacos, Pedreira do Gaio (19°57'50"S, 43°47'18"W, 1251 m asl)."

DESCRIPTION: As for the genus.

DISTRIBUTION: *Calassomys apicalis* is known only from Cerrado habitats within Parque Nacional Sempre Vivas in Minas Gerais state, Brazil, at elevations between 1,100 and 1,450 m.

SELECTED LOCALITIES (Map 254): BRAZIL Minas Gerais, Arrenegado, about 46 km N of Macacos (Pardiñas et al. 2014), 3.25 km NW by road of Macacos (type locality

Map 254 Selected localities for *Calassomys apicalis* (●).

of *Calassomys apicalis* Pardiñas, Lessa, Salazar-Bravo, and Câmara).

SUBSPECIES: *Calassomys apicalis* is monotypic.

NATURAL HISTORY: *Calassomys apicalis* inhabits rocky outcrops within *campos rupestres*, an open physiognomy that characterizes plateaus and mountaintops. Here, vegetation displays characteristic marked xerophytic adaptations and occurs on acidic or lithosolic, poorly developed soils, with exposed rock often covered by lichens and rupes-trial plants. This species co-occurs with the sigmodontines *Calomys* sp. and *Cerradomys subflavus*, the echimyids *Thrichomys apereoides* and *Trinomys albispinus*, and the marsupial *Monodelphis domestica*.

REMARKS: The reported karyotype is $2n=62$, $FN=116$ and consists of 28 pairs of biarmed and two pairs of uniarmed autosomes, a medium uniarmed X chromosome, and a uniarmed Y chromosome.

Genus *Calomys* Waterhouse, 1837

Jorge Salazar-Bravo

The genus *Calomys* is one of the most widespread genera of the Neotropical rodent fauna. Members of this genus—colloquially known as vesper mice, lauchas, or *rato bolinhas*—are small to very small, mostly granivorous rodents, abundant to common in most of the habitats where they occur.

The genus has a disjunct geographic distribution that is unique among sigmodontine rodents, with the exception of

Necromys. One species occurs in northern South America, in the llanos of Colombia and Venezuela and islands off the Venezuelan coast (Aruba, Curaçao, and Trinidad); all other species are associated with grasslands, savannas, and forest fringes in parts of Brazil, Bolivia, Peru, Argentina, Paraguay, Uruguay, and northern Chile. Although *Calomys* was the subject of a major revision in the early 1960s (Hershkovitz 1962) and an unpublished revision in the late 1980s (Olds 1988), the systematic status and both geographic and taxonomic limits of several species remain uncertain. Fortunately, the past decade has seen a renovated interest on the taxonomy of the genus and consequently the building of consensus on the identity and number of species that should be included in the genus, as well as a more comprehensive attempt (in techniques used and specimens analyzed) to understand the diversity of the genus. Nonetheless, much work in the field and museum remains to be done.

Until the early 2000s, much of what was known or inferred about species boundaries and relationships within the genus was based on morphological, chromosomal, and biochemical (protein electrophoresis) data. Most of these studies recognized species groups based on body size, tail length, skull morphology, or chromosomal counts of diploid numbers (e.g., Olds 1988). This approach was successful only at a very coarse level; at the heart of the problem is that many species in *Calomys* share a uniform morphology (in coloration, size, body proportions, etc.) yet occupy many ecological habitats and show high (in some cases, extreme) levels of chromosomal diversity. Interestingly, cladistic analysis of molecular sequence data only weakly supported some of the groups or species proposed earlier and indicated that, like in other muroid rodents, the burst of diversification in *Calomys* was accompanied by ecomorphological or chromosomal divergence only at a very coarse level (Salazar-Bravo et al. 2001; F. C. Almeida et al. 2007; Haag et al. 2007).

In the accounts that follow, I have been guided by criteria postulated by Musser and Carleton (2005), with more recent additions to the diversity of the genus (Bonvicino et al. 2010). It is very likely that this arrangement will change in the near future; nonetheless, these authors provide a solid base from which to start.

All species of *Calomys* are small to medium-sized mice well deserving of their Latinized Greek name (καλός = beautiful, μύς = mouse). Head and body length ranges from 70 to 150 mm (Hershkovitz 1962), usually with small to medium-sized and well-haired ears (between 13 and 19 mm [Olds 1988]). Most species have white or light buffy postauricular patches with some also presenting preauricular patches of the same color. Dorsal and ventral colors are often well differentiated with the venter

paler. Pelage coloration, length, and appearance vary greatly among species and sometimes among populations of the same species; often, high-elevation species or populations of widespread ones show particularly long, thick, and smooth pelages. Dorsal color ranges from bright buffy or pale yellowish-brown to dark brown or gray. Ventral color ranges from pure white to white-tipped gray hairs to medium gray, but it is never the same color as the dorsum. Hindfeet are small (always <23 mm [Olds 1988; Bonvicino et al. 2010]) and covered with white hairs above; soles are naked, except for the heel, and possess six small plantar pads. The tail is less than or equal to the head and body length, covered with short fine hairs, and lacks a tuft at the tip; it may be either weakly to strongly bicolored, darker above. Mammary usually number 8 to 10 (4 to 5 pairs), but can range from 6 to 14 (Herskovitz 1962; Olds 1988).

The skull is delicate to robust with parallel-sided to posteriorly divergent interorbital regions that may have either smooth edges or sharply beaded ridges. Zygomatic arches are expanded in adults, usually convergent anteriorly, rarely parallel sided. The anterior borders of the zygomatic plates are slightly concave, but never to the point of defining zygomatic spines; zygomatic notches are deep and broad. Incisive foramina are long, extending to the middle of the M1s; the palate is also long, extending beyond the M3s, and may or may not present posterolateral palatal depressions but often possess posterolateral palatal pits. The parapterygoid fossae are shallow and always much broader than the mesopterygoid fossa. Sphenopalatine vacuities are large. The carotid circulation is primitive or pattern 1 (*sensu* Voss 1988), with a large stapedial foramen and posterior opening of alisphenoid canal, squamosal-alisphenoid groove, and sphenofrontal foramen present (Olds 1988; Stepan 1995). An alisphenoid strut may or may not be present.

Upper incisors are opisthodont to nearly proodont, ungrooved, and faced with smooth enamel colored yellow to deep orange. Molar rows are generally parallel sided; individual cheek teeth are brachydont, tetralophodont, and crested; labial and lingual cusps alternate along the anteroposterior axis of the toothrow. The antercone of M1 is always divided by an anteromedian flexus (except in very old individuals), and the anterolabial conule is often larger than the anterolingual one. M2 is square shaped and slightly smaller than M1; M3 is about 50% the size of M2 and more roundly shaped (Olds 1988). There is no reduction in the mesoflexus of M3 relative to that of M2 (Stepan 1995). The mandible is delicate but relatively deep; the coronoid process is slightly higher than the condylar process; a capsular process is not well developed and is located below the anterior portion of the sigmoid notch and under

the coronoid. The masseteric crest is variable in both presence and development, from a barely visible chevron to a distinct knob.

Hooper and Musser (1964) described the male reproductive structures of two species of *Calomys* (*C. callosus* and *C. laucha*); in general, these were similar to each other and equally similar to those of *Eligmodontia* and *Graomys* (Hooper and Musser 1964:48). Voss and Linzey (1981) detailed the male reproductive tracts of the same species and concluded that each represented the plesiomorphic character state of glandular polarity for the Sigmodontinae. The stomach is unilocular and hemiglandular (Carleton 1973), and a gall bladder is present (Voss 1991a). Current karyotypic data on *Calomys* document remarkable diversity, with the number of known karyotypes higher than the number of recognized species and ranging from $2n=36$ to $2n=66$ and FN=48 to FN=72 (see Bonvicino et al. 2010 for a recent compilation of diploid and fundamental numbers for recognized species of *Calomys*).

Calomys fossils are known from as early as the lower Pleistocene of Bolivia and Argentina (Pardiñas et al. 2002) and as late as the Pleistocene-Holocene boundary of Patagonia and northern Argentina (P. E. Ortiz and Jayat 2007b; Pardiñas, Teta, D'Elía, and Lessa 2011).

SYNONYMS:

Mus: Olfers, 1818:209; part (description of *laucha*); not *Mus* Linnaeus.

Calomys Waterhouse, 1837:21; as subgenus; type species *Mus bimaculatus* Waterhouse (= *Mus laucha* G. Fischer), by original designation.

Hesperomys Waterhouse, 1839:75; type species *Mus bimaculatus* Waterhouse, by subsequent designation (Coues 1874:177); objective junior synonym of *Mus* (*Calomys*) Waterhouse, 1837.

Mus (*Hesperomys*): Wagner, 1843a:545; part (listing of *expulsus*); neither *Mus* Linnaeus nor *Hesperomys* Waterhouse.

Callomys Lesson, 1842:133; incorrect subsequent spelling of *Calomys* Waterhouse.

Eligmodontia: Lesson, 1842:133; part (listing of *bimaculatus* and *gracilipes*); not *Eligmodontia* F. Cuvier.

Hesperomys (*Calomys*): Burmeister, 1879:225; part (listing of *bimaculatus*); not *Hesperomys* Waterhouse.

Hesperomys (*Akodon*): E.-L. Trouessart, 1800:142; part (listing of *pusillus*); neither *Hesperomys* Waterhouse nor *Akodon* Meyen.

Oryzomys: Thomas, 1894a:359; part (description of *venustus*); not *Oryzomys* Baird.

Zygodontomys: E.-L. Trouessart, 1904:423; part (listing of *expulsus*); not *Zygodontomys* J. A. Allen.

Baiomys: Husson, 1960:34; part (description of *humelincki*); not *Baiomys* True.

REMARKS: Waterhouse (1837) described *Calomys* as a subgenus of *Mus*, designating *bimaculatus* Waterhouse as the type species. Two years later, he (Waterhouse 1839) defined *Hesperomys*, without specifying a type species, to contain New World muroid rodents with bunodont and brachydont teeth. Coues (1874:177) designated *Mus* (*Calomys*) *bimaculatus* Waterhouse as the type species of *Hesperomys* and, on the previous page, equated *Calomys* with *Eligmodontia* F. Cuvier. In his 1877 monograph on rodents, Coues (1877:43–44) reiterated his selection of *bimaculatus* as the type of *Hesperomys*, again equated *Calomys* with *Eligmodontia*, and inexplicably asserted that Waterhouse, in 1837, had “established the subgenus *Calomys* upon *C. elegans*” [= *Eligmodontia elegans*, a junior synonym of *E. typus* F. Cuvier]. Notwithstanding this incorrect statement, *Calomys* Waterhouse and *Hesperomys* Waterhouse are based on the same type species (*Mus bimaculatus*), the former by Waterhouse’s unequivocal original designation (“Subgenus 4. *Calomys* . . . Type *Mus* (*Calomys*) *bimaculatus*,” Waterhouse 1837:21) and the latter by Coues’s equally unequivocal subsequent designation (“we may properly therefore elect the latter [*M. bimaculatus*] as technically the type;” Coues 1874:177). The two names are, thus, objective genus-group synonyms and the older name *Calomys* Waterhouse, 1837, assumes priority over *Hesperomys* Waterhouse, 1839.

Two different studies have questioned the monophyly of *Calomys*, one using mtDNA sequences (Engel et al. 1998) and the other morphology (Steppan 1995). Various lines of evidence suggest that the claim by Engel et al. (1998) was based either on a misidentified specimen or on a misread cryovial label (Mares and Braun 2000; Steppan and Sullivan 2000); their hypothesis thus requires no additional comment. On the other hand, most characters suggested by Steppan (1995) to support a closer relationship between *C. sorellus* and other phyllotines instead of a monophyletic *Calomys* can arguably be considered polymorphic and/or symplesiomorphic and thus do not support his hypothesis for the paraphyly of *Calomys*. Cladistic analyses of both mtDNA cytochrome-*b* (Salazar-Bravo et al. 2001; F. C. Almeida et al. 2007) and nucDNA IRBP sequences (Salazar-Bravo et al. 2013) have supported a monophyletic *Calomys* that includes *Calomys sorellus*.

KEY TO THE SPECIES OF CALOMYS:

1. Tail length always less than head and body length, tail less than 45% of total length; edges of supraorbital region divergent posteriorly and with distinct ledges in adults 2
- 1'. Tail length variable, greater or less than 45% of total length; edges of interorbital region parallel or divergent

- posteriorly, occasionally with slight beading, but never heavy ridges 9
2. Greatest length of skull of adults generally less than 24 mm; total length generally less than 170 mm, hind-foot shorter than 19 mm, maxillary tooththrow between 3.1 and 3.9 mm; venter often dark, and dorsum frequently with a reddish or chestnut color; alisphenoid strut usually present; occurring in Cerrado and altered Atlantic Forest tracts from central and eastern Brazil south to northeastern Argentina (Misiones province), eastern Paraguay, and northeastern Santa Cruz department, Bolivia; $2n=66$, $FN=66$ *Calomys tener*
- 2'. Overall larger than above; venter gray to whitish, dorsal coloration brown, olive-brown or grayish (no reddish or chestnut); alisphenoid strut absent; widespread and occupying several types of habitats 3
3. Larger overall, maxillary tooththrow averaging above 4.45 mm (range: 4.2–4.9 mm), average breadth of braincase above 11.5 mm (11.3–12.5 mm) 4
- 3'. Overall, size smaller than above; maxillary tooththrow averaging below 4.3 mm, braincase breadth below 11.5 mm 5
4. Dorsal coloration brownish gray with some black and reddish hairs mixed in. Total length (head and body plus tail) of adults generally greater than 210 mm; greatest length of skull above 29 mm; maxillary tooththrow generally greater than 4.30 mm (range: 4.37–4.59 mm); occurring in the Espinal and southern Humid Chaco in central Argentina, in the provinces of Cordoba, San Luis, and Santiago del Estero; $2n=56$, $FN=66$ *Calomys venustus*
- 4'. Dorsal coloration grayish somewhat washed with dull yellow, especially toward the rump; slightly smaller than above; occurring in the Yungas of central and southern Bolivia to northern Argentina (and associated habitats, above and below the Yungas vegetation belt), between 600 and 2,700 m; $2n=54$, $FN=66$ *Calomys boliviae*
5. Diploid chromosomal count of $2n=50$ or above 6
- 5'. Diploid chromosomal count below $2n=50$ 7
6. Breadth of palatal bridge below 4.32 mm; length of the orbital fossa above 9.2 mm and length of the molar row above 4.1 mm; tail only slightly bicolor; occurring in central and northeastern Brazil, in habitats associated with Cerrado and Caatinga vegetation (and related ecotones); $2n=66$, $FN=68$ *Calomys expulses*
- 6'. Breadth of palatal bridge above 4.26 mm; length of the orbital fossa below 9.6 and length of the molar row below 4.1 mm; tail sharply bicolored; occurring in southwestern Brazil, eastern and northeastern Bolivia, western Paraguay, and northeastern Argentina,

- often associated with Chacoan vegetation (and human altered habitats); $2n=50$; FN=66 *Calomys callosus*
7. Dorsal coloration cinnamon-brown; head paler than dorsum; $2n=36$ or 38, FN=66 *Calomys cerqueirai*
- 7'. Dorsal coloration drab olive; head of the same color as the dorsum; $2n$ greater than 36 or 38 8
8. Ratio of length of molar row to greatest length of skull 0.15 or below; occurs in nonflooded grasslands of the Argentinean Mesopotamian and enclaves of grassy vegetation and old fields of western Brazil, from Rondônia in the north to Mato Grosso do Sul in the south; $2n=48$; FN=66 *Calomys callidus*
- 8'. Ratio of length of molar row to greatest length of skull 0.16 or above; occurs in central Brazil, in the upper basin of the Rio Araguaia; $2n=46$; FN=66 *Calomys tocantinsi*
9. Tail shorter than 60 mm 10
- 9'. Tail longer than 60 mm, may be equal to head and body length 12
10. Dorsum bright buffy ochraceous; occurs in grasslands and other nonforested habitats, below 700 m, often on sandy soils in northern, mainland Venezuela and Colombia, and on the islands of Curaçao and Aruba *Calomys hummelincki*
- 10'. Dorsum yellow-brown, gray or buffy; occurs in the grasslands and other nonforested habitats (0 to 4,600 m) south of the Equator 11
11. Dorsal pelage marbled in appearance, fluffy; hairs of venter gray based; tail whitish or pale gray (not distinctly bicolor), very short, less than 55% of head plus body length; rostrum narrow; maxillary tooththrow longer than 3.2 mm; occurring at elevations above 2,500 m in the Andes of northern Argentina, extreme northeast Chile, the central plateau of Bolivia and the southern half of the Altiplano of Peru *Calomys lepidus*
- 11'. Dorsal pelage not marbled, short hairs; venter white; tail bicolored, more than one-half of head plus body length; rostrum not narrowed; maxillary tooththrow shorter than 3.3 mm; occurring in grasslands and forest fringes up to 950 m in Argentina, Paraguay, southeast Bolivia, Uruguay, and southern Brazil *Calomys laucha*
12. Tail approximately equal to head plus body length; dorsum golden brown lined with black hairs; sides of interorbital region divergent posteriorly; occurring at moderate to high elevations (2,000 to 3,500 m) in the eastern slopes of the southern Bolivian and northern Argentinean Andes as well as lowlands below 1,000 m in the dry Chaco of Paraguay and the Pampas and agricultural landscapes of central Argentina, south to at least

- the Patagonian province of Santa Cruz; $2n=38$ *Calomys musculus*
- 12'. Tail shorter than head plus body; dorsum brown; sides of interorbital region parallel; occurring at high elevations in the Andes of Peru and likely Bolivia; $2n=62$ or 64 *Calomys sorellus*

Calomys boliviae (Thomas, 1901)

Bolivian Laucha

SYNONYMS:

Eligmodontia callosa boliviae Thomas, 1901f:253; type locality "Rio Solocame, 67°W., 16°S. [La Paz,] Bolivia. Altitude 1200 m."

[*Hesperomys callosus*] *boliviae*: Thomas, 1916a:141, name combination

Hesperomys fecundus Thomas, 1926c:321; type locality "Tablada, 2000m," Tarija, Bolivia.

Calomys callosus boliviae: Cabrera, 1961:477; name combination.

Calomys boliviae: Musser and Carleton, 1993:696; first use of current name combination.

DESCRIPTION: Medium sized (measurements for series of specimens from near the type locality in B. D. Patterson [1992b]). General color above grayish, more or less washed with dull yellowish turning richer toward rump; sides buffy and indistinctly separated from under surface by buffy line; under surface uniformly pale buff, with base of hairs slate colored; color of face like back but cheeks paler, similar to sides. Ears of medium size (18–19 mm), thinly haired, covered internally by grayish hairs and externally by olive brown hairs, overall same color as head; inconspicuous whitish postauricular patches noticeable, but no preauricular ear patch present. Arms and legs grayish white; hands and feet clear buffy white. Tail very finely scaled, finely haired, and bicolored, brown above and whiter below. Hindfeet short and narrow; plantar surface naked, except for heel; interdigital pads small, hypothenar smaller than interdigital pads, thenar pad enlarged and narrow. Adult females from type locality in Yungas of La Paz department, Bolivia, with five pairs of mammae; those from southern Bolivia (Tarija department) and Argentina with seven pairs, the increase perhaps related to larger body size of latter populations (Olds 1988). Gall bladder present (J. Salazar-Bravo, pers. obs.), and four individuals examined by Steppan (1995) had 12 thoracic, 7 lumbar, and about 25 caudal vertebrae.

Skull with straight lateral profile; rostrum heavy and short, sides tapering gradually; nasals broad and slightly turned down at tip, overhanging and thus obscuring the incisors when viewed from above. Dorsal margins of nasals not extending beyond suture junction of maxillary, frontal, and lacrimal bones; lacrimals present but not especially enlarged. Interorbital region flat, with sharp and posteri-

only divergent frontal margins that produce supraorbital shelves in most adults. Coronal suture broadly U-shaped. Braincase relatively narrow, with temporal and lambdoidal ridges present in very old individuals. Zygomatic plates broad, without zygomatic spines; zygomatic notches shallow. Zygomatic arches project forward and not very broad. Parietals with only small extensions onto squamosal; postglenoid foramen reduced with respect to subsquamosal fenestra. Incisive foramina long, extending past anterior roots of M1s; premaxillary process occupies three-fourths of foraminal opening. Palate long and wide (*sensu* Hershkovitz 1962); mesopterygoid fossa slightly wider than that in other species of large *Calomys*, with anterior portion slightly broader than remainder of fossa; median palatine process lacking. Sphenopalatine vacuities present and well developed. Carotid circulation primitive (pattern 1 of Voss, 1988). Alisphenoid strut absent.

Mandible with ascending portion of coronoid initiated below gum line of teeth; upper ridge of masseteric crest weakly developed, lower ridges well developed; capsular projection present but not prominent, located between base of coronoid process and sigmoid notch; coronoid process falciform, smaller than condyloid process, unremarkable except in younger individuals where it forms less acute angle with main axis of mandible than in older individuals.

Upper incisors opisthodont with bright orange enamel; upper molars crested (*sensu* Hershkovitz 1962), with labial and lingual cusps of about same height, brachydont, and with cusps opposite in pattern. M1 subrectangular in outline with well-developed procingulum and antero-medial flexus fused at base of cusp; hypoflexus and protoflexus broad and parallel, especially in older individuals; in younger individuals, protoflexus somewhat comma shaped; anterolabial style usually present as thickening of labial cingula but without trace of anteroflexus. M2 square in outline; protoflexus present even old individuals; mesoflexus alternate to hypoflexus. M3 triangular and moderately reduced with respect to M2; hypoflexus evident; mesoflexus persists; protoflexus small but present. Lower molars, like uppers, crested. Lower m1 with well-developed procingulum with anteromedial flexid in some individuals (e.g., holotype), but in others this structure not easily seen; mesoflexid broad and deep, almost isolating the metaconid; protoconid and hypoconid subtriangular in outline; entoconid bulbous; and posterolophid reduced. Lower m2 squared in outline, with well-developed flexids, including protoflexid; m3 Z-shaped in outline, with mesoflexid and hypoflexid almost touching at midline.

DISTRIBUTION: *Calomys boliviae* is known from the eastern slopes of the Andes, between ca. 600 and 2,700 m, from west-central Bolivia to northwestern Argentina.

SELECTED LOCALITIES (Map 255): ARGENTINA: Jujuy, Santa Bárbara (M. M. Díaz and Barquez 2007), on Hwy 9 at border with Salta, at campground on the way to El Carmen (M. M. Díaz and Barquez 2007); Salta, 48.8 km NW of junction of Rtes 50 and 18, on road to Isla de Cañas, sobre Rte 18 (OMNH 35262), 5 km WSW of Pulares (OMNH 35260); Santiago del Estero, Virgen del Valle picnic area on Hwy 64 (Dragoo et al. 2003); Tucumán, Faimalla (De Catalfo and Wainberg 1974). BOLIVIA: 2 km E of Chuhuayacu (Salazar-Bravo, Dragoo et al. 2002), Horcas, 80 km SE of Sucre (S. Anderson 1997), 2 km SE of Monteagudo (Salazar-Bravo et al. 2001); Cochabamba, ca. 2 km NW of Peña Blanca (S. Anderson 1997); La Paz, 1 mi W of Puerto Linares (S. Anderson 1997), Río Solocame (type locality of *Eligmodontia callosa boliviae* Thomas); Tarija, 3 km WNW of Caraparí (Salazar-Bravo, Dragoo et al. 2002), 4 km by road N of Cuyambuyo, Fábrica de Papel (UMMZ 156322), Porvenir (Salazar-Bravo, Dragoo et al. 2002), 1 km E of Tucumilla (Salazar-Bravo, Dragoo et al. 2002).

SUBSPECIES: *Calomys boliviae* is monotypic, although southern populations (to which the name *fecundus* Thomas would apply) are somewhat larger in body size than northern samples that represent the nominotypical form.

NATURAL HISTORY: This species has been trapped in diverse habitats, ranging from the Yungas and Chaco (M. M. Díaz and Barquez 2007) to humid Puna (Jayat, Ortiz, and Miotti 2008), to old fields and cultivated areas (J. Salazar-Bravo, pers. obs.) in central Bolivia and northern Argentina. Little is known about its ecology in Bolivia (S. Anderson 1997), but Barquez et al. (1991), M. M. Díaz et al. (2000), and M. M. Díaz and Barquez (2007) provided data on Argentina populations. Pregnant females (one with 10 embryos) or enlarged nipples were captured toward the end of the summer (February) in Jujuy, with scrotal males caught in February and May and young individuals trapped from April to August (M. M. Díaz and Barquez 2007). In the Yungas of La Paz, Bolivia, individuals serve as a reservoir for *Leishmania* (J. Vargas Matos, pers. comm.). Archeological samples probably assignable to this species were described from Ruinas Jesuíticas de San José de Lules in Tucumán province, Argentina, and dated to about 350 to 150 ybp (P. E. Ortiz et al. 2011b).

REMARKS: Both the geographic and taxonomic limits of this species require further work. Originally described as a species of *Eligmodontia*, *boliviae* was reassigned to *Hesperomys* (viewed as equivalent to *Calomys*) by Thomas (1916a). Since then, the status of *C. boliviae* has fluctuated repeatedly from a subspecies of *Calomys callosus* (Hershkovitz 1962) or *Calomys venustus* (Olds 1988; S. Anderson 1997) to a valid species (Musser and Carleton 1993). Salazar-Bravo, Dragoo et al. (2002) and Dragoo et al.

(2003), based on molecular characters (analyses of mtDNA D-loop and cytochrome-*b* sequences and AFLP fragments) and chromosomal data, recognized *Calomys fecundus* as a valid species but were unable to comment of the status of *Calomys boliviae* because of the lack of available material. Subsequently, Salazar-Bravo et al. (2003) suggested that *boliviae* Thomas might be a senior synonym of *fecundus* Thomas, a position earlier advocated by Musser and Carleton (1993) and subsequently supported by M. M. Díaz et al. (2006) and M. M. Díaz and Barquez (2007). Although I follow this hypothesis herein, I stress that the studies advocated by both Salazar-Bravo et al. (2003) and Musser and Carleton (2005) have yet to be conducted, so the taxonomic composition of *C. boliviae* should be viewed with caution.

B. D. Patterson (1992b) reported measurements of 23 specimens of *C. boliviae* from the Bolivian department of La Paz under the name of *C. venustus*. His series of specimens were part of a lot collected by Alfonso Olalla and sold to the Royal Natural History Museum in Stockholm in the late 1930s or early 1940s. Although all the measurements are those of adult *Calomys boliviae*, the figured skull said to be a representative of the species (his Fig. 11) is not;

Map 255 Selected localities for *Calomys boliviae* (●). Contour line = 2,000m.

two of Olalla's specimens had the field identification number AMO 334, one corresponding to *Calomys boliviae*, one to a specimen of *Hylaeamys megacephalus*; during the last steps of the editorial process, the *Hylaeamys* skull was photographed by mistake (B. D. Patterson, pers. comm.).

De Catalfo and Wainberg (1974) and Salazar-Bravo, Dragoo et al. (2002) reported a karyotype with $2n=54$ and $FN=66$ for specimens from northern Argentina and southern Bolivia.

Calomys callidus (Thomas, 1916)

Crafty Vesper Mouse, Crafty Laucha, Reclusive Laucha

SYNONYMS

Hesperomys venustus callidus Thomas, 1916b:182; type locality "Goya, Corrientes. 600'," Argentina.

Calomys venustus callidus: Cabrera, 1961:481; name combination.

Calomys callosus callosus: Hershkovitz, 1962:172; part; *callidus* treated as synonym.

Calomys callidus: Vitullo, Kajon, Percich, Zuleta, Merani, and Kravetz, 1984:486; first use of current name combination.

DESCRIPTION: One of large species; pelage short and appressed, dorsal coloration grayish, buffy wash on flanks, and venter pale gray (hairs slaty basally, white or grayish terminally). Ears large, with brown inner and black outer surfaces; inconspicuous postauricular patch present. Tail shorter than head and body, thinly haired, bicolored (pale brownish above and grayish white on sides and below), and without tuft of hair at tip. Mammary usually number 10 (Thomas 1916b).

Skull robust, slightly bowed in lateral profile, and with its greatest length averaging 25 mm in females and 26.7 mm in males (Bonvicino et al. 2010). Interorbital region flat, posteriorly divergent, and with sharp supraorbital edges that continue as visible temporal crests. Nasals with raggedy posterior margins; do not extend dorsally beyond triple-point suture between maxillary, frontal, and lacrimal. Zygomatic plates with straight dorsal edges, without zygomatic spines, posterior margins anterior to alveoli of M1s; zygomatic notches moderately narrow but deep. Incisive foramina long, extending between protocones of both M1s. Mesopterygoid fossa with squared anterior border that does not reach alveoli of M3s; sphenopalatine vacuities present. Alisphenoid strut absent. Upper incisors orthodont, with bright orange enamel band. Upper molar series parallel, with teeth terraced. M1 divided by shallow groove, M2 squared, and M3 small and rounded. Mandible strong; capsular projection straight and located ventral to coronoid process.

No information available on axial elements of skeleton or soft anatomical structures.

DISTRIBUTION: *Calomys callidus* occurs in grasslands and grassland/monte ecotone of the Mesopotamian alluvial system of Argentina as well as in enclaves of grassy vegetation and old fields of western Brazil, from Rondônia in the north to Mato Grosso do Sul in the south.

SELECTED LOCALITIES (Map 256): ARGENTINA: Chaco, Parque Nacional “Chaco” (Vitullo et al. 1984); Corrientes, Estancia San Juan Poriahú (Lareschi et al. 2005), Goya (type locality of *Hesperomys venustus callidus* Thomas); Entre Ríos, Parque Nacional “El Palmar” (Vitullo et al. 1984), Diamante (Massa 2010), Puerto Ruiz (Massa 2010). BRAZIL: Mato Grosso, Barão de Melgaço (Bonvicino et al. 2010), Campo Novo do Parecis (Bonvicino et al. 2010); Mato Grosso do Sul, Municipalities of Dois Irmãos de Buriti and Terenos (Caceres et al. 2011); Rondônia, Pimienta Bueno (Mattevi et al. 2005).

SUBSPECIES: *Calomys callidus* is monotypic.

NATURAL HISTORY: Little is known about the ecology of this species; apparently, it prefers microhabitats with nonflooded, tall grass in areas of the Argentinean Mesopotamia. Smaller-sized individuals are preferentially taken in pitfall traps in Brazil (Caceres et al. 2011). Massa (2010) found signs of Barn Owl (*Tyto alba*) predation over *C. callidus* in almost 60% of the localities she studied in southern Entre Ríos province (Argentina). V. L. Hodara et al. (1994) reported on blood, serum, and urine chemistry while Percich and Hodara (1990) examined growth and development.

REMARKS: Both taxonomic and geographic limits of *C. callidus*, especially with respect to its relationship to *C. callosus*, require attention. J. R. Contreras et al. (2003) suggested that *callidus* Thomas may be a synonym of *C. callosus* (Rengger), since specimens from 60 km S Pilar (near the type locality of *Calomys callosus*, as amended by J. R. Contreras 1992) had a chromosomal complement of $2n=48$, $FN=70$, similar to the $2n=48$, $FN=68$ for specimens examined from Entre Ríos and assigned to *C. callidus* (Vitullo et al. 1984). Support for this argument included the apparent restriction of the $2n=48$ cytotype of *Calomys* to Argentinean Mesopotamia (e.g., Entre Ríos province). However, recent studies have reported populations of large *Calomys* with a $2n=48$, but with an $FN=66$ from western Brazil (Mattevi et al. 2005; Bonvicino et al. 2010), suggesting that *C. callidus* is present throughout eastern Paraguay and into western Brazil. One implication of the linkage of *callidus* to *callosus* would be that the widely distributed, large, and lowland mice with $2n=50$, for which the name *C. callosus* is now used (e.g., Bonvicino et al. 2010; see that account) would require a new name combination, as this taxon represents an independent monophyletic clade (Salazar-Bravo, Dragoo et al. 2002). This taxonomic hypothesis requires work beyond the scope of this volume.

Scapteromys modestus (Miranda-Ribeiro 1914) was described from Caceres in the Brazilian state of Mato Grosso based on two young adult specimens. In the original description, Miranda-Ribeiro compared his two samples to *Scapteromys labiosus* [= *Bibimys labiosus*], *Oryzomys* [= *Oligoryzomys*] *longicaudatus*, and *Mus musculus*, but concluded that they deserved specific status. Since the original description, the identity of these animals has only been cursorily examined: Winge (1941:145) commented on the quality of the “indistinct photographs of the skull” yet did not hesitate to suggest that this form may be a synonym of “*Hesperomys expulsus*” [= *Calomys expulsus*]. Hershkovitz (1966:97) likewise noted that “judg[ing] from the published figure of its skull ‘. . . *S. modestus*’ corresponds to *Calomys callosus*.” Neither Winge nor Hershkovitz, however, examined any of Miranda-Ribeiro’s specimens before assigning them to *Calomys*. To compound the problem, Avila-Pires (1968) in effect synonymized *Scapteromys modestus* with [*Oligoryzomys*] *utiaritensis*, a species recently shown to be a valid form of *Oligoryzomys* (Agrellos et al. 2012). The two specimens of *S. modestus* are not members of *Scapteromys*, *Bibimys*, *Mus*, or *Oligoryzomys* and indeed belong to the genus *Calomys* (U. F. J. Pardiñas, pers. comm.; M. Weksler, pers. comm.). Furthermore, morphological characters (e.g., the lack of alisphenoid struts) and morphometric data (J. A. Oliveira, pers. comm.) indicate that these specimens belong to either *Calomys callosus* or *Calomys callidus*. Regrettably, nowadays the only useful marker to separate these two species

Map 256 Selected localities for *Calomys callidus* (●). Contour line = 2,000 m.

is the diploid chromosome count (see the Key), and obviously this information is not available for the specimens that Miranda-Ribeiro had on hand while describing *S. modestus*. On biogeographic and distribution grounds, it is plausible—or even likely—that *modestus* might be a senior synonym of *callidus*, but data at hand are too limited to support this hypothesis strongly, especially as there is still much doubt regarding the position of *C. callidus* with respect to other species of lowland *Calomys*. For the present, therefore, I treat *modestus* Miranda-Ribeiro as a *nomen dubium*, and list it neither in the synonymies of either *C. callidus* or *C. callosus*.

While the position I advocate here with respect to *C. callidus* and its relationships with other species of the genus is unsatisfactory, it is the most defensible hypothesis at present. What is required to clarify this systematic and taxonomic tangle is a multiloci, inclusive systematic work that includes topotypic material for *callidus*, *boliviae*, and close relatives of the other Brazilian, eastern Bolivian, and northern Argentinean forms of the genus.

Calomys callosus (Rengger, 1830)

Large Vesper Mouse, Big Laucha

SYNONYMS:

Mus Callosus Rengger, 1830:231; type locality “am Ufer des Paraguaystromes, ungefähr unter dem sieben und zwanzigsten Breitengrade” [= on the banks of the Paraguay river, below roughly 27°]; interpreted as “opposite mouth of Río Bermejo, Department of Villa del Pilar” by Hershkovitz (1962:172); amended by J. R. Contreras (1992:2) to vicinity of Ciudad Pilar, Corrientes, Argentina.

Oryzomys callosus: Thomas, 1898i:3; name combination.

Hesperomys callosus: Thomas, 1916a:141; name combination.

Hesperomys muriculus Thomas, 1921:623; type locality “San Antonio, Parapiti, on 20°S, about 250 km. south of Santa Cruz de la Sierra. Alt. 600 m,” Santa Cruz, Bolivia.

Calomys callosus: Cabrera, 1961:477; first use of current name combination.

Calomys hildebrandii Enría, Mills, Bausch, Shieh, and Peters, 2011:453; *nomen nudum*.

DESCRIPTION: Medium sized (head and body length 99–122 mm; tail length 78–110 mm; S. Anderson 1997) with long and moderately lax pelage (or short and appressed in wetter habitats). Upper parts of body ochraceous to tawny and often with fine mixture of black or dark brown; rump and sides generally paler; weakly defined ochraceous lateral band sometimes present; and venter whitish to gray, sometimes washed with buff, individual hairs dark gray at their bases. Eye-ring defined by buffy hairs sometimes evident. Tail bicolored, grayish

brown above and whitish below. Ears small (range: 16 to 19 mm), rounded and lightly haired; pale-colored postauricular patches present. Both forefeet and hindfeet white above, with whitish unguis tufts; hindfeet narrow. Mammary count 10 to 14.

Skull strongly built, dorsal aspect flat in lateral profile, with short rostrum and deep zygomatic notches. Anterior edges of zygomatic plates slightly concave, delimiting small zygomatic spines; posterior borders terminate anterior to frontal plane of M1s. Borders of supraorbital region of skull divergent posteriorly, strongly beaded, and form broad ledges in fully mature individuals; midfrontal width always greater than maximum width of rostrum. Interparietal well developed. Zygomatic arches converge anteriorly. Alisphenoid strut absent. Incisive foramina long, reaching protocones of M1s, but with anterior part narrower than posterior. Palate short, somewhat narrow, and rugose, with conspicuous palatine foramina and deep posterolateral pits. Bullae triangular in shape, their bony tubes long and narrow. Middle lacerate foramen large, and foramen ovale small but distinct. Mesopterygoid fossa parallel sided, with anterior border not reaching line connecting posterior edges of M3s; sphenopalatine vacuities present. Upper incisors orthodont, each fronted by orange enamel. Main cusps of molars alternate in anteroposterior position, with molars bileveled. M1 with deeply divided anterocone, and no sign of anterolabial style or anteroflexus. Bonvicino et al. (2010) provided external and cranial measurements.

Modal counts of thoracic, lumbar, and caudal vertebrae 12, 7, and 22–25, respectively (Steppan 1995). Gall bladder present (Voss 1991a); Hooper and Musser (1964) described male phallus of specimen from Matto Grosso; and Voss and Linzey (1981) detailed morphology of male accessory glands from Paraguayan specimens.

DISTRIBUTION: As herein understood *C. callosus* occurs from northern Argentina, throughout Paraguay, eastern and northeastern Bolivia, and western Brazil.

SELECTED LOCALITIES (Map 257): ARGENTINA: Corrientes, Pilar (J. R. Contreras et al. 2003); Formosa, 13 km S of Clorinda (Pardiñas and Teta 2005), Reserva El Bagual (Pardiñas and Teta 2005); Salta, Aguaray (M. M. Díaz et al. 2000), 31 km SSW of Dragones, along Río Bermejo (M. M. Díaz et al. 2000); Santiago del Estero, San Antonio (MACN 17612); Tucumán, Concepción (MACN 997–34). BOLIVIA: El Beni, Nueva Calama (S. Anderson 1997), Mangal, 25 km NW of Exaltación (S. Anderson 1997), El Consuelo (B. D. Patterson 1992b), San Ignacio (S. Anderson 1997); Santa Cruz, El Refugio, Parque Nacional Noel Kempff Mercado (Emmons et al. 2006), La Hoyada, 30 km S of Valle Grande (Bonvicino and Almeida 2000), Las Cruces (Salazar-Bravo, Dragoo et al. 2002), San Ramón (Salazar-Bravo, Dragoo et al. 2002). BRAZIL:

Mato Grosso, Aquidauana (Bonvicino et al. 2010), Si-brolândia (Bonvicino et al. 2010). PARAGUAY: Amambay, Parque Nacional Cerro Corá (Salazar-Bravo et al. 2001).

SUBSPECIES: *Calomys callosus* is monotypic. The polytypic *C. callosus* envisioned by both Cabrera (1961) and Hershkovitz (1962) included taxa regarded as distinct species herein (e.g., *boliviae* Thomas and *expulsus* Lund). Nevertheless, specimens from more humid localities (eastern Santa Cruz department, Bolivia and enclaves of Cerrado and Pantanal vegetation in Paraguay) are both smaller in size and darker in color, both dorsally and ventrally, than those from more xeric geographic areas.

NATURAL HISTORY: The natural history of the species is entrenched in the morass that currently encompasses the taxonomy of the large body species of lowland *Calomys*. Because this species shares many morphological characters with other sympatric and quasi-sympatric species, it is not always possible to ascertain in the published literature which species was actually studied in the field. Based on the reported localities recognized here, the species occupies a range of habitats, from dry Chaco to grassy enclaves, secondary growth, and both old fields and agriculture-dominated landscapes (Myers 1982). For example, Yahnke (2006) found the species almost exclusively in agricultural habitats where pregnant females had an average of 6.25 embryos ($N=4$, range: 4–11) and were captured in the months of May, August, and December. Renger (1830:232) noted that individuals were found in pairs within burrows about a foot long and close to water. He saw them active during the day feeding on seeds and roots.

Calomys callosus was identified as the reservoir for Latino virus (reviewed in Salazar-Bravo, Ruedas, and Yates 2002) as well as the reservoir for Laguna Negra hantavirus (Levis et al. 2004).

REMARKS: See Remarks under *C. callidus* for the possible relationship between these two species and possible assignment of *modestus* Miranda-Ribeiro. As currently understood, the karyotype of *C. callosus* is $2n=50$, $FN=66$, and composed of nine pairs of metacentric, with one pair much smaller than the others, and 15 pairs of acrocentric autosomes, a large and metacentric X chromosome, and a small acrocentric Y chromosome. This karyotype is uniform in specimens from Bolivia (Salazar-Bravo, Dragoo et al. 2002) and Brazil (Bonvicino et al. 2010) and is identical to that reported for a specimen identified as *C. fecundus* from Beni, Bolivia (Pearson and Patton 1976).

Molecular data (Salazar-Bravo, Dragoo et al. 2002) suggest the presence of an undescribed taxon of *Calomys* in the Bolivian department of Beni; individuals of this form serve as reservoirs to Machupo arenavirus, the etiological agent of Bolivian hemorrhagic fever. Because individuals in these populations are morphologically, morphometrically,

Map 257 Selected localities for *Calomys callosus* (●). Contour line = 2,000m.

and chromosomally ($2n=50$, $FN=66$) indistinguishable from *C. callosus*, I treat them here as members of the same species. Enría et al. (2011) referred to the Beni samples as *Calomys hildebrandii*, a *nomen nudum* because this taxon was not formally described in that paper, or elsewhere.

Calomys cerqueirai Bonvicino, Oliveira, and Gentile, 2010

Cerqueira's Vesper Mouse, Rato-bolinha de Cerqueira

SYNONYM:

Calomys cerqueirai Bonvicino, Oliveira, and Gentile, 2010: 27; type locality "Margins of 'Buraco do Cachorro' stream, situated near the head of 'Café' stream, close to Capitaõ Andrade city center ($19^{\circ}04'35''S$, $41^{\circ}52'30''W$), Capitaõ Andrade Municipality, state of Minas Gerais, Southeastern Brazil."

DESCRIPTION: Medium sized (mean head and body length 99 mm, greatest length of skull 26 mm) with tails shorter than head and body (75–87%), moderately long and narrow hindfeet, and small, rounded pinnae (16–18% of head and body length). Dorsal pelage soft and dense, colored cinnamon-brown overall; head paler than dorsum; the rostrum covered with yellow to ochraceous-tawny hairs; sides of body slightly paler than dorsum due

to reduction in black guard hairs; ventral pelage well delineated from sides, covered with whitish hairs with gray bases. Pinnae internally covered by entirely orange hairs or hairs with long orange bands, and externally by sparse brownish hairs; postauricular patch of completely white hairs present. Forefeet and hindfeet covered dorsally with entirely white hairs; silvery unguis tufts present on distal phalanges of digits II–V of the manus and digits I–V of pes. Tail sharply bicolored, with white hairs ventrally and dark hairs dorsally. Mammary count in adult females unknown.

Skull robust, with rostrum about 36% of greatest skull length and somewhat bowed lateral profile. Interorbital region divergent posteriorly, with sharp supraorbital edges; interorbital breadth wider than length of upper molar row. Nasals with blunt posterior margins that do not extend beyond suture between maxillary, frontal, and lacrimal. Zygomatic plates project slightly anteriorly, lacking any trace of zygomatic spines; zygomatic notches moderately deep and broad. Carotid circulation pattern primitive (pattern 1, *sensu* Voss 1988). Incisive foramina longer than upper molar row and reach imaginary line across protoflexi of M1s. Mesopterygoid fossa with squared dorsal edge; does not reach alveoli of M3s. Sphenopalatine vacuities present. Alisphenoid strut absent.

Upper incisors opisthodont, and upper series (M1–M3) parallel. Shallow anteromedian flexus in M1 divides anterocone into subequal anterolingual and anterolabial conules; M2 squared and M3 small and rounded. Mandible strongly built; capsular projection present as subtle elevation and located ventral to coronoid process. No data available on axial elements of skeleton.

DISTRIBUTION: *Calomys cerqueirai* is known only from riparian grasslands in southeastern Minas Gerais, Brazil.

SELECTED LOCALITIES (Map 258): BRAZIL: Minas Gerais, Capitão Andrade (type locality of *Calomys cerqueirai* Bonvicino, Oliveira, and Gentile), Lagoa Santa (F. C. Almeida et al. 2007).

SUBSPECIES: *Calomys cerqueirai* is monotypic.

NATURAL HISTORY: Bonvicino et al. (2010) captured specimens of *Calomys cerqueirai* in rural areas along streams, in grassy vegetation, less than 2 m from stream margins. These authors recorded both tapeworms (*Taenia* sp.) and nematodes (probably *Hassalstrongylus epsilon*) in individuals they trapped.

REMARKS: F. C. Almeida et al. (2007) referred to this species as *Calomys* sp. nov.

Chromosomes reported as $2n=38$ and FN=66, with 15 pairs of biarmed and three pairs of uniarmed autosomes for specimens of the type locality, and $2n=36$, FN=66 for specimens from Lagoa Santa (Bonvicino et al. 2010).

Map 258 Selected localities for *Calomys cerqueirai* (●).

Colombi et al. (2011) reported a $2n=36$, FN=66 animal from Nova Venécia, Espírito Santo, Brazil, that is probably best referred to *C. cerqueirai*, based both on karyotype and similarity in mtDNA cytochrome-*b* sequences. I refrain from accepting this assignment until a proper comparison of the voucher specimens provides confirmation.

Calomys expulsus (Lund, 1840)

Caatinga Laucha, Rato-bolinha da Caatinga

SYNONYMS:

Mus expulsus Lund, 1839a:233; *nomen nudum*.

Mus expulsus Lund, 1840b:50 [1841c:280]; type locality “Rio das Velhas’s Floddal,” Lagoa Santa, Minas Gerais, Brazil.

Mus [*Hesperomys*] *expulsus*: Wagner, 1843a:545; name combination.

Hesperomys expulsus: Burmeister, 1854:175; name combination.

[*Oryzomys*] *expulsus*: E.-L. Trouessart, 1897:528; name combination.

[*Zygodontomys*] *expulsus*: E.-L. Trouessart, 1904:423; name combination.

Calomys expulsus: Cabrera, 1961:478; first use of current name combination.

Calomys callosus expulsus: Hershkovitz, 1962:174; name combination.

DESCRIPTION: Size average for a large, lowland species of genus (mean head and body length 99.7 ± 14 mm in

21 specimens from central Brazil; Bonvicino and Almeida 2000); tail short, averaging about 74% of head and body length; upper parts of body yellowish to olive brown, finely streaked with black hairs; sides of body tawny, not as dark as dorsum, sharply countershaded relative to venter; no lateral line separating side and ventral coloration; head same color as dorsum; venter covered with white-tipped but gray-based hairs throughout but completely white around chin. Moderate to well-developed eye-ring present. Forefeet and hindfeet covered dorsally with short, white hairs; claws tufted. Tail only weakly bicolored (Bonvicino et al. 2010), slightly darker above; ears average length for genus (ca. 17 mm) and covered by darker hairs.

Skull with comparatively (but not statistically) shorter rostrum than other species of large bodied, lowland *Calomys*, but with slightly narrower interorbital region (Bonvicino et al. 2010) and more heavily bowed in lateral view. Nasals long, projecting beyond anterior plane of upper incisors. Zygomatic plates broad, with slightly to markedly concave anterior margins; zygomatic spines comparatively more developed than in other species of lowland, large *Calomys*, even in young specimens; zygomatic notches broad and deeply excavated. Zygomatic arches convergent anteriorly. Interorbital region with sharply squared and posteriorly divergent dorsolateral margins. Temporal crests relatively weak, but lambdoidal crest rather strongly developed, especially in older individuals. Incisive foramina long, extending between M1s, and slender, with widest point at about premaxillomaxillary suture. Palate long, without any special marks except for pair of palatine foramina and pair of deep posterolateral palatal pits. Mesopterygoid fossa slightly narrower at midpoint; anterior edge rounded or, in many cases, bullet shaped, and does not reach end of M3s; sphenopalatine vacuities well developed. Bullae of average size for genus. Alisphenoid strut absent. Mandible strongly built with relatively deep body; capsular projection present, slanted backward and located below sigmoid notch.

Upper incisors opisthodont; enamel bright orange. Molars robust, broad, and with principal cusps alternating. Maxillary tooththrow averages about 4.06 mm (Bonvicino et al. 2010). Procingulum of M1 deeply divided by anteromedian flexus; both paraflexus and metaflexus deep, bending backward; anterolabial style (*sensu* Hershkovitz 1962) present but anteroflexus is not; protoflexus and hypoflexus laterally oriented and straight; M2 about 70% size of M1, squared, and with well-developed paraflexus, metaflexus, and hypoflexus; M3 squared in profile, with well-developed flexi; many individuals have enamel island in middle of M3. Anteromedian flexid of m1 undivided; cusps arranged in alternating pattern; entoflexid much smaller than either mesoflexid or hypoflexid; all labial struc-

tures conserved in m2, and m3 S-shaped and about 80% on size of m2.

DISTRIBUTION: *Calomys expulsus* occurs throughout the Caatinga and Cerrado biomes, and ecotones between them, of the central “Planalto” region of Brazil, from the states of Tocantins and Piauí in the north and northeast to Bahia and Goiás in the south (Bonvicino, Oliveira, and D’Andrea 2008; Nascimento et al. 2011).

SELECTED LOCALITIES (Map 259): BRAZIL: Bahia, Caetité (F. C. Almeida et al. 2007), Corentyne (F. C. Almeida et al. 2007), Fazenda Jucurutu, Jaborandi (Bonvicino, Lima, and Almeida 2003), Ideate (Nascimento et al. 2011); Goiás, Campo Alegre de Goiás (Nascimento et al. 2011), Fazenda Flandeirias, 65 km SSW of Cavalcante (Bonvicino, Lima, and Almeida 2003), Fazenda Vão dos Bois (Bonvicino, Lima, and Almeida 2003), Ipa-meri (Haag et al. 2007), Mambai (Haag et al. 2007), Mimoso de Goiás (F. C. Almeida et al. 2007), Mineiros, Emas National Park (F. C. Almeida et al. 2007), Morro dos Cabeludos, Corumbá de Goiás (F. C. Almeida et al. 2007); Minas Gerais: Juramento (Nascimento et al. 2011); Piauí, Coronel José Dias (Nascimento et al. 2011), São João do Piauí (Bonvicino, Lima, and Almeida 2003); Tocantins, Buriti (Nascimento et al. 2011).

SUBSPECIES: *Calomys expulsus* is monotypic. However, Nascimento et al. (2011) found patterns and levels of mtDNA sequence divergence supporting the Rio São Francisco as a biogeographic barrier to gene flow, thus marking the boundary between subpopulations that may warrant formal recognition.

NATURAL HISTORY: This species is practically indistinguishable morphologically from three (perhaps four) congeners of large, lowland *Calomys* with which it may overlap substantially in central Brazil (but see Cordeiro-Estrela et al. 2006, who identified size-free shape differences between this species and *C. tocantinsi*). Therefore, much of the older (e.g., Mello and Teixeira 1977) and some of the newer (e.g., R. A. L. Santos and Henriques 2010) published reports on the ecology, population biology, and/or epidemiology of the species are impossible to assign to *C. expulsus* or any other species with certainty. Nonetheless, in the last several years, various aspects of the biology of this species have been documented. For example, Araripe et al. (2006) studied and compared life-history characteristics (fertility, growth, and rate of postnatal development) in laboratory-raised populations. Hingst-Zaher et al. (2000) detailed changes in patterns of cranial shape through ontogeny. Predators include the Barn Owl (*Tyto alba*; Magrini and Facure 2008).

REMARKS: The karyotype of *C. expulsus* is $2n=66$, $FN=68$, with two pairs of biarmed and 30 uniarmed pairs (Bonvicino and Almeida 2000).

Map 259 Selected localities for *Calomys expulsus* (●).

Calomys hummelincki (Husson, 1960)
Hummelinck's Vesper Mouse, *Hummelinck's Laucha*,
Dwergwitvoetmuis

SYNONYMS:

Baiomys hummelincki Husson, 1960:34; type locality "Klein Santa Martha, N.W. Curaçao, Netherlands Antilles [now = Caribbean Netherlands]."

Calomys hummelincki: Handley, 1976:53; first use of current name combination.

DESCRIPTION: Small (head and body length 55 mm or less) with soft and silky pelage often brightly colored ochraceous-buff, and traversed mid-dorsally by band of hairs varying from buffy brown to dark brown. Sides colored sandy orange and clearly marked from venter by ochraceous line; venter white, but individual hairs (except those from throat and chin) gray based with white tips. Mystacial vibrissae short. Buffy preauricular and pale white postauricular patches present. Forefeet and hindfeet white above; soles of hindfeet naked, with six small plantar pads. Tail weakly bicolored, averaging <35% of total length (Olds 1988), pale above, lighter below, and terminates in short pencil (Husson 1960). Four pairs of mammae.

Skull small but robust (mean greatest length 20.87 ± 0.54 mm s.d.; Olds 1988), and flat in lateral profile; rostrum relatively short but nasals still obscure incisors when viewed from above; supraorbital region divergent posteri-

orly but lacks ridges; interorbital breadth wider than length of upper molar row. Anterior border of zygomatic plates straight; zygomatic spines lacking; zygomatic notches broad but not deep. Incisive foramina longer than molar series and extend posteriorly between M1 alveoli. Anterior border of mesopterygoid fossa squared and does not reach alveoli of M3s; sphenopalatine vacuities present; and parapterygoid fossae flat and often lightly perforated. Alisphenoid strut absent (Olds 1988). Tympanic bullae small.

Mandible delicate, with body relatively shallow; capsular projection conspicuous but not well developed, located at dorsal base of the sigmoid notch. Upper incisors orthodont with enamel deep orange in color. Molar rows parallel and teeth delicate, narrow, and with principal cusps alternating along anteroposterior axis of toothrow, which is <3.3 mm in length (Olds 1988). M1 with anterocone deeply divided by anteromedian flexus, defining anterolingual and anterolabial conules of unequal size, the latter larger; anteromedian style rarely present (<10%; Olds 1988); M2 about 60% size of M1, with well-developed anterocone; M3 small (ca. 70% of M2), circular, and with paraflexus and mesoflexus evident in young individuals, but no hypoflexus; in older individuals, all flexi of M3 tend to be lost. First lower molar with deep anteromedian flexid; m2 about 75% of m1; and m3 with Z-shaped occlusal surface.

Axial skeletal elements vary in number. Stepan (1995) recorded five individuals with 12 thoracic, 7 lumbar, and 21 to 23 caudal vertebrates, two individuals with 12 thoracic, 6 lumbar and 21–22 caudal, and one individual with 13 thoracic and 6 lumbar but without information on the number of caudal elements. Pérez-Zapata et al. (1987) described sperm morphology and compared it to that of *Calomys laucha*.

DISTRIBUTION: *Calomys hummelincki* occurs in grasslands and other nonforested habitats (below 700 m) on sandy soils in northern Venezuela and Colombia, and on the islands of Curaçao and Aruba. Eshelman and Morgan (1985) reported this species in Pleistocene deposits from Tobago, where it is unknown in the Recent fauna.

SELECTED LOCALITIES (Map 260): CARIBBEAN NETHERLANDS: Aruba, Sero Blanco (Bergmans 2011); Curaçao, Klein Santa Marta (type locality of *Baiomys hummelincki* Husson). COLOMBIA: La Guajira, Cabo de la Vela, Arroyo Cerrejón, Cerro Pilón de Azucar (ICN 19177). VENEZUELA: Anzoátegui, El Merey (A. M. G. Martino et al. 2002); Apure, Puerto Paez (A. M. G. Martino et al. 2002), Río Cinaruco, 38 km NNW of Puerto Paez (Handley 1976); Bolívar, Sipao (A. M. G. Martino et al. 2002); Falcón, Isiro (Salazar-Bravo et al. 2001); Lara, Curarigua (A. M. G. Martino et al. 2002); Monagas, 55 km SSE of Hato Mata de Bejuco (Handley 1976), 8 km NNW of Los Barrancos (KU 135126); Zulia, near Cojoro,

34 km NNE of Paraguaipoa (Handley 1976), confluence of Río Lajas with El Palmar (EBRG 22817).

SUBSPECIES: *Calomys hummelincki* is monotypic. However, the ventral pelage of some individuals from Aruba is completely white, lacking the gray-based hairs that are present in the holotype and other individuals from Curaçao and mainland populations (Husson 1960). Moreover, animals from Zulia and Guárico states on mainland Venezuela are darker and grayer on the dorsum, contrasting with the yellowish or buffy coloration of populations from insular or more northern mainland, dryer habitats in Colombia and Venezuela. Finally, insular samples average slightly smaller but have broader interorbital regions than their mainland conspecifics (comparison of measurements in Husson 1960 and Olds 1988).

NATURAL HISTORY: *Calomys hummelincki* was always trapped on the ground often associated with dry and/or thorny forests and in localities below 700 m in elevation (Handley 1976). It is present but apparently rare in the diet of the Barn Owl (*Tyto alba*) in Curaçao (Debrot et al. 2001); in Aruba, *C. hummelincki* is preyed upon by rattlesnakes (Goode et al. 1990), the Giant centipede (*Scolopendra gigantea*), and the American Kestrel (*Falco sparverius*) (Bekker 1999). Reproduction information is limited: Olds (1988) reported six pregnant females with two to five embryos each (no collection date was provided) among specimens from Guárico state, Venezuela. One female with four embryos was captured in early August in Monagas state (EBRG 14946). Bekker (1999) studied Aruba populations and presented the most complete ecological study to date. Estimates of abundance, averaged from 0.4 animals per 100 trap-nights, were that the home

range was 4,100 m² for males and 713 m² females, and a bimodal polyestrous cycle with youngsters was present in early January and late August, indicating births at the end of December and middle of August.

REMARKS: Pérez-Zapata et al. (1987) reported a karyotype with $2n=60$ and $FN=64$. A. M. G. Martino and Capanna (2002) provided data on differential staining and chromosomal banding patterns, demonstrating a close homology of chromosomal arms between this species and those of *Calomys laucha* as well as some marked differences. A. M. G. Martino et al. (2000) inferred relatively low levels of gene flow among populations using protein electromorphic characters.

Calomys laucha (G. Fisher, 1814)

Small Vesper Mouse, Laucha Chica, Lauchita

SYNONYMS:

Mus Laucha et *Lauchita* G. Fischer, 1814:71; the local common name cited by F. d'Azara (1801:102) for his "rat septieme ou rat laucha."

[*Mus*] ? *Laucha* Illiger, 1815:108; *nomen nudum*.

M[us]. laucha Olfers, 1818:209; based on Azara's (1801:102) "rat laucha"; type locality "Paraguay," restricted to the "neighborhood of Asunción, Paraguay" (Hershkovitz 1962:153).

Mus (?) *dubius* J. B. Fischer, 1829:326; type locality "Paraguay," amended by Pardiñas et al. (2007) to "Saõ Gabriel (30°19'S, 54°19'W, 118 m, Rio Grande do Sul, Brazil); see Tate (1932c) for discussion of the applicability of this name to the synonymy of *C. laucha*.

Mus bimaculatus Waterhouse, 1837:18; type locality "Maldonado," Maldonado, Uruguay.

Mus gracilipes Waterhouse, 1837:19; type locality "Bahia Blanca," Buenos Aires, Argentina.

Mus (Calomys) bimaculatus: Waterhouse, 1837:21; name combination.

Mus (Calomys) gracilipes: Waterhouse, 1837:21; name combination.

Eligmodontia bimaculatus: Lesson, 1842:133; name combination.

Eligmodontia gracilipes: Lesson, 1842:133; name combination.

H[esperomys]. laucha: Wagner, 1843a:543; name combination.

Mus pusillus Philippi and Landbeck, 1858:79; type locality "Valparaiso," Valparaíso, Chile (see Osgood 1943b, for discussion of the applicability of this name to the synonymy of *C. laucha*).

Hesperomys bimaculatus: Burmeister, 1861:415; name combination.

Hesperomys [Calomys] bimaculatus: Burmeister, 1879:225; name combination.

Map 260 Selected localities for *Calomys hummelincki* (●). Contour line = 2,000 m.

- Calomys dubius dubius*: Cabrera, 1961:477; name combination.

DESCRIPTION: Smallest species in genus (mean total length 125 mm, greatest skull length 20.46 mm; Olds 1988). Dorsal pelage gray mixed with brown to golden brown; in populations with grayer coloration, upper parts with marked concentration of blackish-tipped hairs forming broad, dark dorsal band from forehead to rump; sides always paler but often with some mix of gray and brown hairs; buffy line often separates dorsal from ventral coloration; venter always washed with white; in some populations, chin and throat have fully white hairs. Buffy hair tufts occur anterior to ears in populations from drier habitats, but all specimens throughout range have conspicuous white postauricular patches. Tail bicolored, brown above, white below; short, no more than 43% of total body length. Mammary count in adult females 8–10 (Olds 1988).

Skull with straight lateral profile; rostrum short and moderately narrow, with sides tapering gradually; nasals narrow and projecting forward above incisors; lacrimals of moderate size; interorbital region wide and posteriorly divergent but lacking supraorbital shelves or ridges; braincase large and rounded; temporal and lambdoidal ridges absent; parietals with small expansion onto lateral surface on

squamosal, forming shallow deflection at level of squamosal zygomatic root in mature specimens; interparietal large for size of skull. Zygomatic plates broad, with upper free borders enclosing poorly developed zygomatic notches; no sign of zygomatic spines. Zygomatic arches delicate, not expanded and mostly parallel. Alisphenoid strut variably present. Hamular process robust, dividing large subsquamosal fenestra and relatively smaller postglenoid foramen. Incisive foramina broad and long, slightly surpassing anterior roots of M1s; premaxillary part of septum occupies about three-fourths length of foramina. Palate wide and long, rather flat, with small posterolateral palatal pits on sides of mesopterygoid fossa. Mesopterygoid fossa wide for genus but never wider than parapterygoid fossae measured at same level, and with round anterior border; sphenopalatine vacuities small but present. Parapterygoid plates broad and excavated. Auditory bullae globular of medium size and with short and wide bony tubes.

Mandible delicate; masseteric crest forms well-developed knob, more evident in older individuals; capsular projection inconspicuous; coronoid process long, narrow, strongly curved backward, and ends at plane higher than short and wide condyloid process; angular process short; sigmoid notch deep and well developed.

Upper incisors hyperopisthodont and faced with light orange enamel (Steppan 1995). Upper molars brachydont and small with respect to skull. M1 subrectangular in outline; procingulum well developed with anterocone deeply divided by anteromedian flexus (in 77% of specimens; Olds 1988); anteromedian style present (Olds 1988); mures longitudinally oriented; hypoflexus and protoflexus parallel; protocone and hypocone about same size; paracone and metacone subequal in size and both about 60% smaller than protocone and hypocone; small parastyle (and accompanying anteroflexus) present (Steppan 1995); and hypoflexus narrow and laterally directed. M2 square in outline, trilophodont, and about 60% smaller than M1; both anteroloph and mesoloph absent; mesoflexus opposite to hypoflexus present but very narrow; and posteroflexus small but present (Olds 1988). M3 cylindroform, moderately reduced with respect to M2 (from 64–67%; Olds 1988); hypoflexus reduced; and mesoflexus persists as small fossette. Lower molars have their main cusps moderately alternating. Lower first molar tetralophodont, with procingulum divided by anteromedian flexid, small but present anterolabial cingulum, transverse and well-developed protoflexids and hypoflexids opposite metaconid and entoconid, respectively, and with conspicuous posterolophid. Second lower molar trilophodont, with large proto-, hypo-, meso-, and posteroflexids and well-developed posterolophid. Third lower molar subtriangular in outline, with complex dental pattern (almost right-facing "w"), well-

developed hypoflexid opposite small entoconid, and also with well-developed posterolophid.

Axial skeleton composed of 13 thoracic, 6 lumbar, and 21–23 caudal vertebrae (Steppan 1995). Stomach unilocular-hemiglandular (Carleton 1973). Only one pair of preputial glands present among male accessory reproductive glands (Voss and Linzey 1981). E. R. S. Roldán et al. (1985) described sperm structure.

DISTRIBUTION: *Calomys laucha* inhabits grasslands and forest fringes (up to an elevation of 950 m) in Argentina, Paraguay, southeastern Bolivia, northeastern Argentina, Uruguay, and east into Rio Grande do Sul state, Brazil. Unverified records may extend the range to Paraná state, Brazil (L. T. M. D. Souza et al. 2002). Several authors have suggested that *C. laucha* (like *Calomys musculus*) may have increased in abundance and expanded its range to otherwise forest wetlands and agricultural fields and adjacent habitats (e.g., in Misiones province, Argentina) only in the last few centuries, likely as a direct result of anthropogenic influences (Pardiñas et al. 2000; Pardiñas and Teta 2005; P. E. Ortiz et al. 2011b). Fossils assigned to *Calomys* cf. *laucha* were reported from the late Pliocene–early Pleistocene and the Holocene of southern Bolivia (Hoffstetter 1986; Pardiñas and Galliari 1998c) and from the same time period in northern Argentina (Pardiñas et al. 2002).

SELECTED LOCALITIES (Map 261): **ARGENTINA:** Buenos Aires, Bahia Blanca (Waterhouse 1837), José C. Paz (Massoia et al. 1968), near Otamendi (MSU 19000), 30 road km SW of La Plata, Punta Blanca (UMBW 72276); Córdoba, Colonia Tirollesa (TTU 32992); Jujuy, Yuto (AMNH 167856); Misiones, Candelaria, Río Yabebyrí (CFA 9551), Oberá, Campo Viera (CFA 10052); Río Negro, Chimpay (Hershkovitz 1962), Villa Regina (MACN 14584); Salta, Corralito (TTU 32996); San Luis, Naschel (TTU 32997); Santiago del Estero, Lavelle (TTU 32998). **BOLIVIA:** Santa Cruz, Boyuibe, near Camiri (S. Anderson 1997), Cerro Colorado (S. Anderson 1997); Tarija, 8 km S and 10 km E of Villa Montes (S. Anderson 1997). **BRAZIL:** Rio Grande do Sul, Faxinalzinho (Badzinski et al. 2012), Fazenda Marcelina (A. O. Rosa and Vieira 2010), Praia do Cassino (C. R. Camargo et al. 2006). **PARAGUAY:** Boquerón, Parque Nacional Teniente Enciso (TK 67304); Canendiyú, Estancia Salazar, Río Verde (TK 66816); Ñeembucú, Estancia San Felipe (TK 61623). **URUGUAY:** Maldonado, Maldonado (type locality of *Mus bimaculatus* Waterhouse).

SUBSPECIES: Geographical variation is extensive in pelage coloration (Waterhouse 1837; Osgood 1933d), diploid chromosomal counts (Brum Zorrilla et al. 1990), the proportion of individuals with an alisphenoid struts in samples (Olds 1988), and the number of mammae (Olds

1988). Osgood (1933d) described *Hesperomys bimaculatus bonariensis* from samples of *C. laucha* from around Buenos Aires and based on the smaller size and “somewhat darker-colored” phenotypes; he also commented on the variability observed in the amount of white hairs on ventral surfaces of this and other species, suggesting that this character was variable and likely of little taxonomic value.

Based on the patterns of pelage coloration, the ratio of tail to total length, the proportion of white hairs in the venter, and the presence/absence of alisphenoid strut in individuals per population, Olds (1988) recognized two species of *Calomys* within our current understanding of *Calomys laucha*. She used the name *C. bimaculatus* for populations of small bodied *Calomys* from Uruguay, southern Brazil, and various localities in Buenos Aires province (e.g., Torrecitas) based on her observation that this form tended to have a dorsal pelage coloration that was overall grayer, often with a darker band of black hairs from the muzzle to the base of the tail, and white hairs on the venter restricted to the chin and throat; one of the 12 specimens she examined of this form had an alisphenoid strut. Olds (1988) restricted the name *C. laucha* for populations from dry biotopes from south central Bolivia, north and northeastern Argentina, and western Paraguay. These populations are characterized by having golden-brown dorsal and fully white ventral colorations (including chins and throats); in addition about 91% of the 35 animals she examined had alisphenoid struts. However, craniodental dimensions of the two taxa Old’s recognized overlapped extensively in multivariate space.

Recent work on captive populations of *C. laucha* have elegantly demonstrated that pelage color change in this species is controlled by an endogenous circannual rhythm wherein individuals molt from an orange-colored pelage during summer to a dark gray color during winter (C. R. Camargo et al. 2006). The hypothesis, therefore, is that populations living in warmer, dryer biotopes of Argentina, Bolivia, Paraguay, and parts of Brazil have golden-brown pelage similar to that of the summer pelage of populations living in more seasonal environments on Uruguay, Argentina, and southernmost Brazil.

Despite apparent marked geographic variation in some external phenotypic characters, divergence in mtDNA cytochrome-*b* gene sequences from Bolivian, Paraguayan, Argentinean, and Brazilian populations indicate a pattern of genetic structure coincident with isolation by distance (R. González-Ittig, pers. comm.).

NATURAL HISTORY: The natural history of this species is relatively well known (e.g., Kravetz, Busch et al. 1981; Kravetz, Manjon et al. 1981; Mills, Ellis, McKee, Maiztegui, and Childs 1991; K. Hodara et al. 1997; Bilenca

and Kravetz 1999; Yahnke 2006; Courtalon and Busch 2010). In the grassland of Buenos Aires province, Mills, Ellis, McKee, Maiztegui, and Childs (1991) reported a seasonal pattern of population fluctuation with high densities in the summer and autumn, declining to almost nil during winter months and expanding again in the spring. Individuals were more abundant in the center rather than along the edges of field, possibly due to competition with *Akodon azarae* (Courtalon and Busch 2010). In the Argentinean Pampas, *C. laucha* preferentially occupied cornfields in current agricultural production, in contrast with sympatric *C. musculus*, which was present only in adjacent old fields (Villafañe et al. 1992). In the Chaco region of central Paraguay, *Calomys laucha* was trapped in pastures, cropland, thorn scrub, and thorn forest, being most abundant in the first three types of habitats; it was more highly associated with less herbaceous ground cover than other small mammal species (Yahnke 2006). Reproduction is seasonal, occurring from September to May in east-central Argentina (Mills, Ellis, McKee et al. 1992) and from April to August in the central Chaco (Yahnke 2006). The mean number of embryos ranged from 5.15 (in the Chaco) to 6.2 in the pampas of Argentina (Mills, Ellis, Childs et al. 1992). This may be a monogamous species (Laconi and Castro-Vazquez 1999). The diet is reported as omnivorous (Castellarini et al. 2003). In Bolivia and Paraguay, *C. laucha* is the natural reservoir of Laguna Negra hantavirus (A. M. Johnson et al. 1997; Yahnke et al. 2001), of a *Syphacia* nematode in Buenos Aires province, Argentina (E. J. R. Herrera et al. 2011), a *Physaloptera* nematode in Uruguay (Sutton 1989b), and may be infected with *Trypanosoma cruzi* in Córdoba province, Argentina (Moretti et al. 1980). *Calomys laucha* is preyed upon by at least two species of owls (Bellocq and Kravetz 1994).

REMARKS: Musser and Carleton (1993:698; 2005:1107) incorrectly cited “[G.] Fischer, 1814. In Eschwege, J. Brasilien, Neue Bibliothek. Reisenb., 15(2):209” as the author and source of *Calomys laucha*. W. L. Eschwege’s *Journal von Brasilien, oder vermischte Nachrichten aus Brasilien, auf wissenschaftlichen Reisen gesammelt* was published in 1818, and I. von Olfers was the author of chapter 10, the description and list of mammals contained within, with Olfers’s citation of *M. laucha* given on p. 209. Fischer had earlier published *Mus laucha* on p. 71 in his 1814 treatise *Zoognosia tabulis synopticis illustrata*. Both Fischer’s and Olfers’s *laucha* were based directly on F. d’Azara’s (1801) “*rat septieme ou rat laucha*.” Hershkovitz (1959b:339, 1962:150) identified Olfers (1818) as the author of *laucha* but did not cite Fischer (1814). Further discussion on the acceptability of Fischer’s names can be found in Musser et al. (1998: 28ff.).

Olds (1988) suggested the presence of *Calomys laucha* in the Brazilian state of Mato Grosso, based on a specimen collected by Leo Miller in 1914 at Utiarity on the Rio Papagaio during the Roosevelt Brazilian Expedition. The specimen in question (AMNH 37543) was originally identified as *Oryzomys (Oligoryzomys) microtis* and at some later unknown date reidentified as *Calomys laucha* (as can be seen on the museum catalogue entry for the specimen). Currently, there are no records of this species in the states of Rondônia, Mato Grosso, or Mato Grosso do Sul in Brazil, even at localities where longitudinal trapping programs (with both live and pitfall traps) have been conducted (e.g., Cáceres et al. 2010; Cáceres et al. 2011; Mallmann et al. 2011). Furthermore, the species has not been recorded at Bolivian localities near the Brazilian border (e.g., Emmons et al. 2006), where a similar composition of small mammal fauna to that of Utiarity is currently found, and where equally long-term studies have taken place. A parsimonious explanation is that AMNH 37543 represents another species of *Calomys*, most likely *Calomys tener*, a species found in other inventories in Mato Grosso and Mato Grosso do Sul (Cáceres et al. 2008) that shares a handful of morphological and morphometric characteristics with *C. laucha*.

Thomas (1898h) reported *Eligmodontia gracilipes* (a junior synonym of *Calomys laucha*) from near Rawson in the Patagonian province of Chubut; this report was based on two specimens collected in 1878 by Henry Durnford, who explored and collected along the basin of the Chubut River between 1876 and 1878 (Durnford 1878). Discussing the identity of the two specimens, Thomas clearly assigned them to the same species represented by “Azara’s Laucha” (*Calomys laucha*). Based on the fact that there are no confirmed records of *Calomys laucha* south of the Río Colorado in Patagonia—but those of *C. musculus* are abundant (Pardiñas, Teta, D’Elía, and Lessa 2011)—and that Thomas did not recognize (and would eventually describe) *musculus* as a biological entity distinct from *laucha* until 13 years after his 1898 publication, it is safe to assume that the specimens trapped by Durnford in March 1878 are early records of *C. musculus* in Patagonia. Steppan (1995: 104) reidentified as *C. laucha* two specimens from Chimay (Rio Negro province, south of the Colorado River) originally assigned to *C. murillus* (= *C. musculus*) by Olds (1988). I disagree with Steppan’s reidentification; in fact, extensive and intensive studies by U. F. J. Pardiñas and collaborators over the last decade indicate that currently *Calomys laucha* does not range south of the Río Colorado. The only species of *Calomys* found in northern Patagonia, at least since the late Holocene, is *Calomys musculus* (Udrizar Sauthier 2009).

Map 261 Selected localities for *Calomys laucha* (●). Contour line = 2,000m.

Some karyotypic variability is known for specimens assigned to this species from Argentina and Uruguay, with the most common karyotype being $2n=64$, $FN=68$ (Brum Zorrilla et al. 1990). This karyotype is the only one found in Brazilian samples (Mattevi et al. 2005). The single report of animals from Artigas (Uruguay) with $2n=56$, $FN=59$ (Brum 1962), has never been independently confirmed. M. L. Ortiz et al. (2007) reported the distribution of telomeric signals in various internal positions of the karyotype, suggesting multiple chromosomal rearrangements in the evolutionary history of the species. Ciccioli and Poggio (1993) reported on genome size.

Calomys lepidus (Thomas, 1884)

Andean Vesper Mouse, Graceful Laucha, Hiska Achaco

SYNONYMS:

Hesperomys (Calomys) bimaculatus var. *lepidus* Thomas, 1884:454; type locality "Junin," Peru.

Hesperomys lepidus montanus Sanborn, 1950: 4: type locality "El [La] Cumbre, [La Paz,] Bolivia. Altitude 15,200 feet."

Hesperomys ducillus: Pearson, 1951:141; name combination.

Calomys lepidus: Cabrera, 1961:479; first use of current name combination.

Calomys lepidus marcarum: Cabrera, 1961:480; name combination.

Calomys lepidus ducillus: Cabrera, 1961:480; name combination.

DESCRIPTION: Small (total length <140mm) with very short tail (<50mm), averaging less than <40% of total length (Olds 1988). Fur long, soft, and silky; dorsal coloration dull fawn or grayish fawn, somewhat darker on center of back because of intermixture of numerous longer black hairs; dorsum with marbled appearance, nearly uniform in tone from head to rump (Olds 1988); ventral coloration white, but hairs with gray bases. Ears large, pale brown, each with conspicuous white postauricular spot. Tail uniformly hairy, weakly bicolored, sandy white above, clear white below. Forefeet and hindfeet light above; hindfeet with six small plantar pads, heel and proximal portion of sole hairy. Mammary number 8 to 10 (Hershkovitz 1962).

Frontal outline of skull markedly convex; interorbital region parallel sided and supraorbital edges squared but not ridged (Gyldenstolpe 1932); rostrum short and moderately broad; nasals short but relatively broad, especially first third, covering incisors when skull seen from above and terminating at site of triple juncture of maxillary, frontal, and lacrimal; coronal suture shaped as open U; zygomatic plates about 7% of condyloincisive length, with slightly concave anterior borders and very shallow zygomatic notches; zygomatic arches delicate and parallel at midpart, broader near parietal root; midpoint dips ventrally but remains discernibly above level of orbital floor; jugal narrow but distinctly separates maxillary and squamosal portions of arch; braincase small and somewhat globular; parietals with small extensions in lateral view; interparietal wide across braincase but frontodorsally depressed; postglenoid foramen vestigial, obscured internally by lateral border of tegmen tympani. Incisive foramina long, borders parallel, and surpass only slightly anterior roots of M1s; premaxillary part of the septum

occupies about half of opening length. Palate long and wide (*sensu* Hershkovitz 1962), with small posterolateral palatal pits. Mesopterygoid fossa short, narrow, and divergent posteriorly (strongly V-shaped; Stepan 1995), its anterior border behind posterior face of M3; roof of fossa perforated by well-developed sphenopalatine vacuities. Auditory bullae somewhat inflated, pear-shaped in outline.

Upper incisors orthodont and faced with bright orange enamel. Upper molars brachydont, with rows posteriorly divergent (Braun 1993). M1 subrectangular in outline with well-developed procingulum and anteromedian flexus dividing anterocone into anterolingual and anterolabial conules in 95% of specimens (Olds 1988); anteromedian style present in about 33% of specimens examined (Olds 1988); mures longitudinally oriented; both hypoflexus and protoflexus transverse; protocone and hypocone are about same size; and hypoflexus wide and posteriorly directed. M2 square in outline, about 60% smaller than M1; anteroloph persistent, a mesoloph is absent; mesoflexus and hypoflexus well developed. M3 squared, about 67% of the transverse length of M2 (Olds 1988); both hypoflexus and mesoflexus well developed; and anteroloph present. Lower molars crested, with main cusps clearly alternating; both mesolophids and ectolophids absent, but mesostylids and ectostylids present. Procingulum of m1 well developed and divided by anteromedian flexid; mesoflexid narrow and directed backward; posterolophid well developed; m2 with intercalating cusps, well-developed mesoflexids and hypoflexids, and well-developed posterolophid; m3 complex, Z-shaped, with small but well-defined protoflexid; posteroflexid lost with age but otherwise present. Mandible with capsular projection of ramus obsolete or absent (Hershkovitz 1962; Braun 1993).

Vertebral count of 13 thoracic, 6 lumbar, and 20–22 caudal elements (Stepan 1995); the same author also reported a single large lateral pair of preputial glands. Sperm morphology identical to that of *C. musculinus* (Espinosa et al. 1997).

DISTRIBUTION: *Calomys lepidus* occurs in high-elevation, rocky grasslands above 2,900 m from central Peru south to northern Chile, Bolivia, and into northwestern Argentina.

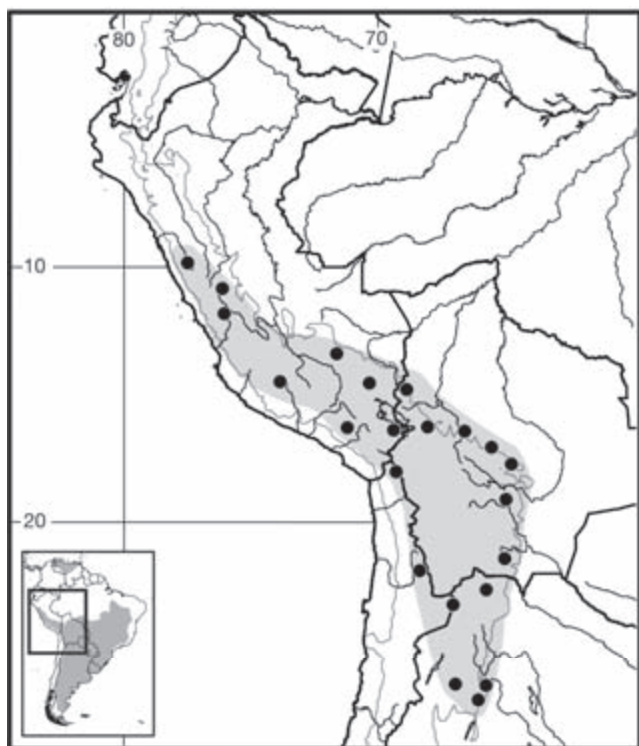

SELECTED LOCALITIES: (Map 262): ARGENTINA: Catamarca, Belén (Jayat, Ortiz, Pacheco, and González 2011); Jujuy, Abrapampa (type locality of *Hesperomys carillus argurus* Thomas), El Toro, 50 km W of Susques (MSB 75238); Tucumán, Huaca Huasi (Ferro and Barquez 2008), La Junta, naciente del Río Pavas (Ferro and Barquez 2008). BOLIVIA: Chuquisaca, 2 km N of Tarabuco (CBF 1090); Cochabamba, Ayopaya (S. Anderson 1997), Choro (type locality of *Eligmodontia carilla* Thomas), ca. 13 km N of Co-

lomi (S. Anderson 1997), 101 km by road SE of Espinaza, Siberia Cloud Forest (AMNH 246798); La Paz, La Cumbre (type locality of *Hesperomys lepidus montanus* Sanborn), Reserva de Fauna Ulla-Ulla (Salazar-Bravo et al. 2001). CHILE: Antofagasta, Ojos de San Pedro (Hershkovitz 1962); Tarapacá, Parinacota (MSB 210378). PERU: Ancash, Rachacoco, 45 km S of Huaraz (MVZ 135689); Arequipa, ca. 48 km by road E of Arequipa (LSUMZ 27888); Ayacucho, 23 km W (by road) of Pampamarca (MVZ 174337), Tucumachay Cave (UMMZ 122623); Cusco, Lauramarca [= Labramarca] (type locality of *Hesperomys carillus marcarum* Thomas); Junín, Carhuamayo (Hershkovitz 1962); Puno, 4 km E of Juli (Olds 1988), San Antón (type locality of *Eligmodontia ducilla* Thomas).

SUBSPECIES: *Calomys lepidus* is polytypic, with extensive morphological and morphometric variation evident from the number of formal taxa recognized across its range, either as separate species or subspecies. Hershkovitz (1962) reviewed patterns of diversification, and delineated four subspecies: the nominotypical form in the Andes of central Peru south to Cusco department; *C. l. ducillus* Thomas from the Altiplano of southern Peru, northeastern Chile, and northern Bolivia; *C. l. carillus*, from La Paz and Cochabamba departments, Bolivia; and *C. l. argurus*, restricted to its type locality in Jujuy province, Argentina.

NATURAL HISTORY: The species is widespread in Puna grassland and ecotonal habitats, at elevations between 2,950 m to about 4,850 m, and from central Peru to Catamarca in Argentina (Hershkovitz 1962; S. Anderson 1997; Yensen and Tarifa 2002; Zeballos and Carrera 2010; Jayat, Ortiz, Pacheco, and González 2011). Pregnant females have been trapped throughout the year, with a mode of four embryos (range: 1 to 6) from Lima department, Peru, to Tarija department, Bolivia (Olds 1988; S. Anderson 1997). In northern Argentina, M. M. Díaz and Barques (2007) recorded scrotal males in March and young individuals in February and December. Pearson and Ralph (1978) reported a density of 0.81 individuals per hectare in bunch grass habitat at 3,900 m in Puno (Peru), and Zeballos and Carrera (2010) recorded abundances of about 0.3 animals/100 trapnights. The Culpeo (*Lycalopex culpaeus*; Mercado and Miralles 1991) and owls (Pearson 1951; P. E. Ortiz, Cirignoli et al. 2000) are known predators.

REMARKS: It is highly likely that at least two species are masquerading within the concept of *C. lepidus* presented here. Patterns of morphometric and morphological diversity found along the almost 1,500 km of the distribution added to the difference in chromosome numbers in populations at the extremes of the distribution, and genetic distances among haplotypes of the mtDNA cytochrome-b for individuals from Puno (Peru) and Tarija (Bolivia),

Map 262 Selected localities for *Calomys lepidus* (●). Contour line = 2,000 m.

which average 3.35%, support this hypothesis (J. Salazar-Bravo, unpubl. data).

The karyotype is geographically variable, with $2n=36$, $FN=68$, reported for Peruvian samples (Pearson and Patton 1976), but $2n=44$, $FN=68$, in specimens from north-western Argentina (Espinosa et al. 1997).

Calomys musculus (Thomas, 1913)

Drylands Vesper Mouse, Drylands Laucha, Corn Mouse

SYNONYMS:

Eligmodontia laucha musculina Thomas, 1913a:138; type locality "Maimara, [Jujuy, Argentina]. 2230 m."

[*Hesperomys laucha*] *musculus*: Thomas, 1916a:141; name combination.

Hesperomys murillus Thomas, 1916b:183; type locality "La Plata City," Buenos Aires, Argentina.

Hesperomys murillus cordovensis Thomas, 1916b:184; type locality "Yacanto, [Córdoba, Argentina,] 900 m.

Hesperomys musculus: Thomas, 1920d:116; name combination.

Hesperomys musculus cortensis Thomas, 1920a:190; type locality "Jujuy, [Jujuy, Argentina,] 1,258 m.

Hesperomys murillus murillus: Yepes, 1935a:227; name combination.

H[esperomys]. murillus cordobensis Yepes, 1935a:227; name combination and incorrect subsequent spelling of *cordovensis* Thomas.

Calomys laucha cordovensis: Cabrera, 1961:478; name combination.

Calomys laucha musculus: Cabrera, 1961:479; name combination.

Calomys musculus: Massoia and Fornes, 1965b:6; first use of the current name combination.

DESCRIPTION: Medium sized (total length 140–200 mm) with tails as long as head and body (about 50% of total length) and clear countershading of dorsal and ventral coloration (in most populations). Dorsal color sandy brown lined with black hairs to gray all over with usually darker rumps; head about same color as dorsum; sides of body often bit lighter and contrast sharply with white appearance of ventral region; often hairs on ventral area white only at tips (gray at base), but some populations with fully white hairs on throat. Populations from Paraguay, southern Bolivia, and northern Argentina often with buffy line demarcating sides from venter. Ears about average for small forms of genus (ca. 14 mm long), rounded, covered internally by short, delicate brownish yellowish hairs, and contrasted from head color with concha and tragus white. Hindfeet long and narrow (ca. 18 mm), covered dorsally by small white hairs. Tail often bicolored, dark brown to black above and clear to creamy-white below. Plantar surfaces of hindfeet largely naked but with some hairs covering calcaneus and extending to thenar pad; six plantar pads present. Mammae number 10 to 12 (Olds 1988).

Skull with straight profile when viewed laterally; rostrum moderately short and narrow, with nasals projecting forward so that incisors covered when skull viewed from top. Interorbit about 30% of zygomatic breadth; supraorbital region posteriorly divergent but lacks marked ridges or ledges (Olds 1988). Coronal suture broadly open U-shape. Braincase somewhat elongated, without temporal and lambdoidal ridges; parietals with very poorly developed lateral extensions onto squamosal; interparietal expanded across braincase. Zygomatic plates broad and high, without zygomatic spines, and defining poorly developed zygomatic notches; frontal edge of zygomatic plates variable, either somewhat rounded or straight. Hamular process narrow, separating reduced postglenoid foramen with respect to subsquamosal fenestra. Incisive foramina long and narrow, reaching between anterior roots of M1s; premaxillary part of septum occupies about 50% of its length. Palate broad and long (*sensu* Hershkovitz 1962), with very small posterolateral palatal pits. Mesopterygoid fossa narrow, with squared anterior edge and without trace of median palatine process; sphenopalatine vacuities present. Auditory bullae slightly inflated (Olds 1988), and carotid circulatory pattern primitive (pattern 1 of Voss 1988).

Mandible small but robust; mental foramen not visible from labial view; masseteric crest evident, its upper

and lower ridges producing thickened chevron running from point of contact (below about second lateral root of m1) to slightly above level of mental foramen; capsular projection very conspicuous, lying at about middle point of sigmoid notch. Coronoid process strong, falciform (with blunt edge in some adults), and inflected backward; condyloid process long and narrow; sigmoid notch well defined.

Upper incisors opisthodont and faced with pale yellow (old adults) to orange enamel; dentine fissure long straight slit (*sensu* Steppan 1995). Upper molars crested and brachydont, markedly opposite in pattern, and small with respect to skull. M1 tetralophodont; an anteromedian flexus divides relatively narrow anterocone; hypoflexus and protoflexus straight and transversal; protocone and hypocone about equal in size; both parastyle and mesostyle present as thickening of labial cingulum; and no trace of a shallow anteroflexus (Steppan 1995). M2 square in outline, bilophodont, and about 60% the length of M1 (Olds 1988); wide mesoflexus opposite to hypoflexus. M3 trilophodont, moderately reduced with respect to M2 (between 72% and 74%); hypoflexus, mesoflexus, and paraflexus all persist, even in old individuals, as small fossettes. Lower molars crested with alternating main cusps. Lower first molar with anteromedian flexid fused at base of cusp; the hypoconid is larger and broader than the protoconid; the entoconid is bulbous, well-developed posterolophid, and posterostylid subequal in size to hypoconid; m2 trilophodont, with posterolophid and metaflexids, mesoflexids, and hypoflexids well developed; m3 sigmoid in outline, with hypoflexid deep and curved upward, but mesoflexid persistent as fossette.

Vertebral elements highly variable in number, with thoracic 12–14, lumbar 5–7, and caudal 24–29 (Steppan 1995). E. R. S. Roldán et al. (1985) described sperm morphology; spermatozoa from mature males with hooked heads with roughly polygonal nucleus, similar in morphology to those present in males of *C. lepidus* and *C. hummelincki* (Espinosa et al. 1997). R. A. Cutrera et al. (1992) described female genital morphology, and Buzzio and Castro-Vazquez (2002) detailed gross morphology of male accessory glands. Stomach unilocular-hemiglandular (Rouaux et al. 2003), with digestive tract structures described and compared with those of other Pampean species of rodents by Ellis et al. (1994). Bee de Speroni and Peregrini de Gstaldo (1988) detailed allometry of brain growth, and Cavia et al. (2008) examined hair microstructure.

DISTRIBUTION: *Calomys musculus* is known from sea level to 3,300 m in habitats ranging from the Pampas, Espinal, and Monte of central Argentina, to the Yungas and Puna of northern Argentina and south and central Bolivia, and dry Chaco of Paraguay.

SELECTED LOCALITIES (Map 263): ARGENTINA: Buenos Aires, La Plata (type locality of *Hesperomys murillus* Thomas), Mar del Plata (Salazar-Bravo et al. 2001); Catamarca, 13 km NNW of Andalgalá (Salazar-Bravo et al. 2001); Chaco, General Pinedo (Olds 1988); Chubut, Esquel (CFA 02166), 8 km ESE (by road) of Puerto Madryn (Salazar-Bravo et al. 2001), Valle Hermoso, Comodoro Rivadavia (CFA 09070); Córdoba, Yacanto (type locality of *Hesperomys murillus cordovensis* Thomas); Entre Ríos, Gualeguay (MACN-MA 21236); Jujuy, Maimara (type locality of *Eligmodontia laucha musculina* Thomas), Santa Catalina (Olds 1988); La Pampa, 40 km N of Anzoátegui (TTU 64423); La Rioja, El Pesebre (Jayat, Ortiz, González et al. 2011); Mendoza, 10.5 km W of Old Rte. 40, along road to Lago Diamante (OMNH 15360); Neuquén, 5 km N of Las Coloradas (MVZ 159401); Salta, 3 km E of La Poma (Jayat, Ortiz, Pacheco, and González 2011); San Juan, 4 km W of Complejo Astroneómico “El Leondito” (OMNH 20023), Tudcum, Nacadero (OMNH 30022); Santa Cruz, Laguna del Diez, 40 km SW of Monumento Natural Bosques Petrificados (Jayat et al. 2006), Estancia La Julia (CNP-E 489), Estancia Cerro Ventana (PNG 830); Santa Fe, San Javier (MACN-Ma 15734); Santiago del Estero, 1 km S and 2 km E of Pampa de los Guanacos (OMNH 35124); Tucumán, Paso El Infiernillo (MSU 19219). BOLIVIA: Chuquisaca, 4 km N of Tarabuco (S. Anderson 1997); Cochabamba, Cochabamba (S. Anderson 1997); La Paz, Mecapaca (S. Anderson 1997); Potosí, 10 km SSE of Otavi (FMNH 162892); Santa Cruz, 1 km N and 8 km W of Comarapa (S. Anderson 1997), Tarija, Cariazo (S. Anderson 1997). PARAGUAY: Boquerón, Fortín Toledo (MSB 80553), Loma Plata (MSB 80556).

SUBSPECIES: Although several taxa originally described as species or subspecies are included within the synonymy of *C. musculus*, for the present this species is regarded as monotypic. Cabrera (1961) included *musculus* Thomas and *cordovensis* Thomas as a valid subspecies of his polytypic *C. laucha*, but Hershkovitz (1962) included all names herein associated with *C. musculus* as simple subjective junior synonyms of his *C. l. laucha*. Geographic variation in size and color is, however, present, prompting Olds (1988) to divide geographic segments of *C. musculus* into separate species (see Remarks).

NATURAL HISTORY: Studies on the ecology and natural history of this species have been conducted primarily in three foci of its distribution: central Argentina (e.g., Mills, Ellis, McKee, Maiztegui, and Childs 1991; Mills, Ellis, Childs et al. 1992; Villafañe et al. 1992), in the Monte Desert of Mendoza province (recent review by R. A. Ojeda et al. 2011), and the central region of the Paraguayan Chaco (Yahnke 2006).

In central Argentina, *C. musculus* is abundant in agricultural areas, especially corn and wheat fields, and along linear habitats (fencerows, roadsides, and railroad beds). Population densities were described as relatively high in spring and remaining so through summer and early autumn from November to April (Mills, Ellis, McKee, Ksiazek et al. 1991). Ellis et al. (1997) found that *C. musculus* was statistically associated with linear habitats (roadsides and fence lines), which contrasted with the results by M. Busch et al. (1997), who found no habitat preference in any season, overlapping with both *C. laucha* and *Akodon azarae* in fields and linear habitats. In the Argentinean Pampas, Villafañe et al. (1992) found *C. musculus* to occupy preferentially old fields that had been out of agricultural production for several decades. Gonnet and Ojeda (1998) found this species to be one of the two most dominant in the Andean foothills of the Monte Desert of Argentina, where it preferred grassy microhabitats and where population densities were rather constant throughout the year (R. A. Ojeda et al. 2011). In contrast, Yahnke (2006) found *C. musculus* to occupy several habitats types in the Paraguayan Chaco but with a preference for microhabitats with low herbs, grassy vegetation, and cropland. The species is apparently highly adapted to xeric environments as it appears independent of free water (Mares 1977a) and shows daily torpor (Bozinovic and Rosenmann 1988b).

Calomys musculus is omnivorous in agroecosystems in Argentina, with the relative proportions of seeds, insects, and vegetation consumed varying seasonally (Ellis et al. 1998). In contrast, animals in the Monte Desert are granivorous (Giannoni et al. 2005). Buzzio and Castro-Vasquez (2002) summarized known reproduction biology, with high seasonality but a long duration from September to June in Argentinean agroecosystems (Mills, Ellis, McKee et al. 1992). The number of embryos ranged from average of 6.07 in the Chaco (Yahnke 2006) to 7.5 in central Argentina (Mills, Ellis, McKee et al. 1992). Both Laconi and Castro-Vasquez (1999) and Yunes et al. (1991) examined nesting and parental behavior. Villafañe (1981) examined reproduction and growth in a laboratory colony, where females reached sexual maturity at age 72.5 days, the gestation period was estimated at 24.5 days and estrous cycle at 5.7 days, average litter size was 5.4 young, a postpartum estrous occurred in 50–64% of females, and males reached sexual maturity at 82 days.

Known predators include several species of owls (García Esponda et al. 1998; P. E. Ortiz, Cirignoli et al. 2000; Pardiñas, Teta et al. 2003) and the Geoffroy's cat (*Leopardus geoffroyi*; Bisceglia et al. 2011). Ticks (Nava et al. 2006; Sanchez et al. 2010; Guglielmo and Nava 2011), lice (Abrahamovich et al. 2006), fleas (Lareschi et al. 2004), and trypanosomes (Basso et al. 1977) are known parasites.

Calomys musculus also serves as a reservoir for the Junín arenavirus, the etiological agent of the Argentine hemorrhagic fever (Massoia and Fornes 1965b; Salazar-Bravo, Ruedas, and Yates 2002).

REMARKS: In her unpublished doctoral thesis, Olds (1988) suggested that our present understanding of *C. musculus* includes two species. She used the name *C. musculus* for populations ranging from 1,000 to 3,000 m on the eastern slopes of the Andes in Bolivia and northern Argentina and *C. murillus* for those populations below 1,200 m elsewhere in Argentina. She differentiated between these two on the basis of size and pelage coloration, although she acknowledged that these differences were “difficult to distinguish.” Morphometric analyses conducted by Provençal and Polop (1993) suggested no geographic variation among populations from central Argentina, but did

Map 263 Selected localities for *Calomys musculus* (●). Contour line = 2,000 m.

document significant differences between individuals collected in different years. Since these two reports, evidence has accumulated supporting a recent population expansion of populations in central Argentina (González-Ittig et al. 2007), perhaps as a result of either or both anthropogenic activities (Pardiñas et al. 2000) and climate change (P. E. Ortiz, Madozzo Jaen, and Jayat 2012). In addition, molecular evidence has supported that individuals from populations assigned to either binomial appear to belong to a single species, for which the name *C. musculinus* has priority (Salazar-Bravo et al. 2001).

Myers (1982) mentioned the presence of *Calomys musculinus* in eastern Paraguay, but extensive collections in various localities east of the Paraguay river have recorded both *Calomys tener* and *C. callosus* but not *C. musculinus*. Examination of the two specimens at the Smithsonian currently identified as *C. musculinus* (USNM 390144 and USNM 531236) indicate that these specimens may represent *Calomys tener* (S. Peurach, pers. comm.).

A karyotype of $2n=38$ and $FN=48$ (Forcone et al. 1981; Ciccioli 1991) has been described for central Argentinean populations. The autosomal complement is composed of one large metacentric pair, seven pairs of medium-sized metacentric and submetacentric chromosomes, five pairs of medium submetacentrics, three pairs of small submetacentrics, and two pairs of small metacentric chromosomes. The X chromosome is a large submetacentric, and the Y an extremely small submetacentric. No karyotype is known for populations in Bolivia or Paraguay.

Calomys sorellus (Thomas, 1900)

Peruvian Vesper Mouse, Peruvian Laucha

SYNONYMS:

Eligmodontia sorella Thomas, 1900f:297; type locality "eight miles south of Huamachuca, [La Libertad,] N.W. Peru. Altitude 3500m."

[*Hesperomys*] *sorella*: Thomas, 1916a:141, name combination.

Hesperomys frida Thomas, 1917g:1, type locality "Chospyoc, [Cusco, Peru] 10,000 feet."

Hesperomys frida miurus Thomas, 1926b:314; type locality "Yano Mayo," Río Tarma, Junín, Peru, 8,500 ft.

Calomys frida frida: Cabrera, 1961:478; name combination.

Calomys lepidus sorellus: Cabrera, 1961:481; name combination.

Calomys sorellus: Hershkovitz, 1962:137; first use of current name combination.

DESCRIPTION: Medium sized (mean total length 148.05 ± 13.8 mm, maxillary tooththrow 3.61 ± 0.13 mm; Olds 1988) with short tails (<45% of total length) and long, smooth, and fine fur. General dorsal color grayish

brown, sometimes dark brown, finely lined with black; tip of muzzle usually ochraceous (Hershkovitz 1962); body sides paler than dorsum, separated from venter by well-defined buffy line; ventral color whitish, with individual hairs slate-gray basally. Ears moderately long (mean 17.0 ± 1.8 mm), brownish when folded, colored like head, and with white postauricular patch. Upper surface of hands and feet pale to white; proximal third of soles thinly haired. Tail sharply bicolored, brownish above, darkening toward tip, white below and on the sides. Adult females with four pairs of mammae.

Skull moderate to large for genus (mean greatest length 23.4 ± 1.29 mm; Olds 1988), with straight profile in lateral view. Rostrum moderately short and deep throughout, although sides taper gradually toward front. Nasals broad, almost covering breadth of rostrum throughout; when seen from above nasals cover incisors. Lacrimals minute. Interorbital region parallel sided or slightly divergent posteriorly, with squared but not beaded edges; coronal suture U-shaped; braincase rounded and lacks well-defined lambda-dorsal ridges; parietals only slightly expanded over lateral surface; interparietal depressed dorsoventrally but covers entire back of the braincase. Zygomatic arches delicate, almost straight or convergent toward front, not bowed; zygomatic plates broad, about 10% of skull length, with straight anterior borders; zygomatic spines absent; zygomatic notches visible but neither deep nor broad. Alisphenoid strut absent (Olds 1988). Hamular process long and narrow, subdividing reduced postglenoid foramen and larger subsquamosal fenestra. Incisive foramina long and narrow, compressed anteriorly, and extending posteriorly between procingula of M1s; premaxillary part of septum occupying about half of opening. Palate broad and long (*sensu* Hershkovitz 1962), with small but clearly present palatal posterolateral pits positioned just dorsal to mesopterygoid fossa. Mesopterygoid fossa very narrow; sphenopalatine vacuities present; parapterygoid plates excavated, lyre shaped, and very broad. Auditory bullae small (Olds 1988). Carotid circulatory pattern primitive, pattern 1 (*sensu* Voss 1988; see Stepan 1995).

Mandible small but robust, but lacks well-developed masseteric crest; capsular projection conspicuous and located near base of coronoid process, which is short and inflected backward; condyloid process long and narrow; angular process short and almost as wide as condyloid process.

Upper incisors opisthodont (Stepan 1995), with bright orange enamel and smooth surfaces. Upper molars crested, with markedly alternating labial and lingual cusps along major axis of tooththrow; molars brachydont, and moderate in size with respect to skull. M1 subrectangular in outline; anterocone usually with well-developed anterome-

dian flexus; anteromedian style present in about 44% of specimens (Olds 1988); hypoflexus and protoflexus transverse; protocone slightly larger than hypocone; no trace of parastyle/anteroflexus (Steppan 1995); and hypoflexus posteriorly directed. M2 square in outline, trilophodont, and about 62% length of M1; anteroloph well developed; mesoflexus wide and posteriorly directed, alternating with hypoflexus. M3 moderately bilophodont, rounded in shape, and about 70% of M2 in length (Olds 1988); hypoflexus and mesoflexus vestigial and opposite each other. Lower molars crested, with main cusps alternating; mesolophids and mesostylids absent; m1 trilophodont with well-developed, fan-shaped procingulum with deep anteromedian flexid, well-developed anterolabial cingulum, both ectostylid and mesostylid present, a mesoflexus narrow and posteriorly directed, both entoconid and metaconid subequal in size, and a reduced posterolophid; m2 trilophodont, with well-developed posterolophid; m3 subrectangular in outline, sigmoid, with reduced mesoflexid and deep hypoflexid.

Number of vertebral elements variable, with 13–14 thoracic and 27–31 caudal vertebrae, but six lumbar elements consistently present (Steppan 1995). Dorst (1973b) described stomach morphology, and heart weight relative to mass at about 0.85% (Dorst 1973a). Steppan (1995) reported two pairs (one very small, less than 1 mm in length) of preputial glands.

DISTRIBUTION: *Calomys sorellus* is largely confined to Puna vegetation at high elevation (typically above 2,500 m) in Peru, although it likely extends into Bolivia in the vicinity of Lake Titicaca. A few specimens from the loma vegetation of coastal Arequipa department, Peru (specimens in the MVZ and MUSA) deserve closer scrutiny.

SELECTED LOCALITIES (Map 264): PERU: Ancash, Callon, 2 km S and 11 km W of Huaras (MVZ 137998), 25 km S of Huaras (MVZ 137999), Rachacoco, 45 km S of Huaras (MVZ 135684); Apurímac, 10 km N of Abancay (MVZ 119957), 36 km S (by road) of Chalhuanca (MVZ 174022); Arequipa, ca. 33 road km E of Arequipa (LSUMZ 27863), 2 mi E of Atiquipa (MVZ 145615), 1 km N of Chivay (MVZ 145616); Ayacucho, 2 mi SE of Huanta (MVZ 141362), 11 mi NW of Puquio (MVZ 116030); Cusco, Chirapata, Cossireni Pass (Hershkovitz 1962), Chospayoc (type locality of *Hesperomys frida* Thomas), 5 km N of Huancarani (MVZ 171549), 20 km N (by road) of Paucartambo, km 100 (MVZ 171544); Huancavelica, Huancavelica (Hershkovitz 1962), Lircay (Hershkovitz 1962), Río Mantaro (MVZ 119959); Huánuco, Cullcui (Hershkovitz 1962), Panao mountains (Hershkovitz 1962); Junín, 17 mi WNW of Huancayo (MVZ 141361), 16 km NNE (by road) of Palca (MVZ 172670), Pomacocha, Yauli Valley (MVZ 138001); La Libertad, 8 mi S of Huamachuca (type

locality of *Eligmodontia sorella* Thomas), mountains NE of Otuzco (Hershkovitz 1962), 10 mi WNW of Santiago de Chuco (MVZ 138022); Lima, 1 mi W of Canta (MVZ 119960), 1 mi E of Casapalca (MVZ 119961); Pasco, Huaríaca (Hershkovitz 1962); Puno, 3 mi NE of Arapa (MVZ 116669), 6 km N of Putina (MVZ 171559), 4.5 km NE (by road) of San Antón (MVZ 173429), 12 km S of Santa Rosa [de Ayaviri] (MVZ 171555).

SUBSPECIES: I regard *Calomys sorellus* as monotypic.

NATURAL HISTORY: Dorst (1971, 1973b), Pearson and Ralph (1978), Pizzimenti and DeSalle (1980), and Pacheco et al. (2007) have reported on various aspects of the natural history. This species may account for about 4–41% of the biomass at trapsites (Dorst 1971), with population densities ranging from eight to nine animals per hectare (Dorst 1973b) and abundances between 0.24 and 0.36 per 100 trap-nights in the basin of the Río Apurímac (Pacheco et al. 2007). The species is primarily nocturnal, with an activity peak between 7:00 PM and 10:00 PM (Dorst 1971). Individuals may be mainly insectivorous (Pizzimenti and DeSalle 1980) or granivorous (Dorst 1971). A tick (*Ixodes andinus*) is the only published parasite of the species (Hershkovitz 1962). The limited reproductive data indicate breeding active from July to September (Dorst 1971; Olds 1988). Morrison et al. (1963) and Reynafarje and Morrison (1962) examined hematocrit values and myoglobin levels with respect to high-altitude adaptations.

Map 264 Selected localities for *Calomys sorellus* (●). Contour line = 2,000 m.

REMARKS: Ample morphological and chromatic variation has been reported for *Calomys sorellus* across its range, with specimens from northern Peru paler, more grizzled, and smaller throughout, while those from further south are darker, browner, and slightly larger (Olds 1988). Slight chromosomal polytypy is also known (Pearson and Patton 1976), with $2n=64$, $FN=68$, in populations ranging from Ancash department in the north to Puno in the south, with $2n=62$ for a specimen from Apurimac. Lacking detailed analyses of phenotypic variation and/or molecular phylogeographic structure, it is premature to determine whether infraspecific units warrant formal recognition.

Calomys tener (Winge, 1887)

Delicate Vesper Mouse, Delicate Laucha

SYNONYMS:

Hesperomys tener Winge, 1887:15; type locality "Lagoa Santa," Minas Gerais, Brazil; given as "Rio das Velhas, Lagoa Santa" by Gyldenstolpe (1932:75) and as "Lapa da Escrivania [=Escrivânia] Nr. 5" by Hansen (2012:48).

Eligmodontia tener: Shufeldt, 1926:503; name combination.

Calomys tener: Cabrera, 1961:481; first use of current name combination.

Calomys laucha tener: Hershkovitz, 1962:157; name combination.

DESCRIPTION: Size average for genus, with head and body length 74–88 mm ($N=10$, from central and eastern Brazil; Bonvicino and Almeida 2000). Both external and cranial measurements smaller when compared with sympatric congeners. Upper parts of body are yellowish to dark brown, with reddish hue in some specimens, but hairs gray at base; venter pale to dark gray, finely streaked with black hairs; sides softer color but easily differentiable from venter; ventral region grayish to whitish with base of hairs gray; no lateral line separating dorsal and ventral colors; some specimens with fully white hairs on chin. Most specimens with eye-ring. Ears average 14.2 mm (Bonvicino and Almeida 2000), covered with short hairs about same color as rest of head. Tail proportionally short, about 45% of total length, mean length 60.6 mm (range: 38 to 77 mm; Bonvicino and Almeida 2000), and slightly bicolored, dorsally with grayish brown, pale below. Pale postauricular patches and ochraceous preauricular spots present. Five pairs of mammae usually present, three pectoral and two inguinal, but Olds (1988) reported one female with only three pairs, two pectoral and one inguinal.

Skull domed in lateral profile, higher above tympanic bullae, with moderately broad and long rostrum (averaging 34% of greatest length; Olds 1988, Bonvicino and Almeida 2000). Nasals parallel sided, protrude beyond plane of incisors such that they cannot be seen from above, and

dorsally terminate bluntly at same level as premaxillaries. Lacrimals minute. Interorbital region wide and flat, with supraorbital margins distinctly ledged and divergent posteriorly. Zygomatic plates broad, with dorsal edges mostly straight and upper free borders enclosing poorly developed zygomatic notches, posterior margin anterior to alveolus of M1. Zygomatic arches delicate, not expanded, and widest at squamosal root of zygomatic arch. Incisive foramina long and narrow, with parallel borders, posterior ends rounded and reaching at least to level of M1 protocones; premaxillary part of septum occupying about 60% of length of opening. Anterior border of mesopterygoid fossa rounded, without median palatine process, and not reaching posterior face of M3s; roof of fossa with large sphenopalatine vacuities. Alisphenoid strut typically present in most specimens (Olds 1988). Auditory bullae of medium size, with short but wide bony tubes; carotid circulation primitive (pattern 1 of Voss 1988).

Mandible delicate, with conspicuous capsular projection lying at base of coronoid process; coronoid process small and inflected backward; condyloid process broad and short; angular process short; sigmoid notch scarcely developed. Upper incisors orthodont and faced with bright orange enamel band. Lingual and labial molar cusps alternate on both upper and lower teeth. Upper molar rows parallel, maxillary tooththrow length 3.2–3.6 mm. Anterocone of M1 divided by anteromedian flexus, and with anteromedian style (*sensu* Hershkovitz 1962) complete most specimens; weakly developed anterolabial style and anteroflexus also potentially present; metaflexus and mesoflexus deep and directed backward; hypoflexus deep and opposite to paracone. M2 squared in shape, about 67% of M1 length; anteroloph reduced. M3 with well-defined hypoflexus, mesoflexus, and paraflexus, especially in young individuals. Anterocone of m1 sometimes divided by shallow groove but not by deep anteromedian flexid; m2 conserves all structures but in reduced state; m3 S-shaped. One specimen had 12 thoracic, 7 lumbar, and 24 caudal vertebrae (Steppan 1995).

DISTRIBUTION: *Calomys tener* occurs mainly in open vegetative formations in the Cerrado of central Brazil (e.g., grasslands, gallery forests, woodland savanna, or *cerradão*) and secondary vegetation of both the Amazon and the Atlantic Forest adjacent to the Cerrado, from central and eastern Brazil to Misiones province in eastern Paraguay and Santa Cruz department in southeastern Bolivia.

SELECTED LOCALITIES (Map 265): BOLIVIA: Santa Cruz, Santa Rosa de la Roca (Salazar-Bravo et al. 2001). BRAZIL: Bahia, Jaborandi (F. C. Almeida et al. 2007); Goiás, Serra de Mesa (Haag et al. 2007); Mato Grosso do Sul, Nova Alvorada do Sul (Cáceres et al. 2008); Minas Gerais, Viçosa (USNM 541497); Rio Grande do Sul,

Quintão (Haag et al. 2007); São Paulo, Campinas (F. C. Almeida et al. 2007); Tocantins, Aliança do Tocantins (Haag et al. 2007). PARAGUAY: Misiones, San Francisco, 36 km NE of San Ignacio (USNM 390144).

SUBSPECIES: *Calomys tener* is monotypic.

NATURAL HISTORY: The ecology of central Brazilian populations is relatively well known, but nothing is known about the biology of those from elsewhere in the species' range. In the Cerrado of the Distrito Federal, several short-term studies (about 1 year in length) revealed little to no seasonal population fluctuation but high levels of habitat specificity; abundance estimates were about five times higher in areas with a more developed secondary structure and higher proportion of woody plants than in areas fully dominated by grasses and herbs (R. Ribeiro and Marinho-Filho 2005; C. R. Rocha et al. 2011). In addition, the species is described as often caught around agricultural areas or in areas around buildings (Umetsu and Pardini 2007). Patterns of daily activity were reported by E. M. Vieira and Baumgarten (1995). Several aspects of the life history of the species were reported by Araripe et al. (2007) based on captive colonies. Litter size averaged 3.6 embryos, and the interval between reproductive bouts was about 22 days. Lactating females were field-trapped in November, and pregnant females (with four embryos each) were recorded in November and February (Dietz 1983). The diet is reported as that of an herbivore-omnivore, rich in plant material and fruits (V. N. Ramos and Facure 2009). In São Paulo state, *C. tener* may be infected with Araquara hantavirus (G. G. Figueiredo et al. 2010). *Calomys tener* is preyed upon by at least two species of owls (A. Bueno and Motta-Junior 2008; Magrini and Facure 2008) and Maned wolves (Dietz 1983). Mites parasitize this species in Brazil (Gettinger 1992a).

REMARKS: *Calomys tener* is currently viewed as monotypic, but limited karyotypic variation has been recorded. Bonvicino and Almeida (2000) identified a karyotype of $2n=66$ and $FN=66$ in five specimens from São Paulo state, Brazil, with an autosomal complement that included a medium-sized pair of metacentrics and 31 acrocentric pairs varying gradually in size. The X chromosome was a large subtelocentric and the Y chromosome a small acrocentric. Mattevi et al. (2005) reported a chromosomal complement for specimens from Rondônia state, Brazil, with $2n=64$ and $FN=64$. Furthermore, F. C. Almeida et al. (2007) identified reciprocal monophyletic mtDNA clades grouping specimens from Brazil versus those from Bolivia, one that may also be associated with different karyomorphs. Further work is needed to determine both the geographic concordance of the cytotypes and molecular clades as well as whether formal recognition of either might be warranted.

Map 265 Selected localities for *Calomys tener* (●). Contour line = 2,000m.

Several reports indicate the presence of *Calomys tener* in Pernambuco state in northeastern Brazil (e.g., J. A. Oliveira et al. 2003). An examination of skull morphology of samples of *C. tener* and *C. expulsus*, however, suggested that specimens from Pernambuco are best assigned to *C. expulsus* (Cordeiro-Estrela et al. 2006). Records of the species from Tarija department in southern Bolivia (S. Anderson 1997) are instead *Calomys musculus*.

Calomys tocantinsi Bonvicino, Lima, and Almeida, 2003
Tocantins Vesper Mouse, Rato-bolinha do Tocantins

SYNONYM:

Calomys tocantinsi Bonvicino, Lima, and Almeida, 2003:301; type locality "Brazil, Tocantins: Formoso do Araguaia (Rancho Beira Rio, 33 km SW, 11°47'S and 49°45'W)."

DESCRIPTION: Medium size (mean head and body 90 mm, mean greatest skull length 25 mm) with tails shorter than head and body. Dorsal pelage soft, brownish-gray, and darker middorsally from muzzle to base of tail. Sides of body slightly paler than back; ventral coloration clearly demarcated from sides and washed with white, individual hairs white-tipped, but gray at base. Tail bicolored, dark above, white below; hands and hindfeet covered with small white hairs; ungual tufts present. Ears small (ca. 17 mm in length), covered with small dark hairs; preauricular and postauricular patches present. Number of mammae unknown.

Skull robust; dorsum bowed in lateral profile; rostrum comparatively short although nasals cover incisors when

viewed from above; molar row long; palatal bridge broad (Bonvicino, Lima, and Almeida 2003). Interorbital region diverges posteriorly with sharp, somewhat beaded, edges. Nasals terminate anterior to premaxillofrontal suture. Zygomatic arches not extremely bowed, broader at their root and thus somewhat convergent anteriorly, and jugal small but robust. Zygomatic plates with concave anterior edges forming relatively well developed zygomatic spines. Incisive foramina long (ca. 80% of diastema length), extending posteriorly between procingula of both M1s; opening widest just behind premaxillomaxillary suture; premaxillary part of septum occupies about three-fourths of opening. Braincase round and somewhat globular, with weak lambdoid and temporal ridges. Upper incisors strongly opisthodont. Upper molars crested, with labial cusps in markedly opposite pattern, brachydont, and rather large with respect to skull. M1 tetralophodont, rectangular in outline; procingulum well developed with deep anteromedian flexus defining anterolingual and anterolabial conules; no trace of antero or protoloph; paraflexus and hypoflexus almost connect opposite each other at central mure; metaflexus deep and laterally oriented; posteroloph not quite evident. M2 and M3 both with well developed hypo- and metaflexus that connect opposite to each other at median mure, so both molars appear almost divided into two parts. M2 about 70% of M1, M3 about 65% of M2. Mandible deep and robust; capsular projection not very well defined, located ventral to coronoid process; coronoid process short, only slightly higher than condyloid process. No data available on axial skeleton or characters of soft anatomy.

DISTRIBUTION: *Calomys tocontinsi* occurs in central Brazil, in the upper basin of the Rio Araguaia, a tributary of the Rio Tocantins.

SELECTED LOCALITIES (Map 266): BRAZIL: Mato Grosso, Cocalinho (Fagundes et al. 2000), São José do Xingu (Bonvicino et al. 2010), Vila Rica (Fagundes et al. 2000); Tocantins, Formoso do Araguaia (type locality of *Calomys tocontinsi* Bonvicino, Lima, and Almeida), Lagoa da Confusão (Bonvicino et al. 2010).

SUBSPECIES: *Calomys tocontinsi* is monotypic.

NATURAL HISTORY: This species has been trapped in gallery forest at the ecotone between Amazonian rainforest and Cerrado vegetation, as well as in various formations of the Cerrado proper (Bonvicino, Lima, and Almeida 2003; Bezerra et al. 2009). It was reported to be an important prey item for the Barn Owl (*Tyto alba*; R. G. Rocha, Ferreira, Leite et al. 2011). Nine of 12 females captured in October and November in 2008 were reproductively active: three were pregnant, with five, seven, and 10 embryos each; five had open vaginas, and one was lactating (R. G. Rocha, Ferreira, Costa et al. 2011). No other data on ecology or behavior are available.

Map 266 Selected localities for *Calomys tocontinsi* (●).

REMARKS: The karyotype consists of a $2n=46$, $FN=66$ (J. F. S. Lima and Kasahara 2001; Bonvicino, Lima, and Almeida 2003), with an equal number of biarmed and uniarmed pairs of autosomes, a medium metacentric X, and a small acrocentric Y chromosome.

Calomys venustus (Thomas, 1894)

Córdoba Laucha

SYNONYMS:

Oryzomys (?) *venustus* Thomas, 1894b:359; type locality "Cosquin [= Cosquín], Cordova [= Córdoba], Argentina."

[*Hesperomys*] *venustus*: Thomas, 1916a:141; name combination.

Calomys venustus: Cabrera, 1961:481; first use of current name combination.

Calomys venustus venustus: Cabrera, 1961:481; name combination.

Calomys callosus: Hershkovitz, 1962:172; part; not *callosus* Rengger.

DESCRIPTION: Largest species in genus (greatest length of skull ca. 28.7 mm; Polop and Provencal 2000). Dorsal pelage soft and long, with dull brownish or yellowish gray colored hairs with black-lined tips; sides sandy buff (Thomas 1894b). Indistinct buffy line separates sides and venter; underparts pale gray with individual hairs gray

at base and white at tips. In many specimens, hairs of chin are white to base. Ears medium to large and almost always with buffy tuft at base and buffy postauricular spot, although it may not be as obvious as in other species. Hands and feet well haired and white. Tail shorter than head and body length, well haired, and distinctly bicolored (brown above and white on sides and below). Number of mammae varies from five to seven pairs.

Skull large; rostrum broad, especially in older individuals; interorbital region with strongly ridged edges that diverge posteriorly. Details of dentition are similar to other large lowland species; an anteromedian style frequently present and anteromedian flexus less well developed. No anteroflexus or anterolabial style visible. Elements of axial skeleton somewhat variable, with 12 or 13 thoracic, 7 lumbar, and 22 to 25 caudal vertebrae (Steppan 1995).

DISTRIBUTION: *Calomys venustus* occurs in central Argentina, in the provinces of Córdoba, San Luis, and Santiago del Estero. Because morphological characters in this and other species of large *Calomys* are often insufficient (or at least unsatisfactory) to differentiate among them, in the list of selected localities below I have only included individuals identified as *C. venustus* based on chromosomal and molecular and/or other biochemical data. It is possible that the species may be found in Buenos Aires province (e.g., F. Fernández et al. 2012).

SELECTED LOCALITIES (Map 267): ARGENTINA: Córdoba, Cosquín (type locality of *Oryzomys venustus* Thomas), Espinillo (Tiranti 1996a); San Luis, 3 km W of Hualtaran, Parque Provincial Sierra de las Quijadas (OMNH 35371), 1.3 km N and 5.8 km W of La Toija, Pampas de las Salinas (OMNH 35370), San Francisco del Monte de Oro (OMNH 35369), Papagayos, camp on left bank Río Papagayos (PY 13, specimen to be deposited at CNP); Santiago del Estero, Buena Vista, 15 km NE of Villa Ojo de Agua on Hwy 13 (Dragoo et al. 2003).

SUBSPECIES: *Calomys venustus* is monotypic.

NATURAL HISTORY: Several aspects of the ecology and natural history of the species in the agroecosystems of the pampas of central Argentina are relatively well known. *C. venustus* is abundant in areas with relatively high vegetation cover including crop field edges, roadsides, railway banks, and remnant areas of native vegetation (Priotto and Polop 1997; Polop and Sabbatini 1993). Population densities fluctuate seasonally, with a peak in May-June (Provencal and Polop 2008), and multiannually in response to the previous year's spring and summer rainfall and spring mean temperature (Andreo et al. 2009). Individuals are apparently capable of facultative torpor (Caviedes-Vidal et al. 1990).

Calomys venustus is reported to be an omnivore with a tendency to folivory in spring and autumn and to gra-

nivory in summer (Castellarini et al. 1998). Reproduction follows a cyclical seasonal pattern characterized by a period of repose and a variable length of the period of sexual activity between August to September and May to June, where three pregnancy peaks were observed (spring, summer, and late summer), each with a different average litter size (Polop et al. 2005). The species is sexually dimorphic (Polop and Provencal 2000); a promiscuous-polygynous mating system was suggested for the species (Priotto et al. 2002). Yunes et al. (1991) examined nesting and digging behavior in the species. There are no known predators reported in the literature and only one tick (*Amblyomma tigrinum*) is known to parasitize individuals (Nava et al. 2006; Guglielmo and Nava 2011). Additional aspects of the biology of the species are treated in Polop and Busch (2010).

REMARKS: The geographic and species limits of *C. venustus* as well as its relationship to other large-body *Calomys* from southern Bolivia and north-central Argentina require detailed study (see remarks under *Calomys boliviae*).

The karyotype of this species has a modal $2n=56$, $FN=66$, composed of six pairs of metacentric or submetacentric autosomes with the remainder acrocentric, a large submetacentric X, and a small subtelocentric Y (Tiranti 1996a; Lisanti et al. 1976; M. I. Ortiz et al. 2007). Lisanti et al. (1976) reported the presence of XO females.

Map 267 Selected localities for *Calomys venustus* (●). Contour line = 2,000 m.

Genus *Eligmodontia* F. Cuvier, 1837

*Cecilia Lanzone, Janet K. Braun, James L. Patton,
and Ulyses F. J. Pardiñas*

Members of the genus *Eligmodontia*, commonly known as gerbil mice, range from southern Peru southward to southernmost Argentina and mainland Chile. This area embraces arid and semi-arid habitats linked to the Andean landscape, from sea level in the southern part of the distribution to above 4,000m in the north. These rodents are highly desert adapted, and exhibit anatomical, physiological, and behavior specializations that enable their xeric existence (Mares 1977b; G. B. Diaz and Ojeda 1999; Giannoni et al. 2001).

The genus is polytypic, and a decades-long confused taxonomy is now becoming stabilized, primarily through the application of karyotypic and molecular sequence analyses. Nevertheless, several systematic issues remain unclear and others controversial. At the intra-generic level, species, or major groups of species, are associated only with weak statistical support in most molecular analyses, and form a polytomy at the base of the *Eligmodontia* tree (Mares et al. 2008; Lanzone, Ojeda et al. 2011; Spotorno et al. 2013). At the intra-tribal level, the position of *Eligmodontia* is also uncertain, appearing in some analyses near the base of phyllotine radiation but with very low statistical support (Steppan et al. 2007). Species of *Eligmodontia* also may be highly variable geographically in morphological, molecular, and others characters, and poorly delineated in morphology, even in multivariate morphometric space. Linear craniodental or even external variables of one species typically overlap in their extremes with those of others, and qualitative characters are also highly variable, especially with respect to specimen age. In this account, we seven species, but on-going studies are likely to expand this number as taxonomic boundaries become better delineated. Zambelli et al. (1992), Hilliard et al. (1997), Sikes et al. (1997), Lanzone, Ojeda, and Gallardo (2007) and Mares et al. (2008) documented sympatry without hybridization between *E. moreni* and *E. typus*, between *E. moreni* and *E. bolsonensis*, and between *E. typus* and *E. morgani*, supporting their respective status as species. The following generic description is, except as noted, largely compiled from information presented by Hershkovitz (1962), Steppan (1995), Lanzone, Ojeda, and Gallardo (2007), Mares et al. (2008) and Lanzone (2009). Mean external measurements provided for each species are compiled from measured samples reported by Sikes et al. (1997), Lanzone, Ojeda, and Gallardo (2007), Mares et al. (2008), Lanzone, Ojeda et al. (2011), and Spotorno et al. (2013), supplemented by nearly 270 specimens in the MVZ collections.

All species of *Eligmodontia* are externally similar small rodents without marked size differences among them. Ears are large, and the dorsal fur color ranges from yellowish to yellowish brown, grayish brown, or dark brown. Ventral hairs vary at their base from completely white to gray to black, but are always white at their tips. A more or less evident yellow to ochraceous lateral line demarcates the transition from dorsum to venter. Pelage around the mouth and behind the eyes is whitish. The tail is moderately haired, bicolored to unicolored (wholly pale), with or without a pencil, and with a length slightly less than or greater than that of the head and body. The hindfeet are elongated and digits I and V are subequal in length. Interdigital pads 2 to 4 are fused to form a hairy cushion, an external autapomorphic trait that easily distinguishes *Eligmodontia* from other similar-sized sigmodontine genera. Eight mammae (in four pairs) have been reported.

The skull is delicate, with a slender rostrum, and posteriorly divergent supraorbital margins that are neither beaded nor raised. Zygomatic arches are generally parallel-sided and little expanded. Zygomatic plates are straight or with slightly concave anterior margins. The bony palate extends beyond the posterior plane of the M3s. The incisive foramina are relatively long and extend at least to the anterior margins of M1s. The parapterygoid fossae are 1.5 to 2.5 times the mesopterygoid fossae width. An alisphenoid strut is present. The bony tubes of the bullae do not reach the posterior edge of the pterygoid processes. Both the stapedia foramen and posterior opening of the alisphenoid canal are large, and the squamosal-alisphenoid groove and sphenofrontal foramen are present, all characteristics of carotid circulation pattern 1 (of Voss 1988). On the mandible, the knob of the anterior masseteric ridge exceeds the dorsal edge of the diastema. The lower incisor root is contained in a capsular process posteroventral to the base of the sigmoid notch, and the coronoid process is short. Molar rows are parallel to slightly convergent posteriorly. The upper incisors are opisthodont and ungrooved. The molars are tetralophodont (lacking any trace of a mesoloph or mesolophid), brachyodont, and the crowns tuberculate and slightly crested. Cusps are approximately alternate in arrangement and mures are obliquely positioned. The anterocone of M1 has an anterior median fold that becomes weak or obsolete when worn. M1 has four roots; m3 is usually two-rooted (Pearson 1995).

Axial skeletal elements have counts of 13 ribs plus 19 thoracolumbar and 25–26 caudal vertebrae. The neural spine of the second cervical vertebra is enlarged into a distinct knob that does not overlap the third cervical vertebra. The second thoracic vertebra has a greatly elongated neural spine.

The stomach is unilocular and hemiglandular (Carleton 1973) and a gall bladder is present (Voss 1991). Male accessory secretory organs consist of two pairs of preputial glands, a single large lateral pair and a medium length lateral pair (Voss and Linzey 1981). The glans penis is complex, with a tridigitate bacular cartilage; the glans is short, without parotoid lobes, and is covered externally by large epidermal spines; the medial mound is longer than lateral mounds; the urethral flap is deeply bifurcate; and the bony baculum is long (equal to glans in length; Hooper and Musser 1964). Spotorno, Zuleta et al. (1998), G. B. Diaz and Ojeda (1999), and Al-kahtani et al. (2004) provided data on renal structure and function, which varies among species. The three species for which diet was studied (*E. typus*, *E. hirtipes*, and *E. moreni*) are considered omnivorous or herbivorous, with leaves the main food item consumed in all three (C. M. Campos, Ojeda et al. 2001; S. I. Silva 2005; Giannoni et al. 2005; Lanzone et al. 2012).

Fossils of *Eligmodontia* are uncommon but have been reported from Chubut, Argentina, from about 1,830 ybp (Pardiñas et al. 2000), the Holocene of Buenos Aires province, Argentina (Pardiñas et al. 2000; Pardiñas 2001), and southern Mendoza province, Argentina, from about 8,900 ybp (Neme et al. 2002). The earliest known material dates from the Middle Pleistocene (Ensenadense, about 1.8 mya) of Argentina (Pardiñas et al. 2002). Latest Pleistocene specimens from the Chilean side of Tierra del Fuego, recovered from the lower levels of the archaeological site Tres Arroyos 1, support the presence of this genus on that island (U. F. J. Pardiñas, unpubl. data), a noteworthy record since the genus today reaches its southern limit at the Straits of Magellan. Uquian deposits in Jujuy province, Argentina, dated at about 2.5 mya lack *Eligmodontia* but contain a morphologically close fossil genus (P. E. Ortiz, García López et al. 2012).

SYNONYMS:

Eligmodontia F. Cuvier, 1837:168; type species *Eligmodontia typus* F. Cuvier, by monotypy (page number incorrectly cited as 169 by Cabrera 1961:482).

Mus: Waterhouse, 1837:19; part (description of *elegans*); not *Mus* Linnaeus.

Mus (*Cal[omys]*): Waterhouse, 1837:21; part (listing of *elegans*); neither *Mus* Linnaeus, 1758, nor *Calomys* Waterhouse.

Elygmodovtia Wiegmann, 1838:388; incorrect subsequent spelling of *Eligmodontia* F. Cuvier.

Elimodon Wagner, 1841:125; incorrect subsequent spelling of *Eligmodontia* F. Cuvier (incorrectly written as *Elimodon* by Cabrera 1961:482).

Heligmodontia Agassiz, 1846:5; 136, 175; unjustified emendation of *Eligmodontia* F. Cuvier.

Hesperomys [(*Calomys*)]: Burmeister, 1879:220; part (listing of *elegans*); neither *Hesperomys* Waterhouse nor *Calomys* Waterhouse.

Eligmodon Thomas, 1896:307; part (see Remarks).

Phyllotis: Thomas, 1902c:225; part (description of *hirtipes*); not *Phyllotis* Waterhouse.

REMARKS: Cabrera (1961:482) listed Wagner (1841) as the author of *Eligmodon* in his generic synonymy of *Eligmodontia*, but Wagner (1841:125) spelled his name *Elimodon*, and in a simple list without further explanation. Rather, the spelling *Eligmodon* stems from Thomas (1896:307), who both coined the name for the species he therein described, *Eligmodon moreni*, and made no reference to Wagner's similar name. Moreover, in a footnote, Thomas (1896:307) explicitly equated his *Eligmodon* to the combined "*Calomys*, Waterh. (1837) nec Is. Geoff. (1830). *Eligmodontia*, F. Cuvier, 1837. *Hesperomys* Waterh., 1839," while stating in the text (p. 308) that "*Eligmodon Moreni* is most nearly allied to *E. elegans* Waterh. (*E. typus*, F. Cuv. [= the type species of *Eligmodontia*])." Thomas's *Eligmodon* is thus not exactly equivalent to Cuvier's *Eligmodontia*. In his review of rodent genera the following year, Thomas (1897a:1020) listed *Eligmodontia*, F. Cuv., with "*Calomys*, Waterh., nec Geoff. *Hesperomys* (s. s.), Waterh." as synonyms but did not list *Eligmodon*.

Cabrera (1961) recognized two species, *E. typus* (including *elegans* Waterhouse, *morgani* J. A. Allen, and *pamparam* Thomas as either valid subspecies or synonyms) and *E. puerulus* Philippi (with *moreni* Thomas, *hirtipes* Thomas, *marica* Thomas, *jacunda* Thomas, and *tarapacensis* Mann). Hershkovitz (1962) regarded each of these 10 nominal taxa then allocated to *Eligmodontia* as part of a single species, *E. typus* F. Cuvier, dividing that broadly distributed taxon into two subspecies: *E. typus typus* (with a southern range and including *elegans* Waterhouse, *morgani* Allen, and *pamparam* Thomas) and *E. typus puerulus* (with a northern range and including *puerulus* Philippi, *moreni* Thomas, *hirtipes* Thomas, *marica* Thomas, *jacunda* Thomas, and *tarapacensis* Mann). Braun (1993) listed six species (*hirtipes* Thomas, *marica* Thomas, *moreni* Thomas, *morgani* J. A. Allen, *puerulus* Philippi, and *typus* F. Cuvier), although her treatise was not directed to documenting species-level taxonomy. Recent revisionary research has overwhelmingly demonstrated greater species diversity than recognized by either Cabrera (1961) or Hershkovitz (1962), with karyotypic, mtDNA sequences, and morphological comparisons delineating the seven species we recognize herein (Ortells et al. 1989; Kelt et al. 1991; Zambelli et al. 1992; Spotorno et al. 1994, 2001; Hillyard et al. 1997; Sikes et al. 1997; Tiranti 1997; Spotorno, Zuleta et al. 1998; Lanzone and Ojeda 2005; Lanzone, Ojeda, and Gallardo 2007; Mares et al. 2008; Lanzone, Ojeda et al.

2011; M. C. Da Silva 2011; Spotorno et al. 2013). Tiranti (1997) offered a Plio-Pleistocene biogeographic interpretation to explain phyletic diversification within the genus. Spotorno et al. (1994, 2001) suggested that both genetic and geographical factors have played a complementary role in the process of speciation and divergence in *Eligmodontia*.

We have excluded some of the natural history literature from the accounts because we are unable to verify the species identity given. And, we preferentially cite records of specimens in the list of selected localities for each species for which either, or both, karyotype and mtDNA sequences have been determined.

KEY TO THE SPECIES OF *ELIGMODONTIA*:

1. Tail proportionally short (<100% head and body length) 2
- 1'. Tail proportionally long (>110% head and body length) 5
2. Dorsal color overall yellowish brown; venter immaculate white; $2n=50$, FN=48 3
- 2'. Dorsal color overall grayish brown; venter with variable color at the based (white, gray, or black); $2n=31-37$, FN=32 or 48 4
3. Body size large (mean head and body length >90 mm); sharply distinct fulvous lateral line; short tail tuft (2–4 mm); zygomatic arches slightly divergent posteriorly; northern Puna *Eligmodontia hirtipes*
- 3'. Body size very small (mean head and body length ~70 mm); indistinct fulvous lateral line; no tail tuft; zygomatic arches parallel; southwestern of the Atacama Desert, northern Chile *Eligmodontia dunaris*
4. Body size medium (mean head and body length >85 mm); venter with gray or black hairs at the base; tail strongly bicolored; tail tuft short; ear length short (mean length ~16 mm); anterior border of mesopterygoid fossa squared, often with median spine; $2n=32-34$, FN=32; Patagonian steppe. *Eligmodontia morgani*
- 4'. Body size small (mean head and body length <85 mm); venter with white, gray or black hairs at the base; tail generally weakly bicolored; tail tuft short; ear length medium (mean length ~18 mm); anterior border of mesopterygoid fossa pointed; $2n=31-37$, FN=48; southern Puna *Eligmodontia puerulus*
5. Tail tuft lacking, or very short; tail unicolored or weakly bicolored; ear short (length <18 mm); bullae uninflated, interbullar distance wide, petrotympanic fossae widely open, bullar tube elongated, stapedial spine protuberant; $2n=44$, FN=44. 6
- 5'. Tail tuft long (>5 mm); tail bicolored; ear long (generally length >19 mm); bullae inflated, interbullar distance narrow, petrotympanic fossae nearly closed, bullar tube

short, stapedial spine very short; $2n=52$, FN=50

. *Eligmodontia moreni*

6. Fur long, lax; venter immaculate white; X chromosome uniarmed; anterior border of mesopterygoid fossa rounded; anterior border of maxilla with developed tubercles; northern Monte Desert

. *Eligmodontia bolsonensis*

- 6'. Fur short; venter white, with gray or white-based hairs; X chromosome biarmed; anterior border of mesopterygoid fossa squared, sometimes with median spine; anterior border of maxilla with tubercles slightly developed or absent; southern and central Monte Desert and Patagonian steppe *Eligmodontia typus*

Eligmodontia bolsonensis Mares, Braun, Coyner, and van den Bussche, 2008

Bolsón Gerbil Mouse, Bolsón Laucha

SYNONYM:

Eligmodontia bolsonensis Mares, Braun, Coyner, and van den Bussche, 2008:15; type locality "ARGENTINA: Catamarca Province: Pomán: Establecimiento Río Blanco, 28 km S, 13.3 m W Andalgalá 27°51'01"S, 66°18'17"W."

DESCRIPTION: Small, with mean head and body length 82.1 mm (range 73–94 mm), tail length 92.3 mm (74–105 mm), hindfoot length 23.5 mm (21–26 mm), and ear length 17.1 mm (15–19 mm). Tail somewhat longer than head and body, averaging about 113%. Pelage long and lax, very pale yellowish brown above with light ochraceous buff hairs distally but grayish proximally, and dark guard hairs providing slightly darker overall appearance; under parts immaculate, with hairs white to base; transition from dorsum to venter well defined, delineated by slightly brighter ochraceous buff lateral line; nose and mouth areas surrounded by white. Whitish patches behind eyes, and ears with moderately developed pale postauricular patches. Both forefeet and hindfeet covered with whitish hairs, soles only slightly covered with hairs. Tail unicolored, pale white above and below, and without terminal pencil of hairs. Skull delicate; nasals do not extend beyond premaxillofrontal suture; and zygomatic arches delicate, parallel, and little expanded; anterior border of zygomatic plates slightly concave; auditory bullae moderately developed, wider than long (averaging 4.89 mm in width, 4.16 in length) and with long bullar tubes, protuberant stapedial spines, and wide petrotympanic fissures; maxillary tooththrow length relatively short for genus, averaging 3.88 mm. Anterior border of maxilla with developed and rounded tubercles. M1 with anteromedian flexus slightly marked or absent; anterolingual style absent or slightly developed, and mesostyle absent; no contact between labial (hypoflexus) and secondary lingual fold (metaflexus); M3 with anteromedian flexid absent; posterolophid pres-

ent. In most dimensions, *E. bolsonensis* quite similar to means and ranges of *E. typus* but smaller than those of *E. moreni*. Lanzone, Ojeda, and Gallardo (2007) and Mares et al. (2008) provided mensural comparisons between *E. bolsonensis* (karyotype 1 sample in Lanzone, Ojeda, and Gallardo [2007]), *E. moreni* (karyotype 2 sample in the same paper), and *E. typus*.

DISTRIBUTION: *Eligmodontia bolsonensis* is known from Catamarca and Salta provinces, Argentina, in the area north and west of the Sierra de Ambato and Sierra de Manchao, at elevations largely above 1,800m, with one locality as low as 700m. It is sympatric with *E. moreni* at localities in Catamarca province, and with *E. puerulus* also at a locality in Catamarca province (Lanzone, Ojeda, and Gallardo 2007; Mares et al. 2008). However, *E. puerulus* and *E. moreni* at some localities of Catamarca are indistinguishable in cytochrome-*b* mtDNA (Lanzone, Ojeda et al. 2011); as this was the character used by Mares et al. (2008) to differentiate the two taxa, some of their data need further confirmation.

SELECTED LOCALITIES (Map 268): ARGENTINA: Catamarca, Agua de Dionisio (Mares et al. 2008), Campo Arenal, Los Nacimientos (Lanzone, Ojeda, and Gallardo 2007); 5.2 km S of El Bolsón (Mares et al. 2008), 21 km SW of El Desmonte (Mares et al. 2008), 1.5 km S of El Peñón (Mares et al. 2008), Establecimiento Río Blanco (type locality of *Eligmodontia bolsonensis* Mares, Braun, Coyner, and van den Bussche); Salta, Cafayate (Lanzone, Ojeda, and Gallardo 2007).

SUBSPECIES: *Eligmodontia bolsonensis* is monotypic.

NATURAL HISTORY: Little is known about the natural history. Mares et al. (2008) reported that reproductively active individuals were captured in the spring months of October and November with inactive individuals sampled in March and September. Pregnant females contained embryo counts varying from four to seven. General observations indicated that areas where *E. bolsonensis* and *E. moreni* were sympatric, the former preferred soft, sandy soils with the latter more common on dense clay and gravelly soils; in the absence of *E. bolsonensis*, *E. moreni* occupied sandy substrates (Mares et al. 2008). The universality of these observations requires more explicit study of habitat segregation or preferences.

REMARKS: This species is weakly separable morphologically from *E. typus*, which generally occurs at lower elevations and has a more southern distribution. Apportionment of mtDNA cytochrome-*b* sequences of the two species is equivocal, as these sort into reciprocally monophyletic units but with limited support and low molecular distances (Lanzone, Ojeda and Gallardo, 2007; Mares et al. 2008) or those of *E. bolsonensis* fall within the variation presented by a broader sampling of *E. typus* (E. P. Lessa et al. 2010). Lanzone, Ojeda, and Gallardo (2007)

reported a $2n=44$, $FN=44$, karyotype with an acrocentric X chromosome for specimens from the Salar de Pipanaco, Campo Arenal (both in Catamarca province), and Cafayate (Salta province), which they referred to as “*Eligmodontia* 1.” Mares et al. (2008) regarded these specimens to represent *E. bolsonensis*. Lanzone, Ojeda, and Gallardo (2007) regarded the acrocentric X chromosome to be the ancestral condition for the genus because by mtDNA cytochrome-*b* sequence analysis this karyotype was sister to the $2n=44$, $FN=44$, biarmed X-chromosome karyotype characteristic of *E. typus*. These authors suggested that *marica* Thomas was the appropriate name to apply to this taxon because the type locality of that taxon (Chumbicha, Catamarca province) was only 80 km from the Salar de Pipanaco. DNA sequences, however, place specimens from Chumbicha within the *E. typus* clade and not with *E. bolsonensis* (Mares et al. 2008; E. P. Lessa et al. 2010). Recently, M. C. Da Silva (2011) reported cytochrome-*b* haplotypes she referred to *E. bolsonensis* from two localities in Chubut province, sympatric with *E. typus*. Hence, either *E. bolsonensis* has a larger distribution than previously suspected or cytochrome-*b* haplotypes are not always optimal markers to distinguish the two species. Because the specimens of *E. bolsonensis* from Chubut has not been examined karyotypically or morphologically as yet, neither locality is included in the list of selected localities for this species.

Map 268 Selected localities for *Eligmodontia bolsonensis* (●). Contour line = 2,000m.

Teta, D'Elía, and Pardiñas (2010) indicated that *hypogaeus* Cabrera was a junior synonym of *E. moreni*, and noted that Mares et al. (2008) assigned two specimens to *E. bolsonensis* that Massoia (1976a) had previously stated were indistinguishable from Cabrera's holotype. Teta, D'Elía, and Pardiñas (2010) thus emphasized the need to consider all available names when making taxonomic and nomenclatural decisions, including the description of presumptively new species. Although *E. bolsonensis* shares with *E. moreni* an immaculate white venter with hairs white to their base, the two differ in most external and craniodental dimensions, have distinctly different karyotypes, and belong to markedly divergent mtDNA clades (Mares et al. 2008; Lanzone, Ojeda et al. 2011).

Eligmodontia dunaris Spotorno, Zuleta, Walker, Manriquez, Valladares, and Marín, 2013

Dune Gerbil Mouse, Dune Laucha

SYNONYM:

Eligmodontia dunaris Spotorno, Zuleta, Walker, Manriquez, Valladares, and Marín, 2013:385; type locality "CHILE: Coquimbo Region: comuna La Higuera, Sector Playa Los Choros (29°14'S; 71°18'W, 15 masl), 55 km N of La Serena city."

DESCRIPTION: Smallest species in genus, mean head and body length 70.6 mm (range: 64–77 mm), tail length 67.1 mm (57–76 mm), hindfoot length 18.9 mm (17–20 mm), and ear length 13.5 mm (10–18 mm). Tail shorter than head and body length (about 95%); both ears and hindfeet absolutely shortest relative to other species. Dorsal color very pale yellowish brownish gray; head with slightly darkish band extending from nose to between ears; ears with whitish preauricular tufts reaching proximal part of pinna; venter immaculately white, sharply demarcated from dorsum with imperceptible fulvous lateral line; tail whitish above and below with slight differentiation; tail lacks a terminal tuft; hindfeet white above; hypothenar pad absent. Skull delicate; nasals not extending beyond premaxillary-frontal suture; zygomatic arches parallel; interorbital region with slightly divergent edges; anterior border of zygomatic plates slightly concave; auditory bullae relatively uninflated with wide interbullar distance, elongated bony tubes (stated to be short in the original description, but photographs of holotype reveal tubes equivalent in length to those of *E. bolsonensis* [Lanzone, Ojeda, and Gallardo 2007; Mares et al. 2008], *E. typus* [Lanzone, Ojeda, and Gallardo 2007], and *E. morgani* [Lanzone 2009]), widely open petrotympanic fissures, and thinly protuberant stapedial spines; M1 lacking anteromedian flexus.

DISTRIBUTION: This species is restricted to semidesert habitats south of the Atacama Desert in northern Chile,

occurring in coastal dunes in Coquimbo Region north to the central plains of Atacama Region.

SELECTED LOCALITIES (Map 269): CHILE: Atacama, Bahia Salado, 55 km S of Caldera (Spotorno et al. 2013), 45 km S of Copiapó (Spotorno et al. 2013), Playa Rodillo, 1.5 km N of Caldera (Spotorno et al. 2013); Coquimbo, comuna La Higuera, Sector Playa Los Choros (type locality of *Eligmodontia dunaris* Spotorno et al. 2013).

SUBSPECIES: *Eligmodontia dunaris* is monotypic.

NATURAL HISTORY: The known habitat is the sand dune belt and central plains along the arid coast of northern Chile. Plant cover is xerophytic low matorral, with sparsely distributed small shrubs and trees, semidry most of the year but with erratic rains resulting from El Niño–Southern Oscillation (ENSO) events. Reproductively active individuals were caught in June, September, and February to March; litter size varied between two and five. Stomach contents of one individual included plant parts, insects, and seeds, but a more representative sample of the species and broader spatial and temporal studies are needed to document a general dietary strategy. The small body size was hypothesized to be an adaptation to poor-quality habitat, in which the construction of sandy galleries and possible torpor were hypothesized to be energy saving strategies. Population density was low but considered opportunistic in response to unpredictable rains resulting from local El Niño–Southern Oscillation (ENSO) episodes (data from Spotorno et al. 2013).

Map 269 Selected localities for *Eligmodontia dunaris* (○) and *Eligmodontia moreni* (●). Contour line = 2,000 m.

REMARKS: The karyotype is similar to that of *E. hirtipes*, with $2n = 50$, $FN = 48$, and both X and Y chromosomes uniarmed. Relationships are uncertain, as *E. dunaris* forms a weakly supported association with *E. puerulus* and *E. moreni*, not with the karyotypically similar *E. hirtipes*, in mtDNA cytochrome-*b* sequence analysis. This species can be distinguished from geographically adjacent *E. hirtipes* and *E. puerulus* by its much smaller size, paler dorsal coloration, shorter hindfoot, and much smaller bullae (Spotorno et al. 2013). However, as is true for all species in the genus, the largest specimens *E. dunaris* overlap in external and cranial dimensions with the smallest samples of *E. puerulus* and *E. hirtipes* (Lanzone, Ojeda et al. 2011; Spotorno et al. 2013).

Eligmodontia hirtipes (Thomas, 1902)

Hairy-footed Gerbil Mouse, Hairy-footed Laucha

SYNONYMS:

Phyllotis hirtipes Thomas, 1902c:225; type locality "Challapata, 3750 m," Oruro, Bolivia.

Eligmodontia hirtipes: Thomas, 1916a:141; first use of current name combination.

Eligmodontia hirtipes hirtipes: Gyldenstolpe, 1932:71; name combination.

Eligmodontia puerulus hirtipes: Mann, 1945:78; name combination.

Eligmodontia puerulus tarapacensis Mann, 1945:75; type locality "Churiguaya," Arica y Parinacota, Chile.

DESCRIPTION: Characterized by Thomas (1902c) as small, but larger than other species in genus, with mean head and body length 94.7 mm (range: 87–103 mm), tail length 89.4 mm (82–100 mm), hindfoot length 25.7 mm (24–27 mm), and ear length 18.7 mm (18–20 mm; $N = 25$, specimens from Peru in MVZ collection). Tail always shorter than head and body length (average 94.6%). Fur long, soft, and lax. Dorsal color yellowish brown to sandy buff with gray-based hairs providing darker streaking on back; very distinct buffy lateral line present in adults but less well-developed in younger individuals; undersurface generally immaculate white with hairs white to base; some individuals have very narrow gray-based fur, which typically does not show through from below. Tail weakly bicolored, slightly darker above and paler below, with some individuals having rather dark dorsal stripe and others nearly unicolored; short pencil of 2–4 mm long hairs terminates tail in most, but not all, specimens. Forefeet and hindfeet dirty white above and well clothed with stiff whitish hairs on plantar surfaces. Ears dark brown on external surface; inner surfaces clothed with paler, somewhat buffy hairs; small, pale subauricular patches present on most specimens. Skull unremarkable but slightly larger than most species (mean greatest skull length 25.7 mm, range: 24.3–26.5 mm); auditory bullae notably

small (mean length 18.8% that of skull), interbullar distance thus wide, bullar tubes elongated, petrotympanic fissures wide, and stapedia spines protuberant; anteromedian flexus absent on M1 of adults, weakly visible in very young individuals.

DISTRIBUTION: Geographic limits of *E. hirtipes* are unclear, especially with respect to *E. puerulus*. As currently understood, this species occupies dry Puna habitats of the Altiplano of northern Chile, western and southwestern Bolivia, and southern Peru generally at elevations above 3,000 m. Apparently, the range of *E. hirtipes* does not overlap with those of any other species as currently understood, but more samples are needed in the possible contact zones among *E. hirtipes*, *E. puerulus*, and *E. dunaris* to delimit these geographic ranges.

SELECTED LOCALITIES (Map 270): BOLIVIA: La Paz, 8.5 km W of San Andrés de Machaca (S. Anderson 1997); Oruro, 37 km SW of Camino de Oruro, 3.5 km NE of Toledo (S. Anderson 1997), Challapata (type locality of *Phyllotis hirtipes* Thomas), Estancia Agua Rica, 22 km S and 40 km E of Sajama (S. Anderson 1997); Potosí, 2 km E of ENDE camp, Laguna Colorada (Kelt et al. 1991), 1 mi E of Uyni (MVZ 119973), 5 mi N of Villazón (MVZ 119974). CHILE: Arica y Parinacota (Choquelimpie, 114 km NE of Arica (Spotorno et al. 1994); Tarapacá, Suricayo, Colchane (Mares et al. 2008). PERU: Puno, Mazocruz (MVZ 115772), Pampa de Ancomarca, 123 km W of Ilave (MV 115774); Tacna, 5 km E of Lago Suche (MVZ 115771), 2 km N of Nevado Livine (MVZ 115776).

SUBSPECIES: We treat *Eligmodontia hirtipes* as monotypic.

NATURAL HISTORY: This species is nocturnal (Pearson 1951) and terrestrial. In Peru, *E. hirtipes* occurs in sandy areas where tola (*Lepidophyllum* and *Baccharis* [Asteraceae]) is present with scattered clumps of bunch grass (Pearson 1951). Pearson and Ralph (1978) found it the most abundant small mammal in the tola habitat where individuals reached densities exceeding 1/ha and had an average home range of 92 m. S. Anderson (1997) captured a pregnant female with four embryos in Bolivia in May; little to no reproductive activity was found in July and August in Peru (Pearson 1951). S. I. Silva (2005), in a review of trophic position of small mammals in Chile, described *E. hirtipes* (under the name *E. typus*) as herbivorous.

REMARKS: Previously considered a synonym of *Eligmodontia typus puerulus* (Hershkovitz 1962) or *E. puerulus* (Musser and Carleton 2005), we recognize *E. hirtipes* as a valid species based on its karyotype and well-supported monophyly of mtDNA cytochrome-*b* sequences (Lanzone, Ojeda, and Gallardo 2007; Lanzone, Ojeda et al. 2011; Mares et al. 2008; Spotorno et al. 2013). This species has

a $2n=50$, $FN=48$, karyotype with an acrocentric X chromosome and small biarmed Y (Pearson and Patton 1976 [reported as *E. typus*]; Ortells et al. 1989; Kelt et al. 1991; and Spotorno et al. 1994 [each reported as *E. puerulus*]), similar in all characteristics to that of *E. dunaris* (Spotorno et al. 2013).

Musser and Carleton (2005) listed *tarapacensis* Mann as a synonym of *E. puerulus*, but we align this name with *E. hirtipes*, in part because the type locality is on the border with Bolivia and near that with Peru. Mann's (1945) description of *tarapacensis* lacks sufficient detail, but he did note that the tail of his new form was only weakly bicolored, a characteristic of *E. hirtipes*, while contrasting it with the dark dorsal stripe of most *E. puerulus* specimens. Nevertheless, we caution that examination of the holotype and/or determination of the karyotype of topotypes is necessary to verify our hypothesis.

Lanzone and Ojeda (2005) mapped the purported range of this species but clearly indicated its questionable limits in Bolivia and Chile. S. Anderson (1997) included all Bolivian specimens in his concept of *E. puerulus*, but it is unclear whether these records are of *E. hirtipes* or whether both species occur in that country. Three specimens in the MVZ collection from Potosí department (MVZ 199771, 199772, 199774) are smaller in body size than Peruvian *E. hirtipes* but have the immaculate white venter characteristic of this species.

Map 270 Selected localities for *Eligmodontia hirtipes* (●). Contour line = 2,000 m.

Eligmodontia moreni (Thomas, 1896)

Monte Gerbil Mouse, Monte Laucha

SYNONYMS:

Eligmodon Moreni Thomas, 1896:307; type locality "Chilecito, Prov. Rioja [= La Rioja], Argentina, alt. 1200 metres."

Eligmodontia moreni: Thomas, 1916a:141; first use of current name combination.

Graomys hypogaeus Cabrera, 1934:124; type locality "Corral Quemado, Catamarca (2250 m. de alt.)," Argentina.

Eligmodontia morenoi Yepes, 1935a:226; incorrect subsequent spelling of *Eligmodon moreni* Thomas.

Eligmodontia typus moreni: Cabrera, 1961:483; name combination.

DESCRIPTION: Body small but tail absolutely and proportionately longest in genus; mean head and body length 79.4 mm (range: 69–89 mm), mean tail length 106.2 mm (range: 92–125 mm), mean hindfoot length 24.4 mm (range: 22.1–27 mm), and mean ear length 19.2 mm (range: 16–21.5 mm). Tail much longer than head and body length (about 134% greater). Fur long and lax. Dorsal color either brownish (Lanzone, Ojeda, and Gallardo 2007) or coarsely mixed fawn and brown (Thomas 1896); under parts white, with hairs white to base, although Thomas (1896) noted immature specimens with gray-based hairs; junction of dorsal and ventral colors marked by yellowish lateral line. Tail markedly bicolored and moderately haired, dark above and white below and on sides; terminal pencil of hairs extends 5 mm or longer. Area around mouth white; white postocular patch present. Hindfeet notably large; upper surfaces of forefeet and hindfeet clothed in silvery white hairs, and soles likewise covered by short hairs. Skull with interorbital region slightly divergent posteriorly and with edges angled for approximately half of length and then expanded to their anterior margins; zygomatic arches parallel or slightly divergent posteriorly, narrow, and slender; deep zygomatic notches with oval internal borders; anterior border of maxillae with developed and rounded tubercles; anterior margin of mesopterygoid fossa rounded; small maxillary foramina located at anterior half of M1; teardrop-shaped foramen ovale; pterygoid plates expanded; auditory bullae inflated, with short to very short bullar tubes, distinctly narrowed petrotympanic fissures, and very short but expanded at the base stapedial spines; m1 with anteromedian flexus marked to slightly marked; anterolingual and mesostyle present; m2 with labial fold (hypoflexus) in contact with secondary lingual fold (metaflexus); m3 with two conspicuous folds; M1 with weakly developed or absent anteromedian flexus; M2 with first primary fold well developed; M3 with lingual fold present; condyloid process narrower than angular process.

This species is readily characterized by its long bicolored tail and distinctive structure of the auditory bullae, in which bullar inflation occludes the petrotympanic fissures, the interbullar distance is greatly reduced, and the stapedial spine is narrowed but with a robust base. Lanzone, Ojeda, and Gallardo (2007) compared craniodental measurements of *E. moreni*, *E. bolsonensis* (as *E. sp. 1*), and *E. typus*, as did Mares et al. (2008); Lanzone, Ojeda et al. (2011) compared *E. moreni* with *E. puerulus*. The latter authors also studied the morphometry of two samples of *E. moreni* from Catamarca and Mendoza provinces, recording significant differences in most external and cranial measures between them.

DISTRIBUTION: *Eligmodontia moreni* occurs in Argentina from Salta province south to Mendoza province along the eastern slopes of the Andes in Monte Desert and pre-Puna habitats at elevations from about 500 to 3,900 m. However, as mentioned below, specimens assigned by morphology to both *E. moreni* and *E. puerulus* from one high-elevation locality in Catamarca province share the same mtDNA cytochrome-*b* sequences (Lanzone, Ojeda et al. 2011). Hence, the actual presence of *E. moreni* at high elevation in Salta needs further confirmation. Lanzone, Ojeda, and Gallardo (2007) and Mares et al. (2008) recorded sympatry between *E. moreni* and *E. bolsonensis* in Catamarca province and between *E. moreni* and *E. typus* in both Mendoza and San Juan provinces.

SELECTED LOCALITIES (Map 269): ARGENTINA: Catamarca, Corral Quemado (type locality of *Graomys hypogaeus* Cabrera), 5.2 km S of El Bolsón (Mares et al. 2008), 21 km SW of El Desmonte (Mares et al. 2008), 1.5 km S of El Peñón (Mares et al. 2008); La Rioja, Chilecito (type locality of *Eligmodon Moreni* Thomas), 14.5 km N of Villa Unión (Mares et al. 2008); Mendoza, Malargüe, 70 km NE of Barrancas (Mares et al. 2008), Reserva Telteca (Lanzone, Ojeda et al. 2011), ca. 7 km S of Uspallata (Mares et al. 2008); San Juan, Estancia Leoncito, 1 km W of Observatorio Astronómico (Mares et al. 2008), Ischigualasto, Valle Fértil (Lanzone, Ojeda, and Gallardo 2007).

SUBSPECIES: *Eligmodontia moreni* is monotypic.

NATURAL HISTORY: *Eligmodontia moreni* has been collected in sandy areas with scattered, sparse vegetation in the Monte Desert and pre-Puna of Argentina. Reproduction occurs in the fall (March, April, and May) and spring (October and November). Unpublished observations indicate that this species is nocturnal and terrestrial. Gonnet and Ojeda (1998) examined habitat use of a small mammal community at a midelevation locality in northwestern Mendoza province, Argentina; although identified as *E. typus*, it is probable that the species the studied was *E. moreni*. Traba et al. (2010) described macrohabitat and microhabitat selection by *E. moreni* during both wet and dry seasons, regarding the species as a “fine-grained

generalist” because of a broad ecological amplitude that spanned creosote bush scrub, mesquite woodland, columnar cactus slopes, barrens, chical, and saltbush habitats. The diet of *E. moreni* during a dry season in a hyperarid region of the Monte desert was omnivorous with a tendency to herbivory. Most food items were plant leaves, followed by arthropods, with seeds the least consumed. However, there was high interindividual variability in the proportion of these categories, which suggests high flexibility in the dietary strategy of this species (Lanzone et al. 2012).

REMARKS: Thomas (1896) regarded *E. moreni* to be most closely allied to *E. elegans* Waterhouse (= *E. typus* F. Cuvier). Lanzone, Ojeda, and Gallardo (2007) and Mares et al. (2008) provided limited mtDNA cytochrome-*b* sequence support for *E. moreni* and *E. puerulus* as sister species. In a more geographically expansive analysis, however, Lanzone, Ojeda et al. (2011) failed to recover reciprocal monophyly in cytochrome-*b* haplotypes from specimens assigned to both species by karyotype and morphology. Hershkovitz (1962) recognized the link between *moreni* and *puerulus*, listing the latter as a subspecies of his *E. typus* with *moreni* Thomas as a synonym. Cabrera (1961), on the other hand, regarded *moreni* as a valid subspecies of *E. typus*. The species status of *E. moreni* relative to *E. puerulus* is strongly supported by the former’s unique $2n=52$, $FN=50$, karyotype (karyotype 2 in Lanzone, Ojeda, and Gallardo 2007) and by multivariate morphometric analyses (Lanzone, Ojeda, and Gallardo 2007; Lanzone, Ojeda et al. 2011). The lack of reciprocal monophyly in cytochrome-*b* sequences is thus presumably due to recent splitting of both *moreni* and *puerulus* from a common ancestor, but this hypothesis requires further study. Spotorno et al. (1994) initially assigned the $2n=34$, $NF=48$, karyotype to *E. moreni*, but later Spotorno and colleagues examined specimens from the type locality of *E. puerulus* and reassigned this cytotype to that species (Spotorno, Zuleta et al. 1998; Spotorno et al. 2001; Lanzone and Ojeda 2005; Lanzone, Ojeda et al. 2011). Lanzone, Ojeda, and Gallardo (2007) documented qualitative and quantitative cranial character differences between *E. moreni* (their karyotype 2 sample) and both *E. bolsonensis* (their karyotype 1 sample) and *E. typus*.

Cabrera (1961) referred *Graomys hypogaeus* Cabrera (1934) as a full synonym of *Phyllotis griseoflavus medius*, Massoia (1976a) placed it in synonymy under *E. typus sensu lato*, and D. F. Williams and Mares (1978) questioned whether the type was a composite specimen. Teta, D’Elía, and Pardiñas (2010), however, examined the holotype and concluded that *hypogaeus* Cabrera was a junior synonym of the currently restricted concept of *E. moreni*.

Eligmodontia morgani J. A. Allen, 1901

Morgan's Gerbil Mouse, Western Patagonian Laucha

SYNONYMS:

Eligmodontia morgani J. A. Allen, 1901c:409; type locality "Arroya [*sic*] Else, Patagonia"; J. A. Allen (1905:53) referred to this vague reference as "Balsaltic Cañons, 50 miles southeast of Lake Buenos Aires, Patagonia ('Arroyo Else' on the labels and in the original description)." There is no "Arroyo Else" in Patagonia; according to the notes and itinerary followed by J. B. Hatcher and A. E. Colburn (see Hatcher 1903); the type specimen was collected near the confluence of the Río Ecker and Río Pinturas, about 47°07'S and 70°51'W, Santa Cruz, Argentina.

Eligmodontia elegans morgani: Osgood, 1943b:199; name combination.

Eligmodontia typus morgani: Cabrera, 1961:484; name combination.

DESCRIPTION: One of largest species of genus with regard to length of head and body, with mean head and body length 86.4 mm (range: 75–90 mm), tail length 78.9 mm (range: 63–99 mm), hindfoot length 22.5 mm (range: 21–25 mm), and ear length 16.2 mm (range: 14–19 mm; data from Sikes et al. 1997 and MVZ collection). Tail usually shorter than head and body length (about 92%); bicolored with narrow dark dorsal stripe; terminating in short pencil about 2 mm long. Dorsal fur dark to grayish brown with yellowish mottled; intensity of yellow increases laterally and caudally, but most specimens darker relative to those of other species. Dorsum separated from whitish venter by narrow ochraceous lateral line; venter with gray to black bases of hairs visible, tips white. Ears dark brown and noticeably short (about <20% of head and body length), without evidence of preauricular or postauricular patches of paler color. J. A. Allen (1901c:409) remarked that pelage was "very full, long, and soft," but specimens in the MVZ collections from Río Negro province have noticeably shorter dorsal fur than other species. Dorsal surfaces of forefeet and hindfeet clothed in short, white hairs; plantar surfaces sparsely covered by short hairs. Cranially similar to *E. typus*, but with longer incisive foramina (mean 5.25 mm, range: 4.7–6.0 mm). The nasals of *E. morgani* longest among all species in genus (mean 10.2 mm); zygomatic arches rounded when viewed from above, but delicate, thinner in middle and posterior parts relative to other species; anterolateral border of zygomatic plates slightly concave; braincase small; tubercles on anterior border of maxillae poor developed or absent; parapterygoid plates long, wide, and more elevated in lateral portion than in others species; mesopterygoid fossa relatively long and narrow, with median spine on anterior margin; auditory bullae uninflated (mean length × width: 3.61 × 3.75 mm), with elongated bony tubes terminating in serrations of which

one projection longer than others, very thin protuberant stapedial spines without conspicuous base, and wide petrotympanic fissures; maxillary toothrow length notably short (mean 3.60, range: 3.3–3.9; Sikes et al. 1997; Lanzoni 2009); M1 with anteromedian flexus variable present; mandible with wide angular process with an internal concavity, and condyloid process narrow but longer than in other species.

DISTRIBUTION: *Eligmodontia morgani* occurs in the Patagonian steppe of southern Chile and southern Argentina in Mendoza, Neuquén, Río Negro, Chubut, and Santa Cruz provinces, at moderate to high elevations along the slopes and eastern base of the Andes. This species is sympatric with *E. typus* at multiple localities from Mendoza south to Santa Cruz province where the Patagonian steppe interfaces with Monte or coastal desert habitats (Zambelli et al. 1992; Hillyard et al. 1997; Sikes et al. 1997; Mares et al. 2008; M. C. Da Silva 2011).

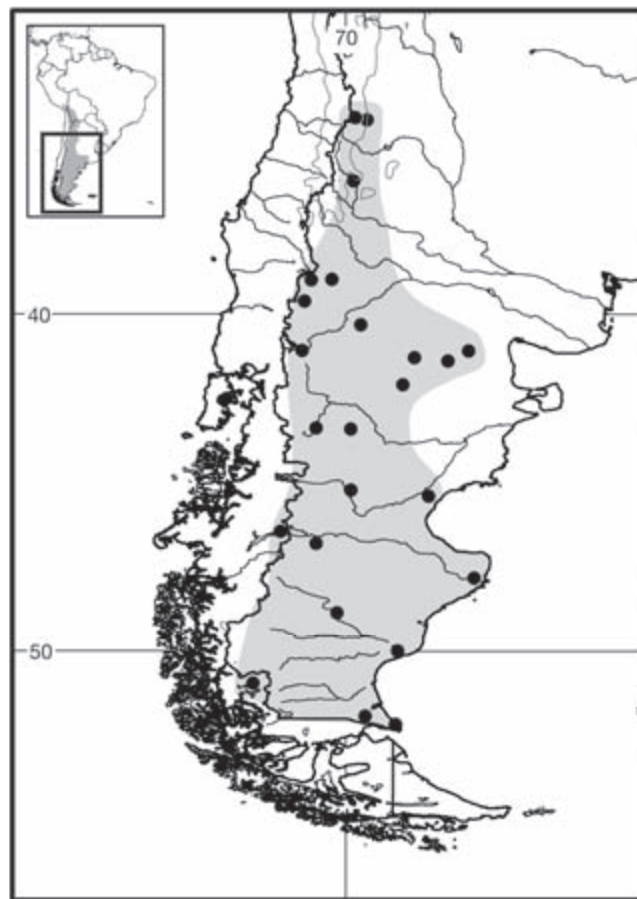

SELECTED LOCALITIES (Map 271): ARGENTINA: Chubut, Estancia La Escondida (Hillyard et al. 1997), Estancia Los Manantiales (E. P. Lessa et al. 2010), Estancia Talagapa (E. P. Lessa et al. 2010), 27 km NW of Pampa de Agnia (Sikes et al. 1997), 3 km N of Tecka along Hwy 4 (Mares et al. 2008); Mendoza, 2 mi E of Gendarmería Cruz de Piedra (Mares et al. 2008), 2 km N of junction Hwy 40 and El Manzano Road along Hwy 40 (Mares et al. 2008), 3 km W of Refugio Militar General Alvarado (Mares et al. 2008); Neuquén, 8.8 km S of Lonco Luan (Mares et al. 2008), Parque Nacional Laguna Blanca (Tiranti 1997), 21 km NW and 1 km N of junction Hwys 60 and 23 (Mares et al. 2008); Río Negro, Cerro Corona (Lessa et al. 2010), Las Victorias, 4.2 km E of Bariloche (E. P. Lessa et al. 2010), 15 km NE of Mengué (Sikes et al. 1997), Meseta de Somuncurá (Sikes et al. 1997), Tembrao (Hillyard et al. 1997); Santa Cruz, Cabo Vírgenes (UP 1201), Estancia Cerro Ventana (E. P. Lessa et al. 2010), Estancia La Vizcaina (Hillyard et al. 1997), Río del Deseado, Estancia Cerro del Paso (M. C. Da Silva 2011), Río Santa Cruz, 4 km W of Punta Quilla s/RP 288 (M. C. Da Silva 2011), RPG Laguna Azul (CNP-E 425). CHILE: Aysén, Chile Chico, 2 km S and 1 km W of Aeródromo (Kelt et al. 1991); Magallanes y Antártica Chilena, Lake Sarmiento, Ultima Esperanza (Osgood 1943b).

SUBSPECIES: *Eligmodontia morgani* is monotypic. Mares et al. (2008) detected a shallow gene-genealogy with a phylogeographic break between southern and northern populations, but this geographic division has not been examined adequately as yet.

NATURAL HISTORY: *Eligmodontia morgani* is terrestrial and nocturnal. It is primarily restricted to the semiarid steppes in western Patagonia, where it may be the most abundant species (Monteverde et al. 2011). Population ecology, microhabitat selection, space use, population dy-

namics, reproduction, and longevity have been studied in northwestern Patagonia (Pearson et al. 1987; Guthmann et al. 1997; Lozada and Guthmann 1998; Lozada et al. 2001). Pearson et al. (1987) characterized the reproductive season as October through April, with an average litter size of 5.9; individuals reached sexual maturity at 1.5 months, and the life span was about nine months. Abundance was highest in the fall (3.5 individuals/ha) and lowest in the spring (0.4/ha). Monteverde et al. (2011) recorded a breeding season from August to March, larger home range sizes for females ($656.72 \pm 90.55 \text{ m}^2$) than for males ($439.58 \pm 114.52 \text{ m}^2$), and abundances ranging from 12 to 71 individuals per hectare. Individuals of this species are prey to both the Magellanic Horned Owl (*Bubo magellanicus*; Trejo et al. 2005; Trejo and Guthmann 2003) and the Great Horned Owl (*Bubo virginianus*; Trejo and Grigera 1998). J. P. Sánchez et al. (2009), J. P. Sánchez et al. (2010), and J. P. Sánchez (2013) described tick and flea ectoparasites. Udrizar Sauthier (2009) enlarged the knowledge of the past distribution and abundance of this species through the Holocene of central Patagonia.

REMARKS: J. A. Allen (1901c) described *morgani* as a species, but this name, as with so many others in the genus, became subsumed as a synonym of *E. typus typus* in Hershkovitz's (1962) revision or as a synonym of *E. typus elegans* in Cabrera's (1961) compilation. The recognition of *E. morgani* as a species distinct from *E. typus* was first supported by its unique $2n=32-34$, FN=32, karyotype (Ortells et al. 1989; Kelt et al. 1991; Zambelli et al. 1992; Tiranti 1997) and has been more recently confirmed by reciprocal monophyly of mtDNA cytochrome-*b* sequences (Hillyard et al. 1997; Mares et al. 2008; Lanzone, Ojeda et al. 2011). At the chromosome level, *E. morgani* possesses both polymorphic and polytypic Robertsonian (Rb) populations. In some localities, the $2n=32$ and $2n=34$ cytotypes are fixed, while in others these diploid numbers are part of a polymorphic Rb system where the $2n=33$ heterozygote is also present. Mares et al. (2008) described two mtDNA cytochrome-*b* clades and suggested that these corresponded to northern and southern divisions concordant with the chromosome differentiation. However, the known karyotype diversity pattern does not exhibit a simple dichotomous distribution, as populations fixed for the $2n=32$ karyotype are found both in the north and south of the distribution range of the species, with both polymorphic and $2n=34$ populations in the center (Ortells et al. 1989; Kelt et al. 1991; Zambelli et al. 1992; Tiranti 1997; Lanzone 2009). Furthermore, Lessa et al. (2010) failed to recover any phylogeographic break across their broad sampling throughout Patagonia in their expanded analysis of cytochrome-*b* sequences. Additional studies are needed to understand distributional relationship between cytotypes and mtDNA se-

Map 271 Selected localities for *Eligmodontia morgani* (●). Contour line = 2,000m.

quences. Both Hillyard et al. (1997) and Mares et al. (2008) discussed historical biogeography with regard to *E. typus*, elaborating upon the complementarity of their present-day distributions to biotic provinces within Patagonia.

Eligmodontia puerulus (Philippi, 1896)

Andean Gerbil Mouse, Altiplano Laucha

SYNONYMS:

Hesperomys puerulus Philippi, 1896:20; type locality "cerca de Atacama," [= San Pedro de Atacama,] Antofagasta, Chile (see Osgood 1943b:198; Hershkovitz 1962:187).

Mus puerulus: Philippi, 1900:79; name combination.

Eligmodontia hirtipes jacunda Thomas, 1919f:131; type locality "Abrapampa [= Abra Pampa], 3500 m," Jujuy, Argentina.

Eligmodontia puerulus: Osgood, 1943b:198; first use of current name combination.

Eligmodontia puerulus puerulus: Mann, 1945:78; name combination.

DESCRIPTION: Size moderate for genus, with mean head and body 82.6mm (range: 67–95 mm); mean tail

length 73.8 mm (range: 59–92 mm), mean hindfoot length 23.6 mm (range: 21–26 mm), and mean ear length 17.9 mm (range: 15–21 mm). Fur long and lax; dorsally colored grayish brown to light brown with yellow; distinctly wide buffy lateral line divides dorsal from ventral fur. Ventral hairs white to gray to black at their base but always white at tip; frequency of these ventral colorations varies among populations. Eyes outlined by darker line of variable length that begins on posterior margin, less marked or absent in specimens from some populations. Tail absolutely and proportionally shortest among species in genus, averaging 89.4% of head and body length; coloration varies from markedly bicolor to almost completely white, although slightly bicolored in most specimens, more pronounced at tip, pale brown above and white below, terminating in short pencil of hairs. Both forefeet and hindfeet covered dorsally with short, dirty white hairs; soles clothed in dense, long white hairs. Skull with nasals relatively large, but shorter than those of *E. morgani*; posterior part of interorbital region relatively angular; zygomatic arches relatively thick and rounded, most robust and least delicate among species; well-developed rounded or ovoid tubercles on anterior border of maxilla, but generally smaller than those of *E. moreni*; short incisive foramina (shortest among species of genus), reaching the anterior border of m1; mesopterygoid fossa relatively long, broad with rounded anterior margin; parapterygoid plate relatively narrow and little elevated in lateral portion; oval foramen large and rounded; petrotympanic fissure narrow (narrower than in *E. typus* but wider than in *E. moreni*), although rather variable within and among populations; bullar tubes short and flat, somewhat irregular anteriorly; stapedial spines relatively short and triangular, wide at insertion point on bullae and thin and detached at anterior tip; M1 with weakly developed anteromedian flexus in young individuals but without flexus in adults; M2 with first primary fold absent or poorly developed; M3 with only second primary fold well developed (labial) and deep, more so than in other species, lingual fold, in general, absent or underdeveloped; m1 with marked anteromedian flexus; no contact between labial fold (hypoflexus) and second major lingual fold in m2; and m3 with two conspicuous folds. Skull differs from geographically adjacent (to southeast) *E. moreni* by much smaller bullae (average length and width, 4.67×5.07 mm), presence of very open petrotympanic fissures, and distinct stapedial spine (Lanzone 2009; Lanzone, Ojeda et al. 2011); craniodental dimensions completely nonoverlapping in multivariate principal component space (Lanzone, Ojeda et al. 2011).

DISTRIBUTION: *Eligmodontia puerulus* occurs in the Puna of the Altiplano of northeastern Chile and northwestern Argentina in the provinces of Jujuy, Salta, and Catama-

rca, at elevations generally above 3,500 m. The possibility that this species is present in southwestern Bolivia requires careful consideration. This species had been recorded in sympatry only with *E. bolsonensis* in Catamarca province (Mares et al. 2008), but the high genetic similarity between *E. puerulus* and *E. moreni* in that region requires a detailed study of multiple taxonomic characters to identify properly species in this province.

SELECTED LOCALITIES (Map 272): ARGENTINA: Catamarca, Antofagasta de la Sierra, Paycuqui (CML [Arg 5296]), Pastos Largos (Lanzone, Ojeda et al. 2011); Jujuy, Abra Pampa (type locality of *Eligmodontia hirtipes jacunda* Thomas), 8 km E of Saladillo (Lanzone, Ojeda et al. 2011), 18 km E of Salinas Grandes (Lanzone, Ojeda et al. 2011), 26 km W of Susques (Lanzone, Ojeda et al. 2011); Salta, Cauchari (Spotorno et al. 1994), Vega Cortadera (OMNH 34756). CHILE: Antofagasta, Ojos de San Pedro (MVZ 116774), San Pedro de Atacama (type locality of *Hesperomys puerulus* Philippi), 40 km SE of Tonocao (Spotorno et al. 2001).

SUBSPECIES: We treat *Eligmodontia puerulus* as monotypic; Lanzone, Ojeda et al. (2011) detected only very slight differences among three sampled populations in five of 29 mensural variables. However, there is high molecular diversity (more than 5% in mtDNA cytochrome-*b* sequences) among Argentinean Puna samples. Additionally, both Spotorno et al. (1994; see also Spotorno, Zuleta et al. 1998) and Lanzone, Ojeda et al. (2011) have described a complex Robertsonian chromosome system in samples from the Puna of Argentina and Chile. The relationship between molecular and chromosomal diversity as well as the taxonomic implications of both requires further study.

NATURAL HISTORY: Like other species of *Eligmodontia*, *E. puerulus* is nocturnal and terrestrial. It is restricted to the high elevations of the Altiplano. In northern Chile, this species is found in “*tolares arenosos*” (Spotorno, Zuleta et al. 1998); near the type locality, it was captured in association with the saltbush *Atriplex etumatacamensis* (Amaranthaceae). Unpublished data indicate reproductive activity occurs in the fall (March).

REMARKS: The karyotype of *E. puerulus* is characterized by a variable $2n$ ranging from 31 to 37, but with a stable FN of 48 signaling Robertsonian polymorphism (Spotorno et al. 2001; Lanzone, Ojeda et al. 2011). Specimens from the type locality of *E. puerulus* (San Pedro de Atacama, Antofagasta, Chile) have $2n=34$ and FN=48 (Spotorno, Zuleta et al. 1998). There are different populations with fixed 32 and 34 chromosomes, and polymorphic ones with $2n=31, 32, 33$ and $2n=32, 34, 35, 36, 37$. Meiosis of a few samples of heterozygotes exhibited normal segregation, with no imbalances detected (Lanzone, Ojeda et al. 2011). Thomas (1919f) described *jacunda* as a sub-

species of *E. hirtipes*, but specimens from the type locality (Abra Pampa, Jujuy, Argentina) have a $2n=31, 32,$ and $33,$ at the lower end of the range characteristic of *E. puerulus*, not the $2n=52$ of *E. hirtipes* (Lanzone, Ojeda et al. 2011). Karyotypic data also support the species status of *E. puerulus* with respect to the geographically adjacent *E. hirtipes* (to the north), *E. dunaris* (to the southwest), and *E. moreni* (to the southeast). Three or all four species form a major clade in some phylogenetic analyses (Lanzone, Ojeda, and Gallardo 2007; Mares et al. 2008; Lanzone, Ojeda et al. 2011; Spotorno et al. 2013). *E. puerulus* is characterized by deep molecular variability and divergences with a complex geographic distribution (Lanzone, Ojeda et al. 2011). Specimens allocated to *E. puerulus* and *E. moreni* are presumptively recently derived species, as their respective mtDNA cytochrome-*b* haplotypes have yet to reach reciprocal monophyly, presenting a polyphyletic pattern. Nevertheless, the two species are markedly distinct in karyotype and differ significantly in 21 of the 29 morphometric variables compared as well as in qualitative traits, such as differences in bullar size and openness of the petrotympanic fossae (Lanzone, Ojeda et al. 2011). All four species have allopatric ranges, but it is possible that ranges overlap between some of them in the Altiplano of northern Chile, western Bolivia, and northwestern Argentina. Additional collections accompanied by karyotypes and molecular sequences are needed to refine the range limits of all four species.

Map 272 Selected localities for *Eligmodontia puerulus* (●). Contour line = 2,000 m.

Eligmodontia typus F. Cuvier, 1837

Highland Gerbil Mouse, Eastern Patagonian Laucha

SYNONYMS:

Eligmodontia typus F. Cuvier, 1837:168; type locality “environs de Buenos-Ayres,” Buenos Aires, Argentina (see Remarks for discussion of the actual type locality).

Mus elegans Waterhouse, 1837:19; type locality “Bahia Blanca [= Bahía Blanca],” Buenos Aires, Argentina.

Eligmodontia morgani pamparum Thomas, 1913c:572; type locality “Peru Station, F.C.P. [= Perú]; about 200 kilometres N.W. of Bahia Blanca,” La Pampa, Argentina.

Eligmodontia marica Thomas, 1918c:483; type locality “Chumbicha, Catamarca. Alt. 600 m,” Argentina.

Eligmodontia typus elegans: Cabrera, 1961:483; name combination.

Eligmodontia typus marica: Cabrera, 1961:483; name combination.

Eligmodontia typus: Cabrera, 1961:483; first use of current name combination.

Eligmodontia typus typus: Cabrera, 1961:484; name combination.

DESCRIPTION: Size similar to *E. bolsonensis*, *E. moreni*, and *E. puerulus*, slightly smaller on average than *E. morgani*, much smaller than *E. hirtipes*, but not as small as *E. dunaris*. Mean head and body length 76.21 (Lanzone, Ojeda, and Gallardo 2007) to 84.03 mm (Mares et al. 2008), with range across both studies 61–88 mm; averages from same two studies for tail length 92.1 mm and 94.67 mm, respectively (combined range: 72–110 mm), hindfoot length 21.26 and 22.01 mm (range: 16–25 mm), and ear length 17.21 and 17.83 mm (range: 11–23 mm). Tail proportionally long, 110–121% of head and body length; slightly bicolored with dark and especially wide dorsal stripe; usually either lacking penciled tip or, if present, one less than 5 mm. Fur short, as in *E. morgani*, with overall brownish dorsal tones; upper parts separated from venter by buffy lateral line of varying distinctness; white under parts with hairs gray or white at their base throughout or confined mainly to margins. Forefeet and hindfeet white above; soles appear naked or nearly so, clothed in sparse, short white hairs. Ears moderately long, 20–23% of head and body length. Skull unremarkable except for overall small size, with mean greatest cranial length varying from 22.75 mm (Mares et al. 2008) to 23.85 mm (Lanzone, Ojeda, and Gallardo 2007), combined range from both studies 20.9–25.7 mm; tubercles on anterior border of maxilla absent or slightly developed and rounded; auditory bullae uninflated, with mean length by width 4.16 mm × 4.31 mm, somewhat larger than parapatric *E. morgani* (Sikes et al. 1997) and distinctly smaller than *E. moreni* (Lanzone, Ojeda, and Gallardo 2007); stapedial spine development and enlarged petrotympanic fissures similar to *E. bolsonensis*,

distinct from conditions in *E. moreni* (Lanzone, Ojeda, and Gallardo 2007); anteromedian flexus of M1 weakly visible in very young individuals but not in adults.

DISTRIBUTION: *Eligmodontia typus* occurs east of the Andes from Catamarca south to Santa Cruz province, and east to Buenos province, Argentina, primarily at elevations below 1,000 m. It has the broadest range across the ecoregions of Argentina, ranging from Espinal and Pampa to Monte Desert and Patagonian steppe. *Eligmodontia typus* is sympatric with *E. moreni* at localities in Mendoza and San Juan provinces (Lanzone, Ojeda, and Gallardo 2007; Mares et al. 2008) and with *E. morgani* at several sites in Chubut, Mendoza, Río Negro, and Santa Cruz provinces (Zambelli et al. 1992; Hillyard et al. 1997; Sikes et al. 1997; Mares et al. 2008).

SELECTED LOCALITIES (Map 273): ARGENTINA: Buenos Aires, Bahía Blanca (type locality of *Mus elegans* Waterhouse), Pechuén-có (Massoia and Fornes 1964d), Pirovano (J. R. Contreras 1972); Catamarca, Chumbicha (type locality of *Eligmodontia marica* Thomas), Quimilo (Mares et al. 2008); Chubut, Estancia Los Manantiales (E. P. Lessa et al. 2010), Istmo Ameghino (Sikes et al. 1997), 30 km NW of Pampa de Agnia (Sikes et al. 1997), Paraje Fofocahuel, Campo Netchovit (E. P. Lessa et al. 2010), Paso de Indios, 18 km W of junction Hwys 29 and 27 along Hwy 27 (E. P. Lessa et al. 2010), Rawson (Teta, D'Elía, and Pardiñas 2010); La Pampa, Lihué Calel (Teta, D'Elía, and Pardiñas 2010), Loventué (Teta, D'Elía, and Pardiñas 2010), Peru Station (type locality of *Eligmodontia morgani pamparum* Thomas); Mendoza, Costa de Araujo (Lanzone, Ojeda, and Gallardo 2007), 35 km S of Pareditas by Hwy 40 and 3 km E (Mares et al. 2008), Reserva Telteca (Mares et al. 2008), Salinas del Diamante (Mares et al. 2008); Neuquén, 20 km E of Zapala (Tiranti 1997); Río Negro, Aguada Cecilio (Hillyard et al. 1997), 10 km S of Comallo (E. P. Lessa et al. 2010), Meseta de Somuncurá (Sikes et al. 1997), 18 km SW of Viedma (Hillyard et al. 1997); San Luis, Pampa de las Salinas (Lanzone, Ojeda, and Gallardo 2007), 12 km N of Varela (by road) (E. P. Lessa et al. 2010); Santa Cruz, Estancia Cerro del Paso (E. P. Lessa et al. 2010), Meseta El Pedrero (Sikes et al. 1997).

SUBSPECIES: We treat *Eligmodontia typus* as monotypic. Although this species occupies a broader ecological range than any other in the genus, no study has as yet determined the patterns of morphological variation that might substantiate geographic races.

There are high levels of protein heterozygosity, polymorphism, and genetic identity within and among populations of Patagonia (G. B. Sousa et al. 1996). Limited cladal structure in mtDNA cytochrome-*b* sequences is present, but this structure has not as yet been placed within a geo-

graphic context (Hillyard et al. 1997; Mares et al. 2008; E. P. Lessa et al. 2010), nor has it been related to morphological patterns of variation.

NATURAL HISTORY: Most information on the natural history of this species is based on studies of populations in the Monte Desert of Mendoza province, Argentina. Here, and presumably elsewhere, *E. typus* is nocturnal and terrestrial. The diet is omnivorous, with leaves and seeds predominating (Giannoni et al. 2005), and seed hoarding has been reported (Giannoni et al. 2001; C. M. Campos et al. 2007; Tababorelli et al. 2009). The species is resistant to water deprivation (Bozinovic et al. 2007), and is highly efficient at concentrating urine as a means to minimize water loss (G. B. Diaz and Ojeda, 1999). The species is a quadrupedal saltator, but locomotion varies according to the openness of the habitat (Taraborelli et al. 2003). In the Monte Desert, this species prefers areas of low cover in sandy areas, but higher cover where creosote bush (*Larrea* [Zygophyllaceae]) or mesquite (*Prosopis* [Fabaceae]) is present (Corbalán and Ojeda 2004; Corbalán 2006; Corbalán and Debandi 2006; Corbalán et al. 2006). This species does well in areas disturbed by cattle grazing (Tabeni and Ojeda 2005). Known predators include Geoffroy's Cat (*Leopardus geoffroyi*; Bisceglia et al. 2011), the Culpeo (*Lycalopex culpaeus*; Corley et al. 1995), and the Barn Owl (*Tyto alba*; De Santis et al. 1994; García Espoñda et al. 1998). Despite possible bipedal locomotion and an erratic escape behavior, individuals were consumed in a greater proportion than their availability, likely due to the open habitat the species utilizes (Tabani et al. 2012).

REMARKS: Although *E. typus* has been recognized as a species by virtually all authorities over the past century and a half, the current and considerably more geographically constrained concept of this species did not coalesce until the application of karyotypic and molecular sequence data within the past two decades. Ortells et al. (1989), Kelt et al. (1991), Zambelli et al. (1992), and Tiranti (1997) each documented the unique karyotype of $2n=44$, $FN=44$, for specimens of this species. More recently, mtDNA cytochrome-*b* sequences have substantiated specimens with this chromosome complement as a monophyletic lineage relative to other species in the genus (Hillyard et al. 1997; Lanzone, Ojeda, and Gallardo 2007; Lanzone, Ojeda et al. 2011; Mares et al. 2008; E. P. Lessa et al. 2010; M. C. Da Silva 2011), except possibly *E. bolsonensis* (E. P. Lessa et al. 2010).

The application of Cuvier's name *typus*, however, to the $2n=44$ karyotypic form is not straightforward because the type locality of Cuvier's mouse ("environs de Buenos-Ayres") is both imprecise and in doubt. Hershkovitz (1962:185), Massoia and Fornes (1964d), and Ortells et al. (1989) have each discussed the uncertainty of the type locality,

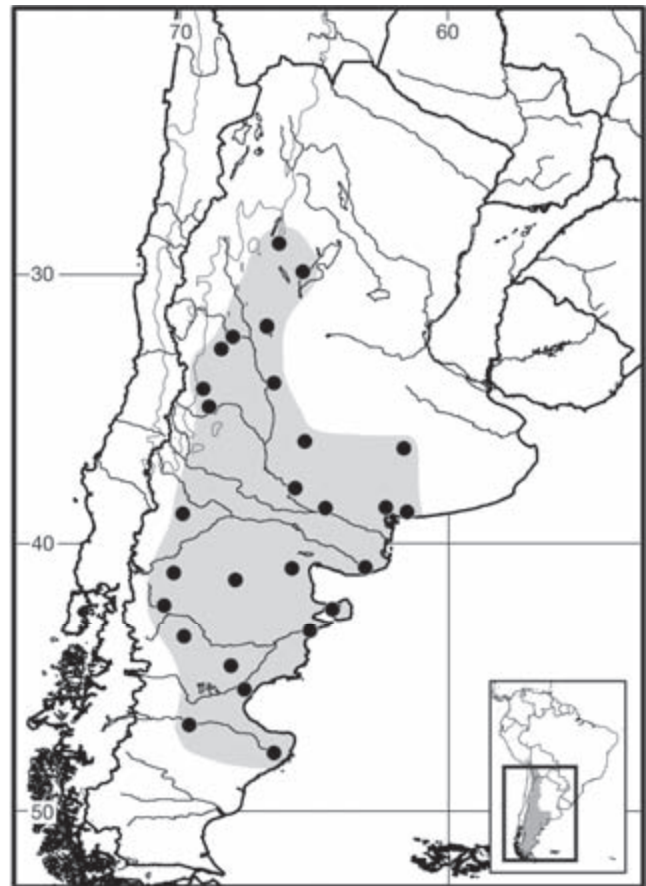

noting that, at the time of Cuvier's work, the "environs de Buenos-Ayres" included a large area that cannot be equated to the surroundings of the city of Buenos Aires today. Thomas (1929:39), reflecting on the problem, stated "no doubt Cuvier's giving of Buenos Ayres as the original locality was merely due to this latter term being then used in a general significance—just as if we said Argentina now." He and more recent authors (Cabrera 1961:484; Honacki et al. 1982:410) concluded that the type locality should be "Corrientes," citing d'Orbigny and Gervais (1847). But Alcide d'Orbigny, who apparently collected the specimen upon which Cuvier's figure of *E. typus* was drawn, simply stated (in d'Orbigny and Gervais 1847:24) "nous avons rencontré cette espèce dans la province de Corrientes, où elle est peu commune" (roughly translated, "we encountered this species in the province of Corrientes, where it is uncommon"); he made no specific reference to where the specimen he provided to Cuvier had originated. To our knowledge, there is no confirmed record of any *Eligmodontia* from Corrientes province, the Mesopotamian region of Argentina; the nearest known locality for the genus is about 500 km distant. If the type of *E. typus* was, in fact, collected by Alcides d'Orbigny, it was most likely obtained in southernmost Buenos Aires province, as he spent several months traveling around Carmen de Patagones and San Blas. The issue of the type locality of Cuvier's *typus*, and thus the correct application of this name to the $2n=44$ karyomorph, remains unresolved, but needs to be "formally restricted in order to settle the morphological identification of *E. typus* and a critical definition of the species within the genus" (Musser and Carleton 2005:1114).

Waterhouse's *elegans*, published in the same year as Cuvier's *typus*, has been uniformly regarded a synonym of *typus* Cuvier (Waterhouse 1839; Lesson 1842; J. A. Allen 1905). Furthermore, all specimens of gerbil mice from the broad vicinity of Bahía Blanca, Buenos Aires province, the type locality of *elegans* Waterhouse, share the $2n=44$ karyotype allocated to *E. typus*, and specimens from nearby Villarino are part of the *E. typus* mtDNA clade (E. P. Lessa et al. 2010). Thus, unless future research is able to contradict the long-accepted association of *typus* Cuvier with *elegans* Waterhouse, we follow those before us and continue to use Cuvier's name for this species.

Thomas (1913c) originally described *pamparum* as a subspecies of *E. morgani*. However, as noted by Mares et al. (2008), the type locality of Peru Station, La Pampa province, is well removed from the currently known range of *E. morgani* and is within the Monte Desert ecoregion that characterizes *E. typus* but not *E. morgani*, and other specimens from this province possess the $2n=44$ karyotype of *E. typus* (e.g., Tiranti 1997). We thus agree with

Mares et al. (2008), who followed both Thomas (1929) and Musser and Carleton (2005), and assign *pamparum* Thomas to *E. typus*.

M. M. Díaz et al. (2006) regarded *marica* Thomas as a valid species, but this taxon is allocated as a synonym of *E. typus* herein based on mtDNA cytochrome-*b* sequences of specimens from near the type locality (Chumbicha, Catamarca province; Mares et al. 2008; E. P. Lessa et al. 2010). However, the low mtDNA cytochrome-*b* sequence divergence between *E. bolsonensis* and *E. typus* (less than 3%) and thus a potential polyphyletic relationship between both taxa cannot be ruled out at present. It is thus possible that Thomas's *marica* is actually a senior synonym of *bolsonensis*. This hypothesis needs to be examined in detail, especially because Thomas (1918c:483) explicitly noted that the type series of *marica* had the "whole of the under surface pure sharply defined white, all the hairs, even laterally, white to their bases." Emilio Budin, who collected the type series of *marica*, noted that the species was "evidently very rare" (Thomas 1918c:484). Given the extensive anthropogenic modification of the

Map 273 Selected localities for *Eligmodontia typus* (●). Contour line = 2,000 m.

habitat around Chumbicha, the potential replacement of *marica* by *typus* also remains a valid, if difficult to falsify, hypothesis.

Genus *Galenomys* Thomas, 1916

Jorge Salazar-Bravo

This monotypic genus ranges between about 16°S and 18°S latitude in southern South America. The single species occurs in arid and semiarid Puna, at elevations between 3,720 and 4,675 m in the departments of La Paz and Oruro in Bolivia and Puno in Peru. Except as noted, the following account is abstracted from Steppan (1995) and Hershkovitz (1962), which should be consulted for additional details on morphological characters. The genus is not known from the fossil record. Phylogenetic analysis based on morphological characters placed *Galenomys* as the sister to *Auliscomys* (Steppan 1995). This topology was generally supported by Braun (1993), but she erected *Maresomys* for *Auliscomys boliviensis* based on its sister-group relationship with *Galenomys*, thus creating an otherwise paraphyletic *Auliscomys* (see Steppan 1995, and account for *Auliscomys*).

Galenomys is characterized by the following combination of characters: medium size (head and body length ranging from 105 to 132 mm) with a stout body, short tail (30 to 44 mm [Pearson 1957; S. Anderson 1997]), and pale color. The upper parts are buffy, thinly lined with brown; the sides are clearer; and the under parts and legs are sharply defined white, the individual hairs wholly white on legs, feet, and hands, and from the chin to the anterior part of chest, but basally gray elsewhere. The ears are large, well haired on their outer sides. The forefeet and hindfeet are white above. The plantar surface of the hindfeet is thinly covered with long white hairs except on the tubercles and terminal phalanges; the thenar pad is absent, and the remaining plantar pads are unfused. The tail is relatively short, only one-third to one-half of the combined head and body length. It is thickly haired white above and below, the scales are not visible, and a terminal tuft is not conspicuous.

The dorsal shape of the skull in lateral profile is strongly arched in the supraorbital region with the rostrum inflected downward; the interorbital region is narrow with squared but not beaded or ridged edges; zygomatic arches are delicate with a pronounced downward inflection; the zygomatic plates are nearly as wide as is the least interorbital breadth, with their anterior borders straight and slanted backward; the palate is arched; the incisive foramina are long, reaching to the middle of the M1s; the mesopterygoid fossa is narrow; and the bullae are moderately in-

flated, with its length approximating the alveolar length of the maxillary toothrow. A large stapedial foramen is present, an internal groove is present on the alisphenoid and squamosal bones, and a sphenofrontal foramen is present (all indicators of pattern 1 [of Voss 1988] to the carotid circulation), and an alisphenoid strut is present. The upper incisors are delicate, asulcate, and orthodont; the lower incisors are highly procumbent. M1 and m1 both have four roots, m3 has three. The crowns of each tooth are low and slightly crested, with ovate cusps. M2 and M3 are square in shape (as long as wide). A distinct anteromedian flexus is present on M1, a reduced hypoflexus on M3, and a highly reduced mesoflexid on m3. The axial skeletal elements consist of 13 ribs, 19 thoracolumbar vertebrae, and 17–19 caudal vertebrae.

SYNONYMS:

Galenomys Thomas, 1916b:143; type species *Euneomys* (*Galenomys*) *garleppii* Thomas, by original designation, as subgenus.

[*Galenomys*]: Thomas, 1926b:317; elevation to genus.

REMARKS: Thomas (1916a) originally regarded *Galenomys* as a subgenus of *Euneomys* but later (Thomas 1926b) raised the taxon to generic status. Ellerman (1941), Osgood (1947), and Corbet and Hill (1991) treated it as a subgenus of *Phyllotis*. Hershkovitz (1962) and Steppan (1995) revised *Galenomys*, considering it to be a distinct genus. Pearson (1958) likewise regarded *Galenomys* separate from *Phyllotis* in his revision of the latter.

Galenomys garleppii (Thomas, 1898)

Garlepp's Pericote

SYNONYMS:

Phyllotis (?) *Garleppii* Thomas, 1898c:279; type locality "Esperanza, a 'tambo' in the neighbourhood of Mount Sahama," La Paz, Bolivia.

Euneomys (*Galenomys*) *garleppi*: Thomas, 1916a:143; name combination.

Galenomys garleppii: Gyldenstolpe, 1932a:96; first use of current name combination.

Phyllotis [(*Galenomys*)] *garleppii*: Ellerman, 1941:455; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Galenomys garleppii* is known from seven localities in the Altiplano of northern Bolivia and southern Peru, all between 3,300 and 4,650 m.

SELECTED LOCALITIES (Map 274): BOLIVIA: La Paz, Esperanza (type locality of *Phyllotis Garleppii* Thomas); Oruro, Huancaroma (S. Anderson 1997). PERU: Puno, Hacienda Pichupichuni, 6 km NW of Huacullani (Pearson 1957), Pampa de Ancomarca, 123 km W of Ilave (Pearson 1957).

SUBSPECIES: *Galenomys garleppii* is monotypic.

Map 274 Selected localities for *Galenomys garleppii* (●). Contour line = 2,000 m.

NATURAL HISTORY: *Galenomys garleppii* is very poorly known in all aspects of its ecology and behavior. All known localities are in bunch grass dominated Altiplano. Pearson (1957) obtained the two Peruvian specimens in heavily grazed pampa dominated by dwarf grass and prostrate forbs with scattered thorn bushes about 1 foot tall. His unpublished field notes (O. P. Pearson, MVZ archives) suggest that this species might be diurnal. No information is available on food habits. In Bolivia, one female had four embryos in December, and four young were taken in December (S. Anderson 1997).

REMARKS: Both Hershkovitz (1962) and Musser and Carleton (2005) included northern Chile in the range of this species, but no localities in this country from which voucher species exist have been reported. However, given the proximity of both Bolivian and Peruvian localities to the Altiplano of northeastern Chile, it is quite possible that *Galenomys garleppii* will be found there.

Genus *Graomys* Thomas, 1916

Janet K. Braun and James L. Patton

Members of the genus *Graomys* range from about 17°S (south central Bolivia) southward through western Paraguay and adjacent Brazil to about 49°S in southern Argentina (Hershkovitz 1962; Udrizar Sauthier, Formoso et al. 2011); the genus is not known to occur west of the Andes in Chile. Species in the genus generally occupy arid and semi-

arid habitats, and occasionally transitional forest, from sea level to about 3,100m. The following generic description is, except as noted, compiled from information presented by Gyldenstolpe (1932), Ellerman (1941), Hershkovitz (1962), and Stepan (1995).

All species of *Graomys* are externally similar, with large ears, long, lax fur, and well-haired, slightly penicillate, bi-colored tails that are usually longer than head and body. The venter is white with hairs white terminally, and white or gray basally. The hindfeet are unwebbed, with digit I distinctly shorter than digit V; the plantar surface is naked (from heel to toes) with six small, but well-defined tubercles (thenar, hypothenar, and four interdigitals). There are eight mammae (in four pairs).

The skull, in dorsal view, has a relatively broad and characteristic interorbital region that is evenly convergent V-shaped; supraorbital margins are generally beaded and project as ledges. Lacrimals are conspicuous. Zygomatic arches are usually parallel sided or slightly convergent. Zygomatic plates have concave anterior margins, resembling those of *Reithrodon*, and zygomatic notches are deep and well developed. Frontals are relatively broad and the interparietal is well developed. The orbital wings of the presphenoid are posterior to the maximum constriction. The roof of the mesopterygoid fossa has large sphenopalatine vacuities. The parapterygoid fossae are flat and about even with the bony palate. A vertical stout strut of the alisphenoid is present. Bullae are moderately to well developed; the stapedial spine is laterally appressed to the bullae. The tegmen tympani contacts a posterior suspensory process of the squamosal; the hamular process of the squamosal is well developed, long, and distally spatulate; postglenoid foramen is at least twice as large as the subsquamosal fenestra. The coronoid process of the mandible is not well developed. The lower incisor root is contained in a moderately developed capsular process. The condyle is well projected and the angular notch is characteristically excised forward.

Incisors are ungrooved and opisthodont. The molars are tetralophodont (lacking any trace of a mesoloph or mesolophid), moderately hypsodont, and flat-crowned to slightly raised. Molar rows are parallel sided. Cusps are opposite in position. The procingulum of M1 lacks an anteromedian flexus. The anterolabial cingulum of m1 is distinct and large, and the mesoflexid of m3 is not shifted anteriorly relative to m2. M1 and m1 have four roots.

Axial skeletal elements have counts of 12–13 ribs, 19 thoracolumbar vertebrae, and 31–35 caudal vertebrae. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and the first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. The entepicondylar foramen of the humerus is present.

The stomach is unilocular and hemiglandular (Carleton 1973), and a gall bladder is present, the widespread condition for the tribe. Male accessory secretory organs consist of one pair each of bulbourethral, anterior, and dorsal prostate, ampullary, and vesicular glands, and two pairs each of preputial and dorsal prostate glands (Voss and Linzey 1981). The glans penis is complex; three bacular mounds are present, the medial one truncate and the lateral pair slightly double-peaked; hooks are absent. Two pairs of preputial glands are present, a single large lateral pair and a medium length medial pair.

The genus *Graomys* is known from the late Pliocene of Argentina and early Holocene of Bolivia. Reig (1978) described *G. dorae*, a fossil species he considered similar to *G. domorum*, from the Chapadmalal Formation (Upper Pliocene) of southeastern Buenos Aires province. Fossils referred to the living species *G. griseoflavus* have been identified from Middle to Late Pleistocene (Ensenadan, Bonarian and Lujanian) deposits in Buenos Aires province (Burmeister 1879, as *Hesperomys bravardi*; see Hershkovitz 1962; Reig 1978; Pardiñas 1995c; Pardiñas et al. 1996; and Voglino and Pardiñas 2005).

SYNONYMS:

Mus (Phyllotis): Waterhouse, 1837; part (description of *griseoflavus*); neither *Mus* Linnaeus nor *Phyllotis* Waterhouse.

Hesperomys: Waterhouse, 1839:76; part (listing of *griseoflavus*); not *Hesperomys* Waterhouse.

Hesperomys (Phyllotis): Wagner, 1843a:510; part (listing of *griseoflavus*); neither *Hesperomys* Waterhouse nor *Phyllotis* Waterhouse.

Hesperomys [(Calomys)]: Burmeister, 1879:219; part (listing of *griseoflavus*); neither *Hesperomys* Waterhouse nor *Calomys* Waterhouse.

Bothriomys Ameghino, 1889:118; type species *Bothriomys catenatus*, by original designation; *nomen oblitum* (see Remarks).

Eligmodontia: Thomas, 1898h:210; part (listing of *griseoflava*); not *Eligmodontia* F. Cuvier.

Graomys Thomas, 1916a:141; type species *Mus (Phyllotis) griseoflavus* Waterhouse, by original designation; *nomen protectum* (see Remarks).

REMARKS: Hershkovitz (1962) revised the genus *Graomys*, assigning nine nominal taxa to two species, the monotypic and questionably valid *G. edithae* Thomas and the highly polytypic and widespread *G. griseoflavus*, with two subspecies, the nominotypical form plus *domorum* Thomas. Cabrera (1961) also recognized two species, *G. domorum* (with three subspecies, including *lockwoodi* Thomas and *taterona* Thomas in addition to the nominotypical form) and *G. griseoflavus* (with five subspecies [*cachinus* J. A. Allen, *centralis* Thomas,

chacoensis J. A. Allen, *griseoflavus* Waterhouse, and *medius* Thomas], with *edithae* Thomas listed as a synonym of the latter).

The composite nature of Hershkovitz's concept of *G. griseoflavus*, however, has been demonstrated by a series of studies documenting karyotypic polytypy that, together with cross-breeding experiments, allozymes, mtDNA sequences, and morphometric analyses diagnose at least three geographically segregated species: *G. chacoensis*, *G. domorum*, and *G. griseoflavus*. We provisionally include *G. edithae* Thomas as a fourth species, pending an adequate review of the holotype and other specimens from the vicinity of the type locality. We emphasize that, although the geographic boundaries of these taxa have become reasonably well understood in Argentina (e.g., J. J. Martínez, Krapovickas, and Theiler 2010; J. J. Martínez and Di Cola 2011; Udrizar Sauthier, Formoso et al. 2011), few of the recent studies substantiating species boundaries in the genus have treated samples from Bolivia or Paraguay. Most localities provided in the following accounts are based on specimens for which karyotype and/or DNA sequence data are available.

Pardiñas (1995c) reviewed the available fossil material of *Bothriomys catenatus* Ameghino, from Pleistocene deposits in Córdoba province, Argentina and identified its synonymy with *Graomys* Thomas. Hershkovitz (1962) had earlier listed *Bothriomys* as a junior synonym of *Euneomys* Coues without having seen the referred specimens (pg. 496, 498). Citing Article 23(b) of the International Code of Zoological Nomenclature (ICZN 1985), Pardiñas (1995c:177) argued that *Bothriomys* be suppressed in favor of *Graomys* because (1) *Bothriomys* was based on fragmentary material (a partial left mandible with incisor and molars in place), with limited useful characters, and (2) *Bothriomys* had not been used as a valid name in the prior 50 years whereas *Graomys* had been cited by a minimum of five authors in 10 publications during the same period. Pardiñas thus concluded that replacement of *Graomys* by Ameghino's earlier but unknown *Bothriomys* would result in nomenclatural instability. The rationale provided by Pardiñas (1995c:177) satisfies both Articles 23.9.1 and 23.9.2 of the current Code (ICZN 1999) in his choice of the younger name *Graomys* as valid relative to *Bothriomys*. The latter would thus become a *nomen oblitum*, the former a *nomen protectum* (see also Musser and Carleton 2005:1116–1117), although a formal declaration from the Commission is still required.

KEY TO THE SPECIES OF *GRAOMYS*:

1. Tail without a well-defined tuft of hairs; dorsal coloration olivaceous to rufous; hairs of venter dark basally; bullae smaller, length <6 mm *Graomys domorum*

- 1'. Tail with a well-defined tuft of hairs; dorsal coloration buffy to tawny; hairs of venter white to whitish basally; bullae larger, length >6 mm. 2
2. Size small, averaging about 230 mm and always less than 265 mm; supraorbital edges without beading *Graomys edithae*
- 2'. Size larger, averaging about 260 mm and often more than 300 mm; supraorbital edges with beading. 3
3. Found in Monte desert and Patagonian steppe habitats from northwestern to southern Argentina; bullae larger; length of maxillary tooththrow longer; width of M1 wider; $2n=34-38$ *Graomys griseoflavus*
- 3'. Found in Chaco and associated habitats from southern Bolivia (and adjacent Brazil), Paraguay, central Argentina; bullae smaller; length of maxillary tooththrow shorter; width of M1 narrower; $2n=42$ *Graomys chacoensis*

Graomys chacoensis (J. A. Allen, 1901)

Chaco Pericote

SYNONYMS:

Phyllotis chacoensis J. A. Allen, 1901c:408; type locality "Waikthlatingwayalwa, Chaco boreal, [Presidente Hayes,] Paraguay." According to Thomas (1898f:272), "Waikthlatingwayalwa" is an old Chacoan mission, located at about 23°25'S and 58°10'W (Paynter 1989, as Waikthlatingwayalwa).

[ligmodontia]. chacoensis: Thomas, 1902b:132; name combination.

Eligmodontia griseoflavus centralis Thomas, 1902d:240; type locality "Cruz del Eje," Córdoba Province, Argentina.

Graomys chacoensis: Thomas, 1916a:142; first use of current name combination.

Graomys griseoflavus centralis: Thomas, 1916a:142; name combination.

Graomys medius Thomas, 1919d:494; type locality "Chumbicha, Catamarca," Argentina.

Graomys griseoflavus chacoensis: Gyldenstolpe, 1932a:91; name combination.

Phyllotis griseoflavus centralis: Cabrera, 1961:495; name combination.

Phyllotis griseoflavus medius: Cabrera, 1961:495; name combination.

[Graomys] centralis: Tiranti, 1998:35; name combination.

Graomys centralis: Theiler, Gardenal, and Blanco, 1999:

971; name combination.

DESCRIPTION: Similar in size to *G. domorum*, with dimensions of holotype including head and body length 142 mm, tail length 185 mm, hindfoot (with claw) 33 mm, and ear length 24 mm. Pelage thick and soft, dorsal color

overall varying from yellowish brown to grayish drab, varied with black-tipped hairs; nose and top of head more grayish; and ventral color pure white to base of hairs. Ears uniformly brown, thinly hairs on both surfaces. Tail much longer than head and body, well haired, bicolored brown above and white below, and terminates in well-developed pencil or tuft of elongated hairs. Dorsal surfaces of forefeet and hindfeet white. Skull with bullae only slightly larger than those of *G. domorum* but conspicuously smaller than *G. griseoflavus* (mean length by width measurements 6.35×4.48 mm; J. J. Martínez, Krapovickas, and Theiler 2010). Cheek teeth notably small, and especially narrower than those of *G. domorum* (M1 breadth in holotype, for example, 1.5 mm compared with 1.8 mm in *G. domorum*); mean length of maxillary tooththrow 5.35 mm (J. J. Martínez, Krapovickas, and Theiler 2010). Supraorbital ridges well marked, with rudimentary postorbital projections, and overhanging points of zygomatic plates well defined. Thomas (1902d) noted that his *centralis* was readily distinguished from *G. griseoflavus* by its small bullae and from *G. domorum* by its small molars.

DISTRIBUTION: *Graomys chacoensis* occurs through the Dry and Humid Chaco ecoregions, secondarily within the Espinal, of northern Argentina and Paraguay (see J. J. Martínez and Di Cola 2011). Hershkovitz (1962) assigned the single record of *Graomys* from Brazil (Mato Grosso do Sul state; Kühlnhorn 1954) to his *G. griseoflavus*, but this specimen is likely *G. chacoensis* on geographic grounds and is so mapped here. We also include those specimens from the Chaco of southeastern Bolivia that S. Anderson (1997) allocated to *G. g. griseoflavus* under the assumption that only a single species of *Graomys* occurred within the Chaco ecoregion (see Lanzone, Novillo et al. 2007; J. J. Martínez and Di Cola 2011).

SELECTED LOCALITIES (Map 275): ARGENTINA: Catamarca, Chumbicha, 0.5 km E of Rte 38 over Rte 60 (J. J. Martínez and Di Cola 2011), La Carrera (Zambelli et al. 1994); Chaco, 1 km E of Puente General Belgrano, Río Paraná (J. R. Contreras 1982b); Córdoba, Laguna Larga (Zambelli and Vidal-Rioja 1995), 10 km N of Santiago Temple (J. J. Martínez and Di Cola 2011), Yacanto (J. J. Martínez and Di Cola 2011); Formosa, 7 km N of junction of Rte 81 and 95 (J. J. Martínez and Di Cola 2011), 35 km S and 5 km E of Ingeniero Guillermo Juárez, Puesto Divisadero (J. J. Martínez and Di Cola 2011), Parque Nacional Río Pilcomayo (Heinonen Fortabat 2001), Reserva El Bagual (Pardiñas and Teta 2005); La Rioja, Guayapa, Patquía (J. J. Martínez and Di Cola 2011); San Luis, 23 km N of Rte 20, Pampa de las Salinas, near La Botija (J. J. Martínez and Di Cola 2011); Salta, Cabeza de Buey, Campo La Peña (J. J. Martínez and Di Cola 2011); Santa Fe, Berna (J. J. Martínez,

González-Ittig et al. 2010), Jacinto L. Arauz (Teta and Pardiñas 2010), Recreo (Pautasso 2008); Santiago del Estero, Buena Vista, 15 km NE of Villa Ojo de Agua on Hwy 13 (J. J. Martínez and Di Cola 2011), 6 km S and 2 km E of Pampa de los Guanacos (J. J. Martínez and Di Cola 2011); Tucumán, San Pedro de Colalao (J. J. Martínez and Di Cola 2011). BOLIVIA: Chuquisaca, Tomina (S. Anderson 1997); Santa Cruz, 7 km E and 3 km N of Ingeniero Mora (S. Anderson 1997); Tarija, 35 km by road SE of Villa Montes, Taringuiti (S. Anderson 1997). BRAZIL: Mato Grosso do Sul, Ivinheima (Hershkovitz 1962). PARAGUAY: Alto Paraguay, Puerto Casado [= Puerto La Victoria] (Hershkovitz 1962); Boquerón, 420 km NW (by road) of Villa Hayes (MVZ 145247); Presidente Hayes, Waikthlatingwailwa (type locality of *Phyllotis chacoensis* J. A. Allen).

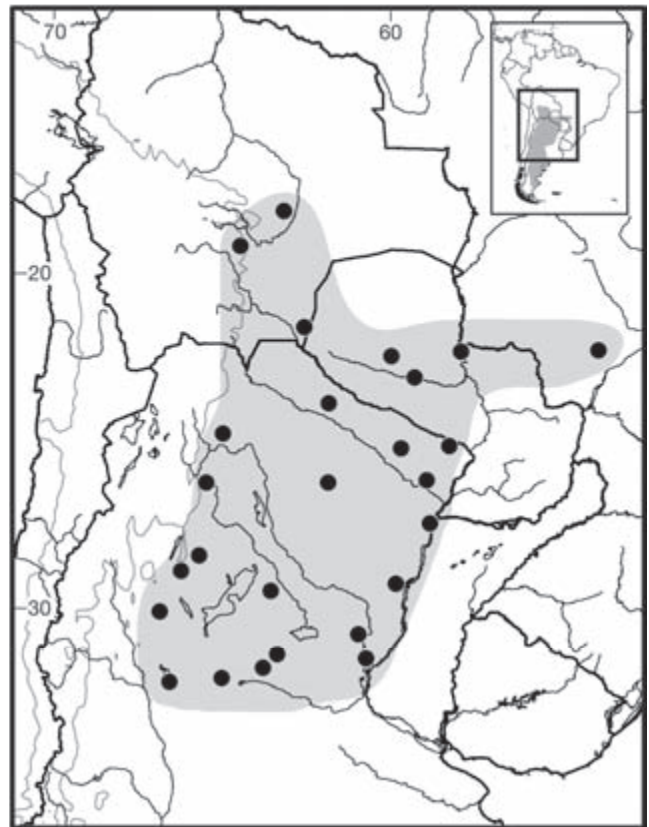

SUBSPECIES: We treat *Graomys chacoensis* as monotypic.

NATURAL HISTORY: *Graomys chacoensis* occupies the Chacoan and Espinal ecoregions (Myers 1982; Tiranti 1998b; J. J. Martínez and Di Cola 2011) where it may be trapped in a variety of habitats such as woodland, grassland, monte, and marginal areas. It is generally uncommon everywhere (Polop et al. 1985; Polop 1991; Polop and Sabbatini 1993). Like most species of *Graomys*, *G. chacoensis* is scansorial, nocturnal, and predominately herbivorous, feeding on grasses and seeds (Hershkovitz 1962). Theiler, Ponce et al. (1999) summarized information on reproductive barriers between *G. centralis* and *G. griseoflavus*. In La Rioja province, pregnant females and reproductively active males were collected in the fall; males and females were not reproductively active in the winter (J. K. Braun, unpubl. data). Because the distributional limits for this species are unclear, it is not possible to determine whether some published research on ecology and natural history pertains to this species or to *Graomys griseoflavus* (e.g., Polop et al. 1982). However, a large study on development and reproduction based on a lab colony surely applies to this species, as it is now understood (Puig and Nani 1981; cited as *G. griseoflavus*). Venzal et al. (2012) recorded the tick *Ornithodoros quilinensis* from specimens identified as *G. centralis* from the Argentine Chaco.

REMARKS: Recognition of this taxon as a species distinct from *G. griseoflavus* is substantiated by allozymes, karyotypes, mtDNA sequences, multivariate morphometrics, and cross-breeding experiments (Wainberg and Fronza 1974; Theiler and Gardenal 1994; Zambelli et al. 1994; Zambelli and Vidal-Rioja 1995; Theiler and Blanco 1996a,b; Theiler, Gardenal, and Blanco 1999; Theiler, Ponce et al. 1999; Catanesi et al. 2002, 2006; Lanzone, Novillo et al. 2007; Ferro and Martínez 2009; J. J. Martínez, González-Ittig et al. 2010; J. J. Martínez, Krapovickas, and Theiler 2010;

J. J. Martínez and Di Cola 2011). Most of these studies employed *centralis* Thomas as the name for this taxon (see also M. M. Díaz et al. 2006) because topotypes from its type locality (Cruz del Eje, Córdoba province) had the $2n=42$ karyotype (e.g., Lanzone, Novillo et al. 2007; J. J. Martínez, Krapovickas, and Theiler 2010); Tiranti (1998:35) was the first to connect the $2n=42$ karyomorph with the name *centralis*. However, Lanzone, Novillo et al. (2007) suggested that *chacoensis* J. A. Allen was the oldest name applicable because specimens from near its type locality in Paraguay had the same $2n=42$ karyotype. Ferro and Martínez (2009) and J. J. Martínez and Di Cola (2011) showed that *centralis* Thomas was best considered a synonym of *chacoensis* J. A. Allen, based both on molecular and morphometric analyses.

The assignment of *medius* Thomas as a synonym of *G. chacoensis* is also based on both karyotypic and morphometric grounds (Lanzone, Novillo et al. 2007), a decision supported by the descriptive details of color and smaller cranial features provided by Thomas (1919d; compare with data in J. J. Martínez, Krapovickas, and Theiler 2010). However, in southern La Rioja province, where the type locality (Chumbicha) of *medius* is placed, both $2n=42$ and $2n=36-38$ diploid complements have been recorded and overlap

Map 275 Selected localities for *Graomys chacoensis* (●). Contour line = 2,000 m.

in transitional Chaco-Monte areas (e.g., Theiler and Blanco 1996a,b; Tiranti 1998). Moreover, the Chumbicha local environment sampled by E. Budin (the collector of the type series of both *edithae* and *medius*) has changed sharply in the last century due to overgrazing and wood extraction. Consequently, and especially considering the substantial variability among the series of *Graomys* from this locality recognized by Thomas (1919d:494–495), the hypothesis that *medius* Thomas is junior synonym of *chacoensis* J. A. Allen must be confirmed by direct study of the holotypes. The reasonable assumption that only a single species of *Graomys* occupies the Chacoan biome, and thus our assignments of both Bolivian and Brazilian localities to *G. chacoensis*, also requires verification.

The karyotype is $2n=41-42$, $FN=44-46$, with 17–18 pairs of unarmed and two to three pairs of banded autosomes, a large metacentric X and small acrocentric Y chromosome. *Graomys chacoensis* has a significantly larger genome size than the $2n=34-38$ karyotypes of *G. griseoflavus* (P. B. Ramirez et al. 2001).

Graomys domorum (Thomas, 1902)

Pale Pericote

SYNONYMS:

Eligmodontia domorum Thomas, 1902b:132; type locality “Tapacari. Altitude 3000 m,” Cochabamba, Bolivia.

E[ligmodontia]. g[riseoflavus]. domorum: Thomas, 1902d:240; name combination.

Graomys domorum: Thomas, 1916a:142; first use of current name combination.

Phyllotis (Graomys) domorum: Osgood, 1916:207; name combination.

Phyllotis domorum taterona: Cabrera, 1961:494; name combination.

Phyllotis griseoflavus domorum: Hershkovitz, 1962:458; name combination.

Phyllotis griseoflavus griseoflavus: Hershkovitz, 1962:452; part; inclusion of *taterona* Thomas as synonym.

Graomys domorum taterona: Reig, 1978:180; name combination.

Graomys domorum domorum: Reig, 1978:182; name combination.

Graomys domorum lockwoodi: Reig, 1978:182; name combination.

DESCRIPTION: Similar in size to *G. chacoensis*, with head and body length 102–150 mm, tail length 140–170 mm, hindfoot length 26–32 mm, and ear length 20–27 mm (Hershkovitz 1962:Table 62). Overall dorsal color olivaceous (as in juveniles of *G. griseoflavus*) to rufous; sides clear buffy; hairs of ventral surface dark basally, but hairs of throat white to their base. Ears finely haired, grayish brown. Upper surfaces of forefeet and hindfeet white as in other species of genus. Tail long and prominently bicolor, dark brown above and white beneath; tail tip differs from other species by being much less tufted terminally, with pencil rarely longer than 4 mm. Skull similar to congeners except that bullae conspicuously small, with bullar length (excluding bony tubes) 6.1 mm or less, approximately equal to or less than length of upper molar toothrow.

DISTRIBUTION: *Graomys domorum* occurs in Yungas and transitional forests at elevations from 600 to 2,700 m east of the Andes in south-central Bolivia and northwestern Argentina.

SELECTED LOCALITIES (Map 276): ARGENTINA: Jujuy, Laguna La Brea (M. M. Díaz and Barquez 2007), Maimará (M. M. Díaz and Barquez 2007); Salta, 20 km W of General Ballivián, on Puerto Baulés road (Mares, Ojeda, and Kosco 1981), 25 km SE of La Viña (OMNH 33334), Manuel Elordi, Vermejo (type locality of *Graomys lockwoodi* Thomas); Tucumán, El Cadillal, Estación de Piscicultura (Barquez et al. 1991), Las Tipas, Parque Biológico Sierra de San Javier (Capllonch et al. 1997). BOLIVIA: Cochabamba, Tapacari (S. Anderson 1997); Potosí, 30 mi WNW of Cotagaita (MVZ 119979), Yuruma (MVZ 119981); Santa Cruz, Comarapa (S. Anderson 1997); Tarija, 2 km S and 5 km E of Palos Blancos (S. Anderson 1997), Tablada (type locality of *Graomys taterona* Thomas).

SUBSPECIES: S. Anderson (1997) distinguished two subspecies in Bolivia, the nominotypical form from Cochabamba, Chuquisaca, northern Potosí, and Santa Cruz departments, and *G. d. taterona* from southern Potosí and Tarija, and presumably extending south into northern Argentina. Capllonch et al. (1997) regarded populations from northern Argentina, especially those from Tucumán and Salta province, to represent *G. d. lockwoodi*. To date, however, there has been no evaluation of character variation of morphological or other traits to establish the validity of any of these races.

NATURAL HISTORY: Little natural history information is available for this species. In Bolivia, it occurs in transitional forest at low to middle elevations. Reproductive activity apparently spans the summer (S. Anderson 1997). In Argentina, animals were captured in Yungas and transitional forest and were both reproductively active

and inactive during the spring (Mares, Ojeda, and Kosco 1981). S. Anderson (1997) summarized data on ectoparasites from Bolivian specimens.

REMARKS: Hershkovitz (1962) regarded *domorum* Thomas as a valid subspecies of *G. griseoflavus* (Waterhouse), allocating both *lockwoodi* Thomas and *taterona* Thomas to the nominotypical race based on the intermediate size of the bullae and geographic range. S. Anderson (1997), following Cabrera (1961), placed *taterona* with *G. domorum* and recognized two subspecies, but commented that additional research was needed to assess their systematic relationship. Cabrera (1961) and S. Anderson (1997) also allocated *lockwoodi* Thomas as a synonym of *G. domorum taterona*. Capllonch et al. (1997), however, regarded *lockwoodi* Thomas as a valid subspecies of *G. domorum*. Pending an adequate revision of this species, one that should include examination of holotypes and topotypic series, both *lockwoodi* Thomas and *taterona* Thomas are included herein within the synonymy of *G. domorum*, following Capllonch et al. (1997) and M. M. Díaz et al. (2006). It is interesting to note that Thomas (1902b:133) remarked on the “extraordinary resemblance” between *G. domorum* and *Tapecomys wolffsohni* in external morphology.

Map 276 Selected localities for *Graomys domorum* (●). Contour line = 2,000 m.

Pearson and Patton (1976) described a karyotype with $2n=28$, FN=46, consisting of 10 pairs of biarmed and three of uniarmed autosomes, and both uniarmed X and Y chromosomes for specimens from Cochabamba, Bolivia. They concluded (p. 341) that this karyotype was so different from the $2n=36-38$ karyotype of *G. griseoflavus* they described that “there is little doubt that Thomas’s (1902b) separation of *domorum* as a separate species on the basis of less hairy tail, less inflated bullae, and underparts with gray-based hairs was warranted, and lumping by Hershkovitz (1962:448) unjustified.” J. J. Martínez and Di Cola (2011) included a small series (three specimens) of *G. domorum* in their analysis of geometric morphometric differentiation of *Graomys* samples, documenting that *domorum* was indeed phenetically distinct from both *G. chacoensis* and *G. griseoflavus*. Although the species status of *G. domorum* relative to the more broadly distributed *G. griseoflavus* seems incontrovertible, given their morphological and karyological differences, delimitation of the ranges of each in southern Bolivia and northern Argentina remains to be firmly understood.

Graomys edithae Thomas, 1919

Otro Cerro Pericote

SYNONYMS:

Graomys edithae Thomas, 1919d:495; type locality “Otro Cerro,” Catamarca Province, Argentina (= Otro Cerro, 28°45’S, 66°17’W, 2,023 m, Capayán, Catamarca, about 4 km SSE of Cerro Catalán; Pardiñas et al. 2007).

Graomys griseoflavus medius: Cabrera, 1961:495; *edithae* Thomas listed as synonym.

DESCRIPTION: Supposedly smallest species in genus; measurements of holotype head and body length 108 mm, tail length 127 mm, hindfoot 25 mm, ear length 20 mm, greatest skull length 28.5 mm, condyloincisive length 26.5 mm, zygomatic breadth 15.0 mm, nasal length 10.5 mm, interorbital breadth 4.5 mm, braincase breadth 13.5 mm, palatal length 12.8 mm, incisive foramina length 6.7 mm, bullar length 6.0 mm, and upper molar series 4.7 mm (Thomas 1919d). Dorsal color similar to that of *G. griseoflavus*, but without buffy wash on sides of latter. Under parts white, as in *G. centralis*, lacking slaty base characteristic of *G. domorum* and some populations of *G. griseoflavus*. Tail absolutely and proportionately shorter than *G. griseoflavus*, less heavily haired terminally but bicolored, brown above and white below. Skull a miniature of those of other species but notable for absence of beading on supraorbital edges.

DISTRIBUTION: *Graomys edithae* is currently known from two nearby localities in Catamarca province, Argentina, at elevations of 400 and 2,000 m.

SELECTED LOCALITIES (Map 277): ARGENTINA: Catamarca, Chumbicha (Thomas 1919d), Otro Cerro (type locality of *Graomys edithae* Thomas).

SUBSPECIES: *Graomys edithae* is monotypic.

NATURAL HISTORY: Nothing is known of the natural history of this species. However, the habitat around Otro Cerro, the type locality, is grassland at the top of the Cerro de Ambato.

REMARKS: Although *G. edithae* is currently recognized as distinct species, its taxonomic status should be considered uncertain pending systematic revision, including the review of the type series and the collection of additional specimens from the type locality and vicinity (Musser and Carleton 2005; Pardiñas et al. 2007). *Graomys edithae* has, judging from the holotype, an almost perfect coincidence in cranial traits with the other species in the genus, as Thomas (1919d) initially remarked. In contrast, in external morphology, the holotype of *G. edithae* embraces several traits that depart from congeners, including a very short ear and very long vibrissae. Additional diagnostic traits may include more opisthodont upper incisors, a wide U-shaped anterior border of the mesopterygoid fossa that lacks a median process, and a unique morphology of the presphenoid.

Thomas (1919d:495) wrote “this interesting little *Graomys* agrees with the larger species in all the essential characters of the group.” The type is an old male with worn teeth. In that paper, Thomas recognized three species of *Graomys* from Catamarca province, one he referred to *G. cachinus* J. A. Allen (junior synonym of *G. griseoflavus*), the largest of the three with a skull length between 33.5 and 35.0 mm; the second he named *G. medius* (also now junior synonym of *G. chacoensis*; see Remarks in that account), similar to *G. cachinus* but slightly smaller in size (skull length of holotype, an “adult male” 31.2 mm), and differing from it by less development of buffy band on sides, tail shorter and less tufted, smaller skull with shorter nasals, sharply angular supraorbital edges but with less distinct beads, and smaller bullae; and the third *G. edithae* based on a single old adult male with skull length 28.5 mm.

Cabrera (1961:495) placed *edithae* Thomas as a junior synonym of *Graomys griseoflavus medius* Thomas. Hershkovitz (1962:455, 461) retained *edithae* as a valid species, being impressed by both the small size and lack of supraorbital beading of the holotype. D. F. Williams and Mares (1989:216) regarded the holotype as notable for “the narrow procingulum of M1 . . . which is deeply divided from the protocone-metacone by deep anterior median folds, and the deep major fold on the M3” but noted that “the paratypes of *G. edithae* (from near Chumbicha, Catamarca, at an elevation nearly 2,000 m lower than the type locality), represent, in our opinion, *G. griseoflavus medius*” (= *G. chacoensis* herein). Pardiñas et al. (2007) clarified the location of the type locality as Otro Cerro, 28°45'S,

Map 277 Selected localities for *Graomys edithae* (●). Contour line = 2,000 m.

66°17' W, 2,023 m, about 4 km SSE of Cerro Catalán, Capayán, Catamarca province, Argentina.

Graomys griseoflavus (Waterhouse, 1837)

Common Pericote

SYNONYMS:

Mus (Phyllotis) griseo-flavus Waterhouse, 1837:28; type locality “Rio Negro,” Argentina; restricted to mouth of the Río Negro, Río Negro Province, Argentina (see Hershkovitz 1962:453).

Mus griseo-flavus: Waterhouse, 1839:62; name combination.

Phyllotis griseoflavus: Gray, 1843b:112; name combination.

Eligmodontia griseoflava: Thomas, 1898h:210; name combination.

Phyllotis cachinus J. A. Allen, 1901c:409; type locality “Upper Cachi River, Salta Province, Argentina.”

Graomys griseoflavus: Thomas, 1916a:142; first use of current name combination.

Graomys cachinus: Thomas, 1916a:142; name combination.

Graomys griseoflavus cachinus: Gyldenstolpe, 1932a:91; name combination.

Graomys griseoflavus griseoflavus: Gyldenstolpe, 1932a:91; name combination.

Phyllotis griseoflavus cachinus: Cabrera, 1961:494; name combination.

Phyllotis griseoflavus griseoflavus: Cabrera, 1961:495; name combination.

DESCRIPTION: Waterhouse (1837) provided brief review of relevant morphological details in original description, and wrote a more expansive description two years later (Waterhouse 1839). Although Waterhouse noted (1839:62) “tail rather shorter than the head and body taken together,” Hershkovitz (1962:453) argued that the “original measurements for combined head and body length (6” 8” = 169 mm) and for tail length (5” 6” = 140 mm)” of the holotype were incorrect, likely transposed, and in specimens he examined the “tail is always longer than combined head and body length.” Of samples for which Hershkovitz (1962:Table 61) provided external measurements, those clearly applicable to *G. griseoflavus* as understood herein range in head and body length 118–169 mm, tail length 134–171 mm, hindfoot length 27–31 mm, and ear length 23–25 mm. General dorsal color grayish yellow, less bright and buffy than *G. chacoensis*; ventral color white, but belly hairs typically gray at base rather than white throughout. Tail, like that of *G. chacoensis*, longer than head and body, bicolor, dark above and pale below, and well haired, with hairs increasing in length toward end, forming slight to bushy pencil at tip. Most craniodental dimensions average larger than their counterparts in *G. chacoensis* (J. J. Martínez, Krapovickas, and Theiler 2010), most notably in basilar length, incisive foramina length, post-palatal length, and bullar dimensions. Maxillary toothrow ranges 5.0–6.1 mm (Hershkovitz 1962:Table 61). Rossi (1983) reported morphometric data for confirmed *G. griseoflavus* populations from Mendoza province, and Carrizo and Díaz (2011) described postcranial skeletal anatomy.

DISTRIBUTION: *Graomys griseoflavus* occurs east of the Andes primarily in Monte, Espinal, and Patagonian steppe ecoregions of Argentina. J. J. Martínez and Di Cola (2011) mapped point localities for northwestern Argentina (Catamarca, Mendoza, Salta, San Juan, San Luis, and Tucumán provinces) and Udrizar Sauthier, Formoso et al. (2011) detailed more than 150 locality records in Patagonia (southern Buenos Aires, Chubut, Neuquén, Río Negro, and Santa Cruz provinces), where *G. griseoflavus* deeply penetrates the Patagonian Province along the major watercourses that dissect the region, but is absent from highland areas.

SELECTED LOCALITIES (Map 278; from Udrizar Sauthier, Formoso et al. 2011, except as noted): ARGENTINA: Buenos Aires, Bahía San Blas, Médanos (Theiler and Blanco 1996a); Catamarca, 4.6 km SW, 0.7 km N of Belén (OMNH 34926); Chubut, Comodoro Rivadavia (V. A. Rodríguez 2005), Escuela N 859, Fofó Cahuel, Península Valdez (J. J. Martínez and Di Cola 2011), Puerto Pijo, Rawson (Hershkovitz 1962), 17 km W of Sarmiento;

Jujuy, La Quiaca (MACN 36.802); La Pampa, 12 km NNE of Naicó, Estancia Los Toros (Tiranti 1998b); Mendoza, near Divisadero Largo (J. J. Martínez and Di Cola 2011); Neuquén, 1 km SE of bridge RNN 840 on Río Neuquén, Sierra del Portezuelo; Río Negro, El Espigón, 29 km S of El Cóndor on RPN 1, Las Grutas; Salta, ca. 3 km N of Cachi Adentro (OMNH 33335); San Juan, Castano Nuevo, 9 km NW of Villa Nueva (J. J. Martínez and Di Cola 2011), Tudcum, Nacedero (J. J. Martínez and Di Cola 2011); San Luis, 11 km W of Buena Esperanza (IADIZA 5439), Papagayos (J. J. Martínez and Di Cola 2011); Santa Cruz, Estancia La María, Piedra Clavada Sur, Port Desire (Hershkovitz 1962); Tucumán, Hualinchay (J. J. Martínez and Di Cola 2011).

SUBSPECIES: We regard *Graomys griseoflavus* as monotypic, despite a large geographic range that encompasses several different ecoregions within Argentina. Of the five subspecies recognized by Cabrera (1961), three are names now regarded as synonyms of *G. chacoensis* (*centralis* Thomas, *chacoensis* J. A. Allen, and *medius* Thomas). If a thorough review of geographic trends in morphology eventually supports the recognition of races, *cachinus* Thomas would be an available name for northern populations with the nominotypical form applicable to southern ones.

NATURAL HISTORY: *Graomys griseoflavus* has been collected in diverse habitats, including Espinal, Monte Desert, Patagonian steppe, and areas of cultivation and secondary vegetation (e.g., Mares, Ojeda, and Kosco 1981; Rosi 1983; Mares, Ojeda, Braun et al. 1997; Monjeau et al. 1997; Yahnke 2006). This species is nocturnal, with individuals using both horizontal terrestrial and vertical arboreal dimensions (Albanese et al. 2011). In the Monte Desert, this species differentially selected microhabitats with high cover of litter, subshrubs, or shrubs and trees in mesquite forest, and those with high cover in creosote bush communities (Corbalán 2006). Reproductive activity generally occurs during the spring, summer, and fall (Mares, Ojeda, and Kosco 1981; Mares, Ojeda, Braun et al. 1997; Yahnke 2006). In the Monte Desert, this species has been categorized as an omnivore with a strong tendency toward folivory (C. M. Campos, Ojeda et al. 2001) and a herbivore (Giannoni et al. 2005). Giannoni et al. (2011) reported food caching behavior. *Graomys griseoflavus* is scansorial and exhibits quadrupedal saltation as an escape mode (Taraboreli et al. 2003). Individuals are prey of Geoffroy's Cat (*Leopardus geoffroyi*; Bisceglia et al. 2011), the Burrowing Owl (*Athene cunicularia*; Nabte et al. 2008), and the Barn Owl (*Tyto alba*; Pardiñas, Teta et al. 2003). S. Anderson (1997) summarized information about ectoparasites for this species in Bolivia; Rojas and Digiani (2003) and Digiani and Durette-Desset (2003) described nema-

todes; and Schramm and Lewis (1988) and Lareschi et al. (2003, 2004) reported on fleas and mites for this species in Argentina.

REMARKS: As noted by J. A. Allen (1901c:409), “doubtless *griseoflavus*, *chacoensis*, and *cachinus* will prove to be closely related forms of the same species, but they show features of difference worthy of note, and, moreover, inhabit quite different faunal districts. The first two are chaco forms, widely separated geographically, while the latter is from the mountain district northwest of Salta.”

Cabrera (1961:495) included *Graomys hypogaeus* Cabrera, 1934, in the synonymy of *Phyllotis griseoflavus medius* (Thomas), but Teta, D’Elía, and Pardiñas (2010) convincingly demonstrated that Cabrera’s *hypogaeus* is a junior synonym of *Eligmodontia moreni* (see that account).

Pardiñas’s (1995c) reallocation of the late Pleistocene taxa *Bothriomys catenatus* and *Oxymycterus [sic] impexus*, described by Ameghino (1889), as full synonyms of *G. griseoflavus* broadens the historic range of this species further to northeastern Buenos Aires province rela-

tive to its current distribution. However, the reference of these fossils to *G. griseoflavus* was made prior to the recognition of *G. chacoensis* as a valid species (see that account).

Wainberg and Fronza (1974) and Pearson and Patton (1976) described a karyotype with a variable diploid number of $2n=34$ to 38 but constant $FN=44$, analyses that have been extended geographically in multiple additional publications (Zambelli et al. 1994, 2003; Catanesi et al. 2002; V. A. Rodríguez 2005). These cytotypes differed by two centric fusions. Theiler and Blanco (1996a) and Thaeiler et al. (1999b) documented reproductive isolation between these karyomorphs and a $2n=42$ cytotype originally allocated to *G. griseoflavus* (e.g., Zambelli et al. 1994) and now regarded as the separate species *G. chacoensis*.

Genus *Loxodontomys* Osgood, 1947

Pablo Teta, Ulises F. J. Pardiñas, Jorge Salazar-Bravo, and Guillermo D’Elía

Members of the genus *Loxodontomys*, commonly known as pericotes, range from the Central Cordillera of Santiago, Chile (about 33°30’S) south to Punta Arenas in southern Chile (latitude 53°30’S) and to Lago Argentino in southwestern Argentina (latitude 50°S). These mice occur at localities between sea level and 2,500m and in a variety of habitats, from Patagonian steppe to forests, meadows, and scrub-dominated valleys in the Andes of central Chile (Osgood 1943b; Hershkovitz 1962; Spotorno, Cofre et al. 1998). Except as noted, the following account is based on Teta, Pardiñas et al. (2009), which should be consulted for further details.

Hershkovitz (1962:391–392) summarized the long and meandering taxonomic and nomenclatorial history of *Loxodontomys*, which changed from placement within *Phyllotis sensu stricto* to *Auliscomys* and *Euneomys*. Briefly, Osgood (1947) erected *Loxodontomys* as a subgenus of *Phyllotis* to allocate *micropus* Waterhouse. Later, based on phenetic analyses of karyotypic and morphological data, Simonetti and Spotorno (1980) moved *micropus* from *Phyllotis* to *Auliscomys*. The generic status of *Loxodontomys* was subsequently supported by the morphology based phylogenetic analyses of Braun (1993) and Steppan (1993, 1995). Phylogenetic hypotheses constructed using molecular data suggested a close association with *Auliscomys* (L. I. Walker and Spotorno 1992; M. F. Smith and Patton 1999; Spotorno et al. 2001; D’Elía 2003a). Steppan et al. (2007) using both mtDNA and nucDNA gene sequences recovered a *Phyllotis* group composed of *Auliscomys*, *Loxodontomys*, *Phyllotis*, *Tapacomys*, and possibly the *Andalgalomys*

Map 278 Selected localities for *Graomys griseoflavus* (●). Contour line = 2,000m.

Salinomys clade. A more recent and more taxon dense analysis, also based on mtDNA and nucDNA markers, retrieved ambiguous relationships among these same genera (Salazar-Bravo et al. 2013).

Recent taxonomic compilations (e.g., Musser and Carleton 2005) recognize two valid species of *Loxodontomys*, *L. micropus* (Waterhouse) and *L. pikumche* Spotorno, Cofre, Manriquez, Vilina, Marquet, and Walker. Our inspection of the skull, mandibles, and skin of the holotype of *L. pikumche* (LCM 1759, Spotorno, Cofre et al. 1998:Fig. 5) indicated their composite nature, with important taxonomic implications (Teta, Pardiñas, and D'Elía 2011). Although the skin belongs to a specimen of *Loxodontomys*, the skull and mandibles belong to a subadult individual of the genus *Phyllotis*. The main anatomical traits that supported this conclusion included the degree of hypsodonty, size of M3, molar tooththrow orientation, bullar morphology, structure of the nasal bones, and the orientation of the mandibular condyle. Given these facts, Teta, Pardiñas, and D'Elía (2011) restricted the name *pikumche* to the skin, an act that maintains the linkage of the name to *Loxodontomys*. Nonetheless, the status of *pikumche*, whether a valid species or a subjective synonym, cannot be addressed until the genus is properly revised. Because analysis of the mtDNA cytochrome-*b* sequences failed to recover *pikumche* as a reciprocally monophyletic lineage (Cañón et al. 2010), for the present we treat *Loxodontomys* as a monotypic genus.

Loxodontomys is a medium-sized, robust sigmodontine rodent (head and body length 83–157 mm) with thick, lax, and lusterless pelage. General color dorsally varies from gray to brownish, grizzled with brownish yellow and intermixed with dusky black dorsally; the ventral surface is paler, often washed with white or yellow. Ears are small, with their length from notch about one-fifth to one-half less than the length of the hindfoot, which is also short. The tail is about as long as the combined head and body length. Postauricular patches are reduced or absent. Soles of the hindfeet are naked and lightly scutellated, with six small tubercles. The scale pattern of dorsal guard hairs is lanceolate (Chehébar and Martín 1989). Specimens from northern populations have a body pelage distinctly countershaded and tails more distinctly bicolored (Pine et al. 1979; Spotorno, Cofre et al. 1998).

The skull in *Loxodontomys* is moderately elongated, with a narrow interorbital region with either concave or parallel sides, sometimes raised, but never ridged nor beaded and lacking supraorbital knobs. The shape of the frontoparietal suture is rounded, and the edge of the frontals is convex. The interparietal is well developed with meandering sutures all around. The zygomatic arches converge anteriorly, forming a triangular outline when seen

from above (especially obvious in adults), without temporal ridges. The nasals are long, with their distal ends slightly to moderately expanded. The anterior borders of the zygomatic plates are either vertical or sometimes slightly concave, with the upper zygomatic roots high on the rostrum; zygomatic spines and the posterior margin of the plates are located at, or anterior to, the alveolus of M1. Incisive foramina are comparatively wide, with their borders almost parallel and terminating at the level of protocone of M1. The mesopterygoid fossa has slightly divergent borders and is distinctly narrower than the adjacent, deeply excavated, parapterygoid fossae. The palate is long, posterior palatal pits are minute, and palatal vacuities are large. Tympanic bullae are moderately inflated. The carotid arterial supply is the primitive pattern 1 (of Voss 1988), with a squamosal alisphenoid groove and sphenofrontal foramen. The alisphenoid strut is absent. The mandible is short and high, with a falciform coronoid process; this process ends at a plane slightly higher than the mandibular condyle; the capsular projection is well defined and lies below the coronoid; the angular process is short and blunt. Both Pearson (1958, 1983) and Hershkovitz (1962) provided external and cranial measurements.

Upper incisors are broad, ungrooved, and opisthodont to hyperopisthodont. Molars are tetralophodont, planar, and hypsodont, with principal cusps ovate, and with crests exhibiting a tendency to laminate obliquely at about 45° along main axis of teeth. Molar tooth rows are slightly divergent posteriorly. Paracone and metacone of unworn and moderately worn M1–M2 are inflected forward; M1 is elongated with subelliptical procingulum; anteromedian flexus of M1 is absent in adult individuals; parastyle/anteroflexus of M1 is present but indistinct; anteroloph of M2 and M3 are well-developed; and M3 has an enamel island. Lower molars have alternating primary cusps; m1 lacks an anteromedian flexid and has a rounded procingulum projected to the protoconid by well-defined anterolabial cingulum; the protoflexid of m2 is present as a groove; and the mesoflexid of m3 is reduced and shifted anteriorly relative to m2. The m3 has an obvious S-shape, subequal in length to m2 (Hershkovitz 1962; Braun 1993; Steppan 1995).

Axial skeletal elements have modal counts of 13 ribs, 13 thoracic vertebrae, 6 or 7 lumbar vertebrae, and 26 to 29 caudal vertebrae. Male accessory glands consist of one pair each of bulbourethral, anterior, and dorsal prostate, ampullary, and vesicular glands and two pairs of dorsal prostate glands (Voss and Linzey 1981). The distal bacular cartilage is tridigitate, with the medial digit longer than the lateral digits, and each lateral digit has a small medial hook. The proximal baculum is long and robust, with a central notch on the base. The urethral process of the phallus is long and unilobed (Braun 1993).

Phyllotis (*Auliscomys*) *micropus alsus*: Ellerman, 1941:455; name combination.

Phyllotis (*Auliscomys*) *micropus fumipes* Osgood, 1943b:214; type locality "Quellon [= Quellón (43.136°S, 73.663°W)], Chiloe Island [= Isla Grade de Chiloé], [Los Lagos,] Chile."

[*Phyllotis* (*Loxodontomys*)] *micropus*: Osgood, 1947:172; name combination.

Loxodontomys micropus: Massoia, 1982:45; first use of current name combination.

Loxodontomys pikumche Spotorno, Cofre, Manríquez, Vilina, Marquet, and Walker, 1998:362; type locality "Cajón del Río Maipo, sector Cruz de Piedra (34°10'S 69°58'W, 2,450 msnm), a 55 km S de la Central Hidroeléctrica de Las Melosas . . . en la Cordillera de Región Metropolitana," Chile.

DESCRIPTION: As for the genus.

DISTRIBUTION: Southern Chile and southwestern Argentina from the Andean area near Santiago in central Chile and western Mendoza province, Argentina, south to islands bordering the Straits of Magellan (at least one record from Isla Riesco; see Markham 1970; but absent from Tierra del Fuego), at elevations from sea level to 2,500 m (Osgood 1943b; Hershkovitz 1962; Spotorno, Cofre et al. 1998; Novillo et al. 2009). The known ecological distribution of *L. micropus*, traditionally considered a denizen of Andean forests (Pearson 1983), has been extended significantly as isolated populations in the basaltic tablelands of Río Negro (e.g., Maquinchao), Chubut (Sierra de Chacays), and Santa Cruz (Bosques Petrificados, Cerro Fortaleza) provinces (Heinonen Fortabat and Haene 1994; Teta et al. 2002; Pardiñas, Teta et al. 2003; Udrizar Sauthier, Teta et al. 2008; V. L. Roldán 2010). This species has been found in several archeological and paleontological deposits of the latest Pleistocene-Holocene in Argentinean Patagonia (e.g., Cueva Trafal I, Cueva Epullán Grande, Alero Santo Rosario; Pearson 1987; Pearson and Pearson 1993; Pardiñas 1998, 1999a; Rebane 2002; A. Andrade and Teta 2003; Teta et al. 2005; Pardiñas and Teta 2013b) and Chile (Cueva del Milodón, La Batea 1; Simonetti and Rau 1989; Simonetti and Saavedra 1994). Some of these records, especially those spanning the last 3,000 years, are extralimital to the current range of the species, suggesting that *L. micropus* had a more extended distribution in steppe areas during the cold-humid phases of the Late Holocene (Pardiñas 1999a; Teta et al. 2005; Udrizar Sauthier 2009).

SELECTED LOCALITIES (Map 279): ARGENTINA: Chubut, El Maitén (type locality of *Euneomys micropus alsus* Thomas), 8.4 km NW of Estancia El Valley, Valle de Lanzaniyeu (CNP-E 521), Estancia Santa María, Puesto El Chango (CNP-E 290), Paso del Sapo (Pardiñas, Teta et al. 2003), 4 km S of Tres Banderas (Udrizar Sauthier, Teta et al. 2008); Mendoza, Laguna del Diamante (A. Novillo, pers. comm.), 6 km NW (by road) of Las Leñas (Jayat et al. 2006); Neuquén, Cajón Grande, A° Curi Leuvú (CNP-E 632), SW end of Lago Hui Hui, 8 km W and 2 km S of Cerro Quillén (MVZ 163400), Paso Puyehue, 32 km WNW of Villa La Angostura (MVZ 181566), 2.6 km NW of Puente Carreri (CNP-E 186); Río Negro, entrance to Estación Calcatreo (CNP-E 287), Estancia Maquinchao, Puesto de Hornos (Teta et al. 2002), Estancia Pilcañeu (Teta et al. 2001); Santa Cruz, Cerro Comisión (CNP-E 413), Cerro Fortaleza (CNP-E 420), Lago Cardiel, La Península, Estación Las Tunas (Massoia et al. 1994b), laguna de los Cisnes (J. A. Allen 1905), Monumento Natural Bosques Petrificados (Heinonen, Fortabat, and Haene 1994), Río Ecker, 500 m aguas abajo Estación Casa de Piedra, margen norte (CNP-E 377). CHILE: Aysén, Fin del Fiordo Ofhidro (J. Guzmán, pers. com.); Biobío, Laguna del Laja, Río Petronquines (Spotorno, Cofre et al. 1998), Sierra de Nahuelbuta (Hershkovitz 1962); Los Lagos, Quellón, Isla Grande de Chiloé (type locality of *Phyllotis (Auliscomys) micropus fumipes* Osgood); Los Ríos, Fundo San Martín, San José, Valdivia (UACH 3115); Magallanes y Antártica Chilena, Lago Pehoe, Torres del Paine (MVZ 175150), Puerto Natales (Osgood 1943b), Punta Arenas (Osgood 1943b), vicinity of Puerto Henry, Isla Riesco (Markham 1970); Santiago, El Colorado, Farellones (Spotorno, Cofre et al. 1998).

SUBSPECIES: Three subspecies have been described, mostly based on subtle differences of metrics and external coloration (Thomas 1919b; Osgood 1943b). Gyldenstolpe (1932) and Ellerman (1941) recognized *micropus* and *alsus* as different; later, Osgood (1943b) included *alsus* under *micropus* and at the same time coined the new subspecies *fumipes* based on immature specimens from Chiloé Island. Both Pearson (1958) and Hershkovitz (1962) dismissed the differences between these nominal forms and considered *micropus* as monotypic. Cañón et al. (2010; see also E. P. Lessa et al. 2010) addressed the phylogeography of *Loxodontomys* with mtDNA cytochrome-*b* gene sequences from 24 Argentinean and Chilean localities, and documented a shallow but geographically structured genealogy. Two main evolutionary lineages, replacing one another geographically at about 44°S, gave support to the recognition of subspecies, the nominotypical *L. m. micropus* (from southern populations) and *L. m. alsus* (from northern populations). No specimen referable to *fumipes* Osgood was analyzed. The northern clade included hap-

lotypes recovered from specimens with $2n=32$ referred to the nominal form *pikumche* by Novillo et al. (2009) and from several Chilean localities ascribed by Spotorno, Cofre et al. (1998) to the range of this putative species as well as from Argentinean and Chilean populations within the range of *L. micropus* (*sensu* Spotorno, Cofre et al. 1998). In light of these results, Cañón et al. (2010) proposed that *pikumche* could be a junior synonym of *L. micropus*. As stated above, if the northern clade deserves taxonomic distinction, *alsus* would have priority given that the haplotype recovered from a topotype falls within the northern clade. Finally, Cañón et al. (2010) suggested a historical scenario whereby ancestral populations of *Loxodontomys* contracted their ranges into a minimum of two glacial refugia (although their location was not stated) to account for the origin of the geographic pattern of current genetic diversity they documented. Most of the Argentinean and Chilean populations lack karyological data, and thus the geographic structure of the chromosome variation is unknown.

NATURAL HISTORY: *Loxodontomys micropus* has been caught in *Nothofagus* forests, precordilleran shrubby steppes, humid dense grasslands (Mann 1978; Pearson 1983; Kelt 1994), and open habitats of spiny shrubs and dry grasslands on hard soil pavements (Spotorno, Cofre et al. 1998). It is nocturnal and both burrows and climbs skillfully (Pearson 1983). This rodent is primarily herbivorous, with stomach contents including green leaves, fungi, grass seeds, and fruits (Pearson 1983; Meserve et al. 1988; Monjeau 1989). In humid dense grasslands of northwestern Patagonia, *L. micropus* excavates tunnel systems, with numerous entrance openings and food chambers (Monjeau 1989). The reproductive season starts at the beginning of the spring and lasts through the end of the summer (Pearson 1983) or early Fall (Kelt 1994). The average number of embryos ranges between 4.1 in Argentina (Pearson 1983) to 4.8 in Chile (Greer 1965; Pine et al. 1979). Both sexes are reproductively active after reaching 48 g of mass (Pearson 1983). Teta, Pardiñas et al. (2009) summarized available information about ontogeny and reproduction, population characteristics, space use, diet, diseases and parasites, and interspecific interactions, mostly based on the original investigations of Pearson and Pearson (1982), Pearson (1983) and Kelt (1994). Specimens collected at different localities from Argentina and Chile were seropositive for hantavirus (Spotorno et al. 2000; Cantoni et al. 2001; Cerda and Sandoval 2004; J. C. Ortiz et al. 2004; Padula et al. 2004). Goff and Gettinger (1995) and D. Castro et al. (2001) described new species of chiggers and lice, respectively, from specimens identified as *L. micropus*.

REMARKS: Charles Darwin collected the type of *Mus micropus* Waterhouse at some point between the mouth of

the Río Santa Cruz (= “Santa Cruz,” as stated by Waterhouse 1837) and the Andean Cordillera (see Waterhouse 1839). According to Hershkovitz (1962:392) this specimen was collected “perhaps in the vicinity of the present locality of La Argentina, province of Santa Cruz, southern Argentina.” However, Darwin did not reach the longitude of La Argentina, as judged by Hershkovitz’s (1962:Fig. 89, p. 393) placement of this locality on the south shore of Lago Argentino. The westernmost point reached by Darwin was about 240km west of the mouth of the Río Santa Cruz, about 30km from the eastern side of Lago Argentino (G. R. Cueto et al. 2008; Teta, Pardiñas et al. 2009).

Spotorno, Cofre et al. (1998) registered two diploid numbers for *L. micropus*. Chilean specimens south of 37°30’S have $2n=34$, $FN=36$, with most chromosomes telocentric. They found the second diploid complement ($2n=32$, $FN=34$) north of this latitude, formally describing these specimens under the name *L. pikumche*. In this karyotype, all elements were telocentric except a single small metacentric pair (Spotorno, Cofre et al. 1998). Novillo et al. (2009) reported the same karyotype for four

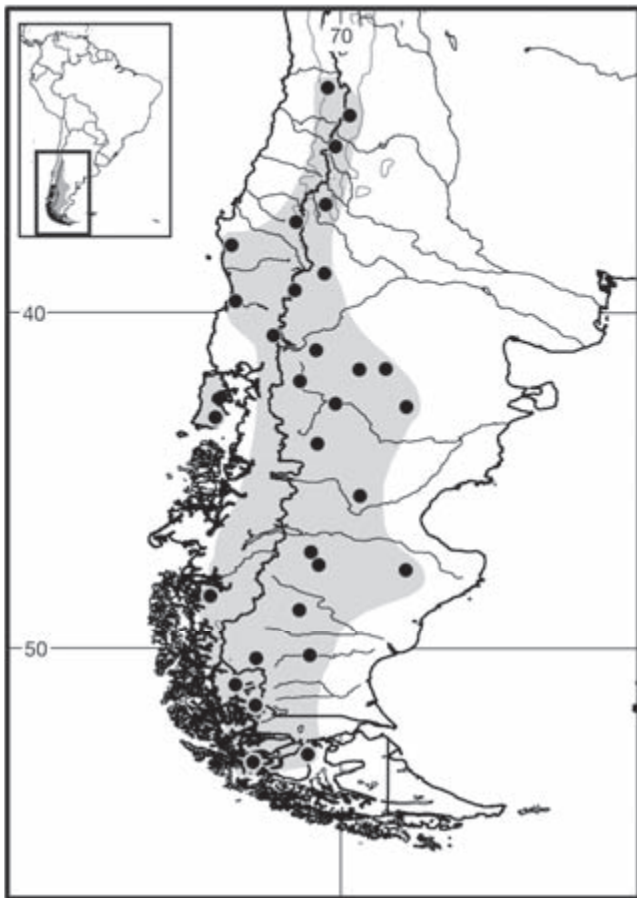

specimens collected in Mendoza province, Argentina, close to the border with Chile. Cañon et al. (2010) misunderstood the data provided by Spotorno, Cofre et al. (1998) and Novillo et al. (2009) about the fundamental numbers of Chilean and Argentinean populations assigned by them to *L. pikumche* and stated that the Argentinean population differed from those of northern Chile and thus represented a third karyomorph for the genus. Spotorno and Walker (1979) provided a banded karyotype from Chilean representatives of *L. micropus*.

Genus *Phyllotis* Waterhouse, 1837

Scott J. Steppan and Oswaldo Ramirez

The leaf-eared mice of the genus *Phyllotis* include 15 named extant species and one undescribed species that live from the highlands (páramo) of Ecuador throughout the Andes and adjacent xeric habitats to the southern tip of continental South America. Although there has been some fluctuation in generic status and placement for several species, the genus as recognized here includes 15 species: *P. alisosiensis*, *P. amicus*, *P. andium*, *P. anitae*, *P. bonariensis*, *P. caprinus*, *P. darwini*, *P. definitus*, *P. gerbillus*, *P. haggardi*, *P. limatus*, *P. magister*, *P. osgoodi*, *P. osilae*, and *P. xanthopygus*. There have been two complete revisions of the genus (Pearson 1958; Hershkovitz 1962) and a review as part of a revision of the tribe Phyllotini (Steppan 1995). Some phylogenetic studies have suggested that the genus is paraphyletic, but these have not provided a robust framework for a revision of the taxonomy. Braun (1993) recommended removing *P. gerbillus* and *P. amicus* to the genus *Paralomys* Thomas, 1926, a recommendation followed in part by Musser and Carleton (2005), but that change was both weakly supported by morphological data (Steppan 1995) and weakly contraindicated by mtDNA cytochrome-*b* sequence data (Steppan 1998). The evidence for exclusion of *P. wolffsohni* came from both morphology and molecules (Steppan 1995; Steppan 1998), but neither study provided a robust alternative hypothesis. More detailed taxon sampling with cytochrome-*b* sequences, however, supported the removal of *wolffsohni* to *Tapecomys* and, along with nuclear RAG1 sequences, the inclusion of *P. gerbillus* and *P. amicus* within *Phyllotis* (Steppan et al. 2007).

Many taxa lumped into a polytypic *P. darwini* (particularly by Hershkovitz 1962, but also by Pearson 1958) have been removed more recently to separate species: *P. caprinus*, *P. definitus*, *P. limatus*, *P. magister*, *P. xanthopygus*, and (*Tapecomys*) *wolffsohni*. L. I. Walker et al. (1984) demonstrated reproductive isolation between *P. darwini* and the subspecies *vaccarum*, and associated *vaccarum* with the elevated *P. xanthopygus*. Many studies still

Map 279 Selected localities for *Loxodontomys micropus* (●). Contour line = 2,000m.

incorrectly refer individuals of *P. xanthopygus* to *P. darwini*, the latter being restricted to central Chile. Musser and Carleton (1993) misinterpreted L. I. Walker et al. (1984) by including northern populations of *P. xanthopygus* in *P. darwini*, although these authors later corrected this assignment (Musser and Carleton 2005). Steppan (1995) elevated *P. xanthopygus chilensis* to species status based on the absence of intermediate phenotypes along elevational transects with *P. xanthopygus rupestris* and due to a putative apomorphy. Subsequent study indicated that it was the Pacific slope populations of *P. x. rupestris* rather than *P. x. chilensis* that possessed a clear apomorphic feature and that could be distinguished from nearby *P. xanthopygus*, leading Steppan (1998) to place the Pacific slope populations of *P. x. rupestris* within *P. limatus* while returning, at least temporarily, *chilensis* to *P. xanthopygus*.

Species of *Phyllotis* live in open, mostly rocky and brushy habitats from sea level to nearly 5,000 m. Fossils attributable to *P. andium* and *P. xanthopygus* have been found from the Early Pleistocene to the Recent (Pardiñas and Dechamps 1996; P. E. Ortiz, Cirignoli et al. 2000) of Ecuador, Peru, Bolivia, Chile, and Argentina, but specific determination is difficult given the relatively undifferentiated molar dentition among the species and the nearly complete absence of cranial characters (U. F. J. Pardiñas and S. J. Steppan, unpubl. data). Ancient DNA assignable to *P. limatus* has been identified from midden remains in the Atacama desert of Chile, dated to near the Pleistocene/Holocene boundary (Kuch et al. 2002).

In addition to the species described here, the genus includes one undescribed species from Peru (V. Pacheco, pers. comm.) that is genetically distinct from other named species, as well as one population currently assigned to *P. amicus* and possibly one to three more that are currently attributed to *P. xanthopygus* (Steppan et al. 2007; S. J. Steppan, unpubl. data).

Phyllotis species are small to medium-sized phyllotine mice with long, fine, and variably colored pelage, the ventrum usually much lighter than the dorsum. The tail is subequal in length to the combined head and body; ears are medium to large, and typically lack postauricular patches. The hindfeet are moderate in length, with a reduced fifth hind toe; the soles are naked with six plantar pads. Females have eight mammae, in four pairs.

The molars are tetralophodont with no trace of a mesoloph or mesolophid; incisors are without grooves, opisthodont to nearly orthodont, and without tripartite dentine fissure. M1 has labial roots; there are two or three roots on M3 and two roots on m3. The anteromedian flexus of M1 is either absent or limited to a shallow groove; mesostyle and parastyle/anteroflexus of M1 are absent; the anterolabial

cingulum m1 is long and distinct, fusing with protoconid and leaving the protoflexid as a lake (with wear); m1 possesses a posterolophid/stylid, at least in juveniles; the hypoflexus of M3 is pinched to form a lake; the mesoflexid m3 is shifted anteriorly relative to m2; the hypoflexid of m3 shows no posterior shift; and the opposing flexi in M3 do not meet.

The dorsal surface of the skull is slightly rounded; the supraorbital region is narrow with convex sides. The zygomatic notches are moderate to deep; a zygomatic spine is absent (anterior border is either flat or vertical) or weakly developed. The antorbital bridge of the zygomata is positioned slightly below the rostrum. The narrowest portion of the interorbital ridge is centrally or anteriorly located; the frontoparietal suture forms an obtuse angle; the interparietal is well developed, >0.45% the length of the parietal measured along the median. The incisive foramina are long, reaching the anterolabial and anterolingual conules of M1. The palate is long and broad, with no medial process on its posterior border. Maxillary toothrows are parallel or posteriorly convergent. The mesopterygoid fossa is distinctly narrower than adjacent parapterygoid fossae, with the orbital wings of the presphenoid anterior to maximum constriction; a sphenopalatine foramen is present, small to moderate in size. The tegmen tympani contacts a suspensory process of the squamosal. The stapedial spine of each auditory bulla is circular to ovoid in cross-section, and not laterally appressed. Both the basioccipital and the ectotympanic portion of auditory bullae bound the internal carotid canal. An alisphenoid strut is absent or filamentous. The medioventral process of the mandibular ramus is absent or weakly developed.

The vertebral column has a modal count of 13 thoracic, six lumbar, four sacral, and 28–36 caudal vertebrae. The tuberculum of the first rib articulates with the transverse process of the seventh cervical and first thoracic vertebrae; the second thoracic vertebra has an elongated neural spine; hemal arches are absent. The entepicondylar foramen of the humerus is absent, but the supertrochlear foramen is present.

The gall bladder is present; the stomach is hemiglandular. Two distinct preputial glands are present, with a third, smaller gland found in some populations. The baculum is complex with short to long distal bacular elements. Hershkovitz (1962) detailed bacular variation within and among taxa.

SYNONYMS:

Mus (Phyllotis) Waterhouse, 1837:28; part; as subgenus; type species *Mus (Phyllotis) darwini* Waterhouse, by subsequent designation (Thomas 1884:449).

Hesperomys: Waterhouse, 1839:76; part (listing of *xanthopygus* and *darwini*).

Phyllotis: Gray, 1843b:xxiii; listed as genus equivalent to *Mus* Linnaeus and *Hesperomys* Waterhouse, the two genera under which most sigmodontine names were at that time allocated.

Hesperomys (Phyllotis): Thomas, 1884:449; part (listing of *darwini*), as subgenus; not *Hesperomys* Waterhouse.

Phyllotis: Thomas, 1897a:1020; elevated to genus.

Paralomys Thomas, 1926b:315; type species *Paralomys gerbillus* Thomas, by original designation.

KEY TO SPECIES OF *PHYLLOTIS*:

1. Small bodied, maxillary molar row <4.7 mm. 2
- 1'. Medium to large bodied, maxillary molar row >4.7 mm 3
2. Tail length <95 mm 4
- 2'. Tail length >95 mm. 5
3. Maxillary molar row between 4.7 and 5.7 mm 6
- 3'. Maxillary molar row >5.7 mm 11
4. Tail shorter than head and body; upper tooththrows posteriorly convergent *Phyllotis haggardi*
- 4'. Tail subequal to or longer than head and body; upper tooththrows parallel sided, ventrum entirely white, dorsum and sides light sandy color. *Phyllotis gerbillus*
5. Upper incisors opisthodont, ears as long or longer than hindfoot *Phyllotis amicus*
- 5'. Upper incisors orthodont, ears shorter than hindfoot. *Phyllotis andium*
6. Mesoflexus of M3 highly reduced relative to M2, or absent 7
- 6'. Mesoflexus of M3 reduced relative to M2 10
7. Ratio of incisor depth to width across both teeth >0.9 *Phyllotis limatus*
- 7'. Ratio of incisor depth to width across both teeth <0.9 8
8. Ratio of M3 length to alveolar length of molar toothrow <0.205 14
- 8'. Ratio of M3 length to alveolar length of molar toothrow >0.205 9
9. Small swellings or knobs on anterior supraorbital region posterior to lacrimal *Phyllotis darwini*
- 9'. Supraorbital swelling or knobs absent *Phyllotis caprinus*
10. Anteroflexus of M2 distinct; if protoflexus present, then procingulum poorly developed as broad, shallow projection with concave anterior edge; if proflexus not present, then distinct anteroflexus or paraflexus present; mesoflexus of M3 reduced relative to M2. *Phyllotis andium*
- 10'. Procingulum of M2 completely absent; posteropalatal pits small, lateral to mesopterygoid fossa, usually even with or behind posterior margin of palate (occasionally slightly anterior); mesopterygoid fossa broad,

- with sides parallel or diverging anteriorly, the anterior border broad and frequently interrupted by a median posterior projection of the palate. . . . *Phyllotis osilae*
11. Nasals broad, clearly greater than minimum interorbital distance 12
 - 11'. Nasals narrow, subequal to or less than minimum interorbital distance. 14
 12. Interorbital region very constricted, <3.7 mm, uniformly cinnamon-colored ventrum *Phyllotis alisosiensis*
 - 12'. Interorbital breadth >3.8 mm, ventrum with gray region 13
 13. Pectoral spot or streak present and well defined; distributed west of the Andean cordillera 14
 - 13'. Pectoral spot or streak absent or weakly defined; confined to Sierra de la Ventana, Argentina *Phyllotis bonariensis*
 14. Mesopterygoid fossa with anterior border square or slightly rounded *Phyllotis magister*
 - 14'. Mesopterygoid fossa with anterior border pointed. *Phyllotis definitus*
 15. Incisor enamel white to yellowish-white; dorsal pelage dark gray; tail slightly bicolored *Phyllotis anitae*
 - 15'. Incisor enamel yellow to orange; dorsal pelage light to medium ochraceous or brown; tail bicolored 16
 16. Karyotype $2n=38$ *Phyllotis xanthopygus*
 - 16'. Karyotype $2n=40$ *Phyllotis osgoodi*

Phyllotis alisosiensis Ferro, Martínez, and Barquez, 2010

Los Alisos Leaf-eared Mouse

SYNONYM:

Phyllotis alisosiensis, Ferro, Martínez, and Barquez, 2010: 526; type locality "El Papal, 2175 m (27°11'S 65°57'W), Parque Nacional Campo de Los Alisos, Departamento Chichigasta, Tucumán, Argentina."

DESCRIPTION: Large, total length 243–342 mm (mean 271 mm), tail length 121–139 mm (mean 131 mm), hindfoot length 29–32 mm, ear length 20–24 mm, mass 35–70 g. Characterized by long and fluffy fur, cinnamon-brown dorsal color flecked with black hairs, and ventral color strongly cinnamon. Mean hair length 16–17 mm on rump; individual hairs tricolored with short basal white band followed by broad plumbeous band and brownish to cinnamon tip; guard hairs entirely black and project 4–5 mm beyond the level of the underfur. Transition between dorsal and ventral colors gradual, not sharply contrasting. Ears dark, scarcely haired except for conspicuous patch on anterior edge; inner surface covered with dark brown hairs. Inconspicuous grayish postauricular patch present. Tail strongly bicolored, dark gray above and whitish below, about same length as head and body. Both manus and pes covered dorsally with short but dense white

hairs; unguis covers each claw. Ventral mystacial vibrissae short and white; dorsal ones longer, black basally and white distally.

Skull robust and wide, with enlarged rostrum. Condylar length 27.1–32.5 mm; zygomatic breadth 14.8–18.8 mm; rostral length 12.1–13.4 mm. Interorbital constriction notably narrow, 3.6 mm or less, especially in comparison to other, codistributed species (*P. anitae*, *P. osilae*, and *P. xanthopygus*). Anterior end of zygomatic arch high and, from lateral view, antorbital bridge flat and barely visible. In fully developed adults, width of zygomatic plates equal to or greater than width of interorbital constriction. Molars above and below hypodont, wide, with simplified occlusal pattern. M1 trilophodont, with major cusps alternating; labial flexus oblique and lingual flexus transverse to medial plane; procingulum well developed, wide, and without anteromedian flexus. M2 S- or Z-shaped, with hypoflexus anteriorly oriented and metaflexus transverse. M3 with deep hypoflexus surpassing medial plane of tooth. Lower m1 trilophodont, m2 bilophodont, and m3 also bilophodont with hypoflexid more developed than metaflexid.

DISTRIBUTION: *Phyllotis alisosiensis* is known from only two localities in Tucumán province, Argentina, at the southernmost end of the Yungas ecoregion across an elevational range from 1,234 to 2,175 m.

SELECTED LOCALITIES (Map 280): ARGENTINA: Tucumán, El Papal (type locality of *Phyllotis alisosiensis*, Ferro, Martínez, and Barquez), Reserva Provincial Los Sosa, Rte 307, km 35, campamento de Vialidad Provincial (CML 4106).

SUBSPECIES: *Phyllotis alisosiensis* is monotypic.

NATURAL HISTORY: Little is known about the natural history, reproductive biology, or other aspects of the population ecology of this species. Specimens from the type locality were obtained in upper montane forest (*Bosques Montanos*) where the landscape is dominated by deciduous forest of Andean alder (*Alnus acuminata* [Betulaceae]), intermixed with bamboo (*Chusquea* sp.), ferns (*Blechnum occidentale* [Blechnaceae]), scattered thickets of queñoa (*Polylepis australis* [Rosaceae]), and native grasses (*Cortaderia* sp.) on steep, rocky slopes. The only other known locality is within cloud forest at the upper part of the Lower Montane Forest (Hueck 1978), habitats dominated by species of *Myrcianthes* (Myrtaceae) with epiphytes, lianas, and grasses.

REMARKS: Ferro et al. (2010) provided detailed morphological and multivariate morphometric comparisons among *P. alisosiensis* and the three other species of *Phyllotis* that occur in Tucumán province, *P. anitae*, *P. osilae*, and *P. xanthopygus*. *Phyllotis alisosiensis* can be easily distinguished from all other species in the genus by its strong cinnamon color on the ventrum and strongly constricted interorbital

Map 280 Selected localities for *Phyllotis alisosiensis* (●). Contour line = 2,000 m.

region. Based on comparative mtDNA cytochrome-*b* sequences, *P. alisosiensis* is closely related to *P. anitae*, with divergence only 1.5% divergent (a measure exceeded by many conspecific populations; Steppan et al. 2007), with these two species forming a sister group with *P. osilae*.

Phyllotis amicus Thomas, 1900

Friendly Leaf-eared Mouse

SYNONYMS:

Phyllotis amicus Thomas, 1900d:355; type locality “Tolon [= Tolón], coast district, Province Cajamarca, N.W. Peru. Altitude 100 m.”

Phyllotis amicus maritimus Thomas, 1900f:296; type locality “Eten, [Lambayeque,] coast of N.W. Peru. Altitude 20 m.”

Phyllotis amicus montanus Thomas, 1900f:297; type locality “Uramarca [= probably Yuramarca], [Ancash,] near Pallasca, N.W. Peru. Altitude 1200 m.”

DESCRIPTION: Characterized by small size, short hindfeet, especially short molar tooththrows (3.5–4.2 mm), and relatively large ears, usually as long or longer than hindfeet. Interorbital region broad and flat, frequently with square or sharp edges; upper incisors opisthodont; auditory bullae large and globular; posteropalatal pits located anterior to mesopterygoid fossa; M2 with two outer entrant angles in unworn teeth. Northernmost coastal specimens small and brightly colored; those inland and from south, even along coast, larger and duller.

Phyllotis amicus meets both *P. limatus* and *P. andium*, and may possibly contact *P. definitus* and *P. gerbillus*. Much smaller in all dimensions relative to *P. definitus* and *P. limatus*, especially smaller teeth, opisthodont incisors, more conspicuous development of two outer entrant angles of M2, shorter fur, and more naked tail. *Phyllotis amicus* distinguished from *P. andium* by smaller dimensions, slightly paler color, more conspicuous development of second out entrant angle on M2, and proportionally larger ears. *Phyllotis gerbillus* with pure white venter, white tail white above and below, and smaller ears.

DISTRIBUTION: *Phyllotis amicus* is limited to western Peru, from Piura south into Arequipa department. In the north it occurs on both slopes of the Cordillera Occidental, but is restricted to the western slope of the Andes further south (Pearson 1972:Fig 2), over an elevational range from sea level to about 2,800 m.

SELECTED LOCALITIES (Map 281): PERU: Ancash, 29 km S (by road) of Casma (MVZ 139263), Uramarca [= Yuramarca], near Pallasca (type locality of *Phyllotis amicus montanus* Thomas); Arequipa, Atiquipa (FMNH 107392); Ayacucho, 35 mi ENE of Nazca (Pearson 1972); Huancavelica, 2 km E of Ticrapo, Pisco Valley (Pearson 1972); Lambayeque, 12 km S and 8 km E of Bayovar (MVZ 135370), Etén (type locality of *Phyllotis amicus maritimus* Thomas); Lima, 19 mi N of Cañete (MVZ 119990), 20 km N and 6 km W of Chancay (MVZ 135723), 1 mi W of Surco (MVZ 119996); Piura, 6.5 mi E (by road) of Canchaque (MVZ 141837), Cerro Amotape, 10 km N and 40 km W of Sullana (MVZ 135736), 45 km W and 15 km N of Chulucanas (MVZ 135731).

SUBSPECIES: Pearson (1958) recognized three subspecies: the nominotypical form ranging from the foothills of Cajamarca south to southern Lima department, at elevations from sea level to 1,800 m; *maritimus* Thomas, known only from the vicinity of the type locality; and *montanus* Thomas, occupying the western slopes of the mountains in La Libertad and Ancash, Peru, between 1,050 and 2,750 m. Hershkovitz (1962) argued that retention of formal subspecies was unwarranted and regarded *P. amicus* as monotypic.

NATURAL HISTORY: *Phyllotis amicus* inhabits sand and rock formations with sparse cover on the coast and Pacific slope of northern and central Peru. It is found in *Tillandsia* (Bromeliaceae) desert, rocky places with sparse cactus vegetation, and dry washes (Pearson 1972), where it may be with *P. limatus* and *P. andium*. Its feeding habits appear broadly omnivorous. Leafy vegetation constituted about half of its diet, which is typical of the genus, but it consumed more insect and less seed than most other species of *Phyllotis* (Pizzimenti and DeSalle 1980). This species maintains low density, highly dispersed populations in a harsh environment, and can reproduce at any time of the year in central Peru

Map 281 Selected localities for *Phyllotis amicus* (●). Contour line = 2,000 m.

(Arana et al. 2002). Movement distances calculated from six individuals in Lachay Lomas was 44.5 m; litter size varied between one and three pups (Arana et al. 2002).

REMARKS: *Phyllotis amicus* appears most closely related to *P. gerbillus* in mtDNA cytochrome-*b* sequences (Steppan et al. 2007), with this pair of species sister to *P. andium* and an undescribed taxon. A sample from Puno department, Peru, far south of the previously known range and attributed to *P. amicus* on morphological grounds may represent a distinct species (Steppan et al. 2007).

The $2n=38$ karyotype consists of 18 pairs of metacentric and submetacentric autosomes grading from large to small, a large acrocentric or submetacentric X and a small metacentric Y chromosome (Pearson 1972). The morphology of the X chromosome is apparently geographically structured, metacentric in all individuals and localities sampled in the Región de Lima but acrocentric in those further to the south in Huancavelica. The complement with the metacentric X chromosome is shared with *P. caprinus*, *P. darwini*, *P. gerbillus*, *P. magister* (except for the morphology of the Y chromosome), *P. haggardi*, and *P. xanthopygus* (Pearson 1972; Pearson and Patton 1976).

Phyllotis andium Thomas, 1912

Andean Leaf-eared Mouse

SYNONYMS:

Phyllotis andium Thomas, 1912b:409; type locality "Cañar, [Cañar,] Ecuador. Alt. 2600 m."

Phyllotis melanius Thomas, 1913b:407; type locality “Porvenir, Bolivar, Ecuador. Alt. 1800 m”; corrected to Cañar, Cañar, Ecuador by Pearson (1958:440).

Phyllotis andium stenops Osgood, 1914b:165; type locality “Rio Utcubamba, 15 miles above Chachapoyas, [Amazonas,] Peru.”

Phyllotis tamborum Osgood, 1914b:165; type locality “Tambo Carrizal, mountains east of Balsas, [Amazonas,] Peru. Altitude 5,000 ft.”

Phyllotis fruticicolus Anthony, 1922:1; type locality “Gua-chanamá, [Loja,] southern Ecuador; altitude, 9050 ft.”

Phyllotis andium tamborum: Thomas, 1926e:614; name combination.

Phyllotis lutescens andium: Osgood, 1944:194; name combination, as subspecies of what is now *Phyllotis osilae* J. A. Allen.

DESCRIPTION: Medium-sized, rich-brown species, with delicate vibrissae, lightly haired tail, relatively small ears, pale gray venter with distinct buffy pectoral streak in some specimens, and occasionally entire belly tinged with buff. Comparing *P. andium* to four other species within range, *P. amicus* has a smaller body size with proportionately larger ears (usually as long as hindfeet), small molars, and opisthodont upper incisors; *P. definitus* is much larger in almost all dimensions, especially toothrow; *P. haggardi* is a shorter-tailed species (tail <95 mm and shorter than head and body length) with longer palate, posteropalatal pits usually sunk in depressions, toothrows tending to converge posteriorly, zygomatic arches more widely flaring, and interorbital edges rather sharp; and *P. xanthopygus* has fluffier fur, hairier tail, heavier vibrissae, and larger ears. In Lima department, Peru, where *P. andium* contacts *P. xanthopygus*, there is almost no overlap between them in ear length (19–25 mm versus 24–29 mm, respectively).

DISTRIBUTION: *Phyllotis andium* occurs on both slopes of the Andes, although mostly on the western slope, from Lima department, Peru, north to Tungurahua province in Ecuador, mostly at elevations between 1,500 and 4,000 m but extending down the west slope in northern Peru (Lambayeque department) to about 300 m (Pearson 1958).

SELECTED LOCALITIES (Map 282): ECUADOR: Azuay, Yunguilla Valley (FMNH 53240); Cañar, Cañas (type locality of *Phyllotis andium* Thomas); Loja, Gua-chanamá (type locality of *Phyllotis fruticicolus* Anthony); Tungurahua, Baños (Pearson 1958). PERU: Amazonas, Río Utcubamba, 15 mi above Chachapoyas (type locality of *Phyllotis andium stenops* Osgood), Tambo Carrizal, mountains east of Balsas (type locality of *Phyllotis tamborum* Osgood); Ancash, Huaraz (FMNH 81202), Macate (FMNH 20935); Cajamarca, Cajamarca (FMNH 19465), El Arenal, 1 km S and 6 km W of Pomahuaca (MVZ 135774); Huánuco, Ambo (FMNH 24724); Lam-

bayeque, Chongoyape (Hershkovitz 1962); La Libertad, 5 mi SW of Otuzco (MVZ 138045); Lima, Huaros (MVZ 120015), Lomas de Lachay, 22 km N and 11 km W of Chancay (MVZ 139269), 5 mi E of Yauyos (MVZ 137638); Piura, Aisayacu (FMNH 84206), Porculla Pass (MVZ 138078).

SUBSPECIES: Despite the association as synonyms of four named taxa, both Pearson (1958) and Hershkovitz (1962) failed to document geographic trends worthy of recognition and thus regarded *P. andium* as monotypic.

NATURAL HISTORY: This is a species of brushy habitats on both sides of the Andes (Pearson 1972), where it replaces *P. xanthopygus* in central Peru. Specimens from the Rímac Valley in Lima department illustrate the contact between the two species. The brushy zone and the small areas of forest between these elevations are occupied by *P. andium*. On the south side at 4,000 m near Casapalca, traps among rock and grass with many woody lupine bushes (the upper limit of this lupine) caught about equal numbers of *P. xanthopygus* and *P. andium*. Among lupine bushes at 3,700 m, only *P. andium* was taken, and only *P. andium* among brush between 2,000 and 2,900 m. *Phyllotis andium* is sympatric with *P. haggardi* in southern Ecuador, with *P. limatus* and *P. x. posticalis* in central Peru, with *P. definitus* on the Pacific slope of northern Peru, and with *P. magister* and *P. amicus* in central and southern Peru (Pearson 1958). *Phyllotis andium* utilizes more leafy vegetation and less seed than most other species in the genus (43% grass, 31% forbs, 4% seeds, and 22% insects; Pizzimenti and DeSalle 1980). Along the Peruvian coast near Lima, *P. andium* show clear seasonal reproductive activity between July and October (Arana et al. 2002). Based on data from three individuals, the movement distance between captures varied between 40.8 and 68.8 m; the gestation period was 24 days, and the litter size varied between one and four young (Arana et al. 2002). Although *P. andium* is sympatric with several other congeneric species, the regions of overlap are always restricted to small contact areas, suggesting local spatial segregation.

REMARKS: Pearson (1958:440) concluded that the holotype of *melanius* Thomas was composite, consisting of a skin of *Akodon aerosus* (the dark color of which was, unfortunately, the basis for the name *melanius*) and a skull of a *Phyllotis*. Because Thomas (1913b) attached the name *melanius* to a *Phyllotis* and not *Akodon*, Pearson selected the skull as the type while noting that a skin-only specimen of a *Phyllotis andium* (also collected by P. O. Simons and bearing the same field number) should be associated with the type skull. This *Phyllotis* skin bears the locality designation of Cañar, Ecuador, which Pearson (1958) argued should be regarded as the correct type locality of *melanius* Thomas.

The karyotype of *P. andium* consists of a $2n = 64$, FN = 72, with five pairs of medium and small metacentrics and sub-

Map 282 Selected localities for *Phyllotis andium* (●). Contour line = 2,000 m.

metacentrics, a graduated series of 26 pairs of acrocentrics, a large submetacentric X chromosome, and a medium-sized submetacentric Y chromosome (Pearson 1972).

Phyllotis anitae Jayat, D'Elía, Pardiñas, and Namen, 2007

Anita's Leaf-eared Mouse

SYNONYM:

Phyllotis anitae Jayat, D'Elía, Pardiñas, and Namen, 2007: 778; type locality "Argentina: Province of Tucumán, Department of Trancas, 10 km by road south of Hualinchay on the trail to Lara (26°19'20.2"S, 65°36'45.5"W, 2316 m."

DESCRIPTION: Distinguishable from congeners externally by large size (head and body length 89–123 mm, tail length 94–112 mm); dark gray dorsal coloration; light ochraceous venter; ears covered internally and externally by dark brown hairs; manus with digits and distal dorsum covered with white hair, proximal dorsum of both manus and pes dark; tail slightly bicolored and haired but not penicillate; markedly hypsodont molars; and narrow interorbital region hourglass in shape.

DISTRIBUTION: *Phyllotis anitae* is known only from the type locality in the Yungas forest in northwestern Argentina.

SELECTED LOCALITIES (Map 283): ARGENTINA: Tucumán, 10 km by road S of Hualinchay (type locality of *Phyllotis anitae* Jayat, D'Elía, Pardiñas, and Namen).

Map 283 Single known locality for *Phyllotis anitae* (●). Contour line = 2,000 m.

SUBSPECIES: *Phyllotis anitae* is monotypic.

NATURAL HISTORY: Little is known about this species. The type was trapped in the ecotone between montane forest and high-altitude grasslands, a sparse cloud forest habitat (Jayat, D'Elía et al. 2007), near isolated and large rocks. This species is believed to be a rare specialist of the high-elevation *Alnus* (alder, Betulaceae) forest.

REMARKS: *Phyllotis anitae* is sympatric with *P. osilae* and occurs near to some *P. xanthopygus* populations. It can be distinguished by its darker coloration, especially dorsally. The karyotype is unknown.

Phyllotis bonariensis Crespo, 1964

Buenos Aires Leaf-eared Mouse

SYNONYMS:

Phyllotis darwini bonariensis Crespo, 1964:99; type locality "Abra de la Ventana, part. de Tornquist, prov. de Buenos Aires, a 500 m s.m.," Parque Provincial Ernesto Tornquist, Buenos Aires, Argentina.

Phyllotis bonariensis: Reig, 1978:180: first use of current name combination.

DESCRIPTION: One of larger species (head and body length ranges from 127 to 151 mm), similar in size to *P. magister*, but with ears and hind legs relatively small, vibrissae well developed, dorsal coat light in color (similar to *P. xanthopygus rupestris*), and ventral pelage gray white (similar to *P. xanthopygus xanthopygus*), flanks and belly very well defined, and tail bicolored with scarce hairs and paler than the body. Pectoral buffy band very slightly marked.

Ear length (23–25 mm) shorter than hindfoot length (25–28 mm). Skull large (greatest length 31.4–35.1 mm); minimum interorbital width 4.1–4.5 mm, with sides diverging backward slightly; large posterolateral palatal pits located anterior to mesopterygoid fossa; distal portion of nasals markedly wide, 30–35% of length of nasal suture line; auditory bullar length (4.8–5.3 mm) shorter than upper alveolar molar length (5.4–6.1 mm). Upper incisors orthodont and anteriorly pigmented; upper molar rows parallel; M2 lacks procingulum.

DISTRIBUTION: *Phyllotis bonariensis* is restricted to the Sierra de la Ventana in Buenos Aires province, eastern Argentina.

SELECTED LOCALITIES (Map 284): ARGENTINA: Buenos Aires, Abra de la Ventana (type locality of *Phyllotis darwini bonariensis* Crespo).

SUBSPECIES: *Phyllotis bonariensis* is monotypic.

NATURAL HISTORY: *Phyllotis bonariensis* lives in rocky places at about 400 m elevation in a range of hills north of Bahía Blanca, in Buenos Aires department. There are no published data on ecology or behavior of this species.

REMARKS: Originally described as a subspecies of *P. darwini* (= *P. xanthopygus* herein), Reig (1978) and Galliari et al. (1996) elevated *P. bonariensis* to species status, a decision followed by some authors (e.g., Musser and Carleton 1993, 2005) but not by others (e.g., M. M. Díaz et al. 2006). This species is known only from the eight specimens used in the original description and a few collected subsequently. As noted by Pearson (1972), this taxon is geographically isolated from other species of *Phyllotis* by broad expanses of pampa. Molecularly, *P. bonariensis* is included within a widespread clade otherwise composed of

Map 284 Single known locality for *Phyllotis bonariensis* (●). Contour line = 2,000 m.

P. limatus, *P. x. xanthopygus*, *P. x. vaccarum*, and some *P. x. rupestris* (Steppan et al. 2007). A more thorough geographic sampling of these taxa is required to resolve species-level boundaries within this clade. The karyotype is unknown.

Phyllotis caprinus Pearson, 1958

Capricorn Leaf-eared Mouse

SYNONYMS:

Phyllotis caprinus Pearson, 1958:435; type locality “Tilcara, 8,000 feet, Jujuy, Argentina.”

Phyllotis darwini caprinus: Hershkovitz, 1962: name combination.

DESCRIPTION: Large, relatively short-furred, with flat, sharp-edged, long-waisted interorbital region, long frontal bones, V-shaped frontoparietal suture, and heavy rostrum. Zygomatic plates sharply vertical or project forward slightly above, their anterior margins straight or concave; posteropalatal pits anterior or lateral to mesopterygoid fossa; nasals even with or project posteriorly behind the premaxillae. M3 small with or without an island; M2 with one outer entrant angle and usually second smaller notch.

In color, *P. caprinus* similar to sympatric or nearly sympatric *P. xanthopygus* but larger in body size (head and body length 102–140 mm, mean 118 mm, as opposed to 87–130 mm, mean of 103 mm), with thicker tail, and typically with buffy pectoral streak that is absent in latter.

DISTRIBUTION: *Phyllotis caprinus* occurs on the eastern Andean slopes in northern Argentina and southern Bolivia, between 2,100 and 4,500 m.

SELECTED LOCALITIES (Map 285): ARGENTINA: Jujuy, Humahuaca (Pearson 1958), Sierra de Zenta (Pearson 1958), Tilcara (type locality of *Phyllotis caprinus* Pearson). BOLIVIA: Chuquisaca, Camargo (MVZ 120121); Potosí, Yuruma (MVZ 120211); Tarija, Rancho Tambo, 61 km by road E of Tarija (AMNH 262987).

SUBSPECIES: *Phyllotis caprinus* is monotypic.

NATURAL HISTORY: *Phyllotis caprinus* occurs in brushy habitats in southern Bolivia and northern Argentina. At the type locality in northern Argentina, *P. caprinus* lives in brushy hedgerows and stonewalls, but just east of Tilcara, at Alfarcito where there is a mixture of brushy and open habitats, *P. caprinus* is sympatric with *P. xanthopygus*. Pearson (1958) collected large numbers of individuals among scattered bushes and *Opuntia* at 2,600 m in southern Bolivia.

REMARKS: Hershkovitz (1962:335–339) disputed Pearson’s (1958) conclusion that *P. caprinus* was a species distinct from others in the genus and regarded it merely as a geographic race of *P. darwini* (= *P. xanthopygus* herein). Most other authors, however, have accepted the morphological and distributional data provided by Pearson as substan-

Map 285 Selected localities for *Phyllotis caprinus* (●). Contour line = 2,000 m.

tiating his hypothesis of species-level status (e.g., Cabrera 1961; Musser and Carleton 1993, 2005; Steppan 1998). Pearson (1958) suspected that *P. caprinus* was most closely related to "*P.*" *wolffsohni* (now *Tapecomys wolffsohni*), but Steppan's (1993) phylogenetic analysis of morphological traits placed the species as the sister to *P. darwini* (*sensu stricto*). Molecular phylogenetic analyses, to date, have not included *P. caprinus* (e.g., Steppan et al. 2007). The karyotype is $2n=38$, $FN=72$, with 36 size-graded biarmed autosomes, a large submetacentric X, and a small metacentric Y chromosome (Pearson and Patton 1976). It appears identical to that found in most populations of *P. xanthopygus*.

Phyllotis darwini (Waterhouse, 1837)

Darwin's Leaf-eared Mouse

SYNONYMS:

Mus (Phyllotis) darwini Waterhouse, 1837:28; type locality "Coquimbo," Coquimbo, Chile.

Hesperomys darwini: Thomas, 1884:449; name combination.

Mus melanonotus Philippi and Landbeck, 1858:78; type locality "prov. Santiago prope locum [= near the place of] Angostura," Chile.

Mus dichrous Philippi, 1900:14, plate III, Fig. 2; type locality "provincia Santiago, prope [= near] Peine," Chile.

Mus megalotis Philippi, 1900:15, plate III, Fig. 3; type locality "provincia Santiago," Chile.

Mus mollis Philippi, 1900:23, plate VII, Fig. 1; type locality "provincia Santiago," Chile.

Mus illapelinus Philippi, 1900:28, plate IX, Fig. 1; type locality "prope [= near] Illapel," Coquimbo, Chile.

Mus Segethi Philippi, 1900:30, plate XI, Fig. 2; type locality "provinciae Santiago loco dicto Peine," Chile.

Mus campestris Philippi, 1900:38, plate XVI, Fig. 1; type locality "Choapa," Coquimbo, Chile.

Mus melanotis Philippi, 1900:39, plate XVI, Fig. 3; no type locality given, but certainly in Chile (Hershkovitz 1962:321).

Mus platytarsus Philippi, 1900:47, plate XIX, Fig. 4; type locality "La Ligua," Aconcagua, Chile.

Mus Boedeckeri Philippi, 1900:53, plate XXII, Fig. 2; type locality "provincia Maule; in praedio Coroney [= Coronel]," near Quirihue, Maule, Chile (see Osgood 1943b:202).

Mus griseoflavus Philippi, 1900:55, plate XXIV, Fig. 1; preoccupied by *Mus (Phyllotis) griseoflavus* Waterhouse; type locality "La Serena in provincia Coquimbo," Chile.

Phyllotis darwini: Thomas, 1902b:131; first use of current name combination.

Phyllotis darwini boedeckeri: Osgood, 1943b:202; name combination.

Phyllotis darwini fulvescens Osgood, 1943b:204; type locality "Sierra Nahuelbuta, west of Angol, Malleco, Chile. Altitude about 4,000 feet."

DESCRIPTION: Relatively short-furred, dark-colored coastal mouse with very large ears and occasional buffy pectoral streak. In comparison to *P. x. vaccarum*, which occurs at higher elevations in Chilean Andes, *P. darwini* has smaller body (mean head and body length, 119.5 versus 124.2 mm), tail (mean length, 119.2 versus 129.6 mm), skull (mean greatest length, 29.63 mm versus 31.90 mm), and especially molars (mean toothrow length, 5.26 versus 5.74 mm). Darker and browner in dorsal color, with paler lateral line; fur shorter; and ears more naked. In comparison to *P. x. rupestris*, which replaces *P. darwini* to north in coastal Chile, *P. darwini* somewhat smaller (mean head and body length, 105.0 versus 112.3 mm), colored darker brown, and with slightly larger (mean height, 26 versus 25 mm) and also more naked ears. Under parts may be nearly white but often creamy or even pale buffy rather than white (Osgood 1943b).

DISTRIBUTION: This species is limited to the coastal region and western slopes of the Andes in central and northern Chile, from Antofagasta south to Cautín regions, at an elevation range from sea level to 2,200 m (Osgood 1943b; Pearson 1958; Spotorno, Zuleta et al. 1998).

SELECTED LOCALITIES (Map 286): CHILE: Antofagasta, Paposo (MVZ 119184); Atacama and Parinacota, 10 mi N of Caldera (MVZ 150056), Vallenar (MVZ 118659); Araucanía, Galvarino (USNM 93254); Biobío, Sierra de Nahuelbuta (type locality of *Phyllotis darwini fulvescens* Osgood); Coquimbo, Cerro Potrerillos, 4 km E of

Guañeros (MVZ 150059), Las Palmas, 95 km N of Los Vilos (MVZ 150060), 10 km N of Pte. Los Molles (FMNH 119508); Santiago, Farellones (LCM 746); Valparaíso, Valparaíso (Pearson 1958).

SUBSPECIES: Osgood (1943b) listed three subspecies for *Phyllotis darwini* (*sensu stricto* as currently understood, not the broader view espoused by Osgood [1943b], Pearson [1958], and Hershkovitz [1962]) along the central coast of Chile: the broadly distributed nominotypical form was well as *P. d. boedeckeri* and *P. d. fulvescens*, both known only from their respective type localities near the coast. Pearson (1958) retained both *boedeckeri* Philippi and *fulvescens* Osgood as valid, the former as a short-tailed coastal form and the latter as a darkly colored inhabitant of *Araucaria* forests. Hershkovitz (1962) regarded *boedeckeri* Philippi as a synonym of *P. d. darwini* but retained *fulvescens* Osgood as a valid subspecies. As yet, lacking appropriate samples and analyses, no hypothesis regarding infraspecific groups within *P. darwini* has been tested adequately.

NATURAL HISTORY: *Phyllotis darwini* occurs in semiarid thorn scrub and sparse desert habitats. It is a granivorous-folivorous rodent with an average adult weight of about 50 g (Meserve and Le Boulengé 1987). Large numerical fluctuations and temporal variation in demographic variables has been found (M. Lima and Jaksic 1999; M. Lima et al. 2001), with population size varying between less than 10 (Meserve et al. 1995) to 230 individuals ha⁻¹ during El Niño events (M. Lima and Jaksic 1999; M. Lima et al. 1999). The mean home range length varied from 36.3 m (± 2.42 m s.d.) to 76.9 m (± 9.00 m s.d.) (Fulk 1975). Breeding is markedly seasonal, starting in September and lasting until January or February (Fulk 1975; Meserve and Le Boulengé 1987). Females produce two or three litters per reproductive season (Fulk 1975; Meserve and Le Boulengé 1987). The mean litter size was calculated as 4.21 (L. I. Walker et al. 1984) and 5.2 (Meserve and Le Boulengé 1987).

REMARKS: As noted above, *P. darwini* has been traditionally viewed as a highly polytypic species of immense range (from central Peru to southern Argentina; Osgood 1943b; Pearson 1958; Hershkovitz 1962). Both Osgood (1943b) and Pearson (1958) recorded what they believed to be intergrades between *P. d. darwini* and *P. d. rupestris* (now *P. x. rupestris*) in northern Chile and between *P. d. darwini* and *P. d. vaccarum* (now *P. x. vaccarum*) where they replace one another elevationally in central Chile. However, L. I. Walker et al. (1984; see also L. I. Walker et al. 1999) demonstrated very limited hybrid production in laboratory crossings, with male hybrids exhibiting testicular sterility and female hybrids with greatly reduced fecundity, supporting reproductive isolation in the wild. Nevertheless, the failure of some subsequent authors to recognize the taxonomic restriction of *P. darwini* to central Chilean populations (the

Map 286 Selected localities for *Phyllotis darwini* (●). Contour line = 2,000 m.

recommendation of L. I. Walker et al. 1984) has resulted in many studies and some GenBank sequences incorrectly attributing observations to *P. darwini* rather than correctly those of *P. xanthopygus*. *Phyllotis darwini* does not occur in Peru, Bolivia, Argentina, or high elevations in Chile (>2,200 m), and all studies from these areas are more correctly referred to *P. xanthopygus* or other species.

The karyotype consists of a $2n = 38$, FN = 72, with 18 pairs of metacentric and submetacentric autosomes plus a large, slightly submetacentric X chromosome and a small metacentric Y chromosome (Pearson 1972). This complement is identical to that of *P. xanthopygus* but with much larger blocks of centromeric heterochromatin on all chromosomes (L. I. Walker et al. 1984). It is also identical to *P. magister* except for the latter's subtelocentric Y chromosome (L. I. Walker et al. 1999). Hybrids between *P. darwini* and *P. magister* conform to Haldane's Rule, with fertile females but sterile males (L. I. Walker et al. 1999).

Phyllotis darwini has been the focus of numerous studies on physiology and metabolism (e.g., Bozinovic and Nespolo 1997; Bacigalupe et al. 2012) and the quantitative genetic characterization of these traits.

Phyllotis definitus Osgood, 1915

Ancash Leaf-eared Mouse

SYNONYMS:

Phyllotis definitus Osgood, 1915:189; type locality "Maconate, 50 miles northeast of Chimbote, [Ancash,] Peru. Altitude 9,000 ft."

Phyllotis magister definitus: Pearson, 1958:431; name combination.

Phyllotis darwini definitus: Hershkovitz, 1962:296; name combination.

DESCRIPTION: Large bodied (mean head and body length 126.3 mm, range: 111–146 mm) with tail about equal in length (mean 120.6 mm, range: 109–136 mm). Overall dorsal color tones deep and rich, cinnamon brown mixed liberally with dusky, but with rump slightly paler than back and shoulders and nape inclining to grayish. Nose, forehead, and sides of face decidedly grayish, in definite contrast to body. Venter buffy ochraceous, paler and more whitish on throat and inguinal region, with definite buffy band across pectoral region; all hairs slate gray at base. Forefeet and hindfeet white, with proximal part of pes more or less ochraceous. Inner surface of ears rufous. Tail bicolored, dusky above and buffy white below.

Skull large (mean length, 31.6 mm, range: 29.4 to 35.0 mm) and stoutly built, with broad nasals, heavy zygomatics, and broad teeth as part of long toothrow (>5.8 mm). As noted by Pearson (1958, 1972), cranially *P. definitus* quite similar to *P. magister*.

DISTRIBUTION: *Phyllotis definitus* is confined to the upper slopes of the western Andes in Ancash department, Peru, with the four known localities ranging in elevation from 2,590 to 3,800 m (Pearson 1972).

SELECTED LOCALITIES (Map 287): PERU: Ancash, Macate (type locality of *Phyllotis definitus* Osgood), 1 km N and 12 km E of Pariacoto (MVZ 135794).

SUBSPECIES: *Phyllotis definitus* is monotypic.

NATURAL HISTORY: This species inhabits the brushy zone on the western Andean slopes where habitat loss may have reduced population sizes. It is sympatric with *P. andium*. No other data on reproduction, behavior, or ecology has been published.

REMARKS: *Phyllotis definitus* was described originally as a species (Osgood 1915), but was relegated by both Pearson (1958) and Hershkovitz (1962) to geographic races of *P. magister* or *P. darwini* (*sensu lato*), respectively. Pearson (1958:431) pointed out that *magister* and *definitus* were similar in most characters except color and occupied the same elevational zones on the western Andean slope. He noted, however, the lack of specimens from intervening localities between their respective ranges. In a subsequent study based on more specimens, Pearson (1972) reevaluated his 1958 opinion and agreed with Osgood's (1915) original hypothesis that *P. definitus* was a valid species, distinguishable from *P. magister* by both a richer coloration and karyotype. Steppan's (1993; see also Steppan and Sullivan 2000) cladistic analysis of morphological traits placed *P. definitus* either as the sister to *P. magister*, to the

Map 287 Selected localities for *Phyllotis definitus* (●). Contour line = 2,000 m.

exclusion of *P. darwini*+*P. xanthopygus* although with low support, or as part of an unresolved polytomy that formed the base of *Phyllotis* (Steppan and Sullivan 2000). More thorough geographic sampling and molecular data are critically needed.

The karyotype is $2n = 54$, FN = 72, with 20 biarmed and 32 acrocentric autosomes, a large submetacentric X chromosome, and a smaller acrocentric that is probably the Y chromosome (Pearson 1972).

Phyllotis gerbillus Thomas, 1900

Peruvian Leaf-eared Mouse, Gerbil Leaf-eared Mouse

SYNONYMS:

Phyllotis gerbillus Thomas, 1900a:151; type locality "Piura, [Piura,] N.W. Peru, alt. 50 m."

Paralomys gerbillus: Thomas, 1926b:315; name combination, *Phyllotis gerbillus* Thomas, 1900 given as genotype of *Paralomys* Thomas.

Hesperomys [(*Paralomys*)] *gerbillus*: Ellerman, 1941:448; name combination.

P[*hyllotis*]. (*Paralomys*) *gerbillus*: Osgood, 1947:167; name combination.

DESCRIPTION: Smallest member of genus (mean head and body length 83.2 mm, range: 77–96 mm) with tail subequal in length relative to body (mean length 78.1 mm, range: 62–90 mm). Overall, upper parts of head and body ochraceous or salmon-colored, finely peppered with dark brown; upper half of sides of body like back but hairs without dark tips; lower half wholly white like under parts. Hairs of limbs, cheeks, and sides of rostrum white. Tail thinly haired throughout, overall white in color, but sometimes with occasional dark hair or patch of hairs, with integument of terminal one-fourth to one-third of tail dark brown, contrasting sharply with whitish basal portion; pencil rudimentary. Hindfoot broad and short (19 to 21 mm), sole sparsely set with whitish bristles except on six well-developed plantar pads. Ear comparatively small (17 to 18 mm); white preauricular spot usually present.

DISTRIBUTION: This species is restricted to the Sechura desert on the coast of northwestern Peru.

SELECTED LOCALITIES (Map 288): PERU: Lambayeque, 2 mi SE of Morrope (MVZ 138023); Piura, 10 km E of Piura (MVZ 135706), Reventazon, 64 km S and 19 km W of Sechura (MVZ 135710), 30 km SSE of Sechura (MVZ 135709), 10 km ENE of Talara (Pearson 1972).

SUBSPECIES: *Phyllotis gerbillus* is monotypic.

NATURAL HISTORY: *Phyllotis gerbillus* is nocturnal, spending the day underground, and does not need to drink free water (Koford 1968). The habitat is mounded with loose sand, from drifts around dead bushes to dunes several meters high and half covered with low green shrubs, principally thick-leaved evergreens, *Capparis scabrida*, *C. avicennifolia* (Capparaceae), and the deciduous legume *Prosopis juliflora* (Fabaceae); under many bushes, the ground was littered with dry fruits and seeds (Koford 1968). Habitat loss in the Sechura desert may threaten the remaining populations of this most morphologically distinctive *Phyllotis*. It may be caught together with the introduced *Mus musculus* but does not contact the ranges of any other member of the genus. The number of embryos in eight pregnant females ranged from one to four (average three; Pearson 1972).

REMARKS: The name refers to the gerbil-like and contrasting pale sandy dorsal versus white ventral coloration, a combination unique among species of *Phyllotis*. Pearson (1958) regarded *Paralomys* a valid genus closely related to *Phyllotis* but later changed his mind (Pearson 1972). Hershkovitz (1962) placed *gerbillus* within *Phyllotis*. Cladistic analysis of morphological characters led Braun (1993) to remove *gerbillus* from *Phyllotis* and resurrect *Paralomys*, including *amicus* within that genus. Stepan (1993; 1995) found support for removing *gerbillus* but felt the removal was premature given the weak signal in the data. More recent molecular data indicated that *P. gerbillus* is most closely related to *P. amicus* (Stepan et al. 2007),

Map 288 Selected localities for *Phyllotis gerbillus* (●). Contour line = 2,000 m.

with these two species together with *P. andium* forming a well-supported clade within *Phyllotis*.

The karyotype is $2n=38$, $FN=72$, and consists of 18 pairs of metacentric and submetacentric autosomes, a large submetacentric X chromosome, and a small metacentric Y chromosome (Pearson 1972).

Phyllotis haggardi Thomas, 1898

Haggard's Leaf-eared Mouse

SYNONYMS:

Phyllotis Haggardi Thomas, 1898f:270; type locality "Mount Pichincha, [Pichincha,] Ecuador, altitude 3400–4000 metres."

H[esperomys]. elegans: Tomes, 1860a:213; part; not *Mus elegans* Waterhouse [= *Eligmodontia typus* F. Cuvier].

Phyllotis elegantulus Thomas, 1913a:139; type locality "Pallatanga, [Chimborazo,] Ecuador."

Phyllotis fuscus Anthony, 1924a:1; type locality "Contraerbas, Provincia del Azuay, 11,000 feet, Western Andes," Ecuador.

Phyllotis haggardi haggardi: Pearson, 1958:442; name combination.

Phyllotis haggardi fuscus: Pearson, 1958:442; name combination.

Phyllotis haggardi elegantulus: Pearson, 1958:443; name combination.

DESCRIPTION: Small species (head and body length 99–115 mm), with proportionally short tail (less than head and body length, 72–89 mm), short ears, colored buffy to dark brown above with head and rump not markedly different from back; venter gray, well defined from sides, and usually lacking even hint of pectoral streak. Tail bi-colored, clothed with short hairs and with virtually no terminal pencil. Palate relatively long for a *Phyllotis*, large posteropalatal pits tending to be sunk in depressions, upper tooththrows tending to converge posteriorly, and nasals pointed at posterior ends and extending behind premaxillae. In comparison with *P. andium*, with which it overlaps in range, *P. haggardi* with more abruptly flared zygomatic arches, shorter maxillary tooththrow (range: 4.0–4.7 mm versus 4.2–5.0 mm for Ecuadorean samples of *P. andium*), and shorter tails (length <95 mm versus >100 mm).

DISTRIBUTION: *Phyllotis haggardi* occurs on the upper slopes on both sides of the Andes through Ecuador, typically between 2,500 and 4,500 m, but may extend to as low as 2,000 m in Pichincha province.

SELECTED LOCALITIES (Map 289): ECUADOR: Chimborazo, Mt. Chimborazo (FMNH 53306), Urbina (Pearson 1958); Napo, Papallacta (AMNH 46824); Pichincha, Pichincha (type locality of *Phyllotis haggardi* Thomas), Solaya (FMNH 53309), Tanda (Pearson 1958).

SUBSPECIES: Pearson (1958) recorded substantial geographic variation within *P. haggardi*, with increasing duskiness in coloration from north to south, together with increased length of the skull and a narrowing and lengthening of the nasals. He recognized this trend by distinguishing a broadly ranging *P. h. fuscus* from the nominotypical form, which he restricted to the northern part of the range of the species in the vicinity of Pichincha and Quito to Mt. Mojanda. Pearson also recognized *P. h. elegantulus* Thomas, restricted to its type locality and based on only two specimens, although he did so with reluctance: “I have retained *elegantulus* as a subspecies primarily to avoid having to place the clearly defined *P. h. fuscus* into synonymy under the almost unknown *elegantulus*” (p. 443). Hershkovitz (1962) regarded *P. haggardi* as monotypic.

NATURAL HISTORY: This species usually lives at higher elevations than *P. andium* at the same latitude, although *P. haggardi* itself descends to relatively low elevation at the northern end of its range. Almost nothing is known about of its ecology and reproductive traits.

REMARKS: Pearson (1958:443) gave the type locality of *elegantulus* Thomas as “Nadonbi, Pallatanga, about 6,5000

Map 289 Selected localities for *Phyllotis haggardi* (●). Contour line = 2,000 m.

feet” but suggested that this locality was likely incorrect. As noted by Tomes (1860a:211), the collection of which the holotype was a part was “believed to have been collected at Pallatanga, on the western slope of the Cordillera; but the exact locality is not certain, from the specimens having been unfortunately mixed together.” Pearson suggested that the two known specimens might have actually come from near Quito or from the vicinity of Riobamba, where the collector L. Frazer had also worked.

The karyotype is $2n=38$, $FN=72$, with both autosomal and sex chromosome complements similar to those of *P. amicus*, *P. caprinus*, *P. darwini*, *P. gerbillus*, *P. magister*, and *P. xanthopygus* (Pearson 1972; Pearson and Patton 1976).

Phyllotis limatus Thomas, 1912

Lima Leaf-eared Mouse

SYNONYMS:

Phyllotis darwini limatus Thomas, 1912b:407; type locality “Chosica, near Lima, [Lima,] Peru. Alt. 850 m.”

Phyllotis limatus: Stepan, 1998:582; first use of current name combination.

DESCRIPTION: A member of *darwini* species group, distinguishable from others by deep and narrow upper incisors (depth at midarc >90% of width across both incisors at cutting edge), short to moderate maxillary tooththrow (4.2–5.8 mm), light coloration, venter frequently white, and two pairs of preputial glands. Stepan (1998) provided comparative measurements for *P. limatus*, *P. xanthopygus* (subspecies *chilensis*, *posticalis*, and *rupestris*), *P. darwini*, and *P. magister*.

DISTRIBUTION: This species is restricted to the arid coast and Pacific slopes of the Andes from Lima in central Peru south to Tarapacá in northern Chile, at an elevational range from sea level to 2,500m in the north and sea level to 4,000m in the south.

SELECTED LOCALITIES (Map 290): CHILE: Antofagasta, San Pedro de Atacama (MVZ 150069); Arica y Parinacota, Putre (FMNH 133844); Tarapacá, mouth of Río Loa (LCM 511). PERU: Arequipa, 43km E of Arequipa (LSUMZ 27858), 5 mi ENE of Camaná (MVZ 143701), Chala (MVZ 139311); Ayacucho, 35 mi ENE of Nazca (MVZ 138092); Ica, 10km SSE of Pisco (MVZ 136328); Lima, 4km ENE of Pucusana (MVZ 137658), Rímac Valley (MVZ 120067), 1 mi W of Surco (MVZ 120023), Yangas (MVZ 136332); Tacna, Morro Sama, 65 km W of Tacna (MVZ 143722).

SUBSPECIES: Steppan (1998) documented a sharp step in the clinal length of the auditory bullae, with the break between samples in northern and central coastal Arequipa, Peru. He thus informally designated a “northern *limatus*” (from Lima south along the coast to extreme northwestern Arequipa) and a “southern *limatus*” (from central Arequipa south to Antofagasta, Chile). Steppan (1998) went on to note that, were one to recognize these geographic units formally, the southern group currently lacked a name.

NATURAL HISTORY: *Phyllotis limatus* is an inhabitant of arid foothills, rocky outcrops, foggy lomas among a pure stands of *Tillandsia* as well as in more varied habitat supporting cacti and scattered weeds (Pearson 1958) on the west slope of the Andes. Diet is primarily insects and forbs, consuming more of them than nearby *P. x. chilensis* of southern Peru (54% versus 35%) and a lower proportion of seed and grass (6% versus 28%; Pizzimenti and DeSalle 1980). The breeding season seems to coincide largely with the wet season (November to April), but some females were pregnant in every month. Litter size is modest, embryo counts in 29 females from the mountains of southern Peru averaged 3.69, but at Morro Sama on the Tacna coast to southern Peru, litters were larger than in any of the other populations during an El Niño event (embryo counts of 6, 6, 7, 2; Pearson 1976).

REMARKS: Pearson (1958) and Hershkovitz (1962) both regarded *limatus* to be a subspecies of *P. darwini* (*sensu lato*) and mapped its range to include Lima, Ica, and Arequipa regions in Peru. These authors regarded populations from southern Peru (southern Arequipa, Moquegua, and Tacna) as well as those in northern provinces of Antofagasta and Tarapacá in Chile to represent *P. darwini rupestris*. Steppan (1998), however, documented both the commonality of morphology of these more southern populations to *limatus* (especially in the width and depth of the upper incisors) and the composite nature of the samples

from this area that Osgood (1943b), Pearson (1958), and Hershkovitz (1962) had referred to *P. d. rupestris*. As a consequence, Steppan extended the range of *P. limatus* to Tarapacá and Antofagasta, Chile, while solidifying its status as a species separate from *P. xanthopygus* (*P. darwini* of these earlier authors). As noted in the account for *P. xanthopygus*, *Mus rupestris* P. Gervais might more correctly apply to *P. limatus* than to that species (see Steppan 1998). If so, it would be the senior name for what we, and earlier authors, herein call *P. limatus*.

Cytochrome-*b* sequences for the few specimens of *P. limatus* examined supported its monophyly, but these are nested within those of *P. xanthopygus*, including representatives of *P. x. chilensis*, *P. x. posticalis*, *P. x. rupestris*, and *P. x. vaccarum* as well as *P. bonariensis* (Steppan 1998; Steppan et al. 2007; Riverón 2011). Incomplete lineage sorting of nuclear RAG1 sequences (Steppan et al. 2007) due to recency of ancestry has likely resulted in the lack of complete reciprocal monophyly of these taxa. Mitochondrial affinity to nearby *P. x. rupestris* might be due either to mitochondrial introgression or very recent morphological divergence and speciation. Both Kuch et al. (2002) and Steppan et al. (2007) have argued that *P. limatus* was derived recently, perhaps during the most recent ice age.

Pearson (1972) recorded a karyotype for specimens from Lima department, Peru with $2n=38$, FN=72 and the same autosomal and sex chromosome morphology as representatives of three subspecies of *P. xanthopygus* (*chilensis*, *posticalis*, and *rupestris*).

Map 290 Selected localities for *Phyllotis limatus* (●). Contour line = 2,000m.

Phyllotis magister Thomas, 1912

Master Leaf-eared Mouse

SYNONYMS:

Phyllotis magister Thomas, 1912b:406; type locality “Arequipa, [Arequipa,] Peru. Alt. 2300 m.”

Phyllotis magister magister: Pearson, 1958:430; name combination.

Phyllotis darwini magister: Hershkovitz, 1962:288; name combination.

DESCRIPTION: Large (head and body length 108–145 mm), coarse-haired species with buffy pectoral streak, long tail (averaging longer than head and body length, range: 117–158 mm), unusually large molars (toothrow length 5.5–6.5 mm), broad rostrum, sharp interorbital edges, nasals that seldom reach posterior to premaxillae, large postero-palatal pits anterior to mesopterygoid fossa, and bullae that usually taper evenly toward bullar tubes. Dorsal color buffy or ochraceous finely lined with black; head and shoulders sometimes contrastingly paler than back; under parts grayish, with gray basal color of hairs visible. Tail bicolored, thinly to moderately haired.

DISTRIBUTION: *Phyllotis magister* is distributed from west-central Peru to northern Chile on the western slope of the Andes. The northern limit appears to be Pacomanta, near Huarochiri, in Lima department (Arana-Cardó and Ascorra 1994), while the southern limit is the basin of the Río Loa near Calama, Antofagasta, Chile (Spotorno, Zuleta et al. 1998). It has been collected from sea level near the mouths of rivers draining the high elevations, but the normal habitat is between 2,300 and 4,000 m.

SELECTED LOCALITIES (Map 291): CHILE: Antofagasta, Calama (LCM 1817); Arica y Parinacota, Putre (USNM 541790). PERU: Arequipa, Arequipa (type locality of *Phyllotis magister* Thomas), 1 km N of Chivay (MVZ 174035); Huancavelica, 2 km E of Ticrapo, Pisco Valley (MVZ 136335); Lima, Pacomanta (Arana-Cardó 1994), 8 mi NE of Yauyos (MVZ 137663); Moquegua, 5 mi NE of Toquepala (MVZ 145610); Tacna, Morro Sama, 65 km W of Tacna (MVZ 143708), 6 km NE of Tarata (MVZ 141556).

SUBSPECIES: *Phyllotis magister* is monotypic.

NATURAL HISTORY: *Phyllotis magister* inhabits brushy zones on the Pacific slope of the Andes. It is omnivorous, but about 60% of its diet was based on five species of locally abundant forbs in southern Peru (Pizzimenti and DeSalle 1980). This species may be sympatric with *P. andium*, *P. limatus*, *P. x. posticalis*, *P. x. chilensis*, and *P. amicus*. Pearson (1976) recorded an average litter size of 2.3, based on embryo counts; L. I. Walker et al. (1999) reported two litters with a mean neonate count of 3.5.

Map 291 Selected localities for *Phyllotis magister* (●). Contour line = 2,000 m.

REMARKS: *Phyllotis magister* has been almost uniformly treated as a valid species since Thomas's (1912b) original description (e.g., Ellerman 1941; Pearson 1958), with Pearson demonstrating morphological separation from sympatric or near-sympatric *P. darwini rupestris* in southern Peru (now *P. limatus*; see that account) and with *P. andium* in central Peru. Hershkovitz (1962) interpreted Pearson's data differently and regarded *magister* as a subspecies of *P. darwini (sensu lato)*. Pearson and Ralph (1978) documented the ecological separation between these two species when in sympatry at several localities on their elevational transect in Tacna department, Peru. *Phyllotis magister* forms a well-supported clade in mtDNA cytochrome-*b* sequences completely separate from (although sister to) one that contains the various subspecies of *P. xanthopygus* as well as *P. limatus* and *P. bonariensis*, thus confirming its species status (Steppan et al. 2007).

The karyotype is $2n = 38$, FN = 72, with the same evenly graded series of metacentric and submetacentric autosomes as other members of the *darwini* complex. However, it appears to have a uniquely metacentric X chromosome and small acrocentric Y (Pearson 1972).

Phyllotis osgoodi Mann, 1945

Osgood's Leaf-eared Mouse

SYNONYMS:

Phyllotis osgoodi Mann, 1945:81; type locality “en los alrededores de Parinacota,” Arica y Parinacota, Chile.”

Phyllotis darwini rupestris: Hershkovitz, 1962:304; part; neither *darwini* Waterhouse nor *rupestris* Gervais.

DESCRIPTION: As indicated in the Key to species and noted in the Remarks here, with present information this species can be diagnosed definitively only by its karyotype. Mann (1945) described *P. osgoodi* from a single individual (a young male) captured among rocks near Parinacota; specimen described as a mouse with dorsal buffy-brown coloration and pale neutral-gray belly, long tail (53% of total length), auditory bullae of regular size, and inter-orbital region posteriorly extended. However, Spotorno (1976) published a redescription of *P. osgoodi* based on evaluation of five specimens that emphasized the following features: medium sized, cryptic and sympatric with *P. xanthopygus chilensis*, with variable coat color (predominantly gray on brown). Skull might be distinguishable from *P. xanthopygus chilensis* by molar cusps and folds, more symmetrical and rounded in adults; both hypoflexus and metaflexus of M2 tend to be symmetrical. In addition to central constriction, stomach with prepyloric constriction visible both external and internally. Base of baculum with clear notch in dorsal-ventral view. Karyotype with 40 chromosomes (NF=72); X chromosome submetacentric, Y metacentric.

DISTRIBUTION: *Phyllotis osgoodi* is known only from its type locality in the Puna of northern Chile.

SELECTED LOCALITIES (Map 292): CHILE: Arica y Parinacota, Parinacota (type locality of *Phyllotis osgoodi* Mann).

SUBSPECIES: *Phyllotis osgoodi* is monotypic.

NATURAL HISTORY: This species has not been studied in the field, so no data on ecology or behavior are available. Little is known about this species because of the difficulty in identifying it.

REMARKS: The status of *P. osgoodi* as a species, or even as a valid subspecies of another *Phyllotis*, is in doubt, largely owing to the fact that no morphological traits have been identified to distinguish it from sympatric *P. xanthopygus*. Indeed, Pearson (1958:415) listed *osgoodi* Mann as a synonym of *chilensis* Mann, reasoning that a “single immature specimen of *osgoodi* and the few specimens of *chilensis* available from the type locality could hardly have been adequate to define two similar species from the same area” (p. 416). He went on to note that, while *osgoodi* had page priority over *chilensis*, he believed “it is wiser to base this form on an old specimen at hand [= the type of *chilensis*] than on an immature specimen [= type of *osgoodi*].” Hershkovitz (1962) placed *osgoodi* Mann as a synonym of *Phyllotis darwini* (= *xanthopygus rupestris*, agreeing with Pearson that *osgoodi* did not warrant recognition while disagreeing with him as to the status of *chilensis* vis-à-vis *rupestris*. Nev-

Map 292 Single known locality for *Phyllotis osgoodi* (●). Contour line = 2,000 m.

ertheless, Musser and Carleton (1993, 2005) elevated *osgoodi* Mann to species status based on Spotorno (1976) and Spotorno and Walker (1979, 1983). Samples these authors identified as *P. osgoodi* had a $2n=40$ karyotype, as opposed to $2n=38$, and were basal to *P. darwini* (*sensu stricto*) and *P. xanthopygus* in electrophoretic phenograms. Unfortunately, the morphometric analyses that Spotorno and Walker (1983) presented to distinguish the latter two species did not include their specimens of *P. osgoodi*, nor did they apparently compare either to Mann’s type. Consequently, it is not possible as yet to diagnose *P. osgoodi* with reliable morphological characters or even to determine whether the specimens examined by Spotorno and colleagues are correctly assigned. Steppan’s (1998) initial mtDNA cytochrome-*b* sequence analysis, which included a specimen (LCM 638) from the type locality at Parinacota, seemed to support the hypothesis of Spotorno and colleagues, although this sequence was subsequently found to be composite (Steppan et al. 2007). Resequencing of a small fragment of that specimen, however, suggested it was a basal member of the *darwini* species group, the sister species to either the *P. xanthopygus* complex or to *P. magister* (S. J. Steppan, unpubl. data). Clearly, additional series from the vicinity of the type locality, with all specimens karyotyped and sequenced and properly compared morphologically to other taxa from the general area, will be necessary before the status of *osgoodi* Mann can be firmly established.

Phyllotis osilae J. A. Allen, 1901

Bunch Grass Leaf-eared Mouse

SYNONYMS:

Phyllotis osilae J. A. Allen, 1901b:44; type locality "Osila" [= Asillo, Puno], Peru (alt. about 12,000 feet)."

Phyllotis lutescens Thomas, 1902b:131; type locality "Choro [= El Choro,] 3500 m," Cochabamba, Bolivia.

Phyllotis darwini tucumanus Thomas, 1912b:408; type locality "Cunbre [= Cumbre] de Mala-mala, Sierra de Tucuman. Alt. 3300 m," Tucumán, Argentina.

Phyllotis tucumanus: Thomas, 1919d:492; name combination.

Phyllotis nogalaris Thomas, 1921k:611; type locality "Higuerilla, 2000 m., in the Department of Valle Grande, about 10 km. east of the Zenta range and 20 km. of the town of Tilcara," Jujuy, Argentina (Thomas 1921k:609). Pardiñas et al. (2007) equated Higuerilla (an abandoned ranch) to the modern village of Pampichuela (23°32'S, 65°02'W, 1,735 m).

Phyllotis phaeus Osgood, 1944:193; type locality "Limhani, Puno, Inambari drainage, Peru. Altitude about 9,000 feet."

Phyllotis osilae osilae: Pearson, 1958:426; name combination.

Phyllotis osilae tucumanensis: Pearson, 1958:427; name combination.

Phyllotis osilae nogalaris: Pearson, 1958:427; name combination.

Phyllotis osilae phaeus: Pearson, 1958:427; name combination.

DESCRIPTION: Both Pearson (1958) and Hershkovitz (1962) characterized *P. osilae* in detail and noted numerous external and cranial characters that separate it from sympatric *P. xanthopygus* (*P. darwini* to them). Head and body length slightly longer in *P. osilae* than *P. xanthopygus* in southern Peru (*P. o. osilae* versus *P. x. chillensis*) but reverse in Catamarca, Argentina (*P. o. tucumanensis* versus *P. x. vaccarum*). Tail of *P. osilae* varies from about 80% to 130% of body length and ears comparatively small, rarely exceeding 25 mm and usually less than 23% of combined head and body length. Upper parts of body buffy or ochraceous to dark brown, more or less mixed with blackish; animals from more humid eastern Andean slopes in southern Peru and northern Bolivia (*P. o. phaeus*) noticeably darker and cocoa colored than those from adjacent Altiplano (*P. o. osilae*). Under parts rarely sharply defined, usually dark gray with plumbeous basal portions of hairs visible. Pectoral streak, patch, or midventral line typically present. Inner and outer sides of ears thinly haired but with dark-brown edging. Tail clothed with short hairs and terminates in weakly developed pencil; sharply bicolored or with terminal one-half to two-thirds or more uniformly brown.

Hershkovitz (1962:Fig. 86) provided idealized drawings of ear, ventral body, ventral cranium, and baculum illustrating differences between *P. osilae* and *P. darwini* (*sensu lato*).

DISTRIBUTION: *Phyllotis osilae* occurs from southern Peru to northwestern Argentina, along the eastern Altiplano and Andean slopes, from 2,700 to 4,000 m in the north and down to 500 m in the south.

SELECTED LOCALITIES (Map 293): ARGENTINA: Catamarca, Chumbicha (Pearson 1958); Jujuy, Higuerilla (type locality of *Phyllotis nogalaris* Thomas), 1 mi W of León (MVZ 120164); Tucumán, Cunbre [= Cumbre] de Mala-mala, Sierra de Tucumán (type locality of *Phyllotis darwini tucumanus* Thomas). BOLIVIA: Cochabamba, El Choro (type locality of *Phyllotis lutescens* Thomas), 6 mi W of Parotani (MVZ 141579), 10 mi NE of Punata (MVZ 120175); La Paz, Sorata (AMNH 91504); Potosí, Lagunillas (Hershkovitz 1962); Tarija, 10 mi NE of Tarija (MVZ 120165). PERU: Cusco, Machu Picchu (USNM 194576), 90 km SE (by road) of Quillabamba (MVZ 166793); Puno, Asillo (type locality of *Phyllotis osilae* J. A. Allen), Hacienda Ontave (MVZ 141570), Huacullani (FMNH 52596), Limhani (type locality of *Phyllotis phaeus* Osgood), 6 km N of Putina (MVZ 171540), Santa Rosa [de Ayaviri] (MVZ 120159).

SUBSPECIES: Both Pearson (1958) and Hershkovitz (1962) recognized four subspecies of *P. osilae*: *P. o. osilae* from Cusco department in southern Peru south across Bolivia to northern Argentina, in bunch grass habitats between 2,750 and 4,200 m; *P. o. tucumanensis*, on the eastern slope of the Andes in Tucumán and Catamarca provinces, Argentina, across a broad elevation amplitude from 500 to 5,000 m; *P. o. nogalaris*, known only from its type locality in Jujuy province, Argentina; and *P. o. phaeus*, from the eastern slope of the Andes in Puno department, Peru south to La Paz department, Bolivia between 3,400 and 4,300 m.

NATURAL HISTORY: *Phyllotis osilae* is largely restricted to *Stipa*-dominated bunch grass habitats on the Altiplano, notably in thick stands of *Stipa ichu* (Pearson 1958). It was caught on grassy hillsides and on the grassy banks of gullies at Pairumani, Peru. It differs, therefore, from the rock-inhabiting *P. xanthopygus*. No pregnant females or breeding males were caught at Pairumani in July. The diet of *P. osilae* resembles both *P. xanthopygus* and *P. magister* in being omnivorous and including a wide variety of items. It differs from both in that it relies most heavily on grass and grass seeds (Pizzimenti and DeSalle 1980). Dorst (1971, 1973b) reported *P. osilae* ate mostly leafy vegetation plus some insects and seeds.

REMARKS: *Phyllotis osilae* is another species very similar to *P. xanthopygus* in many respects, although not closely related phylogenetically (Steppan 1998; Steppan et al. 2007). West of Lake Titicaca, convergence between

Map 293 Selected localities for *Phyllotis osilae* (●). Contour line = 2,000 m.

these two is most dramatic, and no single morphological character is diagnostic. Hershkovitz (1962) provided detailed summaries of several transects, including the means of distinguishing *P. xanthopygus* (= *P. darwini* to him) from *P. osilae*. Some of Hershkovitz's difficulties in identification probably stemmed from the composite nature of his *P. darwini*, but individuals can be difficult to assign (S. J. Steppan, unpubl. data). There is no genetic evidence for hybridization (Steppan et al. 2007; S. J. Steppan, unpubl. data).

The karyotype is $2n=70$, $FN=68$, with 39 pairs of acrocentric autosomes grades in size from large to small and acrocentric X and Y chromosomes (Pearson 1972). It is markedly distinct from the 38-chromosome complement that characterizes *P. xanthopygus* and other members of the *darwini* complex of species.

Phyllotis xanthopygus (Waterhouse, 1837)
Yellow-rumped Leaf-eared Mouse, Patagonian Leaf-eared Mouse

SYNONYMS:

- Mus (Phyllotis) xanthopygus* Waterhouse, 1837:28; type locality "Santa Cruz," Santa Cruz, Argentina.
 [*Hesperomys*] *xanthopygus* Waterhouse, 1839:76; incorrect subsequent spelling of *xanthopygus* Waterhouse.
Mus rupestris P. Gervais, 1841:51; type locality "un trou de rocher des hautes montagnes de Cobija," Antofagasta, Chile (see Pearson 1958).
Mus capito Philippi, 1860:159; type locality "Hueso parado," [= Hueso Parado, near Taltal,] Antofagasta, Chile (Osgood:1943b:205); preoccupied by *Mus capito* Olfers [= *Hylaeamys megacephalus* (G. Fischer)].

Hesperomys Xanthopygus: Burmeister, 1879:225; name combination.

Hesperomys glirinus Philippi, 1896:19, plate VII, Fig. 3; type locality "Atacama," [= San Pedro de Atacama,] Antofagasta, Chile.

Phyllotis arenarius chilensis Mann, 1945:84; type locality "los alrededores de Parinacota," Tarapacá, Chile.

Phyllotis darwini chilensis: Pearson, 1958:415; name combination.

Phyllotis darwini ricardulus: Pearson, 1958:418; name combination.

Phyllotis chilensis: Steppan, 1995:79; name combination.

DESCRIPTION: Highly variable geographically, as noted below under Subspecies. As a consequence, difficult to encapsulate morphology of *P. xanthopygus* in short and simplistic manner, a task made more difficult since revisions of Pearson (1958) and Hershkovitz (1962), both of

which contain detailed descriptions across geography, include two nominal taxa (*P. darwini* and *P. limatus*) that have since been elevated to species status.

Body size average for genus, with head and body length almost always longer than 90 mm (range: 87–148 mm). Tail relatively long, almost always longer than 90 mm and usually longer than 90% of head and body length (range: 89–165 mm). Ears large, sometimes as long as hindfoot (ear length 22–32 mm; hindfoot length 19–31 mm). Dorsal fur denser at higher elevations, less fluffy at lower ones, a typical characteristic for nearly any species distributed across wide elevational band that encompasses warm to cold climates. Vibrissae elongated and luxuriant. Dorsal color varies greatly geographically pale buff through gray and darker tones, depending upon elevation and latitude. Ventral color whitish, grayish, to buffy; pectoral streak variably present both within and among populations. Skull with long and slender rostrum, even in old specimens; palate extends beyond plane of last molars; posteropalatal pits anterior to anterior border of mesopterygoid fossa; bullae inflated, with tubes short and usually emerging abruptly rather than tapering evenly away from each bulla; interorbital edges square or slightly rounded, only occasionally sharp; and frontoparietal suture usually broadly U-shaped.

Most easily confused with *P. andium* near northern edge of range, and with *P. magister*, *P. caprinus*, *P. osilae*, and *Tapecomys wolffsohni* near center of range. One should consult Pearson (1958) in particular but also Hershkovitz (1962) for details of distinguishing any single pair of these species in areas of overlap or near contact.

DISTRIBUTION: *Phyllotis xanthopygus* has the largest range of any member of the genus, with a distribution in the high Andes, and adjacent brush habitats to the east, from central Peru (Junín department) to the southern tip of continental South America (the provinces of Magallanes in Chile and Santa Cruz in Argentina), over an elevational range from 1,900 to 5,030 m in the north (and, like *P. limatus* and *P. magister*, isolated sea level populations at river mouths) and from sea level to 2,000 m in the south. This 5,000 m elevational spread is one of the greatest among mammals. East of the Andes in Argentina, populations extend to lower elevations than to the west in Chile and Peru, where instead *P. xanthopygus* is replaced by *P. darwini* or *P. limatus* below about 2,000 m.

SELECTED LOCALITIES (Map 294): ARGENTINA: Catamarca, Otro Cerro (type locality of *Phyllotis ricardulus* Thomas), 22 km NE of Tinogasta (MVZ 134257); Chubut, 4 km W of Lago Blanco (MVZ 151026), 5 km W of Leleque (MVZ 152166), Pico Salamanca, Comodoro Rivadavia (Pearson 1958); Córdoba, Pampa de Achala, 14 km E of Cura Brochero (MVZ 165848); Jujuy, Tilcara (MVZ 141417); Mendoza, 35 km WNW of 25 de Mayo,

Cerro Medio (MVZ 181569); Neuquén, 3 km W of Rahue (MVZ 173703), 7 km NE of Zapala (MVZ 134261); Río Negro, Cerro Leones, 15 km ENE of Bariloche (MVZ 171145), Huanuluan (MCZ 19029); San Juan, Reserve Ischigualasto (MNC 1107); Santa Cruz, 4.4 km E of Los Antiguos, Estancia la Aurora (MVZ 206375), Monumento Nacional Bosque Petrificado (MVZ 160119), Santa Cruz (type locality of *Mus (Phyllotis) xanthopygus* Waterhouse). BOLIVIA: Chuquisaca, Tarabuco (AMNH 263899); La Paz, 20 mi S of La Paz (MVZ 120054); Oruro, 40 mi S of Oruro (MVZ 120100); Potosí, 20 mi S of Potosí (MVZ 120106), 5 mi N of Villazón (MVZ 120108), Uyuni (type locality of *Phyllotis arenarius* Thomas); Tarija, 12 mi NW of Iscayachi (MVZ 141583). CHILE: Antofagasta, Ojos San Pedro, 55 mi NE of Calama (MVZ 118660), 5 mi S of San Pedro de Atacama (MVZ 150069); Arica y Parinacota, Timar (USNM 391808); Atacama, Salar de Pedernales (LCM 405); Magallanes y Antártica Chilena, Laguna Lazo, Última Esperanza (FMNH 50539); Santiago, Farellones (LCM 730). PERU: Apurímac, 36 km S (by road) of Chalhuanca (MVZ 174041); Arequipa, 5 km W of Cailloma (MVZ 174039); Ayacucho, 2 mi SE of Huanta (MVZ 141587), 15 mi WNW of Puquio (MVZ 138113); Cusco, Marcapata (FMNH 75464), Occobamba Pass (USNM 194577); Huancavelica, 3 mi SE of Izcuchaca (MVZ 141593), Río Mantaro (MVZ 120006); Junín, 1 mi E of Casapalca (MVZ 120081), 10 km W of Jauja (MVZ 139310); Pasco, Huariaca (Hershkovitz 1962); Puno, Abra Aricoma, 13 mi ENE of Crucero (MVZ 139561), 11 km W and 12 km S of Ananea (MVZ 172774), 4 km NE of Pomata (MVZ 115873); Tacna, Morro Sama, 65 km W of Tacna (MVZ 143748), 5 km SE of Tarata (FMNH 107577).

SUBSPECIES: Excluding those nominal taxa regarded herein as valid species (*P. darwini*, *P. limatus*), and their synonyms, Pearson (1958) recognized, diagnosed, and mapped the ranges of six subspecies, including: (1) *P. x. chilensis*, a dark gray, short-tailed taxon intermediate in size and color between *P. x. posticalis* and *P. x. rupestris*, distributed on the Altiplano west and southwest of Lake Titicaca in Peru and Bolivia, and the high Andes between Tarapacá, Chile, and Bolivia above 3,300 m; (2) *P. x. posticalis*, a large and long-tailed subspecies with gray back and sides, larger than *P. x. chilensis*, which it replaces in the mountains of central and southern Peru, on both slopes of the Andes to elevations as low as 1,800 m; (3) *P. x. ricardulus*, a richly colored animal with a bright buffy lateral line, buffy under parts, large ears, and relatively hairy tail, that is distributed along the central and eastern Andes in northwestern Argentina at elevations from 500 to 4,800 m; (4) *P. x. rupestris*, a small, short-tailed, and pale race that ranges across the Bolivian plateau, extending down

the eastern slope into Jujuy, Argentina, and at intermediate elevations on the west slope in northern Chile and southern Peru; (5) *P. x. vaccarum*, a large-bodied, long-tailed, pale with more gray on the head and neck form that occurs on both sides of the Andes from Atacama (Chile) and Catamarca (Argentina) in the north to Talca (Chile) and Neuquen (Argentina) in the south, between 800 and 4,000 m; and *P. x. xanthopygus*, a large animal with a proportionately short tail, relatively dark coloration with a distinctly buffy venter that ranges from Neuquen province, Argentina, south almost to the Straits of Magellan and reaching the coast in Santa Cruz, Argentina, with one locality in Chile at the southern end of its range.

NATURAL HISTORY: This is a mouse of rocky microhabitats on the arid Andean slopes where boulder fields, rock slides, cliffs, small shale outcroppings, stone walls, and stone huts are all satisfactory habitations. The species is also found in rocky outcrops in the monte and Patagonian steppes of Argentina and at higher elevations in the Sierras de San Luis and Córdoba, Argentina. *Phyllotis xanthopygus* is sympatric with (and at times difficult to distinguish from) *P. osilae* (see that account), and may be sympatric in places with *P. magister*, *P. andium*, or *P. limatus* on the western Andean slopes. Like *P. magister* and *P. limatus*, populations of *P. xanthopygus chilensis* exist near sea level along the mouths of rivers, giving the species an elevational range of nearly 5,000 m, one of the largest for any mammal. As a consequence, the species has been the subject of physiological studies regarding adaptation and acclimatization to high altitude (e.g., Bozinovic and Marquet 1991).

Phyllotis xanthopygus is strictly nocturnal. Several wild-caught individuals had green vegetable pulp in their stomachs, but a caged specimen ate assorted grains and ignored the tola bush (*Senecio adenophylloides*; Pearson 1951). In the southern Peruvian Altiplano, pregnant females were caught at Santa Rosa on July 28 and August 1, but at Caccachara none were caught until October 5. Pregnant females and breeding males were caught frequently between this date and December 19, and immature specimens were caught on December 9. The average number of embryos was four. In all six cases where the necessary data were recorded, there were more embryos in the right horn than in the left. The ratio of sexes was 64 males to 44 females (Pearson 1951). Kramer et al. (1999) summarized additional details, although some studies referenced were actually conducted on *P. darwini*, as currently understood.

REMARKS: *Phyllotis xanthopygus* represents the residuum from earlier concepts of *P. darwini*, particularly that of Pearson (1958), after removal of *P. bonariensis* (Musser and Carleton 1993; Steppan 1995), *P. limatus* (Steppan 1998), and true *P. darwini* (L. I. Walker et al. 1984). This

remains by far the most widespread species in the genus, and it was suggested to be the parental species for others through a process of peripheral isolate formation and successive range expansions across the Andes onto the Pacific slopes (Steppan 1998). It is paraphyletic with respect to *P. limatus* (Kuch et al. 2002; Riverón 2011). Additional DNA sequence data suggest that this is a composite taxon, containing at least one and possibly three additional species (Steppan et al. 2007; S. J. Steppan et al., unpubl. data), and the taxonomy will likely change pending ongoing revisionary studies. Riverón (2011) detected multiple deep divergences and strong geographic structuring among mitochondrial lineages of southern populations. It seems likely that northern, Altiplano populations currently allocated to the subspecies *posticalis*, *chilensis*, and parts of *rupestris* will be removed to one or more additional species.

The correct attribution of Philippi's names *Mus capito*, *Hesperomys glirinus*, and *Hesperomys lanatus* to this species, which Osgood (1943), Pearson (1958), and Hersh-

Map 294 Selected localities for *Phyllotis xanthopygus* (●). Contour line = 2,000 m.

kovitz (1962) all listed as synonyms of *P. darwini rupestris* (= *P. xanthopygus rupestris*, herein) is provisional. As noted by Steppan (1998), the types have been lost, so it not possible to determine whether these names are most appropriately applied here or more correctly to *P. limatus* instead.

Genus *Salinomys* Braun and Mares, 1995

Cecilia Lanzone and Janet K. Braun

This monotypic genus ranges between about 30°S and 34°S in southern South America, with the single species *Salinomys delicatus* having both a restricted and patchy distribution, with local populations of small size. Only a few studies of the ecology of the species have been published since its description (Braun and Mares 1995). The species occurs in the arid and semiarid landscape of west-central Argentina, especially in halophytic habitats, with individuals exhibiting morphological and physiological adaptations to these extreme environments (G. B. Diaz and Ojeda 1999). The few studies available indicate special ecological, physiological, and genetic characteristics that warrant further investigation. The following generic description is abstracted from Braun and Mares (1995). External measurements are from D. Rodríguez et al. (2012a), who examined the largest available sample and included data on the holotype and other specimens used in the original description.

Salinomys has large ears, whitish postauricular and supraorbital patches, soft grayish olive fur, a white venter, and a tufted bicolored tail that exceeds the combined length of the head and body. The hindfeet are long, with unwebbed digits; the plantar surface is naked but has six small tubercles (thenar, hypothenar, and four interdigitals). These rodents are small, with a mean head and body length of 71.2 mm (range: 50.0–84.0 mm), tail length 102.1 mm (range: 85.0–123.0 mm), hindfoot length 21.3 mm (range: 18.0–23.0 mm), and ear length 17.0 mm (range: 15.0–21.0 mm).

The skull is delicate, with a long and slender rostrum, slightly convergent supraorbital margins, and an inflated braincase. The foramen magnum is dorsoventrally flattened and oriented slightly posteroventrally. The zygomatic arches are parallel to slightly convergent anteriorly (widest across the squamosal roots). The anterior margins of the zygomatic plates are more or less straight; zygomatic notches are deep (>50% of zygomatic plate width). Incisive foramina are long (>90% of the diastemal length); palatal foramina are often long slits. The stapedial process of each bulla extends nearly to or is in contact with the pterygoid plate. The bullae are not inflated, and the ectotympanic does not completely cover the periotic bone. A vertical

strut of the alisphenoid is present. The coronoid process of the mandible is small. A capsular process is present. The angular notch does not extend anteriorly beyond the capsular process.

The incisors are orthodont; the molars are tetralophodont, brachydont, and slightly crested. The anterocone of M1 is divided; an anteromedian style or shelf is present. The posterior border of M1 has a small notch.

Axial skeletal elements have modal counts of 12 ribs, 19 thoracolumbar vertebrae, 3–4 sacral vertebrae, and 31–33 caudal vertebrae. The entoglossal process of the hyoid is absent. The entepicondylar foramen of the humerus is absent.

Kidneys have a single, very elongate renal papilla, the most extreme condition among all murid rodents inhabiting the Monte Desert. Renal indices (relative medullary thickness, ratio of inner medulla to cortex and relative medullary area) are also high, as is the ability to concentrate urine to minimize water loss (G. B. Diaz and Ojeda 1999).

SYNONYM:

Salinomys Braun and Mares, 1995:505; type species *Salinomys delicatus* Braun and Mares, 1995, by original designation.

Salinomys delicatus Braun and Mares, 1995

Delicate Salt Flat Mouse

SYNONYM:

Salinomys delicatus Braun and Mares, 1995:514; type locality “Province of San Luis, Departamento de Ayacucho, ca. 23 km N Route 20, Pampa de Las Salinas, cerca La Botija, at 1,300 feet elevation,” Argentina.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Salinomys delicatus* occurs between 400 and 600 m elevation in several isolated populations at the edge of salt flats (or *salares*) in west-central Argentina, in the provinces of Catamarca, La Rioja, San Juan, Mendoza, and San Luis (Braun and Mares 1995; R. A. Ojeda et al. 2001; Lanzone et al. 2005; D. Rodríguez, Lanzone, Chillo et al. 2012). No fossils have been reported.

SELECTED LOCALITIES (Map 295): ARGENTINA: Catamarca, Bolsón de Pipanaco (Lanzone et al. 2005), Quimilo (ARG 5147); La Rioja, 26 km SW of Quimilo (OMNH 30224), Salar La Antigua, 45 km NE of Chamental (CML 3795; R. A. Ojeda et al. 2001); Mendoza, Estancia El Tapón (D. Rodríguez, Lanzone, Chillo et al. 2012), Laguna del Rosario (D. Rodríguez, Lanzone, Chillo et al. 2012); San Juan, 15 km ESE of José de Martí on road to Chañar Seco (OMNH 23603); San Luis, Pampa de Las Salinas, ca. 23 km N of Rte 20, near La Botija (type locality of *Salinomys delicatus* Braun and Mares), 15 km SSE of Salinas de Bebedero (OMNH 23602).

SUBSPECIES: *Salinomys delicatus* is monotypic.

NATURAL HISTORY: *Salinomys delicatus* has been collected in xeric and semiarid habitats on the edge of salt flats, and in small patches of mesquite trees (*Prosopis* [Fabaceae]) with a hardpan substrate (Braun and Mares 1995; R. A. Ojeda et al. 2001; D. Rodríguez, Lanzone, Chillo et al. 2012). Unpublished field notes indicate that this terrestrial species is scansorial and nocturnal (R. A. Ojeda and Tabeni 2009). Reproductive activity apparently is highest in late summer and early fall (Braun and Mares 1995), although a pregnant female was recorded in spring (D. Rodríguez et al. 2012a). Data from births in captivity and from field-caught pregnant females indicate litter sizes ranging from two to six. The diet of *S. delicatus* is omnivorous, consisting in similar proportions of seeds, arthropods, and halophytic plants (D. Rodríguez et al. 2012a).

REMARKS: The diploid number is the lowest among phyllotine species, but the complement is sexually dimorphic in *S. delicatus*, $2n=18$ for females and $2n=19$ for males. The number of autosomal arms (FN) is 32, and all autosomes biarmed. The sex chromosome system is complex due to an X-autosomal translocation, with XY_1Y_2 sex chromosomes in males. Multiple sex chromosomes are uncommon in mammals and *S. delicatus* seems to have undergone a major chromosome restructuring during its karyotypic evolution (Lanzone et al. 2005; Lanzone, Rodríguez et al. 2011).

Salinomys delicatus is also unusual among rodents (and mammals more generally) morphologically, as females are larger than males in head and body length and other ex-

ternal and cranial measurements (D. Rodríguez, Lanzone, Chillo et al. 2012). Field data for this species are very limited, but in most sampling efforts females were more abundant than males, suggesting that either the primary sex ratio or survivorship is biased in favor of females (D. Rodríguez, Lanzone, Chillo et al. 2012). The species is considered rare and vulnerable to extinction, based on its restricted and patchy distribution, few known occurrences, low local abundances, and specialization to halophytic habitats (Lanzone et al. 2005; D. Rodríguez, Lanzone, Teta et al. 2012).

Genus *Tapecomys* S. Anderson and Yates, 2000

Jorge Salazar-Bravo

Mice of the genus *Tapecomys* include only two species living, both from Andean localities in central Bolivia and northern Argentina. Until recently, the genus *Tapecomys* was considered monotypic (S. Anderson and Yates 2000; Musser and Carleton 2005), but morphological (Steppan 1993) and molecular data (Steppan et al. 2007) strongly supported the inclusion of *Phyllotis wolffsohni* Thomas within *Tapecomys*. I thus recognize two species: *T. primus* and *T. wolffsohni*. These mice live at moderate to high elevations (1,200 to 3,900 m) on the eastern versant of the Andes, from Cochabamba (Bolivia) to Salta (Argentina) where they occupy Yungas forests (*T. primus*) or brush and scrub in ecotonal localities above Yungas forests (*T. wolffsohni*). Except as noted below, the following account is abstracted from Pearson (1958), Hershkovitz (1962), Steppan (1993, 1995), S. Anderson (1997), and Barquez et al. (2006), which should be consulted for additional details.

Tapecomys is characterized by the following combination of characters: medium to large with dorsal pelage agouti brownish, bright ochraceous lateral line, and ventral pelage whitish gray (but individual hairs always gray based); a well-defined pectoral streak may or may not be present; tail distinctly bicolored, not penicillate, moderately furred, slightly longer than head and body (6–15% longer); manus white; relatively large pes, covered with white hairs, a darker spot on top near base of each toe may or may not be present; genal and superciliary vibrissae present, extending to the edge of the pinnae when laid back; hindfoot with conspicuous tufts of unguis hairs at the base of the claws on digits II–V, digit I with unguis tufts present but much less conspicuous; hypothecar pad present and large.

The skull has a robust rostrum flanked by deep zygomatic notches. The interorbital region is posteriorly diver-

Map 295 Selected localities for *Salinomys delicatus* (●). Contour line = 2000 m.

gent in *T. primus* but mostly parallel in *T. wolffsohni*, but always with sharp edges. The braincase is oblong or globular, usually with clear temporal ridges; lambdoid ridges are not present (if so, poorly developed). The zygomatic plates are broad (*sensu* Voss 2003), their posterior margins anterior to each M1. The nasals extend posteriorly behind the lacrimals in *T. wolffsohni* but are shorter (extending to but usually not behind the lacrimals) in *T. primus*. The frontoparietal suture is U-shaped; the incisive foramina are very long, extending posteriorly between molar alveoli, widest at their midlength; and the bony palate extends slightly behind the M3s. The mesopterygoid fossa is parallel sided, with its bony roof pierced by sphenopalatine vacuities. An alisphenoid strut is absent (buccinator-masticatory foramen and accessory foramen ovale are confluent) and the carotid circulatory pattern is primitive (pattern 1 of Voss 1988).

The upper incisors are opisthodont and fronted by orange enamel. The molars are hypsodont, appear somewhat prismatic, and have planed occlusal surfaces; upper and lower second molars possess a deep hypoflexus(id) and protoflexus(id); and M3s have a hypoflexus(id) that alternates with metaflexus(id) and posteroflexus(id) so that when worn this molar acquires a distinct S- or Z-shape.

SYNONYMS:

Phyllotis: Thomas, 1902b:131; part (description of *wolffsohni*); not *Phyllotis* Waterhouse.

Tapecomys S. Anderson and Yates, 2000:21; type species *Tapecomys primus* S. Anderson and Yates, 2000, by monotypy and original designation.

REMARKS: Initial mitochondrial sequence analyses (S. Anderson and Yates 2000) suggested a phyletic relationship between *Tapecomys* and both *Salinomys* and *Andalgalomys* among the limited set of phyllotine taxa these authors examined. Steppan et al. (2007), however, supported a sister relationship between *Tapecomys* as part of a triad of genera also including *Auliscomys* and *Loxodontomys* that are sister to *Phyllotis* rather than to *Salinomys* and *Andalgalomys*. Of the two more expansive and recent molecular studies, Salazar-Bravo et al. (2013) failed to resolve relationships among the non-*Calomys* phyllotine genera, but Schenk et al. (2013) recovered a grouping of *Tapecomys* with, successively, *Auliscomys*, *Loxodontomys*, and *Phyllotis*, and within a clade that otherwise contained *Andalgalomys* and *Graomys*.

KEY TO THE SPECIES OF TAPECOMYS:

1. Skull with sharp, posteriorly divergent interorbital region; nasals short, extending to lacrimals, and posteriorly not pointed; hindfoot larger (range: 29–34 mm; mean 32 mm); molar tooththrow longer (range: 6.4–6.7 mm; mean 6.6 mm); $2n=56$; found between 1,200

and 1,500 m in Yungas forests of southern Bolivia and northern Argentina. *Tapecomys primus*
1'. Skull with sharp, evenly constricted interorbital region; nasals long, extending posterior to lacrimals, and posteriorly pointed; hindfoot smaller (range: 26–30 mm; mean 27.5 mm); molar tooththrow shorter (range: 5.1–6.5 mm; mean 5.7 mm); $2n=54$; usually caught in scrub and brush on eastern slope of the Andes from central Bolivia to northern Argentina. *Tapecomys wolffsohni*

Tapecomys primus S. Anderson and Yates, 2000

Tapecua Leaf-eared Mouse

SYNONYM:

Tapecomys primus S. Anderson and Yates, 2000:21; type locality “Tapecua, 1,500 m, 21°26’S, 63°55’W, Department of Tarija, Bolivia.”

DESCRIPTION: Medium sized with head and body length 124–139 mm; tail longer than head and body (length 143 mm in single specimen with complete tail), and ears long (33–34 mm). Pelage brownish agouti overall, only slightly paler and with ochraceous hue on venter. In contrast, tail strongly bicolored. Manus white on dorsal surface; pes with darker hairs at base of each toe but paler more proximally. Skull notable for posteriorly divergent supraorbital edges, sharply angled, slightly beaded, and continuing across parietal bone as distinct temporal ridges.

DISTRIBUTION: *Tapecomys primus* is known only from three localities, one in southern Bolivia and two in northern Argentina.

SELECTED LOCALITIES (Map 296): BOLIVIA: Tarija, Tapecua (type locality of *Tapecomys primus* S. Anderson and Yates). ARGENTINA: Jujuy Province, Finca Las Capillas (Barquez et al. 2006), Rte 83, on road to Valle Grande, 9 km N of San Francisco (M. M. Díaz et al. 2009).

SUBSPECIES: *Tapecomys primus* is monotypic.

NATURAL HISTORY: The four known specimens were obtained in lower Yungas Forest vegetation, at elevations ranging from 1,200 to 1,500 m. In southern Bolivia and northern Argentina, this type of forest is often referred to as *Bosque Boliviano-Tucumano* (G. Navarro and Maldonado 2002) or *selva montana* (Barquez et al. 2006), and is characterized by the juxtaposition of montane elements with an abundance and dominance of Myrtaceae intermixed with xeric adapted elements more characteristic of the Chaco at lower elevations to the east (G. Navarro and Maldonado 2002). At the type locality in southern Bolivia, this combination creates a mosaic of patches of columnar cacti and leguminous trees in open areas and broadleaf canopy trees and thick brush on hillsides and in ravines (Anderson and Yates 2000). Barquez, Ferro, and Sanchez (2006) noted large, moss-covered rocks and dense litter at one Argentinean site,

Map 296 Selected localities for *Tapecomys primus* (●). Contour line = 2000m.

and M. M. Díaz et al. (2009) reported myrtaceous trees (including myrtle, horco molle, and others) at a second. All known specimens are males: one adult collected 14 July 1991 in Bolivia had small, undescended testis measuring 9×5 mm; no reproductive data are known for the other three individuals. Lareschi et al. (2010) reported the flea *Craneopsylla minerva minerva* from one Argentinean specimen.

REMARKS: The karyotype of *T. primus* consists of $2n=56$, $FN=76$, with 11 pairs of metacentric-submetacentric and 16 pairs of acrocentric autosomes; the X is a large submetacentric, and Y is a small submetacentric (S. Anderson and Yates 2000).

Tapecomys wolffsohni (Thomas, 1902)

Wolffsohn's Leaf-eared Mouse

SYNONYMS:

Phyllotis wolffsohni Thomas, 1902b:131; type locality "Tapacari, 3000 m," west of Cochabamba, Cochabamba, Bolivia.

Phyllotis darwini wolffsohni: Hershkovitz, 1962:339; name combination.

Tapecomys wolffsohni: Steppan, Ramirez, Banbury, Huchon, Pacheco, Walker, and Spotorno, 2007:799; first use of current name combination.

DESCRIPTION: Somewhat larger (head and body length 110–150 mm, mean 132 mm) than *T. primus*, with slightly shorter tail (length 118–160 mm, mean 138 mm) and much smaller ear (height 23–29 mm, mean 25.8 mm).

Overall dorsal color yellowish brown streaked with black; hairs bicolored, with elongated basal gray band and narrow phaeomelan in tip. Venter white but gray base of hairs show through; pectoral streak may or may not be present. Tail moderately bicolored, dark yellowish brown above and paler yellow to white below. Dorsal surfaces of both forefeet and hindfeet white. Ears darker than body. Skull possesses similar sharply edged and divergent supraorbital ledges, but these do not extend across parietals as notable ridges, unlike in *T. primus*.

DISTRIBUTION: *Tapecomys wolffsohni* ranges from central Bolivia to northern Argentina along the eastern slopes of the Andes between 1,300 and 3,875 m.

SELECTED LOCALITIES (Map 297): ARGENTINA: Jujuy, on road between San Francisco and Pampichuela (Jayat et al. 2006). BOLIVIA: Cochabamba, Cuchicancha (Hershkovitz 1962), 15 mi E of Tapacari (Hershkovitz 1962), Ucho Ucho (B. D. Patterson 1992b); Chuquisaca, 9 km by road N of Padilla (S. Anderson 1997), 1.3 km W of Jamachuma (S. Anderson 1997); Santa Cruz, Comarapa (S. Anderson 1997), Guadalupe (Hershkovitz 1962).

SUBSPECIES: *Tapecomys wolffsohni* is monotypic, although Pearson (1958) noted that specimens from more humid habitats near Comarapa, on the border of Cochabamba and Santa Cruz departments in Bolivia, are darker and smaller than those from the type locality.

Map 297 Selected localities for *Tapecomys wolffsohni* (●). Contour line = 2000m.

NATURAL HISTORY: This species inhabits brush and scrub habitat at moderate to high elevations (2,200 to 3,500 m; Pearson 1958). Little is known about the natural history of this species. S. Anderson (1997) recorded a single pregnant female (with two embryos) in March, a lactating female in July, and nonpregnant females in March, July, and September.

REMARKS: *Tapecomys wolffsohni* was originally described as a species of *Phyllotis*, and affirmed so by Pearson (1958), but was treated as a subspecies of *P. darwini* by Hershkovitz (1962). Steppan (1993) and Steppan et al. (2007) allocated *wolffsohni* Thomas to *Tapecomys* based on morphological and molecular phylogenetic analyses, respectively. The identity of some Argentinean specimens assigned to this species is controversial (Jayat et al. 2006).

The karyotype consist of a $2n=54$, FN=72, with 16 pairs of acrocentric and 10 pairs of metacentrics or submetacentrics autosomes, a large metacentric X chromosome, and a small metacentric Y chromosome (Pearson and Patton 1976).

Tribe Reithrodontini Vorontsov, 1959
Ulyses F. J. Pardiñas, Carlos A. Galliari, and Pablo Teta

The history of, and justification for the tribe Reithrodontini is given in the general account of the Sigmodontinae, and the characteristics of the sole member of the tribe, the genus *Reithrodon*, are in the following account.

Genus *Reithrodon* Waterhouse, 1837

Representatives of *Reithrodon* are among the most beautiful and widespread sigmodontine rodents of the open lands in the South American Southern Cone. With two recognized living species (*R. auritus* and *R. typicus*) but at least 10 nominal forms in current synonymy, *Reithrodon* occurs in crop fields, grasslands, steppes, and semideserts of Argentina, Chile, Uruguay, and adjoining southernmost Brazil (Musser and Carleton 2005). It is the most frequently encountered genus in the sigmodontine fossil record of Argentina, and several names have been used to describe Plio-Pleistocene remains (Reig 1978; Pardiñas 1995b).

Reithrodon has been placed as a member of the Sigmodontini (see Hershkovitz 1955b) or Phyllotini (see Olds and Anderson 1990; Braun 1993; Steppan 1993, 1995), closely related to other extant and fossil genera that comprised a “*Reithrodon* group” (Steppan 1995; Pardiñas 1997; Steppan and Pardiñas 1998; P. E. Ortiz, Cirignoli et al. 2000). However, phylogenetic analyses of molecular sequences

have indicated the distinctiveness of the genus within the sigmodontine radiation (Engel et al. 1998; M. F. Smith and Patton 1999; D’Elia 2003a) and have thus supported Vorontsov’s (1959) monotypic tribe Reithrodontini. Several contributions have documented the status, diversity, and morphological traits of *Reithrodon* species (Osgood 1943b; Hershkovitz 1955b; Reig 1978; Ortells et al. 1988; Pearson 1988, 1995; Steppan 1995). The present account is largely based on an extensive summary of the available information compiled for *R. auritus* (Pardiñas and Galliari 2001) and for *R. typicus* (Barlow 1969).

The two species are among the largest sigmodontines in present-day communities in Patagonia and Pampas biomes (head-body length >130 mm; mass about 90 g). Herbivorous in diet and nocturnal in habits, these animals reach high densities under suitable environmental conditions where they are heavily preyed upon by raptorial birds. They live in moderately complex burrow systems and construct runways in short grassland vegetation; their presence is easily recognized by accumulations of cylindrical feces with one edge rounded and the other pointed (Pearson 1988). They share none of the traditional morphological features typical of semifossorial rodents; their common name “conyrat” belies a convergence with the leporid genus *Ochotona* (Lagomorpha; Ortells et al. 1988).

Reithrodon has one of the longest temporal ranges within the sigmodontine radiation (Reig 1972). The oldest known remains are from Monte Hermoso deposits (in southwestern Buenos Aires province, Argentina) with an approximate age of 4–5 mya (Pardiñas 2000). During the Chapadmalalan (Early to Middle Pliocene, 3–4 mya) the genus was well represented in fossil assemblages from central Argentinean latitudes, being one of the most common sigmodontines present. In fact, Florentino Ameghino coined the genus *Proreithrodon*, with two species, to accommodate these fossils; both are recognized today as full synonyms of *R. auritus*. However, an important temporal gap is present in the fossil record, one corresponding to the Sanandresian (Late Pliocene, 2.5 mya). Based on the caviomorph fossil record, Verzi and Quintana (2005) suggested that hyperarid conditions, presumably coupled with strong glaciation, might have depressed the abundance of *Reithrodon*. Subsequently, the genus recovered its earlier dominance to characterize Middle Pleistocene micromammal assemblages, especially those around 1 mya (Ensenadan) or between 0.3–0.15 mya ago (Lujanian). From Lujanian (Late Pleistocene) deposits another two supposedly extinct genera, *Tretomys* and *Ptyssophorus*, were erected to allocate *Reithrodon* fossil remains. P. E. Ortiz et al. (2011b) recorded the genus from Late Pleistocene deposits at several places outside the current geographic range (e.g., around Córdoba city in central Argentina and in the low-

lands of northwestern Argentina; see also P. E. Ortiz and Jayat 2012b), and Ubilla et al. (2004), Hadler and Ferigolo (2004), and R. P. Lopes and Buchmann (2011) documented late Pleistocene fossils from Uruguay and Brazil. Over the last 10,000 years, the history of *Reithrodon* has been one of gradual decline in the Pampean region, with a precipitous drop during the Late Holocene. As seems to be the case with several other mammal species, *Reithrodon* populations were probably deeply affected by human-induced landscape changes over the last five centuries, most importantly by massive introduction of cattle and agricultural practices, both of which have affected fire-regime and associated vegetation-structure changes (Pardiñas, Teta, and D'Elía 2010).

Reithrodon species are easily distinguishable from other sigmodontine rodents by their large heads, ears, and eyes, massive bodies, moderately short and haired tails (<105 mm), and short and blunt claws of both manus and pes. Conspicuous bands of lighter pelage form a mask around the eyes and ears that usually decays in stored museum skins. The general color varies from dark brown to pale buffy gray dorsally, whereas the ventral surface is white to brownish ochraceous; flanks and belly have a variable amount of yellow and white (Gyldenstolpe 1932). The fur is soft, luxurious, and dense; regular and rhomboidal cuticular scales of the dorsal guard hairs clearly distinguish *Reithrodon* from other sympatric sigmodontines (M. Busch 1986). The tail is bicolored and densely haired but without an apical tuft. Long whitish hairs cover the dorsal surfaces of both manus and pes and unguis tufts surpass the tip of each claw. Plantar pads on the hindfeet are reduced to four in number, with two large interdigital pads for both digit II and IV embedded in a strongly squamate surface. *Reithrodon* has four pairs of mammary glands, one each in pectoral, postaxial, abdominal, and inguinal positions (Gyldenstolpe 1932; Steppan 1995).

Hooper (1962) described the glans penis and baculum of a specimen from Tierra del Fuego, Argentina, as short and blunt, covered externally by conical tubercles, and divided externally into four indistinct lobes; the three bacular mounds plus the baculum resembled a fleur-de-lis in ventral view. The baculum is shorter than the glans, with a wide bony base divided by a deep medial notch and a thin flat tip; three distal segments are cartilaginous with a more elongated middle segment, ending in a point. The stomach (based on a specimen from Buenos Aires province, Argentina) is unilocular-hemiglandular with the glandular epithelium reaching the corpus (Carleton 1973). Barlow (1969:37) noted, in reference to *R. typicus*, that the single chambered stomach is somewhat sacculated in the fundic region and an enlarged caecum is present at the junction of the large and small intestines. A gall bladder is present (Voss 1991a;

based on a specimen of *R. typicus* from Uruguay, and the same condition was detected in several *R. auritus* from Argentina [authors, unpubl. data]).

Cranially, *Reithrodon* is characterized by a unique combination of traits including a very domed skull in lateral profile, a narrow and parallel-sided interorbital region, a denticulate V-shaped coronal suture, a very large interparietal bone, deep and narrow zygomatic plates with upper well-projected spines, an arched premaxillomaxillary suture, molar tooththrows that converge anteriorly, an excavated, narrow, and long palate, small auditory bullae, very large parapterygoid plates, and the absence of the tegmen tympani. The mandible is deep and robust and has a long condyloid process internally excavated by a spoon-like fossa (Pearson 1995; Steppan 1995). Carotid circulatory pattern is the derived pattern 3 (*sensu* Voss 1988).

Upper incisors are opisthodont, faced with orange enamel and two frontal grooves (Steppan 1995:Fig. 9e); molars are noticeably hypsodont, with alternating main cusps and flat crowns (*sensu* Hershkovitz 1962); mesoloph/lophids (including mesostyle/stylids) and enterostyle/stylids are absent. The M1 is trilophodont with the procingulum compressed anteroposteriorly, and there is no evidence of an anteromedian flexus; protoconid and hypoconid areas are subequal. M2 and M3 are similar in occlusal design, the latter is slightly smaller, with the metaflexus more penetrating and directed posteriorly; m1 is elongated and tetralophodont, with a subtriangular procingulum coalescent with anterolabial cingulum at an early stage of wear; m2 has a reduced protoflexid, and lingual lophids are not equal in extent; m3 is simplified relative to m2, with a clearly sigmoidal pattern. Number of roots per molar is M1, 5–4; M2, 3; M3, 4–3; m1, 4; m2, 3; and m3, 3–2 (Pearson 1995).

Number of vertebrae varies in *R. auritus*: each of 10 specimens had 12 thoracic, 7 lumbar, and 24 caudal vertebrae whereas one specimen had 13, 6, and 25–26 (Steppan, 1995). All specimens had 12 ribs.

The alpha taxonomy of *Reithrodon* is still unclear, and revision of the genus is clearly needed. Unfortunately, the few series of specimens preserved in museum collections make this desirable goal presently difficult. The first significant approach to delineating *Reithrodon* diversity was sketched by Thomas (1920b), who recognized three informal groups based on “colour and by the degree of hairiness of the soles.” According to Thomas, southern nominal forms in Argentina and Chile (*cuniculoides*, *hatcheri*, *flammarum*) have the plantar hairs extending forward to the anterior pair of sole pads, whereas central Argentinean forms (*auritus*, *pampanus*, *marinus*) show the main mass of the hairs ceasing at the posterior pair of pads. In contrast, specimens from Corrientes and Uruguay (*currentium*, *typicus*) but also those from northern Argentina (*caurinus*)

are characterized by a naked pad region. Osgood (1943b) subsumed all available names under *auritus* and treated *Reithrodon* as monotypic although he recognized the potential existence of several subspecies: *cuniculoides* and *pachycephalus* for southern populations, and *auritus*, *typicus*, and *caurimus* for central and northern ones. Ortells et al. (1988) resurrected *R. typicus* as valid species based primarily on chromosomal data.

A preliminary exploration of mtDNA cytochrome-*b* sequences (E. P. Lessa et al. 2010; E. P. Lessa et al., unpubl. data) covering almost the known *Reithrodon* geographic distribution supported the recognition of *auritus* and *typicus* but also indicated high genetic distances between isolated northern Argentina *auritus* populations and those in Patagonia.

Reithrodon auritus (G. Fischer, 1814)

Hairy-soled Conyrat

SYNONYMS:

Mus auritus G. Fischer, 1814:71; type locality "les Pampas, au Sud de Buenos-Ayres" (Azara 1801:91), equated to "south bank of the Río de la Plata," Buenos Aires Province, Argentina, by Hershkovitz (1959b:349). After a study of Azara's itinerary, particularly the monograph by Mones and Klappenbach (1997), we conclude, however, that Azara most likely made his observations on this rodent in the current Pila county, on the south side of the Río Salado, approximately 150 km S Buenos Aires.

M[us]. *physodes* Illiger, 1815:108; *nomen nudum*.

M[us]. *physodes* Olfers, 1818:209; name based on bibliographic reference to Azara's (1801) "rat quatrième or rat oreillard."

Mus auritus Desmarest, 1819e:64; name based on bibliographic reference to Azara's (1801) "rat quatrième or rat oreillard."

M[us]. *pyrrhogaster* Brants, 1827:145; in synonymy of *Mus auritus* (fide Hershkovitz, 1959b:348).

Reithrodon cuniculoides Waterhouse, 1837:30; type locality "Santa Cruz." Santa Cruz, in the meaning of Charles Darwin, the collector, must have been the mouth of the Santa Cruz river where the HMS *Beagle* was anchored on the southern bank, near the present locality of Puerto Santa Cruz (ca. 50.117°S, 68.415°W), Santa Cruz, Argentina.

Mus pachycephalus Philippi, 1900:42; type locality "Freto Magellanico," restricted, although with weak support, to the vicinity of Punta Arenas by Osgood (1943b:221–222).

Reithrodon cuniculoides obscurus J. A. Allen, 1903b:190; type locality "Punta Arenas, Patagonia," Magallanes y Antártica Chilena, Chile.

Reithrodon hatcheri J. A. Allen, 1903b:191, type locality "Pacific slope of the Cordilleras, head of the Rio Chico de Santa Cruz," restricted to Perito Moreno National Park by Galliari and Pardiñas (1999:119). However, this restriction is incorrect. Our review of the geographical notes made by J. B. Hatcher (1903), coupled with fieldwork following his itinerary in this portion of the Patagonian territory, suggests that O. A. Peterson and Hatcher collected the type of *hatcheri* close to the course of the Río Tucu Tucu (ca. 48.47°S, 71.87°W, Río Chico county, Santa Cruz province, Argentina), about 8 km downstream from its headwaters.

Reithrodon cuniculoides flammarum Thomas, 1912b:411; type locality "Tierra del Fuego . . . from Spring-hill [= Springhill], in the north of the island," Tierra del Fuego, Chile.

Reithrodon cuniculoides pampanus Thomas, 1916g:305; type locality "Southern pampas of Buenos Ayres Province . . . Peru [= Estación Perú], F.C.P., about 200 kilometres N.W.

of Bahia Blanca [= Bahía Blanca],” La Pampa Province, Argentina.

Reithrodon caurinus Thomas, 1920b:473; type locality “Otro Cerro, Catamarca. Alt. 3000m.” Pardiñas et al. (2007) recently delineated the history of this frequently mentioned Argentinean type locality, and located Otro Cerro at about 28°45'S, 66°17'W in the top of Sierra de Ambato, Catamarca Province (see also Cabrera 1961:501). [*Reithrodon*] *auritus*: Thomas, 1920b:474; first use of current name combination.

Reithrodon auritus marinus Thomas, 1920b:474; type locality “Mar del Plata, on the south-eastern sea-coast of Buenos Ayres [= Buenos Aires] Province,” Argentina.

Reithrodon cuniculoides evae Thomas, 1927d:652; type locality “Zapala,” Neuquén Province, Argentina.

Reithrodon physodes caurinus: Cabrera, 1961:501; name combination.

Reithrodon physodes cuniculoides: Cabrera, 1961:501; name combination.

Reithrodon physodes evae: Cabrera, 1961:501; name combination.

Reithrodon physodes pachycephalus: Cabrera, 1961:501; name combination.

Reithrodon physodes physodes: Cabrera, 1961:502; name combination.

DESCRIPTION: General characters as in generic description. Soles more densely haired than in *R. typicus*; tail bicolored; diploid complement = 34.

DISTRIBUTION: *Reithrodon auritus* occurs from sea level to ca. 3,000 m (Pardiñas and Galliari 2001), with a relatively uniform range across the open areas of Patagonian region of Argentina and Chile, from Tierra del Fuego island to about 36°S. North of 36°S, this species is found more patchily or restricted to a few high-elevation (>2,000 m) localities in the Sierras Pampeanas in central and northern Argentina (P. E. Ortiz and Jayat 2012b). Records obtained from Tierra del Fuego are restricted to the northern steppe portion of the island, north of Lago Fagnano (J. A. Allen 1905; Osgood 1943b). In continental Patagonia, *R. auritus* is widespread, but a detailed survey of its distribution indicates several gaps; for example, it is very scarce or virtually absent in the high portions of the basaltic plateaus that characterize the central region (e.g., Somuncura). In central latitudes of Argentina, *R. auritus* is restricted to the Pampean region and the eastern portion of the Monte desert but completely absent from the arid diagonal. A few records are known from piedmont and Andean ranges in Mendoza province, most of them associated with *Payunia* environments (Pardiñas, Teta, and Udrizar Sauthier 2008). Contrary to the prediction of Dalby and Mares (1974), surveys conducted in northwestern Argentina over the last 20 years (Mares, Ojeda, and Barquez 1989; Barquez et al. 1991; Mares, Ojeda, Braun et al. 1997; Jayat

2009; P. E. Ortiz and Jayat 2012b) have reported few new localities for this rodent. In fact, *R. auritus* is known from only five isolated high-elevation, grassland localities in the Argentinean provinces of Jujuy, Tucumán, Catamarca, and Córdoba. Two specimens (MACN 33.246, from Salí, Tucumán, and MACN 31.37, from Maimará, Jujuy) trapped by Emilio Budin and listed by Dalby and Mares (1974:205) as vouchers of the occurrence of *R. auritus* in northwestern Argentina are misidentified (MACN 33.246 is a *Loxodontomys micropus*, and MACN 31.37 is a *Phyllotis caprinus*, not a *Graomys domorum* as indicated by M. M. Díaz and Barquez (1999:331). Ihering (1927) provided an unsubstantiated report of the genus from the Malvinas (Falkland) Islands.

SELECTED LOCALITIES (Map 298): ARGENTINA: Buenos Aires, Granja 17 de Abril (Massoia 1988d), Laguna Alsina (J. R. Contreras 1972); Puesto El Plátano (Leveau et al. 2006), Saladillo (Massoia 1988b); Catamarca, Barranca Larga (P. E. Ortiz, Cirignoli et al. 2000), Otro Cerro (type locality of *Reithrodon caurinus* Thomas); Córdoba, Pampa de Achala (Ortells et al. 1988), Washington (UNRC 8273); Jujuy, Cochinoca (Pardiñas and Galliari 2001); La Pampa, General Pico (MACN 37.100), Laguna Guatraché (Massoia, Tiranti, and Diéguez 1997); Mendoza, Caverna de las Brujas (Gasco et al. 2006), Volcán Carapacho (incorrectly given as “Cerro Morocho” by Jayat et al. 2006 and Pardiñas, Teta, and Udrizar Sauthier 2008); Neuquén, 3–5 km upstream of Chos Malal (Tiranti 1996); Río Negro, Cerro Leones (Pearson 1987); Santa Cruz, Alero Destacamento Guardaparque (Pardiñas 1998), Río Tucu Tucu, about 8 km downstream from headwaters (type locality of *Reithrodon hatcheri* J. A. Allen); Tierra del Fuego, north end of Lake Fagnano (Osgood 1943b), Estancia Via Monte (Osgood 1943b); Tucumán, Paso El Infiernillo (Dalby and Mares 1974). CHILE: Aysén, 3 km N of Coyhaique, Reserva Nacional Coyhaique, Laguna Verde (Kelt 1996); Magallanes y Antártica Chilena, Cueva del Milodón (U. F. J. Pardiñas, unpubl. data), Punta Arenas (type locality of *Reithrodon cuniculoides obscurus* J. A. Allen), Río Verde, east end of Skyring Water (Osgood 1943b).

SUBSPECIES: Although many taxa have been proposed as subspecies, recent evaluations using modern data or methods to document even general geographic trends are lacking. In his revision, Osgood (1943b) retained *cuniculoides* and *pachycephalus* as valid geographic units within the continuously distributed southern populations, with *R. a. cuniculoides* distributed along steppes, prairies, and sparse shrublands (Massoia and Chebez 1993) of the Magellan Straits and Tierra del Fuego, and *R. a. pachycephalus* restricted to the southernmost tip of South America (Osgood 1943b; Reise and Venegas 1987; Tamayo and Frassinetti 1980), in Aysén (XI Region) as well as Última Esperanza, Magallanes y Antártica Chilena, and Tierra del Fuego (XII Region; Mann

1978) of Chile. Cabrera (1961) recognized five subspecies (under the combination of *R. physodes*): *R. a. caurinus* in northwestern Argentina; *R. a. auritus*, in the Pampean region of Buenos Aires; *R. a. evae* for southern Mendoza and Neuquén; *R. a. cuniculoides*, from Chubut and Santa Cruz to the Magellan Straits; and *R. a. pachycephalus* in the western Andean ranges from Neuquén to Tierra del Fuego and adjoining parts of Chile. Molecular sequences (E. P. Lessa et al. 2010; E. P. Lessa et al., unpubl. data) failed to recover structure among austral populations that might support subspecies recognized by Osgood (1943b).

NATURAL HISTORY: In Patagonia, reproductively active males and pregnant females are found mostly in the spring (Kelt 1994; Pearson 1988), but the reproductive season can extend to the end of summer (Guthmann et al. 1997). Litter size varied from 1–8, with a mean of 4.53 in utero fetuses (Pearson 1988; Pine et al. 1979). Juveniles (<50 g) were recorded in spring and in higher numbers and proportions during the summer and autumn. Spring populations are composed of a few old overwintering individuals, some middle-aged overwintering individuals, and numerous young individuals, which mature in summer. In autumn, the oldest individuals disappear and are replaced by middle-aged individuals (Kelt 1994; Pearson 1988). *Reithrodon auritus* reaches its population maxima at the end of austral autumn (Guthmann et al. 1997). From very low minimum abundances, *R. auritus* can reach peaks of ca. 10–15 individuals (minimum known alive) per hectare. Longest recapture times were eight months, but the study of cohorts suggests maximum longevity of 15 months. Nests are made of plant materials, or, in Tierra del Fuego, sheep's wool. *Reithrodon* is most common in open habitats, such as steppes and prairies, usually near green grass (Pearson 1988). However, individuals may inhabit a wide range of environments, from high-elevation bunchgrass prairie in northern Argentina (Dalby and Mares 1974) to southern beech forest (*Nothofagus pumilio*) or shrublands in Tierra del Fuego (Pine et al. 1979). At Pampa de Achala (Córdoba province, Argentina), *R. auritus* was founded on the banks of streams, prairies, and bluffs from 1,850 to 2,170 m (Polop 1991). In Patagonia, Pearson (1988) found animals only in soils with minimum degree of humidity, but overly wet conditions cause individuals to abandon tunnels. In southeastern Buenos Aires province, stomach contents of *R. auritus* consisted only of grasses, especially *Poa* spp. and *Lolium multiflorum*. In captivity, they ate an amount of fresh green vegetation equal to their mass nightly (Pearson 1988). In Chilean winters, individuals remain active in burrows under the snow. Activity began in the evening and lasted until the early hours of the morning (Pearson 1988). Feeding occupies most of the active period, with short foraging periods interspersed. Individuals are not strongly at-

tracted to common baits and traps (Reig 1964), one reason for the paucity of specimens in museum collections. Animals excavate tunnel systems 4–7 cm in diameter, usually vertically through the turf, with grouped entrance openings, but without evidence of earth plugs (Pearson 1988). Sometimes *R. auritus* uses tunnels dug by *Ctenomys* (Dalby and Mares 1974; Pine et al. 1979) and even coinhabits the tunnels with these and *Abrothrix longipilis*, *Loxodontomys micropus*, and *Oligoryzomys longicaudatus* (Pearson 1988). Feces are common near tunnel openings. Feces are fibrous, thick (Pearson 1988), short, and greenish, similar to those of *Euneomys* (Mann 1978) but pointed at one end (Pearson 1988).

A number of ectoparasites can be found on individual *R. auritus* (Autino and Lareschi 1998; Lareschi and Mauri 1998), including the fleas *Tetrapsyllus bleptus*, *Craneopsylla minerva wolffhuegeli*, and *Neotyphloceras crassispina*; and the mites *Androlaelaps fahrenheitsi*, *Eulaelaps stabularis*, *Haemolaelaps reithrodonis*, *Laelaps mazzai*, and *L. paulistanensis*. J. P. Sánchez (2013) recovered fleas from specimens collected in Chubut province: *Agastopsylla boxi boxi*, *Craneopsylla minerva wolffhuegeli*, *Ectinorus (Ectinorus) hapalus*, *Ectinorus (Ectinorus) ixanus*, *Ectinorus (Ectinorus) levipes*, *Ectinorus (Ichyniurus) onychius*, *Hectopsylla (Hectopsylla) gracilis*, two undescribed species of *Neotyphloceras*, *Polygenis (Polygenis) platensis*, *Tetrapsyllus (Tetrapsyllus) tantillus*, and *Tiarapsylla argentina*. Lice of the genus *Hoplopleura* have been recovered from Patagonian specimens (species *H. argentina*; D. Castro and Cicchino 1987; Durden and Musser 1994) and those from Catamarca province (*H. serrulata*; D. Castro 1997). Specimens from Buenos Aires province (Balcarce) contained the nematode endoparasite *Stilestrongylus aureus* (Durette-Desset and Sutton 1985; Sutton 1989a). This species is a major prey item for several birds of prey and mammalian carnivores (Jaksic et al. 1978; De Santis et al. 1983, 1994, 1996; García Espoñda et al. 1998; Massoia 1983, 1985a, 1988b, 1988d, 1988e; Massoia and Pardiñas 1988a, 1988b; Pearson 1987; Tiranti 1992, 1996; Travaini et al. 1997; Trejo and Grijera 1998; M. M. Martínez et al. 1996).

REMARKS: As was noted previously, the taxonomy of *R. auritus* as well as the entire genus needs a fresh review. It is likely that northwestern Argentinean populations deserve full specific rank; if so, *caurinus* Thomas would be an available name. Recent compilations of localities (e.g., Herculini 2007; Teta, González-Fischer et al. 2010) indicate the existence of a major discontinuity in distribution in northeastern Buenos Aires province where this species occurs patchily (e.g., Massoia 1988d). This fact indicates a potential gap of about 200 km long between the ranges of *R. auritus* (south of the Río Salado) and *R. typicus* (north of the Río Paraná). However, Late Pleistocene and Holocene fossil samples show that this gap is perhaps very recent, probably due to land-cover changes

Map 298 Selected localities for *Reithrodon auritus* (●); northwestern localities are shown as disjunct from main distribution (see Distribution). Contour line = 2,000 m.

resulting from the spread of agriculture and urbanization that have occurred in this densely populated area.

Ortells et al. (1988) described a karyotype with $2n=34$, $FN=32$, for specimens from Buenos Aires and Córdoba provinces, Argentina. Using comparative G-banding, these authors demonstrated that this karyotype differs from that of *R. typicus* by at least four centric fusions, including one each involving both X and Y chromosomes, one paracentric inversion in a large autosome, and either a gain or loss of chromatin in another autosomal pair.

Reithrodon typicus Waterhouse, 1837

Naked-soled Conyrat

SYNONYMS:

Reithrodon typicus Waterhouse, 1837:30; type locality "Maldonado," Maldonado, Uruguay.

Reithrodon typicus currentium Thomas, 1920b:475; type locality "Corrientes. Type from Goya," Argentina.

Reithrodon typicus typicus: Gyldenstolpe, 1932a:77; name combination.

Reithrodon auritus typicus: Osgood, 1943b:223; name combination.

Reithrodon physodes typicus: Cabrera, 1961:502; name combination.

DESCRIPTION: General characters as in generic description. Soles of forefeet and hindfeet naked or tending to be less haired than those of *R. auritus*; tail unicolorous; and diploid complement = 28.

DISTRIBUTION: *Reithrodon typicus* occurs in natural or modified grasslands in the Argentinean provinces of Entre Ríos and Corrientes, throughout Uruguay (Barlow 1969; Mones et al. 2003; E. M. González and Martínez Lanfranco 2010), and in a small portion of southeastern Brazil close to the Uruguayan border (T. R. O. Freitas, Mattevi, and Oliveira 1983; Bonvicino, Oliveira, and D'Andrea 2008).

SELECTED LOCALITIES (Map 299): ARGENTINA: Corrientes, Goya (type locality of *Reithrodon typicus currentium* Thomas). Estancia Rincón de Animas, 20 km NE of Sauce (MFA-ZV-M 1176); Entre Ríos, Estación Parancito (J. R. Contreras 1972), Villa Ramírez (Massa 2010). BRAZIL: Rio Grande do Sul, 8 km E of Aceguá (T. R. O. Freitas, Mattevi, and Oliveira 1983). URUGUAY: Cerro Largo, 10 km NW of Paso del Dragón (= Plácido Rosas; Barlow 1969); Rocha, 22 km SE of Lascano (Barlow 1969); Maldonado (type locality of *Reithrodon typicus* Waterhouse).

SUBSPECIES: Thomas (1920b:475) distinguished within *R. typicus* a "dull sea-coast form," that is, the non-otypical *R. t. typicus* originally collected at Maldonado, Uruguay, and an "inland form . . . [with] well-contrasted markings," which he named as *R. t. currentium* based on a single specimen collected by R. Perrens at Goya, Corrientes, Argentina. Osgood (1943b) dismissed the distinction between these putative geographical forms based on pelage color. Ortells et al. (1988; see also T. R. O. Freitas, Mattevi, and Oliveira 1983) indicated chromosomal differences between Brazilian and Uruguayan populations, although both shared the same diploid number, which may warrant subspecific recognition.

NATURAL HISTORY: Very little is known about this species. Most information stems from Barlow (1969) and is based on 16 trapped specimens and observations made throughout Uruguay. Barlow (1969:35–36) stated that *R. typicus* was "usually found in overgrazed pasture, among rocky outcrops or on well-drained slopes with scanty vegetation . . . Coney rats dig burrows in soil varying from sandy to hard-baked clay, or utilize with or without mod-

ification abandoned burrows . . . or natural crevices and holes among rocks . . . The nearness of burrows to each other suggests that this cony rat may be variously gregarious or solitary . . . The burrow entrances averaged 5 cm in diameter. From each a passageway descended vertically an average of 25 cm, at which depth the tunnels became level and followed a course parallel to the surface. Active systems were marked by fresh cuttings and droppings near the entrances.” Barlow (1969:36) also excavated an extensive burrow system near the Río Olimar Chico and noted “all burrows were less than 2 m in length and had two entrances. They were occasionally branched and tortuous . . . The burrow entrances were from 3 to 5 cm in diameter. The tunnels were 5 to 7 cm in diameter and were 10 to 25 cm beneath the surface. Some burrows contained central, oval chambers up to 30 cm in diameter. In one such chamber we found a nest platform composed of a fine dry grass . . . Defecation sites were just outside of the entrances of the burrows or within a radius of 9 m from them. No distinct runways led to any of these burrows.” Most individuals secured by Barlow (1969) were obtained by shooting; E. M. González (2001) noted the same, reporting capture of individuals directly by hand when tracing burrows or locating nests. T. R. O. Freitas, Mattevi, and Oliveira (1983) reported captures using nets. Pregnant females were taken in January (one with four embryos) and May (three); males with scrotal testes activity were recorded in January, March, April, and May (Barlow 1969). Like *R. auritus*, *R. typicus* appears to be strictly nocturnal. Preferred plants consumed by this rodent in Uruguay include corms of *Oxalis* sp. (Oxalidaceae) and rhizomes and roots of the grass *Digitaria* sp.; Barlow (1969:37) also noted that they do not store food within their burrows.

REMARKS: The geographic boundary between *R. auritus* and *R. typicus* is not clear (Pardiñas and Galliari 2001). In Argentina, specimens from Goya, Corrientes province, were referred to *R. typicus* (see Thomas 1920b), whereas specimens from Villa Paranacito and Concordia, both in Entre Ríos province and north of the Río Paraná, were identified as *R. auritus* (see J. R. Contreras 1972; Crespo 1982a). According to unpublished mtDNA cytochrome-*b* sequence data, one specimen from Entre Ríos (MLP 26.VIII.01.17) was sister to Uruguayan representatives of *R. typicus* although diverging at 3%. This finding supports the reference of Argentinean Corrientes and Entre Ríos populations of conyrats to *R. typicus* and also the potential recognition of *currentium* Thomas as a valid subspecies. The “*orejón*,” described by Azara (1802:82), was tentatively included in the list of synonyms of *R. auritus* by Pardiñas and Galliari (2001), in part because the type locality of Azara’s taxon was

considered to be in Entre Ríos province, Argentina (Tate 1932c; Hershkovitz 1959b). We are now confident that Azara made his observations on the “*orejón*” as well as other rodents (e.g., *Akodon azarae*) around San Gabriel de Batovi (= São Gabriel), Río Grande do Sul, Brazil (see Pardiñas et al. 2007 for discussion). Consequently, the geographical context Azara’s “*orejón*” should be considered a “synonym” of *R. typicus*. However, in the Spanish version of his work, Azara (1802) also included observations made at the southern margin of the Río La Plata, which suggests that his “*orejón*” may also be based on both *R. auritus* and *R. typicus*. A similar situation arises around his “*hocicudo*,” a supposed synonym of *Oxymycterus rufus*, based on populations today referred to *O. rufus* and *O. nasutus* (J. R. Contreras and Teta 2003; see those accounts).

Brum-Zorrilla (1965) recorded a karyotype with $2n=28$, $FN=26$, for specimens from Uruguay but both T. R. O. Freitas, Mattevi, and Oliveira (1983) and Ortells et al. (1988) described a karyotype with $2n=28$ and $FN=40$ from specimens collected both in Uruguay and Rio Grande do Sul, Brazil. The apparent arm number differences between these two karyotypes were believed to be technical artifacts (see Ortells et al. 1988) rather than real geographic variation.

Map 299 Selected localities for *Reithrodon typicus* (●).

Tribe Sigmodontini Wagner, 1843

Robert S. Voss

This tribe includes only a single Recent genus, *Sigmodon*. Although other Recent genera were once considered to be closely related to *Sigmodon*, all are now referred to other tribes or unnamed clades. Hershkovitz (1955), for example, placed *Holochilus*, *Neotomys*, and *Reithrodon* together with *Sigmodon* in his “sigmodont group,” primarily on the basis of molar morphology and characters of the facial skeleton associated with the masticatory musculature. Subsequent research based on different anatomical characters and/or molecular sequence data, however, have provided convincing evidence that *Holochilus* is an oryzomyine, and that *Neotomys* and *Reithrodon* are not closely related either to *Sigmodon* or to *Holochilus* (Hooper and Musser 1964; Voss and Carleton 1993; Steppan 1995; Weksler 2003, 2006; J. J. Martínez et al. 2012; Parada et al. 2013; Schenk et al. 2013). Although earlier molecular phylogenetic results suggested that *Sigmodon* was an isolated basal lineage within the subfamily Sigmodontinae (Engel et al. 1998; Patton and Smith 1999; D’Elía 2003a), more taxon-dense analyses supported an ancient sister-group relationship with ichthyomyines, with the two tribes together forming the basal clade to all other Sigmodontinae (Weksler 2003; Parada et al. 2013; Schenk et al. 2013). Whether or not any fossil taxa (e.g., *Prosigmodon*, from the late Tertiary of North America; McKenna and Bell 1997) properly belong to the tribe Sigmodontini is a question beyond the scope of this volume.

Because the tribe Sigmodontini is essentially monotypic, its morphological characteristics and geographic distribution are the same as those described below for the genus *Sigmodon*.

Genus *Sigmodon* Say and Ord, 1825

Species of *Sigmodon*, commonly known as cotton rats, range from about 41°N (in the United States) southward throughout most of Mexico and Central America to northern South America. Four species are currently recognized from South America, where they occur in natural grasslands and deforested landscapes below about 3,800 m elevation from Colombia southward to coastal Peru and eastward to the Guianas and northeastern Brazil. Except as noted below, the following account is abstracted from Voss (1992), which should be consulted for additional details about taxonomy, morphology, distribution, and natural history.

All species of *Sigmodon* are externally similar, with small ears, short vibrissae, coarsely grizzled brownish fur,

and a sparsely haired tail that never exceeds the combined length of the head and body. The hindfeet are narrow and unwebbed, with the three middle digits (II, III, and IV) much longer than the outer two (I and V); the plantar surface is entirely naked (from heel to toes) with six small tubercles (thenar, hypothenar, and four interdigitals). There are usually either eight mammae (in four pairs) or 10 (in five pairs).

The skull is distinctive in dorsal view, with a short, blunt rostrum; deep zygomatic notches; and convergent, beaded supraorbital margins. The supraorbital beads are continuous with prominent temporal crests, and the zygomatic arches are usually convergent anteriorly (widest across the squamosal roots). The zygomatic plates are very broad, with concave anterior margins and prominent spinous anterodorsal processes. The incisive foramina are relatively long (exceeding 70% of diastemal length), and the mesopterygoid roof is always fenestrated, with large sphenopalatine vacuities. The parapterygoid fossae are broad and deeply excavated. A vertical strut of the alisphenoid separates the buccinator-masticatory and accessory oval foramina. The tegmen tympani overlaps a posterior suspensory process of the squamosal, and a slender hamular process of the squamosal separates the postglenoid foramen from the subsquamosal fenestra.

The mandible is dorsoventrally deep in proportion to its length, with a strong, falciform coronoid process and an angular process that extends posteriorly well behind the condyle. The lower incisor root is contained in a prominent capsular process posteroventral to the base of the coronoid process.

The molars are tetralophodont (lacking any trace of a mesoloph or mesolophid), hypsodont, and flat crowned, with the principal cusps and crests connected in a more or less continuous sigmoidal pattern (hence the generic name). The anterocone of M1 is undivided, as is the anteroconid of m1. M1 always has four roots, and m1 has either three or four roots; all remaining molars are three rooted.

Axial skeleton elements have modal counts of 12 ribs, 19 thoracolumbar vertebrae, 4 sacral vertebrae, and 23–25 caudal vertebrae. The tuberculum of the first rib articulates with the transverse processes of the seventh cervical and the first thoracic vertebrae, and the second thoracic vertebra has a greatly elongated neural spine. The entepicondylar foramen of the humerus is absent.

The stomach is unilocular and hemiglandular (Carleton 1973), and a gall bladder is present. Male accessory secretory organs consist of one pair each of bulbourethral, anterior prostate, dorsal prostate, ampullary, and vesicular glands, and two pairs each of preputial and dorsal prostate glands (Voss and Linzey 1981). The glans penis is complex

(*sensu* Hooper and Musser 1964), with a tridigitate bacular cartilage and a deep terminal crater containing three bacular mounds, one dorsal papilla, two lateral papillae, and a bifurcate urethral flap (Hooper 1962).

SYNONYMS:

Sigmodon Say and Ord, 1825:354; type species *Sigmodon hispidus*, by monotypy.

Lasiomys Burmeister, 1855b:16; type species *Lasiomys hirsutus* Burmeister, by monotypy.

Lasiuromys: Giebel, 1857:caption to plate 5, Fig. 1; inadvertent misuse of *Lasiuromys* Deville for *Lasiomys* Burmeister (Winge 1941:153).

Deilemys Saussure, 1860:98; type species *Hesperomys toltecus* Saussure, by monotypy.

Isothrix: E.-L. Trouessart, 1880b:178; part (listing of *hirsutus*); not *Isothrix* Wagner.

Reithrodon: Thomas, 1881a:691; part (description of *alstoni*); not *Reithrodon* Waterhouse.

Sigmomys Thomas, 1901e:150; type species *Reithrodon alstoni* Thomas, by original designation.

REMARKS: Thomas (1901e:150) erected *Sigmomys* in recognition of the many morphological characters that distinguish *S. alstoni* from *Reithrodon* (the genus to which he originally referred this species) noting, however, that “it seems probable that this form is rather a groove-toothed *Sigmodon* than any close relation to *Reithrodon*.” Hershkovitz (1955, 1966a), Cabrera (1961), and Voss (1992) concluded that *alstoni* was only what Thomas suggested—a species of *Sigmodon* with grooved upper incisors—and treated *Sigmomys* as a subjective junior synonym. Other authors have disagreed, continuing to recognize *Sigmomys* as a valid genus (e.g., Husson 1978; S. L. Williams et al. 1983) or subgenus (Musser and Carleton, 2005). Continued recognition of *Sigmomys* as a valid taxon at any rank, however, is unjustified. The notion of uniquely “important” morphological characters—such as the incisor grooving emphasized by Husson (1978) and S. L. Williams et al. (1983)—is obsolete, and current phylogenetic results (Henson and Bradley 2009) do not support the hypothesis that *Sigmodon alstoni* is the sister taxon to other members of the genus (contra the previous results of Peppers et al. 2002).

Because neither the South American species of *Sigmodon* nor the North American species appear to form monophyletic groups (Henson and Bradley 2009), the biogeographic history of the genus (discussed, inter alia, by Reig [1986] and Voss [1992]) must have included multiple intercontinental movements. Future phylogenetic research on this genus should make a particular effort to obtain molecular sequence data from *S. inopinatus*, the only living species that remains unrepresented in recent analyses. Additional nuclear gene sequences would also

be helpful for resolving currently problematic interspecific relationships.

KEY TO THE SOUTH AMERICAN SPECIES OF *SIGMODON*:

1. Upper incisors deeply grooved and strongly opisthodont; m1 always with three well-developed roots *Sigmodon alstoni*
- 1'. Upper incisors ungrooved, strongly opisthodont or procumbent; m1 with three or four roots 2
2. Stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen present (carotid arterial pattern 1; Voss 1988); palatal bridge short, narrow, and prominently grooved, with deep posterolateral sulci; auditory bullae large; molars with alternating, acutely angled cusps; m1 usually with three well-developed roots *Sigmodon peruanus*
- 2'. Stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen indistinct or absent (carotid arterial pattern 3; Voss 1988); palatal bridge long, broad, and smooth, without prominent grooves or deep posterolateral sulci; auditory bullae small; molars with opposite, rounded cusps; m1 usually with four well-developed roots 3
3. Nasal bones short (exposing incisors to dorsal view; interorbital region constricted (least interorbital breadth <23% of zygomatic breadth); posterior palatal foramina usually bordered by maxillary and palatine bones; upper incisors procumbent (but still weakly opisthodont). *Sigmodon inopinatus*
- 3'. Nasal bones long (concealing incisors from dorsal view); interorbital region broad (least interorbital breadth >26% of zygomatic breadth); posterior palatal foramina usually enclosed by palatines; upper incisors not procumbent (strongly opisthodont) *Sigmodon hirsutus*

Sigmodon alstoni (Thomas, 1881)

Groove-toothed Cotton Rat

SYNONYMS:

Reithrodon alstoni Thomas, 1881a:691; type locality “Venezuela,” subsequently restricted to Cumaná, Estado Sucre, Venezuela by Thomas (1901e:150).

Sigmomys alstoni: Thomas, 1901e:150; name combination.

Sigmomys savannarum Thomas, 1901e:150; type locality “on the savannas near their base,” Kanuku Mountains, Upper Takutu–Upper Essequibo District, Guyana.

Sigmomys venester Thomas, 1914e:412; type locality “El Trompillo, near Lake Valencia, [Carabobo,] N. Venezuela. Alt. 1300’.”

Sigmodon alstoni: Cabrera, 1961:508; first use of current name combination.

Sigmodon alstoni alstoni: Cabrera, 1961:508; name combination, as subspecies.

Sigmodon alstoni savannarum: Cabrera, 1961:508; name combination, as subspecies.

Sigmodon alstoni venester: Cabrera, 1961:508; name combination, as subspecies.

DESCRIPTION: Small (see Voss [1992] for measurement data), distinguishable from other congeners by broad, strongly opisthodont, and deeply grooved upper incisors. Additionally, *S. alstoni* differs from other South American species by its long nasal bones; unconstricted interorbital region; incisive foramina that usually extend to or between molar alveoli; unconstricted palatal bridge; posterior palatal foramina always bordered by both maxillary and palatine bones; derived stapedial circulation (pattern 3 of Voss 1988); small auditory bullae; upper molars with opposite, obtusely rounded cusps; and first mandibular molars with only three well-developed roots.

DISTRIBUTION: *Sigmodon alstoni* occurs below about 1,300m elevation from northeastern Colombia eastward across the Maracaibo Basin, through the llanos, and into the deforested foothills of the Venezuelan coastal cordilleras. Another large and possibly isolated series of populations (surrounded by forests) inhabits the Gran Sabana of southeastern Venezuela, the contiguous Rupununi savannas of Guyana, and the adjacent Rio Branco savannas of Brazil. A few scattered collections document the presence of this species in the coastal and interior savannas of Surinam and Amapá state, Brazil (Husson 1978; S. L. Williams et al. 1983; C. T. Carvalho 1962). Pleistocene fossils have been reported from Tobago (Eshelman and Morgan 1985), but *S. alstoni* is not known to be part of any Recent insular fauna.

SELECTED LOCALITIES (Map 300): **BRAZIL:** Amapá, Macapa (C. T. Carvalho 1962); Roraima, Serra da Luna (AMNH 27039). **COLOMBIA:** La Guajira, Villanueva (USNM 280382); Meta, Los Micos (FMNH 88015). **GUYANA:** Upper Takutu–Upper Essequibo, Kanuku Mountains (type locality of *Sigmomys savannarum* Thomas). **SURINAM:** Para, Zanderij (RMNH 19620); Sipaliwini, Sipaliwini-savanne-vliegeveld (RMNH 17217). **VENUEELA:** Amazonas, Paria Grande (USNM 415034), San Juan Manapiare (USNM 415027); Anzoátegui, Río Orutipano (MHNLS 3823); Bolívar, Arabupu (AMNH 75653), La Llagual (AMNH 16971), Vetania (USNM 442581); Sucre, Manacal (USNM 415020); Zulia, Empalado Savannas (FMNH 18685), Río Cogollo (FMNH 27038).

SUBSPECIES: I treat *Sigmodon alstoni* as monotypic.

NATURAL HISTORY: *Sigmodon alstoni* is usually trapped in open, grassy habitats such as savannas, airfields, pastures, overgrown gardens, and weedy roadsides (Hand-

ley 1976; Husson 1978; O'Connell 1981, 1982; Ibáñez and Moreno 1982; S. L. Williams et al. 1983; Vivas 1986; Soriano and Clulow 1988). Strictly terrestrial, *S. alstoni* constructs runways through low vegetation and is active both in the daytime and at night (Osgood 1912; Tate 1939; O'Connell 1981, 1982; Vivas et al. 1986). Like other cotton rats, *S. alstoni* is predominantly herbivorous and exhibits a strong preference for grass in feeding experiments (O'Connell 1981), but populations in agricultural fields eat large quantities of grain (A. M. G. Martino and Aguilera 1993). Reproductive autopsies suggest that this species breeds throughout the year, even in habitats with seasonal cycles of flooding and drought (Ibáñez and Moreno 1982). Voss (1992) summarized information about predators and arthropod ectoparasites. Originally suspected to be the principal rodent reservoir of Guarinito virus, the etiologic agent of Venezuelan hemorrhagic fever (Tesh et al. 1993), *S. alstoni* was subsequently shown to carry the related Piritral virus that is not known to cause any human disease (Fulhorst, Bowen et al. 1999; Fulhorst et al. 2008).

REMARKS: As noted here, *Sigmodon alstoni* was previously referred to the genus or subgenus *Sigmomys* (e.g., by Thomas 1901e; Husson 1978; S. L. Williams et al. 1983), a biologically arbitrary distinction based on the supposed importance of incisor grooving for rodent classification. Recent analyses of chromosomal and DNA sequence data (Peppers et al. 2002; Carroll and Bradley 2005; Bradley et al. 2008; Henson and Bradley 2009) have failed to convincingly resolve the phylogenetic position of *S. alstoni* with respect to congeners.

A historical record of *Sigmodon alstoni* from French Guiana (Menegaux 1902; discussed by Voss et al. 2001) was based on an old specimen in the National Histoire Naturelle, Paris (1902–44), only the skull of which can now

Map 300 Selected localities for *Sigmodon alstoni* (●). Contour line = 2,000m.

be found (F. Catzeflis, pers. comm.). The specimen in question, a young adult example of *Hylaeamys megacephalus*, was obviously misidentified by Menegaux. Although the presence of *S. alstoni* in Surinam and Amapá (Brazil) suggests that the species could occur in French Guiana, it remains formally undocumented from that country.

Reig et al. (1990) stated that Reig (1987) reported karyotypes with diploid counts of 80 and 82 chromosomes. Reig (1987), however, made no reference to *Sigmodon* karyotypes, although Reig (1986) reported $2n=82$ for *S. alstoni* without noting the geographic origin of his specimen(s). Voss (1992) reported modal diploid counts of 78 to 82 chromosomes from Venezuelan material.

Sigmodon hirsutus (Burmeister, 1854)

Burmeister's Cotton Rat

SYNONYMS:

Lasiomys hirsutus Burmeister, 1855b:16; type locality "von Maracaibo," Zulia, Venezuela.

Lasiuromys hirsutus: Giebel, 1857:caption to plate 5, Fig. 1; name combination.

Isothrix villosus hirsutus: E.-L. Trouessart, 1880b:178; name combination.

Sigmodon bogotensis J. A. Allen, 1897d:121; type locality "Plains of Bogota, [Cundinamarca] Colombia."

Sigmodon sanctaemartae Bangs, 1898c:189; type locality "Pueblo Viejo, [Cesar,] Colombia," "in the center of the Sierra Nevada [de Santa Marta], not far from the source of Rio Ancho" (p. 189, footnote).

Sigmodon hirsutus: Thomas, 1914e:413; first use of current name combination.

Sigmodon hispidus bogotensis: Cabrera, 1961:508; name combination.

Sigmodon hispidus hirsutus: Cabrera, 1961:508; name combination.

DESCRIPTION: Large (see Voss [1992] for measurement data), distinguished from South American congeners by long nasal bones; broad interorbital region; long incisive foramina; broad and long palatal bridge without conspicuous longitudinal grooves; posterior palatal foramina usually enclosed by palatine bones; derived stapedia circulation (pattern 3 of Voss 1988); small auditory bullae; narrow, strongly opisthodont, ungrooved upper incisors; upper molars with opposite, obtusely rounded cusps; and first mandibular molars usually with four well-developed roots.

DISTRIBUTION: In South America, *Sigmodon hirsutus* occurs below about 2,600m from the Caribbean coast of Colombia southward throughout the valley of the Río Magdalena and eastward to northern Venezuela. The range of *S. hirsutus* overlaps that of *S. alstoni* in northwestern Venezuela, where both species have been collected sympatrically at several localities. Pleistocene fossils from Aruba,

Netherland Antilles (Hooijer 1967), are possibly referable to this species, but no Recent insular populations of *S. hirsutus* are known. According to Bradley et al. (2008), the North American distribution of *S. hirsutus* extends from Panama northward to southwestern Mexico, excluding Belize, eastern Guatemala, and northern Honduras.

SELECTED LOCALITIES (Map 301): COLOMBIA: Cundinamarca, near Bogotá (type locality of *Sigmodon bogotensis* J. A. Allen); Huila, Valle de Suaza (USNM 542102); Magdalena, Bonda (FMNH 15281); Norte de Santander, Guamalito (USNM 280877); Tolima, Mariquita (BM 12.4.2.6). VENEZUELA: Barinas, near Altamira (USNM 416758); Cojedes, Hato Itabana (MHNLS 3851); Guárico, San Juan de los Morros (USNM 314995); Mérida, near Mesa Bolívar (USNM 388120); Miranda, Curupao (USNM 388131).

SUBSPECIES: As currently recognized (e.g., by Peppers and Bradley 2000; Musser and Carleton 2005), *Sigmodon hirsutus* is monotypic.

NATURAL HISTORY: Like other cotton rats, *Sigmodon hirsutus* is always trapped on the ground, usually in grassy or weedy habitats such as savannas, pastures, and agricultural fields (Handley 1976). In the Venezuelan llanos, the diet of this species consisted principally of the green (vegetative) tissues of grasses and herbaceous dicots (Vivas and Calero 1988). Llanoan populations breed throughout the annual cycle of flooding and drought in this seasonal landscape, although reproductive activity is perhaps most intense in the rainy season when population densities are highest (Vivas and Calero 1985, 1988). Voss (1992) summarized information about predation and arthropod ectoparasites.

REMARKS: *Sigmodon hirsutus* was long considered to be a subspecies or synonym of *S. hispidus* (e.g., by Cabrera 1961; Honaki et al. 1982; Voss 1992; Musser and Carleton 1993), but phylogenetic analyses of DNA sequence data have consistently failed to recover *hirsutus* and *hispidus* as sister taxa (Peppers and Bradley 2000; Peppers et al. 2002; Carroll and Bradley 2005; Bradley et al. 2008). Although these species are phenotypically similar in most respects, the morphology of the posterior palate provides a potentially useful criterion for sorting museum series unaccompanied by molecular data. In typical examples of *S. hispidus* (from the southeastern United States), the palate is marked by deep posterolateral sulci flanking a well-defined keel that is produced posteriorly as a strong median palatal spine. By contrast, South American specimens of *S. hirsutus* have a smooth palate that lacks posterolateral sulci and never develops a distinct median keel or spine.

Venezuelan specimens of *Sigmodon hirsutus* appear to have the same diploid number ($2n=52$) and autosomal chromosome morphology as specimens of *S. hispidus* from North and Central America (Voss 1992).

Map 301 Selected localities for *Sigmodon hirsutus* (●). Contour line = 2,000 m.

Sigmodon inopinatus Anthony, 1924

Ecuadorean Cotton Rat

SYNONYMS:

Sigmodon inopinatus Anthony, 1924a:3; type locality “Urbina, slopes of Chimborazo, [Chimborazo,] Ecuador; altitude 11,400 feet.”

Sigmodon hispidus inopinatus: Cabrera, 1961:509; name combination.

DESCRIPTION: Large (see Voss [1992] for measurement data), distinguished from other congeners by short nasal bones (exposing incisors to dorsal view); very narrow interorbital region; long incisive foramina (usually, but not always extending between molar alveoli); unconstricted palatal bridge; posterior palatal foramina usually bordered both by maxillary and palatine bones; derived stapedial circulation (pattern 3 of Voss 1988); small auditory bullae; procumbent (but still weakly opisthodont), ungrooved upper incisors; upper molars with opposite, obtusely rounded cusps; and first mandibular molars usually with four well-developed roots.

DISTRIBUTION: *Sigmodon inopinatus* is currently known from just two localities in the high Andes of Ecuador.

SELECTED LOCALITIES (Map 302): ECUADOR: Azuay, Las Cajas National Park (Voss 1992); Chimborazo, Urbina (type locality of *Sigmodon inopinatus* Anthony).

SUBSPECIES: *Sigmodon inopinatus* is monotypic.

NATURAL HISTORY: All known specimens of this species were trapped in treeless vegetation between 3,500 and 3,800 m. At the type locality, Anthony (1924a) reported 12 captures among tufts of coarse grass, presumably on well-drained slopes, but five specimens from Las Cajas were all trapped near water (riverbanks, marshes, and bogs; Barnett 1999). No other information is available on the ecology, natural history, or behavior of this poorly known species.

Map 302 Selected localities for *Sigmodon inopinatus* (●). Contour line = 2,000 m.

REMARKS: The karyotype of *Sigmodon inopinatus* is unknown.

Sigmodon peruanus J. A. Allen, 1897

Peruvian Cotton Rat

SYNONYMS:

Sigmodon peruanus J. A. Allen, 1897c:118; type locality “Trujillo, [Libertad,] Peru.”

Sigmodon simonsi J. A. Allen, 1901a:40; type locality “Eten, coast region of northwestern [Lambayeque,] Peru.”

Sigmodon puna J. A. Allen, 1903a:99; type locality “Puná, Puná Island, [Guayas,] Ecuador, . . . altitude 10 m.”

Sigmodon chonensis J. A. Allen, 1913a:479; type locality “Chone, Manavi [= Manabí] Province, Ecuador (altitude less than 100 feet).”

Sigmodon lönnbergi Thomas, 1921f:448; type locality “Quevado, lowlands of Western Ecuador, due north of Guayaquil,” Los Ríos province.

Sigmodon hispidus chonensis: Cabrera, 1961:508; name combination.

Sigmodon hispidus peruanus: Cabrera, 1961:509; name combination.

Sigmodon hispidus puna: Cabrera, 1961:509; name combination.

Sigmodon hispidus simonsi: Cabrera, 1961:509; name combination.

Sigmodon peruanus peruanus: Reig, 1986:407; name combination.

Sigmodon peruanus simonsi: Reig, 1986:407; name combination.

Sigmodon peruanus chonensis: Reig, 1986:407; name combination.

Sigmodon peruanus puna: Reig, 1986:407; name combination.

DESCRIPTION: Large (see Voss [1992] for measurement data), distinguished from all congeners by complete, primitive stapedial circulation (pattern 1 of Voss 1988). From other South American species, *S. peruanus* distinguished by long nasal bones; unconstricted interorbital region; short incisive foramina (seldom extending to or between molar alveoli); very narrow, short, and grooved palatal bridge with deep posterolateral sulci; posterior palatal foramina always bordered by both maxillary and palatine bones; large auditory bullae; broad, strongly opisthodont, ungrooved upper incisors; upper molars with alternate, acutely angled cusps; and first mandibular molars usually with only three well-developed roots.

DISTRIBUTION: *Sigmodon peruanus* occurs below about 1,600m elevation in the Pacific littoral and adjacent Andean foothills of western Ecuador and northwestern Peru.

Map 303 Selected localities for *Sigmodon peruanus* (●). Contour line = 2,000m.

SELECTED LOCALITIES (Map 303): ECUADOR: Azuay, Tunguilla Valley (FMNH 53375); Chimborazo, Puente de Chimbo (AMNH 63027); Loja, Malacatos (FMNH 53381); Los Ríos, near San Carlos (MSU 32638); Manabí, Chone (type locality of *Sigmodon chonensis* J. A. Allen), Río de Oro (AMNH 34295). PERU: Lambayeque, Trujillo (type locality of *Sigmodon peruanus* J. A. Allen); Piura, Jilili (MCZ 41136).

SUBSPECIES: I treat *Sigmodon peruanus* as monotypic.

NATURAL HISTORY: Specimens of *Sigmodon peruanus* have been collected in xeric and semiarid open habitats, as well as in agricultural fields and secondary vegetation, generally in regions of western Ecuador and northwestern Peru with a long and severe annual dry season. Unpublished field notes indicate that this species, like other cotton rats, is both diurnal and nocturnal, and constructs runways through grass or other low herbaceous vegetation. No other information of ecology, natural history, or behavior of this species is known.

REMARKS: Phylogenetic analyses based on cytochrome-*b* sequence data that suggest that *Sigmodon peruanus* is more closely related to North American cotton rats of the *S. fulviventor* group (Peppers et al. 2002) than to South American or Central American congeners are contradicted by recent molecular results that do not convincingly resolve the relationships of this species (Henson and Bradley 2009). The karyotype of *S. peruanus* is unknown.

Tribe Thomasomyini Steadman and Ray, 1982
Víctor Pacheco, James L. Patton, and Guillermo D'Elía

The concept of a thomasomyine group of genera among the Sigmodontinae has been enigmatic since Thomas (1906c) originally recognized that taxa with pentalophodont molars could be divided into those with short palates without posterolateral pits (e.g., *Thomasomys* and *Rhipidomys*) and those with long palates and well-developed pits (e.g., *Oryzomys*). A separate group related to *Thomasomys*, including *Aepeomys*, *Chilomys*, *Delomys*, *Phaenomys*, *Rhagomys*, and *Rhipidomys*, was varyingly placed into an all-inclusive oryzomyine complex (Tate 1932g), formalized with all pentalophodont taxa into the Oryzomyini (Vorontsov 1959; see also Reig 1986), or informally recognized as “thomasomyines” (Hershkovitz 1962, 1966a). Hershkovitz envisioned thomasomyines as a sylvan pentalophodont grade at the base of the sigmodontine radiation from which one lineage gave rise to the oryzomyines (*sensu stricto*) and another to what he termed the pastoral tetralophodont representatives, such as the Akodontini and Phyllotini. He conceived (Hershkovitz 1966a:125) a

thomasomyine group as one of the most coherent among the clustered South American genera he recognized, describing the group as “forest dwelling, broad footed, long tailed, 6-mammate, brachydont-pentalophodont mice with wide-short palate and weakly projecting zygomatic plate.” Critically, Hershkovitz emphasized that the characters shared by the members may be ancestral rather than indicative of phyletic affinity.

Steadman and Ray (1982), in their analysis of relationships of the extinct Galapagos giant rat *Megaoryzomys*, erected the tribe Thomasomyini to include this genus as well as *Thomasomys* and *Rhipidomys*, diagnosing the group by the combination of short palate and pentalophodont molars of medium to large size. This formal concept of the Thomasomyini was followed by Cerqueira (1982), who included *Delomys*, *Phaenomys*, *Rhipidomys*, and *Thomasomys* as extant representatives of the tribe; Eisenberg and Redford (1999), who added *Wilfredomys* to the tribe while regarding *Abrawayaomys*, *Phaenomys*, and *Rhagomys* as problematic; and McKenna and Bell (1997), who included *Abrawayaomys*, *Aepeomys*, *Chilomys*, *Delomys*, *Phaenomys*, *Rhipidomys*, and *Wilfredomys*, while regarding *Rhagomys* as of uncertain status. Voss (1993), however, in his revision of the Atlantic Forest *Delomys*, challenged the validity of the thomasomyines as a natural group, arguing that this assemblage of genera was diagnosed only by shared primitive characters. His view reinforced the “pentalophodont grade” designation espoused by Hershkovitz (1962, 1966a), and Voss thus recommended that thomasomyine genera simply be recognized as an informal group of “pleisiomorphic Neotropical muroids.”

Pacheco (2003) provided the first thorough cladistic analysis of morphological traits across a wide range of New World cricetid rodents, using Old World taxa as outgroups. His study included both an expanded character dataset (122 external, soft anatomical, craniodental, and skeletal attributes) and dense sampling of 59 taxa, including multiple representatives of each recognized sigmodontine group or lineage. Contrary to Voss’s (1993) results, Pacheco recovered a monophyletic Thomasomyini that included 11 genera (*Abrawayaomys*, *Aepomys*, *Chilomys*, *Delomys*, *Juliomys*, *Phaenomys*, *Rhagomys*, *Rhipidomys*, *Thomasomys*, *Wiedomys*, and *Wilfredomys*). Ten traits supported the node connecting this assemblage of genera, including (1) a posterodorsal extension of the premaxillae that terminates either anterior to the nasals but posterior to the zygomatic notch or anterior to both the nasals and zygomatic notch; (2) large and inflated ethmoturbinals (*Abrawayaomys*, *Aepeomys*, *Chilomys*, some *Rhipidomys*, some *Thomasomys*), or present but neither conspicuously large nor inflated (*Delomys*, *Juliomys*, some *Rhipidomys*, some *Thomasomys*, *Wilfredomys*) ethmoturbinals; (3) short pal-

ates, with the mesopterygoid fossa extending to or between the posterior margins of M3 (except *Chilomys* and *Rhagomys*, which have long palates); (4) small pits in the maxillary bone located on both sides of the palate at the level of M1 and between the incisive foramina and the posterior palatine foramina (except in *Chilomys* and *Rhagomys*); (5) a lack of sphenopalatine vacuities or, if present, limited to narrow slits on both sides of the presphenoid-basisphenoid suture (more enlarged and elongated in *Juliomys*, *Wiedomys*, and *Wilfredomys*); (6) either posteriorly convergent or parallel-sided mesopterygoid fossa (in *Abrawayaomys*, *Aepeomys*, *Chilomys*, *Wiedomys*, and *Wilfredomys*); (7) a triangular shaped parapterygoid fossa, defined by the ratio of breadth at the level of the posterior tip of the hamular process versus its breadth at the presphenoid-basisphenoid suture; (8) a delicate processus brevis of the incus, with its base distinctly narrow, long, and slender; (9) a distinct anteromedian flexus that divides the anterocone of M1 into labial and lingual cuspules; and (10) a short peroneal process of the metatarsal V, one that does not extend to the proximal edge of the cuboid.

In the phylogenetic hypothesis supported by these characters (Pacheco 2003:Figs. 15 and 16), an “Andean thomasomyine clade” composed of *Aepeomys*, *Chilomys*, *Rhipidomys*, and *Thomasomys* was successively sister to six presumptive thomasomyines from southeastern Brazil: *Abrawayaomys*, *Juliomys*, *Phaenomys*, *Rhagomys* (also Andean in its distribution), *Wiedomys*, and *Wilfredomys*. Therefore, Pacheco (2003) considered Wiedomyini to be a synonym of Thomasomyini. Pacheco’s “Andean thomasomyine clade” was diagnosed by five characters, including (1) an indistinctly squamated plantar surface of the hindfeet; (2) a shallow zygomatic notch, in which the depth is less than half the width; (3) an “open” condition of the ectotympanic ring wherein the anterodorsal edge does not extend far posteriorly sufficiently to contact the petrosal, leaving a dorsal margin of the auditory meatus that is bordered by a well-exposed tegmen tympani; (4) a distinctly reduced anterolingual conule relative to the anterolabial conule of a divided anterocone; and (5) a carotid circulation matching either pattern 1 or pattern 3 (of Voss 1988).

The content of the Thomasomyini that we envision here is equivalent to Pacheco’s “Andean thomasomyine group” or what M. F. Smith and Patton (1999) referred to as “Thomasomyini *sensu stricto*” (*Aepeomys*, *Chilomys*, *Rhipidomys*, and *Thomasomys*) plus *Rhagomys*. Our more restricted view is based on the limited molecular analyses derived from both mitochondrial and nuclear DNA sequences, which have consistently identified a clade, albeit with limited support, composed of these five genera while excluding the remainder of the southeastern Brazilian members of

Pacheco's Thomasomyini, notably *Delomys*, *Juliomys*, and *Wiedomys* (M. F. Smith and Patton 1999; Weksler 2003; D'Elía et al. 2005, 2006; Salazar-Bravo et al. 2013; Ventura et al. 2013). In these analyses, *Delomys* is placed as sister to Phyllotini, and *Juliomys* is inconsistently placed within the Sigmodontinae, although in general it is associated with Andean taxa previously considered to be phyllotines.

Unfortunately, sequence data are unavailable to date for *Phaenomys* and *Wilfredomys*, but mitochondrial and nuclear gene sequences (Ventura et al. 2013) for *Abraway-aomys* suggest it is more closely related to the Akodontini rather than to the Thomasomyini, where it was placed in Pacheco's morphological analysis. All molecular studies support *Wiedomys* as a lineage sister to Abrotrichini, one to be retained in the small tribe Wiedomyini originally diagnosed by Reig (1980). Excluding *Wiedomys*, all of these genera are regarded herein as Sigmodontinae *incertae sedis* (see the *incertae sedis* account). We emphasize, however, that our view of the Thomasomyini is provisional and acknowledge that no morphological synapomorphy is currently known to support the group as we use it herein. The composition of the Thomasomyini, therefore, is highly likely to change as future molecular studies expand both taxon representation and number of genes examined.

Our restricted set of five thomasomyine genera includes three with limited species diversity and narrow ranges (*Aepeomys*, *Chilomys*, and *Rhagomys*, with two species each) and two highly speciose genera with cumulatively very broad ranges (*Rhipidomys*, currently 23 species; *Thomasomys*, currently 44 species). Pacheco (2003) questioned the generic status of *Aepeomys*, although it is included herein as valid, and he noted that *Thomasomys*, as currently understood, was polyphyletic while *Rhipidomys* might be paraphyletic. In his revision of *Rhipidomys*, Tribe (1996) tentatively recognized its monophyly but did not support this opinion with a phylogenetic analysis; however, Pacheco (2003:278, 378), with a denser taxon sampling, recovered a monophyletic *Rhipidomys* and provided an emended diagnosis. Substantial systematic work, at all levels, will be necessary to resolve these vexing problems, and it is likely that future work will divide both of these genera to maintain monophyletic taxa, much the way Weksler et al. (2006) did recently for *Oryzomys (sensu lato)*. These unresolved issues make the construction of a suitable key for identifying the five genera currently recognized difficult, at best.

KEY TO THE GENERA OF THE THOMASOMYINI:

1. Palate long, with mesopterygoid fossa not extending anteriorly to level of M3s. 2
- 1'. Palate short, with mesopterygoid fossa extending anterior to or between M3s. 3

2. Dorsal aperture of ectotympanic ring closed, extending posteriorly to contact or closely approach the petrosal; anterodorsal margin of zygomatic plate deep (depth greater than half width of notch); simple posterolateral palatal pits placed distinctly anterior to mesopterygoid fossa *Rhagomys*
- 2'. Dorsal aperture of ectotympanic ring open, not extending posteriorly to contact petrosal but bordered by a well-exposed tegmen tympani; anterodorsal margin of zygomatic plate shallow (depth less than half width of notch); simple posterolateral palatal pits placed at level with or posterior to anterior margin of mesopterygoid fossa *Chilomys*
3. Gall bladder absent; dark metatarsal patches always present; no gap present between hypothenar and thenar pads of hindfeet; hypothenar pad level or overlapping with interdigital pad 4; claw of hallux long, extending to first interphalangeal joint of dII or beyond; mystacial vibrissae very long, extending well past posterior margin of pinna; body pelage moderately to distinctly countershaded; tail penicillate, typically with long tuft of hairs extending posteriorly from tip; anterior margin of zygomatic plate usually vertical; squamosal roots of zygomatic arch to not expand laterally, joining braincase at oblique angle; zygomatic arches typically parallel; interorbital region convergent and usually distinctly beaded when viewed in cross section; subsquamosal fenestra placed in low position, distinctly below the squamosal root of the zygomatic arch; mesopterygoid fossa convergent anteriorly *Rhipidomys*
- 3'. Gall bladder present; dark metatarsal patches variably present, or absent; gap present between hypothenar and thenar pads usually present; distinct gap present between hypothenar and interdigital pad 4; claw of hallux variable in length; mystacial vibrissae short to variable in length; body pelage usually indistinctly or not countershaded; tail typically nonpenicillate, or with very short extension of hair tuft posterior to tip; anterior margin of zygomatic plate typically slopes backward; squamosal roots of zygomatic arch laterally expanded, joining the braincase more perpendicularly; zygomatic arches typically converge anteriorly; interorbital region hourglass in shape, with supraorbital region smoothly rounded when viewed in cross section or weakly squared or edged; subsquamosal fenestra in high position, level with the squamosal root of the zygomatic arch; mesopterygoid fossa typically parallel sided. 4
4. Dark metatarsal patches absent; gap between hypothenar and thenar pads always present; claw on hallux short, not extending beyond metatarsal of dII; genal I vibrissae absent; mystacial vibrissae short, not extending to the posterior margin of the pinna; masseteric tubercle

- prominent; anteroflexus of M1 small to indistinct
 *Aepeomys*
- 4'. Dark metatarsal patches usually present; gap between
 hypothenar and thenar pads usually present; claw on
 hallux variable, short to long; genal I vibrissae variably
 present; mystacial vibrissae variable, from short to very
 long; masseteric tubercle typically absent, or reduced in
 size; anteroflexus of M1 typically distinct.
 *Thomasomys*

Genus *Aepeomys* Thomas, 1898

Víctor Pacheco

Aepeomys comprises two species, *A. lugens* and *A. reigi*. This South American endemic occurs in premontane and montane tropical forests along the Venezuelan Andes, including the Sierra de Mérida, at elevations above 1,000 m in western Venezuela (O. J. Linares 1998; Soriano et al. 1999; Ochoa et al. 2001). The following description is based mainly on Thomas (1896), Ochoa et al. (2001), Voss (1991), Voss et al. (2002), and Pacheco (2003).

Species of *Aepeomys* are medium-sized sigmodontines distinguished by a slender tail slightly longer than length of head and body (head and body 100–125 mm, tail 114–142 mm), narrow and slender hindfeet (25–30 mm), and moderate mass (32.0–44.5 g). The tail is thinly haired, uniformly colored above and below, and lacks a white tip. The ears are large (18–21 mm), brown, and furred inside and out. The body pelage is dense, soft, and velvety. Dorsal coloration varies from dark gray-brown to reddish gray-brown in *A. reigi* or olive brown in *A. lugens*, and the ventral pelage is slightly paler than dorsum. Ungual tufts on manus are absent. Digit I of the pes (hallux) is short, its first phalanx (p1) not extending beyond the metatarsal of dII, and the claw does not extend more than half the length of p1 of dII. Claws on manus are medially keeled. Legs, ankles, and dorsal surface of the pes are sparsely covered by brown hair. Dark metatarsal patches are absent. A gap between the hypothenar and thenar pads is present. The mammary complement consists of three pairs, one each in inguinal, abdominal, and thoracic positions (terminology of Pacheco 2003). Genal vibrissae are lacking. Mystacial vibrissae are short, not extending to the posterior margin of the pinna. A prominent protuberant anus is present.

Cranially, the rostrum is long, tapering, and the nasals and premaxillae form a prominent bony tube that projects well beyond incisors. Posterodorsal extensions of the premaxillae are very short, terminating anterior to the nasals and the zygomatic notch. The lumen of the infraorbital foramen is moderately open. The zygomatic notches are shallow, zygomatic plates are narrow and slope posterodorsally,

and the masseteric tubercle is comparatively prominent. The incisive foramina are large but do not reach the level of the M1s. The interorbital region is broad and hourglass in shape, with rounded supraorbital margins. The ethmoid foramen is placed dorsal or posterodorsal to the M2/M3 contact. An alisphenoid strut is absent. The braincase is rounded and inflated; the palate is short to relatively long but does not extend posteriorly much behind the last molar; posterolateral palatal pits are poorly developed; and the mesopterygoid fossa is wide and flanked by narrow, shallow, and unperforated parapterygoid fossae. Carotid circulation is pattern 1 of Voss (1988) with a large stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen present. The tegmen tympani overlaps a posterior suspensory process of the squamosal. The anterodorsal edge of ectotympanic is short and does not extend posteriorly to contact the petrosal. The postglenoid foramen is very small and subequal in size to the tegmen tympani. The parieto-supraoccipital suture is intermediate, about one-third the posterior margin of the parietal. Bullae are noninflated. The malleus lamina is square shaped; and the thoracic basket has 13 pairs of ribs (Steppan 1995). The mandible is very slender, and the capsular processes are absent. Upper incisors are narrow, orthodont, and moderately developed; upper and lower molars have comparatively high crowns with well-developed mesoloph and mesolophids; internal segments of paraflexus and metaflexus are oriented antero-posteriorly along the midline of M1–M2; protoflexus and hypoflexus are both narrow and shallow; M1 anterocone exhibits a small or indistinct anteromedian flexus, but anteroconid of m1 is undivided.

Steppan (1995) counted 13 ribs and 13 thoracic, 6 lumbar, and about 38 caudal vertebrae in the postcranial skeleton of a single specimen of *A. lugens*. The stomach is unilocular (single-chambered) and discoglandular (gastric glandular epithelium restricted to a small pouch-like structure on the greater curvature); a gall bladder is present. The glans penis body, lateral mounds, urethral flaps, and dorsal papilla lack spines. The genus is unknown from the fossil record.

SYNONYMS:

Oryzomys: Thomas, 1896:306; part (description of *lugens* Thomas); not *Oryzomys* Baird.

Aepeomys Thomas, 1898e:452; type species *Oryzomys lugens* Thomas, by original designation.

Thomasomys: Anthony, 1932:1; part (description of *ottleyi* Anthony); not *Thomasomys* Coues.

REMARKS: Osgood (1933a) considered *Aepeomys* to be a synonym of *Thomasomys*, an arrangement followed by Ellerman (1941), Cabrera (1961), and Handley (1976). Alternatively, Gyldenstolpe (1932), A. L. Gardner and Patton (1976), and more recent authors (e.g., Aguilera et al. 1994, 2000; Musser and Carleton 1993, 2005) argued for generic status.

Neither of these options, however, is sustained by a phylogenetic hypothesis or a thorough comparison between species of both genera. Much of the support for recognizing *Aepeomys* as a distinct genus came from A. L. Gardner and Patton (1976) who reported a karyotype of “*Aepeomys fuscatus* J. A. Allen” that differed appreciably from those of species in the thomasomyine genera *Thomasomys* and *Rhipidomys* and was more similar to that of oryzomyine rodents. However, after Voss et al. (2002) convincingly removed *fuscatus* to *Handleyomys* Voss, Gómez-Laverde, and Pacheco, *Aepeomys* became restricted to *A. reigi* and *A. lugens*. Although *Aepeomys* needs to be further contrasted with *Thomasomys*, it is tentatively retained here as a separate genus based on cranial characteristics that distinguish it from *Thomasomys sensu stricto* (Ochoa et al. 2001; Pacheco 2003), and by the karyological differences reported by Aguilera et al. (2000). Pacheco’s (2003) phylogenetic assessment based on morphological characters suggested that *Aepeomys* is nested within a clade of *Thomasomys* spp., but the support for this clade was weak.

Thomas (1898e) described *Aepeomys vulcani* based on a specimen with a partially crushed skull from Pichincha, Ecuador. Philip Hershkovitz, Charles Handley, and Víctor Pacheco independently found that this specimen shared more characteristics with *Thomasomys sensu stricto* than with *Aepeomys* (as determined by Voss et al. 2002, and herein). *Aepeomys vulcani* Thomas (1898e) was then referred to *Thomasomys* (Voss et al. 2002; see also the account for the genus *Thomasomys*).

Aepeomys lugens was not available to M. F. Smith and Patton (1999) for their phylogenetic assessment based on mtDNA cytochrome-*b* sequence data, but they suggested that *Aepeomys* might belong to a clade composed of *Thomasomys*, *Chilomys*, and *Rhipidomys*. *Aepeomys lugens* was included for the first time in a phylogenetic analysis based on nucDNA IRBP sequences (D’Elía, Luna et al. 2006) where *Aepeomys* appeared as the sister to a *Rhagomys-Thomasomys* clade.

KEY TO THE SPECIES OF *AEPEOMYS*:

1. Head and body length (average 110.1 mm, range: 100–119 mm); fur on head and body shorter and rougher; legs, ankles, and dorsal surface of pes densely haired; digit V of pes moderately long, extending beyond the interphalangeal joint of digit IV; posterior margin of zygomatic ramus of the maxilla lacking a distinct notch; incisive foramina broad and oval; interparietal of moderate size, with anteroposterior midline between 30–40% of parietal length; palate extending to the posterior border of M3 or barely beyond; posterior margin of palate with small medial process; maxillary tooththrow (average 4.3 mm, range: 4.0–4.4 mm); M3 small and round in occlusal view; paraflexus of M1 and M2 un-

divided; coronoid and condylar processes not notably broad nor large, sigmoid and angular notches not markedly deep; protolophid of m1 reduced or absent; karyotype $2n=28$, FN=48 *Aepeomys lugens*
 1’. Head and body length longer (average 113.6 mm, range: 104–125 mm); fur on head and body shorter and rougher; legs, ankles, and dorsal surface of pes sparsely haired; digit V of pes shorter, not extending beyond the interphalangeal joint of digit IV; posterior margin of zygomatic ramus of the maxilla with a distinct notch; incisive foramina broader with more convergent anterior margins; interparietal longer in most specimens with anteroposterior midline near half of the parietal length; palate longer, extending behind M3; posterior margin of palate shallow and lacking a medial process in most specimens; maxillary tooththrow longer (average 4.5 mm, range: 4.3–4.8 mm); M3 larger and triangular in occlusal view; M1 and M2 with paraflexus divided by an enamel bridge; coronoid and condylar processes broader and larger, producing deeper sigmoid and angular notches; protolophid in m1 usually present; karyotype $2n=44$, FN=46 *Aepeomys reigi*

Aepeomys lugens (Thomas, 1896)

Mérida Aepeomys

SYNONYMS:

Oryzomys (?) *lugens* Thomas, 1896:306; type locality “La Loma del Morro, near Merida, Venezuela, alt. 3000 metres.”

[*Aepeomys*] *lugens*: Thomas, 1898e:452; first use of current name combination.

Thomasomys ottleyi Anthony, 1932:1; type locality “Paramo de los Conejos, about fifteen miles north of Merida, Venezuela; altitude 9600 feet.”

[*Thomasomys*] *lugens*: Osgood, 1933a:161; name combination.

DESCRIPTION: Similar to *A. reigi*, differing in slightly smaller size (mean head and body length 110.1 mm, tail length 121.7 mm, hindfoot length 27.0 mm, and condyloincisive length of skull 26.6 mm), proportionately longer digits I and V of hindfoot, broad and oval incisive foramina, moderate-sized interparietal with its midline 30–40% of parietal length, no distinct notch on posterior margin of zygomatic ramus of maxilla, palate extending to posterior border of M3 or slightly beyond, and other details of cranium. Karyotype distinctly different, $2n=28$, FN=48, versus $2n=44$, FN=46; see Ochoa et al. (2001) and the *A. reigi* account.

DISTRIBUTION: Mérida Andes of Venezuela (states of Táchira and Mérida), between 1,990 and 3,500 m.

SELECTED LOCALITIES (Map 304): VENEZUELA: Mérida, La Montana, 4.1 km SE of Mérida (USNM

579550), Paramito, 3 km W of Timotes (Handley 1976), Páramo de los Conejos, 15 mi N of Mérida (Anthony 1932), Santa Rosa, 2 km N of Mérida (Handley 1976); Táchira, Páramo el Zumbador, 8 km SSW El of Cobre (Ochoa et al. 2001).

SUBSPECIES: I treat *Aepeomys lugens* as monotypic.

NATURAL HISTORY: *Aepeomys lugens* is nocturnal, may be semiarboreal (O. J. Linares 1998) or strictly terrestrial (Aagaard 1982). These are solitary and largely insectivorous mice, eating primarily arthropods, larvae, and worms (Díaz de Pascual 1993). Individuals can breed year-round but with a preference on the rainy season, with pregnant females recorded in September and lactating females between May and November. Litter size was usually two, but seven young have been found. *Aepeomys lugens* is found in primary cloud forest and rarely in secondary habitats (Díaz de Pascual 1993), and also in seasonal forests and páramos (Soriano et al. 1999). Microhabitat preferences are apparently similar to those of *A. reigi*. Handley (1976) recorded captures both species of *Aepeomys* beside logs and at the base of trees and tree ferns, among boulders covered with moss and lichen, in thick cover of herbs and ferns on the ground, and on logs; usually in damp habitats and rarely in dry places, all within Lower Montane very humid forest (bmh-MB), Montane rain forest (bp-M), Lower Montane humid forest (bh-MB), and Montane very humid forest (bmh-M1), in the life zone categories of Ewel and Madriz (1968). Aagaard (1982) found this species most abundant in the lower montane wet forest and montane wet forest in the Holdridge system. Males averaged 3.6% heavier than females (Aagaard 1982). O. J. Linares (1998) probably combined data for both *A. lugens* and *A. reigi*, as the latter species was not described until after Linares's book was published.

Aepeomys lugens is the host for several genera of mites, including the acarid genus *Eutropicola* (Brennan and Reed 1974a) and laelapid genus *Hymenolaelaps* (Furman 1972a). Brennan and Reed (1975) documented additional chiggers, including species in the genera *Crotiscus*, *Hoffmannina*, and *Adontacarus*. P. T. Johnson (1972) described anopluran lice in the genus *Hoplopleura*, E. K. Jones et al. (1972) reported ticks of the genus *Ixodes*, and Tipton and Machado-Allison (1972) described fleas in the genera *Ctenidiosomus*, *Neotyphloceras*, *Plocopsylla*, and *Cleopsylla*. All records are from Mérida state, with the host originally identified as *Thomasomys lugens*.

REMARKS: Osgood (1933a) synonymized *Thomasomys otteleyi* Anthony with *A. lugens*, a conclusion supported by Voss et al. (2002). Cuervo Díaz et al. (1986) and Alberico et al. (2000) reported *A. lugens* for Colombia, but these records appear to have been based on misidentified material (Voss et al. 2002). The reported distribution in

Map 304 Selected localities for *Aepeomys lugens* (●) and *Aepeomys reigi* (○). Contour line = 2,000 m.

Andean Ecuador (Eisenberg 1989; Musser and Carleton 1993; Eisenberg and Redford 1999) was apparently based on the erroneous inclusion of *Aepeomys vulcani* Thomas, 1898 (= *Thomasomys vulcani*) as a synonym of *A. lugens* by Cabrera (1961).

Aguilera et al. (2000) reported the karyotype ($2n=28$, $FN=48$) and noted its strong divergence from the karyotype ($2n=44$, $FN=46$) of an unnamed population subsequently described as *Aepeomys reigi* (Ochoa et al. 2001).

Aepeomys reigi Ochoa, Aguilera, Pacheco, and Soriano, 2001

Reig's Aepeomys

SYNONYMS:

Thomasomys lugens: Handley, 1976:51; part; not *Oryzomys* (?) *lugens* Thomas (= *Aepeomys lugens* [Thomas]).

Aepeomys lugens: O. J. Linares, 1998:309; part; not *Oryzomys* (?) *lugens* Thomas (= *Aepeomys lugens* [Thomas]).

Aepeomys reigi Ochoa, Aguilera, Pacheco, and Soriano, 2001:230; type locality "El Blanquito, Parque Nacional Yacambú, 17 km SE Sanare, Lara State, Venezuela, 1600 m (approx. 9°40'N; 69°37'W)."

DESCRIPTION: Larger of two known species in genus, but only slightly so (mean head and body length 113.6 mm, tail length 127.1 mm, hindfoot length 27.9 mm, condyloid-

cisive length of skull 27.8 mm). Differs from *A. lugens* in that digits I and V of hindfoot do not extend beyond commissure of digits II and III and first interphalangeal of digit IV; posterior margin of zygomatic ramus of maxilla with distinct notch; palate extends to posterior border of M2 or even behind it; interparietal length nearly half parietal length; and enamel bridge, crossing from paracone to base of anteroloph, divides paraflexus of M1 and M2.

DISTRIBUTION: *Aepeomys reigi* occurs in the extreme northeastern part of the Venezuelan Andes (states of Lara and Trujillo), between 1,600 and 3,230 m.

SELECTED LOCALITIES (Map 304): VENEZUELA: Lara, El Blanquito, Parque Nacional Yacambu, 17 km SE of Sanare (type locality of *Aepeomys reigi* Ochoa, Aguilera, Pacheco, and Soriano); Trujillo, Hacienda Misisí, 14 km E of Trujillo (Ochoa et al. 2001), Macizo de Guaramacal, 9 km ESE of Boconó (Ochoa et al. 2001).

SUBSPECIES: *Aepeomys reigi* is monotypic.

NATURAL HISTORY: Handley (1976) and Ochoa et al. (2001) wrote that *A. reigi* inhabited primary cloud forest and small patches of páramo, and that it was not rare in cloud forest habitats. Specimens have been trapped on the ground in densely forested areas (beside logs, at the base of trees and tree ferns, in rocky places, along trails, or near small streams) or in open areas (close to the ecotone between páramo and forest) covered by shrubs and herbaceous vegetation (Ochoa et al. 2001). Brennan and Reed (1974a) described three new species of acarid mites in the genus *Eutrombicula* from specimens of this species, J. T. Reed and Brennan (1975) described three new species of chiggers in the genus *Odontacarus*, and Tipton and Machado-Allison (1972) reported a flea in the genus *Cleopsylla* from *A. reigi* (all reported as *Thomasomys lugens*).

REMARKS: Specimens from Trujillo were formerly recorded as *Thomasomys lugens* (Handley 1976) or as *Aepeomys* sp. (Aguilera et al. 1994, 2000; Soriano et al. 1990). Ochoa et al. (2001) differentiated *A. reigi* from *A. lugens* on the basis of larger size, shorter fur, more sparsely haired legs, ankles, and hindfeet, deeper zygomatic notches, and other cranial and dental features in addition to the distinctive karyotype ($2n=44$, FN=46), which differs substantially from that of *A. lugens* ($2n=28$, FN=48).

Genus *Chilomys* Thomas, 1897

Víctor Pacheco

Chilomys comprises two species, *C. fumeus* and *C. instans*. This South American endemic occurs in premontane and montane tropical forests along the Andes from the Cordillera of Mérida in western Venezuela (O. J. Linares 1998;

Soriano et al. 1999) south through the three main cordilleras in Colombia to central Ecuador (Musser et al. 1998). The following description is based primarily on Thomas (1895c), Osgood (1912), and Pacheco (2003).

Species of *Chilomys* are small-sized sigmodontines distinguished by a long and slender tail that exceeds the length of head and body (head and body 72–102 mm, tail 102–137 mm) and narrow and relatively long hindfeet (hindfoot length 22–26 mm). The dorsum varies from dark gray to gray-brown with the venter not counter-shaded. The pelage hair is short and woolly. The tail is covered with very short hairs, uniform in color, and often exhibits a white tip. The ears are medium sized and also covered with short hairs (ear length 14–18 mm). The soles of the hindfeet lack imbrications, but the dorsal surface is unusually scaly. The mammary complement consists of three pairs, one each in inguinal, abdominal, and thoracic positions (terminology of Pacheco 2003). Genal vibrissae are typically present. Mystacial vibrissae are of moderate length, extending to the posterior margin of the pinna, but not far beyond. A protuberant anus is not prominent.

The skull has a short and delicate rostrum that contrasts with a large, rounded, and deep braincase; the nasals are shorter than the premaxillae and exhibit a distinct notch on their anterior margin; the interorbital region is broad; the anterodorsal margin of the zygomatic arch is shallow (depth less than half width of notch); the ventral margin of the zygomatic arch is placed distinctly above the orbital floor; the jugal bone is long; the optic foramen is small and placed posterior to M3; the parietosupraoccipital suture is distinctly broad, with the suture at least half the posterior margin of the parietal breadth; carotid circulation is pattern 3 (*sensu* Voss 1988), with a small stapedia foramen and no squamosoalisphenoid groove or sphenofrontal foramen; the incisive foramina are short and do not extend to the protocone of M1; the diastema exhibits a pair of swollen ridges lying on either side of the posterior half of the incisive foramina; the masseteric tubercle is distinctly placed anterior to the root of the zygomatic plate; the palate is long, extending posteriorly beyond M3; sphenopalatine vacuities are absent or expressed only as narrow slits; the condition of the alisphenoid strut is variable; parapterygoid fossae exhibit a sharp triangular outline (terminology of Pacheco 2003); the parapterygoid vacuity is variable; the mesopterygoid fossa has parallel borders and is subequal to or broader than the adjacent parapterygoid fossae; the dorsal aperture of the ectotympanic ring is open and does not extend posteriorly to contact the petrosal; the tegmen tympani overlaps the posterior process of the squamosal; and the malleus lamina is rectangular in shape.

The upper incisors are long, slender, and proodont (*sensu* Hershkovitz 1962:103); molars are small, bunodont, brachyodont, and lack a distinct labial cingulum; the antero-medial flexus on M1 is indistinct, and the anteromedian flexid on m1 is absent. The mandibular diastema is flat and almost horizontal; a distinct capsular process is present. The condylar process is well developed, contrasting with a short angular process, producing a shallow angular notch.

Steppan (1995) recorded 12–13 thoracic, 6–7 lumbar, and more than 33 caudal vertebrae for two specimens of *C. instans*. The gall bladder is present (Voss 1991), and the stomach conforms to the unilocular-hemiglandular type (Carleton 1973). Voss and Linzey (1981) reported one pair of preputials and larger medial and ventral prostates than lateral ones. The genus is not known from the fossil record.

SYNONYMS:

Oryzomys: Thomas, 1895c:368; part (description of *instans*); not *Oryzomys* Baird.

Chilomys Thomas, 1897c:500; type species *Oryzomys instans* Thomas, by original designation.

REMARKS: *Chilomys* has been viewed as an enigmatic genus of peculiar morphology with uncertain affinities. The genus was previously considered an oryzomyine (Tate 1932g; Cabrera 1961; Voss and Linzey 1981; Reig 1984, 1986), but Musser and Carleton (1993) suggested it might be closely related to thomasomyines. Voss and Carleton (1993) subsequently defined and delimited the contents of the tribe Oryzomyini but omitted *Chilomys*. M. F. Smith and Patton (1999) based on mtDNA cytochrome-*b* sequences confirmed the thomasomyine affinities of *Chilomys*, suggesting that it might be sister to *Thomasomys*. Pacheco (2003), based on a broad array of morphological characters and a large representation of thomasomyine rodents, also found *Chilomys* a member of the thomasomyine *sensu stricto* clade, one that contained members of *Thomasomys*, *Aepeomys*, and *Rhipidomys*. More recently, D'Elía, Luna et al. (2006) presented a phylogenetic analysis of nucDNA IRBP sequences that supported the inclusion of *Aepeomys* as well as *Rhagomys* as thomasomyines; unfortunately, *Chilomys* was not included in their analysis.

KEY TO THE SPECIES OF *CHILOMYS*:

1. Nasals short (average 6.96, range: 6.41–7.39), diastema short (average 6.66 mm, range: 6.14–6.96 mm), breadth of zygomatic plate narrow (average 1.75 mm, range: 1.34–1.96 mm), maxillary tooththrow short (<3.15 mm) *Chilomys fumeus*
- 1'. Nasals long (average 8.05, range: 7.4–8.76), diastema long (average 7.51 mm, range: 7.0–7.91 mm), breadth of zygomatic plate broad (average 2.21 mm, range: 2.05–2.41 mm), maxillary tooththrow large (>3.18 mm) *Chilomys instans*

Chilomys fumeus Osgood, 1912

Smoky Chilomys

SYNONYMS:

Chilomys fumeus Osgood, 1912:53; type locality “Paramo de Tama, head of Tachira River, Santander [= Norte de Santander], Colombia. Alt. 6,000–7,000 ft.”

Chilomys instans fumeus: Cabrera, 1961:435; name combination.

DESCRIPTION: *Chilomys fumeus* and *C. instans* very similar in general appearance and size. As detailed by Pacheco (2003), however, skull of *C. fumeus* with especially narrowed zygomatic plates (less than length of M1) and narrowed hypoflexus of M2 (distinctly narrower than mesoflexus). In postcranial skeleton, hemal arches of anterior caudal vertebrae of *C. fumeus* present, with left and right elements fused, and with spinous process on border; distinct gap between trochlear process of calcaneus and posterior articular facet also present.

DISTRIBUTION: *Chilomys fumeus* is known only from the Cordillera de Mérida of Venezuela in the states of Mérida and Táchira, and the Cordillera Oriental of Colombia, in the department of Norte de Santander, at elevations between 1,830 and 2,700 m.

SELECTED LOCALITIES (Map 305): COLOMBIA: Norte de Santander, Páramo de Tamá (type locality of *Chilomys fumeus* Osgood). VENEZUELA: Mérida, Páramo Tambor (FMNH 22172), 6 km ESE of Tabay, Middle Refugio (USNM 387964); Táchira, Páramo El Zumbador, 8 km SSW of El Cobre (CUVLA 5743).

SUBSPECIES: *Chilomys fumeus* is monotypic.

NATURAL HISTORY: This apparently nocturnal, terrestrial, and insectivorous species primarily inhabits cloud forest, rarely extending into secondary growth vegetation, where it feeds on plant material, insects, and worms (O. J. Linares 1998). *Chilomys fumeus* was captured in cloud forests of Venezuela at the base of rotting moss-covered trees, under moss-covered logs and fallen limbs, or under lichen- and moss-covered tree roots; in openings and in dense tangles of vines and bamboo in moist fern, moss, and lichen-laden cloud forests; in the lower montane wet forest and montane rainforest in the Holdridge system (Handley 1976). A female (USNM 579558) with well-developed teats and likely lactating was captured in July, during the local wet season. No other details of reproductive biology are known. O. J. Linares (1998) considered this taxon as rare, in agreement with Osgood (1912) who remarked to have collected only two specimens during some 20 days of trapping. This species hosts chiggers in the genera *Androlaelaps* (Furman 1972a), *Eutrombicula* (Brennan and Reed 1974a), and *Odontacarus*, *Peltoculus* (Brennan and Reed 1975). Tipton and Machado-Allison (1972) reported the flea *Cleopsylla*. *Chilomys instans* was

Map 305 Selected localities for *Chilomys fumeus* (○) and *Chilomys instans* (●). Contour line = 2,000m.

originally indicated as the host species for each of these ectoparasitic records, but all are from *C. fumeus* as currently understood.

REMARKS: Osgood (1912:53) described *Chilomys fumeus* as a species distinct from *C. instans*. Cabrera (1961), without justification, relegated *fumeus* to subspecific status, and the genus has thereafter been considered monotypic (O. J. Linares 1998; Musser and Carleton 1993, 2005). However, based on my examination of the type specimens of *fumeus* and *instans*, and specimens from other available localities (Pacheco 2003), I concur with Osgood (1912) and recognize *fumeus* as a valid species.

Osgood (1912) reported the species at “Paramo de Tama,” but according to his field notes (B. D. Patterson, pers. comm.) the specimens FMNH 18690 and 18689 were collected at the “Hd. of Tachira River.” Paynter (1982) gave an elevation of 3,329m for Paramo de Tamá, but he explicitly stated that Osgood’s camp between 10 February and 6 March 1910 was in temperate forest (not páramo) at 1,825 to 2,450m. Therefore, *C. fumeus* is most likely present in the middle montane humid forests and not in páramo habitats. The karyotype is unknown.

Chilomys instans (Thomas, 1895)

Andean Chilomys, *Colombian Forest Mouse*

SYNONYMS:

Oryzomys instans Thomas, 1895c:368; type locality “Bogotá,” Cundinamarca, Colombia.

[*Chilomys*] *instans*: Thomas, 1897:501; first use of current name combination.

DESCRIPTION: As noted in description of *C. fumeus*, *C. instans* similar in general external and cranial appearance, but differs from its congener in broader zygomatic plates (subequal in size to length of M1), broader hypoflexus of M2 (similar in width to mesoflexus), no hemal arch on anterior caudal vertebrae, and trochlear process of calcaneus level to or overlapping with posterior articular facet.

DISTRIBUTION: *Chilomys instans* is distributed from the central Andes of Ecuador through the three Andean cordilleras of Colombia between 1,100 and 4,000m. This species exhibits an allopatric distribution with *Chilomys fumeus*.

SELECTED LOCALITIES (Map 305): COLOMBIA: Antioquia, 7km E of Sonsón (FMNH 70343), Páramo Frontino (FMNH 71610), Santa Barbara (FMNH 71614); Caldas, Manizales, Río Termales (Castaño et al. 2003); Cundinamarca, San Cristóbal (FMNH 71632), Guasca, Río Balcones (FMNH 71638); Huila, San Adolfo (FMNH 71621), San Antonio (FMNH 71495); Risaralda, La Pastora, Reserva Ucumarí (ICN 16556). ECUADOR: Cañar, Chical (AMNH 62922); Napo, Papallacta (Voss 2003); Pichincha, Volcán Pichincha (Musser et al. 1998); Tungurahua, San Francisco, E of Ambato (AMNH 67542).

SUBSPECIES: *Chilomys instans* is monotypic.

NATURAL HISTORY: O. J. Linares (1998) considered *C. instans* (including *C. fumeus*) to be a nocturnal, terrestrial, and insectivorous species that fed on plant material, insects, and worms. It is not clear if his comment applied to both species or just to *C. fumeus*. Voss (2003) reported a specimen of *C. instans* from Papallacta, Ecuador, trapped on a mossy log over a stream in subalpine rainforest, another on the ground in a narrow runway beneath mossy shrubs in the same habitat, and a third in a mossy tunnel beneath bunch grass in the páramo/forest ecotone. Albuja (1991) listed the species for Ecuador as occurring in the temperate region almost countrywide. Alberico et al. (2000) reported additional specimens of *C. instans* from Valle del Cauca and Quindío, Colombia, but without reference to voucher specimens. Trapido and Sanmartín (1971) processed one specimen of *C. instans* from Munchique for Pichindé virus, but the virus was not detected. SeEVERS (1955) described three new species of staphylinid beetles in the genus *Amblyopinus* from *C. instans* (reported as *Chilomys* sp.), all from localities in Cundinamarca and Huila,

Colombia. Tipton and Machado-Allison (1972) reported fleas of the genus *Sphinctopsilla*, also from Colombian specimens.

REMARKS: The type locality was given by Thomas (1895c) as simply “Bogota,” but in the label on the skin of the holotype reads as “La Selva Estate, plains of Bogota.” Voss (2003) reported that the *Papallacta* specimens closely resembled the holotype of *Chilomys instans* in qualitative characters, except that they have slightly broader interorbital orbits and shorter molar rows, indicating intraspecific variation and the necessity of an updated revision of the genus. Pacheco (2003) also described polymorphism in qualitative characters for this species. Colombian populations from Urrao, Antioquia, and Munchique, Cauca, might represent an undescribed species (V. Pacheco, unpubl. data). The species occurs from lower montane forests to páramo/forest ecotone, a wider elevational and ecological range than that of *C. fumeus*. The karyotype is unknown.

Genus *Rhagomys* Thomas, 1886

Lucía Luna

The genus *Rhagomys* is poorly known and, having no clear systematic affinities, has been regarded as *incertae sedis* in recent accounts of the Sigmodontinae (Reig 1986; M. F. Smith and Patton 1999; McKenna and Bell 1997; Percequillo et al. 2004; Musser and Carleton 2005) or as part of an assemblage that Voss (1993) termed “plesiomorphic Neotropical murids.” Relying solely on cranial morphology, Thomas (1917d) associated the single, then-recognized species *R. rufescens* with both the “*Oryzomys-Oecomys* series” (*Oryzomyini*) and “*Thomasomys-Rhipidomys* series” (*Thomasomyini*). Initial molecular sequence analyses (Percequillo et al. 2004) failed to provide an unequivocal position for *Rhagomys* within the sigmodontine radiation. These authors (p. 254) thus concluded that *Rhagomys* “would constitute an additional divergent lineage interposed among more supported suprageneric groups” of the Sigmodontinae. However, more recent molecular analyses using both mitochondrial and nuclear gene sequenced placed *Rhagomys* within the *Thomasomyini*, together with *Thomasomys*, *Aepeomys*, and *Rhipidomys* (D’Elía, Luna et al. 2006). While this hypothesis is based on relatively low support, it remains the best currently available.

The genus has only two species, each known from only a few localities limited to relatively small geographic areas. Their distributions are disjunct and link two regions known for the remarkable degree of endemism of their respective faunas: *Rhagomys rufescens* (Thomas 1886a), known from a handful of specimens collected in the Atlantic Forest of coastal Brazil (Thomas 1886a, 1917d; Percequillo et al.

2004; P. S. Pinheiro et al. 2004), and *R. longilingua* (L. Luna and Patterson 2003), known from only three specimens collected on the eastern slope of the Andes in Peru (L. Luna and Patterson 2003) and Bolivia (Villalpando et al. 2006). Both Luna Wong (2002) and Pacheco (2003) corroborated the phylogenetic placement of the recently described *R. longilingua* within *Rhagomys* by a cladistic analysis of morphological characters.

Species of *Rhagomys* are small mice with small ears and long mystacial, supraorbital, and genal vibrissae that reach the pinnae. The hindfeet are broad with unusually fleshy plantar pads (Ellerman 1941; Moojen 1952b) and naked soles (Moojen 1952b). Among the Sigmodontinae, the genus is uniquely diagnosed by the presence of a nail (as opposed to a claw) on the hallux and an elongated digit V, which reaches the middle of the second phalanx of digit IV. The tail is slightly shorter than the head and body together and terminates in a small tuft of hairs (Moojen 1952b). *Rhagomys* has six mammae arranged in three pairs, one postaxial, one abdominal, and one inguinal (L. Luna and Patterson 2003; see also Thomas 1917d). Stomach morphology is unilocular and hemiglandular, with the antrum and corpus subequal in area (L. Luna and Patterson 2003; Percequillo et al. 2004).

The ventral and dorsal pelages are strongly countershaded, vividly reddish above in *R. rufescens* and olive brown in *R. longilingua*. Notably, *R. rufescens* has soft hair, whereas the hair of *R. longilingua* is spiny, making *Rhagomys* one of four spiny genera of sigmodontines, together with *Neacomys*, *Scolomys*, and *Abrawayaomys*.

L. Luna and Patterson (2003), Percequillo et al. (2004), and P. S. Pinheiro et al. (2004) each provide expanded morphological descriptions of the genus based on their respective recently collected specimens. Diagnostic cranial characters include the combination of opisthodont upper incisors, prominent incisor capsules, and molars with very conspicuous cusps and thin ridges connecting the conules with the median mure. The skull is delicate and characterized by a short but stout rostrum; nasals strongly tapering posteriorly but extending past the anterior line of the premaxillary bones; a rounded braincase; posteriorly diverging supraorbital ledges; relatively short and narrow incisive foramina; a shallow and narrow zygomatic notch; long and wide palate, with puntiform posterolateral palatal pits; a narrow mesopterygoid fossa and narrow parapterygoid fossae perforated by long and wide fenestrae; a derived carotid circulation (pattern 3 of Voss 1988) that includes a small stapedia foramen, no groove on the internal surfaces of the squamosal and alisphenoid, and no sphenofrontal foramen; a very wide and robust alisphenoid strut; small auditory bullae; an absence of the suspensory process of the squamosal; and a completely planed ventral surface to

the dentary. The genus is easily identified by the presence of a nail instead of a claw on digit V of the pes, a character also present in some Old World Muridae (*Dendromys* and *Chiropodomys*) but unique among the Sigmodontinae.

SYNONYM:

Hesperomys: Thomas, 1886a:250; part (description of *rufescens*); not *Hesperomys* Waterhouse.

Rhagomys Thomas, 1917d:192; type species *Hesperomys rufescens* Thomas, by original designation.

REMARKS: Thomas (1886a:250) originally placed his new species within the then very large and inclusive genus *Hesperomys*, but remarked that *H. rufescens* resembled superficially the smaller species of the “*Oryzomys* section” of *Hesperomys*, with *H. bicolor* (= *Oecomys bicolor*) its only close ally. By 1906, however, Thomas (p. 442) expressed doubt regarding his earlier association of *rufescens* with *Oryzomys* and formalized this doubt in his 1917 erection of *Rhagomys* to contain this enigmatic species.

Percequillo, Tirelli et al. (2011) reported on four molars taken from the scat of an ocelot (*Leopardus pardalis*) at Alta Floresta in northern Mato Grosso, Brazil, that were unambiguously identified as *Rhagomys*. Given the lack of diagnostic occlusal characters distinguishing the two known species, however, these authors were unable to assign their sample to either, or even possibly to a third, undescribed form. Nevertheless, this locality is intermediate geographically between that of *R. longilingua* from the eastern Andean slope in southern Peru and northern Bolivia and *R. rufescens* from the Atlantic Forest of coastal Brazil. As such, this record supports the hypothesis of L. Luna and Patterson (2003) that the apparent large distributional hiatus in the ranges of the two known species was possibly a sampling artifact and provides evidence for a biogeographic connection between the western Amazon–eastern Andean slope and the Atlantic Forest.

KEY TO THE SPECIES OF *RHAGOMYS*:

1. Pelage spiny; distribution in eastern Andes
 *Rhagomys longilingua*
- 1'. Pelage soft; distribution in coastal Brazil
 *Rhagomys rufescens*

Rhagomys longilingua L. Luna and Patterson, 2003

Long-tongued *Rhagomys*

SYNONYM:

Rhagomys longilingua L. Luna and Patterson 2003:3; type locality “Peru: Departamento de Cuzco, Provincia de Paucartambo, below ‘Suecia,’ a roadside settlement in Manu Biosphere Reserve along the Río Cosñipata; coordinates 13°06.032’S, 71°34.125’W; elevation approximately 1900 m.”

DESCRIPTION: Small to medium sized (mass 25–35 g) spiny mouse with small ears and tail subequal in length to head and body. Pelage short and close with markedly spiny texture, dorsal fur more spiny than ventral fur. Color above olive brown but with strongly hispid pattern resulting from both spines and long, thin hairs. Ventral pelage from chin to interior sides of forefeet and hindfeet ochraceous-buff, contrasting sharply with dorsal coloration. Tail weakly bicolored, only slightly paler below, and terminated with small tuft of hairs; scales arranged in annular pattern, with hairs grouped in triplets of same size, shorter at tail base and becoming longer toward tip. Five manual digits unique in being long with broad, squared, narrow, and short claws that minimally project beyond conspicuously blunt tips. Pes with five digits, each with blunt tip bearing calloused surface; hallux noticeably shortened and bearing nail rather than claw. Hindfoot short (length 17 to 20 mm) and broad with well-developed plantar pads. Skull strongly built with short, blunt, and narrow rostrum; short and strongly diverging interorbital region; and large braincase, all conditions that also generally characterize *R. rufescens*. Nevertheless, the two species differ only in subtle ways. For example, *R. longilingua* has strongly beaded supraorbital edges, narrowest anteriorly; somewhat more shallow zygomatic notches; a more conspicuous postorbital process; a smaller posterior opening of alisphenoid canal; and a larger undifferentiated heel on M3 that gives this tooth an inverted triangle shape.

DISTRIBUTION: *Rhagomys longilingua* is known from only four specimens collected on the eastern slope of the Andes of southeastern Peru and northern Bolivia. The maximum distance between collection sites is approximately 520 km (Villalpando et al. 2006). Specimens of *R. longilingua* have been collected over a wide elevational range, from 450 m (in Peru) to 1,900 m (in Peru and Bolivia).

SELECTED LOCALITIES (Map 306): BOLIVIA: La Paz, Parque Nacional y Area Natural de Manejo Integrado Cotapata (Villalpando et al. 2006). PERU: Cusco, Paucartambo, below Suecia, Manu Biosphere Reserve (type locality of *Rhagomys longilingua* L. Luna and Patterson); Madre de Dios, Maskoitania, 13.4 km NNW of Atalaya, left bank Río Alto Madre de Dios (FMNH 175218).

SUBSPECIES: *Rhagomys longilingua* is monotypic.

NATURAL HISTORY: The stomach contents of the holotype of *R. longilingua* contained Diptera, Formicidae, and Lepidoptera, suggesting an insectivorous diet. Insectivory was also indicated by the presence of a relatively short intestine and caecum as well as crested teeth and mandibular characteristics suggesting strong mastication muscles to pierce chitin. A number of characteristics indicate that this species is arboreal, including pedal morphology

Map 306 Selected localities for *Rhagomys longilingua* (●). Contour line = 2,000 m.

(conspicuously fleshy plantar pads, broad feet, long digit V, grooved plantar surface, and minuscule claws) as well as the forward position of the eyes and a short muzzle (L. Luna and Patterson 2003). Three of the four specimens were collected in pitfall traps, and one was collected at 1 m above ground in a bamboo thicket. These findings suggest that *R. longilingua* can easily exploit both ground and above ground environments (L. Luna and Patterson 2003). The long tongue, from which its specific epithet is derived (*longus* = long, *lingua* = tongue), may serve as a probing device to collect insects from crevices (L. Luna and Patterson 2003). No other data are known of the natural history of this species, including behavior, reproductive biology, or population attributes.

Rhagomys rufescens (Thomas, 1886)

Rufescent *Rhagomys*

SYNONYMS:

Hesperomys rufescens Thomas, 1886a:250; type locality “Rio Janeiro [*sic*],” Rio de Janeiro, Brazil.

Rhagomys rufescens: Thomas, 1917d:193; first use of current name combination.

DESCRIPTION: Also small to medium in size, similar to *R. longilingua* but differing from that species in having soft and lax rather than spiny fur, reddish dorsal and reddish-gray ventral coloration. Tail unicolored brownish, with small scales, covered with blackish hairs becoming progressively longer toward tip. Hindfeet short and broad,

about 24% of head and body length, with short hallux reaching interdigital pad at base of digit II. Plantar pads large and well developed, as in *R. longilingua*. Skull quite similar to that of *R. longilingua*; characters that distinguish the two species, based on few available specimens of each, detailed in the account of *R. longilingua*.

DISTRIBUTION: *Rhagomys rufescens* is known only from the Atlantic Forest of Minas Gerais, São Paulo, and Rio de Janeiro states in southeastern Brazil, at elevations ranging from sea level to 650 m.

SELECTED LOCALITIES (Map 307): BRAZIL: Espírito Santo, Santa Teresa (Percequillo, Tirelli et al. 2011); Minas Gerais, Parque Estadual da Serra do Papagaio (Pasmamani et al. 2011), Poços de Caldas (Percequillo, Tirelli et al. 2011), Viçosa, Mata do Paraíso (MNRJ 66056); Rio de Janeiro, Rio de Janeiro (type locality of *Hesperomys rufescens* Thomas); Santa Catarina, Mono, Parque Natural Municipal Nascentes do Garcia (Percequillo, Tirelli et al. 2011); São Paulo, Reserva Floresta Morro Grande, Caucaia do Alto (Percequillo, Tirelli et al. 2011), Ribeirão Grande (Percequillo, Tirelli et al. 2011), Ubatuba, Núcleo Picinguaba, Parque Estadual da Serra do Mar (MNRJ 65545).

SUBSPECIES: *Rhagomys rufescens* is monotypic.

NATURAL HISTORY: Little is known about the ecology, reproductive biology, behavior, or other life history aspects of this species. Preliminary analysis of the stomach contents of one specimen revealed three unidentified species of ants (P. S. Pinheiro et al. 2004). As in the case of *R. longilingua*, limb and foot morphologies suggest arboreal and scansorial habits (Thomas 1917d; P. S. Pinheiro et al. 2004). Also like *R. longilingua*, this species has recently been collected in pitfall traps (Percequillo et al. 2004; P. S. Pinheiro et al. 2004). The specimen from Viçosa, Minas Gerais, was obtained in second growth semideciduous tropical forest (*floresta estacional semidecidual*; Percequillo et al. 2004; P. S. Pinheiro et al. 2004). The recent specimen from the Parque Estadual da Serra do Mar was taken at a site characterized by transition between coastal vegetation on Quaternary sandy plains of marine origin (*restinga*) and tropical forest (*floresta ombrófila densa*; P. S. Pinheiro et al. 2004).

REMARKS: Some published records of this poorly known species are in error, either due to questionable locality provenance or incorrect identifications. Records of *R. rufescens* from Além Paraíba and Passos in Minas Gerais state mentioned by Eisenberg and Redford (1999) are misidentified specimens of *Hylaeamys*. The locality of “Reserva Estadual Itapetinga, Atibaia, São Paulo” given to a specimen in the collection at MZUSP is probably in error and “no precise geographical information can be assigned to it” (Percequillo et al. 2004:241).

Map 307 Selected localities for *Rhagomys rufescens* (●) and *Rhagomys* sp. (○; see Percequillo, Tirelli et al. 2011).

Testoni et al. (2010) described the karyotype of *R. rufescens* from Santa Catarina state with a $2n=36$, FN=50, including GTG, CBG, Ag-NOR, and CMA(3)/DAPI banding profiles. Both X and Y chromosomes are acrocentric.

Genus *Rhipidomys* Tschudi, 1845

Christopher J. Tribe

Known in English as South American climbing mice and rats, and generally as *ratos arborícolas* (“tree rats”) in Portuguese and *ratas arborícolas* in Spanish, species of *Rhipidomys* are found in forested habitats throughout most of tropical South America. The range of the genus extends from nearly 12°N on the Paraguaná peninsula in northern Venezuela, to 25°S in Salta province in northwestern Argentina and 24°S in Canindeyú department in eastern Paraguay and São Paulo state in southeastern Brazil. It also occurs in eastern Panamá and on certain offshore islands, including Trinidad. Within these latitudes it occupies habitats ranging from lowland rainforest to forest-páramo ecotones at over 3,000 m; no representatives have been found in the arid coastal regions of Peru and Chile, or in the cold, treeless zones of the high Andes. Individuals of several species have been caught in the roofs of buildings. Much of

the following account is drawn from the author’s revision of the genus (Tribe 1996), which deals with morphology and distribution in greater detail.

Adult *Rhipidomys* vary in size from roughly that of a house mouse (*Mus musculus*) to that of a black rat (*Rattus rattus*), with known adult head and body lengths ranging from less than 90 mm to over 210 mm, and mass from under 30 g to nearly 200 g. Several aspects of their morphology are associated with their arboreal habits (Rivas-Rodríguez et al. 2010). These animals have large, protruding eyes and long, stiff mystacial vibrissae, extending well beyond the pinnae when pressed back against the head. The long tail (observed range: 93–180% of head and body length) is covered with short, stiff hairs and tipped with a distinct, often long, pencil. The broad hindfeet have relatively short metatarsals and long digits; digits I and V are longer than those of most other sigmodontine rodents. Digit V is partly opposable. There are six large plantar pads on each hindfoot, the hypothenar lying very close to the 4th interdigital. The dorsal surface of the metatarsus is covered along its midline by a narrow or broad dark patch, which may be distinctly or diffusely outlined. Female *Rhipidomys* have six mammae, in inguinal, abdominal, and thoracic positions (terminology according to Pacheco 2003). In lowland and lower montane forms, the adult body pelage is short and moderately fine to medium-coarse in texture; usually sleek, but short, woolly, juvenile-like fur is retained ventrally in many adult *Rhipidomys leucodactylus* and some other species. At higher elevations (above 1,500 to 2,000 m), the pelage tends to be finer and longer, but not to the extremes found in certain *Thomasomys* species or in phyllotines, and juveniles at those elevations tend to resemble adults. Dorsal color ranges from a fairly bright reddish-orange to a duller grayish-brown agouti; ventral color is white to pale yellow, sometimes suffused with orange. *Rhipidomys macconnelli* is exceptional in its generally chocolate-brown dorsum and grayish venter.

Sexual dimorphism in skull dimensions is negligible in most *Rhipidomys* but can be apparent in the larger species, in which males may be 2–3% larger than females on average. Skulls range from about 26–46 mm in occipitonasal length. In dorsal view, skulls have a short, blunt rostrum and shallow zygomatic notches. The zygomatic arches are not greatly bowed and are broadest across their squamosal roots (sometimes across the jugals in older specimens). The squared or beaded supraorbital margins, which may or may not form the broadest part of the interorbital region, diverge posterolaterally and continue as parietal ridges across the large, oval braincase. The braincase profile is domed in smaller species, becoming flatter in adult specimens of larger species. The interparietal bone is long (in the sagittal plane), usually exceeding 40% of its width. A robust

hamular process of the squamosal separates the short postglenoid foramen from the subsquamosal fenestra, the dorsal margin of which is lower than the squamosal root of the zygomatic arch. Ventrally, the skull has relatively long incisive foramina, which may just reach the level of the M1s. The short palatal bridge does not extend beyond the M3s; its posterior margin is never concavely rounded but is roughly squared or biconcave with a small, caudally projecting median process. Small posterolateral palatal pits flank the anterior part of the mesopterygoid fossa. The parapterygoid fossae are triangular and generally shallow. Dorsal to them, an alisphenoid strut separates the buccinator-masticatory foramen from the foramen ovale accessorium. The bony roof of the mesopterygoid fossa is usually complete, but in some specimens it may be pierced by short, narrow sphenopalatine vacuities. The relatively small auditory bullae are suspended anteriorly by contact between the posterior suspensory process of the squamosal and the tegmen tympani, which also partly occludes the postglenoid foramen and sometimes even the subsquamosal fenestra. The mandible is neither very slender nor very robust. Relative to the molar occlusal plane, the condyloid process rises somewhat higher than the small, slightly falciform coronoid process, and extends posteriorly about as much as the angular process, or sometimes a little more.

The upper incisors are slightly opisthodont. The molars are pentalophodont, with distinct mesoloph(id)s on M1/m1 and M2/m2, and brachyodont, with clearly separated main cusps. The upper molars each have three roots, the lowers two, although M1/m1 sometimes exhibit a small accessory root. The anterocone of M1 consists of two subequal conules only slightly smaller than the main cusps. An anteromedian style may be present. The principal cusps of M1 and M2 are arranged in opposite, rather than alternate, pairs. The lingual cusps are flat even when unworn, their occlusal surfaces lying at a shallow angle to the occlusal plane, and are triangular in occlusal view; they are separated by broad hypoflexi and interdental notches. The labial cusps are sugarloaf-shaped when unworn, with rounded cross-sections in the occlusal plane. The paraflexus and metaflexus each describe a quarter-circle around their respective cusps, and are blocked at their outer (labial) ends by a cingular ridge that connects the labial cusps and styles. The lingual ends of the lower molar flexids are similarly obstructed. A distinct anterolabial cingulid is present on m2 and m3.

Axial skeletal counts include 7 cervical, 19 thoracolumbar, 4 sacral and 35–44 caudal vertebrae, and 12 or 13 pairs of ribs. The first ribs articulate with the transverse processes of the 7th cervical and 1st thoracic vertebrae, while the transverse processes of the 6th and sometimes the 5th cervical vertebrae buttress those of the 7th. The neural spine

of the 2nd thoracic vertebra is only slightly elongated. The entepicondylar and supratrochlear foramina of the humerus are absent (Pacheco 2003).

Rhipidomys species lack a gall bladder (Voss 1991a) and have a unilocular-hemiglandular stomach (Carleton 1973; Pacheco 2003). The glans penis has long, deep grooves on the dorsal and ventral surfaces; the lateral bacular mounds are triple-curved (except in *R. macconnelli*) and extend beyond the crater rim (Hooper and Musser 1964; Pacheco 2003).

The known *Rhipidomys* karyotypes (all from the “leucodactylus” and “macconnelli” sections, see below) have a diploid number of $2n=44$, with the exception of those allocated herein to *R. nitela* ($2n=48$ or 50). The number of autosomal arms for specimens with $2n=44$ displays a roughly bimodal distribution, some taxa clustering at $FN=46-52$ and others at $FN=70-80$, although a few intermediate numbers have been found: $FN=56$ (A. L. G. Souza et al. 2007b), $FN=61$ (M. J. de J. Silva and Yonenaga-Yassuda 1999), and $FN=64$ (C. R. Bonvicino, pers. comm.). *Rhipidomys nitela* specimens have $FN=67-72$. Thomazini (2009) listed the published karyotypes for the genus and added new data, and A. H. Carvalho et al. (2012) provided further discussion on comparative karyology in the genus.

Morphologically and ecologically, species of *Rhipidomys* fall into three sections, within which there are few discrete morphological characters by which the constituent species may be distinguished from each other (Tribe 1996; Pacheco 2003). (1) The “fulviventer” section consists of montane forms from the cordilleras of Venezuela, Colombia, and southeastern Peru as well as the Guiana Shield. These have longer, softer, less agouti pelage extending over the ankles and wrists, and the juvenile pelage resembles that of the adults. Their skulls are broader and more rounded, with less pronounced supraorbital-parietal ridges. They lack a protoloph and protostyle in M1, and m1 has a transverse lophid in the procingulid, anterior to the anterolophid. All member species except *R. caucensis* display the primitive carotid circulation pattern, with a large stapedial foramen and an internal groove across the squamosal and alisphenoid, leading to the “sphenofrontal” foramen in the alisphenoid-orbitosphenoid suture (the frontal is rarely involved) (Bugge 1970; pattern 1 of Voss 1988). (2) The “leucodactylus” section, the most widespread of the three, consists of lowland and lower montane species with short agouti adult pelage covering the ankles and wrists; the juvenile pelage is grayer and somewhat woolly. Their skulls are generally less rounded than those in the “fulviventer” section, and their carotid circulation pattern is derived, with a small stapedial foramen, no internal groove across the squamosal and alisphenoid,

and no sphenofrontal foramen (pattern 3 of Voss 1988). A protoloph and protostyle are generally present in M1, as is a transverse lophid in the procingulid of m1. (3) The third section comprises only *Rhipidomys macconnelli*, from the sandstone inselbergs (*tepuis*) of the Guiana shield. This species is less specialized for arboreal life, as reflected in its longer and narrower metatarsi, its slightly smaller and more separate plantar pads, and its lack of body fur on ankles and wrists. Its long, soft dorsal pelage is dark chocolate-brown, while ventrally the cream or buffy tips of the hairs do not disguise their dark gray bases. *Rhipidomys macconnelli* resembles members of the “leucodactylus” section in its skull morphology and its derived carotid circulation pattern (Bugge 1970; pattern 3 of Voss 1988 [not pattern 1 as misstated by Voss et al. 2001:125–126]). A protoloph and protostyle are present in M1, and, uniquely, m1 lacks a transverse lophid in the procingulid, anterior to the anterolophid.

A cladistic analysis of morphological characters in thomomyine rodents, including seven species of *Rhipidomys* representing all three sections of the genus, found a monophyletic *Rhipidomys* but provided no intrageneric resolution, apart from a close relationship between *R. fulviventer* and *R. caucensis* (Pacheco 2003). Another analysis using only a limited subset of the same character data yielded a highly paraphyletic basal arrangement of these *Rhipidomys* species with respect to *Thomasomys* and other genera, but this phylogeny had poor jackknife and bootstrap support values (Salazar-Bravo and Yates 2007). In a molecular analysis of sigmodontine rodents based on the mtDNA cytochrome-*b* gene, six species drawn from all three sections of *Rhipidomys* formed a single clade, within which *R. wetzeli* (of the “fulviventer” section) was the most basal branch, followed by *R. macconnelli* as the sister taxon to a subclade comprising four members of the “leucodactylus” section (M. F. Smith and Patton 1999). A constrained molecular clock based on cytochrome-*b* sequences suggested that the three sections split apart over 6 million years ago (L. P. Costa 2003). Parasitological evidence also suggests some unity of the genus: the anopluran louse *Hoplopleura angulata* Ferris, 1921, described from *Rhipidomys venezuelae*, has also been reported on seven other *Rhipidomys* species from all three sections of the genus, but otherwise only on *Thomasomys cinereus* (see Durden and Musser 1994). Should future studies demonstrate the monophyly of each of these three sections diagnosed, it would be appropriate to grant them subgeneric status within a monophyletic *Rhipidomys*. No genus-group names are currently available for either the “fulviventer” or the “macconnelli” sections.

The morphological variation exhibited by *Rhipidomys* specimens is not easily arranged into discrete species-level

units, and in some cases there is apparently greater individual and geographic variation within species than phylogenetically informative variation among them (Tribe 1996). The uncertainty of specimen allocation based solely on morphological evidence is reflected in the key to species given below. The limited but rapidly increasing amount of karyotype and molecular data, so far available mainly for Brazilian forms, has proven invaluable for distinguishing certain taxa and allying others, often in unexpected ways (e.g., Zanchin, Langguth, and Mattevi 1992; Andrades-Miranda, Oliveira et al. 2002; L. P. Costa 2003; B. M. de A. Costa 2007; Thomazini 2009; A. H. Carvalho et al. 2012). Indeed, three new species were described in 2011 alone based on the combination of renewed fieldwork coupled with molecular and karyotypic data (R. G. Rocha, Costa, and Costa 2011; B. M. de A. Costa et al. 2011). Both of these works also identified an apparently undescribed species from central Brazil allied to *R. cariri* on the basis of molecular data (which they respectively referred to as “*R. sp. 1*” and “*Rhipidomys sp.*,” both citing UFMG 2934 as a member). Clearly, much more work in these fields, particularly analyses that indisputably link molecular evidence to both karyotypes and morphology, is needed to test the hypotheses of species distinction and specimen allocation presented here.

SYNONYMS:

Mus: Lund, 1840a:24 [1841b:240]; part (description of *mastacalis*); not *Mus* Linnaeus.

Rhipidomys Cabrera, 1961:423; incorrect subsequent spelling of *Rhipidomys* Tschudi.

Rhipidomys Saunders, 1975:85; incorrect subsequent spelling of *Rhipidomys* Tschudi.

Rhipodmys Saunders, 1975:85; incorrect subsequent spelling of *Rhipidomys* Tschudi.

Rhyppidomis Guitton, Araújo Filho, and Sherlock, 1986:233; incorrect subsequent spelling of *Rhipidomys* Tschudi.

Rhidpidomys Stallings, 1989:187; incorrect subsequent spelling of *Rhipidomys* Tschudi.

Ripidomys Stallings, 1989:190; incorrect subsequent spelling of *Rhipidomys* Tschudi.

REMARKS: There has been some confusion regarding the year in which the name *Rhipidomys* Tschudi became available. Tschudi first published it in December 1843 (Sherborn 1922:cxxiv) in his article “Mammalium conspectus” (p. 252), as a subgenus of *Hesperomys* Waterhouse: “2. Subg. Rhipidomys. Wagn. in litt. 1844. Tsch.,” below which he listed the only included species: “87. 1. *H. leucodactylus*. Tsch. Fauna peruan. cum fig.” The reference was to his *Untersuchungen über die Fauna peruana*, published in parts between 1844 and 1846. However, the part of the latter work in which he described *Hesperomys leucodactylus* appeared only in 1845 (Sherborn 1922). Because the “Mammalium conspectus” contained neither description nor definition of the species, nor a reference to a previously published description or definition, the species name *leucodactylus* as used therein is not available (ICZN 1999:Art. 12). Consequently, because the subgeneric name *Rhipidomys* as used in Tschudi’s “Mammalium conspectus” was not accompanied by a definition, a description, or an available species-group name, it too is not available from that work under the terms of Article 12. On page 16 of the first part of the *Fauna peruana*, published in 1844, the names *Rhipidomys* and *H. leucodactylus* are again listed without definition, and are therefore also not

available according to Article 10.1.1 of the Code, on interrupted publication. These names become available only from page 183 of the *Fauna peruana*, published in 1845. Here Tschudi first briefly defines the subgenus—“Subgenus RHIPIDOMYS. Wagn. Cauda corpore longior apice penicillata” (tail longer than body, with tufted tip)—and then defines and describes the species *H. leucodactylus* at length. The animal is also figured in an engraving (plate XIII, Fig. 2; i.e., the left-hand rodent illustrated).

KEY TO THE SPECIES OF *RHIPIDOMYS*:

1. Adult dorsal pelage dark chocolate brown, never yellowish agouti; ventral pelage with cream or buffy tips not disguising long, dark gray hair bases; tail bicolored, with the ventral surface paler than the dorsal throughout most of its length; heel and wrist bare, not fur covered; hind foot relatively narrow, with long metatarsus; lateral extension of parietal bone (lateral to parietal ridge) variable in shape but usually much narrower posteriorly; m1 procingulid lacking transverse lophid anterior to the anterolophid; lateral bacular mounds of phallus simple, not complexly curved (Pacheco 2003) *Rhipidomys macconnelli*
- 1'. Adult dorsal pelage from reddish orange to yellowish gray agouti, not chocolate brown; ventral pelage appearing white, cream, or pale orange when unruffled, with or without gray hair bases; tail unicolored, or if paler ventrally then only in proximal one-third; heel and wrist well furred; hindfoot broad with short metatarsus; lateral extension of parietal bone (lateral to parietal ridge) approximately rectangular or only slightly narrower posteriorly; m1 procingulid displaying one or two transverse lophids anterior to the anterolophid; lateral bacular mounds of phallus “triple curved” (Pacheco 2003) 2
2. Pelage soft, long (body hairs 8–14 mm on mid-dorsum, 6–9 mm midventer, guard hairs 2–5 mm longer); dorsally bright reddish-orange; ventrally gray based, even on throat; juvenile pelage similar to adult in texture and color, though less bright; ears darker than dorsal pelage; skull with broad braincase; interorbital region rounded, narrowest in the middle, with squared or beaded supraorbital margins diverging rearward; these continue as weak parietal ridges curving around the braincase; carotid circulation pattern primitive or derived; protostyle and protoloph absent on M1; protoflexus absent on M2 (“fulviventris” section) 3
- 2'. Pelage coarser, short (body hairs typically 5–8 mm on mid-dorsum, 3–5 mm midventer, guard hairs 2–5 mm longer), though rather longer in highland specimens; dorsal pelage brownish-gray to yellowish-gray agouti, occasionally redder; throat and (usually) medial abdo-

- men covered with white or cream hairs without gray bases; juvenile pelage gray and woolly in texture; ear color paler than, similar to, or occasionally darker than dorsal pelage; interorbital region of skull waisted anteriorly, with beaded or slightly ledged supraorbital margins diverging rearward; these continue as evident parietal ridges crossing the sides of the braincase in a straighter line; carotid circulation pattern derived (small stapedial foramen and no internal squamosal-alisphenoid groove or sphenofrontal foramen: carotid arterial pattern 3; Voss 1988); protostyle and (usually) protoloph present on M1; proflexus usually present on M2 (“leucodactylus” section) 9
3. Derived carotid circulation pattern, with small stapedial foramen and no internal squamosal-alisphenoid groove or sphenofrontal foramen (carotid arterial pattern 3; Voss 1988); body size very small (adult head and body length usually <110 mm); upper molar row <4.5 mm *Rhipidomys caucensis*
- 3'. Primitive carotid circulation pattern, with large stapedial foramen and evident internal squamosal-alisphenoid groove and sphenofrontal foramen (carotid arterial pattern 1; Voss 1988); body size from very small through very large; upper molar row 3.5–6.5 mm 4
4. Body size very small (adult head and body length usually <105 mm); upper molar row <4.0 mm; tip of paroccipital process bifurcated *Rhipidomys wetzeli*
- 4'. Body size larger (adult head and body length usually >105 mm); upper molar row >4.1 mm; tip of paroccipital process not distinctly bifurcated 5
5. Body size large (adult head and body length >150 mm); tail very long (>190 mm); upper molar row >6 mm *Rhipidomys ochrogaster*
- 5'. Body size smaller (adult head and body length usually <150 mm); tail length < 200 mm; upper molar row <6 mm 6
6. Body size small to medium (adult head and body length <130 mm); upper molar row <4.7 mm in Venezuela or <5.0 mm in Colombia 7
- 6'. Body size medium to moderately large (adult head and body length usually >125 mm); upper molar row >4.7 mm in Venezuela or >5.0 mm in Colombia 8
7. Dorsal pelage bright chestnut or orange-brown; ventral pelage with cream hair tips; 1–2 pairs of palatal foramina; found in NE Venezuela (Serranía de Turimiquire) *Rhipidomys tenuicauda*
- 7'. Dorsal pelage duller chestnut brown; ventral pelage with orange suffusion; two or more pairs of palatal foramina; found in Eastern Cordillera of Andes. *Rhipidomys fulviventris*
8. Dorsal pelage reddish to orangey brown; ventral pelage with cream or orange tips; tail much longer than head and body; relatively broad skull; supraorbital ridges only slightly developed; upper molar row averaging 5.25 mm (range: 5.0–5.4 mm), rather large in comparison with skull length; found in SW Colombia (Western and Central Cordilleras) *Rhipidomys similis*
- 8'. Dorsal pelage bright chestnut brown; ventral pelage with white or cream tips; tail slightly longer than head and body; skull of average breadth; supraorbital ridges a little more developed than in (8); upper molar row averaging 4.95 mm (range: 4.8–5.2 mm), average in comparison with skull length; found in the mountains of northwestern and northern Venezuela *Rhipidomys venustus*
9. Size large; upper molar row >5.4 mm (>5.0 mm in Peru; >5.6 mm in Venezuela; >5.9 mm in eastern and southern Brazil and Paraguay); adult occipitonasal length >35 mm (>33 mm in Argentina and Bolivia; >36 mm in northern Colombia and Venezuela; >39 mm in Brazil); adult hindfoot length (with claw) ≥28 mm 10
- 9'. Size generally smaller; upper molar row and occipitonasal lengths smaller than in couplet 9; adult hindfoot length (with claw) ≤30 mm (≤32 in the southern Atlantic Forest) 14
10. Tail abundantly furred distally, with long, bushy pencil (extending >15 mm beyond tail tip); adult body pelage sleek or somewhat woolly, especially ventrally; size large to very large; upper molar row 6.2–7.2 mm (>5.8 mm in the Brazilian and Ecuadorian Amazon); skull large, robust, with well-developed supraorbital ridges *Rhipidomys leucodactylus*
- 10'. Tail less well furred, with shorter, sparser pencil (<15 mm beyond tail tip); adult body pelage sleek or somewhat woolly; size moderate to very large; upper molar row 5.0–6.6 mm; skull moderate to large; supraorbital ridges well developed or not 11
11. Adult body pelage somewhat woolly; moderate size; adult hindfoot length (with claw) 28–30 mm; skull with broad interorbit; upper molar row 5.0–5.8 mm; found in eastern Andean valleys of Peru *Rhipidomys modicus*
- 11'. Adult body pelage sleek; moderate to very large size; skull with medium to narrow interorbit; adult hindfoot length (with claw) usually ≥30 mm 12
12. Skull long and rather narrow, with shallow, flattened braincase and well-developed supraorbital ridges *Rhipidomys couesi*
- 12'. Skull with slightly broader and more inflated braincase; supraorbital ridges well developed or not 13
13. Adult hindfoot length usually ≤33 mm; skull with narrow interorbit ranging from hourglass in shape with very slight supraorbital ridges in northwestern Bolivia

- to more angular with moderate supraorbital ridges in southern Bolivia and Argentina; upper molar row usually ≤ 6.0 mm *Rhipidomys austrinus*
- 13'. Adult hindfoot length usually ≥ 33 mm, sometimes shorter especially in northwestern Bolivia; skull with somewhat broader interorbit and moderate supraorbital ridges, more developed in northwestern Bolivia; upper molar row usually ≥ 5.9 mm
. *Rhipidomys gardneri*
14. Combination of small size and small molars; adult hind foot length (with claw) ≤ 28 mm; adult occipitonasal length ≤ 32 mm (occasionally up to 34 mm in Estado Bolívar, Venezuela); upper molar row ≤ 4.7 mm (≤ 4.9 mm in northern Estado Bolívar); tail with distinct pencil; karyotype $2n=48$ or 50 ; found north of the Amazon and east of the Orinoco and Negro or in Trinidad and Tobago. *Rhipidomys nitela*
- 14'. Size small to large; adult hindfoot length (with claw) usually ≥ 25 mm; karyotype $2n=44$; found outside of the region described in (14) 15
15. Dorsal pelage usually bright orange-brown (duller, more olive-brown in Huila, Colombia); ears small; hindfoot usually rather slender (broader in northern Peru and eastern Panama), with narrow, dark metatarsal patch; dark tail with pencil of medium length (usually ca. 10 mm, shorter in Huila); skull moderate to slender with straight supraorbital ridges; found in northern Andean foothills and valleys and in extreme eastern Panama. *Rhipidomys latimanus*
- 15'. Dorsal pelage redder or grayer; hindfoot usually broader, with variable metatarsal patch; skull usually broader; tail pencil short to moderate. 16
16. Dorsal pelage varying from rich reddish brown (in mesic areas) to duller yellowish brown (in more arid areas); ears large; hindfoot with proportionately short digits and faint, indistinctly outlined metatarsal patch; tail usually medium brown with short pencil (usually ≤ 6 mm); skull elongated and becoming flattened with age; braincase not inflated; found in northern Colombia and northern Venezuela *Rhipidomys venezuelae*
- 16'. Combination of characters not as in (16); found south of the Amazon in Brazil and eastern Paraguay. 17
17. Body size small (mean head and body length ≤ 120 mm, maximum < 140 mm); dorsal pelage yellowish to orange brown or gray brown; interorbital region constricted anteriorly, with or without supraorbital beading; molars small to medium (mean upper molar row 4.7–4.8 mm, range: 4.5–5.0 mm) 18
- 17'. Body size larger (mean head and body length > 130 mm, maximum > 150 mm); dorsal pelage color ranges from gray-brown to yellowish or reddish brown; interorbital region from hourglass in shape with rounded sides (no beading) to constricted anteriorly with beaded edges; molars variable, small to moderately large 19
18. Tail pencil short, < 8 mm; skull small, mean occipitonasal length < 32 mm; supraorbital region rounded, without beading. *Rhipidomys tribei*
- 18'. Tail pencil medium to long, > 10 mm; skull moderate, mean occipitonasal length > 33 mm; supraorbital region with moderately developed beading
. *Rhipidomys ipukensis*
19. Interorbital region hourglass in shape (constricted centrally), with slight or no supraorbital beading (rather more prominent in Mato Grosso do Sul and Paraguay); braincase rounded and slightly inflated; incisive foramina bullet shaped. 20
- 19'. Interorbital region constricted anteriorly, with moderate to prominent supraorbital beading; braincase narrower and flatter, especially in older and larger specimens; incisive foramina elliptical to diamond shaped 21
20. Tail proportionally medium to long, mean 124% of head and body length (range: 107–148%); tail pencil short to moderate, ≤ 10 mm in length; dorsal pelage yellowish brown to dark reddish brown; braincase and interorbit broad; supraorbital edges with slight beading; molars medium size, mean toothrow length 5.2 mm (range: 4.9–5.4 mm) *Rhipidomys itoan*
- 20'. Tail proportionally short, mean 113% of head and body length (range: 96–133%, longer in some eastern populations); tail pencil short to moderate 5–15 mm (sometimes longer in southwestern population, i.e., Mato Grosso do Sul and Paraguay); dorsal pelage dull, reddish gray-brown; braincase average breadth; interorbit narrow; supraorbital region rounded, without beading, or beaded in southwestern population; molars medium to large, mean toothrow length 5.1 mm (range: 4.8–5.5 mm) in central and eastern Brazil, and 5.6 mm (range: 5.3–5.9 mm) in southwestern population
. *Rhipidomys macrurus*
21. Body size moderate to large (adult head and body length range: 120–190 mm); dorsal color yellowish-gray brown with conspicuous agouti effect; skull larger and more robust than in other eastern Brazilian species (mean occipitonasal length 35.5 mm, range: 33.6–36.7 mm); interorbit rather narrow, occiput broad; palatal bridge shorter than upper toothrow; bullae large for the genus; molars moderate in size (mean upper toothrow length 5.3 mm, range: 5.0–5.7 mm). *Rhipidomys cariri*
- 21'. Body size moderate (adult head and body length 105–160 mm); dorsal color gray-brown or more intense reddish brown; interorbit broad; palatal bridge often longer than upper toothrow; bullae moderate in size; average toothrow length smaller than in (21) 22

22. Dorsal color dull grayish brown; skull slightly smaller on average, mean occipitonasal length 33.3 mm (observed range: 28.2–36.9 mm); molars rather small, upper tooththrow rarely exceeding 5 mm (mean 4.8 mm, range: 4.5–5.1 mm); hypocone of upper M3 usually greatly reduced; karyotype with low FN=46–52

. *Rhipidomys emiliae*

22'. Dorsal color grayish brown to reddish brown; skull slightly larger on average, mean occipitonasal length 34.2 mm (observed range: 29.8–38.5 mm); molars a little larger than (22) (mean upper tooththrow length 5.0 mm, range: 4.6–5.5 mm); hypocone of upper M3 slightly reduced; karyotype with high FN=70–80

. *Rhipidomys mastacalis*

Although the species of *Rhipidomys* are treated alphabetically in the accounts that follow, their membership in the three sections recognized herein is as follows: (1) “fulviventer” section, including *R. caucensis*, *R. fulviventer*, *R. ochrogaster*, *R. similis*, *R. tenuicauda*, *R. venustus*, and *R. wetzeli*; (2) “leucodactylus” section, including *R. austrinus*, *R. cariri*, *R. couesi*, *R. emiliae*, *R. gardneri*, *R. itoan*, *R. ipukensis*, *R. latimanus*, *R. leucodactylus*, *R. macrurus*, *R. mastacalis*, *R. modicus*, *R. nitela*, *R. tribei*, and *R. venezuelae*; and (3) “macconnelli” section, including only *R. macconnelli*. The majority of these assignments follow Tribe (1996); of the five species described since then, only *R. ipukensis* was explicitly assigned by its authors (R. G. Rocha, Costa, and Costa 2011) to the “leucodactylus” section. Although Patton et al. (2000), Tribe (2005), and B. M. de A. Costa et al. (2011) made no such assignments for *R. gardneri*, *R. cariri*, *R. itoan*, or *R. tribei*, each of these species are best considered part of the same section based both on the diagnostic characters mentioned herein and on their phylogenetic linkage to other species in that complex. It remains for future analyses of morphological or molecular characters, or both, to determine whether these sections reflect true phylogenetic relationships.

Rhipidomys austrinus Thomas, 1921

Southern Andean *Rhipidomys*

SYNONYMS:

Rhipidomys austrinus Thomas, 1921d:183; type locality “Sierra de Santa Barbara, S.E. Jujuy [. . .] Sunchal, 1200 m,” Argentina.

Rhipidomys collinus Thomas, 1925b:578; type locality “Sierra Santa Rosa, 1000 m,” near Itaú, Tarija, Bolivia.

Rhipidomys leucodactylus austrinus: Cabrera, 1961:420; name combination.

Rhipidomys leucodactylus collinus: Cabrera, 1961:421; name combination.

Rhipidomys auritus M. M. Díaz, Braun, Mares, and Barquez, 1997:8; incorrect subsequent spelling of *Rhipidomys austrinus* Thomas.

DESCRIPTION: Size moderate to large (head and body length up to 170 mm) with soft and dense grayish-brown to bright orange-brown agouti dorsal pelage and sharp lateral transition line; ventral pelage also soft with creamy white tips and medium to dark gray hair bases. Hindfeet medium to large (28–33 mm in length), broad, with distinctly outlined dark patch extending to bases of digits II to V (less distinct and more extensive in northwestern samples). Tail long (110–135% of head and body length), medium to dark brown, with short hairs on shaft and short to medium terminal pencil. Ears large and oval. Skull moderate in size and robustness, with short, deep rostrum that does not taper greatly; nasals narrow sharply behind tips, then taper gently to their posterior ends; interorbital region narrow, either hourglass in shape with squared edges or waisted anteriorly with slightly raised supraorbital ridges; braincase rather flattened or only very slightly inflated; auditory bullae prominent; carotid circulation pattern derived (small stapedial foramen, no squamosal-alisphenoid groove, no sphenofrontal foramen); molars generally large compared with skull length, with maxillary tooththrow length ranging from 5.3–6.3 mm. See Massoia (1989) for further details of skull, and Carrizo and Díaz (2011) for comparison of postcranial skeleton with that of *Graomys griseoflavus*.

DISTRIBUTION: *Rhipidomys austrinus* occurs in the eastern Andean foothills and valleys and adjacent forested plains at elevations from 360 to 2,000 m, from southern Salta province, Argentina, northward to Santa Cruz department, Bolivia; farther northwest in La Paz department it has been found in the same valley system as *R. gardneri*, but at higher elevations (1,500 to 1,770 m).

SELECTED LOCALITIES (Map 308): ARGENTINA: Jujuy, Cerro Calilegua (Olrog 1979); Salta, Aguaray (Ojeda and Mares 1989), Anta, Parque Nacional El Rey (Jayat, Ortiz, Teta et al. 2006), Río de las Conchas, 5.7 km W of Metán (Carrizo and Díaz 2011). BOLIVIA: Chuquisaca, Cerro Bufete (Emmons 1997b), Porvenir (AMNH 262259); La Paz, Pitiguaya (AMNH 72632); Santa Cruz, Ingenio Mora, 7 km E and 3 km N (AMNH 247782), Río Ariruma, 7 km by road SE of Ariruma (AMNH 264199); Tarija, Cuyambuho, 4 km N by road, Fábrica de Papel, Río Sidras (UMMZ 155864).

SUBSPECIES: *Rhipidomys austrinus* is monotypic.

NATURAL HISTORY: *Rhipidomys austrinus* occurs in the densely forested valleys of the Yungas on the eastern Andean slopes. For example, the collecting locality at Villa Montes (8 km S, 10 km E), Tarija department, Bolivia, 467 m, was described on the specimen tag as “E. bank Río Pilcomayo. Habitat: dense forest 15 m height, dense understory of 6 m shrubs, 86% ground cover of forbs, grasses and bromeliads.” At the southern limit of its range

Map 308 Selected localities for *Rhipidomys austrinus* (●). Contour line = 2,000 m.

in Argentina, *R. austrinus* inhabits lowland, montane, and transitional forests; Ojeda and Mares (1989) provide general habitat information for that area. The two specimens from the Sierra Santa Bárbara, Sunchal, Jujuy, Argentina, were collected in tall nut trees (*nogales*), and the two from the Chimasi Yungas, La Paz, Bolivia, were found “in corn sack” (specimen tags).

REMARKS: This member of the “leucodactylus” section of *Rhipidomys* is the most southerly of the species that replace each other (with a certain amount of overlap) along the eastern Andean piedmont (from north to south: *R. couesi*, *R. leucodactylus*, *R. modicus*, *R. gardneri*, and *R. austrinus*). The name *R. couesi* has sometimes been misapplied to this species (e.g., Emmons and Feer 1990:184). Specimens from Pitiguaya are distinguished by their rather more slender, less robust skulls from those from Chijchipani, some 800 to 900 m lower in the same valley, here referred to *R. gardneri*. This distinction requires confirmation from molecular and karyotype evidence.

Rhipidomys cariri Tribe, 2005

Cairi Rhipidomys

SYNONYMS:

Rhipidomys cariri Tribe, 2005:137; type locality “BRAZIL—CEARÁ: Crato (07°14’S 39°23’W), Sítio Caiana.”

Rhipidomys cariri baturiteensis Tribe, 2005:141; type locality “BRAZIL—CEARÁ: Pacoti (04°13’S 38°56’W), Sítio Cebola.”

DESCRIPTION: Moderate to large bodied, with adult head and body length usually 130–160 mm (observed range: 120–190 mm). Tail length equals 110–140% of head and body length. Dorsal pelage yellowish gray brown, often somewhat grayer, sometimes redder, but always with conspicuous flecking from dark guard hairs and dark tips to body hairs; dorsal body hairs with mid-gray bases (about 62% of length), orange subterminal bands (about 29%), and dark tip (8–9%). Ventral pelage white or pale cream; some specimens with pale to mid-gray hair bases especially toward sides and occasionally across abdomen, as well as midline pectoral spot. Pelage texture slightly coarse and woolly, especially on ventral surface. Mystacial vibrissae noticeably long and coarse. Tail uniformly colored, varying from pale to rather dark; caudal hairs are dark and short (1–2 mm), especially along proximal half of tail, but may be longer at tip forming terminal tuft up to 15 mm in length. Hindfeet broad and relatively long compared with other species of similar size, averaging 27–30 mm (with claw). Dark patch on dorsal surface of metatarsals varies from narrow to broad, often poorly defined; unguis tufts usually about same length as claws. Ears seem larger than in other similar-sized Brazilian species, but average only a millimeter longer. Mystacial vibrissae long (>50 mm) and coarse; genal and supraorbital vibrissae sparse.

Skull large (occipitonasal length averages 35.5 mm) and robust with well-developed, straight supraorbital ridges diverging from front of interorbital region; rostrum moderately long and zygomatic plates broad, generally with shallow zygomatic notches visible in dorsal view; braincase large and angular rather than rounded, with broad occiput relative to greatest breadth across squamosals; lateral process of parietal rectangular; hamular process of squamosal long and almost horizontal; roughly elliptical incisive foramina terminate between anterior roots of M1s, while mesopterygoid fossa penetrates between posterior roots of M3s, making palatal bridge shorter than molar toothrow; sphenopalatine vacuities absent; auditory bullae relatively large for genus and slightly inflated; carotid circulation pattern derived (pattern 3 of Voss 1988), with small stapedial foramen, no translucent internal groove across the squamosal and alisphenoid, and no sphenofrontal foramen. Upper incisors robust and more opisthodont than in most other *Rhipidomys*; molars moderate in size but generally larger than in other eastern Brazilian species, with maxillary tooththrow averaging 5.1–5.5 mm in length; M1 and m1 both have well-defined anteromedian flexus/flexid; oblique paralophules present in M1–M3; and M3 not greatly reduced in size or occlusal structure.

DISTRIBUTION: *Rhipidomys cariri* occurs in mesic enclaves surrounded by semiarid caatinga thorn scrub in

northeastern Brazil, including the Serra de Baturité and Chapada do Araripe in Ceará state, the Parque Nacional do Catimbau in Pernambuco state, and the Morro do Chapéu in central Bahia state.

SELECTED LOCALITIES (Map 309): BRAZIL: Bahia, Morro do Chapéu (MNRJ 67779); Ceará, Sítio Caiana, Crato (type locality of *Rhipidomys cariri* Tribe), Pacoti, Serra de Baturité (type locality of *Rhipidomys cariri baturiteensis* Tribe); Pernambuco, Buíque, Parque Nacional do Catimbau (Geise, Paresque et al. 2010).

SUBSPECIES: See comment under Remarks.

NATURAL HISTORY: *Rhipidomys cariri* occurs within the semiarid Caatinga in isolated mesic forests (*brejos*), which are maintained by orographic rainfall (Andrade-Lima 1982). Individuals have been caught in forests, palms, and crops, particularly sugar cane and coffee. Two females from Pacoti each had four embryos in late July; six out of seven males captured between mid-August and early September had enlarged testes (Tribe 2005). The specimen from Buíque was captured in wet forest along a dry seasonal riverbed within the Caatinga.

REMARKS: Specimens of this recently described species were included in prior studies under a variety of different name combinations, such as *Rhipidomys cearanus* (Moojen 1943a:10), *Holochilus sciureus* (C. A. de Freitas 1957:131), and *Rhipidomys mastacalis* (Mares, Willig et al. 1981:84).

Rhipidomys cariri is a member of the “leucodactylus” section of the genus. Mitochondrial DNA studies using cytochrome-*b* (B. M. de A. Costa 2007; B. M. de A. Costa

et al. 2011) and cytochrome oxidase I (Thomazini 2009) sequences place specimens of *R. cariri* from Crato (southern Ceará) and Buíque (central Pernambuco) as the sister group to a clade containing certain specimens currently included in *R. macrurus* from central Bahia, eastern Tocantins, northern Goiás, and northern and eastern Minas Gerais states. In view of this and the expansion of *R. cariri* to include specimens from Pernambuco and Bahia, the subdivision of the species into the nominotypical subspecies and *R. cariri baturiteensis*, based on distinctions occurring solely within the state of Ceará (Tribe 2005), requires re-evaluation. Together, the above-mentioned clade and *R. cariri* form the sister clade to *R. macrurus* (*sensu stricto*) (B. M. de A. Costa 2007; Thomazini 2009; B. M. de A. Costa et al. 2011). The karyotype of *R. cariri* from Crato (type locality) and Buíque is $2n=44$, FN=50 (Thomazini 2009; Geise, Paresque et al. 2010), whereas that of a specimen from Pacoti (type locality of *R. cariri baturiteensis*) is $2n=44$, FN=48 (M. J. de J. Silva et al. 2000a).

Rhipidomys caucensis J. A. Allen, 1913

Lesser Colombian *Rhipidomys*

SYNONYM:

Rhipidomys caucensis J. A. Allen, 1913c:601; type locality “[Cerro] Munchique (altitude 8225 feet), Western Andes, Cauca, Colombia.”

DESCRIPTION: Very small (about 100 mm in head and body length) with bright orange-brown dorsal pelage and ventral pelage with cream or pale orange hair tips over dark-gray bases. Tail longer than head and body (130 mm), medium to dark brown in color, with hairs lengthening over the distal 25% and terminating in moderately long pencil (10–15 mm). Ears very dark. Hindfeet short and proportionately narrower than in most other *Rhipidomys* species, with poorly defined dorsal dark patch that, nevertheless, contrasts sharply with pale digits. Skull with hourglass-shaped interorbit, very slight supraorbital ridges, globose braincase, and derived carotid circulation pattern (small stapedial foramen, no groove on the inner surface of the squamosal and alisphenoid, and no sphenofrontal foramen). Mandible with pronounced incisor root capsule. Molars small (maxillary toothrow length 3.8–4.3 mm), even in comparison with skull length; first two upper molars with strong oblique paralophules paralleling mesoloph; part of third upper molar posterior to hypoflexus greatly reduced in size.

DISTRIBUTION: *Rhipidomys caucensis* is known from middle to high elevations in the Western Cordillera of Colombia (departments of Antioquia, Valle and Cauca) and, disjunctly, on the eastern flanks of the Central Cordillera at the head of the Magdalena valley (department of Huila) and in the department of Caldas.

Map 309 Selected localities for *Rhipidomys cariri* (○), *Rhipidomys emiliae* (●), and *Rhipidomys ipukensis* (□).

SELECTED LOCALITIES (Map 310): COLOMBIA: Antioquia, Páramo Frontino (FMNH 71738); Caldas, Bosque de Florencia (Castaño et al. 2003); Cauca, Cerro Munchique (type locality of *Rhipidomys caucensis* J. A. Allen); Huila, San Antonio (FMNH 71736); Valle del Cauca, El Cairo, Cerro del Inglés (M. Alberico, in litt.).

SUBSPECIES: *Rhipidomys caucensis* is monotypic.

NATURAL HISTORY: Specimens of *R. caucensis* were taken at elevations of 2,800–3,500 m in Antioquia and at 2,540 m on the eastern and 1,830 m on the western slope of the Western Cordillera in Cauca; on the eastern slope of the Central Cordillera they were collected at 2,200–2,350 m in Huila and below 1,800 m in Caldas. These elevations generally correspond to cloud forest.

REMARKS: *Rhipidomys caucensis* is placed in the “fulviventer” section of the genus on the basis of cranial and pelage characters, despite its derived carotid circulation pattern. Apart from this and its usually shorter tail, it is morphologically similar to *R. wetzeli* to the extent that in a cladistic analysis of thomatomyine species based on morphological characters, which included seven *Rhipidomys* species, these were the only two of the seven that formed a clade to the exclusion of the others (Pacheco 2003). In both Cauca and Huila, *R. caucensis* occurs sympatrically with the larger *R. similis* at the same elevations but occupying higher elevations than *R. latimanus*.

Map 310 Selected localities for *Rhipidomys caucensis* (●). Contour interval = 2,000 m.

Rhipidomys couesi (J. A. Allen and Chapman, 1893)

Coues's Rhipidomys

SYNONYMS:

Tylomys couesi J. A. Allen and Chapman, 1893:211; type locality “Princetown [i.e., Princes Town], Trinidad,” further restricted to “a point twelve miles north of the southern coast and seven miles southeast of Princetown” (J. A. Allen and Chapman 1893:203).

Rhipidomys couesi: J. A. Allen and Chapman, 1897a:18; first use of current name combination.

Rhipidomys couesii Rendall, 1897:343; incorrect subsequent spelling of *couesi* J. A. Allen and Chapman.

Rhipidomys venezuelae cumananus Thomas, 1900c:271; type locality “Ipure, altitude 700 m,” Sucre, Venezuela.

Rhipidomys sclateri couesi: Cabrera, 1961:42; name combination.

R[hipidomys]. sclateri cousei Furman and Tipton, 1961:192; incorrect subsequent spelling of *couesi* J. A. Allen and Chapman.

DESCRIPTION: Large to very large (head and body length 150–210 mm) with yellowish to reddish brown agouti dorsal pelage, conspicuously flecked with dark brown or black guard hairs; ventral pelage white or creamy yellow, sometimes with rarely noticeable pale to medium gray hair bases; pelage moderately coarse and short. Tail relatively short (100–120% of head and body length), unicolorous, with rather large, dark scales and dark brown to reddish-brown hairs; well haired distally, terminating in pencil of hairs up to 20 mm in length. Hindfeet long (29–32 mm with claw) and broad, with distinctly or indistinctly outlined dark patch that extends at least to bases of digits II to IV. Skull large, robust, and rather narrow for genus, with flattened profile such that interparietal nearly horizontal, especially in older specimens; supraorbital ridges well developed, usually straight and weakly divergent posteriorly; braincase narrow, not inflated, with squamosals oriented dorsolaterally rather than laterally; auditory bullae small; carotid circulation pattern is derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Maxillary tooththrow long for genus, ranging typically from 5.6–6.1 mm, but relatively short in comparison to skull length.

DISTRIBUTION: *Rhipidomys couesi* is known from the island of Trinidad, the Venezuelan island of Margarita (Nueva Esparta state), the coastal region of Sucre, Anzoátegui, and Vargas states up to approximately 1,000 m elevation, the southeast-facing lower slopes of the Mérida Andes in Barinas state, and the foothills of the Eastern Cordillera near Villavicencio, Meta, Colombia. By extrapolation, it can be expected to occur throughout the narrow belt of lowland moist forest that borders the llanos along the southern and eastern foothills of the Venezuelan coastal

range, Mérida Andes and Eastern Cordillera from Sucre in northeastern Venezuela to Meta in Colombia. From this point southward, where the Amazon-Orinoco forests reach the Andes, this species is replaced by the larger *R. leucodactylus*.

SELECTED LOCALITIES (Map 311): COLOMBIA: Meta, Villavicencio (AMNH 75239). TRINIDAD AND TOBAGO: Trinidad, Cumaca (AMNH 235071), 7 mi SE of Princes Town (AMNH 5956/4685). VENEZUELA: Barinas, Altamira (USNM 442302), Reserva Forestal de Ticoporo (Ochoa et al. 1988); Nueva Esparta, Isla Margarita, Cerro Matasiete, 3 km NE of La Asunción (USNM 406100); Sucre, Ensenada Cauranta, 7 km N and 5 km E of Guiria (USNM 409936), Ipure, near Cumaná (type locality of *Rhipidomys venezuelae cumananus* Thomas); Vargas: Los canales de Naiguatá, P. N. El Ávila (Rivas and Salcedo 2006).

SUBSPECIES: *Rhipidomys couesi* is monotypic.

NATURAL HISTORY: The monograph by Montserin (1937) includes data on reproduction, life history, nesting habits, and diet of *R. couesi* in Trinidad, as well as its status as a pest of cacao and the control measures taken against it. The species was found to be relatively common in plantations but difficult to trap. Trap-shyness may mean that abundance estimates based on trapping success are inadequate. Other reports (Urich 1911; Everard and Tikasingh 1973b) suggest it is a common arboreal species in Trinidad plantations and forests. In Barinas state, Venezuela, *R. couesi* was captured in dense rainforest (Ochoa et al. 1988), while in Sucre and Nueva Esparta it was found mainly in evergreen forest or plantations, and in one case inside a house (Handley 1976). For parasites of the species in Venezuela, see Brennan and Reed (1974a), Furman (1972a), Furman and Tipton (1961), P. T. Johnson (1972), and Saunders (1975).

REMARKS: *Rhipidomys couesi* is a large-bodied species in the “leucodactylus” section of the genus. Specimens from the islands of Trinidad and Margarita are larger on average than those from the Venezuelan mainland. If on the basis of new data the mainland form is demonstrated to be sufficiently distinct, the name *cumananus* Thomas is available. At the southwestern end of the range of the species, Colombian specimens have rather more slender skulls. This character, together with their shorter molar row, helps to distinguish skulls of *R. couesi* from the generally more robust skulls of *R. leucodactylus*. Aguilera et al. (1994) described the karyotype of *R. couesi* from Anzoátegui, Venezuela (under the name “*R. sclateri*”; note that *R. sclateri* is here considered a junior synonym of *R. leucodactylus*) as $2n=44$, $FN=48$.

Subfossil material from Tobago (off the northeast coast of Trinidad) identified by Eshelman and Morgan (1985)

Map 311 Selected localities for *Rhipidomys couesi* (●). Contour line = 2,000 m.

as *Rhipidomys leucodactylus* likely represents *R. couesi* instead. Fossilized teeth and skull fragments from the island of Bonaire (Caribbean Netherlands), some 90 km from the Venezuelan coast, which were identified by Hooijer (1959) as “*Thomasomys spec.*” and compared by Tribe (1996) with *Rhipidomys couesi*, have recently been described as the oryzomyine species *Agathaeromys donovani* and *A. praeuniversitatis* (Zijlstra et al. 2010).

Rhipidomys emiliae (J. A. Allen, 1916)

Sneathlage's Rhipidomys

SYNONYMS:

Oecomys emiliae J. A. Allen, 1916c:525; type locality “Rio Mojú, Pará, Brazil.”

Oryzomys [(*Oecomys*)] *emiliae*: Ellerman, 1941:358; name combination.

Rhipidomys emiliae: Goodwin, 1953:306; first use of current name combination.

DESCRIPTION: Medium sized (head and body length 120–150 mm) with dull grayish-brown to brighter orange-brown agouti dorsal pelage and cream or white ventral fur. Tail moderately long, medium to dark brown, moderately well haired, and ends in medium-length pencil (10–15 mm). Ears large, brown, and bare; some specimens have pale postauricular patch. Hindfeet moderate in length (25–28 mm), broad, with relatively long toes, and with narrow or broad dorsal dark patch, usually ill defined, leaving sides of feet and toes pale. Skull with moderately developed supraorbital ridges diverging posteriorly from point well forward, resulting in broad interorbital region; braincase narrow and somewhat angular, especially in older specimens, and moderately flattened; palatal bridge in adults often longer than molar row; auditory bullae small; carotid circulation pattern derived (small stapedial foramen, no internal groove on squamosal and alisphenoid, no sphenoid

frontal foramen); molars small, particularly in comparison with skull length, maxillary toothrow not exceeding 5 mm in length.

DISTRIBUTION: *Rhipidomys emiliae* occurs in the eastern Brazilian Amazon Basin, south of the Amazon River, from the west bank of the Rio Tapajós eastward to the state of Maranhão and southward to southern Mato Grosso state. It has not been found east of the Rio Araguaia in the states of Tocantins or Goiás.

SELECTED LOCALITIES (Map 309): BRAZIL: Maranhão, Alto da Alegria (BM 25.5.21.8); Mato Grosso, Chapada dos Guimarães, Casa de Pedra (MNRJ 24914), Estação Ecológica Serra das Araras (Santos-Filho et al. 2012), Fazenda Noirumbá, 34 km NW of Ribeirão Cascalheira (UFMG 2953), Fazenda São Luis, 30 km N of Barra do Garças (UFMG 2946), Vila Rica (MZUSP [APC 286]); Pará, Aramanaí, Rio Tapajós (AMNH 94810), Belém, Utinga (MNRJ 24195), Melgaço, Floresta Nacional de Caxiuaña (MPEG 34000), Parauapebas, Fazenda São Luiz (B. M. de A. Costa et al. 2011), Parque Nacional da Amazônia (T. K. George et al. 1988).

SUBSPECIES: *Rhipidomys emiliae* is monotypic.

NATURAL HISTORY: Emilie Snethlage, who collected the holotype of *Rhipidomys emiliae*, noted on the specimen tag that this rat was often found in houses and plantations. Pine (1973a) considered the species somewhat uncommon at Utinga, Belém. In the Serra do Roncador, Mato Grosso, one specimen was caught in a house, two in gallery forest, and one at the cerrado-dry forest ecotone; Fry (1970) provided details of the Roncador study area.

REMARKS: *Rhipidomys emiliae* is a member of the “leucodactylus” section of the genus. Specimens from south of the Amazon between the Tapajós and Tocantins rivers that were tentatively included by Tribe (1996) in *R. nitela* are here reallocated to *R. emiliae* on the basis of their karyotype ($2n=44$, FN=52: M. J. de J. Silva and Yonenaga-Yassuda 1999; Andrades-Miranda, Oliveira et al. 2002 [as “*R. leucodactylus* cytotype 1” from locality 5, Caxiuanã]; $2n=44$, FN=46: M. S. Mattevi, pers. comm.) and molecular data (L. P. Costa 2003; R. G. Rocha, Ferreira, Costa et al. 2011; B. M. de A. Costa et al. 2011). They include the “*R. nitela*” sequenced by M. F. Smith and Patton (1999) and by L. P. Costa (2003). Specimens from this area are morphologically intermediate between *R. nitela* from north of the Amazon and *R. emiliae* from the Belém region. The size difference in specimens from Serra do Roncador considered by Tribe (1996) to represent two species (*R. nitela* and *R. emiliae*) is here attributed instead to individual variation within the latter species. Pine et al. (1970; also Pine 1973a) referred to specimens of this species from Serra do Roncador, Mato Grosso, and the Belém region of the eastern Amazon as *R. mastacalis*. Subfossil

Rhipidomys material from the Serra dos Carajás, south-eastern Pará state, dated to between 2,000 and 8,000 ybp (Toledo et al. 1999), may be referable to *R. emiliae*.

In phylogeographic analyses based on the mtDNA cytochrome-*b* gene, *Rhipidomys emiliae* is most closely related to *R. ipukensis*, then *R. mastacalis*, followed by *R. gardneri*, then more distantly to a clade comprising *R. leucodactylus*, *R. itoan*, and *R. tribei* (= *Rhipidomys* “sp. nov.” in L. P. Costa 2003), and more remotely still to *R. macrurus*, which is geographically its neighbor (M. F. Smith and Patton 1999 and L. P. Costa 2003 [both reported as “*R. nitela*”]; R. G. Rocha, Ferreira, Costa et al. 2011; B. M. de A. Costa et al. 2011). The observation by R. G. Rocha, Ferreira, Costa et al. (2011) that the Rio Araguaia appears to separate *R. emiliae* in the states of Pará and Mato Grosso (to the west of the river) from *R. ipukensis* in the state of Tocantins (to the east) suggests that the identification of all these specimens needs confirmation by a phylogenetic analysis that includes material from the type locality of *R. emiliae* at Rio Moju, just south of Belém, which lies to the east of the Rio Tocantins below its confluence with the Rio Araguaia. The situation is further complicated by reports that specimens collected even farther east in Pará (Ourém) and Maranhão (Bacabal), which are here provisionally referred to *R. emiliae*, have karyotypes with FN=64 (C. R. Bonvicino, pers. comm.), substantially different from the FN=46 and 52 mentioned above for this species.

Rhipidomys fulviventer Thomas, 1896

Tawny-bellied *Rhipidomys*

SYNONYMS:

Rhipidomys fulviventer Thomas, 1896:304; type locality “Agua Dulce, W. Cundinamarca, Colombia.”

Rhipidomys fulviventer elatturus Osgood, 1914a:140; type locality “Paramo de Tama, head of Tachira River, Venezuela. Alt. 7,000 ft.”

[*Rhipidomys*] *fulviventris* Tate, 1939:195; incorrect subsequent spelling of *fulviventer* Thomas.

Rhipidomys fulviventer fulviventer: Gyldenstolpe, 1932:48; name combination.

Rhipidomys latimanus elatturus: Cabrera, 1961:419; name combination.

DESCRIPTION (amended from Tribe 1996, including his *R. f. fulviventer* and *R. f. elatturus* accounts): Small to medium sized with long, soft, and sleek fur; dorsal pelage mid-brown, often with olive tint, while gray-based ventral hairs have pale tips usually with orange suffusion throughout. Tail longer than head and body and generally medium to dark with slightly paler proximal area on ventral surface. Ears darker than the dorsal pelage. Hindfeet relatively narrow for genus, with dark metatarsal patch often indistinctly delineated. Skull with weakly developed

supraorbital ridges and thus with rounded, hourglass-shaped interorbital region; braincase rounded, with poorly developed, curved parietal ridges and broad occiput; incisive foramina and mesopterygoid fossa typically narrow and almost parallel sided; posterior medial spine of palate small or absent, resulting in a posterior edge; parapterygoid fossae usually fenestrated; small sphenopalatine fissures usually present; carotid circulatory pattern primitive (large stapedia foramen, internal groove across squamosal and alisphenoid, and sphenofrontal foramen). Mandible with prominent incisor root capsule. Molars fairly large in comparison with skull length (maxillary tooththrow length mostly 4.4–4.8 mm).

DISTRIBUTION: *Rhipidomys fulviventor* is known from elevations between 1,800 and 3,100 m in the Eastern Cordillera of the Colombian Andes, from Norte de Santander (and the Páramo de Tamá just across the Venezuelan border) southward to Cundinamarca and the Distrito Especial of Bogotá. In addition, a single specimen from the Serranía de la Macarena, an isolated tableland situated some 40 km east of the Eastern Cordillera in the department of Meta, is provisionally referred to this species.

SELECTED LOCALITIES (Map 312): **COLOMBIA:** Boyacá, Paipa, Parque Natural Ranchería (Vianchá-Sánchez et al. 2012); Cundinamarca, Guasca, Río Balcones (FMNH 71731), La Aguadita (BM 15.1.3.3); Meta, Serranía de la Macarena (AMNH 142140); Santander, Cachirí (CM 3192). **VENEZUELA:** Táchira, Páramo de Tamá (FMNH 18691).

SUBSPECIES: See comments under Remarks.

NATURAL HISTORY (information from Montenegro-Díaz et al. 1991, except where noted): *Rhipidomys fulviventor* (referred to as “*Rhipidomys latimanus*”) inhabits relatively undisturbed cloud forest and the forest-páramo ecotone in the Eastern Cordillera of the Andes. The home range was found to be 0.2 ha in forest 25 m in height. Reproductive activity was fairly constant throughout the study period (February to August), two females having two embryos each (one Venezuelan specimen had three; USNM specimen tag); gestation lasted roughly one month. The content of five stomachs was 68% fruit and seeds, 26% leaves and other plant matter, and 6% insects. See also López-Arévalo et al. (1993). The individual from La Macarena was taken at 1,140 m (specimen tag). For parasites from the Venezuelan specimens, see Brennan and Reed (1974a), Furman (1972a), E. K. Jones et al. (1972), and Tipton and Machado Allison (1972).

REMARKS: This species belongs to the “fulviventor” section of the genus. Specimens representing the northern known population are smaller on average than those from Cundinamarca, although examined sample sizes are very

small. If the northern population is found to be genetically distinct and to warrant species status, the name *elatturus* Osgood is available. Its range is separated by the Táchira Depression (roughly 1,000 m elevation) from that of the next member of the “fulviventor” section, the moderately large *Rhipidomys venustus* in the Mérida Andes of Venezuela. Southward, lower elevations in the Eastern Cordillera separate *R. fulviventor* from *R. similis*, which also belongs to the same section. The single known specimen from the Serranía de la Macarena is provisionally referred to *Rhipidomys fulviventor* although it is a little larger and differs slightly in skull morphology. Tribe (1996) treated all these forms as subspecies of *Rhipidomys fulviventor*; here, however, *tenuicauda*, *venustus*, *fulviventor*, and *similis* are considered sufficiently isolated and morphologically distinct to warrant separate species status. See also the remarks under *Rhipidomys tenuicauda*. Cabrera (1961) regarded *Rhipidomys fulviventor* and *R. venustus* as subspecies of *R. latimanus*, but Handley (1976) recognized that they are clearly distinct from the latter species. Two specimens resembling *Rhipidomys fulviventor* have recently been collected in Bongará, Amazonas department, Peru, 1,000 km south of La Macarena (C. F. Jiménez and Pacheco 2012). They are not included in the species range given here pending their formal identification.

Map 312 Selected localities for *Rhipidomys fulviventor* (●) and *Rhipidomys similis* (○). Contour line = 2,000 m.

Rhipidomys gardneri Patton, da Silva,
and Malcolm, 2000

Gardner's *Rhipidomys*

SYNONYM:

Rhipidomys gardneri Patton, da Silva, and Malcolm, 2000: 165; type locality “Reserva Cusco Amazónico, left (= north) bank of the Río Madre de Dios, 14 km east of Puerto Maldonado, Departamento de Madre de Dios, Perú, elevation about 200 m (12°33'S, 69°03'W).”

DESCRIPTION: Large-bodied (head and body length 150–190 mm) with relatively short and coarse dorsal fur, gray to orange-brown agouti in color; ventral hairs fulvous to yellow, with gray-based hairs limited to midline of throat and chest. Tail proportionately short to medium in length (110–140% of head and body length), uniformly brown in color, clothed with short hairs, and terminating in short pencil that does not exceed 6 mm. Ears moderate in size and dark brown in color. Hindfeet long (33–34 mm) but broad, with narrow dark dorsal patch limited to metatarsals (not extending onto digits). Skull robust with short, tapering rostrum, deep zygomatic notches when viewed from above, and moderately developed supraorbital ridges that extend imperceptibly onto elongated braincase; mesopterygoid fossa long and narrow, with scalloped anterior border with distinct, posteriorly projecting median spine; auditory bullae very small; carotid circulatory pattern derived (small stapedial foramen, no internal groove on squamosal or alisphenoid, no sphenofrontal foramen). Maxillary toothrow long (>6 mm, with few exceptions), but average in comparison to length of skull.

DISTRIBUTION: *Rhipidomys gardneri* occurs in the upper reaches of the Juruá, Ucayali, Madre de Dios, and Beni drainages (western Brazil, eastern Peru and northeastern Bolivia) from below 200 m to above 2,500 m elevation.

SELECTED LOCALITIES (Map 313): **BOLIVIA:** La Paz, Chijchipani (AMNH 262991). **BRAZIL:** Acre, left bank of the Rio Juruá opposite Igarapé Porongaba (Patton et al. 2000). **PERU:** Cusco, 2 km SW of Tangoshiari (B. M. de A. Costa 2007), Machu Picchu, San Miguel Bridge (USNM 194493), Centro de Investigación Wayqecha (C. E. Medina et al. 2012), Hacienda Cadena (FMNH 68647); Loreto, San Jerónimo, W bank Río Ucayali (BM 28.5.2.180); Madre de Dios, Albergue Cusco Amazónico, Río Madre de Dios, ca. 12 km E of Puerto Maldonado (type locality of *Rhipidomys gardneri* Patton, da Silva, and Malcolm); Puno, La Pampa (MCZ 39498).

SUBSPECIES: *Rhipidomys gardneri* is monotypic.

NATURAL HISTORY: Terborgh et al. (1984) and Woodman et al. (1995) provided ecological information on this species at Cocha Cashu and Cuzco Amazónico, Peru, and Patton et al. (2000) described the capture site on the upper Juruá. Specimens herein referred to *Rhipidomys*

gardneri from San Jerónimo, southern Loreto, Peru, were captured in houses or thatched roofs. Stomach analysis of a specimen from mature forest at the San Martín gas well site in Ucayali, Peru, indicated that it had been feeding on insect larvae living in bamboo stems. Females may become pregnant while still lactating: one individual (USNM 559408, Pakitza, Río Manu, Peru), captured when nursing a litter of three young in a desk drawer, was pregnant with four 20-mm embryos.

REMARKS: *Rhipidomys gardneri* belongs to the “leucodactylus” section of the genus. Tribe (1996) placed the future holotype and a paratype of *R. gardneri* within *R. leucodactylus* on the grounds that there were morphological intermediates between “typical” *R. leucodactylus* and these slightly smaller specimens with less hairy tails from southeastern Peru. Karyotype and molecular data confirmed the species status of this form (Patton et al. 2000). Some morphologically intermediate specimens from the Ucayali-Urubamba and Madre de Dios drainages (also previously included in *R. leucodactylus* by Tribe, 1996) are provisionally referred to *R. gardneri* in the absence of diagnostic molecular or karyotype data, despite their slightly larger molars and, in some cases, rather hairier tails. Likewise, the *Rhipidomys* specimens from Chijchipani, at 850 m elevation in the upper Beni drainage of La Paz, Bolivia (“*Rhipidomys* sp. 1” in Tribe 1996), are here tentatively included in *R. gardneri* pending further analysis. Molecular data link *R. gardneri* with the eastern

Map 313 Selected localities for *Rhipidomys gardneri* (●). Contour line = 2,000 m.

Brazilian species *R. mastacalis* and *R. emiliae* (reported as *R. nitela*), rather than with *R. leucodactylus* (L. P. Costa 2003). It should be noted that GenBank sequence U03550 (MVZ 196059), sometimes cited as *R. leucodactylus*, in fact corresponds to *R. gardneri*.

Rhipidomys ipukensis R. G. Rocha, Costa, and Costa, 2011

Ipuca Rhipidomys

SYNONYM:

Rhipidomys ipukensis R. G. Rocha, Costa, and Costa, 2011: 24; type locality "Fazenda Lago Verde, municipality of Lagoa da Confusão, state of Tocantins, Brazil, 10°52'09.1"S, 49°41'52.1"W, elevation 180 m."

DESCRIPTION: Small to medium sized with adult head and body length averaging 121 mm (observed range: 99–141 mm), tail longer than head and body (114–124%), and short and coarse dorsal pelage. Overall coloration yellowish gray brown to orangish brown, with dorsal hairs gray-based with yellowish to orangish tips mixed with completely black guard hairs; sides of body lighter than dorsum and with well-defined transition to the venter; ventral pelage woolly, varying from whitish to cream in color (some specimens have dark cream ventral midline). Juveniles completely light gray dorsally and white ventrally. Tail completely dark gray and covered with short hairs along anterior half, becoming more elongate along posterior half, ending in medium pencil 10–15 mm in length. Hindfeet broad, with dark dorsal metatarsal markings that vary from narrow and flanked with white fur to broad with poorly defined lateral limits. Ungual hairs white, completely covering but not surpassing claw tips. Ears large (20–23 mm), brown, often with small cream patch of fur at base.

Skull varies from small and more delicate in younger specimens to medium sized and more robust in older ones (occipitonasal length of adults averages 33.7 mm, range: 29.9–36.2 mm); rostrum moderately long (average 9.6 mm); zygomatic notches relatively shallow but visible in dorsal view; zygomatic plates broad with their posterior margins anterior to M1 alveoli; alisphenoid struts present and subsquamosal fenestrae small, almost occluded by hamular process of squamosal; carotid circulation pattern 3 (of Voss 1988), with small stapedia foramen, no squamosal-alisphenoid groove, and no sphenofrontal foramen; palatal bridge short and wide; incisive foramina bullet-shaped with parallel margins extending posteriorly to anterior edge of M1s; anterior margin of mesopterygoid fossa with median spine and extending to midline of M3s; posterior palatal pits simple and small on each side of mesopterygoid fossa; sphenopalatine vacuities either present as small slits or absent, such that mesopterygoid roof completely ossified; auditory bullae small.

Upper incisors opisthodont; molars rather small (maxillary toothrow length 4.5–5.0 mm); M1 with labial accessory root; m1 with both labial and lingual accessory roots; anterocones/conoids of upper and lower molars divided into two conules/conulids by anteromedian flexus(id); relatively small, oblique paralophules present in all upper molars; posterior part of M3 reduced. Mental foramen opens laterally on mandibular body; capsular process well developed as conspicuous swelling.

DISTRIBUTION: This species is known from three localities in Tocantins state, Brazil. It is believed to be endemic to the Araguaia-Tocantins basin east of the Rio Araguaia in the Cerrado of central Brazil.

SELECTED LOCALITIES (Map 309): BRAZIL: Tocantins, Lagoa da Confusão, Fazenda Lago Verde (type locality of *Rhipidomys ipukensis* R. G. Rocha, Costa, and Costa), Pium, Parque Estadual do Cantão (MNRJ 73744), Rio Santa Teresa, 20 km NW of Peixe (UFMG 2952).

SUBSPECIES: *Rhipidomys ipukensis* is monotypic.

NATURAL HISTORY: Little is known of the ecology or other aspects of the population biology of this species. Specimens were captured primarily in *ipucas*, seasonally flooded forest fragments, in traps placed both on the ground and in the understory, including pipe traps used as arboreal refuges for tree frogs. Adult males had scrotal testes, and adult females were lactating when captured in the month of September (R. G. Rocha, Ferreira, Costa et al. 2011).

REMARKS: *Rhipidomys ipukensis* is a member of the "leucodactylus" section of the genus. It has a close sister-relationship with *R. emiliae*, according to a phylogenetic analysis of mtDNA cytochrome-*b* sequences, with the two species differing by an average of 5.1%; together they form a clade with *R. mastacalis* from the Atlantic Forest (R. G. Rocha, Ferreira, Costa et al. 2011). The karyotype of *R. ipukensis* is as yet unknown. Should *Rhipidomys* specimens from northern Goiás state here provisionally referred to *R. mastacalis* because of their high FN=76 and 80 (Andrades-Miranda, Oliveira et al. 2002) prove instead to belong within *R. ipukensis*, it will not only extend the distribution of the species but also indicate that high fundamental numbers probably arose independently more than once in this group, given the low-FN karyotype of *R. emiliae*, the closest relation of *R. ipukensis*.

R. G. Rocha, Ferreira, Costa et al. (2011) noted that *R. ipukensis* was found to the east of the Rio Araguaia whereas *R. emiliae* was found to the west. Stability of the name *ipukensis* and the identity of the specimens found to the west of the river may depend on phylogenetic comparison with material from the type locality of *R. emiliae* at Rio Moju, Pará, which lies to the east of the Araguaia-Tocantins.

Rhipidomys itoan B. M. de A. Costa, Geise, Pereira, and L. P. Costa, 2011

Sky *Rhipidomys*

SYNONYM:

Rhipidomys itoan B. M. de A. Costa, Geise, Pereira, and L. P. Costa, 2011:950; type locality “Garrafão (hillside of the Iconha River in Parque Nacional da Serra dos Órgãos), Guapimirim municipality, state of Rio de Janeiro, Brazil, 22°28′28″S, 42°59′86″W [*sic*], 700 m.”

DESCRIPTION: Medium sized (mean head and body length=136.4 mm) with tail varying from 107–148% of head and body length, mean 124% ($n=18$). Dorsal pelage reddish or yellowish brown to dark reddish brown, with short (ca. 8 mm) body hairs and longer (ca. 16 mm) guard hairs; ventral pelage plain white or white with small areas of light gray at sides of abdomen, sometimes extending to forelimbs, with or without gray spots in pectoral region; dorsal pelage extends for short distance onto tail base; tail unicolored along length, covered by short, brown to black hairs that increase in length distally and terminate in short pencil extending up to 10 mm beyond its tip. Ears small to medium, ranging from 12–22 mm in length, externally brown in color with brown or whitish hairs internally. Hindfeet covered dorsolaterally with white hairs that extend onto toes; mid-dorsal surface of toes with patch of light brown or gray hairs.

Skull small to moderate in size (mean condyloincisive length 31.4 mm); in comparison with other species in eastern and southeastern Brazil, similar in size to *Rhipidomys macrurus* and *R. mastacalis*, and larger than *R. tribei*. Rostrum short and somewhat broad (mean length=10.6 mm, mean width=6.6 mm); lacrimal capsules slightly inflated; gnathic process present, nasal bones broad anteriorly but narrow posteriorly, and not contacting or extending posteriorly beyond maxillary-frontal sutures; anterior edges of zygomatic plates slightly rounded to rectangular but do not protrude anterior to maxillary roots of zygomatic arches; zygomatic notches narrow and quite deep; dorsal projections of lacrimal bones comparatively small, narrow, and slightly prominent; interorbital region broad with rounded, hourglass-shaped edges and slight supraorbital crests; braincase broader in relation to skull length than in other species occurring south of Amazon River; hamular process of squamosal divides postglenoid foramen and subsquamosal fenestra unequally; carotid circulation derived (pattern 3 of Voss 1988), with small stapedia foramen, no translucent internal groove across squamosal and alisphenoid, and no sphenofrontal foramen; thin alisphenoid strut present, as are oval and buccinator-masticatory foramina; incisive foramina long, bullet shaped, with parallel margins that converge anteriorly and also slightly posteriorly, especially in specimens from state of São Paulo, ex-

tending to plane between M1s; mesopterygoid fossa long, with small postpalatal spine at anterior margin, extending anteriorly to posterior margins of M3 alveoli; sphenopalatine vacuities either absent or greatly reduced; triangular parapterygoid plates deeply excavated; auditory bullae small but inflated.

Upper incisors slightly opisthodont. Anteroflexus and anteromedian flexus in M1 usually long and deep, demarcating anterolabial and anterolingual conules; protoflexus and hypoflexus of M1 and M2 moderately long; paraflexus and metaflexus long and sharply angled, sometimes bifurcated at inner ends; both medial and labial fossettes frequently present in M2.

DISTRIBUTION: *Rhipidomys itoan* is found from the Serra da Mantiqueira southward to the coast in the Brazilian states of Rio de Janeiro and eastern São Paulo, including in the Serra dos Órgãos and Serra do Mar, and on inshore islands such as Ilha Grande and Ilha da Marambaia. Its range extends to the Serra de Paranapiacaba in southern São Paulo state.

SELECTED LOCALITIES (Map 314): BRAZIL: Rio de Janeiro, Garrafão (type locality of *Rhipidomys itoan* B. M. de A. Costa, Geise, Pereira, and L. P. Costa), Parque Estadual dos Três Picos (HGB 581), Praia Vermelha, Ilha Grande (MNRJ 24389), Parque Nacional do Itatiaia (HGB-CFVC 5); São Paulo, Estação Biológica de Boracéia (MZUSP 10816), Parque Estadual Intervales, Barra Grande (E. M. Vieira and Monteiro-Filho 2003 [EM 1130]), Pilar to Sul (B. M. de A. Costa et al. 2011 [CIT 1278]), São Sebastião (MZUSP 880).

SUBSPECIES: *Rhipidomys itoan* is monotypic.

NATURAL HISTORY: Specimens have been trapped in dense rain forest or coastal forests of the Serra do Mar range, where continuous cover may be punctuated with streams and rocky outcrops, occasionally with an open understory, including that caused by human disturbance (B. M. de A. Costa et al. 2011). In a capture-mark-recapture study at the type locality, 24 individuals of *Rhipidomys itoan* were captured a total of 61 times, always in trees, and remained on the grid for an average of 10 (± 6.73) months; the breeding period was August to December, in the early wet season (J. Macedo et al. 2007). Davis (1945a, 1947) provided life history notes on a sample from nearby Teresópolis (Rio de Janeiro state) and general ecological information on the habitat. Guitton et al. (1986), Martins-Hatano et al. (2002), and Neri-Bastos et al. (2004) investigated parasites on specimens from Rio de Janeiro and São Paulo states. A specimen from Parati in southwestern Rio de Janeiro state was infected with *Leishmania* (*Viannia*) (Soares et al. 1999).

REMARKS: With available taxon sampling, *R. itoan* and *R. tribei* form a sister-pair within the “leucodactylus”

Map 314 Selected localities for *Rhipidomys itoan* (●) and *Rhipidomys tribei* (○).

section of the genus, based on mtDNA cytochrome-*b* sequences. The two species are, however, quite divergent, with the average sequence difference 8.3% (B. M. de A. Costa et al. 2011). *Rhipidomys itoan* is the correct name for those specimens identified by R. G. Rocha, Ferreira, Costa et al. (2011) as “*R. sp. 2*” in their phylogenetic analysis of mtDNA sequences. Previously, specimens of *R. itoan* had frequently been referred to as “*R. mastacalis*” (e.g. Davis 1945a, 1947), “*R. cf./aff. macrurus*” (e.g. Tribe 1996; E. M. Vieira and Monteiro-Filho 2003) or “*Rhipidomys sp.*” (e.g. Zanchin, Langguth, and Mattevi 1992; Geise 1995; M. F. Smith and Patton 1999 [as “*Rhipidomys sp. 2*”]; L. P. Costa 2003).

The karyotype is $2n = 44$, with the number of autosomal arms varying from 48 to 50 due to polymorphism. The X chromosome is a large submetacentric, one of the largest of the complement; the Y chromosome is the smallest acrocentric. B. M. de A. Costa et al. (2011) also detailed the distribution of NORs within the complement.

Rhipidomys latimanus Tomes, 1860

Northwestern *Rhipidomys*

SYNONYMS:

Hesperomys. *latimanus* Tomes, 1860a:213; type locality not given, but “the greater portion of these [species] are believed to have been collected at Pallatanga, on the western slope of the Cordillera” (Tomes 1860a:211), Chimborazo province, Ecuador.

[*Hesperomys*] (*M[yoxomys]*.) *latimanus*: Tomes, 1861 [1862]:284; name combination.

Rhipidomys microtis Thomas, 1896:304; type locality “Saliña [for “Salina”] del Vatan [possibly near Quebrada Batán], Western Cundinamarca, Colombia.”

Rhipidomys pictor Thomas, 1904e:193; type locality “Rio Verde, [Pichincha,] N.W. Ecuador. Alt. 1000 m.”

Rhipidomys mollissimus J. A. Allen, 1912:78; type locality “Mira Flores [= Miraflores] (alt. 6200 ft.), west slope of Central Andes, near Palmira, Cauca [now Valle del Cauca], Colombia.”

Rhipidomys cocalensis J. A. Allen, 1912:79; type locality “Cocal, Cauca, Colombia, Altitude, 4000 feet.”

Rhipidomys quindianus J. A. Allen, 1913c:600; type locality “El Roble (altitude 7200 feet), Central Andes [Quindío department], Colombia.”

Rhipidomys scandens Goldman, 1913:8; type locality “near head of Rio Limon (altitude 5,000 feet), Mount Pirri [= Cerro Pirre], Eastern Panama.”

Rhipidomys latimanus latimanus: Cabrera, 1961:419; name combination.

Rhipidomys latimanus similis: Cabrera, 1961:419; part; not *Rhipidomys similis* J. A. Allen; attribution of *cocalensis*.

Rhipidomys latimanus microtis: Cabrera, 1961:419; name combination.

Rhipidomys latimanus mollissimus: Cabrera, 1961:419; name combination.

Rhipidomys latimanus pictor: Cabrera, 1961:419; name combination.

Rhipidomys. *scandens* Cuervo Díaz, Hernández Camacho, and Cadena, 1986:498; incorrect subsequent spelling of *scandens* Goldman.

DESCRIPTION (amended from Tribe 1996, for the nominotypical subspecies he recognized): Medium sized (head and body length typically 120–140 mm) with intensely pigmented orange or reddish-brown dorsal pelage, finely flecked with dark brown or black guard hairs; ventral pelage creamy white, sometimes with inconspicuous gray bases to hairs. Hindfeet moderately large and often robust (26–28 mm in length) with rather narrow metatarsal dark patch, broadening at base of digits III to V but rarely extending onto digits. Tail long (120–150% of head and body length), medium to dark brown, with short hair on shaft, distally little longer, with terminal pencil 3–30 mm long but usually about 10 mm. Ears small to medium in size, and rather dark in color. Skull moderate in size and rather slender, with slender rostrum; supraorbital ledges or ridges pronounced, straight, and converge strongly to front of interorbital region; braincase oval, not angular, and not greatly flattened except in old specimens; parapterygoid fossae shallow and not fenestrated; auditory bullae small; carotid circulatory pattern derived

(small stapedial foramen, no squamosal-alisphenoid groove, no sphenofrontal foramen). Incisor root capsule on mandible does not form prominent knob. Upper molar toothrow length 4.7–5.3 mm, average in relation to skull length in *Rhipidomys*.

DISTRIBUTION: At the southern limit of its range, *R. latimanus* occurs in the Chinchipe valley of northern Peru, close to the border with Ecuador, possibly linking northward along the eastern Andean slopes with the population in the upper Napo valley, Ecuador (700 to 1,100 m elevation). It is found along the western flanks and valleys of the Ecuadorian Andes (700 to 1,700 m) and also in the Colonche range of western Ecuador (about 450 m). In Colombia, it occurs from Nariño in the south, along both sides of the upper and middle Cauca valley (Cauca, Valle del Cauca, and Antioquia departments—700 to 2,000 m), spilling over in places to the opposite slopes of the Western and Central Cordilleras (2,200 m at El Roble), and extending eastward to the eastern side of the Magdalena valley in Cundinamarca and Boyacá (1,000 to 1,300 m); an apparently isolated population exists at the head of the Magdalena valley in Huila department (1,350 to 1,400 m). An isolated population in the Darién mountains of eastern Panama (1,250 to 1,550 m) probably extends into the hills across the Colombian border.

SELECTED LOCALITIES (Map 315, South American localities only): **COLOMBIA:** Antioquia, Valdivia, La Cabaña (FMNH 70255); Boyacá, Muzo (FMNH 71711); Cauca, Cocal (type locality of *Rhipidomys cocalensis* J. A. Allen); Huila, San Adolfo (FMNH 71704); Nariño, San Pablo (BM 99.9.3.1); Quindío, El Roble (type locality of *Rhipidomys quindianus* J. A. Allen); Valle del Cauca, Miraflores (type locality of *Rhipidomys mollissimus* J. A. Allen). **ECUADOR:** Chimborazo, Pallatanga (type locality of *Hesperomys latimanus* Tomes); Santa Elena, Cerro Manglar Alto (AMNH 66618); Napo, near Archidona (BM 34.9.10.112); Pichincha, Río Verde (type locality of *Rhipidomys pictor* Thomas). **PERU:** Cajamarca, Perico (MCZ 17043).

SUBSPECIES: As currently understood, *R. latimanus* is monotypic (but see Remarks).

NATURAL HISTORY: Little information has been published on the natural history of *R. latimanus*. Collection localities suggest that it occupies a range of habitats from moist to somewhat drier forests. Specimens from near Cali in the Cauca valley were trapped in coffee plantations and second-growth woodland and tested negative for *Leishmania* (Alexander et al. 1998). Specimen tags indicate that one individual from western Ecuador was taken in long grass, and one from eastern Panama was captured in cloud forest. Another Panamanian specimen was pregnant with three embryos in March.

REMARKS: *Rhipidomys latimanus* is a member of the “leucodactylus” section of the genus. Morphologically, it is closely allied to *R. venezuelae* (q.v.); both species encompass considerable morphological variation, with some populations of each taxon approaching the other in certain characters, especially in northern Colombia. Tribe (1996) therefore tentatively included *venezuelae* as a subspecies within *R. latimanus*, together with an unnamed subspecies corresponding to the specimens from Huila department, Colombia. As pointed out by Musser and Carleton (2005), however, the appreciable morphometric differentiation between the first two of these taxa suggests that they may be retained as separate species, and this arrangement is followed here. The Huila specimens are convergent in some characters with *R. fulviventris*, but a majority of features point to a position within *R. latimanus* (for details, see Tribe 1996). The specimens from the Darién mountains of extreme eastern Panama, considered by most authors a separate species (*R. scandens*), fall well within the range of variation found in Colombian *R. latimanus* and are therefore allocated to this species (Tribe 1996).

The karyotype of a *R. latimanus* specimen from Peñas Blancas, Valle del Cauca, Colombia ($2n=44$, FN=48) was

Map 315 Selected localities for *Rhipidomys latimanus* (●). Contour line = 2,000 m.

the first *Rhipidomys* karyotype to be published (A. L. Gardner and Patton 1976). It remains to be seen whether karyotypes and molecular data from other localities will help to clarify the large amount of morphological variation observed in the species as understood here.

Rhipidomys leucodactylus (Tschudi, 1845)

Great *Rhipidomys*

SYNONYMS:

Hesperomys (Rhipidomys). *leucodactylus* Tschudi, 1843: 252; *nomen nudum*.

Hesperomys (Rhipidomys). *leucodactylus* Tschudi, 1844: 16; *nomen nudum*.

Hesperomys (Rhipidomys). *leucodactylus* Tschudi, 1845: 183; type locality "im Oststriche," i.e., the eastern region of Peru visited by Tschudi, herein restricted to the Montaña de Vitoc area in Junín, Peru (see Remarks).

Nyctomys leucodactylus: Fitzinger, 1867b:89; name combination.

Hesperomys (Rhipidomys) sclateri Thomas, 1887:152 and plate XIX; type locality "Maccasseema" [= Makasima, on Pomeroun River, Pomeroun-Supinaam], Guyana.

Rhipidomys Goodfellowi Thomas, 1900c:270; type locality "upper Rio Napo, at mouth of Rio Coca," Napo, Ecuador.

Rhipidomys bovallii Thomas, 1911a:114; type locality "Potaro Highlands, towards Mt Roraima, British Guiana [Guyana]. Alt. 2000'."

Rhipidomys lucullus Thomas, 1911a:115; type locality "Garita del Sol, valley of Vitoc, Upper Peréné, [Junín], Central Peru. Alt. 5700'."

Rhipidomys equatoris Thomas, 1915:312; type locality "San Domingo, [Santo Domingo de los Tsáchilas,] W. Ecuador (79°6'W., 0°13'S.). Alt. 1600'."

Rhipidomys rex Thomas, 1927f:600; type locality "Chinchavita, 3000'," Huánuco, Peru.

Rhipidomys leucodactylus equatoris: Cabrera, 1961:421; name combination.

Rhipidomys leucodactylus goodfellowi: Cabrera, 1961:421; name combination.

Rhipidomys leucodactylus leucodactylus: Cabrera, 1961: 421; part, excluding *Rhipidomys ochrogaster*, as subspecies.

Rhipidomys. *leucodactylus aratayae* Guillotin and Pether, 1986:541; type locality "saut Pararé, sur la rivière Arataye [Pararé falls, on the Arataye river] (4°3'N, 52°40'W)," French Guiana.

DESCRIPTION (amended from Tribe 1996, excluding specimens that are now recognized as *R. gardneri* [see Patton et al. 2000, and that account herein]): Largest species in genus *Rhipidomys*, with adult head and body length often exceeding 180 mm. Dorsal pelage typically medium-brown

agouti, varying in tone from grayish to yellowish to reddish, with conspicuous dark guard hairs; flanks somewhat paler; ventral pelage white, cream, or yellowish, with gray-based hairs and often with orange suffusion in medial pectoral region; pelage texture somewhat coarse and often slightly woolly, especially on ventral surface. Tail proportionately short, only 95% to 130% of head and body length, reddish to very dark brown in color, unicolored, with shaft well clothed in hairs and tip terminating in long bushy pencil over 15 mm in length, sometimes reaching 40 mm. Ears moderately large. Hindfeet large (32–38 mm in length) and very broad, with dark patch covering most of dorsal surface and extending onto first or even second phalanges of digits II to V, sometimes also digit I; sides of foot and tips of toes silvery to golden. Skull large and robust (adult occipitonasal length usually exceeding 40 mm), relatively broad, with deep and broad rostrum; nasals expanded at anterior end and parallel-sided in posterior half; zygomatic notches small when viewed from above; supraorbital ridges well developed, sometimes converging anteriorly on top of interorbital region, with orbital wall ventrolateral to ridges forms narrowest part of interorbital constriction, providing general hourglass shape to region; braincase moderately broad and slightly inflated, with flatter profile in older specimens; interparietal nearly horizontal and occiput vertical; parietal ridges positioned somewhat dorsally on braincase such that squamosals are oriented dorsolaterally rather than laterally; mesopterygoid fossa broad, especially anteriorly; auditory bullae small and carotid circulation pattern derived (small stapedial foramen, no internal groove on squamosal or alisphenoid, and no sphenofrontal foramen). Molars large and maxillary tooththrow long (6.0–7.0 mm), although slightly smaller on average than might be expected in relation to skull length.

DISTRIBUTION: *Rhipidomys leucodactylus* occurs in the lowland rainforests of the Amazon-Orinoco basin, from the Guiana coast and lower Amazon in the northeast to the Andean piedmont between Colombia (Serranía de la Macarena) and central Bolivia (Cochabamba). It penetrates the moist valleys of the Guiana highlands of Venezuela as well as submontane forests up to 1,750 m elevation in eastern Peru, but apparently not in the upper Urubamba and Madre de Dios drainages. The range of the species as understood here also extends through the Huancabamba Depression in northern Peru to the forests of the western Andean slopes and valleys in northwestern Peru and Ecuador, from where it may be expected to reach the Chocó region of western Colombia.

SELECTED LOCALITIES (Map 316): BOLIVIA: Cochabamba, Yungas (BM 34.9.2.172). BRAZIL: Amapá, Mazagão, Boa Fortuna, upper Igarapé Rio Branco (MPEG 2508); Amazonas, Altamira, right bank Rio Juruá (MVZ

190592); Mato Grosso, Aripuanã (MZUSP APC 260); Pará, Amorim, Rio Tapajós (AMNH 95508); Rondônia, Usina Hidrelétrica de Samuel, Rio Jamarí (UFPPB 1259). COLOMBIA: Caquetá, Florencia (AMNH 33744); Meta, Serranía de la Macarena (AMNH 142141). ECUADOR: El Oro, Los Pozos (AMNH 67508); Orellana, San José Abajo (AMNH 68189); Pastaza, Mera (USNM 548392); Santo Domingo de los Tsáchilas, Santo Domingo (type locality of *Rhipidomys equatoris* Thomas). FRENCH GUIANA: Saut Pararé, Rivière Arataye (type locality of *Rhipidomys leucodactylus aratayae* Guillotin and Petter). GUYANA: Cuyuni-Mazaruni, Potaro Highlands, Venamo River (type locality of *Rhipidomys bovallii* Thomas); Pomerom-Supenaam, Makasima, Pomerom River (type locality of *Hesperomys (Rhipidomys) sclateri* Thomas). PERU: Ayacucho, Huanhuachayo (AMNH 241643); Huánuco, Chinchavito (type locality of *Rhipidomys rex* Thomas); Junín, La Garita del Sol (type locality of *Rhipidomys lucullus* Thomas); Loreto, Mouth of Río Curaray (AMNH 71906); Piura, Canchaque (FMNH 81293). VENEZUELA: Amazonas, Cerro Neblina, Camp VII, 5.1 km NE of Pico Phelps (USNM 560825), Pozón, 50 km NE of Puerto Ayacucho (T. E. Lee et al. 2000); Bolívar, Embalse Guri, Isla Panorama, Río Caroní (T. D. Lambert et al. 2003).

SUBSPECIES: As currently understood, *R. leucodactylus* is monotypic, but the considerable geographic variation in both morphology (Tribe 1996) and molecular sequences (B. M. de A. Costa et al. 2011) exhibited across its large range may underscore subspecific or even specific differentiation (see Remarks). As with many of the widespread species of this genus, larger series coupled with thorough analyses of this variation are needed to properly delimit geographic units.

NATURAL HISTORY: As a large, rat-sized, frugivorous rodent, *R. leucodactylus* is listed as a pest of agricultural crops (Aguilar et al. 1977); in fact, the holotype was captured while gnawing fruit in a pineapple field (Tschudi 1845), and other specimen tags mention sugar cane and yucca. Specimens have often been caught in rural dwellings (specimen tags; Handley 1976). The species generally occurs in moist, evergreen forest (Handley 1976; Ochoa et al. 1988), including floodable riparian habitats adjacent to the llanos (T. E. Lee et al. 2000). The holotype of *Rhipidomys leucodactylus aratayae* was observed to nest in a hole 15 m up in a tree, have a home range of 1.35 ha, and forage on the ground (Guillotin and Petter 1986). Three females from Huánuco, central Peru, were each pregnant with two embryos in August–September, and two from Napo, eastern Ecuador, had three in September and November (specimen tags). For parasites of Venezuelan specimens, see P. T. Johnson (1972) and Saunders (1975). A

specimen of *Rhipidomys leucodactylus* captured in northern Brazil had uncharacterized *Leishmania* isolated from its skin (Lainson, Shaw, et al. 1981), and sylvatic plague (*Yersinia pestis*) was carried by *Polygenis litargus* fleas infesting individuals and nests of *R. leucodactylus* in Piura, northwestern Peru (Machiavello 1957 *apud* Pozo et al. 2005).

REMARKS: *Rhipidomys leucodactylus* is the type species of the genus. As explained in the Remarks on the genus, Tschudi's name *leucodactylus*, like *Rhipidomys*, becomes available from its use on page 183 of the *Untersuchungen über die Fauna peruana (Therologie)*, published in the fourth installment of the work in 1845. Where it appears on page 16 of this work (published in 1844) and on page 252 of the "Mammalium conspectus" (Tschudi 1843) it is a *nomen nudum*. In his description of the material, Tschudi (1845:183–184) mentioned that he found this species "im Oststriche"—that is, the region east of the Andean Cordillera in central Peru—where it was associated with crop fields (his first specimen was shot while gnawing a pineapple) and human habitations. He also stated that Prof. Poeppig reported it from Tocache on the Río Huallaga. Cabrera's (1961:421) restriction of the type locality to the upper Huallaga "on the basis of Tschudi's text" is thus evidently based on a misinterpretation: Tschudi's own specimens came from the region he himself visited and not from the Huallaga, which lies much farther north. Tschudi (1846, 1847) describes his excursion from Lima over the Cordillera to the Montaña de Vitoc, the area between the rivers Anamayo and Tulumayo in Junín department. There he saw many plantations, especially of pineapples. Although he did not specifically mention *Rhipidomys* in this context, this is the only area east of the Andes that he described from firsthand experience. Given also the close similarity between the holotype of *leucodactylus* and other specimens collected later in the same area, it is justifiable to restrict the type locality of this taxon to the Montaña de Vitoc and to reject Cabrera's (1961) mistaken suggestion.

Wagner (1845a:147) also described a specimen of *Rhipidomys* under the name *Hesperomys leucodactylus*, but one now referable to a species different from Tschudi's material. I have been unable to resolve the question of which *leucodactylus*—Tschudi's or Wagner's—was published first in 1845: no month of publication appears in either work, and no clues have been found in the accession records of several libraries consulted. In the absence of any clear priority and in accordance with the principle of the first reviser (ICZN 1999:Art. 24.2), I consider that precedence should be given to *leucodactylus* Tschudi, 1845, over *leucodactylus* Wagner, 1845. This step best serves stability by retaining the name for the taxon with

which it has almost always been associated. In contrast, to my knowledge Wagner's name has been cited only three times in the last 100 years (Tate 1932g:5; Moojen 1952b:75; and C. O. da C. Vieira 1955:419); of these authors, only Tate associated the name with *Rhipidomys*, the others retaining it with *Hesperomys*. Furthermore, it avoids the inconvenience of having to provide a replacement name for the type species of the genus. I additionally propose that *leucodactylus* Wagner be rejected both as a junior primary homonym (in *Hesperomys*) and as a secondary homonym (in *Rhipidomys*) (ICZN 1999:Art. 52.1–3, 53.3, 57.2). Because I attribute Wagner's type specimen to *Rhipidomys macrurus* (P. Gervais, 1955) (*q.u.*), the latter name replaces *leucodactylus* Wagner (ICZN 1999:Art. 60.2).

As treated herein, *Rhipidomys leucodactylus* displays substantial geographic and/or individual variation in characters such as overall size, relative tail length and hairiness, and ventral color. Patton et al. (2000) clearly distinguished between *R. leucodactylus* and *R. gardneri* on the basis of karyotype and mtDNA cytochrome-*b* sequence data as well as morphological characters. Unfortunately, some specimens do not fit neatly with Patton et al.'s morphological descriptions and, therefore, in the absence of karyotype and molecular data, have been allocated subjectively to one species or the other. For example, an individual from the Yungas (wet, forested Andean valleys) of Cochabamba, Bolivia, is here placed in *R. leucodactylus* because of its very large size, long molar row, and skull shape, although in its white ventral pelage and short tail pencil it resembles *R. gardneri*. Most specimens of *R. leucodactylus* from west of the Andes in northwestern Peru and western Ecuador closely resemble populations from the eastern valleys in central Peru and eastern Ecuador, suggesting contact at some time through the Huancabamba Depression.

Known karyotypes for *Rhipidomys leucodactylus* all show a diploid number of $2n = 44$ but vary in number of autosomal arms: FN = 46 (Patton et al. 2000), FN = 48 (Zanchin, Langguth, and Mattevi 1992), and FN = 52 (M. J. J. Silva and Yonenaga-Yassuda 1999, as "*R. cf. mastacalis*," from Aramanaí, Mato Grosso state). The karyotyped specimen identified by Aguilera et al. (1994) as "*R. sclateri*," from the coastal region of Venezuela, represents *Rhipidomys couesi* and not *R. leucodactylus*. It should also be noted that Andrades-Miranda, Oliveira et al. (2002) identified all their specimens with low-FN from Goiás and Pará, Brazil, as "*R. leucodactylus*" without reference to morphology; in fact, they represent *R. macrurus*, *R. emiliae*, and possibly *R. ipukensis*. A molecular phylogeny of 39 *Rhipidomys* specimens (B. M. de A. Costa et al. 2011) placed three *R. leucodactylus* in a sister-group relationship to a clade compris-

Map 316 Selected localities for *Rhipidomys leucodactylus* (●). Contour line = 2,000 m.

ing two subgroups corresponding to *R. itoan* and *R. tribei*. Within the *R. leucodactylus* clade a Kimura 2-parameter distance of 9.24% separated the above-mentioned specimen from Aramanaí from two specimens from different parts of the Rio Juruá, a distance greater than that separating several sister species within the genus. GenBank sequence U03550 (MVZ 196059), sometimes cited as *R. leucodactylus*, in fact corresponds to *R. gardneri*.

Rhipidomys leucodactylus has been collected at the same localities as *R. modicus* in central Peru, and as *R. nitela*, *R. wetzeli*, and *R. macconnelli* in Venezuela.

Rhipidomys macconnelli de Winton, 1900

Macconnell's Tepui Rhipidomys

SYNONYMS:

Rhipidomys Macconnelli de Winton, 1900:52; type locality "summit of Roraima, [Cuyuni-Mazaruni,] Demerara" [Guyana].

[*Rhipidomys*] *macconnelli* E.-L. Trouessart, 1904:409; incorrect subsequent spelling of *macconnelli* de Winton.

[*Thomasomys*] *macconnelli*: Thomas, 1917d:196; name combination.

Thomasomys macconnelli macconnelli: Tate, 1939:194; name combination.

Thomasomys macconnelli subnubis Tate, 1939:195; type locality "South slope Mt. Auyan-tepui, 3500 feet," Bolívar, Venezuela.

Rhipidomys macconnelli Hershkovitz, 1959a:9; incorrect subsequent spelling of *macconnelli* de Winton.

DESCRIPTION: Small (head and body length 115–120 mm), resembling *Thomasomys* in many external characters but cranially closer to other *Rhipidomys*. Pelage

sleep, long, and soft; colored dark chocolate brown dorsally and dark slate overlaid with cream or pale brown ventrally; juveniles darker and greyer than adults. Tail much longer than head and body length (>140%) but slenderer than in most other *Rhipidomys*; paler on its ventral surface and almost bare over much of its length but with pronounced terminal pencil (5–20 mm long). Hindfeet less specialized for climbing, being longer (relative to body length) than in other species of *Rhipidomys* due to longer, narrow metatarsals; plantar pads also smaller and separated, with gap between thenar and hypothenar; dark patch on dorsal surface poorly defined but mid-brown in color and covers most of surface; heels and ankles bare. Ears dark brown, matching dorsal pelage. Cranially, nasals narrow anteriorly and rostrum long and slender in comparison to rounded braincase; interorbital region bounded by distinct, slightly concave supraorbital ridges; the lateral process of the parietal usually triangular rather than rectangular in shape and contacts the occipital barely or not at all; occipital region broad; mesopterygoid fossa broadened anteriorly, parapterygoid fossae often slightly fenestrated; carotid circulation pattern derived (small stapedia foramen, no groove on the inner surface of the squamosal and alisphenoid, and no sphenofrontal foramen); upper molar row length (5.00 ± 0.157 mm, $N=214$) large in relation to skull length for the genus.

DISTRIBUTION: *Rhipidomys macconnelli* lives on the slopes and summits of the Guiana Shield table mountains (*tepuis*) in Venezuela and adjacent areas of Brazil and Guyana, at elevations between 750 m and more than 2,600 m.

SELECTED LOCALITIES (Map 317): GUYANA: Cuyuni-Mazaruni, Mount Roraima, summit (type locality of *Rhipidomys Macconnelli* de Winton). VENEZUELA: Amazonas, Cerro Aracamuri, Cumbre Sur (MBUCV, in litt.), Cerro de Tamacuare (Ojasti, Guerrero, and Hernández 1992), Cerro Duida, Cabecera del Caño Culebra (USNM 406078), Cerro Neblina, Camp VII (USNM 560837); Bolívar, Acopán-tepuí (AMNH 176308), Auyán-tepuí (type locality of *Thomasomys macconnelli subnubis* Tate), km 125, 85 km SSE of El Dorado (USNM 387934).

SUBSPECIES: *Rhipidomys macconnelli* is monotypic (see Remarks).

NATURAL HISTORY: *Rhipidomys macconnelli* inhabits very moist cloud forest and dwarf vegetation on the *tepuis* and the evergreen forests surrounding them, where it occurs principally on the ground and on cliffs, making runways under rocks and trees (Handley 1976). Further habitat data may be found in Handley (1976), Guerrero et al. (1989), and Ojasti et al. (1992). From the large series collected, particularly on Cerro Duida, Auyán-tepuí, and Roraima, *R. macconnelli* appears to be a common animal on the *tepuis*. The animals' molar teeth, even when relatively

unworn, acquire a thick tartar coating, more so than in most other *Rhipidomys* specimens. Museum specimens also show a considerable ectoparasite load of louse nits and carpet-beetle egg cases. For parasites, see Furman (1972a, 1972b), P. T. Johnson (1972), E. K. Jones et al. (1972), Machado-Allison and Barrera (1972), Tipton and Machado-Allison (1972), Brennan and Reed (1974a), Saunders (1975), and Brennan and Goff (1977). Guerrero (1985) listed the ectoparasites recorded from all species of Venezuelan *Rhipidomys*.

REMARKS: *Rhipidomys macconnelli* is the sole member of the “macconnelli” section of the genus. Its generic allocation remained uncertain for many years because of the conflicting evidence of its *Thomasomys*-like external characters and *Rhipidomys*-like cranial morphology. Originally described as a *Rhipidomys* by de Winton in 1900, it was regarded as an aberrant form by Thomas (1906c), who later transferred the species to *Thomasomys* without explanation (Thomas 1917d). This arrangement was generally accepted for the next four decades until Hershkovitz (1959a) equally summarily restored *macconnelli* to *Rhipidomys*. His judgment was confirmed by the species' lack of a gall bladder (Voss 1991a) and by its karyotype ($2n=44$, $FN=50$; Aguilera et al. 1994), which ally it with other *Rhipidomys* species rather than with *Thomasomys*. Cladistic analyses based on molecular (M. F. Smith and Patton 1999) and morphological (Pacheco 2003) data corroborate this. Tate's (1939) description of a subspecies (*subnubis*) appears to have been founded on individual and clinal variation within the Auyán-tepuí populations.

Map 317 Selected localities for *Rhipidomys macconnelli* (●). Contour line = 2,000 m.

Rhipidomys macrurus (P. Gervais, 1855)

Cerrado *Rhipidomys*

SYNONYMS:

Hesperomys leucodactylus Wagner, 1845a:147; not *Hesperomys* (*Rhipidomys*) *leucodactylus* Tschudi; type locality: “Rio Parana,” Porto do Rio Paraná [= Igarapava], São Paulo, Brazil.

Mus (*Hesperomys*) *macrurus* P. Gervais, 1855:111, plate 16, Figs. 1, 1a; type locality “Trixas” [misspelling of Crixás], Goiás, Brazil.

Hesperomys macrourus P. Gervais, 1855:112; incorrect subsequent spelling of *macrurus* P. Gervais.

[*Hesperomys* (*Rhipidomys*)] *macrurus*: E.-L. Trouessart, 1880:136; name combination.

Rh[ipidomys]. macrurus: Thomas, 1896:303; first use of current name combination.

Rhipidomys mastacalis macrurus: Cabrera, 1961:423; name combination.

DESCRIPTION (amended from Tribe 1996, including his *Rhipidomys* sp. 2 and excluding specimens from the Serra da Ibiapaba reassigned herein to *R. mastacalis*): Medium sized (head and body length 125–145 mm, somewhat larger in southwestern part of range) with dull, reddish gray brown dorsal pelage; under parts white or pale cream, frequently with gray bases to hairs. Tail slightly longer than head and body length (100–120%, occasionally up to 140%) and terminates in pencil usually 5–15 mm long; tail medium to dark reddish brown, occasionally paler on proximal half. Ears large and medium brown in color. Hindfeet moderate in length (mostly 24–28 mm, but up to 33 mm in southwest), relatively broad and robust; dark dorsal patch either distinctly outlined or diffuse, either narrow or broad, occasionally extending onto digits; sides of feet and digits golden. Phallic morphology described and illustrated by Hooper and Musser (1964). Skull with short rostrum and small zygomatic notches in dorsal view; supraorbital edges squared or slightly ridged and, except in larger specimens, curved rather than straight, providing general rounded appearance to interorbital region, which is narrower than in neighboring species; braincase of average breadth and rounded, becoming more angular and flattened with age; incisive foramina roughly pear-shaped, broadening posteriorly, and palatal bridge short and broad; auditory bullae range from relatively small in southwest to moderately large elsewhere; carotid circulation pattern derived (small stapedial foramen, no internal groove on squamosal and alisphenoid, no sphenofrontal foramen). Maxillary toothrow length moderate to large in comparison with skull length and between 4.8–5.4 mm long in most of species’ range; up to 5.8 mm in southwestern part.

DISTRIBUTION: *Rhipidomys macrurus* is found in gallery forests and patches of woodland throughout most

of the Cerrado domain in Brazil, from southern Piauí state, where it has also been captured just within the Caatinga domain (M. A. N. Sousa 2005), south through eastern Tocantins state, western and central Bahia (including the semideciduous woods of the Rio São Francisco basin), Goiás, the Distrito Federal, northern and western Minas Gerais, northern and western São Paulo, and Mato Grosso do Sul. Specimens from eastern Paraguay were confirmed as *R. macrurus* by de la Sancha et al. (2011).

SELECTED LOCALITIES (Map 318): BRAZIL: Bahia, Andaraí, Fazenda Santa Rita (B. M. de A. Costa 2007), São Marcelo, Rio Preto (FMNH 21162); Goiás, Anápolis (MNRJ 4323), Crixás (type locality of *Mus* (*Hesperomys*) *macrurus* P. Gervais), Serra da Mesa, 20 km NW of Colinas do Sul (MNRJ 36449); Mato Grosso do Sul, Maracaju (MNRJ 4296), RPPN Cabeceira do Prata (MNRJ 69787); Minas Gerais, Caratinga, Fazenda Montes Claros (B. M. de A. Costa 2007), Coronel Murta, Ponte do Colatino, left bank Rio Jequitinhonha (B. M. de A. Costa 2007), Lavras (Mesquita 2009); Piauí, Caracol, Parque Nacional da Serra das Confusões (M. A. N. Sousa 2005), Estação Ecológica de Uruçuí-Una (MZUSP 30388); São Paulo, Itararé, Fazenda Ibiti (P. S. Martin et al. 2009), São José do Rio Preto (USNM 460533); Tocantins, Lajeado, Fazenda Santa Helena (MNRJ 76732). PARAGUAY: Amambay, Parque Nacional Cerro Corá (USNM 554544); Canindeyú, Sendero Morotí, Reserva Mbaracayú (de la Sancha et al. 2011).

SUBSPECIES: As currently understood, *R. macrurus* is monotypic (but see comments under Remarks).

NATURAL HISTORY: *Rhipidomys macrurus* typically inhabits the gallery forests lining rivers through the savanna-like cerrados of Brazil, as well as areas of woodland savanna (*cerradão*) and semideciduous forest. Mares, Braun, and Gettinger (1989) and Mares and Ernest (1995) provided ecological and population data for the species near Brasília; Gettinger (1992a, 1992b) reported on parasites from there. Mesquita (2009) gave details of the use of space by *R. macrurus* in a mosaic of cerrado, woodland, and farmland near Lavras, Minas Gerais state, where the species was relatively abundant. It was very abundant in semideciduous woodland in western Mato Grosso do Sul state, where Milano (2007) studied its population ecology and use of space. Bonvicino and Bezerra (2003) and Carmignotto and Aires (2011) reported specimens captured inside houses in southwestern Bahia and eastern Tocantins states, respectively. Dietz (1983) gave brief notes on the natural history of *R. macrurus* (as “*R. mastacalis*”) in the Serra da Canastra National Park, Minas Gerais; parasites from there were described by Whitaker and Dietz (1987). M. F. S. Ribeiro et al. (2004) gave some details of water physiology in a specimen (reported as *Rhipidomys mastacalis*)

from mesic forest at Morro do Chapéu (central Bahia; see Remarks).

REMARKS: *Rhipidomys macrurus* is a member of the “leucodactylus” section of the genus. Because the holotype of *R. macrurus*, collected by Castelnau and Deville in May 1844 (P. Gervais 1855), has not been located in the MNHN collections, the identity of this taxon is based on the hypothesis that the type locality (Crixás, Goiás), now deforested, falls within the range of this species of *Rhipidomys* as understood herein. A second specimen collected by Castelnau and marked “Co-type” [BM 49.10.15.32 (skin); 49.12.8.4 (skull)] has the provenance “Bahia”; this may mean that it was collected elsewhere but shipped from Bahia, where Castelnau was French consul from 1848, but equally there is no indication that it was collected at the type locality. Indeed, in his description of *Rhipidomys macrurus*, P. Gervais (1855) made no mention of a second specimen. Because eastern Brazilian species of *Rhipidomys* are morphologically very similar, there is no guarantee that the two specimens represent the same species, let alone the same population. No other specimens are known from that area. Work is in progress to select a suitable specimen to be designated as a neotype for *Rhipidomys macrurus* in order to clarify the identity of the taxon and ensure stability of usage (Tribe et al., in prep.). The specimen selected must not only be consistent with what is known of the geographical origin and morphology of the holotype, but also must agree in karyotype and DNA sequences with specimens assigned to *R. macrurus* (*sensu stricto*), given the importance of such evidence for species distinctions in eastern Brazil, as outlined herein.

Cabrera (1961) placed all *Rhipidomys* smaller than *R. leucodactylus* from Brazil, the Guianas, and Venezuela as subspecies of *R. mastacalis*, reflecting the difficulty in unambiguously distinguishing between them on morphological evidence alone. The advent of karyotyping revealed a dichotomy in fundamental number (number of autosomal arms) in eastern Brazilian *Rhipidomys*, with specimens with $2n=44$, $FN \geq 70$, being associated with the name *R. mastacalis*, and those with the same diploid number but $FN=48-52$, with *R. macrurus* (Zanchin, Langguth, and Mattevi 1992; Svartman and Almeida 1993a; Tribe 1996; M. A. N. Sousa 2005; L. G. Pereira and Geise 2007; Thomazini 2009; A. H. Carvalho et al. 2012). Accordingly, the population of *Rhipidomys* in the Serra da Ibiapaba, western Ceará state, tentatively included in *R. macrurus* by Tribe (1996, 2005), is here provisionally reassigned to *R. mastacalis* on the basis of its karyotype with $FN=70$ (M. A. N. Sousa 2005). B. M. de A. Costa et al. (2011) also pointed out morphological differences between this population and *R. macrurus* from farther south in the cerrado domain, and

an mtDNA phylogeny (Thomazini 2009) suggests it belongs to a clade comprising *R. emiliae*, *R. ipukensis*, and *R. mastacalis*.

Specimens from Morro do Chapéu, central Bahia, have yielded fundamental numbers of 56 (A. L. G. Souza et al. 2007b) and 61 (M. J. de J. Silva and Yonenaga-Yassuda 1999); they may belong to the as-yet-unnamed clade mentioned below. They are sympatric with, and morphologically distinct from, a specimen referred to *R. cariri* (see that account). The fundamental number of 61 is intermediate between the numbers typical of *R. mastacalis* ($FN \geq 70$) and of *R. cariri* and *R. macrurus* ($FN=48-52$), suggesting that that particular specimen might be an inter-specific hybrid (M. J. de J. Silva and Yonenaga-Yassuda 1999).

Recent work with molecular data has uncovered further diversity, separating additional species from the concept of *R. macrurus* employed by Tribe (1996), some of them overlapping geographically (L. P. Costa 2003; B. M. de A. Costa 2007; Thomazini 2009; B. M. de A. Costa et al. 2011; R. G. Rocha, Ferreira, Costa et al. 2011). For example, B. M. de A. Costa et al. (2011) have formalized the form found in Atlantic Forest of São Paulo and Rio de Janeiro states as *R. itoan*. Specimens from generally drier areas in central and western Bahia, northern and eastern Minas Gerais, northern Goiás, and southeastern Tocantins form a sister clade to *Rhipidomys cariri*, and together they are related to *Rhipidomys macrurus* (*sensu stricto*). This more inclusive clade is the sister clade to all other Brazilian *Rhipidomys* (L. P. Costa 2003; B. M. de A. Costa 2007; B. M. de A. Costa et al. 2011). The as-yet-undescribed form is retained here within *R. macrurus* pending formal description. Conversely, the same molecular studies and that of de la Sancha et al. (2011) demonstrate that the population from western Mato Grosso do Sul and eastern Paraguay belongs within *R. macrurus* (*s.s.*), although on morphological and morphometric grounds (not least its larger overall size and molar row length) Tribe (1996) considered it to represent a separate species. Clearly, considerable further research is needed to elucidate the status of all the forms included here in *R. macrurus*.

The specimen collected by Johann Natterer at Porto do Rio Paraná (now Igarapava, on the northern border of São Paulo state) and named *Hesperomys leucodactylus* by Wagner (1845a) was allocated to *R. mastacalis* by Tribe (1996) on biogeographical grounds. The distribution of the specimens used in the molecular studies mentioned herein suggests that Natterer’s specimen should be reallocated to *R. macrurus*. Regarding the invalidity of the species name *leucodactylus* Wagner, see the Remarks section under *R. leucodactylus*.

Map 318 Selected localities for *Rhipidomys macrurus* (●).

Rhipidomys mastacalis (Lund, 1840)

Northern Atlantic Forest *Rhipidomys*

SYNONYMS:

- [*Mus*] *mastacalis* Lund, 1839a:233; *nomen nudum*.
Mus mastacalis Lund, 1840a:24 [1841b:240]; type locality “Rio das Velhas’s Floddal” (Lund 1841b:264, 266), Lagoa Santa, Minas Gerais, Brazil.
Mus mustacalis Lund, 1840b:7 [1841c:279]; incorrect subsequent spelling of *mastacalis* Lund.
Mus mystacalis Wagner, 1843b:750; incorrect subsequent spelling of *mastacalis* Lund.
Mus maculipes Pictet and Pictet, 1844:67; type locality “Bahia,” Brazil.
Mus masculipes Burmeister, 1854:185; incorrect subsequent spelling of *maculipes* Pictet and Pictet.
H[esperomys (Calomys)]. mystacalis Burmeister, 1855a:7; part; name combination and incorrect subsequent spelling of *mastacalis* Lund.
H[esperomys (Calomys)]. maculipes: Burmeister, 1855a:8; name combination.
[*Hesperomys (Rhipidomys)*] *mastacalis*: E.-L. Trouessart, 1880:136; name combination.
Rhipidomys mastacalis: Winge, 1887 [1888]:54; first use of current name combination.
[*Oryzomys*] *musculipes* E.-L. Trouessart, 1897:528; incorrect subsequent spelling of *maculipes* Pictet and Pictet and name combination.
Rhipidomys cearanus Thomas, 1910c:501; type locality “S[ão]. Paulo, on the top of the Serra [da Ibiapaba], at about 900 metres,” Ceará, Brazil.

Rhipidomys venezuelae cearanus: Gyldenstolpe, 1932:47; name combination.

[*Oecomys*] *maculipes*: Tate, 1932g:21; name combination.

Rhipidomys maculipes: Laemmer, Ferreira, and Taylor, 1946:38; name combination.

Rhipidomys mastacalis cearanus: Cabrera, 1961:422; name combination.

Rhipidomys mastacalis mastacalis: Cabrera, 1961:423; name combination.

Rhipidomys mastacalis A. L. Gardner, 1990:412; incorrect subsequent spelling of *mastacalis* Lund.

Rhipidomys masatacalis Voss and Myers, 1991:428; incorrect subsequent spelling of *mastacalis* Lund.

DESCRIPTION: Medium sized (head and body length 125–145 mm) with gray-brown to more intensely red-brown dorsal pelage and cream or white under parts. Tail moderate to long (120–140% of head and body length), light to dark brown, with short hairs proximally but longer ones on distal half, and with short to moderate-length pencil. Ears medium to large, usually medium brown. Hindfeet broad, medium in length (26–29 mm), with medium to dark brown dorsal patch, often broad and ill-defined, which does not extend onto toes; sides of foot and toes pale. Skull with moderately long, relatively slender rostrum; nasals taper regularly from anterior to posterior; supraorbital ridges straight, diverging from front of interorbital region; braincase not greatly inflated or rounded; incisive foramen narrow; palatal bridge long and narrow; carotid circulatory pattern derived (small stapedial foramen, no internal groove on squamosal and alisphenoid, no sphenofrontal foramen). Maxillary tooththrow of moderate length for size of skull, averaging about 5.0 mm.

DISTRIBUTION: *Rhipidomys mastacalis* is found in the Atlantic rainforest of eastern Brazil, from the state of Paraíba in the north along the coastline to eastern Rio de Janeiro state in the south, and also inland on the Chapada Diamantina plateau of central Bahia and in eastern and central Minas Gerais. Apparently isolated populations in western Ceará and northern Goiás are also provisionally referred to this species.

SELECTED LOCALITIES (Map 319): BRAZIL: Alagoas, Anádia, Sítio Vale Verde (MNRJ 17450); Bahia, Fazenda Unacau, 8 km SE of São José (UFPB 425), Palmeiras, Pai Inácio (MNRJ 67751), São Felipe (MNRJ 22274); Ceará, Ibiapina, Sítio Pejuaba (MNRJ 17401); Espírito Santo, Linhares (MNRJ 34492); Goiás, Serra da Mesa, 40 km NE of Uruaçu (MNRJ 37350); Minas Gerais, Brumadinho, Rio Manso (UFMG 1649), Diamantina, Conselheiro Mata (B. M. de A. Costa 2007), Salinas (MNRJ 30015); Paraíba, Areia, Mata do Pau-Ferro (UFPB 3864); Pernambuco, Garanhuns, Sítio Cavaquinho (MNRJ 12500); Rio de Janeiro,

Fazenda União, Casimiro de Abreu (MNRJ 46803); Sergipe, south of Estância (Stevens and Husband 1998).

SUBSPECIES: *Rhipidomys mastacalis* is monotypic.

NATURAL HISTORY: *Rhipidomys mastacalis* occurs in remnants of Atlantic forest in eastern Brazil, including both highland enclaves (*brejos de altitude*) and lowland forest in the northeast (M. A. N. Sousa et al. 2004; Asfora and Pontes 2009), and less-moist forests in eastern Minas Gerais. It is also sometimes caught in the roofs of houses (data from specimen tags). Most captures of this species in forest fragments in Sergipe occurred well inside the fragments (Stevens and Husband 1998). About 59% of a large series of *R. mastacalis* collected for yellow fever research in the vicinity of Ilhéus, Bahia, was taken in young forest, 21% in old forest and 9% in swamp forest; *Rhipidomys* proved to be less important as a host for the virus than most rodents (Laemmert et al. 1946). Near Caruaru, Pernambuco, *R. mastacalis* was captured mainly in hillside forest both in trees and on the ground; only two females out of 17 collected were pregnant in October to December (M. A. N. Sousa et al. 2004). Cerqueira, Vieira, and Salles (1989) analyzed habitat and reproductive data for a population in the Serra da Ibiapaba (western Ceará state; see Remarks). *Rhipidomys mastacalis* is implicated in damage to cacao in southern Bahia, where it is relatively common in and around plantations (Cruz 1983; Cassano and Moura 2004; Pardini 2004). T. Araújo et al. (2006) described behavior in captivity. For parasites, see F. Fonseca (1959) and Hastriter and Peterson (1997).

REMARKS: *Rhipidomys mastacalis* is a member of the “leucodactylus” section of the genus. Having once been applied to *Rhipidomys* specimens from much of northern and eastern South America (Cabrera 1961), the name *R. mastacalis* is now restricted to a taxon occupying a moderately small range in eastern Brazil. This change was due not only to morphological reassessments (Musser and Carleton 1993; Tribe 1996), but especially to the results of karyotype analyses and molecular phylogeographic studies (Zanchin, Langguth, and Mattevi 1992; Svartman and Almeida 1993a; L. P. Costa 2003; B. M. de A. Costa 2007; Thomazini 2009; B. M. de A. Costa et al. 2011; R. G. Rocha, Ferreira, Costa et al. 2011). See also the Remarks under *Rhipidomys macrurus*.

The karyotype of *R. mastacalis* has the same diploid number ($2n=44$) as the majority of other *Rhipidomys* species, but it has a higher fundamental number ($FN \geq 70$) than other eastern Brazilian forms. On the assumption that this combination of diploid and fundamental numbers characterizes a monophyletic group, certain specimens from Serra da Mesa in northern Goiás state with $FN=76$ and 80 (Andrades-Miranda, Oliveira et al. 2002) are here provi-

sionally referred to *R. mastacalis*, although they may well represent a distinct species (see also the Remarks under *R. ipukensis*). They are sympatric with low-FN specimens referred here to *R. macrurus*.

Additionally, the population of *Rhipidomys* in the highland forest enclave in the Serra da Ibiapaba, western Ceará, which Tribe (1996, 2005) tentatively referred to *R. macrurus* on morphological grounds, is here provisionally reallocated to *R. mastacalis* because the first known karyotype from that population (with $FN=70$) appears to be identical to that of *R. mastacalis* from eastern Pernambuco and Bahia (M. A. N. Sousa 2005). A phylogeny based on mitochondrial cytochrome oxidase I sequences places a specimen from Ibiapaba as a distant basal member of a clade allying *R. emiliae* and *R. ipukensis*, to which *R. mastacalis* forms the sister clade (Thomazini 2009). The *Rhipidomys* populations inhabiting isolated mesic forests (*brejos*) within the Caatinga domain of northeastern Brazil thus appear to be split between *R. mastacalis* (high FN) in the more peripheral enclaves and *R. cariri* (low FN) in the more central ones. Whereas specimens from the *brejos* in eastern Pernambuco are closely allied to *R. mastacalis* from the coastal Atlantic Forest (Thomazini 2009), the Serra da Ibiapaba population on the far side of the Caatinga is more distantly related. Should further work demonstrate that the population in the Serra da Ibiapaba deserves species status, the name *cearanus* Thomas is available. The identity of specimens from Serra Negra, western Pernambuco, reported by Botêlho et al. (2001,

Map 319 Selected localities for *Rhipidomys mastacalis* (●); note isolated populations in central and northeastern Brazil.

2003) as "*Rhipidomys cearanus*" in a study of ectoparasites, has not been verified; they may represent either *R. mastacalis* or *R. cariri*.

Rhipidomys modicus Thomas, 1926

Lesser Peruvian Rhipidomys

SYNONYMS:

Rhipidomys modicus Thomas, 1926g:161; type locality Puca tambo ("Puca Tambo, 5100 [feet]"), San Martín, Peru.
Rhipidomys leucodactylus modicus: Cabrera, 1961:422; name combination as subspecies.

DESCRIPTION: Medium to large (head and body length 130–165 mm) with medium to dark yellowish to reddish brown agouti dorsal coloration, well streaked with dark guard hairs, and rather coarse and short; ventral pelage with white-tipped fur with very pale to dark gray bases; orange pectoral spot sometimes present. Tail long (up to 135% of head and body length) and medium to dark brown; shaft lightly haired and terminating in pencil that rarely exceeds 15 mm. Ears rather small. Hindfeet moderately large (28–30 mm) and broad, with broad dark patch on dorsal surfaces that sometimes extends onto digits. Skull moderate in size and robustness; rostrum short and somewhat pointed; nasals taper gradually along length; zygomatic plates not broad and notches small; supraorbital ridges squared rather than raised, diverging strongly posteriorly; interorbital region broad, with narrowest point forward; braincase oval, moderately broad, and not greatly flattened, although interparietal oriented more dorsally than posteriorly; mesopterygoid fossa broad and penetrating between hypocones of M3s; auditory bullae small; carotid circulation pattern derived (small stapedial foramen, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Maxillary toothrow 5.5–5.8 mm in length, comparatively long for size of skull.

DISTRIBUTION: *Rhipidomys modicus* is known from eastern Andean valleys in northern and central Peru, at elevations between 700 and 1,800 m. Collecting localities for *R. modicus* in central Peru are identical with or close to localities where specimens of *R. leucodactylus* have been taken.

SELECTED LOCALITIES (Map 320): PERU: Amazonas, 12 km E of La Peca Nueva (LSUMZ 21873); Huánuco, Chinchavito (BM 27.11.1.130); Junín, Chanchamayo (BM 7.6.15.13); San Martín, Moyobamba (FMNH 19363), Puca tambo (type locality of *Rhipidomys modicus* Thomas).

SUBSPECIES: *Rhipidomys modicus* is monotypic.

NATURAL HISTORY: The holotype was "trapped in brush near stream," and the specimen from Chinchavito was trapped in an abandoned shed (specimen tags).

REMARKS: *Rhipidomys modicus* is a member of the "leucodactylus" section of the genus. It is substantially

Map 320 Selected localities for *Rhipidomys modicus* (●) and *Rhipidomys ochrogaster* (○). Contour line = 2,000 m.

smaller than *R. leucodactylus* in external dimensions, skull length, and molar row length, and appears to occur sympatrically with the latter species in at least part of its range. Specimens exhibit considerable variation in the extent of gray bases to their ventral pelage, even at a single locality.

Rhipidomys nitela Thomas, 1901

Guianan Rhipidomys

SYNONYMS:

Rhipidomys nitela Thomas, 1901e:148; type locality Kwatata, Kanuku Mountains, Upper Takutu–Upper Essequibo, Guyana (see Remarks).

Rhipidomys venezuelæ fervidus Thomas, 1904d:34; type locality "La Unión, lower Orinoco," Caura valley, Bolívar, Venezuela.

Rhipidomys venezuelæ yuruanus J. A. Allen, 1913c:601; type locality "Río Yuruán, [Bolívar], Venezuela."

Rhipidomys milleri J. A. Allen, 1913c:602; type locality "Minehaha Creek (altitude 500 feet), Lower Essequibo River, British Guiana."

R[*hipidomys*]. *v*[*enezuelæ*]. *nitela*: J. A. Allen, 1913c:602; name combination.

Rhipidomys venezuelæ milleri: Gyldenstolpe, 1932:47; name combination.

Rhipidomys mastacalis nitela: Cabrera, 1961:423; name combination.

Rhipidomys mastacalis fervidus: Cabrera, 1961:423; name combination.

Rhipidomys nitela tobagi Goodwin, 1961:16; type locality "Little Tobago, the West Indies," Little Tobago Island, Trinidad and Tobago.

R[*hipidomys*]. *n*[*itela*]. *milleri*: Goodwin, 1961:16; name combination.

DESCRIPTION: Small to medium sized (head and body length typically 110–140 mm) with soft, short, dull gray brown to richer reddish or orange brown dorsal pelage; ventral fur short and creamy white to roots or with inconspicuous pale gray hair bases. Tail moderately long (110–140% of head and body length) with short to medium terminal pencil 5–15 mm in length. Ears pale to dark and moderately large in size, sometimes with pale postauricular patch. Hindfeet short (24–27 mm) and slender, with small plantar pads and dorsal dark patch of varying distinctness rarely extending onto digits. Skull small with short, rather blunt rostrum; interorbit broad with squared or ledged edges, sometimes raised; braincase oval, not inflated, and flattened in older individuals; incisive foramina usually narrow and almost elliptical in shape; mesopterygoid fossa narrow and parapterygoid fossae may be fenestrated; auditory bullae small; carotid circulation pattern derived (small stapedia foramen, no internal groove on squamosal and alisphenoid, and no sphenofrontal foramen). Maxillary toothrow short, between 3.8–5.0 mm in length, but average in size for genus in comparison with skull length.

DISTRIBUTION: *Rhipidomys nitela* as understood here occurs at lower elevations (below 1,400 m) throughout the Guiana Highlands and adjacent forested lowlands in the region bounded by the Orinoco, Negro, and lower Amazon rivers and the Atlantic coast. Specimens found on the island of Little Tobago, northeast of Trinidad, are also referred to this species.

SELECTED LOCALITIES (Map 321): **BRAZIL:** Amapá, 50 km ESE of Porto Grande (MNRJ AN 188); Amazonas, Km 50 Manaus-Itacoatiara road (MNRJ 19614); Pará, Oriximiná, Porto Trombetas, Rio Saracazinho (MPEG 10113); Roraima, Ilha de Maracá (Barnett and Cunha 1998). **FRENCH GUIANA:** Les Nouragues (MNHN V.890), Paracou (AMNH 267021). **GUYANA:** Cuyuni-Mazaruni, Kalakun (AMNH 207387); Upper Takutu–Upper Essequibo, Kwatata, Kanuku Mountains (type locality of *Rhipidomys nitela* Thomas). **SURINAM:** Para, Matta, 15 km W of Zanderij airport (RMNH 21973). **TRINIDAD AND TOBAGO:** Tobago, Little Tobago Island (AMNH 184555). **VENEZUELA:** Amazonas, Cerro Duida, Caño Culebra (USNM 406109); Bolívar, La Unión, Río Caura (BM 4.5.7.34), Río Caroní, Embalse Guri, Isla Panorama (T. D. Lambert et al. 2003), Río Yuruán (type locality of *Rhipidomys venezuelae yuruanus*), Serranía de los Pijiguaos, 140 km SW of Caicara (Rivas and Linares 2006).

SUBSPECIES: As currently understood, *Rhipidomys nitela* is monotypic, although the population from Little Tobago Island has been regarded as a separate subspecies (Goodwin 1961).

NATURAL HISTORY: *Rhipidomys nitela* occurs in lowland rainforest, where it is primarily arboreal but also comes down to the ground (Handley 1976, as "*R. mastacalis*"; Voss 1991a; Voss et al. 2001). Ecological data for the species are provided by Malcolm (1988) near Manaus in the central Amazon (see Remarks), and by Mauffrey (1999) and Mauffrey and Catzefflis (2002) at Les Nouragues, French Guiana. According to specimen tags and published reports, *R. nitela* is often found in the rafters or thatched roofs of buildings (J. A. Allen 1911; Husson 1978; Barnett and Cunha 1998; Lim, Engstrom, Genoways et al. 2005). Specimens from Sinnamary (French Guiana) and Bonda (northern Colombia; see Remarks) were shot in bat roosts (Voss et al. 2001; L. Roguin, pers. comm.). For parasites, see Brennan and Yunker (1969), Furman and Tipton (1961), and Gettinger, Martins-Hatano et al. (2005).

REMARKS: *Rhipidomys nitela* is a member of the "leucodactylus" section of the genus. The type locality given in the published report (Thomas 1901e:149) and the locality recorded in the accession register of the Natural History Museum, London, for the whole type series is "Kwaimattat, Kanuku Mts."; the labels attached to all the skins, however, are marked "Quatata [or "Quatatat"], Kanuku Mts., B. Guiana, 240' [feet]." Kwaimattat and Quatatat, now spelled Kwaimatta and Kwatata, are localities 27 km apart in the savannas north of the Kanuku Mountains in Guyana. Kwatata is here selected as the type locality, because the data accompanying the original material (in this case the specimen tags) should be taken into account first when a type locality is clarified (ICZN 1999:Recommendation 76A).

Specimens from northern Bolívar state, Venezuela, including the holotypes of *Rhipidomys venezuelae fervidus* and *R. v. yuruanus*, tend to be larger and more intensely pigmented than most other *Rhipidomys nitela* specimens, and their skulls are more elongated with strong supraorbital ridges. They are retained here within *R. nitela* because the differences in character states do not appear to be consistent enough for taxonomic separation. Specimens from south of the Amazon considered by Tribe (1996) to be *Rhipidomys nitela* are here referred to *R. emiliae* (see that account); these include the "*R. nitela*" sequenced by M. F. Smith and Patton (1999) and by L. P. Costa (2003). A single specimen from the isolated northern Colombian locality of Bonda, which Tribe (1996) allocated to *R. nitela*, was considered by Voss et al. (2001:127) to represent another taxon; in line with

their judgment, it is here regarded as belonging to an as yet undescribed species of *Rhipidomys*. Less convincing is their suggestion that the specimens from Little Tobago possibly “represent an insular form of the adjacent mainland species *R. venezuelae*” (Voss et al. 2001:127): the nearest part of the known range of *R. venezuelae* (in Estado Guárico, Venezuela) lies farther away from Little Tobago than that of *R. nitela* (in Estado Bolívar, Venezuela, and in Guyana), and the Little Tobago specimens cluster morphometrically with *R. nitela* and not with *R. venezuelae* (Tribe 1996). Additional material from the northern coast of South America and adjacent islands is clearly needed to resolve these relationships fully.

Rhipidomys nitela is the only species of the genus so far karyotyped to have a diploid number other than $2n=44$, with reports of $2n=48$ from southeast Venezuela (Voss et al. 2001); $2n=48$, FN=68, from Roraima state, Brazil (Andrades-Miranda, Oliveira et al. 2002); $2n=48$, FN=71, from French Guiana (Volobouev and Catzeflis 2000); and $2n=50$, FN=71 and 72, from near Manaus (M. J. de J. Silva and Yonenaga-Yassuda 1999, as *Rhipidomys* sp. B). Based on banding analysis, Volobouev and Catzeflis (2000) found considerable differences between the French Guiana and Manaus karyotypes, leading them to question the taxonomic status of the latter population. Pending further study, specimens from near Manaus are here provisionally retained in *R. nitela*.

Map 321 Selected localities for *Rhipidomys nitela* (●); note insular population on Little Tobago Island northeast of Trinidad. Contour line = 2,000 m.

Phylogenetic analyses based on mtDNA cytochrome-*b* sequences place specimens of *R. nitela* from French Guiana as the sister group to a clade consisting of *R. mastacalis*, *R. ipukensis*, and *R. emiliae* (R. G. Rocha, Ferreira, Costa et al. 2011). More extensive molecular analyses of *R. nitela* specimens are needed to elucidate the diversity contained within the species as understood here.

Rhipidomys ochrogaster J. A. Allen, 1901

Buff-bellied *Rhipidomys*

SYNONYM:

Rhipidomys ochrogaster J. A. Allen, 1901b:43.; type locality “Inca Mines, Peru (alt. 6000 feet),” Santo Domingo, Río Inambari, Puno, Peru.

DESCRIPTION: Large (head and body length 152–176 mm), long-tailed (length 198–228 mm) species with orange-brown dorsal fur and pale orange or melon-colored ventral fur. Tail dark, considerably longer than head and body (125–148%), and terminates in long pencil of hairs (20 mm long in holotype). Hindfeet moderately long (34–35 mm) and broad, with metatarsal patch extending onto first phalanges of toes. Skull moderately large, with rather narrow and pointed rostrum, broad interorbital region, and broad, rounded braincase; supraorbital shelf well developed and divergent posteriorly; postorbital ridges absent or weak; zygomatic plates narrow; carotid circulation pattern primitive (pattern 1, of Voss 1988), characterized by large stapedia foramen, squamosal-alisphenoid groove visible but not strong, and sphenofrontal foramen. Upper molar row long (6.1–6.3 mm), large in comparison to skull length for genus. Pacheco and Peralta (2011) provided photographs depicting external appearance (including dorsal, lateral, and ventral views of freshly dead specimen, dorsal and ventral views of hindfoot, and tail tip) as well as skull and both molar series in comparison with *R. gardneri* and *R. leucodactylus*.

DISTRIBUTION: Only five specimens of *Rhipidomys ochrogaster* are known from two localities in southeastern Peru at elevations between 1,200 and 1,940 m. Four of these are from the vicinity of the type locality in the upper Río Inambari drainage at the base of the Cordillera de Carabaya, and the fifth from the valley of the Río Tambopata.

SELECTED LOCALITIES (Map 320): PERU: Puno, Santo Domingo (type locality of *Rhipidomys ochrogaster* J. A. Allen), Yanacocha, valley of Río Tambopata (Pacheco and Peralta 2011).

SUBSPECIES: *Rhipidomys ochrogaster* is monotypic.

NATURAL HISTORY: J. A. Allen (1900a:219) described the type locality (erroneously referred to as Juliaca; see J. A. Allen 1901b:41), quoting the collector H. H. Keays: “The country is very broken, with deep

narrow cañons, and is covered with a dense undergrowth of shrubs and vines, with here or there a palmetto or a cedar rising above the surrounding vegetation.” The recent specimen from the Río Tambopata drainage (Pacheco and Peralta 2011) was collected in a forest of slender trees of 15 m maximum height, dense understory, and forest floor covered with deep soil litter. Plant species included *Ilex* sp. (Aquifoliaceae), *Viburnum* sp. (Adoxaceae) *Miconia* sp. (Melastomataceae), *Myrsine* sp. (Myrsinaceae), *Myrcia* sp. (Myrtaceae), *Clusia* sp. (Clusiaceae), *Cecropia* sp. (Urticaceae), and *Clethra* sp. (Clethraceae). This habitat corresponds to the Yungas, the humid montane forest that flanks the eastern slope of the eastern cordillera of the Andes in southern Peru and Bolivia (Young and Leon 1999; Tovar Narváez et al. 2010). Pacheco and Peralta (2011) proposed that the species be classed as Endangered on account of the increasing deforestation of Yungas habitats in Puno department. Stomach contents of the Yanacocha specimen included both seeds and ants (Pacheco and Peralta 2011).

REMARKS: *Rhipidomys ochrogaster* is by far the largest member of the “fulviverter” section of the genus (not the “leucodactylus” section, as stated by Musser and Carleton 2005:1171), to which it clearly belongs on morphological grounds (see Key to the species of *Rhipidomys*). There is a gap of approximately 1,300 km along the Andean chain from the nearest other known members of the section, which were recently discovered in Amazonas department in northern Peru (C. F. Jiménez and Pacheco 2012; see Remarks under *Rhipidomys fulviverter*). Although the capture elevation of the holotype is given as “6800 ft” (2,075 m) on the specimen tag (AMNH 16481), the figure given in the published type description (“6000 feet,” 1,830 m) is more plausible according to maps of the locality.

Rhipidomys similis J. A. Allen, 1912

Greater Colombian *Rhipidomys*

SYNONYMS:

Rhipidomys similis J. A. Allen, 1912:79; type locality “Cocal, Cauca, Colombia. Altitude, 6000 feet.”

Rhipidomys latimanus similis: Cabrera, 1961:419; part; name combination.

DESCRIPTION: Moderately large with head and body length 125–155 mm and long tail measuring 125% to 150% of head and body length. Dorsum reddish brown to yellowish rufous lined with black, and somewhat darker medially than more orange yellow sides; ventral pelage cream or more usually pale orange hair tips over long, dark gray bases. Tail covered with black hairs, nearly concealing annular scales, and terminates in a pencil. Ears dull brown. Hindfeet moderately long (29–31 mm) and broad. Skull

with rounded interorbital region with slightly developed supraorbital ridges, and broad, rounded braincase; mesopterygoid fossa expanded at anterior end; sphenopalatine vacuities small to medium; parapterygoid fossae fenestrated; carotid circulation pattern primitive (large stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen). Maxillary toothrow larger than average for genus in comparison to skull length, ranging from 5.0–5.4 mm.

DISTRIBUTION: *Rhipidomys similis* is restricted to the Andes of southwestern Colombia. It is known from high elevations on both versants of the Western Cordillera in the departments of Cauca and Valle del Cauca, and from the mountains at the head of the Magdalena valley, department of Huila, including parts of the Central and Eastern Cordilleras. It is likely to occur in the knot of mountains connecting the three cordilleras in Cauca and Nariño departments and may also extend farther north along the Western and Central Cordilleras.

SELECTED LOCALITIES (Map 312): COLOMBIA: Cauca, Cocal (AMNH 32458); Huila, Belén (USNM 294984), San Adolfo, Río Aguas Claras (FMNH 71712), San Antonio (FMNH 71716); Valle del Cauca, Pichindé (Alberico 1983).

SUBSPECIES: *Rhipidomys similis* is monotypic.

NATURAL HISTORY: Specimens of *Rhipidomys similis* from the head of the Magdalena valley were found at between 1,600 m and 2,350 m. Specimens from the Western Cordillera were captured at elevations of 2,400 m on the eastern slope and 1,220 to 1,830 m on the cooler, moister western slope, corresponding to the differing elevations of cloud forest on the two versants. The remarkably low elevation of 1,220 m (“4000 ft”) for a specimen from Cocal is possibly an error (see Chapman 1917:31, footnote 2, regarding bird specimens from the same locality).

REMARKS: *Rhipidomys similis* is the second largest species in the “fulviverter” section of the genus, after *R. ochrogaster*. It occurs sympatrically with *R. caucensis* in Cauca and Huila, and with *R. latimanus* in Valle, Cauca, and Huila, with its elevational range broadly overlapping that of the former and marginally that of the latter (if at all; see note on Cocal in Natural History section). Tribe (1996) treated the Western Cordillera and Huila units as separate subspecies of *Rhipidomys fulviverter*; see the Remarks under that species. Specimens allocated by Alberico (1983:65) to *R. latimanus* are of this species.

Rhipidomys tenuicauda (J. A. Allen, 1899)

Turimiquire *Rhipidomys*

SYNONYMS:

Oryzomys tenuicauda J. A. Allen, 1899b:211; type locality “Los Palmales, [Sucre,] Venezuela.”

[*Rhipidomys*] *tenuicauda*: Tate, 1939:195; first use of current name combination.

Rhipidomys mastacalis tenuicauda: Cabrera, 1961:423; name combination, and incorrect subsequent spelling of *Rhipidomys* Tschudi.

DESCRIPTION: Small species similar to *R. fulviventer*, with head and body length 109–128 mm (holotype exceptionally small at 88 mm). Dorsal pelage often bright orange brown agouti, sometimes more chestnut brown; ventral pelage with cream hair tips on middle to dark gray bases. Tail proportionately long (115–140% of head and body length, 145% in holotype), unicolored dark brown, varying from nearly naked at base but with increasingly long hairs distally, terminating in thick pencil about 10 mm long. Ears brown and lightly haired. Hindfeet small (23–27 mm in length) and narrow, with dorsal dark patch extending to base of toes and buff edges and digits. Skull with rounded interorbital region and slight supraorbital ridges; braincase broad, rounded; lateral processes of parietals narrow posteriorly; parapterygoid fossae sometimes fenestrated; sphenopalatine fissures variable, from long and moderately broad to short and narrow, or absent; carotid circulatory pattern primitive (large stapedia foramen, internal groove along squamosal and alisphenoid, and sphenofrontal foramen). Maxillary tooththrow short, 4.2–4.6 mm, average for genus in comparison with skull length; molars proportionately somewhat narrower than average.

DISTRIBUTION: *Rhipidomys tenuicauda* appears to be restricted to the Serranía de Turimiquire of north-eastern Venezuela, in the states of Sucre, Monagas, and Anzoátegui.

SELECTED LOCALITIES (Map 322): VENEZUELA: Anzoátegui, Cerro La Laguna, cumbre (F. J. García and Sánchez-González 2013); Monagas, San Agustín, 5 km NW of Caripe (USNM 409929).

SUBSPECIES: *Rhipidomys tenuicauda* is monotypic.

NATURAL HISTORY: *Rhipidomys tenuicauda* occurs in premontane humid forest (USNM specimen tags) as well as in coffee and cacao plantations (Tate 1931), at elevations between 945 m and 2,200 m. It may be found at lower elevations than other members of the “fulviventer” section (with the exception of *R. wetzeli*) because the vegetation zones in the Turimiquire Range lie at substantially lower levels than in the Andes and Venezuelan coastal range farther west (Chapman 1925). Two females captured by the Smithsonian Venezuelan Project had four embryos, and one had five in June–July (USNM specimen tags). For parasites, see Furman (1972a), P. T. Johnson (1972), and Tipton and Machado-Allison (1972). Guerrero (1985) listed the ectoparasites recorded from all species of Venezuelan *Rhipidomys*.

Map 322 Selected localities for *Rhipidomys tenuicauda* (○), *Rhipidomys venustus* (■), and *Rhipidomys wetzeli* (●). Contour line = 2,000 m.

REMARKS: This member of the “fulviventer” section of *Rhipidomys* resembles Colombian *R. fulviventer* in its moderately small size, although the holotype is an unusually small specimen (but with molars of normal size). The xeric lowlands of the Depresión de Unare in Anzoátegui state separate its range from that of the larger *R. venustus*, which inhabits the higher parts of the Venezuelan coastal range farther west, and by the llanos of the lower Orinoco drainage from the range of the smaller *R. wetzeli*, found in the region of the tepui inselbergs to the south. Musser and Carleton (2005) considered *tenuicauda* a subjective junior synonym of *R. fulviventer*. It is hypothesized here to be a species in its own right on biogeographical grounds, insofar as it is separated from the range of *R. fulviventer* in the Eastern Cordillera of the Andes by approximately 1,000 km of lowlands and mountains, which are partly occupied by the allied yet distinct form *R. venustus*. Future molecular data may help to demonstrate whether this chain of forms has resulted from a process of vicariant isolation on mountain blocks.

Rhipidomys tribei B. M. de A. Costa, Geise, Pereira, and L. P. Costa, 2011

Tribe's *Rhipidomys*

SYNONYM:

Rhipidomys tribei B. M. de A. Costa, Geise, Pereira, and L. P. Costa, 2011:947; type locality “Reserva Particular do Patrimônio Natural Santuário do Caraça, 25 km SW Santa Bárbara, Minas Gerais, Brazil, 20°05'S, 43°30'W, 1,300 m.”

DESCRIPTION: Small, with average head and body length of 116.8 mm (observed range: 96–130 mm) and long tail 115–137% of body length. Dorsal pelage yellowish brown to reddish brown; coat comprises short (7–9 mm) tribanded hairs, black at tip, reddish brown or dark yellow in middle, with gray bases; longer guard hairs (11–15 mm) typically black but may bleach to reddish brown with translucent tips; ventral pelage white and distinct from dorsal color, sometimes with small areas of light gray hair at sides of abdomen; dorsal fur extends onto base of tail for maximum of 8 mm; tail unicolored; scales small (0.5–0.7 mm in length), three hairs emerging from under each one; tail hairs increase in length gradually from tail base to tip, forming short terminal brush or tuft up to 7 mm in length. Ears small to medium, between 16 and 21 mm in length, sparsely covered with short brown hairs on both surfaces. Hindfeet covered dorsolaterally with white hairs that extend onto toes; mid-dorsal surfaces with patch of light brown or gray hairs.

Skull with smallest average total length of all *Rhipidomys* species in southeastern Brazil, with mean condyloincisive length 28.5 mm. Rostrum short (less than one-third length of skull) and somewhat broad (more than one-half rostral length); lacrimal capsules slightly inflated; gnathic process present; nasal bones broad anteriorly, narrowing to posterior margin; nasals not contacting or extending posteriorly beyond maxillofrontal suture; anterior edges of zygomatic plates slightly rounded to rectangular and not protruding anterior to maxillary roots of zygomatic arches; zygomatic notches narrow and rather shallow; dorsal projections of lacrimal bones relatively large, elongated, and laterally expanded; interorbital convergent anteriorly, with slight medial constriction, strongly divergent posteriorly, with usually rounded borders and no supraorbital crest; hamular processes of squamosals separating enlarged subquamosal fenestrae from smaller postglenoid foramina; slender alisphenoid struts present in all specimens; small stapedial foramen, no translucent groove across the inside of the braincase, and no sphenofrontal foramen signal derived carotid circulatory pattern 3 (of Voss 1988); margins of incisive foramina expanded medially but converging both anteriorly and posteriorly, giving overall diamond shape to opening; foramina extending posteriorly to line joining upper M1 alveoli; mesopterygoid fossa long, with small postpalatal projection, reaching line across posterior margins of M3 alveoli; sphenopalatine vacuities either absent or greatly reduced.

Upper incisors slightly opisthodont. Anteroflexus and anteromedian flexus of M1 small and separate anteroloph into anterolabial and anterolingual conules; protoflexus and hypoflexus of M1 typically small. M2 with Protoflexus absent or reduced and hypoflexus short; both paraflexus

and metaflexus long and angled sharply, sometimes slightly bifurcated at their inner ends; medial fossette frequently present on M2, labial fossette usually absent.

DISTRIBUTION: *Rhipidomys tribei* is known from the type locality and two others in southeastern Minas Gerais state, Brazil, at middle elevations up to 1,300 m. Specimens with low-FN karyotypes from the hills of southern Espírito Santo state may be referred to this species.

SELECTED LOCALITIES (Map 314): BRAZIL: Espírito Santo, Vargem Alta, Hotel Monte Verde (UFPB 345); Minas Gerais, Santa Bárbara, Reserva Particular do Patrimônio Natural Santuário do Caraça (type locality of *Rhipidomys tribei* B. M. de A. Costa, Geise, Pereira, and L. P. Costa), Viçosa, Mata do Paraíso (MZUFV 386).

SUBSPECIES: *Rhipidomys tribei* is monotypic.

NATURAL HISTORY: Little is known about the ecology of this species. The few available specimens were collected in riparian semideciduous submontane forest patches surrounded by grasslands. The habitat at Serra do Brigadeiro was described by J. C. Moreira et al. (2009).

REMARKS: As mentioned in the account of *R. itoan*, this species and *R. tribei* form a sister-clade pair within the limited phylogeny of Brazilian species that have been compared using mtDNA cytochrome-*b* sequences. This pair of species, in turn, is sister to sequences of *R. leucodactylus* within the larger “leucodactylus” section of the genus (B. M. de A. Costa et al. 2011). This is the taxon referred to as “*R. sp. 3*” by R. G. Rocha, Ferreira, Costa et al. (2011) in their phylogenetic analysis of mtDNA cytochrome-*b* sequences. Specimens from southern Espírito Santo state herein referred to this species have karyotypes of $2n=44$, FN=50 (Zanchin, Langguth, and Mattevi 1992; Thomazini 2009).

Rhipidomys venezuelae Thomas, 1896

Venezuelan Rhipidomys

SYNONYMS:

Rhipidomys venezuelae Thomas, 1896:303; type locality “Merida, Venezuela, alt. 1630 metres.”

R[*hipidomys*]. *v*[*enezuelae*]. *typicus* Thomas, 1900c:271; *nomen nudum*; referring to material from the type locality in comparison with his new subspecies *Rhipidomys venezuelae cumananus* (= *Rhipidomys couesi* herein).

Rhipidomys venezuelae venezuelae: Gyldenstolpe, 1932: 46; name combination.

[*Rhipidomys*] *venezuelanus* Tate, 1939:195; incorrect subsequent spelling of *venezuelae* Thomas.

Rhipidomys mastacalis venezuelae: Cabrera, 1961: 423; name combination.

DESCRIPTION: Medium to large (head and body length usually 130–150 mm) with long tail (110–135% of head and body length); dorsal pelage rich reddish to duller

yellowish brown with slight to moderate agouti effect; sides of head and body generally paler; ventral pelage white or cream colored, sometimes with pale grey bases; pelage relatively soft and fine. Tail pale to medium brown, sometimes darker; shaft covered with short hairs, lengthening only close to tip, and terminal pencil short (rarely longer than 6 mm). Ears large relative to body size, pale to medium brown in color. Hindfoot length 26–29 mm; pes moderately broad with proportionally rather short and thick digits; colored pale brown with faint, darker patch over metatarsals. Skull elongated, becoming angular and flattened in older specimens; rostrum broad and nasals parallel sided along posterior half; supraorbital ridges not highly divergent, and interorbit and frontal bones both long; braincase not inflated; mesopterygoid fossa expanded anteriorly, sphenopalatine fissures small or absent; parapterygoid fossae not fenestrated and often recessed; auditory bullae moderate in size. Upper molar row generally 4.9–5.4 mm in length, rather larger in relation to skull length than average for genus.

DISTRIBUTION: *Rhipidomys venezuelae* occurs in northern Colombia and in northwestern and northern Venezuela. It is found at low to lower-middle elevations in the Sierra Nevada de Santa Marta, Serranía de Perijá, Mérida Andes (notably the Chama valley), Serranía de San Luis, and Cordillera de la Costa as far east as Guárico state as well as in the intervening and coastal lowlands.

SELECTED LOCALITIES (Map 323): COLOMBIA: César, El Orinoco, Río César (USNM 280447); La Guajira, Fonseca, Las Marimondas (USNM 280442); Magdalena, Hacienda Cincinati (AMNH 32667). VENEZUELA: Aragua, Estación Biológica Rancho Grande (USNM 517589); Falcón, Cerro Santa Ana, Península de Paranaguá (USNM 456363), La Pastora, 14 km ENE of Mirimire (USNM 442137); Guárico, Parque Nacional Guatopo, 40 km SSE of Caracas (O'Connell 1989); Lara, Caserío Boro, 13 km W of El Tocuyo (USNM 456374); Mérida, Hacienda Santa Catalina, Río Chama (FMNH 21826); Trujillo, Isnotú (USNM 371251); Zulia, Misión Tukuko (USNM 448629).

SUBSPECIES: As currently understood, *Rhipidomys venezuelae* is monotypic.

NATURAL HISTORY: *Rhipidomys venezuelae* inhabits both moist and dry forests in northern South America, its dorsal pelage generally being redder in the former and grayer and more agouti in the latter. Handley (1976) provided habitat data for Smithsonian Venezuelan Project specimens. O'Connell (1989) discussed the population dynamics of *R. venezuelae* (reported as "*R. mastacalis*") in premontane rainforest in Guatopo National Park, on the southern slopes of the Venezuelan coastal range. For parasites, see Ferris (1921), Hopkins (1949), Furman (1972a), P. T. Johnson (1972), E. K. Jones et al. (1972), Machado-

Map 323 Selected locality for *Rhipidomys venezuelae* (●). Contour line = 2,000 m.

Allison and Barrera (1972), Tipton and Machado-Allison (1972), Brennan and Reed (1974a), and Saunders (1975). Guerrero (1985) listed the ectoparasites recorded from all species of Venezuelan *Rhipidomys*.

REMARKS: *Rhipidomys venezuelae* is a member of the "leucodactylus" section of the genus. The taxon has been variously treated as a species in its own right or as a subspecies of *R. mastacalis* (e.g., Cabrera 1961). Tribe (1996) tentatively placed it as a subspecies of *R. latimanus*, to which it is closely allied morphologically (see Remarks under that species). López-Fuster et al. (2001) described cranial allometry in *R. venezuelae*.

A single small specimen from Bonda, on the seaward side of the Sierra Nevada de Santa Marta in northern Colombia, was found by Tribe (1996) to be morphometrically much closer to *Rhipidomys nitela* than to *R. venezuelae*. Voss et al. (2001) considered such an association implausible and suggested that this specimen represented another taxon, possibly allied to *R. venezuelae*. Further material will be needed to resolve this issue.

There have been several reports that a distinct species of *Rhipidomys* inhabits the llanos (Eisenberg et al. 1979; Poulton 1982; O'Connell 1982, 1989; August 1984). Because the only material I have seen from the llanos consists of a possibly mismatched juvenile skull and skin, it is not clear whether these reports involve a new taxon or a geographical variant of *R. venezuelae*, *R. couesi*, or *R. nitela*.

Rhipidomys venustus Thomas, 1900

Mérida Highland *Rhipidomys*

SYNONYMS:

Rhipidomys venustus Thomas, 1900a:152; type locality "Las Vegas del Chama, alt. 1400 m," Mérida, Venezuela.

Rhipidomys latimanus venustus: Cabrera, 1961:420; name combination.

DESCRIPTION: Medium to large (head and body length 120–145 mm) with moderately long tail (120–140% of head and body length). Pelage soft and dense, bright chestnut brown on dorsum and white-tipped over dark slate hair bases below. Tail sometimes reddish rather than dark, terminating in pencil of hairs 10–15 mm in length. Ears large, well haired, and dark. Hindfeet range from 26–30 mm in length and bear well-defined dark patches over metatarsals; sides of metatarsal portion and toes yellowish white. Skull has narrowed interorbital region with supraorbital ridges slightly more pronounced than in related species in “fulviverter” section; braincase rounded rather than angular; parapterygoid fossae often fenestrated; carotid circulation pattern primitive (large stapedial foramen, internal groove on squamosal and alisphenoid, and sphenofrontal foramen present). Maxillary tooththrow averages 5 mm in length (range: 4.81–5.18 mm), average in comparison with skull length for genus.

DISTRIBUTION: *Rhipidomys venustus* is endemic to Venezuela, occurring in the Venezuelan Andes in the states of Mérida and Trujillo at elevations mostly above 2,000 m and potentially also in the adjoining, eastern part of Táchira state. Disjunct populations morphologically referable to this species have been found at elevations above 1,300 m in isolated mountain ranges farther northeast in Falcón and Yaracuy states, and in the Cordillera de la Costa in both Aragua and Vargas states and the Distrito Capital.

SELECTED LOCALITIES (Map 322): VENEZUELA: Aragua, Monumento Natural Pico Codazzi (F. J. García and Sánchez-González 2013); Distrito Capital, Pico Ávila, near Hotel Humboldt (USNM 371236); Falcón, Serranía de San Luis, Parque Nacional Juan Crisóstomo Falcón, Sector Cumbres de Uria, ca. 9 km N of Cabure, ca. 1,320–1,370 m (R. P. Anderson et al. 2012); Mérida, La Coromoto, 7 km SE of Tabay (USNM 387909), Páramo de Mariño, Mérida/Táchira border (Durant and Díaz 1995); Trujillo, Hacienda Misisí (USNM 374528); Yaracuy, Sierra de Aroa, Parque Nacional Yurubí, Sector El Silencio, La Trampa del Tigre (F. J. García and Sánchez-González 2013).

SUBSPECIES: *Rhipidomys venustus* is monotypic.

NATURAL HISTORY: Specimens of *R. venustus* and *R. tenuicauda* captured by the Smithsonian Venezuelan Project (N=52) were collected in cloud forest (55%), evergreen forest (40%), and orchards (5%); most were found in trees and vines (68%), a few in houses (5%), and the remainder under bushes, on rock ledges, and in a log (Handley 1976; all identified as “*Rhipidomys venustus*”). Other specimens were taken in coffee plantations. Capture elevations were mostly between 2,000 and 3,350 m (specimen tag data), but the elevations of Salomón Briceño Gab-

aldón’s capture localities near Mérida as given on specimen tags (from 1,400 to 4,000 m) are questionable. Near Mérida, Aagaard (1982) found the species to be predominantly arboreal, with 80% of captures in trees. Individuals were more likely to come down to the ground in the wetter forests than at higher elevations. Aagaard (1982) also provided data on population ecology and reported that one female had two embryos in the wet season. One USNM specimen had one embryo in September (specimen tag). For parasites, see Ferris (1921), Furman (1972a), P. T. Johnson (1972), E. K. Jones et al. (1972), Machado-Allison and Barrera (1972), Tipton and Machado-Allison (1972), and Brennan and Reed (1974a). Guerrero (1985) listed the ectoparasites recorded from all species of Venezuelan *Rhipidomys*.

REMARKS: *Rhipidomys venustus* is a moderately large species in the “fulviverter” section of the genus. The Táchira Depression (at roughly 1,000 m elevation) separates the range of this species from that of *R. fulviverter* to the southwest. The populations in the Cordillera de la Costa (Vargas to Aragua states) and in the Sierra de Aroá (Yaracuy state) and Sierra de San Luis (Falcón state) are isolated from the main species range in the Mérida-Trujillo Andes by dry lowlands. Further research, preferably using DNA sequences, is needed to determine how closely related these forms are to each other and to other members of the “fulviverter” group. Tribe (1996) treated the two forms in the Mérida-Trujillo Andes and in the Cordillera de la Costa as subspecies of *R. fulviverter*; see also the Remarks under both that species and *R. tenuicauda*.

Rhipidomys wetzeli A. L. Gardner, 1990

Wetzel’s Rhipidomys

SYNONYMS:

Rhipidomys wetzeli A. L. Gardner, 1988:744; *nomen nudum*.
Rhipidomys wetzeli A. L. Gardner, 1990:417; type locality “Camp VII (00°50′40″N, 65°58′10″W), 1800 m, Cerro de la Neblina, Territorio Federal Amazonas, Venezuela.”

DESCRIPTION: Very small (averaging <100 mm in head and body length) with bright orange dorsal pelage finely streaked with black, sides paler than dorsum, and ventral pelage with cream or pale orange hair tips over dark gray bases. Tail uniformly medium to dark brown, long (130–150% of head and body length), inconspicuously covered with short hair proximally but terminating in long pencil extending approximately 20 mm from terminal caudal vertebra. Ears conspicuously darker than back. Hindfeet short (21–25 mm), with dark patch over metatarsal region that may be restricted to small spot at base of toes. Skull small with rounded interorbit, very slight supraorbital ridges, and broad, globose braincase; carotid circulation pattern primitive (large stapedial fo-

ramen, a groove along inner surface of squamosal and alisphenoid, and sphenofrontal foramen); sphenofrontal foramina often contacting frontal bones, in contrast to their position in other “fulviventer” section members; sphenopalatine fissures usually present; paroccipital processes with bifurcated tips. Molar toothrows very short, 3.5–3.8 mm long in northern part of range to 3.8–3.9 mm in south.

DISTRIBUTION: *Rhipidomys wetzeli* is found at middle elevations on the tepui table mountains of the Guiana shield. The species is currently known from only a few localities within Parque Nacional Canaima (eastern Bolívar state) and in central and southern Amazonas state, Venezuela; it has been reported from the Guyanese side of Mount Roraima. It may also occur on the Brazilian side of the mountains along the Venezuelan-Brazilian border.

SELECTED LOCALITIES (Map 322): GUYANA: Cuyuni-Mazaruni, slopes of Mount Roraima (Lim, Engstrom, and Ochoa 2005). VENEZUELA: Amazonas, Cerro Duida, Cabecera del Caño Culebra (A. L. Gardner 1990), Cerro Neblina, Camp VII (type locality of *Rhipidomys wetzeli* A. L. Gardner); Bolívar, Churi-tepui, Camp 5 (A. L. Gardner 1990), km 125, 85 km SSE of El Dorado (A. L. Gardner 1990).

SUBSPECIES: *Rhipidomys wetzeli* is monotypic.

NATURAL HISTORY: Specimens of *Rhipidomys wetzeli* were captured at elevations between 1,032 m and 1,850 m. Those from Bolívar state were trapped in cloud forest, mostly on logs above the ground (data from specimen tags). The holotype was lactating when collected in December; its uterus had two embryo scars (A. L. Gardner 1990). For parasites, see Furman (1972a) and P. T. Johnson (1972).

REMARKS: *Rhipidomys wetzeli* is a very small member of the “fulviventer” section of the genus, closely resembling *R. caucensis* from the Colombian Andes except in its primitive carotid circulation pattern and slightly longer tail. The year of publication is often given as 1989 (e.g., Musser and Carleton 2005), but the book in which *wetzeli* Gardner is described was published on February 6, 1990.

Genus *Thomasomys* Coues, 1884

Víctor Pacheco

I recognize 44 species of *Thomasomys* (Pacheco 2003; Voss 2003; Salazar-Bravo and Yates 2007), all of which are endemic to South America in tropical and subtropical habitats. Members of the genus are distributed mainly along the Andean cordillera in premontane and montane forests and páramo, in shrubby and forested habitats, from about 09°N in the department of Trujillo, northern Venezuela to

nearly 18°S in Cochabamba and Santa Cruz, southern Bolivia, including isolated ranges such as the Serranía de la Macarena. The elevational range spans over 3,300 m, from about 1,200 m to above 4,500 m. *Thomasomys* is absent in the Guiana Shield, lowland tropical forests, desert regions, and oceanic islands.

Pacheco (2003) provided details of external and cranio-dental characters of all *Thomasomys*; the descriptions and terminology that follow stem from this treatise, unless otherwise noted. Species of *Thomasomys* span a considerable range in body size, with head and body length ranging 80–238 mm, and mass 14–335 g. Feet are usually narrow and long, but may be moderately broad and short; length from 14–59 mm. The ears are short or medium sized and hairless, with the length from 12 mm to 33 mm. The tail is slender, medium or long, 85–330 mm, representing from 76%–180% of head and body length. The tail is also naked or finely haired, occasionally with a short pencil of hair at the tip but never as developed as in *Rhipidomys*. The tail is also usually uniform in color but often has a terminal white tip. The hindfoot has relatively moderate or long metatarsals; digits I and V are usually longer than in nonthomasomyine rodents. Digit I of pes (with claw) extends close to or to the interphalangeal joint of dII; dV (with claw) of pes extends about half the length of the second phalanx or to the base of claw of dIV. Digit V is partly opposable in some species. The ventral base of claws on manus is usually closed, although is partially keeled or open in a few species. There are six large or medium plantar pads; the hypothenar and thenar are separated or not by a gap; and the hypothenar and fourth interdigital pad are separated by a gap. The dorsal surface of the metatarsus is uniformly colored, whitish or brownish, but a dark metatarsal patch is present in some species. The feet possess silvery ungual tufts. Female *Thomasomys* have six mammae, in inguinal, abdominal, and thoracic positions. Most *Thomasomys* have a conspicuously protuberant anus, usually approaching the size of the prepuce or larger (first noted by Stone 1914).

Thomasomys is characterized by a dull brown or bright reddish color. The dorsal coloration varies from olivaceous gray, dull olive fulvous, yellowish rufous, orange rufous, golden brown, reddish brown, and grayish brown to dark brown or almost black (Nowak 1999). Dorsal pelage is usually long, dense and soft in contrast to most *Rhipidomys* and *Chilomys*, and uniform except in a few species where a faint mid-dorsal band is conspicuous. The under parts are generally not much paler than the upper parts, with slate-based hairs uniformly extending from the gular to the inguinal region; pectoral spots are rare. Mystacial, superciliary, submental, and interramal vibrissae are present, but genal 1 may be present or absent, and both mystacial and superciliary vibrissae are long or very long,

extending slightly or well beyond the pinnae when pressed back. The eyes are small to medium size, typically without an eye-ring. The muzzle is usually the same coloration as the dorsal pelage. A postauricular patch and a pectoral patch are occasionally present.

Adult skulls of *Thomasomys* range from about 24.9 to 50.7 mm in greatest length. In dorsal view, they have short and blunt to moderately long rostra, and a shallow zygomatic notch (depth less than half the width of notch), except in *T. niveipes* and *Thomasomys* sp. 2. Absence of a rostral tube is the common condition, but a moderate or distinct tube also occurs in some species in the genus. The zygomatic plates are usually moderately broad (i.e., the breadth is subequal to the length of M1), although it is narrow (i.e., the breadth is shorter than the length of M1) in a few species; the plate is either vertical or slopes backward conspicuously from its base. The zygomatic arches are variable, converging anteriorly, widely flaring, or almost parallel; squamosal roots of the zygomatic arches may or may not be laterally expanded. The interorbital region is usually narrow (i.e., the maxillary bridge of the molar rows and the base of the zygomatic plates are well to moderately exposed when the skull is seen in dorsal view), but it is moderately broad in some taxa with the interorbital region obscuring these structures (e.g., *T. erro* and few other species). It is usually hourglass in shape, with rounded or square supraorbital margins (distinct supraorbital crests are absent). Parietal ridges are usually absent, but postorbital ridges are conspicuous in some species, particularly those of the “aureus” group. The dorsal profile of the skull (in lateral view) is usually flattened from nasal tips to midfrontal region. The shape of the braincase varies, either globose or oblong, and is usually unmarked by prominent temporal scars or lambdoidal ridges (except in members of the “aureus” group). The interparietal bone is long (in the sagittal plane), usually exceeding 40% of the length of the interparietal suture, and wide with an oblong, half-oblong, or subrectangular shape. The posterodorsal extensions of the premaxillae (in dorsal view) are usually short, terminating anterior or subequal to the nasals (except in the “baeops” group). Ventrally, the skull has short or relatively long incisive foramina that may extend posteriorly between the M1 procingulum. The palatal bridge (*sensu* Hershkovitz 1962) is short, not extending posteriorly beyond the M3s, and usually broad (except in *T. macrotis* and the “aureus” group); its posterior margin is usually rounded, roughly squared, and with or without a small median process. Posterolateral palatal pits are small, simple inconspicuous perforations (without accessory pits and never recessed in shallow fossae), and placed level with or lateral to the anterior margin of the mesopterygoid fossa. The mesopterygoid fossa is usually broad,

with its breadth greater than the breadth of parapterygoid fossa determined at the level of presphenoid-basisphenoid suture; the anterior margin is usually U-shaped and more or less expanded; the sides are subparallel or converge posteriorly; and the bony roof is complete or pierced by short, slit-like to moderate sphenopalatine vacuities flanking the presphenoid-basisphenoid suture. The parapterygoid fossae are triangular, shallow, or moderately deep. Ethmoturbinals are usually large or moderate. An alisphenoid strut that separates the buccinator-masticatory and accessory oval foramina is usually present. The auditory bullae vary from small and uninflated to large and inflated, and are suspended anteriorly by a broad overlap between the tegmen tympani and the posterior suspensory process of the squamosal. The anterodorsal lamina of the ectotympanic does not contact the petrosal, thus producing a gap in most *Thomasomys* as the dorsal margin of the auditory meatus appears to be “open.” The thin and long hamular process separates a distinct postglenoid foramen from the subsquamosal fenestra. The postglenoid foramen is comparatively small but may be large and elongated, whereas a conspicuous subsquamosal fenestra extends dorsally to the level of the posterior projection of the squamosal root of the zygomatic arch. The carotid circulation pattern is either primitive (pattern 1) or derived (pattern 3), as indicated by the presence or absence of a stapedia foramen, or an internal squamosal-alisphenoid groove and sphenofrontal foramen, respectively (see Voss 1988). A somewhat square-shaped malleus lamina and a slender processus brevis of incus are exhibited in most *Thomasomys*; the orbicular apophysis of the malleus is usually large.

The mandible ranges from slender to moderately robust; the coronoid process is slightly falciform, delimiting a small sigmoid notch, and is somewhat higher than or level to the condylar process. The angular process is usually shorter than the condylar process and delimits a shallow angular notch. A capsular process may be either present or absent. The anterior edge of the masseteric crest is placed distinctly posterior to the procingulum of m1 in most *Thomasomys*. The basihyal is somewhat straight (not strongly arched) and lacks an entoglossal process.

The upper incisors (*sensu* Hershkovitz 1962) are usually orthodont or slightly opisthodont (slightly proodont in a few species). The molars are pentalophodont, with distinct mesolophs in upper and lower molars, brachydont or moderately hypsodont, and lack well-developed cingula and stylar cusps. The labial and lingual folds of upper molars usually do not interpenetrate more than the toothrow axis, except in a few species that show a comparatively slight interpenetration (e.g., *T. kalinowskii*). The upper molars have three roots, and the lower have two, although M1 sometimes exhibits an accessory labial root. Typically, a

deep anteromedian flexus divides the M1 antercone in roughly two conules, although the flexus is indistinct in a few species; the conules are subequal in size except for the small anterolingual conule exhibited in *T. notatus*. The protostyle and enterostyle are usually absent in M1, although both are conspicuous in some species. M1 lacks additional accessory cusps, although the procingulum exhibits an accessory lophule in some members of the “aureus” group. The anteroloph in M1 is typically distinct and oriented perpendicularly to the labial margin, except in the “aureus” group where is labially and posteriorly oriented. The main cusps of M1 and M2 are arranged in slightly alternating pairs. The anteromedian flexid varies either present (e.g., *T. aureus*) or absent to indistinct, even in unworn dentitions (e.g., *T. ucucha*). A ridge on the anterolabial cingulum of m1 is present in most *Thomasomys* (A. L. Gardner and Romo 1993; Pacheco 2003). The anterolabial cingulid in m2 and m3 varies from distinctly present only in m2 to present and well developed in both molars.

The vertebral count is 7 cervical, 13 thoracic, 6 lumbar, 4 sacral, and 36 or more caudal; with 13 pairs of ribs (Steppan 1995; Pacheco 2003). The anconal fossa of the distal humerus has a thin translucent lamina that may be pierced (most often) or not by a small perforation. Separate chevron bones are often seen in *Thomasomys*, although these elements may fuse, forming an arch without a spinous process in several species (Steppan 1995; Pacheco 2003). The trochlear process of the calcaneus is generally level to or overlaps with the posterior articular facet. The peroneal process of the fifth metatarsal is moderately long but does not quite extend to the proximal edge of the cuboid.

Most *Thomasomys* species possess a gall bladder (Voss 1991a; Pacheco 2003) and a unilocular-hemiglandular stomach (Carleton 1973; Pacheco 2003), but see exceptions in the species accounts. The soft palate has two complete diastemal and usually five incomplete intermolar ridges (Pacheco 2003). The glans penis is notably variable within the genus (Hooper and Musser 1964; Pacheco 2003). Its body may be short or long, always covered by spines, with shallow or moderate mid-dorsal and midventral grooves; the lateral bacular mounds are usually simple (except by a triple-curved or pointed shape) and extend to near the crater rim or just beyond it (Hooper and Musser 1964; Pacheco 2003). Lateral mounds, bifurcated urethral flaps, and dorsal papilla may or may not bear spines (Pacheco 2003).

Preputial glands vary in number; they may be absent, present as a single pair, or more numerous (Carleton 1980; Voss and Linzey 1981; Pacheco 2003). The medial and lateral ventral prostates are generally of equal size, although either the medial pair (e.g., *Thomasomys* sp. 5 and *T. emeri-*

tus [reported as *laniger*]) or the lateral ventral pair (e.g., *T. cinereus*) may be distinctly larger (Carleton 1980; Voss and Linzey 1981; Pacheco 2003).

The known karyotypes of *Thomasomys* are conservative, typically with a diploid number of $2n=40, 42,$ or 44 (except *T. niveipes* with $2n=24$). The number of autosomal arms varies slightly, with $FN=40, 42,$ or 44 (A. L. Gardner and Patton 1976; Gómez-Laverde et al. 1997; Aguilera et al. 2000; Salazar-Bravo and Yates 2007), with the exception of *Thomasomys* sp. 4 ($FN=47$; Pacheco et al. 2012).

A phylogenetic analysis of thomasomyine rodents based on morphological characters, including all species of *Thomasomys* reported at that time, found a polyphyletic *Thomasomys* that included the species of *Aepeomys* (Pacheco 2003). After *Aepeomys* was removed as a separate genus from *Thomasomys* (see Remarks), Pacheco (2003) proposed that *Thomasomys* could be differentiated into six species groups (“cinereus,” “aureus,” “baeops,” “gracilis,” “macrotis,” and “notatus”) that he hypothesized constituted natural groups at the genus-group level. Further research has revealed a cluster of species allied to *T. incanus* (V. Pacheco, unpubl. data), which is included here as the “incanus” species group.

Pending further taxonomic and phylogenetic work, I tentatively follow my earlier arrangements as a working hypothesis. (1) The “cinereus” species group includes small and medium-sized species distributed throughout the montane forests from the cordilleras of Venezuela, Colombia, to southeastern Bolivia (although most of the species concentrate in the Northern Andes, from Colombia to northern Peru) with long and soft adult pelage, large protuberant anus, genal 1 vibrissae absent, rostral tube absent, auditory bullae inflated or uninflated, small anterior process of ectotympanic, maxillary palatal pits absent, and carotid circulation primitive (except *T. daphne*) with stapedial foramen, squamosal-alisphenoid groove, and sphenofrontal foramen present (pattern 1 of Voss 1988). M2 protoflexus is faint or absent, capsular process is absent or indistinct, glans penis usually without a notch on midventral crater margin, and preputial glands are usually absent.

(2) The “incanus” species group includes medium-sized rodents distributed throughout the montane forests of the Southern Andes (from northern Peru to northern Bolivia, south of the Huancabamba Deflection). This group is similar to the “cinereus” group except that included taxa exhibit a derived carotid circulation, pattern 3 (Voss 1988); and a rostral tube is usually present.

(3) The “aureus” species group includes mainly large-sized rodents distributed throughout the montane forests from the cordilleras of Venezuela and Colombia to southeastern Bolivia. The dorsal pelage is long and soft and generally brown reddish; hypothenar and thenar pad of pes

level or overlapping; digit I of pes (hallux) is long, extending to the first interphalangeal joint of digit II or beyond; digit V is very long, extending to the base of claw of digit IV or beyond; genal 1 vibrissae are present; mystacial vibrissae are very long, extending well beyond the posterior margin of the pinnae to a point greater than the length of one pinna; and the body pelage pattern is moderately countershaded. Their skulls are characterized by a narrow and convergent interorbital region, not beaded; a large postglenoid foramen, with the anterior margin at level with the tegmen tympani or extended forward; incisive foramina long extending between the M1 procingula; molar-bearing portion of the maxillae rectangular; carotid circulation pattern derived, pattern 3 (*sensu* Voss 1988); upper incisors opisthodont (*sensu* Hershkovitz 1962); the anteroloph labially and posteriorly oriented; M1 paraloph oriented backward to the mesoloph; the molar hypoflexus broad; and lower molars with a distinct anteromedian flexid and broad and curved posteroflexids. The stomach morphology has an intermediate incisura angularis; and preputial glands are numerous.

(4) The “baeops” species group includes small to medium-sized rodents distributed throughout the montane forests of the northern Andes (from Colombia to northern Peru, mostly north of the Huancabamba Deflection). The pelage is comparatively short, and generally grayish or brownish; genal 1 vibrissae are present; and the hindfeet are short and relatively broad. The skull is characterized by a short rostrum, narrow interorbital region, derived carotid circulation (pattern 3, *sensu* Voss 1988); mesopterygoid fossa breadth subequal; anterior process of the ectotympanic small; and distal portion of the lateral bacular mounds pointed.

(5) The “gracilis” species group includes small or medium-sized rodents distributed throughout the montane forests of the southern Andes (from northern Peru to Bolivia, south of the Huancabamba Deflection). The pelage is comparatively moderate or usually long, dense, and soft, and generally brownish; hindfeet are short and relatively broad. The skull has a short to moderate rostrum and narrow interorbital region. The carotid circulation is primitive (pattern 1, *sensu* Voss 1988); and bullae are either inflated with indistinct bony tubes or moderately inflated with short bonytubes.

(6) The “macrotis” species group includes only *T. macrotis*, a large mouse with comparatively large ears that is distributed only in the isolated mountains of the Cordillera Oriental of Peru, between the Río Marañón and Huallaga, south of the Huancabamba Deflection. This species group shares characteristics with both the “incanus” and “aureus” groups. The pelage is soft and long; genal 1 vibrissae are absent; the hindfoot is long and relatively broad;

the ventral base of manual claws are medially keeled; and the tail is moderately long with more than one third of its length white. The skull is characterized by a long rostrum, derived carotid circulation (pattern 3 of Voss 1988), a palate narrow, short premaxillae that terminate anterior to nasals and the zygomatic notch, large molars with the flexus(ids) with an incipient crenulation, and two lingual roots on M1.

(7) The “notatus” species group includes only *T. notatus*. These are medium-sized rodents distributed throughout the montane forests of the central Andes (north and central Peru, south of the Huancabamba Deflection). The dorsal pelage is comparatively short, generally orangish brown, and distinctly countershaded; hindfeet are short and relatively broad; and the tail is moderately long and with a terminal pencil. The skull has a short rostrum and narrow interorbital region, the primitive carotid circulation, a long postglenoid foramen that projects anterior to the tegmen tympani, sphenopalatine vacuities with moderately large perforations, uninflated bullae with distinct bony tubes, and a rectangular-shaped molar-bearing portion of the maxillae. The anterocone also presents a small anterolingual conule. Preputial glands are absent, and the glans penis has shallow middorsal and midventral grooves and large and spiny lateral bacular mounds that are triple curved (Hooper and Musser 1964; Pacheco 2003).

Apparently the Huancabamba Deflection has been a key geographic barrier that limits the distribution of several of these hypothetical species groups.

As mentioned previously, *Thomasomys* species exhibit considerable morphological variation that makes the diagnosis and determination of species and species groups difficult. Karyotype and molecular data remain limited despite the pivotal role these types of data have played in discriminating certain taxa and allying others (e.g., Gómez-Laverde et al. 1997; M. F. Smith and Patton 1999; Salazar-Bravo and Yates 2007). Much more work in the fields of genetic and molecular systematics, in conjunction with basic and detail morphological description, is needed to test the hypotheses of species and species groups presented here. The lack of complete skeletons and specimens preserved in fluid for many species have limited access to key morphological characters (e.g., glans penis, reproductive tract, stomach morphology); greater attention is needed to increase this type of preserved material.

SYNONYMS:

Hesperomys: Tomes, 1860a:219; part (description of *aureus*); not *Hesperomys* Waterhouse.

Hesperomys (*Rhipidomys*): Thomas, 1882:108; part (description of *cinereus* and *taczanowskii*); neither *Hesperomys* Waterhouse nor *Rhipidomys* Tschudi.

Hesperomys (*Vesperimus*): Thomas, 1884:449; part (listing of *cinereus* and *taczanowskii*); neither *Hesperomys* Waterhouse nor *Vesperimus* Coues.

Thomasomys Coues, 1884:1275; as subgenus of *Hesperomys*; type species *Hesperomys cinereus* Thomas, by original designation.

Oryzomys: Thomas, 1894b:349; part (description of *incanus* and *kalinowskii*); not *Oryzomys* Baird.

Peromyscus (*Thomasomys*): E.-L. Trouessart, 1897:512; part (listing of *cinereus* and *kalinowskii*); not *Peromyscus* Gloger.

Aepeomys: Thomas, 1898e:452; part (description of *vulcani*); not *Aepeomys* Thomas.

Thomasomys: Thomas, 1906c:443; raised to rank of genus.

Erioryzomys Bangs, 1900a:96; type species *Oryzomys monochromos* Bangs, by original designation.

Inomys Thomas, 1917d:197; type species *Oryzomys incanus* Thomas, by original designation.

REMARKS: *Thomasomys* is a speciose and taxonomically complex genus whose nomenclatural history is intertwined with *Aepeomys*, *Delomys*, and *Wilfredomys*, taxa that have been viewed as subgenera (e.g., Ellerman 1941; Cabrera 1961; Pine 1980) or as genera (see their accounts). *Thomasomys* has subsequently been restricted (Voss 1993; E. M. González 2000) to a smaller but still speciose group that is endemic to tropical Andean cloud forests. The center of diversity for the genus apparently includes eastern Ecuador (Voss 2003).

With very limited taxon sampling in molecular phylogenetic analyses, both M. F. Smith and Patton (1999) and D'Elía et al. (2003) found *Thomasomys* to the sister genus to *Chilomys*. Alternatively, Pacheco's (2003) cladistic analysis derived from morphological characters supported a polyphyletic *Thomasomys*, with species members of the "baeops," "gracilis," and "notatus" species groups connected to a monophyletic *Rhipidomys*. The phylogenetic analysis of Salazar-Bravo and Yates (2007), based on mtDNA cytochrome-*b* sequences from 15 taxa of *Thomasomys*, revealed some congruence with Pacheco (2003). One clade composed of *T. australis*, *T. daphne*, *T. caudivarius*, and *T. cinnameus* is consistent with my "cinereus" species group; a clade of *Thomasomys* sp. 9, *T. oreas*, and *T. andersoni* is consistent with my "gracilis" species group (although *T. gracilis* was found unrelated); the species pair of *T. aureus* and *T. sp. 2* is consistent with my "aureus" species group; and a strongly supported clade of *T. baeops* and *T. taczanowskii* is consistent with my "baeops" species group. Disagreements between molecular versus the morphological hypotheses might be due to poor taxonomic coverage (e.g., 15 taxa versus 53 taxa, respectively) and/or misidentifications. Should future studies corroborate the

monophyly of the species groups I recognize, it would be appropriate to grant generic status to each of these, an action that would parallel the recent division of *Oryzomys sensu lato* (e.g., Weksler et al. 2006; see also Weksler and Percequillo 2011). Except for the availability of *Thomasomys*, for which *cinereus* Thomas is the type species, and *Inomys* Thomas, for which *incanus* Thomas is the type species, no other genus-group names are currently available for the other species groups.

Species recognized herein basically follow Voss (2003), Pacheco (2003), Musser and Carleton (2005), and Salazar-Bravo and Yates (2007). Very little is known about fossils of *Thomasomys*. Ficcarelli et al. (1992) reported *Thomasomys* sp. as part of a micromammal assemblage of Lujanian Mammal Age in the upper horizon of the Cangahua Formation, Quebrada Cuesaca, Bolívar province, Ecuador.

Ectoparasites or endoparasites are reported for each species in the accounts that follow where these parasites can be unambiguously assigned to a host species. Citations listing only *Thomasomys* sp. are treated here. Jordan (1950) reported the flea *Plocopsylla hector* Jordan from *Thomasomys* sp. from Loja. Pozo et al. (2005) reported the fleas *Polygenis litargus* (Jordan and Rothschild) and *Craneopsylla minerva* (Rothschild) in *Thomasomys* sp. from Ayabaca, Piura. Hastriter and Schlatter (2006) reported *Dasypsyllus* (*Neornipsyllus*) *lewisi*, a new species of flea, on *Thomasomys* sp. from Huanabamba, Piura, Peru, collected by C. Kalinowski, but considered the host a likely accidental association with an undetermined species of ground dwelling/nesting bird. Based on species collected by C. Kalinowski from that area, *Thomasomys* sp. represents either *T. cinereus* or *T. taczanowskii*. Seevers (1955) reported the staphylinid beetle *Amblyopinus sanborni* Seevers off *Thomasomys* sp. from Marcapata, Limapunco, Cuzco (FMNH 75369); specimen currently determined as *Nephelomys levipes* (Thomas).

Durette-Desset (1970b) reported *Longistriata thomasomysi* as a new species of nematode from *Thomasomys* sp. from Pichiude, Valle del Cauca, Colombia. Lack of additional data impede the species determination of the host, although I think the author refers to the locality of Pichindé, a town above the Cauca Valley on lower eastern slope of western Andes near Cali (Paynter 1997). To my knowledge, the only specimens of *Thomasomys* captured in the Pichindé valley and vicinity are those of *T. popayanus* (reported as *T. aureus*) and *T. cinereiventer* (Trapido and Sanmartín 1971), which are proposed as hypothetical hosts. The current name of the nematode is *Hypocristata thomasomysi* (Durette-Desset and Guerrero 2006).

KEY TO THE SPECIES OF *THOMASOMYS*:

1. Molars comparatively large, palatal bridge narrow (except *T. nicefori*); genal 1 vibrissae present (except *T. macrotis*) 2
- 1'. Molars comparatively normal, palatal bridge broad; genal 1 present or absent 3
2. Genal 1 vibrissae absent, auditory bullae small and uninflated; postglenoid foramen comparatively small and not extended in front of the anterior margin of tegmen tympani; upper molars with normal anteromedian flexus, and narrow lingual and labial flexus; first lower molar with anteromedian flexid shallow; lower molars with normal posteroflexids *Thomasomys macrotis*
- 2'. Genal 1 vibrissae present; auditory bullae small and uninflated or large and inflated; postglenoid foramen large, long, and extended to level or in front of the anterior margin of tegmen tympani; upper molars with deep anteromedian flexus, unusually wide hypoflexus, broad mesoflexus and metaflexus; first lower molar with distinct anteromedian flexid; first and second lower molars with broad and curved posteroflexids ("aureus" group) 7
3. Carotid circulation pattern derived (pattern 3, *sensu* Voss 1998) 4
- 3'. Carotid circulation pattern primitive (pattern 1, *sensu* Voss 1998) (except *Thomasomys daphne*) 5
4. Second and fifth digits of manus subequal (*sensu* Pacheco 2003); thenar and hypothenar pads of pes not separated by a gap; digit I of pes (with claw) long, extending to the interphalangeal joint of digit II, and digit V of pes (with claw) very long, extending to the base of claw of digit IV (*sensu* Pacheco 2003); genal 1 vibrissae present or absent; mystacial vibrissae very long, extending well beyond the posterior margin of pinnae to a point greater than the length of one pinna when bent; squamosal roots of zygomatic arch not expanded laterally, joining the braincase at oblique angle; mesopterygoid fossa subequal in breadth (not broad not narrow) with subparallel margins; wear surface of upper incisors more or less flat, facing backward (*sensu* Pacheco 2003); alveolus of first upper molar posterior to the posterior margin of the zygomatic plate; molars brachydont with weak labial cingula; m1 anteromedian flexi present; capsular process present; supratrochlear fenestra of humerus absent; distal portion of the lateral bacular mounds of phallus pointed (Pacheco 2003); preputial glands one pair ("baeops" group) 15
- 4'. Second digit of manus distinctly longer than fifth (*sensu* Pacheco 2003); thenar and hypothenar pads of pes separated by a gap in most cases; digit I of pes (with claw) moderate, extending close to the interphalangeal joint of digit II, and digit V of pes (with claw) long, extending about half the length of the second phalanx of digit IV (*sensu* Pacheco 2003); genal 1 vibrissae absent; mystacial vibrissae long, extending just beyond posterior margins of pinna when bent; squamosal roots of zygomatic arch laterally expanded, joining the braincase more perpendicularly; mesopterygoid fossa broad with subparallel or anteriorly expanded margins; wear surface of upper incisors oriented medially (*sensu* Pacheco 2003); alveolus of first upper molar anterior or subequal to the posterior margin of the zygomatic plate; molars moderately hypsodont; m1 anteromedian flexi absent; capsular process absent; supratrochlear fenestra of humerus present; lateral bacular mounds of phallus simple (Pacheco 2003); preputial glands absent ("incanus" group) 16
5. Genal 1 present; dorsal pelage comparatively short; body pelage pattern distinctly countershaded; auditory bullae small and uninflated; capsular process distinct; molars brachydont even when unworn; no preputials; lateral bacular mounds of phallus "triple curved" (Pacheco 2003) *Thomasomys notatus*
- 5'. Genal 1 present or absent; dorsal pelage comparatively moderate or usually long; body pelage pattern moderately or not countershaded; auditory bullae large and inflated, or small and moderately inflated; capsular process present or absent; moderately hypsodont or brachydont even when unworn; preputials present or absent; lateral bacular mounds of phallus simple or triple curved (Pacheco 2003) 6
6. Genal 1 present; second and fifth digits of manus subequal; squamosal roots of zygomatic arch not flared laterally, joining the braincase at oblique angle; zygomatic arches project anteriorly producing a more parallel outline; capsular process present or absent; molars brachydont with weak labial cingula; wear surface of upper incisors more or less flat, facing backward; margins of lophids, flexus, and flexids crenulated; m3 mesolophid distinct; protostyle and/or enterostyle on M1 present; one pair of preputial glands; lateral bacular mounds of phallus simple or triple curved (Hooper and Musser 1964; Pacheco 2003) ("gracilis" group) 20
- 6'. Genal 1 absent; second digit of manus distinctly longer than fifth; squamosal roots of zygomatic arch flared laterally, joining the braincase more perpendicularly; zygomatic arches convergent anteriorly producing a triangular outline in most cases; capsular process usually absent; molars moderately hypsodont (frequent condition) or brachydont with weak labial cingula; wear surface of upper incisors oriented medially; margins of lophids, lophids, flexus, and flexids usually not crenulated; m3 mesolophid coalesced to entoconid; protostyle

- and/or enterostyle on M1 absent; preputial glands usually absent (when present are numerous); lateral bacular mounds of phallus simple (Pacheco 2003). (“cinereus” group) 22
7. Body size very large (adult head and body length >235 mm); adult upper molar row >9.9 mm; zygomatic notch very shallow; about a third of terminal tail whitish. *Thomasomys apeco*
- 7'. Body size large or medium (adult head and body length <200 mm); adult upper molar row <8.5 mm; zygomatic notch shallow, tail usually unicolor. 8
8. Auditory bullae inflated, bony tube indistinct 9
- 8'. Auditory bullae small and not largely inflated, bony tube distinct 10
9. Auditory bullae comparatively smaller; sphenopalatine vacuities absent or slits; anterior edge on the procingulum of M1 usually present. *Thomasomys auricularis*
- 9'. Auditory bullae largely swollen; sphenopalatine vacuities distinct and moderately large; anterior edge on the procingulum of M1 usually absent *Thomasomys pyrthonotus*
10. Dorsal pelage overall grayish; first and second lower molars with entolophids oriented medially joining the murid, first and second lower molars with mesolophids short or indistinct *Thomasomys praetor*
- 10'. Dorsal pelage overall brownish; first and second lower molars with entolophids oriented forward joining the mesolophids, first and second lower molars with distinct mesolophids 11
11. Skull with moderately broad interorbital region, palatal bridge broad *Thomasomys nicefori*
- 11'. Skull with narrow interorbital region, palatal bridge narrow as usual for the group. 12
12. Lambdoid ridges present, well conspicuous. 13
- 12'. Lambdoid ridges indistinct 14
13. Skull with posterior extension of nasals not extended beyond premaxillae; premaxillomaxillary-frontal intersection placed subequal to zygomatic notch; anterior process ectotympanic large; alveolus of first upper molar subequal to the posterior margin of the zygomatic plate; m1 with ectolophid absent; large specimens (head and body length 160–185 mm) with long tail (125–141% of head and body length) *Thomasomys aureus*
- 13'. Skull with posterior extension of nasals usually longer than premaxillae; premaxillomaxillary-frontal intersection placed anterior to zygomatic notch; anterior process ectotympanic comparatively small; alveolus of first upper molar anterior to the posterior margin of the zygomatic plate; m1 with ectolophid present; comparatively larger specimens (head and body length 173–198 mm) with shorter tail (113–131% of head and body length) *Thomasomys princeps*
14. Body pelage pattern no countershaded; premaxillae slightly longer than nasals in dorsal view; interorbital region narrow with square margins; postorbital ridge incipient; ethmoturbinals moderately developed; incisive foramina broad and long reaching level of M1 plane or slightly between; mesopterygoid fossa broad not greatly expanded anteriorly with closed roof; auditory bullae small, distinct bony tubes; anterior process of ectotympanic large; M1 without an additional anterior edge on the procingulum; M2 protoflexus faint or absent *Thomasomys popayanus*
- 14'. Body pelage pattern moderately countershaded; premaxillae level nasals in dorsal view; interorbital region narrow with marked margins; postorbital ridge distinct; ethmoturbinals small; incisive foramina broader and longer extending between M1 almost to the posterior margin of anterocone; mesopterygoid fossa broad, distinctly expanded anteriorly and with moderately developed sphenopalatine vacuities; auditory bullae small but moderately inflated, bony tubes less distinct; anterior process of ectotympanic smaller; M1 with an additional anterior edge on the procingulum; M2 protoflexus distinct *Thomasomys rosalinga*
15. Interorbital region narrow (5.15–5.76 mm); auditory bullae small and uninflated; zygomatic arches narrow producing a somewhat parallel outline; incisive foramina narrow with extremes contracted and moderately long, extending to M1 anterior border, not between. *Thomasomys baeops*
- 15'. Interorbital region moderately broad (5.38–6.51 mm); auditory bullae moderate size and inflated; zygomatic arches converging anteriorly; incisive foramina narrow extending to slightly between M1 anterocones *Thomasomys taczanowskii*
16. Skull with distinct rostral tube; position of antorbital bridge low (ca. >25% of rostrum); interorbital region broad (most of molar row is concealed in dorsal view); optical foramen small (placed behind M3) 17
- 16'. Skull with rostrum not distinctly projected, rostral tube absent; position of antorbital bridge high (<25% of rostrum); interorbital region moderately broad (molar row is partially seen in dorsal view); optical foramen small (placed behind M3) or larger (level or partially overlap M3) 18
17. Parietosupraoccipital suture comparatively broad (suture is about one-third the posterior margin of parietal); body size small (adult head and body length usually <125 mm); upper molar row <5.1 mm. *Thomasomys incanus*

- 17'. Parietosupraoccipital suture narrow (length of suture is less than one-fourth of the posterior margin of parietal); body size medium (adult head and body length usually >130 mm); upper molar row >5.1 mm. *Thomasomys ischyurus*
18. Body pelage moderately countershaded; optic foramen behind M3; the molar-bearing portion of the maxillae near triangular; molars normal, without interpenetrating flexi. *Thomasomys eleusis*
- 18'. Body pelage no countershaded; optic foramen level or overlap M3; the molar-bearing portion of the maxillae near rectangular; molars with interpenetrating flexi 19
19. Body pelage brownish; mesopterygoid fossa broad and posteriorly convergent; upper incisors opisthodont. *Thomasomys kalinowskii*
- 19'. Body pelage dark grayish; mesopterygoid fossa broad with subparallel margins; upper incisors orthodont *Thomasomys ladewi*
20. Auditory bullae small but moderately inflated; tail with small but conspicuous terminal tuft of long hairs; mesopterygoid fossa with closed roof; upper incisors orthodont. *Thomasomys andersoni*
- 20'. Auditory bullae large and inflated; tail lack pencil of long hairs; mesopterygoid fossa with moderately open sphenopalatine vacuities; upper incisors opisthodont 21
21. Small size; body pelage pattern no countershaded; interfrontal fontanella absent; accessory labial root of M1 present; capsular process absent; glans penis body with shallow groove; lateral bacular mounds of phallus simple (Pacheco 2003), nonspined; spinous urethral flaps nonspined; gall bladder present *Thomasomys gracilis*
- 21'. Medium size; body pelage pattern moderately countershaded; interfrontal fontanella present; accessory labial root of M1 absent; capsular process present; glans penis body with deeper groove, extending to half of body; lateral bacular mounds of phallus "triple curved" (Pacheco 2003) and spined; spinous urethral flaps spined; gall bladder absent *Thomasomys oreas*
22. Angular process of mandible large, somewhat level condylar process in lateral view 23
- 22'. Angular process of mandible short, placed in front of posterior margin of condylar process in lateral view. 27
23. Molar with interpenetrating flexi; incisive foramina moderate close or level M1 anterior plane; upper incisors opisthodont; molars with incipient crenulation 24
- 23'. Molars normal, without interpenetrating flexi; incisive foramina short, not close to the anterocone M1; upper incisors usually orthodont; molars without trace of crenulation 25
24. Medium size (head and body length 112–130 mm, maxillary toothrow 4.7–5.5 mm); body pelage pattern no countershaded; molar bearing maxillae rectangular; interorbital region with rounded margins; upper incisors orthodont *Thomasomys bombycinus*
- 24'. Large size (head and body length 100–147 mm, maxillary toothrow 5.4–6.2 mm); body pelage pattern moderately countershaded; molar bearing maxillae triangular; interorbital region with incipient square margins; upper incisors opisthodont *Thomasomys cinereiventer*
25. Feet with a gap between the thenar and hypothenar pads; m1 anteromedian flexi distinct 26
- 25'. Feet without a gap between the thenar and hypothenar pads; m1 anteromedian flexi absent *Thomasomys vestitus*
26. The fifth digit (dV) of pes moderately long; rostral tube present; zygomatic plate narrow, breadth shorter than the length of M1; optic foramen small and posterior to M3; palatal medial process present; auditory bullae small and noninflated *Thomasomys dispar*
- 26'. The fifth digit (dV) of pes long; premaxillae extends anteriorly beyond the incisors by not more than the depth of the incisors; breadth of zygomatic subequal to the length of M1; optic foramen level or overlap posterior border of M3; palatal medial process absent or weak; auditory bullae small but moderately inflated. *Thomasomys contradictus*
27. Zygomatic plate narrow, breadth shorter than the length of M1. 28
- 27'. Zygomatic plate comparatively broad, breadth subequal to M1 or broader 32
28. Skull with distinct rostral tube 29
- 28'. Skull with rostrum not distinctly projected, rostral tube absent. 30
29. Body size very small (adult head and body length <95 mm); upper molar row <3.6 mm; skull with peculiar rostrum, with a concave dorsal profile; auditory bullae inflated and bony tubes indistinct. *Thomasomys hudsoni*
- 29'. Body size medium (adult head and body length >95 mm); upper molar row >4.5 mm; skull with frontonasal profile somewhat straight, auditory bullae uninflated and bony tubes distinct or poorly distinct *Thomasomys erro*
30. Body size very small (adult head and body length usually <95 mm); upper molar row <4.1 mm *Thomasomys cinnameus*
- 30'. Body size medium (adult head and body length >95 mm); upper molar row >4.4 mm. 31

31. Incisive foramen broad, with anterior and posterior margins contracted; M3 proportionally normal; short-tailed species (tail length usually <115% of head and body length) *Thomasomys fumeus*
- 31'. Incisive foramen oval and elongated; M3 comparatively smaller; long tail species (tail length usually >115% of head and body length)
. *Thomasomys silvestris*
32. Skull with auditory bullae large and inflated 33
- 32'. Skull with auditory bullae small or moderate, not inflated 36
33. Mystacial vibrissae very long, distinctly beyond posterior margins of pinnae when bent; rostral tube absent 34
- 33'. Mystacial vibrissae long, extending just beyond posterior margins of pinna when bent; premaxillae and nasals projected forward, incipient rostral tube present 35
34. Antorbital bridge low, usually 25% of rostrum; sphenopalatine vacuities moderately developed; upper incisors opisthodont *Thomasomys emeritus*
- 34'. Antorbital bridge higher, less than 25% of rostrum; sphenopalatine vacuities absent or present as slits; upper incisors more orthodont *Thomasomys laniger*
35. Skull with zygomatic notch deeper; interorbital region narrow; interfrontal fontanella usually present; ethmoturbinals moderately developed; postglenoid foramen large and projected forward in front of tegmen tympani; palatal medial process absent; anterior process ectotympanic distinct *Thomasomys niveipes*
- 35'. Skull with zygomatic notch shallow; interorbital region moderately broad; interfrontal fontanella usually absent; ethmoturbinals large; postglenoid foramen smaller and shorter than level of tegmen tympani, palatal medial process present; anterior process ectotympanic small *Thomasomys paramorum*
36. Upper incisor proodont, procumbent 37
- 36'. Upper incisor usually orthodont, nonprocumbent 38
37. Tail usually lacking terminal white tip; palatal medial process absent or weak; primitive carotid circulatory pattern; capsular process absent or shelf
. *Thomasomys australis*
- 37'. Tail with a terminal white tip; palatal medial process present; derived carotid circulatory pattern; masseteric crest position subequal, capsular process distinct
. *Thomasomys daphne*
38. The m1 anteromedian flexi present 39
- 38'. The m1 anteromedian flexi absent 41
39. Body pelage pattern moderately countershaded; tail usually lack terminal white tip . . *Thomasomys cinereus*
- 39'. Body pelage pattern no countershaded; tail with a terminal white tip 40
40. Rostral tube absent; ethmoturbinals moderately developed *Thomasomys hylophilus*
- 40'. Premaxillae moderately projected, extending anteriorly beyond the incisors by not more than the depth of the incisors; ethmoturbinals larger
. *Thomasomys caudivarius*
41. Body pelage pattern moderately countershaded; ventral base of claw on manus partially keeled; position of antorbital bridge low (approx. >25% of rostrum); mesopterygoid fossa broad, more open anteriorly; zygomatic plate slope backward; optical foramen small (placed behind M3) *Thomasomys vulcani*
- 41'. Body pelage pattern no countershaded; claws on manus closed at base; position of antorbital bridge high (approx. <25% of rostrum); mesopterygoid fossa broad with subparallel margins; zygomatic plate vertical; optical foramen at level or partially overlap M3 42
42. Upper incisors proodont; molar-bearing maxillae rectangular; capsular process distinct . . . *Thomasomys ucucha*
- 42'. Upper incisors orthodont; molar-bearing maxillae triangular; capsular process absent or shelf 43
43. Gap present between hypothenar and thenar pads of pes; interfrontal fontanella present; molars more brachyodont; M1 anteroloph indistinct; hypoflexus M3 indistinct; M1 with accessory labial root
. *Thomasomys monochromos*
- 43'. Hypothenar and thenar pads of pes closer, no gap; interfrontal fontanella absent; molars moderately hypsodont; M1 anteroloph distinct; hypoflexus M3 distinct; M1 lacks accessory labial root . . . *Thomasomys onkiro*

The Key is based on original species descriptions, recent literature (e.g., L. Luna and Pacheco 2002; Voss 2003; Salazar-Bravo and Yates 2007), and my character descriptions and character matrix presented in the morphological phylogeny of thomasomyine rodents (Pacheco 2003). However, the hierarchical order in which characters are presented is not strictly phylogenetic. This key also includes my unpublished and ongoing research. Although the species of *Thomasomys* are treated alphabetically in the accounts that follow, the species I recognize can be grouped into seven species groups that hypothetically represent natural phylogenetic units; five of these are polytypic, the remaining two are monotypic: (1) "cinereus" species group, which includes *T. australis*, *T. bombycinus*, *T. caudivarius*, *T. cinereiventer*, *T. cinereus*, *T. cinnameus*, *T. contradictus*, *T. daphne*, *T. dispar*, *T. eleusis*, *T. erro*, *T. emeritus*, *T. fumeus*, *T. hudsoni*, *T. hylophilus*, *T. laniger*, *T. monochromos*, *T. niveipes*, *T. onkiro*, *T. paramorum*, *T. silvestris*, *T. ucucha*, *T. vestitus*, and *T. vulcani*; (2) "incanus" species

group, including *T. eleusis*, *T. incanus*, *T. ischyryus*, *T. kalinowskii*, and *T. ladewi*; (3) “aureus” species group, including *T. apeco*, *T. aureus*, *T. auricularis*, *T. nicefori*, *T. popayanus*, *T. praetor*, *T. princeps*, *T. pyrrhonotus*, and *T. rosalia*; (4) “baeops” species group, including only *T. baeops* and *T. taczanowskii*; (5) “gracilis” species group, including *T. andersoni*, *T. gracilis*, and *T. oreas*; (6) the monotypic “macrootis” species group, including only *T. macrotis*; and (7) the monotypic “notatus” species group, including only *T. notatus*.

Finally, the quantitative and qualitative descriptions of species that follow are in large part based on my personal examination of type material and additional series, original descriptions, and relevant literature (e.g., Voss 1996, 2003; Gómez-Laverde et al. 1997; Salazar-Bravo and Yates 2007). I also comment on population samples that appear to represent currently undescribed species in the Remarks section of the appropriate account. As a more detailed species description, including postcranial and soft anatomy will be presented elsewhere, this work does not constitute as yet a proper revision of the genus.

Thomasomys andersoni Salazar-Bravo and Yates, 2007

Anderson's Thomasomys

SYNONYM:

Thomasomys andersoni Salazar-Bravo and Yates, 2007: 752; type locality “an elfin forest near the headquarters of the Corani hydroelectric plant (17°12'43"S, 65°52'09"W, GPS coordinates, map datum WGS 84) at 2,630 m, Department of Cochabamba, Bolivia.”

DESCRIPTION: Medium sized (mean head and body length 109 mm; condyloincisive length of skull 27.21 mm) with soft, dense, and comparatively long dorsal fur (mean length=11 mm). Dorsal coloration dull brownish olive; ventral coloration olive buff with yellowish tinge and distinct yellow pectoral marking. Ears comparatively large (20–21 mm) and blackish brown. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae present. Tail slightly longer than head and body (113–116%) with short terminal pencil (length 8–10 mm). Hindfoot relatively short (22–26 mm) and broad, with dorsal chocolate-brown metatarsal patch that contrasts with white digits. Hallux relatively short, not extending beyond metatarsal of dII, and dV long (claw of dV extending about half length of phalanx 2 of dIV). Skull of moderate proportions with narrow but not long rostrum, and oblong braincase and straight fronto-nasal profile; interorbital region narrow with rounded supraorbital margins, without ridges; zygomatic plates broad and vertically oriented; zygomatic arches converge anteriorly; incisive foramina long and relatively narrow, extending posteriorly slightly between M1s; auditory bullae small

but moderately inflated (ventral margins of bullae extend slightly ventral to hamular process of pterygoids when skull viewed in horizontal plane, bony tubes short (*sensu* Pacheco 2003), and nearly flask shaped; and orbicular apophysis of malleus comparatively small (not enlarged), not basally constricted. Carotid circulatory pattern primitive (large stapedial foramen, groove the inner surface of the squamosal and alisphenoid, and sphenofrontal foramen). Maxillary tooththrow short (4.61 mm in average); molars bunodont and brachydont with weak labial cingula; first upper molar with accessory labial root present; upper incisors orthodont and yellowish; and capsular process comparatively small.

DISTRIBUTION: *Thomasomys andersoni* occurs on the eastern Andean slopes of the Bolivian Andes (La Paz and Cochabamba departments), between 2,000 and 2,630 m.

SELECTED LOCALITIES (Map 324): BOLIVIA: Cochabamba, near headquarters of the Corani hydroelectric plant (type locality of *Thomasomys andersoni* Salazar-Bravo and Yates); La Paz, 30 km by road N of Zongo, cement mine (UMMZ 156298).

SUBSPECIES: *Thomasomys andersoni* is monotypic.

NATURAL HISTORY: *Thomasomys andersoni* inhabits the upper montane rainforest and appears to be arboreal (Salazar-Bravo and Yates 2007). The two specimens from Corani were trapped at about 2 m above ground in a short tree at the bottom of a small ravine. The type locality has a flora dominated by the species *Ocotea jelskii* (Lauraceae) and *Podocarpus oleifolius* (Podocarpaceae). The climate of the region is very humid, with daily fog and mist, and low temperatures.

REMARKS: This species was originally reported only from the type locality (Salazar-Bravo and Yates 2007), but one specimen from 30 km north of Zongo in La Paz department (UMMZ 156298) extends the range to a second locality about 285 km to the northwest. S. Anderson (1997) incorrectly reported the Zongo specimen as *Rhipidomys nitela*; subsequently Voss et al. (2001) viewed this animal as resembling *T. oreas*. Based on the comparatively long dorsal pelage, lack of a dorsal band, small and little inflated auditory bullae, and lack of sphenopalatine vacuities, I regard this specimen as allied to *T. andersoni* and not to *T. oreas*, although other features (such as a midpalate process and wider incisive foramina) might suggest the Zongo specimen represents an unnamed taxon.

In a phylogenetic analysis based on the mtDNA cytochrome-*b* gene, *T. andersoni* was placed as sister to *T. oreas*, which supports its placement in the “gracilis” group. The species, however, does share morphological characters with members of both the “gracilis” and “no-

Map 324 Selected localities for *Thomasomys andersoni* (●). Contour line = 2,000 m.

tatus” groups, and its phylogenetic position may be annectant between these taxon groupings (Pacheco 2003; Salazar-Bravo and Yates 2007; V. Pacheco, unpubl. data).

The karyotype of *T. andersoni* has a diploid complement of 44 with all autosomes acrocentric ($2n=44$, $FN=42$); the X chromosomes also appear to be acrocentric (Salazar-Bravo and Yates 2007).

Thomasomys apeco Leo and Gardner, 1993

Apeco *Thomasomys*

SYNONYM:

Thomasomys apeco Leo and Gardner, 1993:417; type locality “Valle de Los Chochos, ca. 25 km NE Pataz, 3280 m, Parque Nacional Río Abiseo, San Martín, Perú.”

DESCRIPTION: Large (head and body length 237–238 mm, condylobasal length of skull 47.7–47.8 mm, in two adult specimens) with long and dense dorsal fur (underfur as long as 22 mm mid-dorsally with guard hairs reaching 30 mm); dorsal coloration bright with color varying between individuals from raw sienna to ochraceous-tawny and tawny olive streaked with black guard hairs; ventral pelage ochraceous-buff although extension variable among individuals; very long mystacial vibrissae, extending well beyond pinnae; tail longer than head and body (135–137%), and without terminal pencil; interorbital region narrow, elevated but not beaded, with pronounced depression on frontals along midline of skull; zygomatic notches shallow; zygomatic

plates broad and moderately sloped backward from bottom to top; zygomatic arches convergent anteriorly; deep notch between lacrimal and zygomatic ramus of maxilla; thick jugal; auditory bullae small and uninflated; orbicular apophysis of malleus large and elongated; capsular process absent or represented by weak shelf; moderately hypsodont molars with weak labial cingula; accessory labial root of M1 present; orthodont upper incisors; upper molars robust, always longer (anteriorly-posteriorly) than wide, ranging from 10.0–10.2 mm in adults; long hallux and very long dV of pes as typical for “aureus” species group.

DISTRIBUTION: *Thomasomys apeco* is known only from the type locality and the immediately surrounding area in upper montane forests, from 3,200 to 3,380 m, in north central Peru.

SELECTED LOCALITIES (Map 325; from Leo and Gardner 1993): PERU: San Martín, Pampa del Cuy, ca. 24 km NE of Pataz, Puerta del Monte, ca. 26 km from Pataz, Valle de los Chochos, ca. 25 km NE of Pataz (type locality of *Thomasomys apeco* Leo and Gardner).

SUBSPECIES: *Thomasomys apeco* is monotypic.

NATURAL HISTORY: *Thomasomys apeco* inhabits upper montane forests and páramo-like habitats (locally called *jalca*) near forest borders. One specimen was caught at the end of a log and another on a bank above a small stream, on the forest floor in an isolated patch of elfin forest. Others were caught in a runway leading up from a rivulet of water in wet pampa habitat, in a small shallow stream bordered by a few small trees, or within continuous forest. Individuals may be terrestrial or arboreal (Leo and Gardner 1993). This species appears to breed in the dry season. One female was pregnant in August 1987 (dry season) with a single embryo; another female was captured in July with well-developed mammae. Subadult males had well-developed testes in July and August (Leo and Gardner 1993).

REMARKS: *Thomasomys apeco* is the largest living thomasiomyine and among the largest Sigmodontinae known. It was differentially compared with species of the *Thomasomys aureus* complex group and *Megaoryzomys curioi*, an extinct Pleistocene form from the Galapagos Islands (Leo and Gardner 1993), and with *T. macrotis* (A. L. Gardner and Romo 1993). Leo and Gardner (1993) suggested a closer affinity of *T. apeco* with the “aureus” species group, which was corroborated by Pacheco (2003) and followed here. *Thomasomys apeco* was compared also with *Thomasomys* sp., a specimen composed of pieces of maxillae (including the complete molar row), the right premaxilla (including the incisive teeth) and other braincase remains, obtained from Cueva Chaquil, Amazonas Department (O. Fabre et al. 2008). According to these authors, this specimen

Map 325 Selected localities for *Thomasomys apeco* (●). Contour line = 2,000 m.

is slightly larger than *T. apeco*, based on comparisons of mean molar tooththrow length (alveolar; 11.2 mm versus 9.9 mm); however, my own measurement of that specimen is 10.2 mm, the same as the larger specimen of *T. apeco* (Leo and Gardner 1993). Nonetheless, this similar size rat apparently corresponds to an unnamed taxon based on cranial characteristics that include the more pointed posterior ending of the incisive foramina, narrower palatal bridge, and slightly opisthodont upper incisors.

Thomasomys aureus (Tomes, 1860)

Golden *Thomasomys*

SYNONYMS:

H[esperomys]. aureus Tomes, 1860a:219; type locality undetermined.

O[ryzomys]. aureus: Thomas, 1900d:354; name combination.

Thomasomys aureus: Thomas, 1906c:443; first use of current name combination.

Thomasomys aureus altorum J. A. Allen, 1914b:200; type locality "Mt. Pichincha (altitude 11,000 ft.)," Pichincha, Ecuador.

Thomasomys pichinchius Lönnberg, 1921:38; *nomen nudum*.

Thomasomys aureus aureus: Gyldenstolpe, 1932a:51; name combination.

DESCRIPTION: Distinctively large species (head and body length 160–180 mm) with grizzled golden-brown dorsal fur indistinctly differentiated from yellow-washed, dark gray-based ventral fur. Dorsal pelage long, thick, and not very fine, with faint band of dark hairs along midline; long and blackish mystacial vibrissae extending distinctly posterior to pinnae; genal 1 vibrissae present. Hindfeet relatively long (36–40 mm) and moderately broad with dark patch distinctly lined with orange or whitish hairs extending to base of digits, becoming whitish on distal half; fifth digit semiopposable; gap between thenar and hypothenar absent. Hallux long, extending to interphalangeal joint of dII. Digit V of pes very long, claw extending to base of claw of dIV. Tail long (125–141% of head and body length), monocolored, finely annulated, covered with short hairs, and without terminal pencil. Protuberant anus prominent. Skull large, robust (condyloincisive length 35.4–39.5 mm), and zygomatic plates vertical and broad. Contact of premaxillomaxillary-frontal bones level with posterior margins of zygomatic notches. Interorbital region narrow and convergent anteriorly, with squared but not beaded margins, and with pronounced depression in frontals along midline of skull. Postorbital ridge distinctly present just behind, and parallel to, frontosquamosal suture. Braincase oblong, moderately broad, and not inflated; large interparietal subrectangular in shape. Incisive foramina long and moderately narrow, usually extending posteriorly between molar anterocones. Palatal bridge short and narrow with maxillary palatal pits present. Auditory bullae small, uninflated, and flask shaped; anterior process of ectotympanic is large. Ethmoturbinals moderately developed. Mesopterygoid fossa broad and somewhat parallel sided; sphenopalatine vacuities absent or appear only as slit-like vacuities flanking presphenoid-basisphenoid suture. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors opisthodont. Maxillary tooththrow long, ranging typically from 6.8–7.8 mm.

DISTRIBUTION: *Thomasomys aureus* ranges broadly in Andean forests, from 1,460 to 3,850 m, from western Venezuela (see O. J. Linares 1998:Fig. 152), eastern and central Colombia, through Ecuador and Peru, to west-central Bolivia (Musser and Carleton 2005).

SELECTED LOCALITIES (Map 326): BOLIVIA: Cochabamba, 31 km by road W of Comarapa (AMNH 263183); La Paz, Murillo, Cuticucho (CBF 4463); Santa Cruz, approx. 25 km by road W of Comarapa, Siberia (UMMZ 156308). COLOMBIA: Huila, San Agustín, Río

Magdalena (FMNH 71290), San Agustín, Santa Marta (FMNH 71293); Risaralda, Río Termales (FMNH 71264). ECUADOR: Napo, near Papallacta (Voss 2003); Pichincha, Guala (AMNH 36279). PERU: Cajamarca, San Ignacio, Tabaconas, Cerro La Viuda (Tabaconas-Namballe National Sanctuary Buffer Zone) (UMMZ 176556); Cusco, Cordillera de Vilcabamba (MUSM 13062), Machu Picchu (AMNH 91552), Marcapata, Limacpunco (FMNH 75228), 72 km NE (by road) Paucartambo; km 152 (MVZ 171496); Huánuco, Prov. 2 de Mayo, Cayna, Chiliatuna (MUSM 5252), Chinchuragra (MUSM 22892); Junín, Tarma, 22 mi E of Tarma (AMNH 231198); Piura, Batán on Zapalache-Carmen trail (LSUMZ 26945), Cerro Chinguela, ca. 5 km NE of Zapalache (LSUMZ 21896); Puno, 14 km W of Yanahuaya (MVZ 172597); San Martín, Puerta del Monte, ca. 30 km NE of Los Alisos (LSUMZ 27288), P.N. Río Abiseo, Puerta de Monte (MUSM 8051). VENEZUELA: Táchira, Buena Vista, 41 km SW of San Cristóbal, near Paramo de Tamá (USNM 442321).

SUBSPECIES: I consider *T. aureus* to be monotypic (but see Remarks).

NATURAL HISTORY: This species habits primary and secondary forest, preferring places with abundant vegetation such as dense grass and reeds, shrubs, and trees (Barnett 1999) in subalpine rainforest (Voss 2003), temperate forest, or páramo (Tirira 2007). Barnett (1999) pointed out that all known records of *T. aureus* come from forested areas, countering the argument of Reig (1986) and Tirira (2007) that the species may be found in páramo habitat as well. In northern and southern Peru it has been collected only in continuous and dense forest (Leo and Romo 1992; Patton 1987; V. Pacheco, unpubl. data). At Papallacta, Ecuador, Voss (2003) trapped specimens in well-worn paths through mats of moss and liverworts on horizontal tree limbs, and on the ground at the edge of a stream, among tall grass in a clearing, and in a runway through dense mats of moss. Elsewhere in Ecuador, Barnett (1999), Eisenberg and Redford (1999), Jarrín-V. (2001), and M. Brito et al. (2012) reported arboreality with nests built in trees at heights up to 6–7 m. In the Táchira Andes of Venezuela, this species was caught in a tree near a stream in cloud forest and in the lower montane very humid forest (Handley 1976). Individuals are known to feed on fruits, seeds, other plant material, and insects (Eisenberg and Redford 1999), with a preference for *Passiflora* fruits (Passifloraceae; Barnett 1999). Males with descended testes were found in September (Barnett 1999), and embryo counts of two to three have been recorded from Peruvian specimens (Eisenberg and Redford 1999). The species may be infrequently trapped, suggesting that it is either rare or difficult to capture (Barnett 1999).

Known ectoparasites include lice (*Hoplopleura* new sp. 2 on specimens from Cusco, Peru [V. S. Smith et al. 2008]),

laelapid mites (*Hymenolaelaps princeps* on specimens from Táchira, Venezuela [Furman 1972]), fleas (*Polygenis impavidus* [Tipton and Machaco-Allison 1972], *Cleopsylla monticola*, *Polygenis thormani*, and *Neotyphloceras rosenbergi* [Maihuay et al. 1994], all on specimens from Cusco, Peru), and ticks (*Ixodes* sp., on specimens from Táchira, Venezuela [E. K. Jones et al. 1972]).

REMARKS: The type locality of *Thomasomys aureus* was unfortunately not determined in the original description but has been considered either to be Pallatanga, 4,950 ft (01°59'S, 78°57'W; 1,500 m), in the Ecuadorean province of Chimborazo (J. A. Allen 1914b; Ellerman 1941; Cabrera 1961), or Gualaquiza (03°24'S, 78°33'W; 750 m elevation) in the Ecuadorean province of Morona-Santiago (Thomas 1920h; A. L. Gardner 1983a). Musser and Carleton (2005) pointed out that a formal amendment of the type locality is needed, following arguments provided by A. L. Gardner (1983a) and Voss (2003). Voss (2003) stated that neither Pallatanga nor Gualaquiza is within the usual altitudinal range of the species (3,000–4,000 m), although, as I mentioned earlier, *T. aureus* has been reported well below this range. Pallatanga is thus in the range of known distribution of *T. aureus* but Gualaquiza is not (based on current records). In conclusion and based on this limited information, I consider Pallatanga the likely type locality. The Museum of Southwestern Biology holds two specimens (MSB 70707, 70708) collected on the Río Tatahuazo, near Cruz de Lizo, Bolívar province (01°43'S, 78°59'W), which is only 30 km from Pallatanga. To my knowledge these are the closest records to Pallatanga that could represent typical *T. aureus*, as compared with the Guala series from Pichincha that J. A. Allen (1914b) suggested as typical of the species.

Thomas (1900d:355) was first to suggest that *Thomasomys praetor*, *T. aureus*, and *T. princeps* formed a small section of the genus. Later, based on *Thomasomys* material in the British Museum, Ellerman (1941) recognized as natural an *aureus* Group consisting of large bodied species in which he included *nicefori*, *popayanus*, *princeps*, and *praetor*. Cabrera (1961) considered each of these named taxa as subspecies within a highly variable *T. aureus*, without justification. Musser and Carleton (1993) followed this arrangement and also added *altorum* as a synonym or subspecies of *T. aureus*, supporting earlier doubts on the validity of *altorum* (Thomas 1920h:233). Because of the number of available names and the uncertain placement of taxon boundaries, A. L. Gardner and Romo (1993) coined the “*T. aureus* complex,” which they suspected to consist of three or more valid species.

Voss (2003) postulated several attributes for separating *T. aureus* proper from *T. popayanus* and *T. praetor*, while maintaining *princeps* and *altorum* as synonyms of

T. aureus, and stating that *T. popayanus* probably included *nicefori*. Based on morphological traits, Pacheco (2003) also discriminated *popayanus* and *praetor* from *aureus*, but recognized *princeps* and *nicefori* as full species as well. Justifications for these decisions are provided in the separate species accounts that follow. Pacheco (2003) went further and recognized two additional unnamed species allied to *T. aureus* (e.g., *Thomasomys* sp. 1, a population from southern Peru and northern Bolivia, and *Thomasomys* sp. 2 from southern Bolivia). The first of these is large in size, similar to the Ecuadorean series, but the second is a small representative, probably the smallest in the group. Salazar Bravo and Yates (2007) sequenced a specimen of *Thomasomys* sp. 1 (reported as *T. aureus*; MVZ 170076, Cusco, 72 km NE [by road] Paucartambo, km 152), and a specimen of *Thomasomys* sp. 2 (AMNH 260422, Cochabamba, 28 km by road of Comarapa) reporting 12.3% of divergence between them, a large distance usually found between distinct species. Molecular analyses of *T. aureus* proper from Ecuador are still missing. S. Anderson (1997: 412) reported one undetermined *Thomasomys* (AMNH 263183) consisting of fragments of a skull from a fecal pellet of a carnivore from 30 km by road W of Comarapa, which I have identified as *Thomasomys* sp. 2 of Pacheco (2003).

My work in progress indicates that additional populations might warrant also species distinction. The population from the Mérida Andes in Venezuela departs in external and cranial characteristics from *T. aureus* proper and is somewhat isolated; further investigation may show that it merits recognition as a separate species. Similarly, other hypothetical new taxa are samples from Chinguela, Piura, Peru, that have characteristics of *T. pyrhoneotus* and *T. aureus*; the population from Río Abiseo, San Martín, Peru, with a whitish tail; and the population from Unduavi, Bolivia, where specimens are of moderate size, lack the genal 1 vibrissae, and exhibit a comparatively globose auditory bullae. Substantial work is still needed to resolve the taxonomy of this species complex.

Thomasomys aureus is highly differentiated in stomach, glans penis, and reproductive tract morphology relative to other species of *Thomasomys* (Carleton 1973; Hooper and Musser 1964; Voss and Linzey 1981; Pacheco 2003). Pacheco's (2003) phylogenetic analysis, which included these traits, supported a monophyletic "aureus" group.

A. L. Gardner and Patton (1976) reported a karyotype of $2n=44$, $FN=42$, with X and Y acrocentric chromosomes, for specimens of *Thomasomys aureus* from Río Palca, Junín, and Yuraccyacu, Ayacucho, Peru; but this karyotype apparently belongs to *Thomasomys* sp. 1 of Pacheco (2003) (V. Pacheco, unpubl. data). Salazar-Bravo and Yates

Map 326 Selected localities for *Thomasomys aureus* (●). Contour line = 2,000m.

(2007:767) mistakenly listed the karyotype of *T. aureus* as $2n=42$, $FN=42$, citing A. L. Gardner and Patton (1976). A karyotype of *T. aureus* proper from Ecuadorean populations remains unknown.

Thomasomys auricularis Anthony, 1923

Red Andean *Thomasomys*

SYNONYMS:

Thomasomys auricularis Anthony, 1923b:6; type locality "Taraguacocha, on trail from Zaruma to Zaraguro, altitude 10,250 feet, Cordillera de Chilla, Provincia del Oro, Ecuador."

Thomasomys pyrhoneotus: Cabrera, 1961:433, part (*auricularis* listed as a subspecies); not *pyrhoneotus* Thomas, 1886.

DESCRIPTION: Medium sized, slightly smaller than *T. aureus* (head and body length 138–155 mm), which it

resembles superficially, but with light creamy-buff feet, an ochraceous postauricular patch, and larger auditory bullae. Dorsal pelage tawny olive, closely sprinkled with blackish hairs especially along midline of back, with flanks and sides more strongly tawny. Ventral pelage yellow-washed; color rather more intense over pectoral area; no line of demarcation in color between sides and under parts. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae present. Tail relatively long (122–134% of head and body length), dark brown monocolored. Hindfoot moderately long (31–32 mm) with dI and dV long as in *T. aureus*; metatarsals usually covered with silvery white hairs; and no gap between thenar and hypothenar pads. Skull large and robust but smaller than *T. aureus* (condyloincisive length of skull 33.6–34.1 mm). Nasals slender and expanded anteriorly, and braincase not as inflated as in *aureus*. Incisive foramina long and extending backward between procingula of M1s; maxillary septum length long, about half foramina length. Interorbital region narrow, with parallel sides and squared and smooth, not beaded, edges. Interfrontal fontanella absent. Ethmoturbinals moderately developed. Mesopterygoid fossa extends to level of posterior border of last molars or between them; roof unfenestrated or with only reduced slits. Auditory bullae large and inflated (larger than *T. aureus* but comparatively smaller than *T. pyrrhonotus*). Postglenoid foramen and subsquamosal fenestra both long and narrow but subequal in size. Maxillary tooththrow long, ranging typically from 6.6–7.4 mm. Additional anterior edge on procingulum of M1 usually present.

DISTRIBUTION: *Thomasomys auricularis* inhabits the western Andes of southwestern Ecuador in montane forests and isolated *Polylepis* (or *quenoa* [Rosaceae]) forests within the páramo (Barnett 1999), between 2,330 to 4,000 m.

SELECTED LOCALITIES (Map 327): ECUADOR: Azuay, The Cajas Plateau, Torreadora (Barnett 1999); Cañar, San Antonio (AMNH 63315), Chical (AMNH 63326); El Oro, Taraguacocho, small stream 500 ft above camp (type locality of *Thomasomys auricularis* Anthony); Loja, N side of Loja, Malacatos Divide (MCZ 58280).

SUBSPECIES: *Thomasomys auricularis* is monotypic.

NATURAL HISTORY: *Thomasomys auricularis* inhabits montane forest and páramo, degraded *quenoa* forests with open canopies and abundant shrub vegetation, and altered montane forest (Barnett 1999). The type specimen was taken on the bank of a small mountain stream in thick forest growth (Anthony 1923b). Individuals were also captured in traps placed on the lower limbs of *Polylepis* trees (Barnett 1999). Nothing about population biology, reproduction, or behavior is known.

REMARKS: This species has been treated as synonym or subspecies of *T. pyrrhonotus* (Cabrera 1961), and following synopses (e.g., Musser and Carleton 1993, 2005), although both taxa were never formally contrasted. It appears that Anthony (1923b) was not aware of *T. pyrrhonotus* because he compared *T. auricularis* only with *T. aureus* and commented on differences with *T. praetor*, *T. popayanus*, and *T. nicefori*, but not *T. pyrrhonotus*. Gyldenstolpe (1932) and later Pacheco (2003) recognized *T. auricularis* as a valid species, a decision followed by Tirira (1999, 2007).

Thomasomys auricularis is readily distinguished from *T. pyrrhonotus* by its slightly longer tail in relation to head and body length (130%, N=1 adult and 122 to 134%, N=5 subadults versus 120%, N=2 adults, respectively); slightly larger molar tooththrow (6.6 mm, N=1 adult and 6.6 to 7.4 mm, N=5 subadults versus 6.4 mm, N=1 adult, respectively); inflated but comparatively smaller auditory bullae; the roof of the mesopterygoid fossa closed or with reduced slits versus moderately developed; subsquamosal fenestra less developed and more narrow; interfrontal fontanella absent versus present; ethmoturbinals medium in size versus small; and the M1 procingulum usually presenting an additional anterior edge versus almost absent (see also the account of *T. pyrrhonotus* for other morphological traits of the species). *Thomasomys auricularis* also ranges between medium and high elevations, *T. pyrrhonotus* occurs at lower and medium elevations.

Map 327 Selected localities for *Thomasomys auricularis* (●). Contour line = 2,000 m.

The population from Cañar differs slightly from *T. auricularis* proper, and future studies might conclude this sample represents a separate taxon. These specimens have a dark and narrow metatarsal patch, the palatal bridge is narrower, the mesopterygoid fossa extends between M3, and their molar toothrow is slightly larger, among other features. This locality is also separated from the type locality by the deep Río Jubones.

Steppan (1995) reported the vertebral counts of this species (reported as *T. pyrrhonotus*). The karyotype is unknown.

Thomasomys australis Anthony, 1925

Austral Thomasomys

SYNONYMS:

Thomasomys daphne australis Anthony, 1925:4; type locality “Incachaca, 7700 feet, Prov. Cochabamba, Bolivia.”

Thomasomys daphne: Voss, 1991a:112; part; not *daphne* Thomas, 1917.

Thomasomys australis: Voss, 2003:14; first use of current name combination.

DESCRIPTION: Small species (head and body length 89–91 mm; condyloincisive length of skull 24.1–25.5 mm) with cinnamon-brown to auburn dorsal pelage, and flanks almost as dark; ears small and covered with short brown hairs; and both hands and feet, wrists, and ankles washed with clove-brown. Ventral pelage cinnamon-buff. Pelage quite long, soft, and lax. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail very long (144–155% of head and body length), covered by fine scales and unicolored. Hindfoot short (24–25 mm), slender, and dark brown. Skull with comparatively short rostrum and nasals; braincase moderately inflated; incisive foramina long and broad, reaching almost to anterior margin of M1s; and auditory bullae small. Carotid circulation with primitive condition (large stapedia foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Capsular process absent or present as simple shelf. Upper incisors gracile, orthodont to barely proodont (*sensu* Hershkovitz 1962); maxillary toothrow short, ranging from 4.2–4.3 mm.

DISTRIBUTION: *Thomasomys australis* is known from the Bolivian Yungas, at elevations between 2,350 and 2,800 m.

SELECTED LOCALITIES (Map 328): BOLIVIA: Cochabamba, Corani (AMNH 268736), Incachaca (type locality of *Thomasomys daphne australis* Anthony); Santa Cruz, W of Comarapa, Siberia (UMMZ 156307).

SUBSPECIES: *Thomasomys australis* is monotypic.

NATURAL HISTORY: No detailed data are available on habits, behavior, or food. Four pregnant females taken

in October had one embryo and three embryos. A lactating female was recorded in June (S. Anderson 1997). For central Bolivia, the dry season spans from May to September. The species was collected on the ground in upper montane elfin forest (Salazar-Bravo and Yates 2007).

REMARKS: Anthony (1925) described *T. australis* on p. 4, not p. 2 as stated by Cabrera (1961:428). Voss (2003:14) elevated *australis* to full species based on its opisthodont upper incisors (index value of 85°) versus the orthodont condition in *T. daphne* (index value 90°), an angle equivalent to the incisive index of Thomas (1919h). Salazar-Bravo and Yates (2007) followed Voss’s decision in recognizing *T. australis* as a full species. Pacheco (2003) also recognized *T. australis* as a species different from *T. daphne* proper because of its primitive carotid circulation (pattern 1, *sensu* Voss 1988) versus the derived circulation (pattern 3, *sensu* Voss 1988), the unicolor tail versus the usually tip-white tail, and the capsular process indistinct versus distinct, respectively, among other traits. These character differences support the distinction provided by Anthony (1925), who stated that *T. australis* has a more rufous dorsal pelage, darker hindfeet, and longer incisive foramina than *T. daphne*. The Santa Cruz record constitutes the southernmost record for both this species and the genus *Thomasomys*.

Salazar-Bravo and Yates (2007), in a phylogenetic analysis based on the mtDNA cytochrome-*b* gene, found *T. australis* to be more closely related to *Thomasomys* sp. 3 (reported as *T. daphne*), an unnamed taxon (see *T. daphne*

Map 328 Selected localities for *Thomasomys australis* (●). Contour line = 2,000 m.

account) proposed by Pacheco (2003). This result is consistent with Pacheco's (2003) morphological-based phylogeny that found *T. australis* related to both *T. daphne* and *Thomasomys* sp. 3.

Thomasomys baeops (Thomas, 1899)

Short-faced *Thomasomys*

SYNONYMS:

Oryzomys baeops Thomas, 1899b:152; type locality "Pitarío., above the Chillo Valley, [Pichincha,] Ecuador. Alt. 3500 metres."

Thomasomys boeops: Thomas, 1906c:443; name combination.

Thomasomys baeops: Gyldenstolpe, 1932a:57; first use of corrected spelling.

DESCRIPTION: Medium sized (head and body length 106–128 mm; condyloincisive length of skull 25.2–27.5 mm) with dull grayish brown dorsal pelage, darker along middle line of back. Ventral pelage silvery gray with light brown tone extending anteriorly to base of mystacial vibrissae; base of hairs plumbeous. Hands whitish above; hindfeet pale brown above, but metatarsal region without distinct patch; digits whitish. Pelage quite long, soft, and woolly. Mystacial vibrissae very long and extend far behind ears when bent; genal 1 vibrissae present or absent. Tail moderately long (102–139% of head and body length), unicolorous, with or without white tip. Hindfoot relatively short (22–27 mm) and broad. Digit I of pes (hallux) long, with its claw extending to interphalangeal joint of dII; and dV very long, extending to base of claw of dIV. Rostrum of skull short and delicate; nasals short and narrow; frontonasal profile quite flat, not convex; braincase moderately inflated; and interorbital region narrow, with edges faintly marked (neither rounded nor beaded). Zygomatic arches narrow, producing somewhat parallel outline. Incisive foramina narrow with extremes contracted and moderately long, extending to but not between M1s. Auditory bullae small, not inflated. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors opisthodont; capsular process distinct; and maxillary tooththrow short, ranging from 4.2–4.9 mm.

DISTRIBUTION: *Thomasomys baeops* is endemic to the northern Andes in Ecuador and Colombia, north of the Huancabamba Deflection in northern Peru (Voss 2003; Pacheco 2003). It inhabits Andean forests and páramo habitats across an elevation range from 1,300 to 3,800 m.

SELECTED LOCALITIES (Map 329): COLOMBIA: Antioquia, Sonsón, Páramo, 7 km E (FMNH 70341); Cauca, 0.8 km E of Laguna San Rafael, Páramo de Puracé (KU 124030); Huila, San Agustín, Río Magdalena (FMNH 71472); Nariño, Pasto, faldas del Volcán Galeras (ICN

13269). ECUADOR: Azuay, Molleturo (AMNH 61949); Bolívar, Río Tatahuazo, 2.5 km E of Cruz de Lizo (MSB 70704); Loja, Las Chinchas, 1 km WSW (USNM 513595), San Bartolo (AMNH 61363); Morona Santiago, Tinajillas (QCAZ 8869); Napo, Antisana (EPN 944145); Pichincha, Peñas Blancas, comuna Itulcachi (EPN 954421), Volcán Pichincha, oriente (FMNH 91990); Tungurahua, Baños (AMNH 67501).

SUBSPECIES: I consider *T. baeops* to be monotypic (but see Remarks).

NATURAL HISTORY: This species lives in disturbed secondary forest sections of primary/secondary cloud forest mosaics, but prefers areas with abundant shrubby vegetation and little arborescent canopy development (Barnett 1999). A lactating female was obtained on September in the local dry season (Barnett 1999). In cloud forests, *T. baeops* coexists with *T. paramorum* and *T. aureus*. At Papallacta, it was found inside the shrubby páramo/forest ecotone, in subalpine rainforest, and in dense thickets of secondary growth at the bottom of a narrow ravine surrounded by pastures. It was found also in primarily alpine grassland dominated by *Stipa ichu* (Poaceae) with patches of *Polylepis* forests and secondary and riparian forests in Sangay National Park (T. E. Lee et al. 2011). Individuals have been captured most commonly on the ground, along the wet margins of small streams, in narrow trails through mossy debris and damp leaf litter, under mossy logs, or in holes under the roots of trees. Individuals have also been obtained on mossy branches of small trees (Voss 2003). Food includes seeds and insects (Jarrín-V. 2001). One female was captured with three embryos in Sangay National Park during the dry season (T. E. Lee et al. 2011). The species was considered common in Ecuador (Tirira 2007) but rare in Colombia (Gómez-Laverde et al. 2008).

REMARKS: Thomas (1899b) described and reported this taxon with the spelling *boeops*, which was followed by Thomas (1906c), and later by Cabrera (1961). Alternatively, Gyldenstolpe (1932), Tate (1932g), and Ellerman (1941) corrected the spelling to *baeops*. Gyldenstolpe (1932) and Tate (1932g) used the diphthong *æ* for both *T. baeops* and *T. praetor*. Although these spellings might be considered an unjustified emendation (ICZN 1999:Art. 33.2.3), as no explanation or justification was given by either author, it should be noted that the Greek root for "small" is "*baios*," which becomes "*baeo*-" when used within the English language (R. W. Brown 1956). Several mammalian genus-group names use the root *baeo*-, including *Baeodon*, *Baeus*, *Baeolophus*, *Baiostoma*, and *Ceratobaeus*. Recent authors (e.g., Voss 2003; Musser and Carleton 2005) have used the *baeops* spelling, although without an explicit justification. Both spellings (i.e., *boeops*, *baeops*) are homonyms (ICZN 1999:Art. 58.1), and according to

the Principle of Homonymy the senior name should prevail (i.e., *boeops*). However, given the prevailing use of the spelling *baeops* and to maintain the stability, I consider *baeops* as a correct original spelling (ICZN 1999:Art. 33.3.1) because it is in prevailing usage and can be attributed to the original author and date.

Cabrera (1961) and Musser and Carleton (2005) erroneously gave the type locality as “El Oro Prov., Chilla Valley, Río Pita, 3500 m” although Thomas (1899b) clearly referred to the Río Pita, which passes through the Valle de los Chillos in the province of Pichincha (see also Voss 2003).

A phylogenetic analysis of discrete morphological characters for thomasomyine rodents found *T. baeops* more closely related to *T. taczanowskii*, and both members of the unnamed genus (“New Genus B,” *sensu* Pacheco 2003). Salazar-Bravo and Yates (2007) confirmed this relationship in a molecular phylogenetic analysis based on mtDNA cytochrome-*b* sequences, who also reported a divergence of 6.4% between both taxa, the lowest between a species pairs within *Thomasomys*. T. E. Lee et al. (2011) reported *T. baeops* to be more closely related to the pair *T. ischyryus* and *T. silvestris*, also based on cytochrome-*b* sequences, but their sample of *T. ischyryus* (the GenBank sequence AF 108675 [MVZ 181999]) in fact corresponds to *T. taczanowskii* (see Pacheco 2003). Their result, therefore, is thus consistent with previous analyses, although the proposed relationship of *T. taczanowskii* with *T. silvestris* and then with *T. baeops* needs to be corroborated.

Although Pacheco’s (2003) morphological analyses included only Ecuadorean specimens of *T. baeops*, several characters exhibited some degree of geographic differentiation. For example, genal 1 vibrissae were found to be present or absent in separate samples, the terminal tip of tail was white or not, and the premaxillae were positioned either posterior or subequal to nasals. The geographic concordance of these differences suggests that *T. baeops* may be composed of more than one taxon. This argument is in line with the analysis of cytochrome-*b* sequences that supported a specimen from Sangay National Park, identified morphologically as *T. baeops*, as an unknown taxon (T. E. Lee et al. 2011). Furthermore, populations from Caldas and Cauca in Colombia and Papallacta in Ecuador also appear to represent different taxa. The Caldas population exhibits a dorsal band faint and an auditory bullae small but comparatively more globose than typical *T. baeops*. The Cauca population is darker, genal 1 vibrissae are present, and the premaxillae are uniformly longer than nasal. The Papallacta sample lacks genal 1 vibrissae and exhibits both more robust upper incisors and wider incisive foramina and mesopterygoid fossa. These preliminary results still wait throughout analyses comparing side-by-side populations of these relatively common rodents.

Map 329 Selected localities for *Thomasomys baeops* (●). Contour line = 2,000 m.

Thomasomys bombycinus Anthony, 1925

Silky Thomasomys

SYNONYM:

Thomasomys bombycinus Anthony, 1925:1; type locality “Paramillo, Western Andes, [Antioquia,] Colombia; altitude 12,500 ft.”

DESCRIPTION: Medium bodied (head and body length 112–130 mm) with long, soft, and silky pelage. Dorsal color ranges between fuscous and clove-brown sprinkled with black-tipped hairs; sides paler; ears clove-brown; hands and feet arepale brown. Ventral pelage cinnamon-buff to tawny-olive, smoothly transitioned from darker color of flanks, not countershaded. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail relatively short (tail length 99–124% of head and body length), drab colored above, somewhat lighter below, and thinly haired. Hindfoot moderately short (26–30 mm) and narrow, without metatarsal patch. First digit of pes (hallux) short, with claw not extending more than about half length of phalanx 1 of dII. Digit V long, claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 26.8–29.2 mm) with relatively long and narrow rostrum. Interor-

bitar region moderately broad with round margins. Incisive foramina short and open, barely reaching plane of M1s. Mesopterygoid fossa broad, especially anteriorly. Auditory bullae small and uninflated, with main axis less inclined to midline compared with congeners. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper molars moderately hypsodont, with slight interpenetration mainly between hypoflexus and metaflexus of first and second upper molars. Maxillary tooththrow short, ranging from 4.7–5.5 mm. Upper incisors orthodont.

DISTRIBUTION: *Thomasomys bombycinus* occurs in the northern part of the western Andes in Colombia.

SELECTED LOCALITIES (Map 330): COLOMBIA: Antioquia, Paramillo, W Andes (type locality of *Thomasomys bombycinus* Anthony), Urrao, Páramo Frontino (FMNH 71320), Urrao, Santa Bárbara (FMNH 71362); Risaralda, Finca Cañón, Papayal, Río San Rafael, Parque Nacional Tatamá (IAvH-M 5625).

SUBSPECIES: I consider *T. bombycinus* to be monotypic (but see Remarks).

NATURAL HISTORY: Nothing is known of the habitat and ecology of this species, but based on records it is

likely found in moist montane habitats including forest and páramo (Delgado et al. 2008).

REMARKS: Anthony (1925) believed *T. bombycinus* to resemble *T. cinereus* more closely than *T. cinereiventor*, although Pacheco (2003) found *T. bombycinus* closer to *T. cinereiventor* in his cladistic analysis of morphological characters. Specimens from Páramo Frontino and Santa Bárbara exhibit some differences in contrast to the type series, such as the tail bicolored, a distinct gap between the thenar and hypothenar pads of the pes, shorter and narrower incisive foramina with posterior margins extending close to the protocones of the M1s, not to the edge, and a medial process of palate small but distinct. These character differences suggest that *T. bombycinus* might be polytypic.

Thomasomys caudivarius Anthony, 1923

White-tipped Thomasomys

SYNONYMS:

Thomasomys caudivarius Anthony, 1923b:4; type locality “Taraguacocha, Cordillera de Chilla, 10,750 feet [3,277 m], Provincia del Oro, Ecuador.”

Thomasomys cinereus caudivarius: Cabrera, 1961:427; name combination.

DESCRIPTION: Medium sized (head and body length, 116–125 mm) with soft, dense, and comparatively long dorsal fur. Dorsal coloration between mummy-brown and clove-brown with tip of the hairs colored; not counter-shaded with the ventral pelage, which is near chamois or buffy cream. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail longer than head and body (116–134%) and terminates in white tip. Hindfoot moderately long (28.5–31 mm) and narrow; hands and feet approach color of upper parts but lighter; and distinct gap exists between thenar and hypothenar plantar pads. Digit I of pes (hallux) moderate, with its claw extending to about half length of phalanx 1 of dII. Digit V of pes long, with its claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 27.5–29.7 mm) with relatively long and moderately broad rostrum, and anteriorly expanded nasals. Interorbital region moderately broad, hourglass in shape, and with round margins. Incisive foramina oval, more contracted anteriorly, and moderately long, reaching anterior margins of M1s or close. Mesopterygoid fossa broad, with subparallel margins and with weak medial palatal process usually present. Auditory bullae small and uninflated. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen present). Upper molars moderately hypsodont, with interpenetration of flexi. Maxillary tooththrow moderately long, ranging from 4.8–5.3 mm. Upper incisors orthodont. Capsular process absent.

Map 330 Selected localities for *Thomasomys bombycinus* (●). Contour line = 2,000 m.

DISTRIBUTION: *Thomasomys caudivarius* occurs from central Ecuador to northern Peru, in montane forest and páramo habitats of the western Andes, from 2,750 to 3,350 m (L. Luna and Pacheco 2002; Pacheco 2003).

SELECTED LOCALITIES (Map 331): ECUADOR: Bolívar, Río Tatahuazo, 4 km E of Cruz de Lizo (MSB 70712), Río Tatahuazo, 2.5 km E of Cruz de Lizo (MSB 70719); El Oro, Taraguacocha, Cordillera de Chilla, páramo 1000 ft above camp (type locality of *Thomasomys caudivarius* Anthony). PERU: Cajamarca, Las Ashitas, 4 km W of Pachapiriana (AMNH 268150), San Ignacio, Tabaconas, Piedra Cueva in Cerro Coyona (Tabaconas-Namballe National Sanctuary) (UMMZ 176719); Piura, Cerro Chinguela (MUSM 23743), Huancabamba, Tambo (FMNH 81331), Minera Majaz, Campamento Nueva York (MUSM 23565).

SUBSPECIES: I consider *T. caudivarius* to be monotypic (but see Remarks).

NATURAL HISTORY: This species is terrestrial and nocturnal, feeding on seeds and insects (Jarrín-V. 2001). Specimens have been captured along small mountain streams, in a valley with thick shrubbery and low stunted trees, and in open páramo with an abundance of low shrubbery and no trees (Anthony 1923b).

REMARKS: *Thomasomys caudivarius* was considered a large member of the “*cinereus* group” by Anthony (1923b), but was relegated to a subspecies of *T. cinereus* by Cabrera (1961) without justification. Tirira (1999), based on a personal communication from V. Pacheco, listed *caudivarius* as a valid species, a status fully supported by L. Luna and Pacheco (2002), who also reported the species from northern Peru. Steppan (1995) reported the vertebral counts of this species (reported as *T. cinereus*). Jarrín-V. (2001) reported *T. caudivarius* from Otonga, Cotopaxi, but his description and illustration of a species of dark general coloration appears to correspond better to *T. silvestris*. Furthermore, these specimens were taken at 2,000 m, an elevation well below the confirmed range of *T. caudivarius* but within that of *T. silvestris*. For these reasons, I have tentatively omitted this record pending further examination of his specimens; however, if valid, Otonga would represent the northernmost and the lowest record for *T. caudivarius*. Pozo-R. et al. (2007) reported another northern record of *T. caudivarius* from Finca Ana María, Pichincha, at 2,500 m; however, I have not included their record, as the authors provided no description to confirm their identification and because this locality is well outside the range I document herein.

L. Luna and Pacheco (2002) contrasted the species with *Thomasomys onkiro* and *T. silvestris*, but a phylogenetic analysis of morphological characters placed *T. caudivarius* within the “*cinereus*” species group, specifically most closely related to *T. hylophilus* (Pacheco 2003). Although *T. caudivarius* is considered monotypic, there is substantial morpho-

Map 331 Selected localities for *Thomasomys caudivarius* (●). Contour line = 2,000 m.

logical variation in the length of nasals, the breadth of incisive foramina and the degree of their posterior extension, breadth of mesopterygoid fossa, and size of molars among populations. Specimens from northern Peru, for example, exhibit a mesopterygoid fossa without a medial palatal process, and a roof perforated by narrow slits, among other features. These specimens appear more similar to two specimens P. Moreno and Albuja (2012) reported from Reserva de Tapichalaca (04°29'31.5"S, 79°07'47.2"W), Zamora-Chinchipe province, 2,500 m, Ecuador, as *T. onkiro* (see that account). They might represent another taxon allied to *T. caudivarius*. It is thus possible that this species is polytypic.

Thomasomys cinereiventris J. A. Allen, 1912

Asby-bellied Thomasomys

SYNONYMS:

Thomasomys cinereiventris J. A. Allen, 1912:80; type locality “crest of Western Andes (altitude, 10,340 feet [3,152 m]), 40 miles [64 km] west of Popayan [= Popayán], Cauca, Colombia.”

Thomasomys cinereiventris cinereiventris: Gyldenstolpe, 1932a:53; name combination.

DESCRIPTION: Large species (head and body length 100–147 mm) with very dark brown dorsal pelage, hairs of which tipped with lighter brown, and with flanks almost as dark as dorsal region. Ears rather small and brown in color. Ventral pelage ash gray with barely perceptible wash of grayish pale yellow, moderately countershaded with respect to dorsal pelage. Pelage quite long, soft, and lax. Mystacial vibrissae moderately long, extending

slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail variable in length, ranging from comparatively short or moderately long (107–128% of head and body length), uniformly pale brown, covered with short hairs, and without terminal pencil. Hindfoot long (32–36 mm), and pale brown. Digit I of pes (hallux) short, with claw not extending beyond half length of phalanx 1 of dII. Digit V of pes long, claw extending about half length of phalanx 2 of dIV. Skull large (condyloincisive length of skull 30.7–32.6 mm) with long and robust rostrum, tapering anteriorly; braincase oblong, comparatively more elongated than other species; zygomatic notches comparatively deeper; interorbital region intermediate with incipiently square margins. Zygomatic arches strongly convergent; zygomatic plates broad and vertical. Upper molars moderately hypsodont, with slight interpenetrating flexi mainly between hypoflexus and metaflexus of M1 and M2. Maxillary toothrow long, 5.4–6.2 mm. Upper incisors opisthodont and comparatively broad.

DISTRIBUTION: *Thomasomys cinereiventer* is known only from the western Andes in Colombia, from 1,828 to 3,152 m.

SELECTED LOCALITIES (Map 332): COLOMBIA: Antioquia, Mpio. Jardín, Vda. La Linda (ICN 16489); Cauca, Cocal (AMNH 32447), Munchique, E side (AMNH 181476), coast range W of Popayán (AMNH 32417); Chocó, con límite de dpto. Valle (carretera vereda pacífico-Mpio. San José del Palmar) (IAvH-M, 7340); Risaralda, Finca Cañón, Papayal, Río San Rafael, Parque Nacional Tatamá (IAvH-M 5622).

SUBSPECIES: *Thomasomys cinereiventer* is monotypic.

NATURAL HISTORY: Little is known about this species, but it is present in subtropical/tropical moist montane forests (Gómez-Laverde and Pacheco 2008). It was captured in Risaralda in a locality with steep terrain with patches of disturbed (selectively logged) primary cloud forest, agricultural fields, and pastures (Voss et al. 2002). Mendez (1971) described *Cummingsia inopinata* as a new species of mallophagan louse from specimens identified as *T. cinereiventer* from Laguna de la Cocha, Nariño, and Comis, Putumayo, Colombia. However, no voucher specimens are apparently available to confirm or check the identification of these host specimens. I suggest the alleged association of *C. inopinata* with *T. cinereiventer* be cautiously considered pending new evidence. Mendez (1971) also suggested that *T. cinereiventer* is partially arboreal based on the report of *Dasipsyllus gallinulae*, a true bird flea, on three different specimens of this species from Cerro Munchique. Individuals might temporarily occupy tree holes or other sites containing bird nests, from which the mentioned fleas were probably obtained. Brennan (1968) reported the chiggers *Crotiscus desdentatus*,

Map 332 Selected localities for *Thomasomys cinereiventer* (●). Contour line = 2,000 m.

Odontacarus munchiquensis, and *Euschoengastia pamelae* (the latter two as new species) from *T. cinereiventer*. Trapido and Sanmartín (1971) processed specimens of *T. cinereiventer* from the Pichindé valley, Munchique, and La Cocha for Pichindé virus, but failed to detect the virus.

REMARKS: Musser and Carleton (1993, 2005) treated *contradictus* Anthony, 1925 and *dispar* Anthony, 1925 as subspecies or simple synonyms of *T. cinereiventer*. Pacheco (2003) regarded these taxa as full species, a decision I follow herein (see these respective accounts for morphological support for this decision). Cabrera (1961) included *Thomasomys erro* as a subspecies of *T. cinereiventer*, but Voss (2003) recently elevated *erro* to full species by and convincingly contradicting Cabrera's hypothesis. A phylogenetic analysis based on morphological characters found instead found *T. cinereiventer* to be closely related to *T. bombycinus* (Pacheco 2003).

Thomasomys cinereus (Thomas, 1882)

Olive-gray *Thomasomys*

SYNONYMS:

H[esperomys]. (*Rhipidomys*) *cinereus* Thomas, 1882:108; type locality "Cutervo, 9,200' [2,804 m]," Cajamarca, Peru.

Hesperomys (Vesperimus) cinereus: Thomas, 1884:449; name combination.

Hesperomys (Thomasomys) cinereus: Coues, 1884:1275; name combination.

Peromyscus (Thomasomys) cinereus: E.-L. Trouessart, 1897: 512; name combination.

Thomasomys cinereus: Thomas, 1906c:443; first use of current name combination.

DESCRIPTION: Medium sized (adult head and body length 107–146 mm) with long, soft, and dense dorsal fur. Dorsal coloration grizzled ashy gray, hairs being slate-colored at base and white at tips, sprinkled with longer and blackish hairs. Ventral pelage grayish white, hairs also slate-colored at base, and moderately countershaded with dorsal pelage. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail comparatively thick, indistinctly bicolored, and lacks terminal white tip; it ranges from shorter to longer than head and body (96–145%). Hindfeet moderately long (28–32 mm) with metatarsals covered by pure white shining hairs; hands also whitish. Digit I of pes (hallux) moderately long, its claw extending close or to interphalangeal joint of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 29.3–32.3 mm) with relatively long and broad rostrum, nasals well expanded anteriorly, and no rostral tube. Interorbital region narrow or moderate, hourglass in shape with rounded margins. Zygomatic plates moderately broad, subequal to length of M1, and vertical. Zygomatic arches converge anteriorly to moderate degree. Incisive foramina oval but elongated, and long, reaching anterior margins of M1s or slightly between them. Mesopterygoid fossa broad, wider anteriorly or with margins subparallel; medial process usually present. Auditory bullae small and uninflated. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper molars moderately hypsodont, without interpenetration of flexi. Maxillary toothrow moderately long, ranging from 4.8–5.6 mm. Upper incisors orthodont. M1 lacks accessory labial root, and m1 with distinct anteromedian flexid. Capsular process absent.

DISTRIBUTION: *Thomasomys cinereus* is restricted to northwestern Peru, west of the Río Marañón, from 1,198 to 3,100 m.

SELECTED LOCALITIES (Map 333): PERU: Cajamarca, 35 mi WNW of Cajamarca (MVZ 137937), Cutervo, San Andrés de Cutervo, Cutervo National Park, 100 m over El Tragadero (UMMZ 176634), Pisit, T 25 (MUSM 25709); La Libertad, Cachicadán (MUSM 17285), south

of Huamachuco (BM 0.6.6.12); Lambayeque, Bosque de Chiñama (MUSM 5095), Seques (AMNH 73129); Piura Ayabaca, bosque de Huamba, 44 km E of Ayabaca (MUSM 511), 15 road km E of Canchaque (LSUMZ 19315), Cerro Chinguela, ca. 5 km NE of Zapalache (LSUMZ 27147), 33 road km SW of Huancabamba (LSUMZ 19301), Pariamarca Alto (MUSM 23758).

SUBSPECIES: *Thomasomys cinereus* is monotypic (but see Remarks).

NATURAL HISTORY: This species inhabits humid montane forests or Yungas of northern Peru where specimens have been caught on the ground among dense shrubs and on the forest floor. One female (LSUMZ 27081) from Piura was pregnant with three embryos in August (dry season). Several males with scrotal testes were caught at the same place from late July and early August. Known ectoparasites of *T. cinereus* include the flea *Plocopsylla kilya* (Schramm and Lewis 1987) and a staphylinid beetle, *Amblyopinus piurae* (Seevers 1955). P. T. Johnson (1972) and Durden and Musser (1994) reported *T. cinereus* as the host for the anopluran louse *Hoplopleura angulata*, but this allocation is corrected here to *T. ischyryus* (see that account).

REMARKS: Thomas (1882) described *T. cinereus* based mostly on external morphology and basic morphometric values, but it remained for Voss (1993) to detail descriptions of key external, cranial, dental, and soft characters. Pacheco (2003) confirmed these reported attributes and expanded on additional characters of the species.

Thomas (1884) identified a specimen, obtained by M. C. Jelski for the Warsaw Museum, from Maraynioc (near Chanchamayo), Junín department, as *Hesperomys (Vesperimus) cinereus*. However, this record is not included for the species because its description does not fit typical *T. cinereus* and I have not had the opportunity to examine the specimen. Osgood (1914b) also reported some specimens from near Uchco, Amazonas, as the subspecies *T. cinereus ischyryus*, but the taxon *ischyryus* is now regarded as a different species (Pacheco 2003; Musser and Carleton 2005). Previous records of the species from Ecuador (Musser and Carleton 1993) were based on the inclusion of *caudivarius* as a subspecies (following Cabrera 1961), but L. Luna and Pacheco (2002) treated this taxon as a valid species. Other Colombian records of the allegedly *T. cinereus* (from Antioquia [Hooper and Musser 1964] and Huila [Carleton 1973]) are likely based on misidentified specimens because these localities are far from the currently known distribution of the species. As a consequence, the descriptions of glans penis morphology (Hooper and Musser 1964) and stomach morphology (Carleton 1973) intended for *T. cinereus* do not correspond to this species. Rather, Pacheco (2003) reported on these morphological attributes based on correctly allocated specimens. The sample from La Libertad differs from

Map 333 Selected localities for *Thomasomys cinereus* (●). Contour line = 2,000 m.

specimens from the type locality in several discrete characters, such as a narrower and parallel mesopterygoid fossa. Detailed study might reveal that *T. cinereus* is also a complex of separate species. The karyotype is unknown.

Ellerman (1941) was the first to recognize a *cinereus* Group, but his concept was very broadly constructed, and it would include species allocated herein to the “baeops,” “incanus,” and “cinereus” groups of *Thomasomys* as well as some species of now assigned to *Rhipidomys*, *Wilfredomys*, and *Juliomys*. Therefore, Ellerman (1941)’s concept does not correspond to current taxonomy and is no longer useful. The “cinereus” group, in a more restrictive sense, was then first proposed by Pacheco (2003) and is elaborated here.

Thomasomys cinnameus Anthony, 1924

Cinnamon-colored *Thomasomys*

SYNONYMS:

Thomasomys cinnameus Anthony, 1924b:5; type locality “Hacienda San Francisco, east of Ambato, [Tungurahua,] central Ecuador, elevation 8000 feet [2,438 m].”

Thomasomys gracilis cinnameus: Cabrera, 1961:429; name combination.

DESCRIPTION: Small species (head and body length 84–90 mm) with long and soft dorsal fur. Dorsal coloration cinnamon-brown, gradually changing to clay color on sides, with ventral color cinnamon-buff. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail long to very long (126–152% of head and body length), finely annulated and thinly haired, and uniformly clove-brown in color. Hindfoot short (22–24 mm) and slender, clove-brown color; hands of same color. Digit I of pes (hallux) moderately long, with claw not extending more than half length of phalanx 1 of dII. Digit V of pes very long, with its claw extending to base of claw of dIV. Skull small (condyloincisive length of skull 22–23.3 mm) with relatively long and slender rostrum and subglobose inflated braincase. Interorbital region narrow, hourglass in shape, and with round margins. Incisive foramina narrow, more contracted anteriorly, and long, reaching anterior margins of M1s or extending slightly between them. Zygomatic plates narrow, their breadth shorter than length of M1. Mesopterygoid fossa broad with subparallel margins and without medial process; its roof closed, without sphenopalatine vacuities. Auditory bullae small and uninflated, with distinct bony tubes. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen are present). Upper molars moderately hypsodont with weakly developed cingula and styler cusps but no interpenetrating flexi. Maxillary toothrow short, ranging from 3.91–4.03 mm. Upper incisors opisthodont with incipient groove on anterior face.

DISTRIBUTION: *Thomasomys cinnameus* occurs in the Colombian and Ecuadorean Andes, in páramo and montane forests, from about 2,400 to 3,800 m.

SELECTED LOCALITIES (Map 334): COLOMBIA: Antioquia, Páramo, 7 km E of Sonsón (FMNH 70342); Cauca, 0.5 km E of Laguna San Rafael, Páramo de Puracé (KU 124058); Huila, San Agustín, Las Bardas (FMNH 71489). ECUADOR: Azuay, The Cajas Plateau (Barnett 1999); Carchi, Reserva Biológica Guandera (Tirira and Boada 2009); Chimborazo, Cochaseca (AMNH 63039); Morona-Santiago, Río Upano, Sangay National Park (T. E. Lee et al. 2011); Napo, 1.6 km W of Papallacta (UMMZ 155668); Tungurahua, Hacienda San Francisco, east of Ambato (type locality of *Thomasomys cinnameus* Anthony).

SUBSPECIES: I consider *T. cinnameus* to be monotypic (but see Remarks).

NATURAL HISTORY: Individuals of this species have been trapped among mossy boulders in an old lava flow that impounds the Río Tambo to form Laguna Papallacta, and on the ground in subalpine rainforest in the valley of

the Río Papallacta (Voss 2003). Barnett (1999) collected the species only in páramo, in minimally disturbed quenoa forests, always on the ground in areas with dense canopy and little groundcover but deep moss, and in dense and isolated clumps of composite bushes on exposed slopes covered with tussock grass. T. E. Lee et al. (2011) collected the species in a variety of habitats, including elfin forest, bogs, and swampy cloud forest. One female was lactating, and males had scrotal testes in August, during the dry season (Barnett 1999).

REMARKS: Both Cabrera (1961) and Musser and Carleton (1993) treated *T. cinnameus* as a synonym of *T. gracilis*, but Voss (2003) amplified its unique traits in comparisons with both *T. gracilis* and *T. hudsoni* and recognized *T. cinnameus* as a valid species. Both Pacheco's (2003) cladistic assessment of morphological characters and Salazar-Bravo and Yates's (2007) phylogenetic analysis of mtDNA characters support this conclusion. Pacheco (2003) found *T. cinnameus* closely related to *T. ucucha* while Salazar-Bravo and Yates (2007) placed it at the base of the group of species forming the "cinereus" group. Clearly, additional work is needed to resolve relationships, although the validity of *T. cinnameus* as a species seems without doubt.

Map 334 Selected localities for *Thomasomys cinnameus* (●). Contour line = 2,000 m.

Voss (2003) considered *T. cinnameus* to be monotypic based on his review of the type specimen and Ecuadorean material, a decision I follow here. My assignment of some Colombian populations to this species results from their close morphological resemblance to the holotype (AMNH 67401) in most qualitative and quantitative characters, including the cinnamon-brown dorsal pelage and the incisors with incipient groove. However, several traits differ between the Ecuadorean and Colombian samples that suggest the presence of more than one taxon. For example, the sample from Huila is smaller (molar tooththrow 3.59 mm on average) and with a narrow, slightly posteriorly inclined zygomatic plates. Furthermore, the Antioquia sample is probably the most distinct, as the genal 1 vibrissae are present, incisors are orthodont, and incisive foramina are shorter among other traits. Unfortunately, these samples are small, and more specimens would be necessary before a formal revision is possible.

Thomasomys contradictus Anthony, 1925

Central Andes Thomasomys

SYNONYMS:

Thomasomys cinereiventer: J. A. Allen, 1916b:211; part; not *Thomasomys cinereiventer* J. A. Allen.

Thomasomys cinereiventer contradictus Anthony, 1925:3; type locality "Santa Isabel, Quindio Andes, [Quindío,] Colombia; altitude, 12,700 feet [3,871 m]."

DESCRIPTION: Large species (head and body length 107–133 mm) with mummy brown coloration along sides ranging to fuscous on back, with some black-tipped hairs; ears brown; hands and feet drab. Ventral pelage between clay color and honey yellow, transition from darker color of sides very gradual. Pelage quite long, soft, and lax. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail moderately long (111–138% of head and body length), brown above and below, coarsely annulated, sparsely haired, without pencil. Hindfoot long (30–34 mm), and drab in color above; gap between thenar and hypothenar pads present. Digit I of pes (hallux) short, its claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, its claw extending about half length of phalanx 2 of dIV. Skull large (condyloincisive length, 27.8–29.6 mm) with long and comparatively broad rostrum, and oblong braincase comparatively more rounded and less flat than that of *T. cinereiventer*. Zygomatic notches shallow, and nasals extend posteriorly behind premaxillae. Interorbital region moderately broad, hourglass in shape, with rounded margins. Incisive foramina short and broad, and do not reach plane of M1s. Jugal bones long and ethmoturbinals large. Optical foramen placed dorsal to M3. Zygomatic arches weakly convergent; zygomatic plates broad and slightly sloped

backward from bottom to top. Mesopterygoid fossa broad with subparallel margins and without medial process; sphenopalatine vacuities present as narrow slits. Auditory bullae small to medium in size and moderately inflated. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper molars moderately hypsodont, without interpenetrating flexi, and without crenulations. Anteroflexus of M1 distinct, and anteromedian flexid of m1 indistinct. Maxillary tooththrow moderately long (4.8–6.6 mm), but shorter than *T. cinereiventer*. Upper incisors opisthodont.

DISTRIBUTION: *Thomasomys contradictus* is known only from the central Andes of Colombia, from ca. 2,400 to 3,871 m.

SELECTED LOCALITIES (Map 335): COLOMBIA: Antioquia, Mpio. La Unión, Vda. San Miguel de la Cruz, sitio Alto de San Miguel de la Cruz (ICN 17126), Medellín, Las Palmas (FMNH 70339), Sonsón, Páramo, 7 km E (FMNH 70273); Caldas, Manizales, Río Termales (FMNH 71319); Cauca, Almaguer (AMNH 37768), El Roble (AMNH 32960); Tolima, Hacienda Indostán (IAvH-M 5704).

SUBSPECIES: *Thomasomys contradictus* is monotypic.

NATURAL HISTORY: Little is known about any aspect of the ecology or population biology of this species, but it is present in subtropical/tropical moist montane forests (Gómez-Laverde and Pacheco 2008).

REMARKS: Cabrera (1961) and more recent taxonomic synopses (e.g., Musser and Carleton 2005) maintained *contradictus* as a subspecies of *T. cinereiventer*. Following my earlier analysis (Pacheco 2003) based on direct comparisons of available specimens, including the relevant type material, I regard *T. contradictus* as a species distinct from *T. cinereiventer*. *Thomasomys contradictus* is smaller, its zygomatic arches are not strongly convergent, the interorbital region lacks square margins, zygomatic notches are shallow, the rostrum and incisive foramina are broader, the upper molars lack interpenetrating flexi and crenulations, and the anteromedian flexid of m1 is indistinct. Nevertheless, some populations show a degree of variation that should be formally assessed with larger series. The samples from Sonsón and Las Palmas, Antioquia, have orthodont upper incisors and vertical zygomatic plates; these may prove to be a separate species. Anthony (1925) considered the specimens from Almaguer as intermediate between *T. cinereiventer* and *T. contradictus*. I consider this population tentatively as *T. contradictus* based on the ventral pelage with a tendency to yellowish and the lack of overlapping flexi and crenulation in the upper molars, although the rostrum is atypically quite robust. Anthony (1925) selected an adult male specimen as the holotype (AMNH 32955), but this specimen is a female, with a long prepuce covered by long hairs as typical of many *Thomasomys*.

Map 335 Selected localities for *Thomasomys contradictus* (●). Contour line = 2,000 m.

Thomasomys daphne Thomas, 1917

Daphne's Thomasomys

SYNONYMS:

Thomasomys daphne Thomas, 1917g:2; type locality "Ocobamba Valley, 9,100 feet [2,774 m], Cusco, Peru.

Thomasomys daphne daphne: Gyldenstolpe, 1932a:58; name combination.

DESCRIPTION: Small species (head and body length 88–109 mm; condyloincisive length of skull 24.5–26.3 mm) with dull brownish dorsal pelage and flanks almost as dark as dorsal region; ears small and brown, not contrasting markedly with head. Ventral pelage slaty gray but washed with buff, and not countershaded. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail medium to long (106–166% of head and body length), covered by fine scales and unicolor brown, except for white tip in most specimens. Hindfoot short (23–27 mm), slender, and pale brown. Skull comparatively short and narrow rostra and nasals, moderately broad interorbital region with edges not ridged, and moderately inflated braincase. Incisive foramina narrow and relatively short, ending just in front of M1s, not extending to between them. Auditory

bullae small. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Capsular process distinct in adult specimens. Upper incisors gracile and proodont, and maxillary tooththrow short, 3.8–4.2 mm.

DISTRIBUTION: *Thomasomys daphne* occurs along the eastern Andean slopes from southern Peru to northern Bolivia, in montane forests habitats at elevations from 2,000 to 3,540 m.

SELECTED LOCALITIES (Map 336): BOLIVIA: La Paz, Campamento Piara (CBF 6731), Murillo, Cuticucho (CBF 4450), Okara (AMNH 72131), ca. 15 km by road NE of Unduavi at old railroad crossing (UMMZ 155879), 30 km by road N of Zongo, cement mine (UMMZ 156190). PERU: Cusco, Chacarara, Hatunpampa (MUSM 17457), Occobamba Valley, Tocadoqueu (USNM 194902), 32 km NE (by road) of Paucartambo, km 112 (MVZ 166705), 90 km by road SE of Quillabamba (UMMZ 160749); Puno, 3 mi N of Limbani (MVZ 139525), 9 km N of Limbani (MVZ 171501).

SUBSPECIES: I consider *T. daphne* to be monotypic (but see Remarks).

NATURAL HISTORY: Little is known of the ecology or behavior of this species. Specimens in southern Peru were obtained on the ground in the dense understory of disturbed cloud forest and among clumps of bunch grasses in open areas within that forest formation. Known ectoparasites include the fleas *Plocopsylla viracocha* and *Neotyphloceras* sp. (Maihuay et al. 1994).

REMARKS: S. Anderson (1997) used *australis* as a subspecies of *T. daphne* for Bolivian populations, but Pacheco (2003), Voss (2003), and Salazar-Bravo and Yates (2007) each treated this taxon as a species. Although I regard *T. daphne* as monotypic, earlier I (Pacheco 2003) acknowledged this taxon was likely composed of at least two species, with the southern Peruvian population from the Limbani drainage in Puno department and northern Bolivian populations in La Paz department distinguished from topotypic samples from the Urubamba drainage in Cusco department. Compared with *T. daphne*, these populations exhibit the primitive condition of the carotid circulation (pattern 1, *sensu* Voss 1988), a broader interorbital region, and broader incisive foramina, among other features. For these reasons, Pacheco (2003) suggested these populations represent and unnamed taxa, informally named *Thomasomys* sp. 3. Salazar-Bravo and Yates (2007) included a Peruvian and a Bolivian sample of this taxon (reported as *T. daphne*) in a phylogenetic analysis based on mtDNA cytochrome-*b* gene, and found it closely related to *T. australis*, from which it was distinguished by 7.9% of uncorrected percent sequence divergence; a hypothesis also supported by Patton's (1986) species-limited allozyme analysis. The morphological phy-

Map 336 Selected localities for *Thomasomys daphne* (●). Contour line = 2,000 m.

logeny of Pacheco (2003) placed *T. daphne* as closely related to *Thomasomys* sp. 3 followed by *T. australis*.

Thomasomys dispar Anthony, 1925

Colombian *Thomasomys*

SYNONYMS:

Thomasomys cinereiventer: J. A. Allen, 1916b:211; part; not *Thomasomys cinereiventer* J. A. Allen, 1912.

Thomasomys cinereiventer dispar Anthony, 1925:2; type locality "Andalucia, Eastern Andes, Huila, Colombia, elevation 7000 feet."

DESCRIPTION: Medium-sized (adult head and body length 98–119 mm) with soft, dense, and comparatively long dorsal fur. Pelage coloration mummy brown on back and sides, heavily washed with fuscous black in middorsal region. Ventral pelage ranges between ivory-yellow and cream-buff, gradually transitioning into darker color of flanks. Mystacial vibrissae long, extending well beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail very long (125–186% of head and body length), incipiently bicolored, with terminal white tip. Hindfoot moderately long (27.2–33 mm) and narrow; dorsal surface and that of digits light brown; gap present between hypothenar and thenar pads. Pinnae small (20.5–21.5 mm) and clothed with short, brown hairs. Digit I of pes (hallux) moderately long, with claw extending less than about half length of phalanx 1 of dII. Digit V of pes moderately long, with claw barely extending to interphalangeal joint

of dIV. Skull moderately long (condyloincisive length 28.9–32.4 mm) with relatively long and moderately broad rostrum, anteriorly expanded nasals producing distinct rostral tube, and rather straight frontonasal profile. Braincase somewhat oblong and less flat than that of *T. cinereiventer*. Interorbital region moderately broad, hourglass in shape, and typically with smooth margins, rarely marked. Zygomatic arches converge anteriorly. Zygomatic plates narrow (breadth shorter than length of M1) and slightly sloped backward from bottom to top; anterior margins straight. Incisive foramina moderately broad, somewhat oval, but slightly broader posterior to premaxillomaxillary suture, and very short, not extending close to anterior margins of M1s. Mesopterygoid fossa comparatively broad with subparallel margins and with distinct medial process; sphenopalatine vacuities absent or occasionally present as slits between presphenoid-basisphenoid suture. Optic foramen small and placed posterodorsal to M3. Postglenoid foramen smaller than subsquamosal fenestra, and placed somewhat ventral to it. Auditory bullae small and uninflated; bony tubes distinct or poorly distinct. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Alisphenoid strut present. Maxillary tooththrow moderately long (5.2–5.5 mm); upper molars broad, comparatively brachydont, with no interpenetration and no crenulation, but with weak labial cingula. Anteromedian flexus of M1 distinct when unworn; anteromedian flexid of m1 indistinct, even in unworn condition. Upper incisors orthodont. On mandible, condylar and angular processes level, and capsular process absent.

DISTRIBUTION: *Thomasomys dispar* occurs in the central and eastern Andes of southern Colombia, in montane forests between 2,130 and 3,310 m.

SELECTED LOCALITIES (Map 337): COLOMBIA: Cauca, Almaguer (AMNH 33768), Coconuco, Parque Nacional Puracé, Río Bedón, Versailles, N° Calma 141-M (IAvH-M 266), Paletará, PNN Puracé (IAvH-M 1641), PNN Puracé, 0.5 km W of Laguna San Rafael (IAvH-M 3765), Huila, Andalucía (type locality of *Thomasomys cinereiventer dispar* Anthony), San Agustín, Las Bardas (FMNH 71377), San Agustín, Las Ovejeras (FMNH 71399), San Agustín, Santa Marta (FMNH 71405).

SUBSPECIES: I treat *T. dispar* as monotypic (but see Remarks).

NATURAL HISTORY: Little is known about this species, but it is present in subtropical/tropical moist montane forests (Gómez-Laverde and Pacheco 2008).

REMARKS: Cabrera (1961) maintained *dispar* Anthony as a subspecies of *T. cinereiventer*, as did Musser and Carleton (2005). Herein, I treat this taxon as a full spe-

Map 337 Selected localities for *Thomasomys dispar* (●). Contour line = 2,000 m.

cies based on my earlier (Pacheco 2003) side-by-side comparisons of available specimens, including type material. *Thomasomys dispar* can be distinguished from *T. cinereiventer* by a combination of characters, including smaller size but relatively longer tail, moderately long digit V of the pes, rostral tube present, narrow zygomatic plates, small optic foramen posterior to M3, palatal medial process present, interorbital region with incipient smooth margins, and upper incisors orthodont, among other morphological features. Although I consider *T. dispar* as monotypic, a more thorough analysis of geographic trends may result in additional valid taxa. For example, the series from San Agustín, Huila, while generally similar to the type series, may prove to be an undescribed species based on the presence of a derived (pattern 3) carotid circulation, extremely large posterior alisphenoid channel, long jugal, and other morphological features (V. Pacheco, unpubl. data).

Thomasomys eleusis Thomas, 1926

Peruvian Thomasomys

SYNONYMS:

Thomasomys cinereus: Osgood, 1914b:161; part; not *H[esperomys]*. *Rhipidomys cinereus* Thomas.

Thomasomys ischyryus eleusis Thomas, 1926e:614; type locality "Tambo Jenés, 12,000' [3,658 m]," Amazonas, Peru.

Thomasomys eleusis: Musser and Carleton, 1993:749; first use of current name combination.

DESCRIPTION: Medium size (head and body length 126–140 mm) with long, soft, and dense dorsal fur. Dorsal coloration dark gray with slight tinge of brownish on sides. Ventral pelage paler gray, with buffy overtone; hairs slate colored at base with tips dull whitish or slightly buffy; moderately countershaded relative to dorsal pelage. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail approximates head and body length (93–112%), comparatively thick, indistinctly bicolored, and lacks terminal white tip. Hindfoot moderately long (28–31 mm); metacarpals and digits covered with pure white, shiny hairs; gap present between thenar and hypothenar pads; hands whitish. Digit I of pes (hallux) moderately long, with claw extending close or to interphalangeal joint of dIII. Digit V of pes also long, with claw extending about half length of phalanx 2 of dIV. Skull moderate in size (condyloincisive length 28.6–30.3 mm) with moderately broad rostrum that tapers anteriorly. Nasals distinctly projected anteriorly but do not develop as rostral tube; long and narrow, moderately spatulate, with posterior margins distinctly longer than premaxillae. Antorbital bridge positioned high (<25% of rostrum). Zygomatic plates moderately broad, subequal in length relative to M1, and slightly sloped backward. Interorbital region moderately broad (molar row partially visible in dorsal view), hourglass in shape, and with incipiently square edges. Zygomatic arches converge slightly anteriorly. Incisive foramina long, with subparallel margins slightly broader at level of premaxillomaxillary suture, and extend to between M1 anterocones. Ethmoturbinals large; optical foramen small and placed posterodorsal to M3. Molar-bearing portion of maxillae nearly triangular. Mesopterygoid fossa broad, with subparallel margins and palatal medial process absent; roof closed, with sphenopalatine vacuities absent or represented only as slits. Auditory bullae small and uninflated. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Molar rows moderately long (5.2–5.7 mm), individual teeth moderately hypsodont, with interpenetrating flexi and crenulation absent. M1 with accessory labial root; m1 anteromedian flexid weak, even in unworn teeth. Upper incisors orthodont. Capsular process absent.

DISTRIBUTION: *Thomasomys eleusis* is limited to northern Peru, east of the Río Marañón in the Cordillera Oriental, at elevations between 3,050 and 3,660 m.

SELECTED LOCALITIES (Map 338): PERU: Amazonas, Chachapoyas, Tambo Jenés, mountains E of Balsas (type locality of *Thomasomys ischyryus eleusis* Thomas), San Pedro (AMNH 72101); La Libertad, Piedra Negra, on trail from Los Alisos to Parque Nacional Río Abiseo (USNM 582212); San Martín, Parque Nacional Río Abiseo, Pampa de Cuy (Leo and Romo 1992).

SUBSPECIES: *Thomasomys eleusis* is monotypic.

NATURAL HISTORY: This species has been captured in dense humid forest (Osgood 1914b; Thomas 1926e). More recent specimens were found in habitats ranging from Puna grassland, bare or shrub rocky places, shrubby places bordering streams, or at the border of continuous humid montane forests, all within in the Subalpine rain páramo or Montane rainforest of the Holdridge system (Leo and Romo 1992).

REMARKS: Osgood (1914b) apparently had no true *Thomasomys cinereus* at hand to compare when he reported on the series of specimens from the mountain east of Balsas, Amazonas department, Peru, as true *T. cinereus*. He probably relied on Thomas's (1882) original descrip-

Map 338 Selected localities for *Thomasomys eleusis* (●). Contour line = 2,000 m.

tion of *T. cinereus* and on the geographical proximity of its type locality. Later, however, Thomas (1926e) compared the Balsas series with the holotype of *T. cinereus*, documented their distinction, and allied *T. eleusis* to *ischyrus* rather than to *cinereus* based on the general “champagne-bottle” outline of their skulls. Pacheco (2003) reported on external, cranial, dental, and soft morphological characters of this species and confirmed that *T. eleusis* is a species distinct from both *T. cinereus* and *T. ischyryus*. In addition, *T. eleusis* was found near the base of a clade that included *T. incanus* and allies in a phylogeny based on morphological attributes (Pacheco 2003). This clade is informally called here the “incanus” group. Leo and Romo (1992) reported this species from Parque Nacional Río Abiseo, San Martín department, under the name of *T. ischyryus eleusis*. The karyotype is unknown.

Thomasomys emeritus Thomas, 1916

Venezuelan *Thomasomys*

SYNONYMS:

Thomasomys laniger emeritus Thomas, 1916j:479; type locality “Montes de Escaguer, alt. 2500 m,” Mérida, Venezuela.

Thomasomys laniger: P. T. Johnson, 1972:22; part; not *Oryzomys laniger* Thomas.

DESCRIPTION: Medium size (head and body length 104–120 mm) with long, soft, and fluffy dorsal fur. Dorsal coloration similar to that of *T. laniger*, but with more brownish tone, especially on head, and more rufous sides. Ventral pelage dull orangish, not contrasting with sides. Mystacial vibrissae very long, extending distinctly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Postauricular patches whitish but not very conspicuous. Tail slightly shorter to slightly longer than head and body (92–120%), slender, finely haired, monocolored, and without terminal white tip. Hindfoot relatively short (23–25 mm), metacarpals and digits whitish, and gap present between thenar and hypothenar pads. Digit I of pes (hallux) of moderate length, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull relatively small (condyloincisive length 24.7–26.1 mm); braincase rounded; rostrum long and narrow; interorbital region moderately broad, hourglass in shape, with round margins. Zygomatic plates moderately broad, subequal to length of M1, and sloped backward from bottom to top. Zygomatic arches moderately convergent anteriorly. Incisive foramina of moderate length, extending to or only near to anterior margins of M1s; sides parallel to slightly contracted anteriorly. Mesopterygoid fossa more expanded anteriorly and contracted posteriorly; medial process small or absent; and roof usually perforated by

moderate sized sphenopalatine vacuities. Parapterygoid vacuities present. Auditory bullae large and inflated. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper molars moderately hypsodont, with interpenetration of flexi; anteroloph of M1 distinct; protoflexus of M2 inconspicuous; hypoflexus of M3 distinct; ectolophid of m1 present. Maxillary toothrow relatively short, 4.1–4.6 mm. Upper incisors opisthodont. Capsular process absent.

DISTRIBUTION: *Thomasomys emeritus* occurs only in the Venezuelan Andes, in the departments of Mérida and Trujillo, at elevations from 2,090 to 3,550 m.

SELECTED LOCALITIES (Map 339): VENEZUELA: Mérida, Bosque San Eusebio, 7 km SSE of La Azulita (CVULA 1234), Laguna Brava, Páramo de Mariño, CVULA, 2545), Laguna Negra, 5.75 km ESE of Apartaderos (USNM 579462), La Montana, 4.1 km SE of Mérida (USNM 579457), Montes de Escaguer (type locality of *Thomasomys laniger emeritus* Thomas), Monte Zerpa, 6 km N of Mérida (CVULA 4918), Paramito, 4 km W of Timotes (USNM 374554), Sierra de Mérida (FMNH 22121), Tabay, 9 km SE of Tabay, Laguna Verde (USNM 374591); Trujillo, Hacienda Misisi, 15 km E of Trujillo (USNM 495477), Macizo de Guaramacal, 9 km ESE of Bococonó (CVULA 3342).

SUBSPECIES: *Thomasomys emeritus* is monotypic.

NATURAL HISTORY: Handley (1976) caught this species among lichen and moss-covered boulders and in rock slides, in thick, low shrubs on the ground, at the base of trees and logs, in trees, and in a house; most often in relatively dry habitats but frequently in damp places; in cloud forest and páramo. All localities are in the Lower Montane very humid forest, Montane very humid forest, Montane rainforest, or Subalpine páramo (in the vegetative life zones of Ewel and Madriz 1968).

An extensive list of ectoparasites is known from *T. emeritus*, though most with the host species incorrectly identified as *T. laniger*. These include the anopluran louse *Hoplopleura indiscreta* (P. T. Johnson 1972), the ascarid mites *Teratothrix truncata* and both *Eutrombicula cricativora* and *E. webbi* (Brennan and Goff 1979) as well as *Laelaps paulistanensis*, *Gigantolaelaps canestrinii*, and *Androlaelaps fahrenheitsi* (Furman 1972) and *Odontacarus dienteslargus*, *O. schoenesetosus*, *O. tuberculohirsutus*, and *O. vergrandi* (J. T. Reed and Brennan 1975), the chigger *Hoffmannina reedi* (Brennan 1972), the ticks *Ixodes jonesae* (Kohls et al. 1969) and *Ixodes* sp. (E. K. Jones et al. 1972), and the fleas *Cleopsylla monticola*, *Ctenidiosomus perplexus*, *Neotlyphloceras rosenbergi*, *Pleochaetis smiti*, *Plocopsylla ulysses*, and *Sphinctopsylla tolmera* (Tip-ton and Machado-Allison 1972).

REMARKS: Thomas (1916j) thought that *emeritus* was larger than true *laniger*, but he had only the type specimens for comparisons. My unpublished comparisons (12 specimens of *T. laniger* versus five of *T. emeritus*, all the same “age” based on tooth wear) indicate that both species are rather similar in most external and cranial measurements. Although *T. laniger* is slightly larger than *T. emeritus* in most variables, the difference between the two species is more obvious in condyloincisive length (average of 26.1 mm versus 25.2 mm), diastema length (average of 7.96 mm versus 7.46 mm), and least interorbital breadth (average of 4.86 mm versus 4.55 mm). Furthermore, the dorsal color of *T. emeritus* is more brownish, its under-surface more orangish, the dorsal surface of hindfoot light brown, rostrum relatively longer and narrow, the mesopterygoid fossa wider anteriorly (lyre-shaped), the incisive foramina are less open, and upper incisors are opisthodont. Aguilera et al. (2000) reported the karyotype of *T. emeritus* (reported as *T. laniger*) as $2n=42$, FN=40, with an X metacentric and a Y acrocentric chromosomes. This complement is distinct from the karyotypic formula of *T. laniger* proper, reported as $2n=40$, FN=40, with an X chromosome metacentric or submetacentric and a Y acrocentric chromosome (Gómez-Laverde et al. 1997). These morphological and karyotypic differences support the hy-

Map 339 Selected localities for *Thomomys emeritus* (●). Contour line = 2,000 m.

pothesis that *T. emeritus* is a valid species, distinct from *T. laniger*.

Pacheco (2003) presented a phylogeny based on morphological characters where *T. laniger* belonged to the clade “*cinereus*” group. Thomas (1916j) stated the type specimen of *emeritus* (BM 5.1.1.4) is a young adult male; however, my own examination of the type confirmed the specimen is a young adult female, with a long prepuce (typical of many *Thomomys*) and six mammae.

Thomomys erro Anthony, 1926

Wandering *Thomomys*

SYNONYMS:

Thomomys erro Anthony, 1926b:5; type locality “upper slopes of Mt. Sumaco, exact altitude unknown, but probably 8000–9000 feet [approx. 2,438–2,743 m] at head of the Rio Suno [= Río Suno], a tributary of the Rio Napo [= Río Napo],” Napo, Ecuador.

Thomomys cinereiventer erro: Cabrera, 1961:427; name combination.

DESCRIPTION: Relatively large (adult head and body 120–130 mm) with long, soft, and lax dorsal fur. Dorsal pelage coloration grayish brown, paler on sides; ventral pelage washed with cream-buff, not countershaded relative to dorsal pelage. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail long (130% to 139% of head and body length), thinly haired, uniformly brown in color, and terminates with 10–20 mm whitish tip extending as thin tuft of hairs. Hindfoot moderately long (30–32 mm), metacarpals similar in color to dorsum but paler, digits and unguis tuft of bristles whitish, and gap present between thenar and hypothenar pads. Ventral base of manual claw keeled. Digit I of pes (hallux) short, with first phalanx not extending beyond metatarsal of digit II and claw no more than about half the length of p1 of digit II. Digit V of pes moderately long, with claw extending to, but not beyond, first interphalangeal joint of digit IV. Skull moderately long (condyloincisive length 27.2–28.4 mm) and slender, with distinct rostral tube. Braincase inflated, rather globose in shape. Interorbital region broad, hourglass in shape, with rounded margins. Zygomatic plates narrow, shorter than length of M1, with anterior margin straight and vertical. Optical foramen small and placed posterior to M3. Incisive foramina oval, large, more contracted at anterior margins, but short, not reaching anterior margins of M1s. Mesopterygoid fossa broad, slightly expanded anteriorly, followed by subparallel margins posteriorly; medial process absent; and roof closed, or perforated by narrow slits on both sides of presphenoid-basisphenoid suture. Auditory bullae moderately inflated, bony tubes short. Postglenoid

foramen very small. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen are present). Upper molars moderately hypsodont, with no interpenetration of flexi. Maxillary toothrow moderately long, 4.5–4.8 mm. Upper incisors orthodont. M1 with accessory labial root; M3 comparatively small; m1 with indistinct anteromedian flexid. Capsular process absent. Stomach unilocular with reduced glandular epithelium, and with lesser curvature usually lined with cornified squamous epithelium.

DISTRIBUTION: *Thomasomys erro* is known from the Cordillera Oriental of north-central Ecuador, across an elevational range from about 1,900 to 3,600 m.

SELECTED LOCALITIES (Map 340): ECUADOR: Napo, Cosanga, Río Aliso (EPN 902741), 9 km E of Papallacta (UMMZ 127133), 6.2 km W of Papallacta (UMMZ 155711), Volcán Sumaco (type locality of *Thomasomys erro* Anthony).

SUBSPECIES: *Thomasomys erro* is monotypic.

NATURAL HISTORY: Individuals have been captured in dense secondary vegetation, in subalpine rainforest and upper montane rainforest, on the ground, in runways through wet leaf litter and mossy debris, beneath mossy logs, branches, or roots, and inside the trunk of a hollow tree (Voss 2003). Voss (2003) only collected specimens at elevations ranging from 2,830 to 3,570 m, but T. E. Lee et al. (2006) reported the species from 1,900 m. Schramm and Lewis (1987) described *Plocopsylla nungui* as a new species of flea from specimens of *T. erro* from near Papallacta, Napo. Timm and Price (1985) reported the mallophagan *Cummingsia inopinata*, also on specimens from Papallacta, Napo.

REMARKS: *Thomasomys erro* was described on p. 5 in Anthony (1926b), not on p. 3 as given by Cabrera (1961) and Musser and Carleton (2005). Anthony (1926b) considered *T. erro* to be a highly distinctive species that was possibly derived from *T. cinereiventer*, a decision followed by Gyldenstolpe (1932) and Ellerman (1941) but not Cabrera (1961), who formalized the latter opinion as the trinomial *T. cinereiventer erro*. Musser and Carleton (1993) followed Cabrera's synonymy, but Tirira (1999) listed *erro* as a distinct species. Voss (2003) reported new records of *T. erro* from Papallacta, Napo province, enumerating morphological traits that clearly discriminated *T. cinereiventer* and *T. erro* as valid species. He also pointed out some differences between the Papallacta series and the type specimen from Volcán Sumaco, but with the exception of two dental measurements, judged these specimens to represent the same species. The phylogenetic position of *T. erro* is still unclear because the species shares characteristics with both *Thomasomys* and *Aepeomys* (Pacheco 2003).

Map 340 Selected localities for *Thomasomys erro* (●). Contour line = 2,000 m.

Thomasomys fumeus Anthony, 1924

Smoky Thomasomys

SYNONYMS:

Thomasomys rhoadsi fumeus Anthony, 1924b:6; type locality "Hacienda San Francisco, east of Ambato, [Tungurahua,] central Ecuador, elevation about 8000 feet [2,438 m]."

T[homasomys]. fumeus: Tirira, 2007:196; first use of current name combination.

DESCRIPTION: Relatively small to medium sized (head and body length 101–125 mm) with long and soft dorsal fur. Dorsal coloration mixture of dusky neutral gray and pale neutral gray, darkest along back. Ventral color pale neutral gray, not countershaded with dorsal pelage. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail short (76–116% of head and body length), comparatively thick and thinly haired, annular rings conspicuous, uniformly colored, and without terminal white tip. Hindfoot short (24–27 mm), with metatarsals light brown washed with white hairs. Digit I of pes (hallux) short, first phalanx does not extend beyond metatarsal of dII and its claw extends no more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull comparatively short (condyloincisive length, 26.5–27.6 mm) with moderately broad rostrum, and anteriorly expanded nasals that taper posteriorly and extend beyond premaxillae. Interorbital region moderately broad, hourglass in shape, with rounded margins. Zygomatic plates narrow, breadth shorter than

length of M1 and with anterior margins nearly straight and vertical. Zygomatic arches moderately convergent anteriorly. Incisive foramina widely open, with contracted anterior and posterior margins, and moderately long, reaching to anterior margins of M1s. Mesopterygoid fossa broad, wider anteriorly and convergent posteriorly; medial process absent. Auditory bullae small and uninflated. Postglenoid foramen and subsquamosal fenestra subequal in size. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper incisors orthodont. Maxillary tooththrow moderately long, 4.6–5.0 mm. Upper molars moderately hypsodont, with no interpenetration of flexi. M1 with distinct anteroloph; anteromedian flexid of m1 absent or weak; M3 relatively large and with distinct hypoflexus. Capsular process absent.

DISTRIBUTION: *Thomasomys fumeus* is endemic the Cordillera Oriental of Ecuador; it is known only from the type locality.

SELECTED LOCALITIES (Map 341): ECUADOR: Tungurahua, San Francisco, E of Ambato (type locality of *Thomasomys rhoadsi fumeus* Anthony).

SUBSPECIES: *Thomasomys fumeus* is monotypic.

NATURAL HISTORY: Nothing is known about the natural history of this species.

REMARKS: Anthony (1924b) distinguished the Tungurahua series from typical *rhoadsi* Stone (herein regarded as a synonym of *T. vulcani*; see that account), but used the trinomial combination to imply a relationship with *rhoadsi*. This decision was followed in recent synopses (e.g., Musser and Carleton 2005). At present, no revision or other studies of this taxon have been completed, although Voss (2003) recognized that *T. rhoadsi fumeus* was substantially smaller than typical *rhoadsi* and differed from it in qualitative external and cranial characters, as noted originally by Anthony (1924b). Pacheco (2003) was first to recognize *fumeus* as a valid species. Later, Tirira (2007), and based on a personal communication from me, also listed the species as valid, a decision followed by T. E. Lee et al. (2008). However, formal support for species distinction has yet to be established.

Herein, I argue that *T. fumeus* is a valid species, one distinct from *T. vulcani*, based on the following attributes: size generally smaller, hallux smaller, zygomatic plates narrower, anterior margin of zygomatic plates nearly straight, postglenoid foramen and subsquamosal fenestra subequal in size, M1 anteroloph distinct, and M3 hypoflexus distinct. In addition, several mensural attributes differ in size. For example, comparison of nine adult *T. fumeus* (Tungurahua, AMNH specimens) versus 21 adult *T. vulcani* (18 from Pichincha department [AMNH, FMNH, USNM, UMMZ specimens] and three from Napo department [FMNH

specimens]) reveals little or no overlaps in the following variables: head and body length (101–125 mm versus 118–153 mm), hindfoot (24–27 mm versus 27–31 mm), greatest length of skull (29.05–29.87 mm versus 30.85–33.69 mm), condyloincisive length (26.48–27.56 mm versus 28.83–31.05 mm), condylomolar length (17.22–18.10 mm versus 18.57–19.62 mm), length of nasals (11.25–12.87 mm versus 12.82–14.68 mm), length of maxillary tooththrow (4.56–4.95 mm versus 5.07–5.59 mm), breadth of rostrum (4.65–5.06 mm versus 5.51–6.24 mm), breadth of palatal bridge (3.27–3.59 mm versus 3.62–4.40 mm), breadth of nasals (3.19–3.44 mm versus 3.46–3.98 mm), and breadth of zygomatic plate (1.83–2.22 mm versus 2.16–2.65 mm), respectively.

T. E. Lee et al. (2008) reported *T. fumeus* from Volcán Sumaco; however, I consider this record doubtful and suggest that their series more likely corresponds to *T. vulcani* proper. These authors reported that the external measurements are generally indicative of smaller size, but most of the variables either overlap the dimensions of *T. vulcani* or likely represent those of juvenile specimens that, by their inclusion, give the impression of overall small specimens. The Volcán Sumaco specimens should be reexamined and compared carefully with the type series of both *T. fumeus* and *T. vulcani*.

Pacheco (2003) found *T. fumeus* related to *Thomasomys* sp. 10, an undescribed species from Piura, Perú, followed by *T. vulcani*, in a cladistic analysis based on morphological characters, a general hypothesis in line with Anthony

Map 341 Single known locality for *Thomasomys fumeus* (●). Contour line = 2,000 m.

(1924b). However, a phylogeny based on sequences of the mtDNA cytochrome-*b* gene disagreed with the morphological results, placing *T. fumeus* as allied to *T. aureus* and *Thomasomys* sp. (Salazar-Bravo and Yates 2007). Although it is very unlikely that *T. fumeus* is actually more closely related to *T. aureus* than to *T. vulcani*, given the number of trenchant morphological differences that differentiate members of the “cinereus” and “aureus” groups, more expansive studies are needed to resolve this issue.

Thomasomys gracilis Thomas, 1917

Gracile *Thomasomys*

SYNONYMS:

Thomasomys gracilis Thomas, 1917g:2; type locality “Matchu [*sic*] Picchu, 12,000 feet [3,658 m],” Cusco, Peru.

Thomasomys gracilis gracilis: Cabrera, 1961:429; name combination.

DESCRIPTION: Small (head and body length 83–101 mm) with soft, dense, and comparatively long dorsal fur (average length, 11 mm). Dorsal coloration dark grayish buff or clay, with undefined dark region along midline over rump. Ventral color soiled grayish buff with hairs slaty basally, and not sharply contrasting with dorsal color. Ears comparatively large (15–18 mm), blackish, and contrast with head color. Mystacial vibrissae moderately long, extending backward slightly beyond pinnae when bent; genal 1 vibrissae present. Tail long, moderately or distinctly longer than head and body (119–142%), incipiently bicolored but overall blackish brown and uniform, with tip sometimes white. Hindfoot relatively short (22–23 mm), with dark brown metatarsal patch, with edges and digits lighter. No gap between thenar and hypothenar pads. Hallux long, extending to interphalangeal joint of dII. Digit V of pes very long, with claw extending to base of claw of dIV. Skull short (condyloincisive length 22.4–23.6 mm), with narrow and relatively short rostrum, and rounded braincase with large parietals. Interorbital region narrow and with squared edges. Zygomatic plates narrow, subequal to M1, and vertical. Zygomatic arches very slightly flared laterally and parallel oriented forward. Incisive foramina well open and widest anteriorly, at or near premaxillomaxillary suture, and extend posteriorly to slightly between M1 anterocones. Mesopterygoid fossa comparatively broad, converging posteriorly and without medial process; roof perforated by medium-size sphenopalatine vacuities on each side of presphenoid-basisphenoid suture. Auditory bullae comparatively large and rather inflated. Subsquamosal fenestra widely open and larger than postglenoid foramen. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Maxillary toothrow

short (3.8–4.0 mm). Molars small and brachydont, without interpenetration of flexi but with distinct crenulation. M1 with distinct anteromedian flexus and accessory labial root; anteromedian flexid of m1 weak, even in unworn molars. Upper incisors slightly opisthodont. Capsular process absent.

DISTRIBUTION: *Thomasomys gracilis* is known only from the montane forest or Yungas of southeastern Peru, across an elevational range from 2,774 to 4,270 m.

SELECTED LOCALITIES (Map 342): PERU: Cusco, Cordillera del Vilcabamba (MUSM 13067), Idma road (AMNH 95207), Lucma, Cosireni pass, Chirapata (USNM 194813), Machu Picchu, above timberline, Runcaracay ruins (Thomas 1917g), Occobamba valley, Tocapoqueu (USNM 194807), 90 km by road SE of Quillabamba (M. F. Smith and Patton 1999).

SUBSPECIES: I treat *T. gracilis* as monotypic (but see Remarks).

NATURAL HISTORY: Nothing has been published on the natural history of *T. gracilis*. The following comes from the field notes of J. L. Patton (MVZ archives): the habitat where the species was collected varied from very wet bunch grass on gently sloping ground to steep slopes dominated by melastome shrubs and ferns, with a dense understory of grasses, to elfin forest patches composed of bamboo thickets and large, moss and epiphyte covered trees. Runways were everywhere, particularly along the base of logs, through tree root systems, and even coursing through the thick moss growing on tree branches. All of the specimens collected (eight) were trapped on the ground, most in the patches of elfin forest, but two were taken on a steep slope covered by dense melastomaceous shrubs and ferns. Two males had scrotal testes ($t=7$ or 8 mm, $SV=9-10$ mm), two others had very small, nonscrotal testes (3 mm); two females were postlactating. All specimens were caught between 22 and 25 May, 1984, after the local rainy season.

REMARKS: *Thomasomys gracilis* was recognized as a monotypic species (Gyldenstolpe 1932; Ellerman 1941) until it was considered to include *cinnameus* and *hudsoni* as subspecies or referred synonyms (Cabrera 1961; Musser and Carleton 1993; respectively), hypotheses that extended the distribution of *T. gracilis* to Ecuador (Barnett 1999; Eisenberg and Redford 1999). However, these taxa were reinstated as species by Voss (2003) and independently by Pacheco (2003) on morphological grounds, a decision subsequently supported by Salazar-Bravo and Yates (2007) based on mtDNA sequences. Thus, the distribution of *T. gracilis* remains restricted to southern Peru. However, the proper identification of specimens assigned to *T. gracilis* from the Cajas Plateau, Ecuador by Barnett (1999), and allegedly sympatric with *T. cinnameus*,

remains unclear. These may turn out to be *T. cinnameus* or an unknown taxon, but are not *T. gracilis* as understood herein (see the account of *T. hudsoni* for additional comments).

Reports of *T. gracilis* from Tres Cruces, Paucartambo, Cusco department, or Río Pilcopata, Cusco department (Patton et al. 1990; Pacheco et al. 1993), are erroneous (V. Pacheco, unpubl. data). Both reports were based on one specimen (MVZ 115645), determined herein as *T. oreas*. *Thomasomys gracilis* is thus absent from the upper parts of the Manu Biosphere Reserve (see also Solari et al. 2006). Furthermore, the single known specimen from the Cordillera Vilcabamba, Cusco department (Emmons et al. 2001), is provisionally referred to *T. gracilis*, although it is a little smaller and differs slightly in skull morphology than more typical specimens.

Thomas (1920h) postulated that *T. gracilis* was allied to *T. baeops* but also similar to a miniature *T. notatus*. To the contrary, Patton (1987), based on electrophoresis of 24 loci, found *T. gracilis* related to *T. oreas* as compared to other species of *Thomasomys* from southeastern Peru. Pacheco (2003) provided a phylogeny based on external, cranial, dental, and soft morphology that supported a relationship between *T. gracilis* and *T. oreas*. This hypothesis, however, was not supported by a molecular phylogeny based on mtDNA cytochrome-*b* gene sequences (Salazar-Bravo and Yates 2007), but resolution was likely limited by their small taxonomic sampling. The karyotype is unknown.

Map 342 Selected localities for *Thomasomys gracilis* (●). Contour line = 2,000 m.

Thomasomys hudsoni Anthony, 1923

Hudson's *Thomasomys*

SYNONYMS:

Thomasomys hudsoni Anthony, 1923b:3; type locality "Bestion [= Bestión], Provincia del Azuay, 10,100 feet [3,078 m], Ecuador."

Thomasomys gracilis hudsoni: Cabrera, 1961:429; name combination.

DESCRIPTION: Known only by holotype; apparently small species (head and body length 93 mm) with relatively long tail (129% of head and body length). Dorsal pelage grayish brown, between Dresden brown and mummy brown, darker along dorsal area. Fur long and soft. Under-surface grayish buffy, and not countershaded relative to dorsum. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; general 1 vibrissae absent. Hindfeet short (23 mm), metatarsals light brown, and gap present between thenar and hypothenar pads. Hallux moderate in length, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes is very long, with claw extending to base of claw of dIV. Tail long, slender, clothed in short hairs, uniformly colored brown, and without terminal white tip. Skull comparatively small (condyloincisive length 22 mm); braincase rounded and inflated; narrow rostrum peculiarly extended beyond incisors as flaring bony tube with concave (rather than convex) dorsal profile. Interorbital region moderately broad, hourglass in shape, with smooth edges. Zygomatic plates narrow and vertical, breadth shorter than length of M1. Incisive foramina narrow, although wider anteriorly (near premaxillomaxillary suture), and extending backward quite near anterior margins of M1s. Mesopterygoid fossa broad, anteriorly expanded, and posteriorly convergent; palatal medial process absent; roof closed, as sphenopalatine vacuities absent. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Auditory bullae larger and more inflated than those of *T. cinnameus* but smaller and less inflated than those of *T. gracilis* (Voss 2003). Upper incisors orthodont. M1 with distinct anteroloph, anteromedian flexus, and anteroflexus distinct; M2 with indistinct protoflexus; M3 with indistinct mesoloph and hypoflexus. Anteromedian flexid of m1 distinct. Upper molar row small (3.5 mm). Capsular process absent.

DISTRIBUTION: *Thomasomys hudsoni* is known only from its type locality in southern Ecuador.

SELECTED LOCALITIES (Map 343): ECUADOR: Azuay, Bestión (type locality of *Thomasomys hudsoni* Anthony).

SUBSPECIES: *Thomasomys hudsoni* is monotypic.

NATURAL HISTORY: The type specimen was collected almost at the upper limit of forest where the habitat com-

prises rolling grassy meadows with scrub trees on some of the ridges and with thickets of brush on some of the slopes (Anthony 1923b).

REMARKS: *Thomasomys hudsoni* was recognized as a valid species (Gyldenstolpe 1932; Ellerman 1941), until Cabrera (1961) relegated it to a subspecies of *T. gracilis*, likely relying on Anthony's (1923b) argument that *T. hudsoni* and *T. gracilis* were closely related. Musser and Carleton (1993) followed Cabrera's decision. Recently, Voss (2003) contrasted *T. hudsoni* with *T. cinnameus* and *T. gracilis* and returned it to species rank. Independently, Pacheco (2003) also considered *T. hudsoni* a full species following comparisons with its congeners.

Although *T. hudsoni* is known only from the type specimen, it is possible that some specimens collected in Cajas National Park, Azuay (Barnett 1999), and reported as *T. gracilis* are indeed this species. Clearly, Barnett did not confuse his *T. gracilis* with the other small species from this region *T. cinnameus*, as he recorded the two in sympatry. Unfortunately, Barnett (1999) gave little information regarding his specimens beyond providing head and body lengths and mass for two adult female specimens (103 mm, 41 g [BM 82.818] and 86 mm, 16.25 g [BM 84.339]) and several grayish juveniles (head and body length 64 to 100 mm (mean 83.1 mm)). These measurements and the grayish coloration are coincident with the head and body length 93 mm and grayish brown of the type specimen of *T. hudsoni*. This issue might be resolved after a close examination of Barnett's vouchers housed in the Natural History

Museum, London (BM). Barnett has reidentified some "*T. gracilis*" as either *T. cinnameus* or *T. baeops* (P. Jenkins, pers. comm.).

The phylogenetic relationships of this species remain unclear. Pacheco's (2003) cladistic analysis of morphological characters and my unpublished data refuted a relationship with *T. gracilis*, placing *T. hudsoni* with *T. niveipes*, *T. paramorum*, and other species allied to *T. cinereus*. The karyotype is unknown.

Thomasomys hylophilus Osgood, 1912

Woodland *Thomasomys*

SYNONYM:

Thomasomys hylophilus Osgood, 1912:50; type locality "Paramo de Tama [= Páramo de Tamá], head of Río Tachira [= Río Táchira], Santander [= Norte de Santander], Colombia."

DESCRIPTION: Medium sized (head and body length 107–126 mm) with long tail (124–155 mm, 104% to 145% of head and body length) and relatively small ears (17–20 mm). Dorsal pelage colored tawny olive mixed with blackish, sometimes more blackish along middle of back; sides and face wood brown to tawny olive; under parts cinnamon, their hairs slate colored at base. Forefeet silvery gray, forelimbs blackish, and tail uniformly blackish except for white tip. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Hindfoot small to medium in length (24.5–28 mm), whitish drab above with digits white. Skull of moderate size (condyloincisive length 26.4–28.4 mm); braincase large and oblong; rostrum comparatively long and narrow; frontonasal profile straight. Zygomatic plates moderately broad, subequal to length of M1, and vertical. Incisive foramina long and relatively narrow, extending to anterior margins of M1s or quite close to them. Interorbital region moderately broad, hourglass in shape, with slightly square posterior margins. Mesopterygoid fossa broad with sides subparallel; roof closed. Zygomatic arches converge anteriorly. Auditory bullae flask-shaped and moderately inflated, although not as much as in *T. laniger*; bony tubes short and broad; stapedial spine small. Postglenoid foramen and subsquamosal fenestra elongated and subequal in size, latter posteriorly placed. Alisphenoid strut separates buccinator-masticatory and accessory oval foramina present. Ethmoturbinals of moderate size. Posterior opening of alisphenoid canal of normal size. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen present). Upper incisors orthodont, long, and moderately broad. Molars relatively hypsodont but lack well-developed cingula and stylar cusps. Anteroloph and mesoloph of M1 and M2 comparatively well developed;

Map 343 Single known locality for *Thomasomys hudsoni* (●). Contour line = 2,000 m.

anteromedian flexus in M1 distinct; M3 with distinct hypoflexus; anteromedian flexid in m1 distinct. Maxillary toothrow moderately long, ranging from 4.6–5.0 mm. Capsular process either absent or present as an inconspicuous bony ridge.

DISTRIBUTION: *Thomasomys hylophilus* is known from the Cordillera Oriental, in eastern Colombia, and the Cordillera de Mérida, in western Venezuela.

SELECTED LOCALITIES (Map 344): COLOMBIA: Boyacá, East Andes, E side, Hacienda La Primavera (FMNH 92553); Santander, Mpio. Tona, Vda. Guarumales, Finca el Pajal (ICN 16680). VENEZUELA: Táchira, Buena Vista (UMMZ 156382), Buena Vista, 41 km SW of San Cristobal, near Páramo de Tamá (USNM 442306), Páramo de Tamá (CVULA 850).

SUBSPECIES: *Thomasomys hylophilus* is monotypic.

NATURAL HISTORY: The species was found in dense forests on the upper slopes of the páramo living among the innumerable galleries naturally formed under mossy roots, logs, and debris (Osgood 1912). Individuals are nocturnal, terrestrial to scansorial, solitary, and omnivorous. Handley (1976) described details where specimens were captured, including at the bases of trees and among tree roots, often in bamboo thickets, beside and under mossy rotting logs, in thick growths of shrubs and tree ferns, on mossy tree limbs, in litter on stream banks, and under tangled vines, near streams and in other damp places, most often in cloud forest, but also in clearings used for pasture and crops, in evergreen forest, all within the Lower Montane very humid forest (vegetative life zone of Ewel and Madriz 1968). Individuals feed on seeds and fruits (O. J. Linares 1998).

Known ectoparasites include the acarid mites *Crotiscus danae* (Brennan and Goff 1978) and *Eutrombicula goeldii*, *E. lukoschusi*, *E. tachirae*, and *E. webbi* (Brennan and Reed 1974a); the laelapid mite *Hymenolaelaps princeps* (Furman 1972); the chiggers *Peltoculus bobbiannae* (Brennan 1972) and *Aitkenius senticosus*, *Odontacarus comosus*, and *O. dienteslargus* (Brennan and Reed 1975); the tick *Ixodes* sp. (E. K. Jones et al. 1972); and the fleas *Cleopysylla monticola*, *Ctenidiosomus perplexus*, *Neotyphloceras rosenbergi*, *Pleochaetis apollinaris*, *Plocopsylla ulysses*, and *Sphinctopsylla tolmera* (Tipton and Machado-Allison 1972).

REMARKS: Little is known about intraspecific variation within *T. hylophilus*. Pacheco's (2003) morphological assessment revealed some degree of character polymorphism, in particular the Boyacá sample that differed in some attributes from the Páramo de Tamá samples. These Boyacá specimens are overall darker, with an undefined dorsal band, and are also darker ventrally, with less trace of brownish; the hindfoot lacks a gap between the thenar and hypothenar pads; nasals are narrower, their sides more parallel and less expanded anteriorly, and their posterior

Map 344 Selected localities for *Thomasomys hylophilus* (●). Contour line = 2,000 m.

margin usually blunt; anterior margin of the nasals also exhibits a distinct notch at the midline. These differences might suggest the presence of an unnamed taxon that merits further investigation. Hooper and Musser (1964:Fig. 6) described and illustrated the glans penis of one specimen of *T. hylophilus* (FMNH 92555), but reported as *T. laniger*. Voss (2003) compared the morphology of this species with *T. ucucha*. The karyotype of *T. hylophilus* is unknown.

Thomasomys incanus (Thomas, 1894)

Inca Thomasomys

SYNONYMS:

Oryzomys incanus Thomas, 1894b:350; type locality "Valley of Vitoc [= Río Tulumayo]" Junín, Peru.

Thomasomys incanus: E.-L. Trouessart, 1897:409; first use of current name combination.

Inomys incanus: Thomas, 1917d:197; name combination.

Thomasomys fraternus Thomas, 1927f:602; type locality "Alcas, 25 miles N.E. of Cerro, Junin," Pasco, Peru.

Thomasomys incanus incanus: Ellerman, 1941:370; name combination.

Thomasomys incanus fraternus: Ellerman, 1941:370; name combination.

DESCRIPTION: Medium size (adult head and body length 111–134 mm) with relatively short tail (92–110%

of head and body length) and short hindfeet (22–28 mm). Dorsal pelage grizzled brownish gray in color; undersurface rather dirty fulvous and not countershaded. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears small (18–21 mm). Gap present between the nar and hypothenar pads on plantar surface of hindfeet; distinct gap also present between hypothenar and digital pad 4; metatarsals and digits covered dorsally with silvery white hairs. Digit I of pes (hallux) moderate in length, with claw extending close or to interphalangeal joint of dII; and claw of digit V extends to interphalangeal joint of dIV. Tail finely annulated, clothed in short hairs, incipiently bicolored dark brownish above and paler below, and without whitish terminal tip. Skull of medium size (26.9–28.4 mm); rostrum long and narrow; braincase broad and rounded. Distinct rostral tube formed by premaxillae and nasals that project forward of upper incisors. Zygomatic arches slender, delicate, and converge anteriorly. Position of antorbital bridge low (about >25% of rostrum). Premaxillomaxillary-frontal intersection and posteromedian margin of premaxillae placed in front of zygomatic notch; posterior margin of nasals distinctly longer than premaxillae but does not surpass maxillary-frontal-lacrimal intersection. Anterior margin of M1 placed anterior to posterior border of zygomatic plate. Interorbital region broad (most of molar row concealed in dorsal view), hourglass in shape, with smooth margins. Optical foramen small (placed behind M3); ethmoturbinals large; alisphenoid strut present. Zygomatic plates moderately broad, breadth subequal to length of M1 and slightly sloped backward from bottom to top. Interparietal rather small; parietosupraoccipital suture moderately broad (suture about one third posterior margin of parietal). Incisive foramina long and moderately broad, extending to or quite close to anterior margins of M1s. Mesopterygoid fossa broad with either subparallel or posteriorly converging sides, and palatal medial process absent; roof closed, with sphenopalatine vacuities absent or represented as narrow slits. Auditory bullae small but moderately inflated, and flask shaped; bony tubes short and broad. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors small, delicate, and orthodont. Molars small and hypsodont without interpenetrating flexi. Upper molar row short, 4.3–5.0 mm in length. Mandible slender and delicate; capsular process absent.

DISTRIBUTION: *Thomasomys incanus* occurs along the eastern slope of the Andes in central and northern Peru, from Junín to San Martín departments, across an elevation range from 2,430 to 3,850 m.

SELECTED LOCALITIES (Map 345): PERU: Campamento Regional (MUSM 22951), Huánuco, mountains

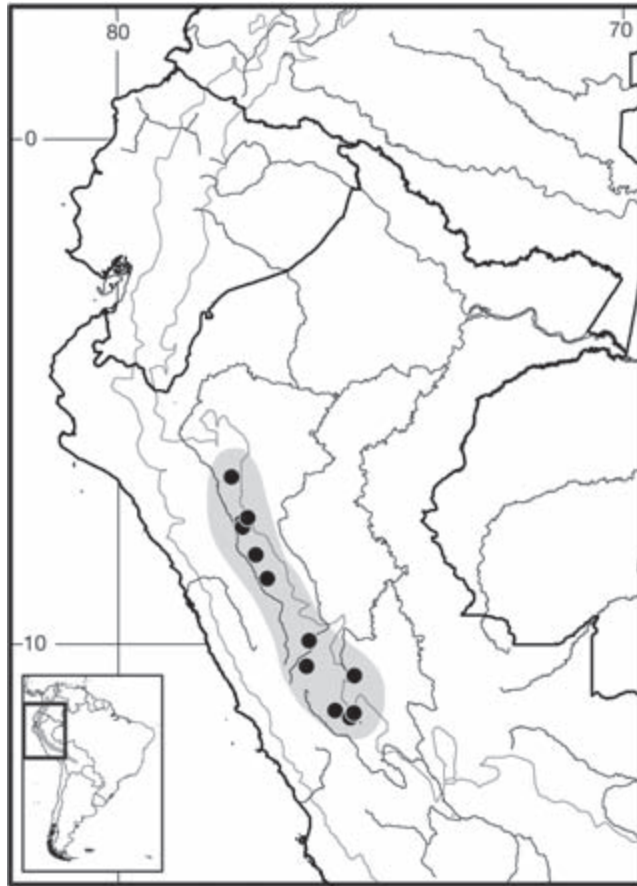

15 mi NE of Huánuco (FMNH 23734); Junín, Maraynioc, 45 mi. NE of Tarma (MCZ 38537), Tarma, Tiambra (MUSM 22014), Vitoc valley (type locality of *Oryzomys incanus* Thomas); La Libertad, Mashua, E of Tayabamba, on trail to Ongón (LSUMZ 24809); Pasco, Estación Biológica de San Alberto (MUSM 11482), Millpo, E Tambo de Vacas on Pozuzo-Chaglla trail (LSUMZ 29169); San Martín, Las Papayas, ca. 5 km W of Pajaten ruins (LSUMZ 27300), Laurel (MUSM 24401), P.N. Río Abiseo, Pampa de Cuy (MUSM 8003).

SUBSPECIES: I consider *T. incanus* to be monotypic (but see Remarks).

NATURAL HISTORY: Thomas (1927f) mentioned that specimens were collected under rocks in scrub vegetation. Other individuals from Pasco and Huánuco were collected in dense humid forests, near streams; those from San Martín were collected in páramo vegetation, under rocks in grassland or scrub vegetation, in fragmented or continuous forest, and near streams either on riverine vegetation or on sandy banks (Leo and Romo 1992).

REMARKS: *Thomasomys incanus* is the type species of *Inomys* Thomas, a taxon recognized as valid by Gyldenstolpe (1932) but not Osgood (1933a), who found no diagnostic character to justify the generic-group name. *Inomys* has thus been listed as a synonym of *Thomasomys* in the more recent literature (Ellerman 1941; Cabrera 1961; Musser and Carleton 1993, 2005). However, Pacheco (2003) recovered a clade that included *T. incanus*, *T. ischyryus*, *T. kalinowskii*, *T. ladewi*, and other species with the derived carotid circulatory pattern in a phylogeny based on morphological characters. Although this clade included also *Aepeomys* and *Thomasomys erro*, probably caused by a long-branch effect (Bergsten 2005), the hypothesis of *Inomys* as a valid genus requires further examination and testing, particularly by molecular methods. Meanwhile, I recognize a group of species allied to *T. incanus* in an informal “incanus” group.

Osgood (1933a) doubted also the validity of *fraternus* Thomas, even as a subspecies, a decision followed by Cabrera (1961), Musser and Carleton (2005), and Pacheco (2003). Leo and Romo (1992) recorded the species from the Parque Nacional Río Abiseo in San Martín department, but this population is distinctly larger and with larger interparietals than the type series, and thus may prove to be a different species. Pacheco (2003) treated the sample from Las Papayas in San Martín department as the undescribed *Thomasomys* sp. 5. Other specimens, collected in Puerta del Monte, San Martín, are on the contrary quite small, with delicate and slender skulls, and small molar toothrow; Pacheco (2003) informally named them *Thomasomys* sp. 6. My more recent unpublished studies suggest that other populations might also constitute different species. The karyotype is unknown.

Map 345 Selected localities for *Thomasomys incanus* (●). Contour line = 2,000 m.

Thomasomys ischyryus Osgood, 1914

Long-tailed *Thomasomys*

SYNONYMS:

Thomasomys cinereus ischyryus Osgood, 1914b:162; type locality “Tambo Almirante, near Uchco”; defined as “Perú, Amazonas Dept., 65 km E Chachapoyas, near Uchco, Tambo Almirante, 5000 ft (1524 m)” by Musser and Carleton (2005).

Thomasomys ischyryus: Thomas, 1926e:613; first use of current name combination.

Thomasomys ischyryus ischyryus: Gyldenstolpe, 1932a:53; name combination.

Thomasomys ischyryrus Cabrera, 1961:430; incorrect subsequent spelling of *ischyryus* Osgood.

Thomasomys ischyryrus ischyryrus: Cabrera, 1961:430; name combination, and incorrect subsequent spelling of *ischyryus* Osgood.

DESCRIPTION: Medium sized (adult head and body length 132–138 mm) with relatively short tail (100–121% of head and body length) and moderately long hindfoot (30–31 mm). Dorsal pelage colored rich burnt umber finely

sprinkled with sooty; ventral surface washed with fulvous brown and not countershaded. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears medium in length (23 mm), blackish, hairs near inner bases with whitish roots. Hindfeet slender with dorsal surface of metatarsals brownish contrasting with whitish digits; gap present between thenar and hypothenar pads. Forefeet also brownish, ventral base of manual claw keeled along proximal half. Digit I of pes (hallux) moderately long, as claw does not extend more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Tail dull brownish above, scarcely lighter below, and without terminal white tip. Skull medium in size (condyloincisive length 30.1–30.4 mm) with long and narrow rostrum and broad and rounded braincase, similar to *T. incanus* but larger; rostral tube formed by forward projecting premaxillae and nasals present. Zygomatic arches slender, delicate, and converge anteriorly. Position of antorbital bridge low (ca. >25% of rostrum). Premaxillomaxillary-frontal intersection lies in front of zygomatic notch; posterior margins of nasals distinctly longer than premaxillae, and level to or extend beyond lacrimal. Distal half of nasals expanded, but taper posteriorly. Interorbital region broad (most of molar row concealed in dorsal view), hourglass in shape, with smooth margins. Optical foramen small (placed behind M3); ethmoturbinals large; alisphenoid strut present or absent. Zygomatic plates moderately broad, breadth subequal to length of M1, with anterior margin convex and slightly sloped backward from bottom to top. Incisive foramina long and moderately broad, extending to anterior margins of M1s. Mesopterygoid fossa broad, anteriorly expanded with converging margins posteriorly; medial palatal process absent; roof closed, with sphenopalatine vacuities either absent or represented as narrow slits. A medial palatal process absent. Parietosupraoccipital suture narrow (length of suture less than one-fourth of posterior margin of parietal). Auditory bullae small but moderately inflated, and flask shaped; bony tubes short and broad. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors orthodont. Molars relatively large and hypsodont and upper molar row moderately long, 5.2–5.7 mm. Capsular process absent.

DISTRIBUTION: *Thomasomys ischyryus* is known only from the eastern slope of the Andes in northern and central Peru, in the departments of Amazonas, San Martín, and Huánuco, at an elevational range between 2,280 and 3,350 m.

SELECTED LOCALITIES (Map 346): PERU: Amazonas, ACP Abra Patricia–Alto Nieva (MUSM 25179), ACP

Huiquilla El Choctamal (MUSM 25758), Cordillera Colán, E of La Peca (LSUMZ 21857), Cordillera Colán, NE of La Peca (LSUMZ 21847), Goncha (USNM 297482), Rodríguez de Mendoza, Tambo Almirante, near Uchco (type locality of *Thomasomys cinereus ischyurus* Osgood); Huánuco, Caserío de San Pedro de Carpish (MUSM 19093); San Martín, Laurel (MUSM 24402).

SUBSPECIES: I treat *T. ischyurus* as monotypic (but see Remarks).

NATURAL HISTORY: Little is known about the ecology or population biology of this species. Specimens have been collected on the ground in pristine humid montane forests and in disturbed forests near potato crops in the Cordillera Carpish (V. Pacheco, unpubl. data), where trees are slender, reach heights of 10 to 15 m, and are densely covered by orchids, bromeliads, ferns, lichens, and mosses (Beltrán and Salinas 2010). Similarly, at Huiquilla in Amazonas department, individuals were obtained in montane forests with low or high canopies, where trees (*Morus insignis* [Moraceae] and some Lauraceae) reached 15 to 20 m and were covered with orchids and bromeliads as well as

tree ferns of the genus *Cyathea* (C. Jiménez, pers. comm.). Ectoparasites include the anopluran louse *Hoplopleura angulata* (P. T. Johnson 1972; specimens reported as *T. cinereus*).

REMARKS: Leo and Romo (1992) reported specimens from Parque Nacional Río Abiseo, San Martín department as *T. ischyruzeleusis*, but these belong to *T. eleusis* not to *T. ischyurus* as understood herein. The southern population from the Cordillera Carpish has a disjunct distribution and may represent an undescribed species (V. Pacheco, unpubl. data).

Osgood (1914b) considered *T. ischyurus* most similar to *T. cinereus*. However, Pacheco's (2003) phylogenetic assessment based on morphology included *T. ischyurus* in a small, resolved clade that contained *T. incanus*, *T. kalinowskii*, and their allies. The report by T. E. Lee et al. (2011), which placed *T. ischyurus* as related to *T. silvestris* based on mtDNA cytochrome-*b* sequences, needs reevaluation. The GenBank sequence (AF 108675; MVZ 181999) used by these authors is a specimen of *T. taczanowskii* (see the *T. baeops* account), not *T. ischyurus*. The karyotype is unknown.

Map 346 Selected localities for *Thomasomys ischyurus* (●). Contour line = 2,000 m.

Thomasomys kalinowskii (Thomas, 1894)

Kalinowski's Thomasomys

SYNONYMS:

Oryzomys kalinowskii Thomas, 1894b:349; type locality "Valley of Vitoc [= Río Tulumayo]" Junín, Peru.

Peromyscus (Thomasomys) kalinowskii: E.-L. Trouessart, 1897:513; name combination.

Thomasomys kalinowskii: E.-L. Trouessart, 1904:408; first use of current name combination.

DESCRIPTION: Moderately large (head and body length 136–143 mm) with relatively short tail (101–114% of head and body length), and moderately long hindfoot (28–35 mm). Dorsal pelage finely grizzled brownish gray, hairs dark slate at their bases with tips dull yellow; under-surface with dirty fulvous tone. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears medium in length (21–26 mm). Plantar surface of hindfeet naked and pads prominent, with distinct gap between thenar and hypothenar pads; dorsal surface of metatarsals dark brown with sides and fingers silvery white. Forefeet also brownish; ventral base of manual claw keeled on proximal half. Digit I of pes (hallux) moderately long, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Tail uniformly black, finely haired, dull brownish above, scarcely lighter below, and without terminal white tip or pencil. Skull moderately long (condyloincisive length 30.1–31.9 mm)

with rostrum long and slender but not distinctly projected anteriorly (rostral tube absent) and braincase broad but not rounded. Zygomatic arches normally built, not delicate, and convergent anteriorly. Position of antorbital bridge high (<25% of rostrum). Premaxillomaxillary-frontal intersection lies in front of zygomatic notch, but postero-medial margin of premaxillae placed posterior to it. Posterior margin of nasals distinctly longer than premaxillae and level maxillary-frontal-lacrimal intersection or slightly longer. Interorbital region moderately broad (the molar row partially visible in dorsal view) with marked edges. Optical foramen partially dorsal to M3 and ethmoturbinals large. Zygomatic plates moderately broad, breadth subequal to length of M1, and slope slightly backward from bottom to top. Interparietal typically broad, parietosupraoccipital suture narrow (suture about one quarter or less posterior margin of parietal), and not distinctly large anteroposteriorly. Incisive foramina long and moderately broad, more contracted anteriorly, and barely extend between M1s. Mesopterygoid fossa broad with lateral margins converging backward; palatal medial process absent; roof closed, with sphenopalatine vacuities absent or represented as slits. Molar-bearing portion of maxillae somewhat triangular in shape. Auditory bullae small but moderately inflated and flask shaped; bony tubes short and broad. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors opisthodont. Molars broad, hypsodont, with slight interpenetration of flexi. Anteromedian flexus, anteroloph, and anteroflexus of M1 distinct; M2 protoflexus absent; M3 hypoflexus distinct even in worn molars. Molar toothrow moderately long (5.5–6.1 mm). Mandible elongated, moderately robust, not delicate as in *T. incanus*, and without capsular process.

DISTRIBUTION: *Thomasomys kalinowskii* occurs only in the Andes of central Peru from the departments of Huánuco south to Ayacucho, in montane forests from 2,050 to 3,673 m.

SELECTED LOCALITIES (Map 347): PERU: Ayacucho, Anchiuay (MUSM 26501), Yanamonte (MUSM 21476); Cusco, Cordillera del Vilcabamba (MUSM 13066); Huánuco, Bosque Zapatagocha above Acomayo (LSUMZ 18440), Dos de Mayo, Cayna, Chilitatuna (MUSM 1314), Iscarag (MUSM 22893), Kenwarajra (MUSM 23004), Pampa Hermoza (MUSM 23018), Shogos (MUSM 22679); Junín, Maraynioc, 45 mi NE of Tarma (FMNH 54202), 16 km NNE (by road) of Palca (MVZ 172599); Pasco, Cumbre de Ollón, ca. 12 km E of Oxapampa (LSUMZ 25899), Millpo, E of Tambo de Vacas on Pozuzo-Chaglla trail (LSUMZ 29165).

SUBSPECIES: I treat *T. kalinowskii* as monotypic (but see Remarks).

NATURAL HISTORY: *Thomasomys kalinowskii* was reported in Apurímac department in humid upper montane forest composed of tall shrubs, narrow trees of 5 to 10 m high, and stands of *Chusquea* bamboo, and near maize and squash crops at high relative abundance (Pacheco et al. 2007). It was collected also on the ground in humid montane pristine forests and in disturbed forests near potato crops in Carpish (V. Pacheco, unpubl. data), where trees are slender, reach heights of 10 to 15 m, and are densely covered by orchids, bromeliads, ferns, lichens, and mosses (Beltrán and Salinas 2010). Noblecilla and Pacheco (2012) found *T. kalinowskii* to feed mainly on plant material (67.7%, including mainly Piperaceae seeds) and arthropods (21.5%). Price and Emerson (1986) described *Cummingsia barkleyae* as a new species of Mallophaga from *Thomasomys* sp., from Unchog, Huánuco. The host indeed represents a new species allied to *T. kalinowskii*, named as *Thomasomys* sp. 7 by Pacheco (2003).

REMARKS: Thomas (1884: 455) reported *T. cinereus* from Maraynioc; his description, however, agrees more closely *T. kalinowskii* and not *T. cinereus*, which is restricted to northern Peru (see that account). Specimens from Panao, Huánuco, collected by J. T. Zimmer, and housed at the Field Museum were confirmed as *T. kalinowskii* (Pacheco 2002), although they differ slightly from the type series with paler metatarsals, alisphenoid strut present, and maxillary pits absent, among other features. Other populations that show some differences from the type series and may represent new taxa; these include a single specimen collected from the Cordillera Vilcabamba, Cusco department (Emmons et al. 2001), which exhibits an unusual straight ventral edge of the mandible, among other features. A sample from Unchog, Huánuco, named *Thomasomys* sp. 7 by Pacheco (2003), has darker dorsal pelage, a moderate rostral tube, and subparallel zygomatic arches. Finally, the sample from Yuraccyacu, Ayacucho has a white tipped tail, short and broad rostrum, and wide and squarish molars.

A. L. Gardner and Patton (1976) reported the karyotype ($2n=44$, FN=44), with X and Y acrocentric chromosomes, based on samples from Yuraccyacu, Ayacucho. M. F. Smith and Patton (1999) sequenced mtDNA cytochrome-*b* from two specimens of *T. kalinowskii* (reported as *Thomasomys* sp.) from Junín (MVZ 172598, 172599). A phylogenetic analysis based on morphological attributes suggested that *T. kalinowskii* is more closely related to *T. eleusis* in a clade here named the “incanus” group. However, Salazar-Bravo and Yates (2007), using mtDNA cytochrome-*b* sequences, placed *T. kalinowskii* as sister to a group that included *T. baeops*, *T. taczanowskii*, *T. notatus*, and *T. ladewi*, despite

Map 347 Selected localities for *Thomasomys kalinowskii* (●). Contour line = 2,000 m.

the trenchant morphological differences that separates *T. kalinowskii* from the “baeops” and “notatus” groups. A similar phylogeny, also based on cytochrome-*b* gene sequences, found *T. kalinowskii* (reported as *T. sp.*) as a sister taxon to *T. notatus* and *T. ladewi* but not to members of the “baeops” group. These contrasting phylogenetic hypotheses may simply result from limited taxon sampling.

Thomasomys ladewi Anthony, 1926

Ladew's Thomasomys

SYNONYM:

Thomasomys ladewi Anthony, 1926a:1; type locality “Río Aceramarca, northeast of La Paz [La Paz], Bolivia, altitude 10,800 feet [3,292 m].”

DESCRIPTION: Medium sized (head and body length 120–138 mm) with soft, lax, and long fur (individual hairs up to 15–16 mm long). Pelage coloration above and below plumbeous, but tipped sooty black, fuscous, and brown on back, providing overall impression of very finely grizzled fuscous-black. Cheeks, sides, and lower rump darker than midback. Under parts washed with pale smoke gray to drab gray; pectoral area darker than rest of under parts; small patch of white hairs may be present on chest or throat; venter not countershaded relative to dorsal coloration. Hands, feet, and tail (above and below) grayish brown. Tail longer than head and body (107–132%), very sparsely haired, indistinctly bicolored, and terminates in white tip that extends 10–60 mm. Ears short

(20–23 mm). Mass 42–64 g. Mystacial vibrissae moderately long, extending slightly past posterior margins of the ears when bent; genal 1 vibrissae absent. Hindfoot moderately long (28–33 mm). Digit I of pes (hallux) moderately long, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes also long, with claw extending about half length of phalanx 2 of dIV. Skull relatively large, broad, and robust (condyloincisive length 30–31.7 mm), with rostrum broad and short and not distinctly projected; position of antorbital bridge high (<25% of rostrum). Zygomatic arches converge anteriorly; zygomatic plates broad, slightly sloped backward from bottom to top, anterior margin straight. Interorbital region moderately broad (molar row partially seen in dorsal view), hourglass in shape, with margins rounded to little edged; postorbital ridge present; and optic foramen level with or overlaps M3. Incisive foramina open, somewhat oval, with posterior margins reaching plane of M1s. Molar-bearing portion of maxillae near rectangular. Subsquamosal fenestra subequal and posterior to postglenoid foramen, which is elongated and level with anterior margin of tegmen tympani. Mesopterygoid fossa broad with subparallel margins. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Auditory bullae small and not inflated. Upper incisors orthodont. Molars moderately hypsodont, with interpenetrating flexi. Maxillary toothrow moderately long (5.5–5.8 mm). Capsular process absent.

DISTRIBUTION: *Thomasomys ladewi* inhabits montane forests from 2,360 to 3,300 m in a restricted region in the Andes in La Paz department of northwestern Bolivia.

SELECTED LOCALITIES (Map 348): BOLIVIA: La Paz, Río Aceramarca (type locality of *Thomasomys ladewi* Anthony), 2° Estación climatológica (CBF 7654), Franz Tamayo, Palcabamba (MNK 3597), Franz Tamayo, Pelchucu, Llamachaqui, on road to Apolo (CBF 4042).

SUBSPECIES: *Thomasomys ladewi* is monotypic.

NATURAL HISTORY: *Thomasomys ladewi* is terrestrial, with individuals captured on rocky and wooded hillsides. No other details about habits, behavior, diet, or reproduction are known (S. Anderson 1997).

REMARKS: Almost nothing is known about phylogenetic relationship of this species. Anthony (1926a) stated that *T. ladewi* was superficially more similar to *T. vulcani* (reported as *rhoadsi*), *T. cinereus*, or *T. cinereiventer*, although he thought the skull of *T. ladewi* matched more closely those of his *aureus* group. Pacheco (2003) placed *T. ladewi* in a clade that included *T. incanus* and allies in his phylogenetic hypothesis based on morphological characters. The karyotype of *T. ladewi* is unknown.

Map 348 Selected localities for *Thomasomys ladewi* (●). Contour line = 2,000 m.

Thomasomys laniger (Thomas, 1895)

Soft-furred *Thomasomys*

SYNONYMS:

Oryzomys laniger Thomas, 1895b:59; type locality "Bogota"; corrected to Bogotá Region, 8,750 ft (2,667 m), Cundinamarca, Colombia by Musser and Carleton (2005).

[*Oryzomys (Erioryzomys)*] *laniger*: E.-L. Trouessart, 1904: 423; name combination.

Thomasomys laniger: Thomas, 1906c:443; first use of current name combination.

Thomasomys laniger laniger: Gyldenstolpe, 1932a:56; name combination.

DESCRIPTION: Medium sized (head and body length 101–119 mm) with long, soft, and fluffy dorsal fur. Dorsal pelage colored dull olivaceous gray, with hairs dark slate-colored at base and olive at tips. Ventral pelage similarly grayish but paler, with hair tips dull yellowish; counter-shaded relative to dorsal pelage. Mystacial vibrissae very long, extending distinctly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears relatively large and naked; postauricular patches conspicuous. Tail similar to or longer than head and body (103–123%), slender, finely haired, monocolored, and occasionally with terminal white tip. Hindfoot relatively short (24–26 mm), metatarsals dark brown mesially, edges and digits white, gap present between thenar and hypothenar pads. Digit I of pes (hallux) moderate, with its claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of

phalanx 2 of dIV. Skull relatively small (condyloincisive length 25.6–27.3 mm), thin, and delicate, with large and rounded braincase, and relatively long and broad rostrum. Zygomatic plates moderately broad, subequal in length to M1, and slant backward from bottom to top. Interorbital region moderately broad, hourglass in shape, and with smooth to scarcely squared edges. Zygomatic arches moderately convergent anteriorly. Incisive foramina large and open, more contracted anteriorly, maximally extending to anterior margins of M1s. Mesopterygoid fossa broad with subparallel sides; sphenopalatine vacuities present as slits. Parapterygoid vacuities usually absent. Auditory bullae large and inflated. Subsquamosal fenestra smaller or subequal to postglenoid foramen. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen are present). Upper incisors orthodont. Molars broad; upper molars moderately hypsodont, with no interpenetration. Maxillary tooththrow relatively small, 4.2–4.8 mm. M1 anteroloph indistinct; M2 protoflexus distinct; M3 hypoflexus indistinct; and m1 ectolophid absent. Capsular process absent.

DISTRIBUTION: *Thomasomys laniger* is known from the Cordillera Central and Oriental of Colombia, from 2,600 to 3,600 m.

SELECTED LOCALITIES (Map 349): COLOMBIA: Boyacá, Villa de Leyva, sector Chaina, vereda Río Abajo (IAvH-M 6922); Cundinamarca, Bogotá, San Francisco (FMNH 71459), Guasca, Río Balcones (FMNH 71408), Fusagasugá (AMNH 76717), Finca el Soche, 15 km W of Soacha (KU 124056); Huila, San Agustín, Páramo de las Papas (FMNH 71486).

SUBSPECIES: *Thomasomys laniger* is monotypic.

NATURAL HISTORY: This species is terrestrial and has been captured more often in Andean temperate forest and forest-páramo ecotone than in páramo proper (Lopez-Arévalo et al. 1993; Gómez-Laverde et al. 1997). Lopez-Arévalo et al. (1993) reported that density increased in the wet season (June to August), that sexual maturity was observed at approximately 3.5 months, and that the gestation period was about 24 days. The diet was composed of fruits, seeds, and insects, with an increase of insects in the wet season (Lopez-Arévalo et al. 1993). Density of *T. laniger* in Cerro Majuy, Cundinamarca was eight individuals/ha (Zuñiga et al. 1988). The latter authors provided also detailed information on soil, vegetation, and climate for the sample localities where *T. laniger* was found. Timm and Price (1985) reported the louse *Cummingsia inopinata* on specimens of *T. laniger* from Páramo, Antioquia, Colombia, which is likely a misidentification of the host species as *T. laniger* is unknown from this region. Rather, *Handleyomys intectus* (Thomas) (*sensu* Voss et al.

2002) is the likely host because several specimens were collected from Páramo and Río Negrito, near Sonsón, by Philip Hershkovitz, but mislabeled as *Thomasomys laniger*. This same interpretation applies to the report of Tipton and Machado-Allison (1972) of the flea *Pleochaetis smiti* from *T. laniger* from Páramo, a specimen also collected by P. Hershkovitz. Seevers (1955) described the staphylinid beetle *Amblyopinus emarginatus*, and Tipton and Machado-Allison (1972) reported the flea *Sphinctopsilla tolmera*.

REMARKS: Thomas (1916j) described *emeritus* as a subspecies of *T. laniger*, but this taxon was subsequently elevated to a valid species (see that account). Cabrera (1961) considered *niveipes* a synonym of *laniger* without justification; however, Gómez-Laverde et al. (1997) convincingly provided chromosomal, mensural, and ecological discrimination of *T. laniger* and *T. niveipes* in Colombia. The karyotypic formula revealed a diploid number of $2n=40$ and $FN=40$, with metacentric or submetacentric X chromosome and an acrocentric Y chromosome (Gómez-Laverde et al. 1997). The $2n=42$, $FN=40$ karyotype reported by Aguilera et al. (2000) for populations of *T. laniger* from Venezuela is based on misidentified samples of *T. emeritus* (see that account).

Ellerman (1941) included this species in his *cinereus* Group. Pacheco (2003) placed *T. laniger* in a clade with

other species of the “cinereus” group in his cladistic analysis derived on morphological characters.

Thomasomys macrotis A. L. Gardner and Romo 1993

Large-eared *Thomasomys*

SYNONYM:

Thomasomys macrotis A. L. Gardner and Romo 1993:762; type locality “Puerta del Monte, ca. 30 km NE [of] Los Alisos, ca. 3250 m. [Parque Nacional Río Abiseo], San Martín, Perú.”

DESCRIPTION: Large sized (head and body length 153–168 mm) with soft, dense, and comparatively long dorsal fur (mid-dorsal hairs 15 mm). Dorsal coloration bone brown to sepia, finely streaked with pale brown imparting an agouti pattern; paler brown tones cover sides and flanks; and venter, including inside of legs, pinkish cinnamon; ventral and dorsal pelage not countershaded. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears large (28 to 33 mm). Hindfoot long (44–48 mm) and narrow, with metacarpal surface as dark as body dorsum, but with paler claws and digital bristles; metacarpals of forefeet dark with paler toes, claws, and digital bristles; ventral base of claws keeled; distinct gap present between thenar and hypothenar pads. Tail longer than head and body (126–143%), and uniformly dark brown except for terminal one-third to two-fifths where both scales and hairs are white. Digit I of pes (hallux) moderate, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull large and robust (condyloincisive length 34.3–41.0 mm) with comparatively broad and deep rostrum and spatulated nasals. Zygomatic plates broad and vertical. Incisive foramina comparatively broad, contracted at both anterior and posterior margins, and moderately long, reaching anterior margins of M1s. Interorbital region narrow, hourglass in shape, and with elevated and rounded margins. Palatal bridge narrow, and postorbital ridge present. Mesopterygoid fossa subequal in breadth to parapterygoid fossae; sides subparallel, not expanded anteriorly; lacks medial process; roof either closed or only slightly perforated by sphenopalatine vacuities. Auditory bullae relatively small and uninflated. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors orthodont. Molars large, moderately hypsodont, with no interpenetration, but flexi somewhat crenulated. M1 anteroflexus distinct; m1 anteromedian flexid is shallow and narrow. Accessory labial root of M1 present. Maxillary toothrow long, 8.0–8.3 mm. Capsular process absent.

Map 349 Selected localities for *Thomasomys laniger* (●). Contour line = 2,000 m.

DISTRIBUTION: *Thomasomys macrotis* is known only from the type locality and vicinity, at elevations ranging from 3,250 to 3,380 m, in the north-central Peruvian Andes.

SELECTED LOCALITIES (Map 350): PERU: San Martín, 24 km NE of Pataz, Pampa del Cuy, Parque Nacional Río Abiseo (USNM 567243), Puerta del Monte, ca. 30 km NE of Los Alisos (type locality of *Thomasomys macrotis* A. L. Gardner and Romo).

SUBSPECIES: *Thomasomys macrotis* is monotypic.

NATURAL HISTORY: Individuals of this species occur in upper montane elfin forest, where they were captured in a rocky area, in grasslands near a fragmented forest in the Pampa del Cuy Valley (Leo and Romo 1992).

REMARKS: *Thomasomys macrotis* corresponds to *Thomasomys* sp. nov. 2 of Leo and Romo (1992). A. L. Gardner and Romo (1993) compared and differentiated *T. macrotis* from *T. aureus* and postulated that *T. macrotis* was more closely related to *T. ischyryus* based on dental and cranial features, although these were not explicitly mentioned. Pacheco (2003) suggested that *T. macrotis* might

Map 350 Selected localities for *Thomasomys macrotis* (●). Contour line = 2,000 m.

belong to its own group because the species exhibits characteristics of both the “aureus” and “incanus” groups. The karyotype is unknown.

Thomasomys monochromos Bangs, 1900

Unicolored *Thomasomys*

SYNONYMS:

Oryzomys (Erioryzomys) monochromos Bangs, 1900a:97; type locality “Paramo (= Páramo) de Macotama, Sierra Nevada de Santa Marta, 11,000 feet altitude,” Magdalena, Colombia.

Thomasomys monochromos: Thomas, 1906c:443; first use of current name combination.

Thomasomys monochromus Gyldenstolpe, 1932a:57; incorrect subsequent spelling of *Oryzomys (Erioryzomys) monochromos* Bangs.

Thomasomys laniger monochromos: Cabrera, 1961:431; name combination.

DESCRIPTION: Relatively small (head and body length 105–120 mm) with rich brown dorsal pelage, more yellowish or raw umber on sides, and under parts dull yellowish wood-brown; venter not countershaded relative to dorsal pelage. Mystacial vibrissae moderately long, but not as long as in *T. laniger*, extending only slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Hindfoot small to medium (24–27 mm), white above but irregularly marked with dusky. Tail short to medium for genus (96–124% of head and body length), uniformly dusky brown, and finely haired. Ears small (18–20 mm), nearly naked, and dusky in color. Skull small (condyloincisive length 25.9–27.4 mm) and delicate, with large and rounded braincase, comparatively broad rostrum, and nearly straight lateral profile. Zygomatic plates moderately broad, subequal to length of M1, and slightly slanting backward from their root. Incisive foramina wide and short, oval in shape, and extend to anterior margins of M1s or quite close. Interorbital region moderately broad, hourglass in shape, and with rounded margins. Interfrontal fontanella present. Mesopterygoid fossa broad with subparallel sides. Auditory bullae moderately inflated, but not as much as in *T. laniger*, with large stapedial spine. Postglenoid foramen and subsquamosal fenestra triangular shaped, but later larger and placed posteriorly. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen present). Upper incisors orthodont. Maxillary toothrow length short, 4.3–4.6 mm. M1 with moderate accessory labial root.

DISTRIBUTION: *Thomasomys monochromos* occurs only in extreme northern Colombia, over an elevational range from 2,000 to 3,600 m in and around the Sierra Nevada de Santa Marta.

SELECTED LOCALITIES (Map 351): COLOMBIA: Magdalena, Cerros San Lorenzo, San Lorenzo (USNM 507270), Mamancanaca, near (FMNH 69190), Páramo de Macotama, Sierra Nevada de Santa Marta (type locality of *Oryzomys (Erioryzomys) monochromos* Bangs), Santa Marta, Serranía San Lorenzo, Estación INDERENA (ICN 5415).

SUBSPECIES: *Thomasomys monochromos* is monotypic.

NATURAL HISTORY: The species is known from montane forest and páramos. Specimens were taken in National live traps on the ground in a tropical cloud (wet) forest remnant at the INDERENA (former Instituto Nacional de los Recursos Naturales Renovables y del Ambiente, Colombia) forestry station, where most of the adjacent land (steep hillsides on the slope of the Sierra de Santa Marta) had been converted to open pasture or planted to eucalyptus and Caribbean pine (A. L. Gardner, pers. comm.). No other information on ecology, population biology, or behavior has been reported.

REMARKS: Cabrera (1961) included *monochromos* Bangs as a subspecies of *T. laniger*, but A. L. Gardner and Patton (1976) considered it a valid species and reported the karyotype ($2n=42$, FN=42) with a submetacentric X and an acrocentric Y chromosomes. Bangs (1900a) compared

his species to *T. laniger*, with which it shares strong resemblance. Pacheco (2003) allied this species to *T. cinnameus* and *T. ucucha* in his phylogenetic assessment based on morphological features; however, the lack of skeletons and fluid specimens, and therefore access to a number of relevant characters, have probably limited a better resolution.

Thomasomys nicefori Thomas, 1921

Nicéforo María's Thomasomys

SYNONYMS:

Thomasomys nicefori Thomas, 1921j:355; type locality "San Pedro, north of the town [= Medellín]," Antioquia, Colombia.

Thomasomys aureus nicefori: Cabrera, 1961:425; name combination.

DESCRIPTION: Large sized (head and body length 154–172 mm) with long tail (114–136% of head and body length), and relatively small ears (21–23 mm). Dorsal pelage almost as buffy or ochraceous as that of *T. aureus*, although head and foreback rather less richly fulvous; under parts also buffy, and moderately countershaded. Mystacial vibrissae very long, extending distinctly beyond posterior margin of pinnae when bent; genal 1 vibrissae present. Hindfoot comparatively long (33–36 mm), buffy whitish above, with small, dark patches on ankles and metatarsals. Tail uniformly brown, clothed in short hairs, without terminal white tip. Skull large (condyloincisive length 32.9–35.2 mm), although smaller than *T. aureus*, with slender rostrum, and narrow, short nasals that taper posteriorly. Zygomatic plates moderately broad, breadth subequal to length of M1, and rather vertical. Interorbital region comparatively broad, margins marked or incipiently squared, with indistinct postorbital ridge. Incisive foramina long and moderately open, extend to level anterior margins of M1s or between anterocones. Palatal bridge short and comparatively broad; maxillary palatal pits present. Auditory bullae small, although moderately inflated, and bony tubes distinct. Anterior process of ectotympanic relatively small. Mesopterygoid fossa broad and somewhat parallel sided; sphenopalatine vacuities absent or present as slit-like vacuities flanking presphenoid-basisphenoid suture. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Lambdoid ridge distinct. Upper incisors orthodont. Maxillary toothrow long (5.9–6.6 mm), but comparatively shorter than *T. aureus*. M1 with perceptible protostyle and enterostyle; m1 with ectolophid. Capsular process absent or represented as inconspicuous bony ridge.

DISTRIBUTION: *Thomasomys nicefori* occurs in Colombia, in the northern parts of both the Cordillera Central and Occidental of the Andes, from 1,900 to 3,810 m.

Map 351 Selected localities for *Thomasomys monochromos* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 352): COLOMBIA: Antioquia, Finca de Margarita Molina (ICN 16762), Medellín, Las Palmas (FMNH 70326), Paramillo (AMNH 37738), Páramo Frontino, Urrao (FMNH 71265), San Pedro (type locality of *Thomasomys nicefori* Thomas), SW of Santa Elena (AMNH 37736), Sonsón, Páramo, 7 km E (FMNH 70307), Valdivia, Las Ventanas (FMNH 70322); Caldas, Manizales, Río Termales (FMNH 71263); Quindío, Salento (AMNH 33941); Risaralda, La Pastora, PRN Ucumarí (ICN 12196).

SUBSPECIES: I treat *T. nicefori* as monotypic (but see Remarks).

NATURAL HISTORY: Little is known about the ecology of this species. Thomas (1921j) reported the holotype was “trapped in a wood.” Kohls (1956) described *Ixodes tropicalis* as a new species of tick from *T. nicefori* (reported as *T. aureus*). Seevers (1955) reported *Amblyopinus colombiae* as a new species of staphylinid beetle from *T. nicefori* (reported as *T. aureus nicefori*). And Trapido and Sanmartín (1971) processed some specimens of *T. nicefori* (reported as *T. aureus*) for Pichindé virus, but none yielded the virus.

REMARKS: Thomas (1921j) defined *T. nicefori* based from a male specimen (BM 21.7.1.20); however, the holotype turns out to be a female specimen determined by myself by the presence of six teats and the long and narrow prepuce. Thomas compared his new species with both *T. aureus* and *T. princeps*. However, Voss (2003) suggested that *T. nicefori* might be included in *T. popayanus* based on similar size of feet and molar toothrow, a hypothesis not supported by Pacheco (2003), who accepted both *T. nicefori* and *T. popayanus* as valid species. *Thomasomys nicefori* can be readily separated from *T. popayanus* and *T. aureus* by the general smaller size and by the comparatively broader palatal bridge. In addition, *T. nicefori* compared with *T. popayanus* exhibits a light metatarsal patch, shorter nasals not distinctly longer than premaxillae, broader inter-orbital region, perceptible lambdoid ridge, auditory bullae moderately inflated, and smaller anterior process of ectotympanic. Additional comparisons are provided in the *T. popayanus* account.

The population on the western Cordillera, from Urrao, Páramo Frontino, is provisionally considered *T. nicefori*, although they have narrower zygomatic plates, broader incisive foramen, less convergent zygomatic arches among other features that suggest it might correspond to a different species (V. Pacheco, unpubl. data). This population is sympatric with *T. popayanus* (see that account). The specimen from Quindío, Salento (AMNH 33941), is considered conspecific, based on the relatively small size (33 mm hind-foot and 6.35 mm molar toothrow); it represents the southernmost record of the species along the Central Cordillera. The karyotype has not been described.

Map 352 Selected localities for *Thomasomys nicefori* (●). Contour line = 2,000 m.

Thomasomys niveipes (Thomas, 1896)

White-footed *Thomasomys*

SYNONYMS:

Oryzomys niveipes Thomas, 1896:305; type locality “La Oya del Barro, W. Cundinamarca, Colombia”; spelling corrected to La Hoya del Barro [= La Hoya del Barro Blanco], small basin situated at the head of the Río Teusacá and includes the Laguna El Verjón (Gómez-Laverde et al. 1997).

Thomasomys niveipes: Thomas, 1906c:443; first use of current name combination.

Thomasomys laniger laniger: Cabrera, 1961:431; part; not *laniger* Thomas.

DESCRIPTION: Medium sized (head and body length 116–130 mm) with comparatively short tail (96–122% of head and body length) and moderate-size ears (19–22 mm). Dorsal pelage dull olive-fulvous, darker mesially, paler on sides and below, with fulvous tone on ventral surface, and indistinctly countershaded. Forefeet silvery white. Tail brown, incipiently bicolored, thinly haired, and lacks whitish tip. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Hindfoot of medium length (26–31 mm);

metatarsals silvery white. Skull of moderate size (condyloincisive length 27–29.4 mm); rostrum long and slender; braincase smoothly rounded; a moderately developed rostral tube present; frontonasal profile convex. Zygomatic notches comparatively deep for genus. Zygomatic plates moderately broad, subequal to length of M1, and vertical. Incisive foramina long and relatively narrow, and extend just past anterior margins of M1s. Interorbital region narrow with rounded edges. Mesopterygoid fossa somewhat narrow, subequal to parapterygoid fossae at level of presphenoid-basisphenoid suture, sides subparallel, and roof perforated by moderately open sphenopalatine vacuities; palatal medial process absent or weak. Zygomatic arches approach rectangular shape, converging only slightly anteriorly. Auditory bullae inflated, bony tubes indistinct, and anterior process of ectotympanic large. Postglenoid foramen smaller than large subsquamosal fenestra, and placed posterodorsally. Alisphenoid strut that separates buccinator-masticatory and accessory oval foramina absent or incomplete. Ethmoturbinals of moderate size. Posterior opening of the alisphenoid canal of normal size. Interfrontal fontanella present. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen present). Upper incisors opisthodont. Molars relatively hypsodont and lack well-developed cingula and styler cusps. Anteroloph and mesoloph of M1 and M2 comparatively well developed; M3 with distinct hypoflexus; anteromedian flexus in M1 distinct, parallel to distinct anteromedian flexid in m1; anterolabial cingulum distinct on m2, but not on m3. Maxillary tooththrow length moderate, 4.7–5.2 mm. Capsular process absent.

DISTRIBUTION: *Thomasomys niveipes* occurs in the Cordillera Oriental of the Andes in central Colombia, in the departments of Boyacá and Cundinamarca, from 2,550 to 3,500 m.

SELECTED LOCALITIES (Map 353): COLOMBIA: Boyacá, Villa de Leyva, sector Chaina, vereda Río Abajo (IAvH-M 6921), Villa de Leyva, sector Chaina, vereda Río Abajo (IAvH-M 6915); Cundinamarca, Bogotá (MVZ 113965), Chipaque (AMNH 34589), Finca El Tabacal (IAvH-M 7088), Guasca, Río Balcones (FMNH 71465), La Regadera, Usme (IAvH-M 1169), Laguna Verde, Páramo de Guerrero (IAvH-M 7221), Páramo de Choachí (MCZ 27589), Reserva Forestal, Vda. Quebrada Honda (IAvH-M 7090), San Francisco, Bogotá (FMNH 71460), Usaquen (USNM 251973).

SUBSPECIES: *Thomasomys niveipes* is monotypic.

NATURAL HISTORY: This species was captured more often than expected in páramo habitat (Gómez-Laverde et al. 1997). Lopez-Arévalo et al. (1993) reported that *Thomasomys* sp. (here referred to *T. niveipes*) was terrestrial, that a pregnant specimen was captured in July (lo-

cal wet season), and that the diet was composed mainly of young leaves and other green part of plants. Schramm and Lewis (1987) described the flea *Plocopsylla nungui* from specimens of *Thomasomys* sp. collected by P. Hershkovitz from San Francisco, Bogotá. The actual host, however, may be attributed to either *T. niveipes* or *T. princeps* as Hershkovitz collected both species at this locality.

REMARKS: Thomas (1896) considered this species very similar externally to *T. laniger*, differing mainly in hindfoot color, notably the brownish feet in *T. laniger* versus whitish feet in *T. niveipes*. Cabrera (1961) included *niveipes* Thomas as a synonym of the nominate subspecies in his concept of a polytypic *T. laniger* (which also included *emeritus* Thomas and *monochromos* Bangs as subspecies, two taxa herein treated as species), without justification. Later, Musser and Carleton (1993) returned the taxon to species status based on their own specimen comparisons. Gómez-Laverde et al. (1997) described the karyotype of *T. niveipes* ($2n=24$, FN=42), and reinforced its separation from *T. laniger* ($2n=40$, FN=40), based on morphological, karyotypic, and ecological differences. Ellerman (1941) included this species in his *cinereus* Group, but Pacheco (2003) allied *T. niveipes* to *T. paramorum* and *T. hudsoni* in his phylogenetic assessment based on morphological characters, all members of his “cinereus” group.

Map 353 Selected localities for *Thomasomys niveipes* (●). Contour line = 2,000 m.

Thomasomys notatus Thomas, 1917

Dusky-footed *Thomasomys*

SYNONYM:

Thomasomys notatus Thomas, 1917g:2; type locality "Torontoy," Cusco, Peru.

DESCRIPTION: Medium sized (head and body length 110–128 mm) with close, thick, and rather woolly fur. Dorsal fur comparatively short (average length 6–9 mm, guard hairs 13 mm) and colored ochraceous tawny with perceptible dorsal stripe present, grayer on head, and more tawny posteriorly. Ventral coloration soiled whitish, hairs slaty basally but dull whitish terminally; lips and throat white, with hairs white basally; contrasts sharply with the dorsal coloration. Ears comparatively small (18–23 mm), blackish, contrasting with head coloration, and with whitish postauricular patch present. Dark orbital ring present. Mystacial vibrissae long, extending backward distinctly beyond pinnae when bent; genal 1 vibrissae present. Tail long (141–160% of head and body length), monocolored or incipiently bicolored, its ventral side indistinctly paler on proximal quarter, blackish brown, short haired, and with small tuft of long hairs at tip. Hindfoot relatively short (24–27 mm) and moderately broad, with dark brown metatarsal patch, sides and digits whitish; no gap between thenar and hypothenar pads. Hallux long, extending to interphalangeal joint of dII. Digit V of pes is very long, claw extending to base of claw of dIV. Protuberance anus raised, but not as prominent as in members of "cinereus" group. Skull moderate in size (condyloincisive length 26.1–29.3 mm) with narrow and relatively short rostrum, and rounded braincase with large parietals. Nasals narrow and long, tapering posteriorly beyond maxillary-frontal-lacrimal joint. Premaxillomaxillary-frontal joint lies posterior to zygomatic notch. Interorbital region narrow, hourglass in shape, and with squared and slightly raised edges. Zygomatic arches more parallel oriented not converging forward. Interfrontal fontanel present. Ethmoturbinals usually moderate in size. Molar bearing maxilla with rectangular shape. Zygomatic plates moderately broad, subequal to M1, and vertical. Incisive foramina long, narrow, with parallel sides, and extend posteriorly slightly between M1 anterocones. Mesopterygoid fossa somewhat narrow, breadth subequal to breadth of parapterygoid fossae at level of presphenoid-basisphenoid suture, and with lateral margins converging posteriorly or subparallel; no medial palatal process; roof perforated by slits on each side of presphenoid-basisphenoid suture. Auditory bullae small and uninflated, bony tubes distinct and narrow, and anterior process of ectotympanic comparatively large. Subsquamosal fenestra and postglenoid foramen narrow, elongated, and subequal; latter extends anteriorly even more than tegmen tympani. Carotid circulatory pattern

primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper incisors opisthodont. Maxillary toothrow short (4.1–4.5 mm); molars brachydont, without interpenetration but distinct crenulation. M1 exhibits distinct anteromedian flexus, anteroflexus, anteroloph, and mesoloph; hypoflexus narrow; protostyle and enterostyle present; and accessory labial root absent. Protoflexus on M2 and hypoflexus M3 distinct. The m1 anteromedian flexid absent or faint even in unworn molars. Mandible exhibits angular process shorter than condylar process and distinct capsular process present.

DISTRIBUTION: *Thomasomys notatus* occurs in montane forests on the eastern Andean slopes of Peru, at elevations between 1,400 to 3,400 m.

SELECTED LOCALITIES (Map 354): PERU: Amazonas, Río Utcubamba, Uchco (FMNH 19834); Ayacucho, Chiquintirca (MUSM 26308); Cusco, 72 km by road NE of Paucartambo (UMMZ 160588), Pillahuata (FMNH 172380), Torontoy (type locality of *Thomasomys notatus* Thomas); Huánuco, Campamento Provias (MUSM 22953), east slope Cordillera Carpish (LSUMZ 14368), Shogos (MUSM 22743); Junín, Cordillera del Vilcabamba (MUSM 13061), 22 mi E of Tarma (AMNH 231084); Pasco, Cumbre de Ollón, ca. 12 km E of Oxapampa (LSUMZ 25898), Santa Cruz, ca. 9 km SSE of Oxapampa (LSUMZ 25901); San Martín, Las Palmas, Parque Nacional Río Abiseo (MUSM 7947), San Martín, Pampa de Cuy, Parque Nacional Río Abiseo (MUSM 7956).

SUBSPECIES: I treat *T. notatus* as monotypic (but see Remarks).

NATURAL HISTORY: Few data on the natural history or ecology have been reported for this species. Individuals fed primarily on monocots in the families Cyperaceae and Poaceae (89.2% of diet) plus a few arthropods (< 5%; Noblecilla and Pacheco 2012). They are apparently in low abundance in montane forests (C. E. Medina et al. 2012).

REMARKS: Little is known on this species. After Thomas (1917g) described *T. notatus* from Cusco department, additional specimens were collected from Tambo Jenés, Amazonas (Thomas 1926e), and from Cordillera Carpish, Huánuco (A. L. Gardner 1976). Recent work reported the species (as *Thomasomys* sp. nov.) in Abiseo National Park, San Martín department (Leo and Romo 1992), in the Cordillera Vilcabamba, Junín (Emmons et al. 2001), and in Yanachaga National Park, Pasco (Vivar Pinares 2006). Based on these new records (25 in total), the potential distribution of the species was evaluated using the algorithm of Maxent, and estimated to be 182,420 km² (Quintana Navarrete 2011). Although, the species is currently considered endemic to the Peruvian Andes (Pacheco et al. 2009), the Maxent map predicted that

the species could range to Ecuador and Bolivia along the Yungas habitats (Quintana Navarrete 2011).

Pacheco (2003) found that some characters varied regionally, which may suggest the presence of unknown taxa. In northern populations, from Amazonas and Pasco departments, the incisive foramina are long but do not penetrate between the M1s, the protostyle and enterostyle are more developed, and molar crenulation is weak or absent. Other variations include the absent of maxillary pits are in the sample from Huánuco, and the small ethmoturbinals in specimens from Pasco (V. Pacheco, unpubl. data). Additional studies are needed to determine the systematic status of these variable local populations.

Thomas (1920h) pointed out the difficulty in placing *T. notatus* within a systematic arrangement, stressing the broad hindfeet reminiscent of typical *Rhipidomys* rather than the long and narrow feet usually seen in *Thomasomys*, although the skull of this species does not have the broadly diverging interorbital region typical of *Rhipidomys*. Although Patton et al. (1990) noted that *T. notatus* exhibits considerable similarities in cranial structure and body proportions to *T. oreas*, these two species were not closer sister taxa in an analysis based on electrophoresis of 24 loci as compared to other species of *Thomasomys* from southeastern Perú (Patton 1987). A phylogenetic assessment based on morphological attributes found *T. notatus* more related to a monophyletic *Rhipidomys* and a cluster of species allied to *T. oreas* and *T. gracilis* than to

the remaining species of *Thomasomys* (Pacheco 2003). He proposed the species represents a distinct species group, probably at the genus-group level (his “New genus E”). However, Salazar-Bravo and Yates (2007), in a molecular phylogeny based on mitochondrial cytochrome-*b* gene sequence, found *T. notatus* closely related to *T. ladewi*, despite the trenchant morphological differences between these two taxa. This result needs to be verified with denser taxon sampling and a broader assortment of gene.

A. L. Gardner and Patton (1976) described the standard karyotype ($2n=44$, FN=44) with X and Y acrocentric chromosomes based on samples from the Cordillera Carpiash, Huánuco department.

Thomasomys onkiro L. Luna and Pacheco, 2002

Ashaninka Thomasomys

SYNONYM:

Thomasomys onkiro L. Luna and Pacheco, 2002:835; type locality “PERU: Department of Cuzco, Province of La Convención, Vilcabamba Cordillera, eastern slope of the Andes, between the Ene and Urubamba rivers, 325 km northwest of city of Cuzco, 11°39'36"S, 73°40'02"W, at 3,350 m elevation in elfin forest patches of *Polylepis*, *Weinmannia*, and *Chusquea*,” corrected to Province of Satipo, Junín department by Quintana Navarrete (2011).

DESCRIPTION: Medium sized (head and body length 94–114 mm) with soft, dense, and comparatively long dorsal fur. Dorsal pelage colored buffy brown and not countershaded with ventral pelage, which is buffy yellow. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Tail long (144–159 mm), much longer than head and body (131–153%), and monocolored with terminal white tip. Hindfoot moderately long (26–28 mm) and narrow; dorsal surface mixture of dark brown and whitish hairs to base of digits, uniformly silvery white; proximal margin of hypothenar pad level with distal margin of thenar pad. Pinnae small (19–20 mm), outer and inner edges clothed with short, dark-brown hairs. Digit I of pes (hallux) moderate long, but claw does not extend more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 25.45–27.33 mm) with relatively long and slender rostrum and anteriorly expanded nasals. Interorbital region moderately broad, hourglass in shape, and with smooth margins. Zygomatic arches anteriorly convergent. Zygomatic plates moderately broad (subequal to length of M1), with anterior margins straight and vertical. Incisive foramina narrow, parallel sided but slightly broader at premaxillomaxillary suture, and moderately long, reaching close to anterior margins of M1s. Mesopterygoid fossa comparatively broad with subparallel

Map 354 Selected localities for *Thomasomys notatus* (●). Contour line = 2,000 m.

margins and without medial process; sphenopalatine vacuities absent or occasionally present as slits between the presphenoid-basisphenoid suture. Auditory bullae small and uninflated. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen are present). Alisphenoid strut present. Upper incisors slender and orthodont; lower incisors slender. Maxillary toothrow moderately long (4.5–4.65 mm), with upper molars moderately hypsodont, with no interpenetration of flexi, and weak labial cingula close to mesoloph of M1 and M2. M1 anteromedian flexus deep; m1 anteromedian flexid shallow; ectolophids present in m1 and m2. Capsular process absent; lower diastema slender.

DISTRIBUTION: *Thomasomys onkiro* is known only from elfin forest at the type locality in southern Peru.

SELECTED LOCALITIES (Map 355): PERU: Junín, Cordillera Vilcabamba (type locality of *Thomasomys onkiro* L. Luna and Pacheco).

SUBSPECIES: *Thomasomys onkiro* is monotypic.

NATURAL HISTORY: L. Luna and Pacheco (2002; also L. H. Emmons, pers. comm.) collected *T. onkiro* on the ground in elfin forest patches dominated by *Polylepis* (Rosaceae), *Weinmannia* (Cunoniaceae), and *Chusquea* (Poaceae) in places with deep moss on the ground. It was found in sympatry with *Mazama chunyi*, *Mustela frenata*, *Gracilinanus* cf. *aceramarcae*, *Cuscomys ashaninka*, *Cavia tschudii*, *Akodon torques*, *Microrhynchomys minutus*, *Thomasomys* cf. *aureus*, *T. cf. kalinowskii*, and *T. cf. gracilis* (Emmons et al. 2001).

REMARKS: L. Luna and Pacheco (2002) reported the type locality of *T. onkiro* to be in Cusco department, Province of La Convención, Cordillera de Vilcabamba, at 11° 39' 36" S, 73° 40' 02" W. However, mapping these coordinates in digital maps revealed this point is actually in Junín department, very near the border with Cusco (Quintana Navarrete 2011). The type locality is thus corrected accordingly. This change also applies to the type locality of the Ashaninka Arboreal Chinchilla Rat *Cuscomys ashaninka* Emmons, an abrocomid rodent reported as new species from the same locality of *T. onkiro* by Emmons (1999). L. Luna and Pacheco (2002) compared *T. onkiro* with both *T. caudivarius* and *T. silvestris*, finding it morphologically more similar to the latter. Phylogenetic relationships of this species with congeners are unresolved, although Pacheco (2003) argued that it was related to other species of the "cinereus" group. It is presumed to be a relict restricted to the Cordillera Vilcabamba (L. Luna and Pacheco 2002). Its karyotype is unknown.

P. Moreno and Albuja (2012) claimed to have the first record of *Thomasomys onkiro* from Ecuador, based on two specimens from Reserva de Tapichalaca (04°29'31.5"S,

Map 355 Selected localities for *Thomasomys onkiro* (●). Contour line = 2,000 m.

79°07'47.2" W), Zamora-Chinchipe province. However, these specimens do not have the slender upper and lower incisors, and the slender lower diastema observed in *T. onkiro* proper. Compared to *T. onkiro* proper, the Ecuadorean specimens have a mesopterygoid fossa with a medial process and roof perforated by narrow slits. I believe that these Ecuadorean specimens are best allocated to *T. caudivarius* (see *T. caudivarius* account), and this record is not included here.

Thomasomys oreas Anthony, 1926

Montane Fairy Thomasomys

SYNONYMS:

Thomasomys oreas Anthony, 1926a:2; type locality "Cocapuncu [= Cocapuncu], about 80 miles north of La Paz, Bolivia, altitude 10,000 feet."

Thomasomys taczanowskii: S. Anderson, 1993:37; part; not *taczanowskii* Thomas.

DESCRIPTION: Small sized (head and body length 90–108 mm) with long and soft dorsal fur (average length 15 mm, guard hairs 19 mm). Dorsal pelage colored Prout's brown, finely sprinkled on back with fuscous black; cheeks and sides brighter than back; dusky orbital ring present; ventral pelage pinkish buff, with hairs gray basally and moderately countershaded with dorsal coloration. Ears comparatively large (19 mm) and blackish brown. Mystacial vibrissae long, extending backward distinctly beyond pinnae when bent; genal 1 vibrissae present. Tail

longer than head and body (126–139%), faintly bicolored, clothed with and short hairs, brown above but grayish below, and without terminal white tip or pencil tuft. Hindfoot relatively short (23–25 mm) with clove-brown metatarsal patch, edges and digits cartridge-buff; no gap between thenar and hypothenar pads. Hallux long, extending to interphalangeal joint of dII. Digit V of pes very long, its claw extending to base of claw of dIV. Protuberant anus raised but not as prominent as in *T. cinereus*. Skull short (condyloincisive length 25.3–25.8 mm) with long and slender rostrum and well-inflated braincase with rather antero-posteriorly broad interparietal. Interorbital region narrow, hourglass in shape, with rounded edges. Interfrontal fontanelle present. Zygomatic arches with limited lateral flaring, either parallel or converging anteriorly. Zygomatic plates vertical and moderately broad, breadth subequal to length of M1. Molar bearing maxilla with rectangular shape. Distinct notch present between zygomatic maxillary root of zygomatic arch and lacrimal bone in dorsal view. Incisive foramina long and narrow, extending posteriorly between M1 anterocones. Mesopterygoid fossa moderately broad, slightly converging posteriorly, with weak or absent palatal medial process; roof perforated by medium-size sphenopalatine vacuities on each side of presphenoid-basisphenoid suture. Auditory bullae large and inflated. Subsquamosal fenestra well open and larger than postglenoid foramen. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper incisors opisthodont. Maxillary toothrow short (4.1–4.3 mm); molars small and brachydont, without interpenetrating flexi but distinct crenulation. M1 exhibits distinct anteromedian flexus and anteroloph, but anteroflexus mostly coalesced; anteromedian flexid of m1 weak even in unworn molars. Capsular process present.

DISTRIBUTION: *Thomasomys oreas* occurs from northern Peru to central Bolivia, in eastern montane forests from 2,460 to 3,650 m.

SELECTED LOCALITIES (Map 356): **BOLIVIA:** Cochabamba, Ayopaya, El Choro (FMNH 74866), Totorá, 2 km N of Cocapata (CBF 4954); La Paz, Chuncani (CBF 7427), Cocapunco (type locality of *Thomasomys oreas* Anthony), Franz Tamayo, Pelechuco, Llamachaqui, on road to Apolo (CBF 4041). **PERU:** Amazonas, mountains east of Balsas (FMNH 19830), 10 mi E of Molinopampa (FMNH 19832); Ayacucho, Comunidad Estera, Cerro Calle Nueva (MUSM 34718); Cusco, Ccachubamba (FMNH 75224), 32 km NE (by road) of Paucartambo; km 112 (MVZ 172344), Puesto Vigilancia Acjanaco (MUSM 6727), Topoqueu, Occobamba valley (USNM 194876).

SUBSPECIES: I provisionally consider *T. oreas* to be monotypic (but see Remarks).

NATURAL HISTORY: Bolivian records summarized by S. Anderson (1997) unfortunately lack data on habitat, habits, behavior, food, or reproduction. However, Salazar-Bravo and Yates (2007) reported that recent specimens were collected on the ground in upper montane elfin forest. One female specimen, with no embryos, was caught at Tres Cruces, Cusco department, Peru, on the edge of cloud forest (O. P. Pearson field notes, MVZ archives). Known ectoparasites include the lice *Hoplopleura tiptoni* and *Pterophthirus imitans* (although the latter may be a straggler; V. S. Smith et al. 2008) and the flea, *Sphintopsylla* sp. (Maihuay et al. 2004). Visceral parasites include the tapeworm *Taenia pisiformis* (Tantaleán and Chavez 2004).

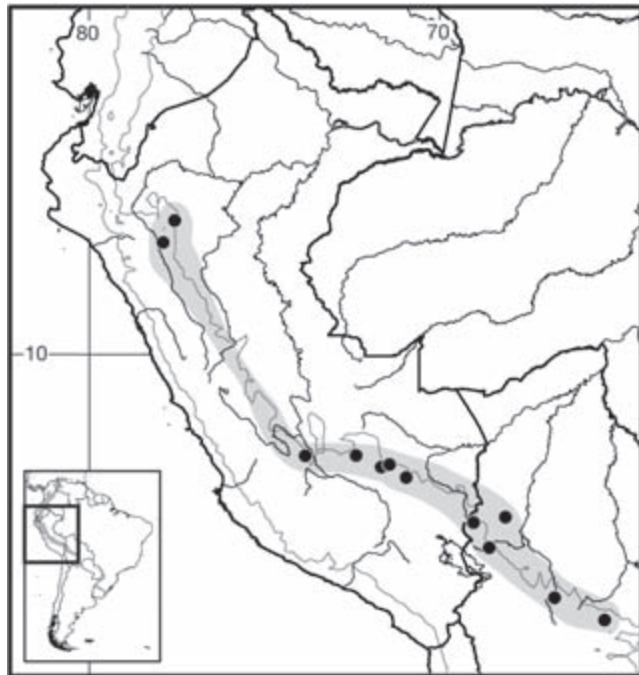

REMARKS: S. Anderson (1997:91) corrected the spelling of the type locality of Cocopunco to Cocapunco. This species includes several records that appeared in the literature as *T. taczanowskii* (Thomas 1920h; A. L. Gardner 1976; A. L. Gardner and Patton 1976; S. Anderson 1993, 1997), based on my own examination of the reported specimens. Patton et al. (1990) tentatively referred *T. oreas* to one specimen from Cusco, Ocobamba valley as *T. taczanowskii* by Thomas (1920h). This locality belongs to the Río Urubamba, not to the Río Apurímac drainage as indicated in Patton et al. (1990). Pacheco (2003) observed considerable geographic and interspecific variation and suggested that *T. oreas* represents a species group that includes at least *T. oreas* s. and two other currently undescribed species, which he informally referred to as *Thomasomys* sp. 8 (from Yuraccyacu, Ayacucho department) and *Thomasomys* sp. 9 (from Paucartambo, Cusco department). The first exhibits larger and broader incisive foramina and a broader parapterygoid fossa; the second is distinguished by narrower incisive foramina, the lack of a palatal medial process, a larger postglenoid foramen, comparatively smaller auditory bullae, and subparallel zygomatic arches. Salazar-Bravo and Yates (2007) differentiated *T. oreas* from both *T. andersoni* and *T. notatus* by morphology as well as mtDNA cytochrome-*b* sequences. However, it should be noted that the genetic sequences came from a specimen from Cochabamba (MSB 87126) rather than from the type locality.

Cochabamba specimens are slightly smaller in body size and molar toothrow length than the type specimen from La Paz, and depart in other attributes, such as general 1 absent, slightly broader rostrum, interparietal anteroposteriorly shorter, palatal medial process absent, and smaller squamosal fenestra, which might indicate the presence of another unknown taxon. S. Anderson (1997:411) was probably misled by these differences and misidentified two Cochabamba's specimens (FMNH 74866, 74867) as *T. taczanowskii* at the same time he recognized *T. oreas*

for Bolivia. Pending further analyses, ideally based on additional specimens, I tentatively allocate the Cochabamba sample to *T. oreas*. A single specimen collected from the Cordillera Vilcabamba, Junín, might also represent an unknown taxon. This specimen has grayish tones, short dorsal pelage, and an undefined dorsal band, among other features.

Anthony (1926a) considered *T. oreas* as most closely related to *T. paramorum*. On the contrary, Patton (1987), based on electrophoresis of 24 loci, found *T. oreas* related to *T. gracilis* as compared with other species of *Thomasomys* from southeastern Perú. This result that was later supported by cladistic analysis of morphological characters where *T. oreas* appears related to a species cluster that included *Thomasomys* sp. 8, *Thomasomys* sp. 9, and *T. gracilis* (Pacheco 2003). The phylogenetic analysis based on mtDNA cytochrome-*b* sequences placed *T. oreas* as sister to *Thomasomys* sp. 9 and well removed from *T. gracilis* (Salazar-Bravo and Yates 2007).

The karyotype of *T. oreas* (reported as *T. taczanowskii*) with a diploid number $2n=44$ and, $FN=44$, X and Y autosomal chromosomes, from a specimen from Yuraccyacu, Ayacucho department, in the Río Apurímac drainage was reported by A. L. Gardner and Patton (1976), a sample that I earlier (Pacheco 2003) referred to as *Thomasomys* sp. 8. Given the extensive geographic variation in samples currently allocated to *T. oreas*, the karyotype of a toptype is critically lacking.

Map 356 Selected localities for *Thomasomys oreas* (●). Contour line = 2,000 m.

Thomasomys paramorum Thomas, 1898

Páramo *Thomasomys*

SYNONYM:

Thomasomys paramorum Thomas, 1898e:453; type locality “Paramo [= Páramo] south of Chimborazo [= Mt Chimborazo],” defined as “Urbina (1°30’S, 78°44’W) just a few kilometers SE of Chimborazo” by Voss (2007), Chimborazo, Ecuador.

DESCRIPTION: Small sized (head and body length 85–113 mm) with long, soft, and woolly dorsal fur. Dorsal color even brownish olive to reddish brown; ventral color pale gray to whitish; creamy line separating flank and abdomen; moderate countershading between dorsum and venter. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears relatively large (15–22 mm), evenly rounded, well haired, and dark brown. Tail short to moderately long (101–147% of head and body length), well haired, incipiently bicolored brown above and paler below, and occasionally with terminal white tip. Hands and feet whitish above. Hindfoot relatively short (19–28 mm); gap present between thenar and hypothenar pads. Hallux moderately long, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull comparatively small (condyloincisive length 22.8–25.6 mm), slender and delicate, with narrow, long, and rounded braincase, and relatively narrow rostrum. Zygomatic plates narrow, breadth less than length of M1, or moderately broad, subequal to length of M1, and may slope backward or be vertically oriented. Interorbital region moderately broad, hourglass in shape, with smooth edges. Zygomatic arches slightly convergent anteriorly. Incisive foramina long, oval shaped, more contracted anteriorly, and extended backward between M1 procingula. Mesopterygoid fossa broad with subparallel sides; sphenopalatine vacuities present as slits or moderately open. Parapterygoid vacuities present or absent. Auditory bullae large and inflated. Subsquamosal fenestra slightly larger and more open than postglenoid foramen. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper incisors narrow and opisthodont or orthodont. Maxillary toothrow relatively short, 3.8–4.5 mm; upper molars moderately hypsodont, with no interpenetration of flexi. Anteroloph of M1 indistinct; M3 with indistinct mesoloph and hypoflexus. Capsular process absent, or as only swollen ridge if present.

DISTRIBUTION: *Thomasomys paramorum* is an endemic species of the northern Andes, occurring north of the Huancabamba Deflection (Voss 2003) within mon-

tane forests and páramo habitats from southern Colombia to central Ecuador, between 2,000 and 4,300 m.

SELECTED LOCALITIES (Map 357): COLOMBIA: Nariño, Pasto, slopes of Volcán Galeras (ICN 13267). ECUADOR: Azuay, Cajas Plateau (Barnett 1999); Bolívar, Sinche (AMNH 66984); Carchi, Mantufar, Atal (UMMZ 77215); Chimborazo, Urbina (type locality of *Thomasomys paramorum* Thomas); Napo, Cerro Antisana (FMNH 53239); Napo, Cuyuco [probably Cuyuja], below Papallacta (AMNH 46629); Pichincha, E side of Mt. Pichincha (MVZ 137603), Guarumos West (FMNH 56238), Upper Río Pita (USNM 270151).

SUBSPECIES: *Thomasomys paramorum* is monotypic (but see Remarks).

NATURAL HISTORY: On the Cajas Plateau in Ecuador, this species occurs in primary, secondary, and recently disturbed forests, typically in habitats with moist mossy ground cover, fallen logs, and proximity to stands of *Chusquea* bamboo, but not in páramo (Barnett 1999). At Papallacta, also in northern Ecuador, individuals were captured in subalpine rainforest, in *Polylepis* (Rosaceae) thickets in the páramo, and in the shrubby páramo/forest ecotone (Voss 2003). It is mainly terrestrial, and uses runways through moss, along banks of small streams, in wet leaf litter under shrubs and branches, and under clumps of grass. It was also trapped in low, moss-covered trees (Voss 2003). M. Brito et al. (2012) described nets located under root masses and among dead leaves of *Espeletia* (Asteraceae) shrubs, at heights between 15 cm and 1.5 m. A female from the east side of Mt. Pichincha (MVZ) was collected with an embryo at the end of June.

REMARKS: The stomach morphology corresponds to the unilocular-hemiglandular model (Carleton 1973). The few karyotypes available suggest some geographic variation in Ecuador. Haynie et al. (2006) reported $2n=44$, FN=42, for specimens from Tungurahua, similar to that reported previously by A. L. Gardner and Patton (1976) from Mount Pichincha (reported as *Thomasomys* sp.), except that X and Y chromosomes are acrocentric instead of submetacentric. A karyotype from the type locality is lacking.

Thomasomys paramorum exhibits some geographic polymorphism in several characters that might suggest a species complex (Pacheco 2003). Samples from southern Colombia in Nariño and northwestern Ecuador, Carchi, differ from typical *paramorum* by their reddish pelage, broader nasals, very inflated bullae that are strongly placed forward so that the middle lacerate foramen is closed, a broad mesopterygoid fossa with posteriorly convergent sides, the upper incisors are less opisthodont rather than strongly opisthodont, and the postglenoid foramen and subquamosal fenestra are narrow and elongated, not rounded. Voss (2007) also noted that the topotypic series from Chimborazo average larger

Map 357 Selected localities for *Thomasomys paramorum* (●). Contour line = 2,000 m.

than Papallacta specimens in most measurements and have proportionately narrower zygomatic plates, but he judged both to represent the same taxon. Pacheco (2003) also noted that the zygomatic plates are slightly sloped backward in these specimens, not vertical.

Little is known about the phylogenetic position of *T. paramorum*. Ellerman (1941) included this species in his *cinereus* Group. Pacheco (2003) found the species closely related to *T. niveipes* in his phylogenetic assessment based on morphology. And T. E. Lee et al. (2011) allied the species to an apparently unknown taxon, morphologically identified as *T. baeops*, from Sangay, based on an mtDNA cytochrome-*b* molecular phylogeny. Unfortunately, no additional data were provided on this taxon to understand this discrepancy. However, if this unknown taxon were certainly a type of *baeops*, the hypothesis of the “cinereus” and “baeops” groups presented here would be rejected despite the trenchant morphological differences between them. Because Robert S. Voss confirmed the identification of this taxon as *T. baeops* but the gene sequence suggests that the specimen is a member of the “cinereus” group, the possibility of a mismatch should be considered. Additional studies are needed to resolve this issue and the phylogenetic relationships of *T. paramorum*.

Thomasomys popayanus J. A. Allen, 1912

Popayán Thomasomys

SYNONYMS:

Thomasomys popayanus J. A. Allen, 1912:81; type locality “crest of Western Andes (alt. 10,340 ft [3,152 m]),

40 miles [64 km] west of Popayan [= Popayán], Cauca, Colombia.”

Thomasomys aureus popayanus: Gyldenstolpe, 1932a:51; name combination.

DESCRIPTION: Large species (head and body length 145–164 mm) with general coloration similar to *T. aureus*. Dorsal pelage long, thick, and not very fine, yellowish rufous with faint but dark median band along midline; top of head darker than back and slightly grayish; ventral surface deep ochraceous buff. Hindfeet long (33–38 mm), moderately broad, and with upper metatarsal dark brown and digits whitish. Tail long (129–145% of head and body length), monocolored, finely annulated, covered with very short hairs, and without terminal pencil. Skull large (condyloincisive length 34.5–36 mm); nasals long, taper posteriorly, and longer than premaxillae. Zygomatic plates rather vertical and moderately broad. Interorbital region narrow with incipient square margins; postorbital ridge indistinct. Incisive foramina long and moderately narrow, extending posteriorly slightly between M1 anterocones. Palatal bridge short and narrow. Auditory bullae small, and not inflated; anterior process of ectotympanic is large. Mesopterygoid fossa broad and somewhat parallel sided; roof closed. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Lambdoid ridge indistinct or absent. Upper incisors opisthodont. Maxillary toothrow long, 6.4–7.0 mm. M1 lacks perceptible protostyle and entostyle; m1 with ectolophid. Capsular process absent.

DISTRIBUTION: *Thomasomys popayanus* occurs in the Cordillera Occidental of Colombia, between 1,830 m and 3,300 m.

SELECTED LOCALITIES (Map 358): COLOMBIA: Antioquia, Urrao, Santa Bárbara (FMNH 71287), Urrao, Páramo Frontino (FMNH 71269); Cauca, coast range W of Popayán (MCZ 17317), Cocal (AMNH 32460), Munchique (FMNH 89273); Valle del Cauca, San Antonio (AMNH 32187).

SUBSPECIES: I consider *T. popayanus* to be monotypic.

NATURAL HISTORY: Little is known about this species. Delgado-V. (2009) reported it from the Reserva San Sebastián-La Castellana, Valle de Aburrá, Antioquia, Colombia, by both captures and from remains in scat of the Crab-eating Fox *Cerdocyon thous*. Trapido and Sanmartín (1971) screened specimens of *T. popayanus* (reported as *T. aureus*) for Pichindé virus, but failed to detect the virus.

REMARKS: *Thomasomys popayanus* was described only on the basis of coloration and standard measurements (J. A. Allen 1912). Without substantive arguments, Thomas (1921j) doubted that *popayanus* was separable from *T. aureus*, and Ellerman (1941) formally reduced it to a subspecies of *T. aureus*, an action followed by Ca-

Map 358 Selected localities for *Thomasomys popayanus* (●). Contour line = 2,000 m.

brera (1961) and Musser and Carleton (1993) but not by Voss (2003) or Pacheco (2003). Voss (2003) recognized *T. popayanus* (in which he provisionally included *nicefori*) based on shorter (33–34 mm) hindfeet and smaller (6.0–6.6 mm) molar tooththrows than *T. aureus*. However, for unknown reasons, Voss’s (2003) measurements do not coincide with my own data of hindfeet (33–38 mm, N=4, AMNH adult specimens) or molar tooththrow (6.44–6.96 mm, N=4, AMNH adult specimens), or J. A. Allen’s (1912) data (35–38 mm, 7.0 mm, respectively), both sets of which are slightly larger than hindfoot (33–36 mm), and molar tooththrow (5.9–6.6 mm) of *T. nicefori* (N=10). In addition, *T. popayanus* has the tail usually longer than *T. nicefori* (129–145% versus 114–136% of head and body length). Pacheco (2003) presented additional morphological traits to separate both species, and which are detailed above (see *T. nicefori* account). The karyotype is unknown.

Thomasomys praetor (Thomas, 1900)

Cajamarca Thomasomys

SYNONYMS:

Oryzomys praetor Thomas, 1900d:354; type locality “Eastern slope of Paramo [= Páramo] between San Pablo and Cajamarca, [Cajamarca,] Peru,” 4,000 m elevation.

Thomasomys praetor: Thomas, 1906c:443; first use of current name combination.

Thomasomys aureus praetor: Cabrera, 1961:426; name combination.

DESCRIPTION: Large sized (head and body length 161–187 mm) with comparatively short tail (107–116% of head and body length). Fur long, soft, close, and thick, with hairs on midback 13–15 mm long. Dorsal color olivaceous grayish, darkened on middle and posterior back; head, cheeks, shoulders, and sides clearer yellowish gray, undersurface buffy white with slate-based hairs. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae present. Hindfoot long (35–38 mm); metatarsals silvery white. Hallux long, extending to interphalangeal joint of dII, or moderate, not reaching that joint. Digit V of pes moderately long, claw extending close to base of claw of dIV. Tail incipiently bicolored, uniformly brown above, rather paler below, short haired, and usually with terminal white tip. Ears of medium size (23–25 mm), blackish brown, and conspicuous white postauricular patch present. Skull large (condyloincisive length 36.9–37 mm), within range of *T. aureus*; braincase rather broad and flat; rostrum short and comparatively broad; nasals expanded anteriorly and taper posteriorly, with posterior margins level with or longer than premaxillae. Zygomatic plates moderately broad, breadth subequal to length of M1, rather vertical, and more projecting such that zygomatic notches well defined. Interorbital region narrow, sides parallel or slightly convergent, and flat above; edges squared and traceable across parietals to outer margins of interparietal; postorbital ridge distinct. Molar bearing maxillae with triangular shape. Parietals with large lateral projections. Interparietal broad, strap-like, and shorter anteroposteriorly. Incisive foramina large and open, extending backward usually between M1 anterocones. Palatal bridge short and narrow, with maxillary palatal pits present. Auditory bullae small but moderately inflated, with bony tubes short but distinct; anterior process of ectotympanic relatively small; processus brevis of incus unusually robust. The mesopterygoid fossa is broad and somewhat parallel sided; its roof perforated by moderate sphenopalatine vacuities flanking presphenoid-basisphenoid suture. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Lambdoid ridge distinct. Upper incisors orthodont, molars large. Maxillary toothrow length long, ranging from 7.1–7.5 mm, similar to *T. aureus*. The m1 entolophid oriented to murid, and coalesced with minute mesolophid. Capsular process absent.

DISTRIBUTION: *Thomasomys praetor* is known from the western versant and inter-Andean valleys of the north-

ern Andes in Peru, between the Huancabamba Deflection and the Río Marañón, from 2,050 to 4,000 m.

SELECTED LOCALITIES (Map 359): PERU: Ancash, Carhuaz, Jangas, Antauran, Cordillera Negra, Quebrada Lancash (MUSM 11644), Cuenca del Río Pampas, below Conzuso (MUSM 23326). Quebrada Chahuacocha, Acrana (MUSM 23332); Cajamarca, Celendín, Hacienda Limón (FMNH 19256), San Pablo (type locality of *Oryzomys praetor* Thomas); La Libertad, 5 mi SW of Otuzco (MVZ 137941), Sanagorán (MUSM 17301).

SUBSPECIES: *Thomasomys praetor* is monotypic.

NATURAL HISTORY: This species has been collected in páramo thickets (Thomas 1900d) and at the edge of the timberline in the dry forests of the Río Marañón valley (Osgood 1914b). I have obtained additional specimens in dense and tall shrub habitats on rocky substrates, near rivers or streams.

REMARKS: *Thomasomys praetor* is another of the large *Thomasomys* relegated to a subspecies of *T. aureus* by Cabrera (1961). However, Voss (2003) and Pacheco (2003) independently recognized *T. praetor* as a valid species. Voss (2003) followed and highlighted Thomas's (1900d) main characteristics provided in the original diagnosis: grayish dorsal fur, pale-silvery ventral fur, pale hindfeet, shorter tail, narrower interorbital, and a broad and distinctively flattened braincase. Pacheco (2003) scored new and numerous external, hard, and soft morphological characters in his phylogenetic analysis of the genus. In addition to Thomas's description, *T. praetor* can be readily separated from *T. aureus* by the smaller hallux and digit V, shorter mystacial vibrissae, deeper and better defined zygomatic notch, and entolophids oriented to the murid and coalesced with a minute mesolophid.

T. E. Lee et al. (2011) claimed to have the first record of *T. praetor* from Ecuador, based on four specimens collected in Atillos lagoons, Chimborazo, Sangay National Park, that have the following external range measurements: total length 376–432 mm, tail length 211–249 mm, hindfoot 38–42 mm, and ear 24–25 mm. However, these specimens are much larger in the first three dimensions than the holotype of *T. praetor* (total length 348 mm, tail length 180 mm, hindfoot 35 mm, and ear 25 mm), an adult specimen of age 3 (*sensu* Voss 1991a), and the average of 13 other specimens (total length 337.15 mm, tail length 180.69 mm, hindfoot 34.92 mm, and ear 23.54 mm). Although the fur color of their specimens did not match that described for *T. praetor* proper (Thomas 1900d; Voss 2003), T. E. Lee et al. (2011) were convinced of their determination and further claimed that *T. praetor* and *T. aureus* were not sister taxa. Although I have not examined the specimens in question, I doubt that the Atillos' sample corresponds to *T. praetor*

Map 359 Selected localities for *Thomasomys praetor* (●). Contour line = 2,000 m.

because Peruvian specimens (including the holotype) are uniformly smaller and all specimens I have examined exhibit the grayish dorsal fur, pale-silvery ventral fur, and pale hindfeet as stated by Thomas (1900d), Voss (2003), and herein.

Thomas (1900d) allied *T. praetor* to *T. aureus* and *T. princeps*, and suggested they comprised a section of the genus. Pacheco (2003)'s phylogenetic assessment based on morphological attributes found *T. praetor* allied to other species of his "aureus" group, but unexpectedly in a basal position. The karyotype is unknown.

Thomasomys princeps (Thomas, 1895)

Principal *Thomasomys*

SYNONYMS:

Oryzomys princeps Thomas, 1895b:58; type locality "Bogota," corrected to Bogotá Region, 8,750 ft (2,667 m), Cundinamarca, Colombia by Musser and Carleton (2005).

Thomasomys princeps: Thomas, 1906c:443; first use of current name combination.

Thomasomys aureus princeps: Cabrera, 1961:426; name combination.

DESCRIPTION: Distinctively large species (head and body length 173–198 mm), slightly larger than Ecuadorean *T. aureus*. Dorsal pelage long, thick, and not very fluffy, rich orange-rufous in color with faint dark band along midline, richer along sides; undersurface clear orange-buff, not countershaded. Mystacial vibrissae long, extending distinctly posterior to pinnae; genal 1 vibrissae present. Hindfeet relatively long (35–39 mm) and moderately broad, with dark brown patch on metatarsals and silvery whitish on sides and digits. Tail long (113–131% of head and body length), monocolored blackish brown, finely annulated, covered with short hairs, and without terminal pencil. Hallux long, extending to interphalangeal joint of dII. Digit V of pes very long, claw extending to base of claw of dIV. Protuberant anus prominent. Skull large and robust (condyloincisive length 36.7–39.4 mm); rostrum relatively short and broad; braincase oblong, moderately broad, and not inflated. Zygomatic plates broad and vertical. Anterior borders of premaxillae do not project much beyond upper incisors. Premaxillomaxillary-frontal intersection anterior to zygomatic notches. Anterior margin of M1 placed anterior to posterior border of zygomatic plates. Interorbital region narrow, slightly convergent anteriorly, with square (no beaded) margins; postorbital ridge distinct; parietals large with comparatively small and less rectangular lateral processes; interparietal large and half-oblong in shape; lambdoid ridge well developed. Incisive foramina large and comparatively broad, and extend posteriorly level to or between anterocones of M1; maxillary septum usually long, approaching half length of incisive foramen. Palatal bridge short and narrow with maxillary palatal pits present. Auditory bullae small, uninflated, and flask-shaped; anterior process ectotympanic comparatively small. Mesopterygoid fossa broad and somewhat parallel-sided; roof closed, with sphenopalatine vacuities absent or present only as slit-like vacuities flanking presphenoid-basisphenoid suture. Parapterygoid fossae possess large posterior opening of alisphenoid canal. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors opisthodont. Maxillary toothrow long, 7.2–7.6 mm. M1 with anteroflexus coalesced with anterocone, showing indistinct anteroloph; protoflexus of M2 indistinct; ectolophid of m1 present. Capsular process absent but area strongly swollen producing distinct shelf.

DISTRIBUTION: *Thomasomys princeps* is known only from the Cordillera Oriental of Colombia, from about 2,650 to 3,060 m.

SELECTED LOCALITIES (Map 360): COLOMBIA: Cundinamarca, Choachí (USNM 251958), Bogotá region (BM 95.8.1.37, holotype), Laguna Vergon (USNM 251976), Bogotá, San Cristobal (FMNH 71307), Bogotá,

San Francisco (FMNH 71305), Guasca, Río Balcones (FMNH 71304).

SUBSPECIES: *Thomasomys princeps* is monotypic.

NATURAL HISTORY: Individuals have been collected in montane forests. Lopez-Arévalo et al. (1993) collected the species (reported as *T. aureus*) at the forest of the Reserva Biológica Carpanta, Cundinamarca, Colombia, where trees reach heights of 25 m and are covered with epiphytes. Schramm and Lewis (1987) described a new species of flea, *Plocopsylla nungui*, from specimens they only identified as *Thomasomys* sp., which were collected by P. Hershkovitz from San Francisco, Bogotá. However, Hershkovitz collected both *T. niveipes* and *T. princeps* from this locality, so the type host of this flea could be either of these two species.

REMARKS: Thomas (1900d) and Ellerman (1945) recognized *T. princeps* as a valid species, but Cabrera (1961) relegated it as a subspecies of *T. aureus* without justification. Musser and Carleton (1993, 2005) and Voss (2003) followed this arrangement. Alternatively, Pacheco (2003) regarded Thomas's *princeps* as a valid species, one that can be differentiated from *T. aureus* by a number of characters: the short anterior border of the premaxillae not projecting beyond upper incisors; short posterior margin of premaxillae producing a premaxillomaxillary-frontal intersection that lies in front of the zygomatic notch rather than level to it; longer nasals that extend posteriorly usually beyond

the lacrimals; broader and oval-shaped incisive foramina rather than narrow and elongated, with maxillary septum about half the length of foramina opening rather than shorter; the comparatively small anterior process of ectotympanic; comparatively larger posterior opening of the alisphenoid canal; anterior margin of M1 placed anterior to the posterior border of zygomatic plates rather than ventral to them; a strongly swollen capsular process producing a distinct shelf; an indistinct anteroflexus of M1; an indistinct protoflexus of M2; and an ectolophid on m1.

Thomasomys princeps was found to cluster unresolved with other species of the "aureus" group in a phylogenetic analysis based on morphological characters (Pacheco 2003). However, resolution was limited by the lack of skeletons and specimens in alcohol. The karyotype is unknown.

Thomasomys pyrrhonotus Thomas, 1886

Reddish-backed *Thomasomys*

SYNONYMS:

Hesperomys [*Rhipidomys*] *pyrrhorhinus*: Thomas, 1882: 107; part; not *Mus pyrrhorhinus* Wied-Neuwied.

H[esperomys]. pyrrhonotus Thomas, 1886b:422; type locality "Tambillo, [Río Malleta,] 5800 ft [1,768 m]," Cajamarca, Peru.

Thomasomys pyrrhonotus: Thomas 1906c:443; first use of current name combination.

DESCRIPTION: Medium sized comparable to *T. auricularis* (head and body length 137–144 mm), which it resembles superficially, but with slightly shorter tail and slightly shorter toothrow length. Dorsal pelage rich rufous, head similar but lighter; undersurface whitish with small orangish pectoral streak. Bases of dorsal and ventral hairs slated-color. Ears of moderate length (19.5–22 mm), and whitish postauricular patch present. Blackish mystacial vibrissae moderately long, extending slightly or distinctly beyond posterior margin of pinnae when bent; genal 1 vibrissae present. Tail relatively long (120% of head and body length), uniformly dark brown except for basal half-inch portion covered with red-tipped body hairs. Hindfoot moderately long (30–31 mm) with metatarsals pale orange and digits brown. Digit I of pes (hallux) long, extending to interphalangeal joint of dII; digit V moderately long or long, extending to base of claw of dIV or close. Skull large and robust but similar to that of *T. auricularis* (condyloincisive length of skull, 33.9); rostrum long and slender; nasals slender and expanded anteriorly; the braincase oblong and somewhat inflated. Incisive foramina long, open, and extend backward between M1 procingula; maxillary septum length short, less than half incisive foramina length. Interorbital region narrow, sides parallel, edges squared but smooth and not beaded, and interfrontal fontanella present. Ethmoturbinals small and poorly

Map 360 Selected localities for *Thomasomys princeps* (●). Contour line = 2,000 m.

developed. Mesopterygoid fossa broad, sides subparallel, and roof moderately fenestrated. Auditory bullae unusually large and inflated (larger than *T. auricularis*). Postglenoid foramen conspicuous and narrow but smaller than more open subsquamosal fenestra; hamular process narrow and very long. Lamina of malleus with well-defined edge on ventral and posterior margin. Incisors very broad and strong; anterior surface dark orange. Maxillary toothrow long (6.4 mm); molars proportionately large; additional anterior edge on the procingulum of M1 usually absent.

DISTRIBUTION: *Thomasomys pyrrhonotus* occurs only in montane forests in northwestern Peru, from 1,200 to 3,100 m.

SELECTED LOCALITIES (Map 361): PERU: Cajamarca, Bosque Cachil, between Cascas and Contumaza (MUSM [VPT 1670]), 7 km N and 3 km E of Chota (LSUMZ 22317), 1 km NW of Cutervo (LSUMZ 21874), Santa Cruz, Catache, 3.81 km NE of Monteseo (UMMZ, uncatalogued), Tambillo, Río Malleta (type locality of *Hesperomys pyrrhonotus* Thomas); Piura, Ayabaca (FMNH 81296), Cerro Chinguela, ca. 5 km NE of Zapalache (LSUMZ 26947), Huancabamba, Canchaque (FMNH 81295).

SUBSPECIES: *Thomasomys pyrrhonotus* is monotypic.

NATURAL HISTORY: Thomas (1882) stated that this species lived in trees, but few other data on ecology or natural history are known. The species has been collected in tall shrub habitat in Cachil, Cajamarca (V. Pacheco, unpubl. data), in montane secondary forests and montane bamboo forests on the ground and near a stream in Monteseo, Cajamarca (L. Luna, pers. comm.), and in montane cloud forest at Cutervo, Cajamarca (LSUMZ 21874). Short observations on one captured specimen revealed this species is an excellent climber, making good use of the digits of the hindfoot to grasp branches and its long tail for balance (V. Pacheco, unpubl. obs.).

REMARKS: This species has been treated as polytypic after including *auricularis* Anthony as a subspecies (Cabrera 1961), or either as synonym or subspecies in following synopses (e.g., Musser and Carleton 1993, 2005). Pacheco (2003) recognized *T. pyrrhonotus* and *T. auricularis* as species; arguments supporting these hypotheses are provided in the account of *T. auricularis*.

Page 421 of Thomas (1886b) has been commonly cited for the description of this species (Gyldenstolpe 1932; Cabrera 1961; Musser and Carleton 1993, 2005), but the name first appears on p. 422.

Ellerman (1941:368) recognized a *pyrrhonotus* Group, which included *T. pyrrhonotus* and *T. auricularis* based on their enlarged auditory bullae, separate from his *aureus* Group. Pacheco's (2003) phylogenetic assessment found *T. pyrrhonotus* allied to *T. rosalia*, followed by *T. auricula-*

Map 361 Selected localities for *Thomasomys pyrrhonotus* (●). Contour line = 2,000 m.

ris, all within a partially resolved monophyletic clade comprising his “aureus” group, and thus partially supporting Ellerman’s hypothesis. The karyotype is unknown.

Thomasomys rosalia Thomas and St. Leger, 1926 *Rosalinda’s Thomasomys*

SYNONYM:

Thomasomys rosalia Thomas and St. Leger, 1926a:347; type locality “Goncha, Amazonas, 8500’ [2,591 m],” Peru.

DESCRIPTION. Medium size (head and body length 135 mm), comparatively smallest reported species of “aureus” group. Dorsal color reddish gray overall, more grayish on head, foreback, and cheeks, and smoothly more rufous on posterior back, rump, and hindlimbs. Undersurface tawny cinnamon, paler on mental, throat, and inner sides of forelimbs, with indistinct rufous patch on chest, and more rufous on inner sides of hind limbs, inguinal region, and base of tail. Bases of hairs plumbeous all over body. Hairs of moderate length (12 mm), with guard hairs up to 15 mm long. Nose reddish gray contrasting with dark spot at base of mystacial vibrissae. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of

pinnae when bent; genal 1 vibrissae present. Ears of moderate length (20.5 mm), brown, and covered by long hairs for two-thirds of length, surrounded by inconspicuous tawny area. Carpal region tawny silvery, not countershaded with inner sides of forelimbs; metacarpals and fore digits dark. Tail moderately long (126% of head and body length), unicolored brown, and covered by short hairs. Hindfoot of medium length (27.5 mm); metatarsals silvery light brown proximally, becoming slightly darker on distal surface and digits, with ungual tuft silvery white. Hallux long, extending to interphalangeal joint of dII. Digit V of pes very long, claw extending to base of claw of dIV. Skull also of medium length (condyloincisive length 31 mm), with relatively long and narrow rostrum and oblong braincase. Interorbital region narrow with sides angular and divergent. Zygomatic arches converge slightly anteriorly, although maxillary roots exhibit subrectangular outline. Interparietal unusually large, rectangular shaped, with outer corners preventing parietals from contacting occipital bone. Lambdoid ridge weakly developed. Moderately broad and vertical zygomatic plates project slightly forward, producing well-defined zygomatic notches. Incisive foramina large and open, capsular-shaped, and extend backward deeply to posterior margins of M1 anterocones. Mesopterygoid fossa broad, expanded anteriorly and narrowing behind; roof moderately perforated by sphenopalatine vacuities on both sides of presphenoid-basisphenoid suture; palatal medial process absent. Auditory bullae small, although moderately inflated; bony tubes short and broad. Postglenoid foramen and subsquamosal fenestra very large, latter more open. Orbicular apophysis of malleus small. Upper incisors opisthodont. Maxillary toothrow moderate in length (6.4 mm). Procingulum of M1 exhibits distinct additional border; anteroloph and anteroflexus of this tooth distinct, whereas protoflexus of M2 distinct. The m1 exhibits both distinct anteromedian flexid and ectolophids.

DISTRIBUTION: *Thomasomys rosalia* is known only from its type locality in northern Peru.

SELECTED LOCALITIES (Map 362): PERU: Amazonas, Goncha (type locality of *Thomasomys rosalia* Thomas and St. Leger).

SUBSPECIES: *Thomasomys rosalia* is monotypic.

NATURAL HISTORY: This species apparently occurs in montane forests, with the type specimen trapped in wet brush (Thomas and St. Leger 1926a). No other information on ecology or behavior is known.

REMARKS: This species, still known only by the holotype, is one of the most poorly known in the genus. Ellerman (1941:371) unexpectedly placed *T. rosalia* in his widely constructed *cinereus* Group, but Pacheco (2003) confirmed the species as a member of the “aureus” group in his phylogenetic assessment, apparently related to both

Map 362 Single known locality for *Thomasomys rosalia* (●). Contour line = 2,000 m.

T. pyrhoneotus and both with *T. auricularis*. Both the large interparietal, precluding a parietal-occipital contact, and the deep incisive foramina readily differentiate this species from other members of the “aureus” group. The karyotype is unknown.

Thomasomys silvestris Anthony, 1924

Sylvan Thomasomys

SYNONYMS:

Thomasomys silvestris Anthony, 1924a:2; type locality “Las Maquinas [= Máquinas], on Santo Domingo trail, west of Corazon [= Corazón], Western Andes, [Pichincha,] Ecuador; altitude 7,000 feet [2,134 m].”

Thomasomys ischyurus silvestris: Cabrera, 1961:430; name combination.

DESCRIPTION: Medium sized (head and body length 95–136 mm) with soft, dense, and comparatively long dorsal fur. Dorsal color varies from brownish cast (hairs slate-colored basally and tipped with raw umber or mummy-brown) to much darker, more sooty tone; ventral pelage uniformly gray plumbeous, washed with light brown, and

not countershaded with dorsal pelage. Mystacial vibrissae moderately long (ratio of longest mystacial vibrissae to length of head and body 0.44), and extend slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ear moderately long (15–19 mm), clove-brown in color. Tail distinctly longer than head and body (112–150%), slender, almost naked, almost uniformly clove-brown above and slightly lighter below, and with terminal white tip. Hind-foot moderately long (25–30 mm), narrow, and clove-brown above, and with distinct gap between thenar and hypothenar pads. Digit I of pes (hallux) moderate, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 24.7–28.1 mm) with relatively long and moderately narrow rostrum, rounded braincase, and nasals expanded anteriorly but tapering posteriorly. Interorbital region moderately broad, hourglass in shape, and with rounded margins. Zygomatic plates narrow with straight, vertical anterior margins; breadth shorter than length of M1. Zygomatic arches converge anteriorly. Incisive foramina oval, contracted anteriorly, and moderately long, reaching anterior margins of M1s or quite close to them. Mesopterygoid fossa broad, parallel sided, and usually without palatal medial process; roof either closed or with narrow, slit-like sphenopalatine vacuities present. Auditory bullae small and uninflated. Alisphenoid strut present. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen are present). Postglenoid foramen small. Lamina of malleus exhibits unusually well-developed cephalic peduncle and cephalic process. Upper molars moderately hypsodont, with no interpenetration. Upper incisors long and orthodont. Maxillary toothrow moderately long, 4.5–5.1 mm. M1 with anteromedian flexus either absent or indistinct, and anteroloph indistinct; M3 comparatively small; m1 with anteromedian flexid weak or absent; ectolophids absent in m1 and m2. Capsular process absent.

DISTRIBUTION: *Thomasomys silvestris* occurs in Ecuador in montane forest and páramo habitats from Bolívar province in the south to Napo and Pichincha provinces in the north, at elevations from 1,800 to 4,500 m.

SELECTION LOCALITIES (Map 363): ECUADOR: Bolívar, Carmen, near Sinche (AMNH 66886); Napo, Cerro Antisana, oriente (FMNH 43251); Pichincha, Cotopaxi, Atacazo (EPN 225), Guala, Ilambo Valley, 1,800 m (FMNH 94993), Hacienda Monjas, 4,500 m (EPN 190), Las Máquinas, Santo Domingo trail, W of Corazón (type locality of *Thomasomys silvestris* Anthony), San José, occidente (FMNH 53247), Volcán Pichincha, oriente (FMNH 92000), West Mindo, W Andes (USNM 304850), Zapadores, Río Saloya (USNM 513590).

SUBSPECIES: *Thomasomys silvestris* is monotypic.

NATURAL HISTORY: Anthony (1924a) stated that this species appeared to be an exclusive forest-dwelling form, not exploring the thickets of the páramo region. However, Tirira (2007) stated that the species occurred in subtropical, temperate, and adjacent páramo vegetation.

REMARKS: Cabrera (1961) relegated *silvestris* to a subspecies of *T. ischyryus*, although Anthony (1924a) explicitly distinguished these as separate species. Tirira (1999) accepted *T. silvestris* as a valid species following a personal communication from me, a position later supported by L. Luna and Pacheco (2002) and Voss (2003). L. Luna and Pacheco (2002) provided detail comparisons differentiating this species from *T. onkiro* and *T. caudivarius*. T. E. Lee et al. (2011) reported *T. silvestris* from Sangay National Park, in the provinces of Chimborazo and Morona Santiago, claiming they represented the southernmost record of the species. However, the Bolívar record is further south. The specimens collected by T. E. Lee et al. (2011) are also slightly larger than my measurements or those of Voss (2003) in hindfoot length (reaching to 34 versus 30 mm) and ear length (reaching to 25 versus 19 mm), suggesting that additional examination of their specimens is warranted.

Thomasomys silvestris exhibits little variation across its range. Voss (2003) stated that one specimen from Antisana (FMNH 43251), in the eastern Andes, was similar in qualitative characters to the type series collected on the western Andes, although he suggested that the specimen was collected on the western side of that volcano, as was true for specimens of *T. vulcani* from the same area (see that account). The dorsal pelage of specimens from Cotopaxi is

Map 363 Selected localities for *Thomasomys silvestris* (●). Contour line = 2,000 m.

brownish, resembling *T. caudivarius*, but the grayish ventral pelage and skull features correspond to *T. silvestris*.

Little is known on the phylogenetic relationships of *T. silvestris*. Anthony (1924a) compared the species with *T. cinereus*, *T. rhoadsi* (a synonym of *T. vulcani*; see that account), and *T. ischyryus*, and suggested that *T. silvestris* was more nearly related to *T. ischyryus*. A phylogenetic assessment based on morphological characters places *T. silvestris* more related to *T. caudivarius*, both members of the “cinereus” group (Pacheco 2003). This result, however, is not supported by a molecular phylogeny based on mtDNA cytochrome-*b*, where *T. silvestris* was found related to *T. taczanowskii* (reported as *T. ischyryus*, see both species accounts), a member of the “baeops” group, despite the extensive morphological differences between them. Additional studies are necessary to resolve this discrepancy.

Thomasomys taczanowskii (Thomas, 1882)

Taczanowski's Thomasomys

SYNONYMS:

Hesperomys (Rhipidomys) taczanowskii Thomas, 1882:109; type locality “Tambillo, [Río Malleta,] 5800' [1,768 m,]” Cajamarca, Peru.

Hesperomys (Vesperimus) taczanowskii: Thomas, 1884:449; name combination.

Hesperomys (Thomasomys) taczanowskii: Coues, 1884:1275; name combination.

Thomasomys taczanowskii: Gyldenstolpe, 1932a:56; first use of current name combination.

DESCRIPTION: Medium sized (head and body length 97–120 mm; condyloincisive length 25.1–27.7 mm) with soft and woolly fur of medium length. Dorsal color grayish yellow with hairs tipped rufous yellow; head grayer and less yellow. Ventral pelage grayish white, moderately countershaded. Mystacial vibrissae very long, extending far behind ears when bent; genal 1 vibrissae present. Tail moderately long (98–132% of head and body length), unicolored pale brown, and with terminal white tip usually present. Hindfoot relatively short (24–28 mm). Digit 1 of pes (hallux) long and dV very long, as in *T. baeops*. Skull with short and delicate rostrum; short nasals; frontonasal profile quite flat, not convex; and braincase moderately inflated. Interorbital region narrow with faintly marked (not rounded nor beaded) edges, but slightly broader than *T. baeops*. Zygomatic arches narrow and converging anteriorly. Incisive foramina narrow and long, extending backward between anterior borders of M1s. Auditory bullae small but comparatively more inflated than in *T. baeops*. Carotid circulatory pattern derived (stapedial foramen small, no internal squamosal-alisphenoid groove, no sphenofrontal foramen). Upper incisors opisthodont. Maxillary toothrow short, 4.1–4.6 mm. Capsular process distinct.

DISTRIBUTION: *Thomasomys taczanowskii* occurs in montane forests in the Andes of Ecuador and northern Peru, at elevations between approximately 1,150 and 3,350 m.

SELECTED LOCALITIES (Map 364): ECUADOR: Azuay, Girón (FMNH 53242); Carchi, Montufar, Atal (UMMZ 77160); El Oro (above) Salvias, Cordillera de Chilla (AMNH 47671); Loja, Celica (AMNH 47672). PERU: Cajamarca, 35 mi WNW of Cajamarca (MVZ 137928), Las Juntas, 3 km W of Pachapiriana (AMNH 268147), San Ignacio, Tabaconas, Piedra Cueva in Cerro Coyona, Tabaconas-Namballe National Sanctuary (UMMZ 176751), Tambillo, Río Malleta (type locality of *Hesperomys (Rhipidomys) taczanowskii* Thomas); Lambayeque, Seques (AMNH 73124), Uyurpampa (MUSM 21800); Piura, Huancabamba, Canchaque (FMNH 81313), Laguna (USNM 304539), Paríamarca Alto (MUSM 23782), 2 km W of Porculla Pass (MVZ 137942), Portachuelo (MUSM 21741), Quebrada El Gallo, Campamento Bomba Quemada 1 (MUSM 23592); San Martín, Mariscal Cáceres Huicungo, P.N. Río Abiseo, La Playa (MUSM 7983).

SUBSPECIES: I consider *T. taczanowskii* to be monotypic (but see Remarks).

NATURAL HISTORY: Little is known about the ecology, population biology, or other natural history aspects of this species. Individuals have been captured in tall shrub mixed with short and slender trees in upper montane forests at Las Ashitas, Cajamarca (V. Pacheco, pers. obs.). In Paríamarca Alto, the species was taken in Queñua Andean forests (*Polylepis weberbaueri*), among small trees (about 5 m high), densely covered by mosses and lichens, and the ground by short grasses browsed by cattle (V. Pacheco, pers. obs.). Specimens taken at Cerro Chinguela and Quebrada El Gallo, in Piura (about 3,000 m elevation) came from pristine upper montane forest with trees reaching heights of 10 to 25 m high, and with numerous species of shrubs, epiphytes, tree ferns, vines, and epiphytes present (V. Pacheco, pers. obs.), and in montane secondary forests and montane bamboo forests near a stream in Montesecco, Cajamarca (L. Luna, pers. comm.). My brief observations in the field suggest that individuals are excellent and agile climbers. Schramm and Lewis (1987) described a new species of flea, *Plocopsylla kilya*, as from Peruvian specimens of *T. taczanowskii*.

REMARKS: *Thomasomys taczanowskii* has been confused with *T. oreas* in the literature. This includes A. L. Gardner (1976:13) report of *T. taczanowskii* from Yuracacu, Ayacucho, based on two specimens (LSUMZ 16735, 16736), and the karyotype of these specimens reported by A. L. Gardner and Patton (1976). Pacheco (2003) re-identified these specimens as *Thomasomys* sp. 8, an undescribed species allied to *T. oreas* (see *T. oreas* account). Thomas (1920h:236) provisionally identified a specimen

(USNM 194876) from the Occobamba Valley, Cusco, as *T. taczanowskii*, but Pacheco (2003) corrected this assignment as well to *Thomasomys* sp. 9, another undescribed form allied also to *T. oreas* (see that account). S. Anderson (1993:37) recorded *T. taczanowskii* from El Choro, Cochabamba, Bolivia, based on one specimen (FMNH 74866), which also has been tentatively reidentified as *T. oreas* (V. Pacheco, unpubl. obs.; see the account of that species).

A phylogenetic analysis of discrete morphological characters for *Thomasomys* recovered *T. taczanowskii* as most closely related to *T. baeops* (Pacheco 2003), a hypothesis corroborated by mtDNA cytochrome-*b* sequences (Salazar-Bravo and Yates 2007). As mentioned earlier (see *T. baeops* account), the GenBank sequence AF 108675 (MVZ 181999) corresponds to *T. taczanowskii* and not to *T. ischyryus* (see Pacheco 2003).

Two specimens from Carchi, Ecuador, representing the northernmost record of *T. taczanowskii*, are unfortunately both fragmented and juveniles (age class 1, *sensu* Voss 1991a). Cranial and external characteristics of these specimens agree with the typical representatives of the

species, but a revision based on a larger series is required to confirm this hypothesis. A single specimen from Río Abiseo, San Martín, tentatively determined as *T. taczanowskii*, represents the southernmost record of the species, although several features (including absent genal 1 vibrissae, longer nasals, narrow zygomatic plates, and large ethmoturbinals) suggest it might represent an undescribed taxon.

Thomasomys ucucha Voss, 2003

Ucucha Thomasomys

SYNONYM:

Thomasomys ucucha Voss, 2003:10; type locality “11,100 ft (3384 m) in the valley of the Río Papallacta (ca. 3–5 km by trail NNW Papallacta), Provincia Napo, Ecuador.”

DESCRIPTION: Medium sized (head and body length, 94–119 mm) with dense, fine, and soft fur. Dorsal coloration near brownish olive along flanks, shading to dark grayish brown middorsally. Ventral color dark neutral gray basally, with superficial wash of light neutral gray or glaucous, not sharply contrasting with dorsal coloration. Mystacial vibrissae moderately long, extending just behind pinnae when laid back alongside head; genal 1 vibrissae absent. Ears small (17–20 mm) and sparsely covered with short, blackish hairs, not contrasting conspicuously with color of the head. Tail long (122–151 mm), and substantially longer than combined length of head and body (122–125%). Hindfoot of moderate size (26–30 mm) and neither very narrow nor conspicuously broad, without gap between thenar and hypothenar pads. Digit I of pes (hallux) moderately long, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 25.8–29.1 mm) with relatively short and blunt rostrum, and straight frontonasal profile. Interorbital region narrow with rounded supraorbital margins. Zygomatic arches rounded and flare widely. Zygomatic plates moderately broad (subequal to length of M1) and vertically oriented. Incisive foramina widest just behind premaxillo-maxillary suture and short, not approaching M1 anterocones. Mesopterygoid fossa broad and straight sided; bony roof complete or perforated by narrow, slit-like sphenopalatine openings flanking presphenoid-basisphenoid suture. Alisphenoid strut present, separating buccinator-masticatory from accessory oval foramina. Posterior opening of alisphenoid canal comparatively reduced. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen present). Auditory bullae small and uninflated. Upper incisors large, broad, and conspicuously procumbent. Maxillary tooththrow relatively short (4.2–4.6 mm), primar-

Map 364 Selected localities for *Thomasomys taczanowskii* (●). Contour line = 2,000 m.

ily due to conspicuously smaller M3. Molars hypsodont and lack well-developed cingula and styler cusps. In upper molars, anterolophos and mesolophos of M1 and M2 comparatively less developed, and M3 usually lacks distinct hypoflexus. In M1, anteromedian flexus distinct. The m1 anteromedian flexid indistinct and ectolophids absent. Mandible with distinct capsular process and short angular process relative to condylar process. Stomach unilocular-hemiglandular (Carleton 1973); gall bladder present; macroscopic preputial glands absent.

DISTRIBUTION: *Thomasomys ucucha* is known only from the crest of the Cordillera Oriental (between ca. 3,380 and 3,800m) just south of the equator in the Ecuadorean provinces of Carchi, Pichincha, and Napo (Voss 2003; Arcos et al. 2007).

SELECTED LOCALITIES (Map 365): ECUADOR: Carchi, Los Encinos (Arcos et al. 2007), Potrerillos, Ipuerán (Arcos et al. 2007); Napo, Río Papallacta valley (type locality of *Thomasomys ucucha* Voss); Pichincha, Tablón, road to Papallacta (AMNH 46621).

SUBSPECIES: *Thomasomys ucucha* is monotypic.

NATURAL HISTORY: This species has been taken in grassy páramo, in the shrubby páramo/forest ecotone, in grassy glades surrounded by forest, and deep inside subalpine rainforest. Most recorded captures were on the ground, along rabbit trails or runways through dense grass or low herbs, in runways through moss or damp litter, under mossy debris, at the bases of mossy trees, or along the wet margins of small streams. The species is sympatric and syntopic (in the same habitats) with *Akodon mollis*, *Anotomys leander*, *Chilomys instans*, *Microrizomys altissimus*, *M. minutus*, *Neusticomys monticolus*, *Neomicroxus latebricola*, *T. aureus*, *T. baeops*, *T. cinnameus*, *T. erro*, and *T. paramorum* (Voss 2003).

REMARKS: Records of this species include those of *Thomasomys* sp., as reported by Voss (1988:Table 43) in a previous list of Papallacta mammals, and *Thomasomys* sp. 11 in Pacheco (2003). A phylogenetic assessment based on morphological characters finds *T. ucucha* in a cluster with other species of the “cinereus” group, specifically related to *T. cinnameus*, although with weak support (Pacheco 2003). Voss (2003) contrasted *T. ucucha* principally with *T. hylophilus*, another member of the “cinereus” group.

Arcos et al. (2007) reported additional specimens of *Thomasomys ucucha* from Carchi province in northern Ecuador, close to the Colombian border. They reported a hindfoot length of 17.3 mm for one specimen (MECN 5918), which is shorter than the range (26 to 30 mm) given by Voss (2003). The correct measurement of this specimen is, however, 27.5 mm (L. Albuja, pers. comm.). This species is then very likely present in Colombia.

Map 365 Selected localities for *Thomasomys ucucha* (●). Contour line = 2,000 m.

Thomasomys vestitus (Thomas, 1898)

Mérida Thomasomys

SYNONYMS:

Oryzomys vestitus Thomas, 1898e:454; type locality “Río Milla [= Río Milla], Merida [= Mérida], 1630 m,” Venezuela.

Thomasomys vestitus: Thomas, 1906c:443; first use of current name combination.

DESCRIPTION: Large size (head and body length 138–141 mm) with long, soft, and woolly dorsal fur, long tail (138–141 mm, 120% of head and body length), and medium sized ears (17–21 mm). Dorsal pelage colored grizzled fuscous gray, more rufous posteriorly, with grayish head. Under parts uniformly grayish, washed with dull buff; not countershaded relative to the dorsum. Ears thinly haired and pale brown. Hands dull whitish above. Tail monocolored pale brown, and comparatively well haired; terminal white tip absent. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Hindfoot of medium length (33–33.3 mm) and dull whitish above. Digit I of pes (hallux) moderately long, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull large (condyloincisive length 32.5–33.9 mm), broad and depressed in cranial region; braincase large and oblong; rostrum comparatively short and narrow; and frontonasal profile straight. Nasals short, narrow, and taper posteriorly. Zygomatic plates vertical and moderately broad, subequal

to length of M1. Incisive foramina moderate length, relatively narrow, and unusually separated by broad maxillary septum; they extend to anterior margins of M1s, distance equal to length of M1 anterocone. Interorbital region narrow (molar-bearing maxilla rectangular in shape and visible from dorsal view), hourglass in shape, with rounded or faintly squared margins. Mesopterygoid fossa broad, with lateral margins posteriorly convergent; roof closed. Zygomatic arches converge anteriorly. Auditory bullae small and flask shaped, bony tubes short and broad, and stapedia spine small. Postglenoid foramen small, and the subsquamosal fenestra slightly larger and rounded. Alisphenoid strut that separates buccinator-masticatory and accessory oval foramina present. Ethmoturbinals of moderate size. Posterior opening of alisphenoid canal comparatively reduced. Carotid circulatory pattern primitive (stapedial foramen, squamosal alisphenoid groove, and sphenofrontal foramen present). Upper incisors orthodont, long, broad, and robust. Maxillary toothrow length moderate, 5.5–6.6 mm. Molars relatively hypsodont but lack well-developed cingula and styler cusps. In M1, anteromedian flexus indistinct, but anteroloph and anteroflexus distinct; hypoflexus unusually wide. M2 with distinct protoflexus, and M3 with distinct hypoflexus. Anteromedian flexid in m1 present although weak. Condylar and angular processes subequal, and capsular process absent.

DISTRIBUTION: *Thomasomys vestitus* is known only from the Mérida Andes in western Venezuela, at elevations between 1,600 and 2,500 m.

SELECTED LOCALITIES (Map 366): VENEZUELA: Mérida, El Baho, 5 km SW of Santo Domingo (CVULA 2537), Río Milla (type locality of *Oryzomys vestitus* Thomas); Trujillo, Hacienda Misisi, 15 km E of Trujillo (USNM 374544).

SUBSPECIES: *Thomasomys vestitus* is monotypic.

NATURAL HISTORY: These are nocturnal, terrestrial to arboreal, solitary, and omnivorous mice (O. J. Linares 1998). As with other *Thomasomys*, *T. vestitus* is associated with moist habitats and cloud forest habitats (Eisenberg and Redford 1999). Handley (1976) reported one specimen trapped under a mossy log on damp ground and another on a log over a small stream, both in cloud forest (the Lower Montane very humid forest in the Vegetative Life Zone system of Ewel and Madriz 1968). Individuals feed on small fruits, plant material, and insects (O. J. Linares 1998). J. T. Reed and Brennan (1975) described the chiggers *Odontacarus schoenesetosus* and *O. tiptoni* as new species, with *T. vestitus* as the type host. Tipton and Machado-Allison (1972) reported the fleas *Neotyphloceras rosenbergi* (Rothschild) and *Cleopsylla monticola* Smit.

Map 366 Selected localities for *Thomasomys vestitus* (●). Contour line = 2,000 m.

REMARKS: Aguilera et al. (2000) described a karyotype with $2n=44$, $FN=42$, including acrocentric X and Y chromosomes, a complement noted for its general conformity to the hypothesized primitive condition for the genus.

Almost nothing is known on the phylogenetic relationships of *T. vestitus*. My phylogenetic assessment based on morphological characters (Pacheco 2003) placed *T. vestitus* as related to a cluster of species of the “cinereus” group, which included forms allied to *T. cinereiventer* and *T. vulcani*.

Thomasomys vulcani (Thomas, 1898)

Pichincha Thomasomys

SYNONYMS:

Aepeomys vulcani Thomas, 1898e:452; type locality “Mount [Volcán] Pichincha, [Pichincha,] Ecuador, at about 12,000 feet [= 3,658 m].”

Thomasomys rhoadsi Stone, 1914:12; type locality “Hacienda Garzon, Mt. [Volcán] Pichincha, 10,500 feet,” Pichincha, Ecuador.

Thomasomys rhoadsi rhoadsi: Gyldenstolpe, 1932a:54; name combination.

Thomasomys vulcani: Ellerman, 1941:369; first use of current name combination.

Thomasomys lugens vulcani: Cabrera, 1961:432; name combination.

Aepeomys lugens: Musser and Carleton, 1993:688, part; not *lugens* Thomas.

DESCRIPTION: Medium sized (adult head and body length 118–153 mm) with long, soft, and woolly dorsal fur. Underfur about 12 mm long, guard hairs about 15 mm in length. Dorsal color dark buffy gray, slightly darker along top of loins, providing overall very dark appearance, nearly black on back. Ventral pelage moderately counter-shaded, hairs slate-colored at their bases with tips buffy. Ventral base of manual claws keeled. Mystacial vibrissae moderately long, extending slightly beyond posterior margin of pinnae when bent; genal 1 vibrissae absent. Ears short (18–25 mm) and well haired. Tail comparatively short (78–101% of head and body length), fine scaled, clothed in short hairs, and uniformly brown. Hindfoot moderately long (27–31.5 mm), with metatarsals light brown above, darker mesially; sides and digits whitish; gap present between thenar and hypothenar pads. Digit I of pes (hallux) moderately long, with claw not extending more than about half length of phalanx 1 of dII. Digit V of pes long, with claw extending about half length of phalanx 2 of dIV. Skull moderately long (condyloincisive length 28.8–31.1 mm), with relatively long and broad rostrum but no rostral tube. Nasals expanded anteriorly, taper posteriorly, with posterior margins extending posteriorly beyond premaxillae. Premaxillomaxillary-frontal joint placed anterior to zygomatic notches. Interorbital region moderately broad, hourglass in shape, and with rounded margins. Ethmoturbinals large. Zygomatic plates moderately broad, subequal to length of M1, and vertical or only very slightly sloped backward from bottom to top. Zygomatic arches converge very slightly anteriorly. Incisive foramina large, open, and rhomboid-shaped, with anterior half more contracted, and long, extending to anterior margins of M1s or close. Mesopterygoid fossa broad, wider anteriorly, converging posteriorly, lacks palatal medial process, but with closed roof. Optic foramen small and posterodorsal to M3. Alisphenoid strut present. Auditory bullae small and uninflated. Carotid circulatory pattern primitive (stapedial foramen, groove on inner surface of squamosal and alisphenoid, and sphenofrontal foramen present). Upper incisors orthodont. Maxillary tooththrow moderately long, ranging from 5.1 to 5.6 mm, and upper molars moderately hypsodont, with no interpenetration of flexi. M1 with distinct anteromedian flexus and lacks accessory labial root; anteromedian flexid of m1 shallow. Capsular process absent.

DISTRIBUTION: *Thomasomys vulcani* occurs only in páramo and montane forests of the north-central Andes of Ecuador, in Napo and Pichincha provinces, from 1,400 to 4,500 m.

SELECTED LOCALITIES (Map 367): ECUADOR: Napo, Cerro Antisana, oriente (FMNH 43246); Pichincha,

Gualea, Ilambo Valley (FMNH 94992), Hacienda Monjas (EPN 323), Huila North, oriente (FMNH 53406), E side of Mt. Pichincha (MVZ 137610), Mount Pichincha (type locality of *Aepeomys vulcani* Thomas), Pinantura (AMNH 46718), 15 mi S of Quito (AMNH 213548), San José, occidente (FMNH 53210).

SUBSPECIES: I treat *T. vulcani* as monotypic.

NATURAL HISTORY: This species is terrestrial and lives in páramo and both subtropical and temperate forest (I. Castro and Román 2000; Tirira 2007). Specimens have been taken on rocky wooded slopes, where they have burrows from 1 to 3 inches below the surface of the soil and debris (Stone 1914). Pozo-R. et al. (2006) captured individuals in disturbed plant fences that separate cattle ranches, although in lower abundance than in undisturbed forests.

REMARKS: *Thomasomys vulcani* was described as a species of *Aepeomys* and thereafter classified as a subspecies or synonym of *lugens* Thomas, whether this taxon was treated as an *Aepeomys* (Musser and Carleton 1993) or *Thomasomys* (Cabrera 1961). However, Pacheco (in Voss et al. 2002) considered *vulcani* to be a form of *Thomasomys* proper based on his own examination of type material. I elaborate on this view here.

The type specimen of *vulcani* (BM 98.5.1.10) is a female specimen, consisting of a skin in good condition but badly damaged skull. In dorsal view, the occipital and parietal bones are squashed, and zygomatic arches are broken and incomplete. In ventral view, the anterior half of the skull is somewhat complete, with the rostrum and the first molars practically complete; however, the entire posterior part of the skull is destroyed except for the right bulla, which is still in place. To complicate the determination, the type specimen is a juvenile, considered TWC 1 of Voss (1991a) because the m3 is essentially unworn (M3 is lost). Nonetheless, and in spite of the incomplete material, several attributes of the type specimen of *vulcani* are not typical of *Aepeomys* but are of *Thomasomys* (see also *Aepeomys* account, this volume). These include the short tail (although apparently incomplete), lack of a rostral tube, nondeveloped masseteric tubercle, large incisive foramina that extend to the level M1, and paraflexus and metaflexus not oriented anteroposteriorly along the midline of M1–M2.

Based on my own examination of the type specimen of *vulcani* Thomas, paratypes of *rhoadsi* Stone, and available specimens from Pichincha, Ecuador, I hypothesize that *rhoadsi* is a junior synonym of *T. vulcani*. In spite of the incompleteness of the type skull of *T. vulcani*, several attributes can be observed that match those of Stone's *rhoadsi*. These include (1) the nasals, which are both expanded anteriorly and posteriorly are longer than premaxillae; (2) the premaxillomaxillary-frontal joint placed anterior

to the zygomatic notch; (3) the moderately broad interorbital region with rounded margins; (4) the open, large, and rhomboid-shaped incisive foramina that extend posteriorly to be level to the anterior plane of M1; (5) the moderately broad and slightly sloped zygomatic plates; (6) the primitive circulatory pattern 1 of Voss (1998); (7) the well-developed anteroloph and mesoloph of M1 with a weak cingulum; (8) the large and rounded orbicular apophysis; and (9) the malleus lamina with a well-differentiated cephalic process. Some of these morphologies are observable in photos of an additional specimen from Mount Pichincha (BM 98.8.1.10; illustrated by Gyldenstolpe 1932: plate III, Figs. 2, 2a, 2b), which agree with the type specimen. Mensural comparisons between *vulcani* and *rhoadsi* are not very appropriate in this case because of the incomplete specimen and the juvenile condition of the type. Nonetheless, 10 measurements obtained from the holotype of *vulcani* are each smaller than a series of *rhoadsi* (10 adult AMNH specimens from Pichincha), except for nasal breadth (3.65 mm versus an average of 3.66 mm), M1 breadth (1.6 mm versus an average of 1.56 mm), and zygomatic plate breadth (1.9 mm versus an average of 2.35 mm, range: 2.16 mm to 2.49 mm), for which both taxa are quite similar. In addition, the holotype skin of *vulcani* has long and soft hair, a short tail (although apparently incomplete), and is similar in color to specimens of *rhoadsi*. Based on this evidence, I regard *rhoadsi* Stone as a synonym of *T. vulcani*.

Voss (2003) compared specimens from Volcán Antisana that included a series collected by R. Olalla in 1934 from “Cerro Antisana, Andes Orientales” and another collected by C. S. Webb in 1937 from “Mt. Antisana, E. Andes 12,500–13,000 ft” with topotypes of *T. rhoadsi*. Despite slightly larger averages of several external and craniodental dimensions, Voss concluded these samples represented the same taxon. He also remarked that these Antisana specimens were likely collected on the western side of Antisana. The specimens of *T. vulcani* reported herein from Antisana are from the eastern slopes of the mountain. Pozo-R. et al. (2006) reported *Thomasomys* cf. *vulcani* (as *T. cf. rhoadsi*) from Hacienda El Prado, Parroquia San Fernando, Cantón Rumiñahui, Provincia de Pichincha (78°24'44"W, 0°23'20"N), arguing that they were smaller than the topotypes examined by Voss (2003). A morphometric analysis is needed to assess intraspecific variability.

Stone (1914) thought that *T. vulcani* was apparently allied to *T. cinereus*. Pacheco's (2003) phylogenetic assessment based on morphological characters suggested that *T. vulcani* (reported as *T. rhoadsi*) was related to *T. fumeus* and *Thomasomys* sp. 10, both members of his “cinereus” group. *Thomasomys* sp. 10 is an undescribed species collected from the montane forests of Piura and Cajamarca, Peru (Pacheco 2003).

Map 367 Selected localities for *Thomasomys vulcani* (●). Contour line = 2,000 m.

The proposal that *T. vulcani* should be regarded by the IUCN as Critically Endangered (Moreno-Cárdenas and Tirira 2011) needs to be revised because the authors considered *T. vulcani* and *T. rhoadsi* as separate species.

Tribe Wiedomyini Reig, 1980 *Cibele R. Bonvicino*

Reig (1980) erected the tribe Wiedomyini to include the fossil genus *Cholomys* Reig (from eastern Argentina) and the Recent genus *Wiedomys* Hershkovitz (from northeastern Brazil). The phylogenetic position of the tribe is problematic. Historically (see review by Osgood [1933b]), *Wiedomys* has been variously classified as an *Oryzomys* (Thomas 1886b, 1928a; Gyldenstolpe 1932; Moojen 1943a), *Rhipidomys* (Thomas 1882, 1884; Tate 1932g; Osgood 1933b), *Oecomys* (Osgood 1933b), or *Thomasomys* (Moojen 1952b). Moreover, phallic similarities (Langguth and Silva Neto 1993) suggested a linkage with the phyllotines, but primitive karyological traits (Maia and Langguth 1987) and craniodental attributes (Reig 1980; Steppan 1995) suggested that *Wiedomys* was an early offshoot of the South American sigmodontine radiation, possibly derived from a basal thomomyine grade. Weksler's (2006) cladistic analysis of morphological traits placed *Wiedomys* as basal to the oryzomyines. Early phylogenetic analyses of DNA sequences linked the genus either to the abrotichines (mtDNA sequences; M. F. Smith and Patton 1999) or to the oryzomy-

ines (nucDNA; D'Elia 2003; Weksler 2003, 2006). More recent taxon-dense analyses utilizing a larger number of genes and state-of-the-art analytical methods confirmed a sister relationship between *Wiedomys* and the abrotrichine genera (Parada et al. 2013; Schenk et al. 2013). While M. F. Smith and Patton (1999) suggested that *Wiedomys* was one of the most ancient lineages of the Sigmodontinae, placing the basal divergence between 14 and 10 mya, Parada et al. (2013) and Schenk et al. (2013) estimated a more realistic divergence time of 7 to 5 mya.

Genus *Wiedomys* Hershkovitz, 1959

Wiedomys, restricted to the semiarid zone of northeastern Brazil, is the only extant representative of the tribe Wiedomyini (Reig 1980; J. A. Oliveira et al. 2003). Three species are currently recognized, including the fossil *W. marplatensis* from the late Pliocene (Sanandresian) of Argentina (C. A. Quintana 2002) and two extant: *W. pyrrhorhinus* (Wied-Neuwied) and the recently recognized *W. cerradensis* P. R. Gonçalves, Almeida, and Bonvicino.

Externally, *Wiedomys* is characterized by a conspicuous coloration, with an overall grizzled-brown dorsal pelage but with the rump, ears, and muzzle bright orange. The sides of the body are slightly grayer than the dorsum, and the ventral pelage is well delineated with entirely white hairs extending from the gular to the inguinal region, including the ventral region of forelimbs and medial region of the hind limbs. The eyes are surrounded by a conspicuous orange eye-ring due to the presence of short orange hairs. The muzzle is well furred by small orange hairs. The feet, furred dorsally by entirely orange hairs, possess silvery ungual tufts. The tail, entirely dark brown with its proximal ventral surface slightly paler, is larger than the combined head and body length. Adult females possess eight mammae: two pectoral, two thoracic, two abdominal, and two inguinal.

The skull has a relatively short rostrum, laterally expanded braincase, and sharply defined supraorbital edges but lacks distinct supraorbital crests. The interparietal is broad and wide, and does not contact the squamosal laterally. The zygomatic plates are narrow, do not project anteriorly, and have moderately deep and broad zygomatic notches. The incisive foramina are long, extending posteriorly to the protoflexi of the M1s. The palate is short, not extending posteriorly beyond the hypoflexi of the M3s. The mesopterygoid fossa is narrow and U-shaped. The sphenopalatine vacuities are present and well developed. An alisphenoid strut may be present or absent. Parapterygoid fossae are shallow but large. The ectotympanic portion of the auditory bullae is notably inflated and with a globular shape on the ventral surface. The mandible has a

small coronoid process delimiting a small sigmoid notch. The condylar process is well developed, extends posterodorsally to the level of the angular process, and possesses a deep angular notch.

The upper incisors are opisthodont with rounded, yellow enameled bands on the anterior face. The molars are brachydont and crested with alternating cusps. The antero-medial flexus of M1 is well defined, unequally dividing the anterocone in a small anterolingual conule and larger anterolabial conule. The mesoloph is distinct in M1 and M2. The procingulum of m1 is narrower than the breadth of the m2, and the anteroconid of m1 is equally divided by the antero-medial flexid, but the mesolophid is absent.

The phallus of *Wiedomys* is similar to that of some phyllotines and different from those of oryzomyines. The medial bacular mound is longer than the lateral mounds; a small dorsal papilla is present; the urethral flap is divided into two lobes; the base of baculum is convex with a triangular shape; and the cartilage of the lateral digits is thinner and shorter than the medial (Langguth and Silva Neto 1993).

The chromosome complement of this genus varies considerably, with diploid numbers ranging from 60 to 62 and autosome fundamental numbers ranging from 86 to 104 (Maia and Langguth 1987; P. R. Gonçalves, Almeida, and Bonvicino 2005; A. L. G. Souza, Corrêa et al. 2011).

SYNONYMS:

Mus: Wied-Neuwied, 1821:177; part (description of *pyrrhorhinus*); not *Mus* Linnaeus.

Hesperomys (*Rhipidomys*): Thomas, 1882:107; part (allocation of *pyrrhorhinus* [sic]; neither *Hesperomys* Waterhouse nor *Rhipidomys* Tschudi.

[*Hesperomys*] (*Oryzomys*): Thomas, 1886b:422; part (allocation of *pyrrhorhinus* [sic]); neither *Hesperomys* Waterhouse nor *Oryzomys* Baird.

Oryzomys pyrrhorhinus: Thomas, 1928b:154; name combination.

Wiedomys Hershkovitz, 1959a:5; type species *Mus pyrrhorhinus* Wied-Neuwied, by original designation.

REMARKS: The generic placement of *Mus pyrrhorhinus* has been plagued with uncertainty since the taxon was originally described. As noted by Osgood (1933b), Thomas (1882, 1884) initially referred *Mus pyrrhorhinus* [sic] to *Rhipidomys*, previous authors having placed it in the very inclusive *Hesperomys*. Two years later, however, Thomas (1886b:422) erroneously stated that it was a member of the subgenus *Oryzomys*, based on specimens he thought were of this species but were actually those of *Thomasomys* [= *Wilfredomys*] *oenax*. Subsequently, Thomas (1928a), with actual specimens of *pyrrhorhinus* in hand, placed it in *Oryzomys*, which had been elevated to generic rank in 1890 by Elliot Coues. This placement

was continued until Moojen (1952b) regarded *pyrrhorhinos* a species of *Thomasomys*. Hershkovitz (1959a) finally recognized the generic distinction of this species, listing it as the type (and only known) species of his newly erected *Wiedomys*.

KEY TO THE SPECIES OF *WIEDOMYS*:

1. Maxillary tooththrow short (<4.4 mm); incisive foramina narrow (<1.8 mm); alisphenoid strut present in majority of specimens *Wiedomys cerradensis*
- 1'. Maxillary tooththrow long (>4.6 mm, on average); incisive foramina broad (>2.22 mm, on average); alisphenoid strut absent in majority of specimens *Wiedomys pyrrhorhinos*

Wiedomys cerradensis P. R. Gonçalves, Almeida, and Bonvicino, 2005

Cerrado *Wiedomys*, Rato-de-Focinho-Vermelho

SYNONYM:

Wiedomys cerradensis P. R. Gonçalves, Almeida, and Bonvicino, 2005:51; type locality “Fazenda Sertão do Formoso (14°37'888"S and 45°51'293"W), Jaborandi, state of Bahia,” Brazil.

DESCRIPTION: Small mouse (head and body length 107 mm) with long tail (tail length 142 mm) and pelage color of muzzle, ears, eye-ring, and rump bright orange. Skull small, like that of *W. pyrrhorhinos*, but with narrow incisive foramina (<1.8 mm), short maxillary tooththrow (<4.35 mm), and buccinator-masticatory and accessory oval foramina separated by distinct alisphenoid strut; otherwise, nearly identical to *W. pyrrhorhinos*.

DISTRIBUTION: *Wiedomys cerradensis* is endemic to Brazil, ranging from southeastern Bahia to Goiás, Tocantins, and Ceará states.

SELECTED LOCALITIES (Map 368): BRAZIL: Bahia, Fazenda Sertão do Formoso Jaborandi (type locality of *Wiedomys cerradensis* P. R. Gonçalves, Almeida, and Bonvicino); Goiás, São Domingo, Fazenda Cruzeiro do Sul (UNB 2593, Bezerra et al. 2013); Tocantins, Paranã, Fazenda São João (UNB 2594, Bezerra et al. 2013); Ceará, Jaguaruana (LBCE 5205).

SUBSPECIES: *Wiedomys cerradensis* is monotypic.

NATURAL HISTORY: Specimens of *W. cerradensis* have been collected in semideciduous forest (P. R. Gonçalves, Almeida, and Bonvicino 2005), cerrado *sensu stricto* (N. F. Camargo et al. 2012), and in seasonally dry tropical forest and gallery forest (Bezerra et al. 2013). Individuals were active during the night but also early in the morning; one young specimen was observed foraging on the ground after sunrise.

REMARKS: *Wiedomys cerradensis* differs from *W. pyrrhorhinos* in karyotype, smaller cranial and body di-

Map 368 Selected localities for *Wiedomys cerradensis* (○) and *Wiedomys pyrrhorhinos* (●).

mensions, presence of an alisphenoid strut separating the buccinator-masticatory foramen from the accessory oval foramen in the majority of specimens (see Bezerra et al. 2013), and deeply divergent and reciprocally monophyletic mtDNA sequences (P. R. Gonçalves, Almeida, and Bonvicino 2005). Both species display the same color pattern, with rump, ears, and eye-ring bright orange and strongly contrasting with the grizzled-brown color of the head and flanks. The karyotype of topotypes of *Wiedomys cerradensis* is $2n=60$, $FN=88$. The specimen used by Weksler (2003, 2006) in his phylogenetic analyses of DNA sequences, which he referred to *W. pyrrhorhinos*, is instead *W. cerradensis*.

Wiedomys pyrrhorhinos (Wied-Neuwied, 1821)

Red-nosed *Wiedomys*, Rato-de-palmatória

SYNONYMS:

Mus pyrrhorhinos Wied-Neuwied, 1821:177; type locality “Riacho da Ressaque [= Ressaça; see Moojen 1952b],” a small tributary of the Rio Gavião (which flows into the Rio Contas), Bahia, Brazil (Hershkovitz 1959a:6).

Mus pyrrhorhinos Wied-Neuwied, 1823:plate 2; unjustified Latinization of *Mus pyrrhorhinos* Wied-Neuwied.

Hesperomys pyrrhorhinus: Burmeister, 1854:172; name combination and unjustified Latinization of *Mus pyrrhorhinos* Wied-Neuwied.

Hesperomys [*Rhipidomys*] *pyrrhorhinus*: Thomas, 1882: 107; name combination and unjustified Latinization of *Mus pyrrhorhinos* Wied-Neuwied.

H[*esperomys*]. (*Rhipidomys*) *pyrrhorhinus*: Thomas, 1884: 448; name combination and unjustified Latinization of *Mus pyrrhorhinos* Wied-Neuwied.

Oryzomys pyrrhorhinus: Thomas, 1886b:422; name combination (misidentified specimens of *Wilfredomys oenax*); unjustified Latinization of *Mus pyrrhorhinos* Wied-Neuwied

Orizomys [*sic*] *pyrrhorhinus*: Moojen, 1943a:11; name combination and unjustified Latinization of *Mus pyrrhorhinos* Wied-Neuwied.

Thomasomys pyrrhorhinos: Moojen, 1952b:61; name combination.

Wiedomys pyrrhorhinos Hershkovitz, 1959a:5; first use of current name combination.

DESCRIPTION: As for genus, except that *W. pyrrhorhinos* has longer maxillary toothrow (mean=4.75 mm, range: 4.62–4.90 mm) and broader incisive foramina (mean 2.22 mm, range: 2.02–2.45 mm); majority of specimens lack alisphenoid strut.

DISTRIBUTION: *Wiedomys pyrrhorhinos* is endemic to the Brazilian Caatinga, occurring in the states of Ceará, Paraíba, Pernambuco, Alagoas, Sergipe, Bahia, and Minas Gerais.

SELECTED LOCALITIES (Map 368): BRAZIL: Alagoas, Quebrângulo (MNRJ 18549); Bahia, Caetité (MNRJ 63357), Curaça (MNRJ [LBCE 5202]), Fazenda Salinas, Morro do Chapéu (MNRJ 71607), Feira de Santana (MNRJ 18715), Ibipeba (UNB 1379), Tremendal, Rio Riacho da Ressaca (type locality of *Mus pyrrhorhinos* Wied-Neuwied); Minas Gerais, Juramento (UFRJ [FC 50]); Paraíba, Pombal (UFPB 243), Salgado São Felix (UFPB 254); Pernambuco, Bom Conselho (Maia and Langguth 1987); Sergipe, Canindé do São Francisco (A. L. G. Souza, Pessôa et al. 2011), Nossa Senhora da Glória (A. L. G. Souza, Pessôa et al. 2011).

SUBSPECIES: *Wiedomys pyrrhorhinos* is monotypic.

NATURAL HISTORY: *Wiedomys pyrrhorhinos* breed at high rates throughout the year, even during periods of intense, prolonged water stress, but very few young reach adulthood, resulting in typical low populations levels (Streilen 1982c). They are deft climbers and make extensive use of their long tail for balance. Lactating females readily adopt other young; one pregnant female still had a subadult pelage (Streilen 1982a). The preference of *W. pyrrhorhinos* for thorn scrub habitats in the Caatinga morphoclimatic domain suggests a specialist habit

(Streilen 1982d). This species, despite being endemic to semiarid Caatinga, has a very weakly developed urine-concentrating capability (Streilen 1982b). It uses abandoned bird nests, termite nests previously occupied by parrots, and ground bromeliads. In one termite nest, Moojen (1952b) found 21 individuals, including eight adults and 13 young of different size classes. Nests are constructed with leaves and grasses and litter size varies from one to six, usually with five young (Moojen 1952b). There is a report of natural infection of *W. pyrrhorhinos* by *Trypanosoma cruzi* (Pereira Barreiro and Domingos Ribeiro 1972). In Bahia state, population numbers can dramatically increase, equivalent to *ratada* events known in other sigmodontines (A. M. P. de Almeida, pers. comm.).

REMARKS: The type specimen is a skin from a female (AMNH 574). In the original description, Hershkovitz (1959a) erroneously placed the southern limit of his new genus in the state of Rio Grande do Sul, following earlier authors (Ihering 1892; Thomas 1886b). However, Thomas (1928a) had correctly restricted the species distribution to northeastern Brazil, from the states of Minas Gerais to Ceará. Three karyotypes have been reported: $2n=62$, FN=86 or 90, with the variation in autosomal arm number due to a pericentric inversion affecting one member of a medium-size acrocentric pair (P. R. Gonçalves, Almeida, and Bonvicino 2005; Maia and Langguth 1987) and $2n=62$, FN=104, a nearly completely biarmed complement (A. L. G. Souza, Pessôa et al. 2011). The limits of geographic distribution of this species remain controversial, as preliminary phylogenetic studies suggest that the species is restricted to the right bank of Rio São Francisco (A. L. G. Souza, Pessôa et al. 2011).

Subfamily Tylomyinae Reig, 1984

Sergio Ticol Álvarez-Castañeda

The subfamily Tylomyinae comprises four genera (*Nyctomys*, *Otonyctomys*, *Ototylomys*, and *Tylomys*) of largely Middle American mice and rats specialized for an arboreal habitus (Reig 1984; Steppan 1995). Only members of the genus *Tylomys*, which together with *Ototylomys* are in the tribe Tylomyini (Carleton 1980; Bradley et al. 2004; Musser and Carleton 2005), extend into South America. Musser and Carleton (2005:1186) provided an emended diagnosis. Early molecular phylogenetic analyses were unable to resolve relationships of the Tylomyinae relative to the Sigmodontinae and/or Neotominae among the New World Cricetidae (D'Elía et al. 2003, 2005; Jansa and Weksler 2004; Steppan, Adkins, and Anderson 2004), but the most

recent studies (Parada et al. 2013; Schenk et al. 2013) suggested a deep sister relationship with the Sigmodontinae.

Genus *Tylomys* Peters, 1866

Members of this genus are large (over 380 mm in total length, and 45 mm in skull length). Externally, they are recognizable by their tail, which is longer than the head and body, naked, and shiny, with large scales forming wide annular rings. The tail is often held loosely coiled. The hindfeet are short and broad; digit V is nearly equal to digits II–IV; plantar pads are large and closely proximal; unguis tufts are present. The color of the tops of the feet and toes vary among species from white to brown. The eyes are rather small, shine bright, with a reddish reflection. The ears are blackish, large, and naked. Mystacial vibrissae are thick and long. The fur is long, dense, and woolly. Individual hairs are black or brown at the base for about half their length; the tip varies from white to yellowish, depending on the species. Dorsal color ranges from orange tawny, gray, gray-brown to blackish, with an indistinct broad dorsal band of glossy dark hair that extends from just before the ear to the rump. The frontal and the supraorbital areas have a different color than the top of the head; vibrissae arise from dark patches on the muzzle, and dark orbital rings are strikingly defined; the anterior muzzle varies in color from cinnamon-brown to dark gray. The venter varies from creamy white to fulvous, depending on the species.

The skull has pronounced and dorsally reflected supraorbital shelves that extend as a well-defined ridge across the temporal region; the interparietal bone is conspicuous, long, and wide, laterally contacting the squamosal fenestra; the zygomatic plates are relatively narrow; an alisphenoid strut is present; the postglenoid foramen is tiny; the subsquamosal fenestra is absent; the hamular process is undefined; the parapterygoid fossa is shallow and relatively narrow; and the roof of the mesopterygoid fossa is fully ossified (Goodwin 1955; Schaldach 1966; Carleton 1980; F. A. Reid 1997; Musser and Carleton 2005).

The three cheek teeth above and below are pentalophodont, brachydont, and strongly cuspidate with principal cones opposite one another. The mesoloph(id) and other accessory enamel ridges are well developed; M2 has four roots; and m3 is large in size and with coronal topography resembling m2 (Carleton 1980; Musser and Carleton 2005). *Tylomys* shares with *Ototylomys* and *Nyctomys* an entepicondylar foramen located on the medial epicondyle of the humerus, regarded as a primitive condition in the neotomine-peromyscine group (Carleton 1980). It is possible that the three genera (and presumably *Otonyctomys*) represent survivors of a phylogenetically ancient group (Carleton 1980).

Limited soft anatomical data are available for the Mexican and Middle American *T. nudicaudus* and *T. fulviventer*, but few data of any kind are known from *T. mirae*. For example, Hartung and Dewsbury (1978) described both the lack of a copulatory plug and a locking copulatory system with a mechanical tie between the penis and vagina in *T. nudicaudus*, and Hooper (1960) described and figured the gland penis and baculum of *T. nudicaudus* and *T. fulviventer* (Hooper 1960). The glans is broad and relatively short (about one-third the length of the hind foot, densely armed with unusually long spines over its exterior; the urinary meatus is unusually wide, extending across the distal glans face and guarded by a pair of small, soft, spine-tipped papillae; there is no terminal or internal crater (but termed “incipient” by Carleton 1980). The baculum is completely imbedded in dense tissue; it is short and broad, and tipped with a single cone of cartilage. Females of *T. nudicaudus* have a flattened, nonossified penis-like structure placed immediately anterior to the vagina with two pairs of inguinal mammae positioned close to the urogenital openings (Hall and Dalquest 1963). Carleton (1973) detailed the structures of a unilocular-hemiglandular stomach.

In captivity *T. nudicaudus* were active during light hours but accepted food whenever it was offered (Helm 1975). R. H. Baker and Petersen (1965) characterized vocalizations as “a catlike, spitting sound” and “piglike squeals.” Pathak et al. 1973) described the karyotypes of *T. nudicaudus* (including from the subspecies *T. n. gymnururus* and *T. n. villai*) and *T. panamensis*, but the karyotype of the South American *T. mirae* remains unknown.

SYNONYMS:

Tylomys Peters, 1866:404; as subgenus; type species *Hesperomys (Tylomys) nudicaudus*, by original designation. *Neomys* Gray, 1873:417, Fig. 1; type species *Neomys panamensis*, by original designation (= *Tylomys panamensis*; see Alston 1880a:150); preoccupied by *Neomys* Kaup, 1829 (Mammalia, Soricidae).

Tylomys: Thomas, 1884:450; elevation to generic rank. *Tylomis* Villa, 1941:763; incorrect subsequent spelling of *Tylomys* Peters.

REMARKS: Seven species are currently recognized for the genus *Tylomys* (Musser and Carleton 2005), three of which comprise the *nudicaudus* complex (*tumbalensis*, *bul-laris*, and *nudicaudus*) and four the *panamensis* complex (*fulviventer*, *panamensis*, *mirae*, and *watsoni*). However, as noted by Musser and Carleton (2005:1188), a taxonomic review appropriately targeting species boundaries is long overdue.

Hall (1981:626–627) mapped the ranges of the six North and Central American species that range from southern

Mexico through Panama (see also Handley 1966). Cabrera (1961:435–436) listed a single species, *T. mirae* Thomas, in South America, with two subspecies, *T. m. mirae* (from southern Colombia and northern Ecuador) and *T. m. bogotensis* (from the eastern Andes of Colombia). Possibly the Panamanian species *T. fulviventor*, *T. panamensis*, and/or *T. watsoni*, all of which occur in extreme eastern Panamá (as mapped by Hall 1981), extend into adjacent Colombia. Fieldwork in the general region of the Serranía de los Altos is critically needed.

Tylomys mirae Thomas, 1899

Southern Climbing Rat

SYNONYMS:

Tylomys mirae Thomas, 1899c:278; type locality “Paramba, River Mira, [Imbabura,] N. Ecuador, altitude, 1100 meters.”

Tylomys mirae bogotensis Goodwin, 1955:4; type locality “Volcán Caparrapi on the western slopes of the Cordillera Oriental, elevation about 1270 meters, 90 kilometers north-northwest of Bogotá and 10 kilometers west of La Palma,” Cundinamarca, Colombia.

Tylomys mirae mirae: Cabrera, 1961:435; name combination.

DESCRIPTION. Among largest species in genus (head and body length averages about 470 mm) exceeded only by some specimens of *T. nudicaudus*. Fur dense and thick, with individual hairs on back reaching lengths of 20–23 mm. Tail longer than head and body, naked on base with black hairs extending from scales; tail tip colored white to yellowish white. Dorsal body dark gray to brownish in color, with slight tinge of fawn; sides grayer and less fawn (or snuff brown), somewhat buffy. Head similar in color to dorsal body, or grayer; no eye-ring. Under parts white but not very sharply defined; on belly, white area narrow, like broad line down midline, with completely self-colored white fur in pectoral and inguinal regions and rest of under parts with hairs tinged slightly grayish at their bases with white tips. Forelimbs gray laterally, white medially; hindlimbs entirely gray except for narrow white line extending to ankles. Upper surfaces of both forefeet and hindfeet chocolate brown, terminal phalanges and hairs at base of claws white. Ears rather small, naked, and gray.

Skull large and angular without obvious zygomatic notches; nasals narrow, with posterior part truncate in *T. m. bogotensis* and pointed in *T. m. mirae*, ending on line or scarcely surpassed by premaxillaries. Supraorbital ridges well defined with prominent postorbital angle from which they run backward, and curved from little to strongly outward in parietal region. Molariform teeth relatively small and narrow; V-shaped mesopterygoid fossa ex-

tends forward to near posterior margin of M2 (Goodwin 1955; Thomas 1899c).

DISTRIBUTION: The few available specimens of *T. mirae* are known from tropical forest on the lower slopes of the Andean cordilleras of Colombia and Ecuador south along through the Pacific lowlands to northwestern Ecuador, over an elevational range from 200 to 1,300 m (Cabrera 1961; Eisenberg 1989).

SELECTED LOCALITIES (Map 369): COLOMBIA: Antioquía, 4 km NE of Bellavista above Río Porce (FMNH 79553), 25 km S and 22 km W of La Tirana (USNM 499617), Puerto Berrío “Las Virginias” (IAVH), Valdivia, Quebrada Valdivia (FMNH 70554); Boyacá, Muzo (FMNH 71216); Caldas, Samana, Río Hondo (FMNH 71215); Cundinamarca, Nariño, near Río Mira (ICN, Bogotá); Nariño, Buenavista (AMNH 34204), Candelilla (FMNH 89564); Valle de Cauca, 6 km N of Buenaventura (USNM 554237). ECUADOR: Carchi, El Pailón (Diego Tirira, pers. comm.); Esmeraldas, El Salta, estero (Diego Tirira, pers. comm.), Pamibilar (USNM 113318); Imbabura, Paramba, Río Mira (type locality of *Tylomys mirae* Thomas).

SUBSPECIES: Goodwin (1955) distinguished *T. m. bogotensis*, in comparison with the nominotypical form *T. m. mirae*, on the basis of paler dorsal color, dusky instead of white under parts, and smaller teeth. Cabrera (1961) continued to list these two subspecies as valid, but Musser and Carleton (2005:1189) simply list *bogotensis* Goodwin as a synonym. Validation of subspecies boundaries requires a more thorough evaluation of geographic variation than currently available.

NATURAL HISTORY: Current data indicate no strong difference between the habitats of different species of the genus (F. A. Reid 1997). The climbing rats are found in cloud forest and tropical evergreen forest, in dense forest with tall trees (up to 30 m) and a dense shrub layer, where the crowns harbor great masses of vines and creepers with much parasitic and epiphytic growth. Most records state specimens were taken either on the ground, in shrubs, or in trees, in areas often associated with rock outcrops or cliffs. Climbing rats move very quickly through the branches, stems, and vines.

REMARKS: Musser and Carleton (2005) suggested that both *fulviventor* and *watsoni* might be junior synonyms of *T. panamensis*. Goodwin (1955:5), in his description of *T. mirae bogotensis*, remarked that his new subspecies “is not very unlike the type of *T. fulviventor*.” *Tylomys mirae* can be distinguished generally from this complex by gray-based under parts with pectoral and inguinal white spots as opposed to entirely white venters, and skulls with V-shaped versus U-shaped mesopterygoid fossae, narrower rostra and smaller bullae, and heavier supraorbital shelves and their temporal extensions.

Map 369 Selected localities for *Tylomys mirae* (●). Contour line = 2,000 m.

Suborder Hystricomorpha Brandt, 1855
 Infraorder Hystricognathi Tullberg, 1899
 James L. Patton

The New World hystricognathous rodents comprise 10 to 13 families, depending on the authority, typically arranged into four superfamilies that are, in turn, often united into the Caviomorpha (at the categorical level of suborder [Wood 1965] or infraorder [B. Patterson and Wood 1982]). Woods (1993) questioned whether all caviomorphs were part of a single radiation, and McKenna and Bell (1997) excluded the erethizontids from their parvorder Caviida that contained all other New World hystricognaths. However, all available molecular data consistently support the monophyly of the caviomorphs relative to Old World hystricognaths. These same analyses also suggest a single ancestral entry to the New World (Huchon and Douzery 2001; Huchon et al. 2007; Opazo 2005; Poux et al. 2006; Rowe et al. 2010), as does the microstructure of incisor enamel (T. Martin 2004, 2005), cladistic analyses of fossil hystricognathous forms (Sallam et al. 2009; Antoine et al. 2012), and a very stable, but unique, placentation pattern (A. M. Carter and Mess 2013).

The group has a long and very diverse fossil history in the New World, beginning with certainty in the Oligocene (B. Patterson and Wood 1982; Vucetich et al. 1999; Wyss et al. 1993; Pascual 2006; R. do V. Vilela et al. 2009) and possibly as early as the late Eocene (Frailey and Campbell 2004). Huchon and Douzery (2001) suggested that the early caviomorph radiation corresponded to two ecological events, an arrival that coincided with cooling between 25 and 36 mya in which euhiposodont teeth evolved as a key adaptation and subsequent diversification during the climatic perturbations of the mid-Miocene (Vucetich et al. 1999). The basal date of the Caviomorpha radiation estimated from molecular studies ranges from 36.7 ± 3.7 mya (Poux et al. 2006; Huchon et al. 2007), 34.1 mya (31.6–37.4 confidence interval; Upham and Patterson 2012), 33.8 ± 1.6 mya (Opazo 2005), to 30.7 mya (95% credibility interval 29.1–33.4 mya; Sallam et al. 2009), estimates that are consistent with the 31–37 mya age span suggested by Wyss et al. (1993) and Frailey and Campbell (2004). The newly discovered diverse caviomorph assemblage from the late Middle Eocene Yahuarango Formation in Peru (approximately 41 mya) supports an earlier entry of stem caviomorphs from Africa into South America, one that corresponds with the warmer and wetter conditions of the Mid Eocene Climatic Optimum (Antoine et al. 2012). This date is consistent with the estimate of the 40.4 mya (36.1–45.6 confidence interval) for the divergence of the Caviomorpha and African Phiomorpha split (Upham and Patterson 2012).

By the early Miocene (Santacruzian Land Mammal Age), caviomorphs had reached the diverse array of body sizes, locomotory modes, and presumed feeding behaviors observed among extant taxa, with considerable commonality in morphofunctional groupings across these disparate temporal assemblages (Candela et al. 2012). Several early members of extant lineages appeared to eat harder and more abrasive foods than those consumed by their living relatives, and the earliest caviomorphs likely lived in an environment similar to the Brazilian Cerrado today.

The arrangement of genera into family and subfamily groups has been relatively stable for many decades, with a few notable exceptions (e.g., *Chaetomys* as an Erethizontidae or Echimyidae; Woods 1982 versus T. Martin 1994 or R. do V. Vilela et al. 2009) as has been the division of caviomorphs into four superfamilies. However, there has been considerable flux in family and subfamily membership in each superfamily (Simpson 1945; Landry 1957; Wood 1965; Woods 1982, McKenna and Bell 1997). The categorical rank accorded to some groups traditionally given family status has also been debated (e.g., placement

of Hydrochoeridae and Myocastoridae as subfamilies within the Caviidae and Echimyidae, respectively; Woods and Kilpatrick 2005).

The families and superfamilies recognized herein generally follow Woods and Kilpatrick (2005), modified by molecular phylogenetic analyses (Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012). These studies, combining both mitochondrial and nuclear gene sequences and broad taxon sampling, posit the same hypotheses of relationships among families, with two exceptions. First, the Erethizontidae are placed as part of a clade that otherwise comprised the Chinchilloidea and Octodontoidea (Opazo 2005; Rowe et al. 2010) or as the sister to the Cavioidae (Upham and Patterson 2012). Second, these analyses support different topologies of family relationships within the Cavioidae (Dasyproctidae [Caviidae + Cuniculidae], Opazo 2005; Rowe et al. 2010; versus Cuniculidae [Caviidae + Dasyproctidae], Upham and Patterson 2012). Herein, I retain the Erethizontidae within its own superfamily (Erethizontoidea), place the Dinomyidae + Chinchillidae within the Chinchilloidea, group the Abrocomidae + Echimyidae + Ctenomyidae + Octodontidae within the Octodontoidea, and include the Dasyproctidae + Caviidae + Cuniculidae within the Cavioidae. Following the well-supported cladistic relationships established by each of the molecular analyses, the capybaras are regarded as a subfamily (Hydrochoerinae) within the Caviidae and the coypus as a subfamily (Myocastorinae) within the Echimyidae. Resolution of the differences in phyletic placement of the Erethizontidae, and thus potential changes in the higher categorical groups of Caviomorpha, awaits further analyses. Because no molecular analysis can (at least, as yet) encompass the rich diversity of extinct forms, their inclusion requires cladistic analyses of morphological characters of both fossil and extant taxa (e.g., G. A. S. Carvalho and Salles 2004; Candela and Rasia 2012; Olivares et al. 2012). The Capromyidae are not covered, as this group resides completely outside the boundaries of South America (Hall 1981; Woods and Kilpatrick 2005).

Despite highly varied body form and size, all caviomorphs are characterized by an hystricognathous lower jaw, in which the root of the angular process is deflected lateral to the sheath of the lower incisor, an hystricomorphous jaw musculature, with a large masseter medialis penetrating a greatly enlarged infraorbital foramen to insert on the side of the rostrum, hypsodont, often ever-growing cheek teeth with planned occlusal surfaces, and a dental formula of I 1/1, C 0/0, PM 1/1, M 3/3 = 20. The deciduous fourth premolars (dP4/dp4) are apparently replaced in all families with the exception of the Echimyidae (e.g., G. A. S. Carvalho 2000).

KEY TO THE FAMILIES OF SOUTH AMERICAN HYSTRICOGNATHI:

1. Dentary with prominent ridge and groove on lateral side of dentary below and parallel to cheek teeth. Caviidae
- 1'. No prominent ridge and groove on lateral side of dentary. 2
2. Zygomatic arch greatly expanded, forming thickened and rugose cheekplate; body size large, mass >5 kg, skull length >100 mm Cuniculidae
- 2'. Zygomatic arch normally developed, without thickened cheekplate; body size and skull length variable. 3
3. Cheek teeth composed of two to four simplified transverse plates. 4
- 3'. Cheek teeth with more complex occlusal surfaces 5
4. Body bauplan stocky, limbs short, hindfeet with four well-developed digits; pelage short, hairs coarse, color black with rows of white and spots on back; toothrows diverge slightly posteriorly; paroccipital processes short, blunt, extending to ventral plane of bullae; bullae uninflated Dinomyidae
- 4'. Body bauplan more slender, limbs elongated, hindfeet with three well-developed digits; pelage long, thick, hairs fine, no rows of white spots on back; toothrows diverge strongly posteriorly; paroccipital processes elongated, extending well below ventral plane of bullae when bullae uninflated, or curved over bullae when latter inflated Chinchillidae
5. Fur conspicuously spiny, some hairs modified as rounded, barbed quills; hindfeet greatly modified for arboreal life, with hallux replaced by broad, movable pad; cheek teeth either with very wide reentrant folds or nearly laminate, rooted; paroccipital process not greatly lengthened Erethizontidae
- 5'. Spines may be present in fur, but if so always flattened, without barbs; hindfeet usually not modified for arboreal life (except some Echimyidae, with broad soles and short digits, or elongated digits with nail-like claws), hallux never modified into broad, movable pad 6
6. Body bauplan modified for cursorial locomotion, with elongated limbs and short tail; three digits on hindfeet; claws thickened, almost hoof-like; no spines in fur; cheek teeth semirooted, reentrant folds isolating as narrow islands on crown surfaces in adults Dasyproctidae
- 6'. Body bauplan not modified for cursorial life; digits of hindfeet four or five; claws not hoof-like; spines may be present in fur; cheek teeth variable when ever-growing occlusal surfaces rather simplified, when rooted occlusal surface pattern of isolated islands. 7
7. Cheek teeth greatly simplified, labial side of upper series with only one reentrant fold 8

- 7'. Cheek teeth more complex, labial side of upper series always with at least two, typically three, sometimes more reentrant folds Echimyidae
8. Lower cheek teeth prismatic and angular; occlusal surfaces of upper series figure-8 shaped; part of lacrimal canal open on side of rostrum. Abrocomidae
- 8'. Lower cheek teeth not prismatic; occlusal surfaces of both upper and lower cheek teeth with same figure-8 shape or with kidney shape pattern; no part of lacrimal canal opens on side of rostrum 9
9. Occlusal surfaces of cheek teeth weakly kidney shaped, size decreasing notably from front to back; skull heavily ridged; elongated rostral tubes extend dorsolaterally from bullae; foreclaws greatly enlarged . . . Ctenomyidae
- 9'. Occlusal surfaces of cheek teeth figure-8 shaped, similar in size from front to back; skull not heavily ridged; no elongated auditory canal extending from bullae; foreclaws not greatly enlarged Octodontidae

Superfamily Caviioidea G. Fischer, 1817

The Caviioidea comprises three families, Caviidae (which includes the subfamilies Caviinae, Hydrochoerinae, and Dolichotinae), Cuniculidae, and Dasyproctidae. Exclusive of the Cuniculidae and Dasyproctidae, fossils assignable to Caviioidea *sensu stricto* date from as early as the early Oligocene (Deseadan; M. E. Pérez and Vucetich 2011). As noted above, molecular estimates of 26.5 mya for the basal diversification of extant genera, and thus families, are fully consistent with the fossil record (Opazo 2005; Upham and Patterson 2012). Also as noted above, however, there remains ambiguity among family-group relationships, as separate molecular analyses support either the Dasyproctidae (Rowe and Honeycutt 2003; Opazo 2005; Rowe et al. 2010; M. E. Pérez and Pol 2012) or Cuniculidae (Upham and Patterson 2012) as the basal member of the superfamily.

Family Caviidae G. Fischer, 1817

Jonathan L. Dunnunum

Six Recent genera (*Cavia*, *Galea*, *Microcavia*, *Kerodon*, *Dolichotis*, and *Hydrochoerus*) in three subfamilies (Caviinae, Dolichotinae, and Hydrochoerinae) were recognized (Woods and Kilpatrick 2005). The hydrochoerines were included as a subfamily by Tate (1935) and Ellerman (1940), but others (Pocock 1922; Simpson 1945; Woods 1993; McKenna and Bell 1997) have recognized it as a distinct family. Molecular phylogenetic analyses (Rowe and Honeycutt 2002; Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012) provide strong support for the three subfamilies and the position of the Hydrochoerinae as sis-

ter to the Dolichotinae. M. E. Pérez and Pol (2012) corroborated these relationships using both molecular and fossil data. Their topology is recognized here.

The family is well represented in the fossil record from the middle to late Miocene (B. Patterson and Pascual 1972; C. A. Quintana 1998, 2001; Ubilla and Rinderknecht 2003; M. E. Pérez and Vucetich 2011). All current genera are present since the Pleistocene (McKenna and Bell 1997). Recent molecular work has placed the divergence date for the family in the early (18.5 ± 2.5 mya; Opazo 2005) to middle Miocene (14–17 mya; Huchon and Douzery 2001), dates that are consistent with the limited fossil record (M. E. Pérez and Vucetich 2011). In the most recent treatment, M. E. Pérez and Pol (2012) dated the Caviidae split at about 13.5 mya based on combined fossil and molecular data. Molecular data resulted in a mean date of about 16.5 mya (95% HPD 11–24 mya).

The cheek teeth are ever growing, unilaterally hypsodont, simplified in structure, but with sharp folds and projections exhibiting a more or less prismatic effect. The toothrows tend to converge anteriorly. The tibia and fibula are not fully fused (Ellerman 1940). The lower mandible exhibits the least hystricognathous condition of the extant hystricognath rodents. The lateral process of the supraoccipital is lacking (Eisenberg 1989). Body form is robust, the head is large, and the ears and limbs are short in the Caviinae and Hydrochoerinae, while the Dolichotinae exhibit the hare-like traits of long ears and limbs. Head and body length ranges from ca. 200 mm in *Galea* and *Microcavia* to over 1,300 mm in *Hydrochoerus*. The tail is absent in all taxa except *Dolichotis*. The manus is pentadactyl, and the pes is tridactyl, with nails blunt and either claw-like or hoof-like. Members of the family are generally long-lived, and young are well developed at birth and reach maturity quickly. The family exhibits a wide degree of variation in social and mating systems, from highly social and monogamous in the Dolichotinae, to polygynous and highly social in *Hydrochoerus* and *Kerodon*, to promiscuous with low sociality in *Cavia*, *Galea*, and *Microcavia* (Novak 1999; Rowe and Honeycutt 2002; Adrian and Sachser 2011). Diploid number ranges from 52 to 68 (W. George et al. 1972; Maia 1984; Dunnunum and Salazar-Bravo 2006). M. H. Gallardo et al. (2002) described sperm morphology. The family occupies a wide range of habitats, including mesic and xeric grasslands, forest edges, and marsh from sea level to 5,000 m over much of South America and extending north into Panama.

KEY TO THE SUBFAMILIES AND GENERA OF RECENT CAVIIDAE:

1. Head and body length <450 mm 2
1'. Head and body length >450 mm. 5

2. Toes with nails; sternum narrow and rounded.
 Hydrochoerinae, *Kerodon*
- 2'. Toes with claws; sternum broad and flat. . . Caviinae, 3
3. Incisors pigmented yellow; orbital branch of maxillary completely interrupted by lacrimal *Galea*
- 3' Incisors white; orbital branch of maxillary continuous as a narrow strip in front of lacrimals. 4
4. Head and body length <225 mm; prominent eye-ring present; ears with well-developed tragus and antitragus; teeth without cement interleaves between prisms; PM4 with an anterior accessory prolongation in the first prism *Microcavia*
- 4'. Head and body length >225 mm; eye-ring not prominent or absent; ears with poorly developed tragus and antitragus; teeth with cement interleaves between prisms; PM4 without an anterior accessory prolongation in the first prism *Cavia*
5. Size large, head and body length ca. 1,000 mm; feet semiwebbed; M3 longer than combined length of other three molariform teeth
 Hydrochoerinae, *Hydrochoerus*
- 5'. Size medium, head and body length 450–800 mm; feet not webbed; hind toes hoof-like; teeth not as above . . .
 Dolichotinae, *Dolichotis*

Subfamily Caviinae G. Fischer, 1817

The Caviinae include the three guinea pig-like genera (*Cavia*, *Galea*, and *Microcavia*). Fossil taxa date from the mid-Miocene (C. A. Quintana 1998, 2001; Ubilla and Rinderknecht 2003; M. E. Pérez and Vucetich 2011), and divergence of the subfamily ranges from 16.2 ± 2.5 mya (Opazo 2005). Diploid numbers span 62 to 68 (W. George et al. 1972; Maia 1984; Gava et al. 1998; Dunnun and Salazar-Bravo 2006), but see Lobato and Araujo (1980) for a possible exception in the Ecuadorean Cavy.

Genus *Cavia* Pallas, 1766

Medium-sized herbivores, the wild forms of *Cavia* are endemic to South America, occurring over most of the continent, with the exception of portions of Amazonia and the austral parts of Chile and Argentina (Ximénez 1980; Eisenberg 1989; Redford and Eisenberg 1992; Eisenberg and Redford 1999). They occur from mesic lowlands (10 m) to arid highlands (4,200 m) and while primarily associated with grasslands, they also occur in forest edges and swamp-land. Due to its utility to *Homo sapiens*, the domesticated form is now found nearly worldwide in conjunction with human habitation. Woods and Kilpatrick (2005) recognized six species, but Dunnun and Salazar-Bravo (2010a) elevated the Ecuadorean *C. patzelti* to specific status.

The fossil record for *Cavia* dates from the late Pliocene (Verzi and Quintana 2005) to the middle Pleistocene (Ubilla and Alberdi 1990; McKenna and Bell 1997) and Holocene (Hadler et al. 2008). However, molecular data suggest the genus has been present since the Miocene/Pliocene boundary (Opazo 2005; Dunnun and Salazar-Bravo 2010a). *Cavia* specimens have been taken from archeological excavations in Peru and Colombia dating to at least 9,000 years BP and they have been domesticated for the last 4,500–7,000 years for food and spiritual uses (Wing 1986). The human facilitated expansion of the domesticated form and a lack of broad systematic work on the wild forms have complicated our understanding of the evolutionary history, systematics, taxonomy, and biogeography of the genus, although recent work (Dunnun 2003; Spotorno, Valladares, Marín, and Zeballos 2004; Spotorno et al. 2006; Dunnun and Salazar-Bravo 2010a) has provided much resolution.

The skull has a limited interorbital constriction with a sagittal crest developed in adults; the infraorbital foramen is broader below than above; auditory bullae are relatively large; the paroccipital processes are elongated; the hard palate is short, extending to the front of M3; palatal foramina are short and narrow; and the jugal is of medium length and does not approach the lacrimal. Upper cheek teeth are about equal in size and divided into two lobes by an inner reentrant fold in the upper series, the posterior lobe being larger than the anterior one, and with a deeply indenting fold in its outer border. M3 has a posterior projection. Lower cheek teeth have one deep outer fold dividing the tooth into two lobes with an inner fold in the posterior lobe. Incisors are not pigmented (Ellerman 1940). Mean condyloincisive length is 53.8 mm (range: 44.5–63.5 mm; Hückinghaus 1961a). Upper cheek teeth are divided into two lobes by inner reentrant fold, the posterior lobe being larger than the anterior and with a deeply indented fold on its labial border. The third upper molar has a posterior projection. Lower cheek teeth have one deep outer fold dividing each tooth into two lobes and with an inner fold on the posterior lobe. The hindfeet have three digits, each terminated by a sharp claw, with the central digit longest. The forefeet have four digits. The ears are relatively short and rounded (Ellerman 1940). Females have a single pair of inguinal mammae.

SYNONYMS:

Mus: Linnaeus, 1758:59; part (description of *porcellus*); not *Mus* Linnaeus.

Cavia Pallas, 1766:30; type species *Cavia cobaya* by subsequent designation (Palmer 1904) [= *C. cobaya* Marcgraf, = *Mus porcellus* Linnaeus].

Cavia Storr, 1780:39; incorrect subsequent spelling of *Cavia* Pallas.

Lepus: G. I. Molina, 1782:306; part; not *Lepus* Linnaeus; either a *Cavia* or *Galea*, see Tate (1935:344).

Calva Gmelin, 1788:120; incorrect subsequent spelling of *Cavia* Pallas.

Scavia Blumenbach, 1797:80; unjustified emendation of *Cavia* Pallas.

Agouti: Daudin, 1802:166; part (listing of *aperea*); not *Agouti* Lacépède.

Savia Treviranus, 1802:211; unjustified emendation of *Cavia aperea* Erxleben.

Hydrochoerus: É. Geoffroy St.-Hilaire, 1803:163; part (listing of *cobaya*); not *Hydrochoerus* Brisson.

Hydrochaerus G. Fischer, 1814:593; part (listing of *cobaya*); incorrect subsequent spelling of *Hydrochoerus* Brisson.

Anoëma F. Cuvier, 1809:394; type species *Cavia cobaya* Pallas.

Anoema F. Cuvier, 1812:292; justified emendation of *Anoëma* F. Cuvier; type species *Cavia cobaya* Pallas.

Cobaya F. Cuvier, 1817b:481; type species *Cavia cobaya* Pallas.

Anoemas F. Cuvier, 1829a:493; incorrect subsequent spelling of *Anoema* F. Cuvier.

Coiza Billberg, 1827:45; new name for *Cavia* Pallas.

Prea Lund, 1839b:206; included *Cavia aperea* ("Aperera de Marcgraf" = *C. cobaya* Margrave = *Mus porcellus* Linnaeus) and *Cavia rufescens* Lund (= *Cavia aperea* Erxleben).

Kerodon: Wagner, 1844:64; listing of *obscurus*; not *Kerodon* F. Cuvier.

Prea Liais, 1872:541; part (listing of *cobaya*); new name for *Cavia* Pallas.

Mamcaviaus A. L. Herrera, 1899:13; unavailable name because it is based on zoological formulae (ICZN 1987:318).

REMARKS: *Mus porcellus* Linnaeus and *Cavia cobaya* Pallas were both based on the *Cavia cobaya* of Marcgraf (1648), a domesticated form sent to Europe from an unknown place of origin in South America. The name *porcellus* Linnaeus, indicated by Thomas (1916f) as the type species of *Cavia*, is excluded from consideration because it was not included under the generic name at the time of its original publication (see Tate 1935). The generic name *Calva* appears (p. 120) in some but not all versions of Gmelin, 1788; however, *Cavia* is correctly listed in the running header in each. G. I. Molina (1782:306) used *Lepus minimus* in describing a "Cuy," which Tate (1935:344, 347) thought was likely a *Galea* and thus included as a subspecies of *G. musteloides*. Hückinghaus (1961a) followed Tate and assigned *minimus* G. I. Molina to *Galea*, whereas Cabrera (1961) listed it in the synonymy of *Cavia porcellus*.

Tate (1935) summarized the taxonomy of the genus up to 1930, recognizing 11 species. The number of species delimited in subsequent works has varied from three to

eight species (Cabrera 1961; Hückinghaus 1961a; Corbet and Hill 1991; Novak 1999; Woods 1993). Woods (1993) recognized five species (*aperea*, *fulgida*, *magna*, *porcellus*, and *tschudii*), following Hückinghaus (1961a) by including *C. nana* and *C. guianae* in the synonymy of *C. aperea* and *C. anolaimae* in the synonymy of *C. porcellus*. Woods and Kilpatrick (2005) followed Woods (1993) but added the Intermediate Cavy, *C. intermedia*, to the list of species they recognized. In this account I recognize seven species within *Cavia*, including the Ecuadorean cavy *C. patzelti*, and despite its clear derivation from *C. tschudii*, I also treat the domesticated form *C. porcellus* as a species to avoid further complicating the taxonomic understanding of the group.

KEY TO THE SPECIES OF CAVIA:

1. Dorsal pelage multicolored white, black, or tan and occurring in human-occupied areas throughout South America and worldwide as a pet or laboratory animal *Cavia porcellus*
- 1'. Dorsal pelage uniformly brown, tan, or red-brown, not multicolored; occurring in the wild in South America. 2
2. M3 without deep notch on the outer side of the anterior end of the posterior lobe. 3
- 2'. M3 with deep notch on the outer side of the anterior end of the posterior lobe, found in coastal regions of eastern Brazil *Cavia fulgida*
3. Found in highlands above 2,500 m or west of the Andes, in Peru, Bolivia, Ecuador, and Argentina 4
- 3'. Found at elevations below 2,500 m east of the Andes or in the highlands of Colombia 5
4. Occurring in the highlands of Ecuador *Cavia patzelti*
- 4'. Occurring in highlands above 2,500 m or west of the Andes, in Peru, Bolivia, and Argentina *Cavia tschudii*
5. Interdigital membranes enlarged 6
- 5'. Interdigital membranes not enlarged; occurs on eastern versant of the Andes (Bolivia through Colombia) and the non-Amazonian lowlands east of the Andes *Cavia aperea*
6. Coastal marshlands of extreme southeastern Brazil and Uruguay; $2n = 64$, except $2n = 62$ population on Ilha Marinheiros *Cavia magna*
- 6'. Islands of Moleques do Sul, Brazil; $2n = 62$ *Cavia intermedia*

Cavia aperea Erxleben, 1777

Brazilian Guinea Pig

SYNONYMS: See under Subspecies.

DESCRIPTION: Varies among subspecies. Nominotypical subspecies of eastern Brazil among largest, with mean greatest length of skulls from Minas Geraes and São Paulo

states 68.7 mm, with largest 73 mm. Overall coloration grizzled, brownish gray; venter dull whitish with clear white spot usually present at midline of chest below brown collar (Thomas 1917a).

More southerly Brazilian form, *C. a. rosida*, somewhat smaller (greatest length of skull about 63 mm), with reduction in skull length due primarily to reduced rostrum. Dorsal color heavily grizzled mummy brown; median part heavily blackened, with lumbar region sometimes almost completely black; under surfaces and insides of limbs dull cinnamon buff, with hairs pale gray basally; throat markings not easily distinguished, usual dark collar overlaid with dull buffy and white chest patch absent or reduced to small spot. Dimensions of holotype of *rosida* head and body length 395 mm, hindfoot length 46 mm, ear length 20 mm, and greatest skull length 62 mm (Thomas 1917a).

The Argentinean *C. a. pamparum* similar to Brazilian forms but more grayish or olivaceous, less brown; venter whitish or slightly drab, chest pattern well marked. Greatest length of skull 62–63 mm. Dimensions of holotype: head and body length 251 mm, hindfoot length 40 mm, ear length 23 mm, and greatest skull length 62 mm (Thomas 1901e, 1917a).

Colombian *C. a. anolaimae* uniformly dark yellowish gray, with exposed portion of hairs black with narrow subapical band of olivaceous buff; ventral surfaces dingy brownish gray, hairs uniform to base; no white around eyes or ears (J. A. Allen 1916a).

Specimens of *C. a. guianae* from Guyana similar in general characteristics to Brazilian forms but paler and grayer above and less buffy below; general coloration olive gray; dorsally heavily grizzled and lined with black; head, neck, shoulders, flanks, and rump more grayish; under parts whitish or slightly buffy, bases of hair slaty gray; eyes circumscribed by indistinct whitish rings; ears thinly haired in white. Dimensions of holotype head and body length 275 mm, hindfoot length 46 mm, ear length 19 mm, and greatest skull length 59 mm (Thomas 1901c). Husson (1978) reported that a Surinam specimen differed from holotype of *C. a. guianae* only in that type was much whiter ventrally; remainder type series indistinguishable from Surinam specimen. Dimensions of other Surinam specimens, head and body length 160–265 mm, hindfoot length 36–45 mm, and ear length 22 mm.

The Pygmy Cavy of the Bolivian Andean versant, *C. a. nana*, is smallest. Dorsal coloration dark olive brown, with light rings on hairs being buffy or cinnamon; no darkening along median area of back; ventral surface creamy whitish and gray collar well marked; hands and feet pale brown. Dimensions of holotype head and body length 215 mm, hindfoot length 38 mm, ear length 23 mm, and greatest

skull length 52 mm (Thomas 1917a). Specimens from Bolivian lowlands similar in appearance to Pygmy Cavy but overall darker olivaceous and exhibit medial dorsal darkening; ventrally hair longer and tips much more yellow, giving more striking color than muted creamy gray of *C. a. nana* (J. Dunnun, pers. obs.).

DISTRIBUTION: *Cavia aperea* has a disjunct range, with southern populations occurring south of the Amazon Basin from the eastern slopes of the Andes in southeastern Peru and Bolivia, through Paraguay, northeastern Argentina, Uruguay, and to the eastern coast of Brazil, and northern populations from central Colombia east through Venezuela, Guyana, Surinam, and northern Brazil.

SELECTED LOCALITIES (Map 370): ARGENTINA: Buenos Aires, Arroyo Sauce Chico (Massoia 1973b), Lobería (Massoia 1973b), Zelaya (Cabrera 1953); Chaco, El Colorado (Massoia 1973b); Córdoba, Noetinger (Massoia 1973b); Corrientes, Goya (type locality of *pamparum* Thomas); San Luis, Pedernera (J. R. Contreras 1980); Santa Fé, Tostado (Massoia 1973b). BOLIVIA: Beni, Río Itenez, 20 km above mouth (S. Anderson 1997), Santa Rosa (S. Anderson 1997); Chuquisaca, Chuquisaca (S. Anderson 1997); Cochabamba, Incachaca (S. Anderson 1997); La Paz, Chulumani (type locality of *nana* Thomas); Santa Cruz, Parque Nacional Noel Kempff Mercado, 6 km S of Los Fierros (S. Anderson 1997). BRAZIL: Distrito Federal, Brasília (Ximénez 1980); Goiás, Anápolis (Ximénez 1980); Minas Gerais, Serra Caparaó, Fazenda Cardozo (AMNH 61846); Pernambuco, Salinho, Rio Formoso (Ximénez 1980); Rio de Janeiro, Itatiaia (Avila-Pires 1977); Rio Grande do Sul, Tramandaí (Cherem et al. 1999); Roraima, Ilha Maracá (Barnett and Cunha 1994); São Paulo, Ribeirão Preto (Asher et al. 2004); Sergipe, 1 km W of Pacatuba (Ximénez 1980). COLOMBIA: Cundinamarca, Anolaima (type locality of *anolaimae* J. A. Allen); Meta, Condominio Camino Real (Zúñiga 2000). GUYANA: Berbice, Berbice (Thomas 1917a); Upper Takutu–Upper Essequibo, Kanuku Mountains (type locality of *guianae* Thomas). PARAGUAY: Concepción, 7 km NE of Concepción (MSB 82571); Presidente Hayes, Río Negro (Riacho Negro) (AMNH 36517). PERU: Madre de Dios, Pampas de Heath, ca. 50 km S of Puerto Pardo (LSUMZ 22683). SURINAM: Sipaliwini, Sipaliwini airstrip (S. L. Williams et al. 1983). URUGUAY: Cana-lones, Bañado de Tropa Vieja (Barlow 1969), Treinta y Tres, Boca del Río Tacuari (Barlow 1969). VENEZUELA: Bolívar, Altagracia (type locality of *Cavia porcellus venezuelae* J. A. Allen), San Ignacio Yuraní (Voss 1991a); Carabobo, Montalbán (Handley 1976); Monagas, San Agustín (Handley 1976).

SUBSPECIES: I recognize seven subspecies of *C. aperea*.

C. a. anolaimae J. A. Allen, 1916

SYNONYMS:

Cavia anolaimae J. A. Allen, 1916a:85; type locality “Anolaima, on a branch of the Rio Bogotá, west of Bogotá, Colombia,” Cundinamarca.

Cavia porcellus anolaimae: Cabrera, 1961:578; name combination.

Cavia aperea guianae: Hückinghaus, 1961a:58; part (not *guianae* Thomas).

Cavia aperea anolaimae: O. J. Linares, 1998:209; first use of current name combination.

This subspecies is restricted to high elevations (2,400 to 4,000 m) of the Cordillera Oriental in the departments of Boyacá, Cundinamarca, and Santander, Colombia, and the Mérida Andes and Cordillera Central (600 to 1,200 m) in western Venezuela (O. J. Linares 1998; Zúñiga 2000).

Hückinghaus (1961a) stated that *anolaimae* J. A. Allen was likely identical to *guianae* Thomas, and Cabrera (1961) placed it in the species *C. porcellus*. However, some authors (Zúñiga 2000; Zúñiga et al. 2002) suggested that *anolaimae* J. A. Allen, *guianae* Thomas (= *aperea* Erxleben), and *porcellus* Linnaeus were each distinct species based on karyotypic and morphologic characters. Allen's *anolaimae* is included here as a subspecies of *C. aperea* as molecular analyses placed it solidly within the *aperea* complex; however, its distinction from *C. a. guianae* was not supported and merits further investigation (Dunnum and Salazar-Bravo 2010a).

It is possible that the holotype was collected in the Florida swamps in the Engativá region of the Bogotá savanna and that J. A. Allen (1916a) mistakenly deduced that the holotype came from La Florida, a train station in the town of Anolaima (Zúñiga et al. 2002:118). This possibility is supported by the fact that no records other than the type series are known from the temperate region on the eastern flank of the Cordillera.

C. a. aperea Erxleben, 1777

SYNONYMS:

[*Cavia*] *aperea* Erxleben, 1777:348; type locality “Brasil-iae”; restricted to Pernambuco, Brazil (Cabrera 1961).

Calva aperea: Gmelin, 1788:122; name combination.

Agouti aperea: Daudin, 1802:166; name combination.

Hydrochaerus aperea: F. Cuvier, 1817a:18; name combination.

S[*avia*]. *aperea*: Olfers, 1818:214; name combination.

Anoéma hilaria É. Geoffroy St.-Hilaire, 1820:2, text to plate 282; *nomen nudum*.

Cavia leucopyga Brandt, 1835:436; type locality “Patria. Brasilia.”

Anoema Aperea: Lund, 1838:48; name combination.

Cavia gracilis Lund, 1839b:208; *nomen nudum* (a fossil).

Cavia apereoides Lund, 1840b (1841c:294, plate 25, Fig. 16); type locality “Rio das Velhas's Floddal” (Lund 1841c: 292, 294), Lagoa Santa, Minas Gerais, Brazil (a fossil).

Cavia robusta Lund, 1842:14; *nomen nudum*.

Prea obscura: Liais, 1872:541; part; name combination.

[*Cavia*] *porcellus*: E.-L. Trouessart, 1897:637; part; name combination.

[*Cavia*] *aperea aperea*: Tate, 1935:343; first use of current name combination.

The nominotypical subspecies occurs in eastern Brazil; its western limits are unclear.

Tate (1935:342) stated that true *Cavia azarae* Wagner (1844:63, footnote, based upon *Dasyprocta azarae* Lichtenstein) is likely a synonym of *C. a. aperea*. However, Ximénez (1980:152–153) argued that Lichtenstein's specimen was referable to *Dasyprocta*, not *Cavia*. Massoia (1973b) supported the subspecific status of *C. a. aperea* in comparisons with *C. a. pamparum* using external and cranial measurements. Maia (1984) reported a $2n = 64$, $FN = 116$, karyotype from Pernambuco composed of 27 pairs of biarmed and four pairs of acrocentric chromosomes; the X chromosome was submetacentric.

C. a. guianae Thomas, 1901

SYNONYMS:

[*Cavia*] *porcellus*: E.-L. Trouessart, 1897:637; part; name combination.

Cavia porcellus guianae Thomas, 1901e:152; type locality “Four skins of different ages from the Kanuku Mountains, 7th and 8th December, 600 feet, and one from Berbice, on the coast.” Restricted to “Kanuku Mountains, 600 feet” by Husson (1978) as the holotype originates from that locality; Upper Takutu–Upper Essequibo, Guyana.

C[*avia*]. *leucopyga*: Cabanis, 1848:780; not *Cavia leucopyga* Brandt; name combination.

[*Cavia rufescens*] *guianae*: E.-L. Trouessart, 1904:525; name combination.

Cavia porcellus venezuelae J. A. Allen, 1911:250; type locality “Altagracia, Immatataca district, Venezuela,” Bolívar.

C[*avia*]. *rufescens venezuelae*: Osgood, 1915:195; name combination.

Cavia guianae: Thomas, 1917a:153; name combination.

Cavia aperea guianae: Hückinghaus, 1961a:58; first use of current name combination.

Cavia guianae caripensis Ojasti, 1964:148; type locality “Sabana de Piedras, Caripe, Estado Monagas, Venezuela; 1100 m alt.”

Cavia aperea caripensis: O. J. Linares, 1998:209; name combination.

This subspecies occurs north of the Amazon Basin in Surinam, the Guianas, Venezuela, and lowland Colombia.

In his original description, Thomas (1901e:152) considered *guianae* a subspecies of *C. porcellus*, but he elevated it to full species in his 1917 revision of *Cavia*. Cabrera (1961) included it in *C. porcellus*. Husson (1978:451) stated “since the relationship between wild and domestic forms is not quite clear, I prefer to reserve the name *C. porcellus* (Linnaeus, 1758) for the domestic form and to treat the wild forms as distinct species.” He followed Hückinghaus (1961a), who considered the Guianan form to be a subspecies of *C. aperea* Erxleben. Woods (1993) also followed Hückinghaus (1961a:58); however, Corbet and Hill (1991:201) listed *guianae* Thomas as a distinct species. Nowak (1999) wrote “information presented by Woods (1993) and Eisenberg (1989) suggests that the populations of *C. aperea* in Ecuador and Surinam, as well as the entire species *C. anolaimae* and *C. guianae*, may represent feral domestic guinea pigs.” Zúñiga (2000) and Zúñiga et al. (2002) compared populations of Colombian *Cavia* and recognized *guianae* as distinct from *anolaimae* J. A. Allen and *porcellus* Linnaeus, based on karyological and morphologic data. Phylogenetic analyses based on molecular data (Dunnun 2003; Dunnun and Salazar-Bravo 2010a) supported placement within the *aperea* complex.

C. a. hypoleuca Cabrera, 1953

SYNONYMS:

- Cavia aperea hypoleuca* Cabrera, 1953:58; type locality “Paso de la Patria, Corrientes,” Argentina.
- Cavia cobaya*: Moreau de Saint Mery, in Azara, 1801:65; name combination, but not *cobaya* Pallas.
- Cavia aperea*: Rengger, 1830:274; name combination, but not *aperea* Erxleben.
- [*Cavia*] *leucopyga*: E.-L. Trouessart, 1880b:194; part; name combination.
- [*Cavia*] *porcellus*: E.-L. Trouessart, 1897:637; part; name combination.
- [*Cavia*] *rufescens*: E.-L. Trouessart, 1904:525; part; name combination.
- Cavia azarae*: Thomas, 1901g:534; name combination, but not *azarae* Lichtenstein [Dasyproctidae].
- Cavia porcellus aperea*: Bertoni, 1914a:74; name combination.
- Cavia rufescens pamparum*: J. A. Allen, 1916d:567; name combination, but not *pamparum* Thomas.
- Cavia aperea azarae*: Thomas, 1917a:154; name combination.

This subspecies occurs in Paraguay and northern Argentina.

Thomas (1901g, 1917a), in referring to Paraguayan specimens, erroneously assumed that *C. azarae* Wagner was based upon the Paraguayan “*Aperea*” of Azara (1801). Cabrera (1953) thus placed *C. azarae*, in the sense

of Thomas (1901g), in synonymy of *C. a. hypoleuca*. See Ximénez (1980:152–153) and Tate (1935:343) for more discussion on *C. azarae*. Ximénez (1980:152) could find no differences between *C. a. hypoleuca* and *C. a. pamparum*. *Cavia a. hypoleuca* forms a clade with the lowland Bolivian *C. a. aperea*, which in turn is sister to *C. a. pamparum* (Dunnun and Salazar-Bravo 2010a).

C. a. nana (Thomas, 1917)

SYNONYMS:

- Cavia nana* Thomas, 1917a:158; type locality “Chulumani, Yungas, 2000 m,” La Paz, Bolivia.
- Cavia aperea sodalis*: Hückinghaus, 1961a:57; part; name combination.
- Cavia tschudii sodalis*: Cabrera, 1961:579; part; name combination.
- Cavia tschudii nana*: S. Anderson, 1997:480; part; name combination.
- Cavia tschudi nana*: Salazar-Bravo, Tarifa, Aguirre, Yensen, and Yates, 2003:10; part.
- [*Cavia*]. [*a*]. [*perea*]. *nana*: Dunnun and Salazar-Bravo, 2010a:5; first use of current name combination.

This subspecies occurs in the Yungas of central Bolivia along the eastern slope of the Andes. The northern and southern extent of its distribution is unresolved.

Cabrera (1961) recognized *nana* as a valid species, as did Corbet and Hill (1991) and Novak (1999). Hückinghaus (1961a) believed *nana* and *C. t. sodalis* to be synonymous (as did Cabrera 1953) and included both under the name *C. aperea sodalis*. Woods (1993) followed Hückinghaus (1961a) and included *nana* in *C. aperea*. Most recently, Woods and Kilpatrick (2005) included *nana* in the synonymy of *tschudii*. However, molecular (Dunnun 2003; Dunnun and Salazar-Bravo 2010a) and karyological ($2n = 64$, FN = 114; Dunnun and Salazar-Bravo 2006) data supported inclusion within *aperea*. Dunnun and Salazar-Bravo (2010a) found this Bolivian Andean subspecies to be sister to the *aperea* clade north of the Amazon as opposed to the lowland Bolivian clade, suggesting a possible prior Andean corridor linking the disjunct populations of *aperea* north and south of the Amazon.

C. a. pamparum (Thomas, 1901)

SYNONYMS:

- Cavia cobaia* Waterhouse, 1839:89; part; not *C. cobaya* Pallas, 1766; new name for *aperea* Erxleben.
- Cavia aperea*: Waterhouse, 1848:185; part; name combination.
- Cavia leucopyga*: Burmeister, 1861:424; name combination, but not *Cavia leucopyga* Brandt.
- Cavia australis*: Arechavaleta, 1882; name combination, but not *Cavia australis* I. Geoffroy St.-Hilaire and d’Orbigny.

[*Cavia*] *porcellus*: E.-L. Trouessart, 1897:637; part; name combination; not *Mus porcellus* Linnaeus.

Cavia porcella: Ameghino, 1898:183; name combination and incorrect gender agreement of *porcellus* Linnaeus; not *Mus porcellus* Linnaeus.

Cavia rufescens pamparum Thomas, 1901h:538; type locality "Goyas [= Goya], Corrientes," Argentina.

Cavia pamparum: Thomas, 1917a:155; name combination.

Cavia aperea pamparum: Hückinghaus, 1961a:57; first use of current name combination.

This subspecies occurs in eastern Argentina, Uruguay, and southern Brazil.

Cabrera (1961) recognized *C. pamparum* as a valid species while Hückinghaus (1961b) included it as a subspecies of *C. aperea*. Massoia and Fornes (1967a) revalidated the synonymy of *C. pamparum* Thomas and *C. aperea* Erxleben. Molecular sequence data support its subspecies status within *aperea* and a sister relationship with the lowland Bolivian *aperea* and *C. a. hypoleuca* of Paraguay (Dunnum and Salazar-Bravo 2010a). Various authors (e.g., Massoia 1973b; Ximénez 1980) supported the subspecific designation of *C. a. pamparum* and provided distribution maps. J. R. Contreras (1972, 1980) described distributional range extensions and new records. W. George et al. (1972) and Pantaleão (1978) reported identical karyotypes ($2n = 64$, FN = 124) from Entre Rios, Argentina, and Paraná and Rio de Janeiro, Brazil.

C. a. rosida Thomas, 1917

SYNONYMS:

Cavia rosida Thomas, 1917a:154; type locality "Roca Nova. Alt. 1000 m," Serra do Mar, Paraná, Brazil.

Cavia aperea rosida: Cabrera, 1961:577; first use of current name combination.

This subspecies is known only from the Serra do Mar in eastern Paraná state, Brazil.

NATURAL HISTORY: *Cavia aperea* are primarily grazers but will eat grass inflorescences as well. Individuals typically forage in open areas close to shelter. They do not excavate burrows but make interconnecting surface tunnels and runs in the vegetation (Eisenberg and Redford 1999). In Parque Nacional Noel Kempff Mercado [NKM, Santa Cruz, Bolivia], cavys were collected in both Sherman and Tomahawk traps along clear runs and tunnels in the grasses of the wet savannas (grasses about 2 feet high) near "Los Fierros" (J. Dunnum, pers. obs.). Emmons et al. (2006) reported that individuals are found in the upland savannas and grasslands of NKM, which experience brief, shallow flooding, and that they constitute a main prey item of the Maned wolf (*Chrysocyon brachyurus*). In the cerrado of Brazil, *C. aperea* occupied the gallery forest and flooded areas near forest and foraged in the grassy fields in the early evening (Alho et al. 1987).

Individuals of *Cavia a. anolaimae* are diurnal, active primarily in the mornings and evenings. It apparently reproduces year-round as pregnant females and reproductive males have been collected through the year. Females averaged one to three embryos, but all animals close to term except one had a single embryo, the other embryos likely having been reabsorbed. Two pairs of inguinal mammae are present. Avian predators include Black-crested Buzzard Eagle (*Geranoaetus melanoleucus*) and hawks of the genus *Buteo*; known mammalian predators are *Cerdocyon thous*, *Mustela frenata*, *Nasua nasua*, domestic dogs, and man.

At the type locality of *C. a. nana*, I observed Pygmy cavies in the early mornings and evenings grazing in grassy areas. Well-developed runs were evident going from grassy areas into dense shrubby vegetation. I never observed cavies venturing far from protected areas, and they retreated quickly when disturbed.

Cavia aperea has a polygynous social and mating system, with linear dominance hierarchies within each sex (Rood 1972; Sachser et al. 1999). Asher et al. (2004) investigated a wild population exhibiting a system of single males with one to two females occupying stable home ranges (880 ± 217 m² for males and 549 ± 218 m² for females) based on resource availability. In the moist savannas of the Atlantic coast in Rocha department, Uruguay, densities ranged from 27–32 adults/ha. Male home ranges overlapped multiple female ranges. Strong sexual dimorphism existed in the investigated cavy population. Adult males were 17% heavier overall than adult, nonpregnant females. Resident males were 32% heavier than females, 18% heavier than roaming males, and 56% heavier than satellite males. Roaming and satellite males did not differ in weight from females (Asher et al. 2008). Asher et al. (2004) and Rood (1972) reported population densities that ranged from 12.5 individuals/ha in Brazil to 38 individuals/ha in Argentina. Activity periods were highest between 07:00–11:00 and 17:30–20:00 hours. This species exhibits strong sexual dimorphism with males 11–14% heavier than females (Sachser 1998; Asher et al. 2004). Rood (1972) reported individual swimming ability of several kilometers during floods. Captive populations derived from Argentinean stock exhibited a wide acoustic repertoire of ten different call types (Monticelli and Ades 2013).

REMARKS: The specific name *aperea* Erxleben is conserved for this wild form although it is predated by *porcellus* Linnaeus, which is based on the domestic form (ICZN 2003). Furthermore, molecular sequence data do not support *C. aperea* as the source of domestication (Dunnum 2003; Spatorno, Valladares, Marín, and Zeballos 2004; Dunnum and Salazar-Bravo 2010a). Hadler et al. (2008) recorded Mid to Late Holocene fossils from Rio Grande do Sul state, Brazil.

Karyotypes consist of $2n = 64$, with reported FN = 96 (Zúñiga 2000, for individuals of the nominotypical subspe-

Map 370 Selected localities for *Cavia aperea* (●). Contour line = 2,000 m.

cies), 114 (Dunnum and Salazar-Bravo 2006), 116 (Maia 1984), and 124 (W. George et al. 1972; Gava et al. 1998).

Cavia fulgida Wagler, 1831

Shiny Guinea Pig

SYNONYMS:

Cavia fulgida Wagler, 1831a:511 footnote; type locality “Herr von Spix von seiner Reise am Amazonenstrom zurückbrachte,” (likely an error as the species does not occur in the Amazon Basin; see Thomas 1917a:159; Cabrera 1961:577).

Cavia obscura Lichtenstein, 1823:3; *nomen nudum*.

Cavia rufescens Lund, 1839b:206; type locality “bassin du Rio das Velhas,” Lagoa Santa, Minas Gerais, Brazil.

C[avia]. nigricans Wagner, 1844:64; type locality “Als Heimath ist Brasilien angeben”; a redescription of *C. obscura* Lichtenstein.

Kerodon obscurus: Wagner, 1844:64; name combination.

C[avia]. aperea: Giebel, 1855:459; name combination.

Prea obscura: Lias, 1872:541; part; name combination.

Prea rufescens: Lias, 1872:541; name combination.

Prea fulgida: Lias, 1872:541; name combination.

[Cavia fulgida] rufescens: E.-L. Trouessart, 1880b:194; name combination.

DESCRIPTION: Dorsal color rich grizzled reddish-brown, ventral color deep buffy or ochraceous. Relatively

small cavy, with greatest length of skull rarely exceeding 60 mm. Only species in genus diagnosable by consistent dental character: deep notch on outer (labial) side of anterior end of posterior lobe of M3 (Thomas 1917a).

DISTRIBUTION: *Cavia fulgida* is known from the eastern coast of Brazil from Lagoa Santa, Minas Gerais, to Santa Catarina (Thomas 1917a; Ximénez 1980; Woods 1993).

SELECTED LOCALITIES (Map 371): BRAZIL: Bahia, Caravelas (Ximénez 1980), Vitória da Conquista (Ximénez 1980); Espírito Santo, Santa Teresa (Ximénez 1980); Minas Gerais, Alem Paraíba (Ximénez 1980), Parque Estadual do Rio Doce (Stallings 1989), Poços de Caldas (Cherem et al. 1999); Paraná, Estação de Roça Nova (Cherem et al. 1999); Santa Catarina, Rancho Queimado (Cherem et al. 1999); São Paulo, Ubatuba (Ximénez 1980).

SUBSPECIES: *Cavia fulgida* is monotypic.

NATURAL HISTORY: Eisenberg and Redford (1999) stated that this species does not overlap in range with *C. magna* but is sympatric with *C. aperea*. Myers and Hanson (1980) reported their presence along with *Oxymycterus roberti* and *Necomys lasiurus* in the Parque Nacional de Brasília in flooded (3–4 cm deep) marshland dominated by perennial bunch grass of 53 cm in height. This species is the prey of Crab-eating raccoons, *Procyon cancrivorus*, in the coastal plains of Espírito Santo state (Gatti et al. 2006).

Map 371 Selected localities for *Cavia fulgida* (●).

REMARKS: Lund (1839b) described *Cavia rufescens* among the extant (“*vivans*”) mammals of the Lagoa Santa region as a small and reddish (“*plus petit, rougeâtre*”) species; he subsequently (1841c, plate 25, Fig. 15) illustrated the last upper right molar. These characteristics match those of Wagler’s *C. fulgida*, described eight years earlier.

Pantaleão (1978) reported a karyotype of $2n = 64$, FN = 124.

Cavia intermedia Cherem, Olimpio, and Ximénez, 1999
Intermediate Guinea Pig

SYNONYMS:

Cavia aff. *magna*: Gava, Freitas, and Olimpio, 1998:77; not *magna* Ximénez.

Cavia intermedia Cherem, Olimpio, and Ximénez, 1999: 100; type locality “A major das três ilhas que formam o Arquipélago de Moleques do Sul, a 27°51’S, e 48°26’W,” Santa Catarina, Brazil.

DESCRIPTION: *Cavia intermedia* intermediate color and size between *C. aperea* and *C. magna*. Dorsal pelage gray basally and tipped with bands of black, yellow, or both; darker medial line runs from head to rump; ventral pelage gray basally with dull yellow tips; white patch present in throat area. Enlarged interdigital membranes present on hindfeet, as in *C. magna*. Cranially *C. intermedia* differs from other Brazilian *Cavia* by flat sagittal crest, large occipital condyles, broad foramen magnum, shallow labial notch on second prism of upper molars, prisms of lower premolar of similar width, and first prism of last mandibular molar wider than second with small lingual notch on latter prism (Cherem et al. 1999).

DISTRIBUTION: *Cavia intermedia* is known only from the type locality.

SELECTED LOCALITIES (Map 372): BRAZIL: Santa Catarina, Ilhas Moleques do Sul (type locality of *Cavia intermedia* Cherem, Olimpio, and Ximénez).

SUBSPECIES: *Cavia intermedia* is monotypic.

NATURAL HISTORY: This is a predominantly nocturnal herbivore, a major portion of its diet consists of the grasses *Stenotaphrum secundatum* and *Paspalum vaginatum*. Four females collected in May were all lactating (Cherem et al. 1999). Salvador and Fernandez (2008a) examined population dynamics and conservation status, and suggested that the species may be one of the rarest species on the planet and should be listed as critically endangered. Females were reproductively active throughout the year. Litter size was small (one or two young per litter), with well-developed offspring that weighed approximately 19% of the mass of an adult female. Sexual maturity was reached later than in other species of this genus, at around 59 days of age or 70% of adult body size (Salvador and Fernandez 2008b).

Map 372 Selected localities for *Cavia intermedia* (■) and *Cavia magna* (●).

REMARKS: Cherem et al. (1999) suggested that the species may have originated as an insular population derived from the mainland *C. magna* as little as 8,000 years ago. *Cavia intermedia* is one of two species in the genus with a diploid number other than 64 ($2n = 62$, FN = 108; see account for *C. patzelti*). The autosomal complement has 24 biarmed pairs and six acrocentric pairs. The sex chromosomes include a large metacentric X and a large acrocentric Y (Gava et al. 1998).

Cavia magna Ximénez, 1980
Greater Guinea Pig

SYNONYMS:

Cavia aperea rosida: Ximénez, 1967:1; name combination, but not *rosida* Thomas.

Cavia pamparum: Barlow, 1969:43; part; name combination.

Cavia magna Ximénez, 1980:148; type locality “En las orillas del arroyo Imbé, municipio de Tramandaí, estado de Rio Grande del Sur, Brasil.”

DESCRIPTION: Largest species in genus (head and body length 310 mm, hindfoot length 52.6 mm, ear length 26.4 mm, and mass 635 g; Ximénez 1980). Dark agouti brown dorsally and reddish ventrally. Semiaquatic with enlarged interdigital membranes.

DISTRIBUTION: *Cavia magna* occurs in the coastal marshes of extreme southeastern Brazil and eastern Uruguay, from Rocha department (34°S, 54°W) in the south

extending north along the littoral zone through Rio Grande do Sul and Santa Catarina states as far as the city of Circuma (29°S, 49°W; Ximénez 1980; Eisenberg and Redford 1999; E. M. González 2001).

SELECTED LOCALITIES (Map 372): BRAZIL: Rio Grande do Sul, Ilha Marinheiros (Gava et al. 2012), Tramandaí (Cherem et al. 1999); Santa Catarina, Palhoça (Cherem et al. 1999). URUGUAY: Rocha, Parque Nacional Refugio de Fauna Laguna de Castillos (Trillmich et al. 2004).

SUBSPECIES: *Cavia magna* is monotypic.

NATURAL HISTORY: This species occupies mesic grasslands and marshes where individuals use complex networks of tunnels and runs. *Cavia magna* has a solitary social system and overlap promiscuity is the likely mating system (Kraus et al. 2003). Home ranges showed very little stability, and range size was correlated with sex, body size, and water level. The gestation period is 64 days. Reproduction occurred year-round but was concentrated in the spring and early summer (Kraus et al. 2003). Among the Caviinae, *C. magna* is particularly precocial, with individual neonates weighing on average 18% of maternal mass. Individual females produced on average three litters per year. Some females born in early spring conceived successfully between the age of 30 and 45 days (Kraus et al. 2005).

REMARKS: Pantaleão (1978) reported a karyotype from mainland Brazil ($2n = 64$, FN = 124). Gava et al. (2012) found a $2n = 62$, FN = 102, karyotype in an isolated island population. This represents the first case of intraspecific diploid number variation within the Caviidae and provides further support for the sister relationship between *C. magna* and the insular *C. intermedia*, which also has $2n = 62$. Dunnun and Salazar-Bravo (2010a) found that the *C. magna* lineage represented the first split among the living *Cavia* species, diverging around 6.7 mya. This species is known from Holocene deposits in Rio Grande do Sul state, Brazil (Hadler et al. 2008).

Cavia patzelti Schliemann, 1982

Sacha Guinea Pig

SYNONYMS:

Cavia aperea patzelti Schliemann, 1982:81; type locality “Hochkordillere von Alao, Provinz Chimborazo, Ecuador,” Alao, Chimborazo, Ecuador.

Cavia patzelti: Dunnun and Salazar-Bravo, 2010a:5; first use of current name combination.

DESCRIPTION: General dorsal coloration of body and head dark reddish brown; hairs with pale apical bands with only short dark tips. Skull very long and wide, wider in all respects than specimens from Colombia and Peru, particularly so for rostrum and maxilla at M3. Maxillary toothrow especially long, between 16.8–18.7 mm. Head and body length 280–290 mm, hindfoot length from 46–

Map 373 Selected localities for *Cavia patzelti* (●). Contour line = 2,000 m.

50 mm, mean ear length 50 mm, greatest length of skull 63–69 mm, and mass 700–725 g (Schliemann 1982).

DISTRIBUTION: This species is restricted to the highlands of Chimborazo, Ecuador, where it is known only from the type locality; specimens exist only from the type locality but observational records suggest a wider distribution.

SELECTED LOCALITIES (Map 373): ECUADOR: Chimborazo, Alao (type locality of *Cavia aperea patzelti* Schliemann; see Paynter 1993).

NATURAL HISTORY: The type locality is in the páramo between 3,000–3,800 m in an area composed of wide marshy areas and steep grassy slopes; individuals were taken in the moist hollows. The vegetation is dominated by grass of the genus *Stipa*, various shrubs in the families Asteraceae (*Chiquiragua* sp.), Ericaceae, and Hypericaceae (*Hypericum* sp.) as well as *Polylepis* (Rosaceae) forest (Schliemann 1982).

REMARKS: In his description, Schliemann (1982) reported large morphological differences in comparisons with other *Cavia* taxa. However, he assigned the specific epithet *aperea* to this cavy, following Hückinghaus (1961a) who included all highland *Cavia* in *aperea*. Molecular (Dunnun and Salazar-Bravo 2010a) and karyological ($2n = 56$; Lobato and Araujo 1980) data support the species status.

Cavia porcellus (Linnaeus, 1758)

Domestic Guinea Pig

SYNONYMS:

Mus porcellus Linnaeus, 1758:59; type locality “Brasilía,” based on the *Cavia cobaya* of Marcgraf (1648:224).

Cavia cobaya Pallas, 1766:31; type locality “Brazil.”

[*Cavia*] *porcellus*: Erxleben, 1777:349; first use of current name combination.

Prea cobaya: Liais, 1872:541; name combination.

Lepus Minimus G. I. Molina, 1782:306; but see Tate (1935:344), who believed this taxon to possibly be a *Galea*, and Ellerman (1940:243), who listed it as a valid species of *Galea*.

Calva cobaya: Gmelin, 1788:122; name combination.

[*Scavia*] *porcellus*: Blumenbach, 1797:80; name combination.

S[*avia*]. *cobaya*: Treviranus, 1802:211; name combination.

Agouti cobaya: Daudin, 1802:166; name combination.

Hydrochoerus cobaya: É. Geoffroy St.-Hilaire, 1803:163; name combination.

Hydrochaerus cobaya: G. Fischer, 1814:593; name combination.

Savia Cavia porcellus: Oken, 1816:824; name combination, but unavailable (ICZN 1956).

Coiza porcellus: Billberg, 1827:45; name combination.

[*Cavia aperea*] *porcellus*: J. B. Fischer, 1829:383; name combination.

Anoema Cobaya: Poeppig, in Froriep, 1829:279, footnote; name combination.

Cavia cutleri Bennett, 1836:191; type locality "Chile."

Cavia cobaia: Poeppig, 1836:45; name combination.

[*Cavia cobaya*] *alba* Fitzinger, 1867b:155; type locality "Eur," *Cavia porcellus* var. *alba* Erxleben, introduced.

Cavia cobaya helvola Fitzinger, 1867b:155; type locality "Eur," introduced.

[*Cavia cobaya*] *nigra* Fitzinger, 1867b:155; type locality "Eur," introduced.

Cavia cobaya longipilis Fitzinger, 1880:431; type locality "Japan," introduced.

Prea cobaya: Liais, 1872:541; name combination.

[*Cavia cutleri*] *cobaya*: E.-L. Trouessart, 1897:638; name combination, but not *cutleri* Tschudi.

[*Cavia brasiliensis*: E.-L. Trouessart, 1897:637; name combination, republication of invalid pre-Linnaean name (ICZN 1910)

Mamcaviaus cobaya: A. L. Herrera, 1899:13; name combination.

Cavia porcellus porcellus: Cabrera, 1961:578; name combination.

DESCRIPTION: General characteristics as for genus but wide range of colors, hair lengths, and sizes due to breeding for specific traits. Pelage ranges from brown, tan, black, reddish, white, or combinations of those colors. Mass reaches 1,200 g, and overall length ranges 200–500 mm.

DISTRIBUTION: Worldwide as a domestic animal (not mapped).

NATURAL HISTORY: Domesticated in pre-Columbian times by Amerindian peoples (Wing 1986), *Cavia porcel-*

lus now occupies human inhabited areas throughout South America and still serves an important role in native religion, folk medicine, and as a food source in Andean countries. This species is domesticated worldwide as a pet and laboratory animal. The domestication process was likely the result of a single ancient event in the western Andes, followed by multiple modern events from the sixteenth century on leading to the various strains seen today (Spotorno, Valladares, Marín, and Zeballos 2004; Spotorno et al. 2006, 2007). Pigière et al. (2012) reported on archaeological finds and radiocarbon dating of guinea pigs from Europe, suggesting multiple importations by Spanish and Dutch during the 1500s. Three currently recognized wild forms (*C. aperea*, *C. tschudii*, and *C. fulgida*) have at one time been proposed as the possible ancestral form. The characteristics of the M3 (Hückinghaus 1961b), production of infertile males from *porcellus* × *fulgida* crosses (Dettelson 1914), and molecular data (Dunnum 2003; Dunnum and Salazar-Bravo 2010a) are sufficient to eliminate *C. fulgida* as a likely ancestor. Fertile hybrids have been produced in crosses of *porcellus* to both *tschudii* (Weir 1974c) and *aperea* (Trillmich et al. 2004), but molecular data place *porcellus* solidly within *C. tschudii* (Dunnum 2003; Spotorno, Valladares, Marín, and Zeballos 2004; Dunnum and Salazar-Bravo 2010a). Spotorno et al. (2007) suggested two potential points of domestication: southern Peru and the highlands of Colombia. They also noted that examination of archaeological material from Tequendama, near Bogota in Colombia, was warranted as another potential region for initial domestication. Analyses including all potential progenitors from a broad geographic distribution supported an initial derivation from *C. tschudii* populations in the region of Ica, Peru (Dunnum and Salazar-Bravo 2010a), an area where the oldest archaeological site containing guinea pig remains (Ayamachay) is located (Sandweiss and Wing 1997).

Sachser (1986) found long-lasting relationships between individual males and females and a polygynous mating system, with resource availability critical in defining social organization.

REMARKS: Thomas (1901g:533) restricted *porcellus* Linnaeus to include only the domestic form. Subsequently, the International Commission (ICZN 2003) conserved the name *C. porcellus* for the domestic form, although incorrectly assuming *C. aperea* to be the wild progenitor. The domesticated form is included here as a species to maintain taxonomic stability, although it is clear that it is derived from *C. tschudii*. The type locality "Brasilia" for the domestic form is certainly in error (Cabrera 1961), and no type specimen exists. Ellerman (1940) included the fossil taxa *C. gracilis* (Lund, 1839b), *C. apereoides* (Lund, 1840b [1841c]), and *C. robusta* (Lund, 1842), all from Lagoa

Santa, Brazil (the first and third being *nomina nuda*), in the synonymy of *porcellus* Linnaeus. Cabrera (1961:578) suggested that the evidence for this placement was tentative at best, and our current knowledge of the group would suggest these are not referable to the domestic *C. porcellus* or its progenitor *C. tschudii* but likely to *C. aperea*. The correct assignment of Molina's Cuy, *Lepus minimus*, is in doubt. No type specimen exists, and the description is inadequate for an unambiguous decision. Tate (1935:344) regarded it as "apparently a cavy, either of the genus *Cavia* or *Galea*, and more probably the latter." Ellerman (1940) listed it as a valid species of *Galea*. But Cabrera (1961) listed it as a synonym of *Cavia p. porcellus*. I follow Cabrera.

The karyotype consists of $2n = 64$, $FN = 90$, 94 (Awa et al. 1959; Cohen and Pinsky 1966).

Cavia tschudii Fitzinger, 1867

Montane Guinea Pig

SYNONYMS: See under Subspecies.

DESCRIPTION: Body size and dorsal pelage color vary greatly geographically. The Peruvian forms vary from grizzled cinnamon in *C. t. tschudii* and *C. t. festina*, to dark reddish brown in *C. t. osgoodi*, dark olive brown in *C. t. stolidi*, and grizzled gray to blackish in *C. t. umbrata*. Subspecies *C. t. atahualpae* large and dark, with upper parts grizzled cinnamon and blackish, bases of hair broadly dark drab, followed by two or more cinnamon and blackish annulations, sides and lateral parts only slightly paler than back, throat mixed cinnamon and blackish, not different from dorsal area, chin and submaxillary region buffy, forefeet and hindfeet grizzled pale drab, ears thinly haired blackish and not contrasting with surrounding parts, and without a definite eye-ring (Osgood 1913). Specimens assigned to *C. t. sodalis* from Argentina and Bolivia much paler brown; ventral coloration v whitish to gray to buffy. Skull length 59–69 mm (Thomas 1917a, 1926d, 1926g, 1927f; Sanborn 1949a). In *C. t. festina* chin, chest, and venter ochraceous buffy, and collar below neck brown and well marked. Dimensions of holotype head and body length 272 mm, hindfoot length 47 mm, ear length 26 mm, and greatest skull length 69 mm (Thomas 1927f). Venter of *C. t. sodalis* decidedly paler than other subspecies, being almost white. Dimensions of holotype head and body length 218 mm, hindfoot length 36.5 mm, ear length 35 mm, and greatest skull length 55 mm (Thomas 1926d). In *C. t. stolidi*, venter dull soiled buffy color; feet grizzled brown with lighter digits. Skull broad and heavy, nasals particularly broad, exceeding that of all other forms. Dimensions of holotype head and body length 313 mm, hindfoot length 49 mm, ear length 29 mm, greatest skull length 63 mm, zygomatic breadth 39.3 mm, interorbital breadth 17 mm, and

breadth of braincase 25.8 mm (Thomas 1926g). Individuals of *C. t. umbrata* differ from other subspecies by grayer color throughout with rings on hairs whitish instead of cinnamon or buffy; median area of back blackish due to reduction of light-colored rings to about 1 mm in length as opposed to 3–4 mm in other subspecies; venter soiled drab, collar and middle line of chin grayish brown; feet pale brown. Dimensions of holotype hindfoot length 42 mm, ear length 20 mm, and greatest skull length 60 mm (Thomas 1917a). Nominotypical subspecies fairly dark, strongly grizzled dorsally with light rings on hairs being buffy or cinnamon; median area of back not darkened; venter strongly buffy. Skull length 59–61 mm (Thomas 1917a). Subspecies *pallidior* similar to nominotypical subspecies but color much lighter, pale rings on hairs paler buffy, and venter pale creamy buff approaching whitish; collar gray and hands and feet buffy whitish and slightly browner proximally. Dimensions of holotype head and body length 242 mm, hindfoot length 24 mm, ear length 29 mm, and greatest skull length 59.5 mm (Thomas 1917a).

DISTRIBUTION: *Cavia tschudii* is known from the highlands and Pacific coast of Peru, south through the Altiplano of Bolivia, northern Chile, and the Andes of northern Argentina, across an elevational range from sea level to 4,500 m.

SELECTED LOCALITIES (Map 374): ARGENTINA: Catamarca, Highway 4, 10 km S of El Rodeo (P. E. Ortiz and Jayat 2012a); Tucumán, Concepción (type locality of *Cavia tschudii sodalis* Thomas). BOLIVIA: La Paz, Río Desaguadero (S. Anderson 1997); Santa Cruz, 3 km N by road of Torrecillas (S. Anderson 1997); Tarija, Entre Rios (S. Anderson 1997). CHILE: Arica y Parinacota, Valle de Azapa. PERU: Amazonas, Río Utcubamba, about 15 mi S of Chachapoyas (type locality of *Cavia tschudii stolidi* Thomas); Arequipa, Tambo (Thomas 1917a); Cajamarca, Cajamarca (type locality of *Cavia tschudii atahualpae* Osgood); Cusco, Urubamba (Thomas 1917a); Ica, 70 mi E of Pisco (type locality of *Cavia tschudii* Fitzinger); Junín, Incapirca, Zezioro (type locality of *Cavia tschudii umbrata* Thomas); La Libertad, Mashua, east of Tayabamba on trail to Ongón (LSUMZ 24845); Puno, Limbani (type locality of *Cavia tschudii osgoodi* Sanborn).

SUBSPECIES: I tentatively recognize eight subspecies within *C. tschudii* pending further revision.

C. t. atahualpae Osgood, 1913

SYNONYMS:

Cavia atahualpae Osgood, 1913:98; type locality "Cajamarca, [Cajamarca,] Peru. Alt. 9100 ft."

Cavia tschudii atahualpae: Thomas, 1917a:156; first use of current name combination.

Cavia aperea tschudii: Hückinghaus, 1961a; part; name combination.

This subspecies occurs in the interandean valleys of northern Peru.

Cabrera (1961) included *stolida* Thomas in the synonymy of *C. t. atahualpae*, a taxon I regard as a valid subspecies herein.

C. t. festina Thomas, 1927

SYNONYMS:

Cavia tschudii festina Thomas, 1927f:604; type locality "Huariaca, Junin, 9000'," Peru.

Cavia tschudii umbrata: Cabrera, 1961:580; name combination.

Cavia aperea festina: Hückinghaus, 1961a:57; name combination.

This subspecies occurs in the Andes of central Peru, in Junín department.

Woods and Kilpatrick (2005) included *umbrata* in the nominotypical subspecies. Cabrera (1961) considered *festina* Thomas a synonym of *C. t. umbrata* Thomas.

C. t. osgoodi Sanborn, 1949

SYNONYMS:

Cavia tschudii osgoodi Sanborn, 1949a:133; type locality "Limbaní, 12,000 feet, District Limbaní, Province Sandía, Department Puno, Peru."

C. aperea osgoodi: Hückinghaus, 1961a:57; name combination.

This subspecies is known from the Altiplano of southern Peru, north of Lake Titicaca.

C. t. pallidior Thomas, 1917

SYNONYMS:

Cavia tschudii pallidior Thomas, 1917a:158; type locality "Arequipa, 2500m," Peru; not *Kerodon niata pallidior* Thomas [= *Cavia* (*Monticavia*) *niata pallidior*, = *Microcavia niata*; see Osgood (1919:34) and *Microcavia* account].

Cavia tschudii arequipae Osgood, 1919:34; new name for *C. t. pallidior* Thomas.

Cavia tschudii tschudii: Sanborn, 1949a:133; name combination.

Cavia tschudii nana: S. Anderson, 1997:479; part; name combination.

This subspecies occurs from lowland northern Chile and southern Peru into the highlands of Bolivia.

Osgood (1919:34) proposed *arequipae* as a replacement name for *pallidior* Thomas on the grounds that "if *Monticavia* be regarded as no more than a subgenus of *Cavia*, then *C. t. pallidior* Thomas, 1917 is preoccupied

by *K[erodon]. N[iata]. pallidior* Thomas, 1902, and requires a new name. Mr. Thomas, who proposed both names, treats *Monticavia* as a full genus and therefore would make no change." *Monticavia* is now regarded as a synonym of *Microcavia* (C. A. Quintana 1996; Woods and Kilpatrick 2005), thus validating Thomas's original proposal and making Osgood's *arequipae* an objective synonym of *pallidior* Thomas. Sanborn (1949a:133) synonymized *pallidior* Thomas (renamed *arequipae* by Osgood) with *C. t. tschudii* while Woods and Kilpatrick (2005) regarded *arequipae*, but not *pallidior*, as a valid subspecies. S. Anderson (1997) incorrectly referred all Bolivian specimens to *C. tschudii nana* (= *Cavia nana* Thomas, which herein is regarded as a valid subspecies of *C. aperea*; see account of that species). The specimens that Anderson examined, therefore, comprise two separate species. Pine et al. (1979) referred Chilean specimens to the nominotypical subspecies. However, Chilean specimens from Valle de Lluta formed a clade with those from Arequipa, Peru, and highland Santa Cruz, Bolivia (Dunnun and Salazar-Bravo 2010a).

C. t. sodalis Thomas, 1926

SYNONYMS:

Cavia tschudii sodalis Thomas, 1926d:607; type locality "Ñorco, Vivos, 2500m," Tucumán, Argentina.

Cavia tschudii pallidior: Thomas, 1925b:580; name combination, but not *pallidior* Thomas.

Cavia aperea sodalis: Hückinghaus, 1961a:57; name combination.

This subspecies minimally occurs in the higher elevations of Tucumán and Jujuy provinces in northern Argentina, and historically occurred in southwest Salta, Argentina (Tonni 1984). The taxonomic status of *Cavia* populations in Tarija department in extreme southern Bolivia is in need of further investigation.

C. t. stolida Thomas, 1926

SYNONYMS:

Cavia tschudii stolida Thomas, 1926g:166; type locality "Rio Utcubamba, 8500'," about 15 miles south of Chachapoyas (Thomas 1926g:157), Amazonas, Peru.

Cavia stolida: Hückinghaus, 1961a:58; name combination.

Cavia tschudii atahualpae: Cabrera, 1961:579; part (*stolida* Thomas listed as synonym of *atahualpae* Osgood).

This subspecies is known from the Utcubamba Valley in northwestern Peru.

Cabrera (1961) synonymized *stolida* Thomas with *atahualpae* Osgood. Hückinghaus (1961a) considered *stolida* a valid species. Woods (1993) included it in the synonymy of *C. tschudii*.

C. t. tschudii Fitzinger, 1867

SYNONYMS:

Cavia cutleri Tschudi, 1845:195; type locality “in der Umgegend der Stadt Yca,” Ica, Peru. [Tschudi incorrectly assumed this form to be the *C. cutleri* that King collected (Bennett 1836), which was actually the domestic form, *C. porcellus* (Thomas 1917a)].

[*Cavia*] *Tschudii* Fitzinger, 1867b:154 (pg. 98 in separates); new name for *C. cutleri* Tschudi, 1845, type locality “Ica, 70 miles E of Pisco, Peru.”

C[avia]. leucopyga: Giebel, 1855:461; part; name combination.

[*Cavia leucopyga*] *Tschudii*: E.-L. Trouessart, 1880b:195; name combination.

Cavia tschudii tschudii: Thomas, 1917a:157; first use of current name combination.

Cavia aperea tschudii: Hückinghaus, 1961a:57; name combination.

Dunnun and Salazar-Bravo (2010a) restricted the nominotypical subspecies to populations in the Ica region of Peru. This leaves populations from the highlands of Cusco department without an available name and removes the northwestern Peruvian *C. t. umbrata* Thomas (type locality “Incapirca, Zezioro,” Junín, Peru) and *C. t. atahualpae* Osgood (type locality “Cajamarca, Peru. Alt. 9100ft.”) from the synonymy of the nominotypical species as included by Woods and Kilpatrick (2005). Cabrera (1961) recognized both as valid subspecies, including *festina* in the synonymy of *umbrata*. I refrain from formally recognizing these subspecies pending resolution of the taxonomy of cavy in northwestern Peru.

Thomas (1917a:156) discussed *C. cutleri* Bennett, originally referred to as the “Peruvian cavy,” and concluded that it represented the domestic form, *C. porcellus*. Bennett’s name, therefore, is removed from the synonymy of *C. tschudii*.

C. t. umbrata Thomas, 1917

SYNONYMS:

Cavia tschudii umbrata Thomas, 1917a:157; type locality “Incapirca, Zezioro,” Junín, Peru.

Cavia aperea tschudii: Hückinghaus, 1961a:57; part; name combination.

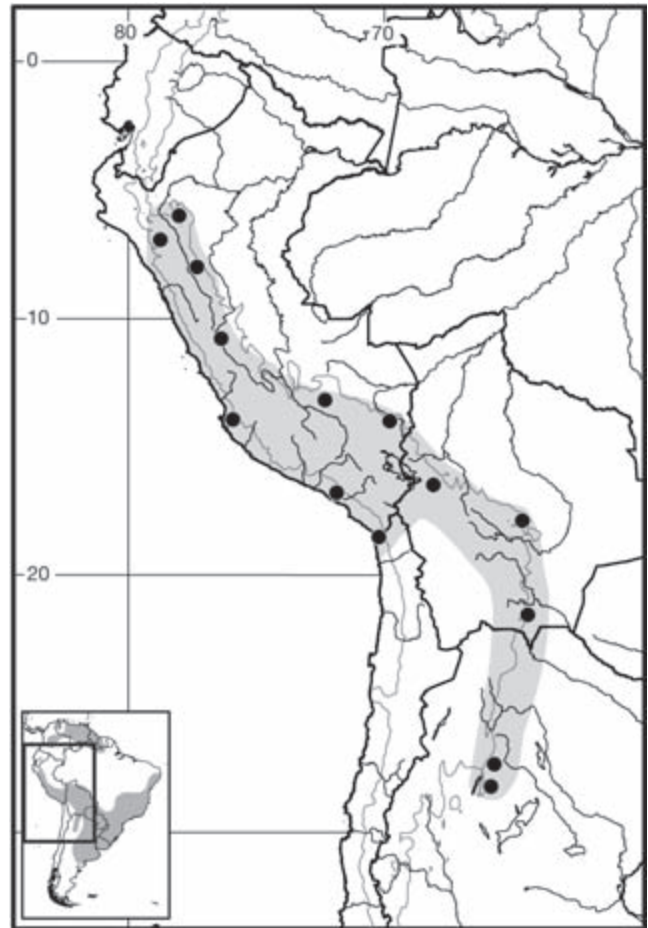

This subspecies is restricted to the Andes of Junín department in central Peru.

Cabrera (1961) included *festina* Thomas in his synonymy of *C. t. umbrata*; I regard both as valid subspecies, pending further review.

NATURAL HISTORY: In northern Argentina and the Altiplano of Peru, this species occupies brush or grasslands and utilizes well-defined runways (Thomas 1926d;

Pearson 1957). In northern Chile, it occurs in the desert regions in the vicinity of rivers, the humid pampas, and from the coast up to 4,200m, where it inhabits brush edges, pastures and alfalfa cultivation, as in the Lluta river valley (Muñoz-Pedrero 2000). In captivity, the gestation period is 63 days, with a mean litter size of 1.9 (range: 1–4); the average age of first reproduction is two months (Weir 1974b).

REMARKS: Woods (1993) incorrectly cited the date of Fitzinger’s (1867b) description as 1857, and many subsequent authors have thus followed suit (S. Anderson 1997; Woods and Kilpatrick 2005; Spotorno et al. 2006). Hückinghaus (1961a) included the *C. tschudii* group (except *C. t. stolidus*) in *C. aperea*. Woods (1993) followed Cabrera (1961) and recognized *C. tschudii* as a valid species. Woods and Kilpatrick (2005) recognized six subspecies (*C. t. arequipae*, *C. t. festina*, *C. t. osgoodi*, *C. t. sodalis*, *C. t. stolidus*, and *C. t. tschudii*). Recent revisionary work (Dunnun and Salazar-Bravo 2010a) did not include material of *festina*

Map 374 Selected localities for *Cavia tschudii* (●). Contour line = 2,000m.

or *stolida* but supported the status of the other four subspecies and restricted the distribution of the nominotypical subspecies. A thorough understanding of the *tschudii* group is still lacking and further work is needed, primarily on the populations in northern and western Peru (*festina* Thomas, *stolida* Thomas, with its synonym *atabualpae* Os-good and *umbrata* Thomas). *Cavia t. festina* is recognized here following Woods and Kilpatrick (2005); however, if future work shows *C. t. festina* to be a synonym of *C. t. umbrata* as suggested by Cabrera (1961), *umbrata* Thomas is the older name. Dunnun and Salazar-Bravo (2010a) followed Woods and Kilpatrick (2005) in using the name *C. t. arequipae*; however, see comments in the account of *C. t. pallidior* for reasons why *pallidior* should be applied to this taxon.

Dunnun and Salazar-Bravo (2006) reported the karyotype of a specimen from the Bolivian highlands as $2n = 64$, FN = 104–108.

Genus Galea Meyen, 1833

Members of the genus *Galea* are terrestrial, diurnal herbivores that inhabit grasslands and rocky scrub areas at both high and low elevations. They are largely colonial, preferring open habitat with good visibility. Females have one pair of inguinal and one pair of lateral thoracic mammae. There is no external tail. Dorsal coloration varies from olivaceous to agouti; the venter is uniformly grayish white. A prominent submandibular gland is present. The cheek teeth are less complex than in *Cavia*, with the upper teeth separated into two lobes by a single lingual fold. M3 has a weak, backwardly projecting heel. Lower cheek teeth have two lobes, and pm4 has a short anterior prolongation. The incisors are yellow rather than white, as in both *Cavia* and *Microcavia*. The orbital branch of maxilla is completely interrupted by the lacrimal (Ellerman 1940). The mean condyloincisive length of the skull is 46.5 mm (range: 41–56 mm; Hückinghaus 1961a). *Galea* is known in the fossil record only from the Pleistocene (Ubilla and Rinderknecht 2001; McKenna and Bell 1997). Opazo (2005) estimated the base of the radiation of the extant species of *Galea*, from molecular sequence data, at 5.9 ± 1.6 mya.

SYNONYMS:

- Cavia*: Wagler, 1831a:512; part (description of *spixii*); not *Cavia* Pallas.
- Galea* Meyen, 1833:597; type species *Galea musteloides* Meyen, by monotypy.
- Cerodon*: Lund, 1840c:313; listing of *bilobidens*; not *Cerodon* Wagler.
- Kerodon*: Lesson, 1842:102; part (listing of *rupestris*); not *Kerodon* F. Cuvier.

- Anoema*: Burmeister, 1861:424 (description of *leucoblephara*); not *Anoema* F. Cuvier.
- Prea* Liais, 1872:541; part (listing of *saxatilis*); replacement name for *Cavia saxatilis* Lund (= *Galea spixii* Wagler).
- Gelea* Woods, 1982:386; incorrect subsequent spelling of *Galea* Meyen.

REMARKS: Woods (1993) and S. Anderson (1997) incorrectly listed the date of Meyen’s description, which was for the year 1832, but published in 1833. Woods and Kilpatrick (2005) listed three species in their concept of this genus (*flavidens* Brandt, *musteloides* Meyen, and *spixii* Wagler). Bezerra (2008) revised the genus based on morphological characters, and analysis largely congruent with the taxa delimited by molecular phylogenetics. Dunnun and Salazar-Bravo (2010b) revised the genus and recognized four species (*G. musteloides*, *G. leucoblephara*, *G. comes*, and an undescribed form from mid elevations [2,000–4,500 m] in Tarija department, Bolivia) within the *musteloides* group. Additionally, they suggested that *spixii* Wagler might warrant generic status based on molecular (K2p distances for mtDNA cytochrome-*b* sequences of 19–21% between *spixii* and the *musteloides* group species) and karyological data ($2n = 68$ in *musteloides* group members versus $2n = 64$ in *spixii*). Herein, I follow the revised taxonomy of Dunnun and Salazar-Bravo (2010b) for the *musteloides* group but include *spixii* within *Galea* and provisionally regard *flavidens* Brandt as a valid species distinct from *C. spixii* pending a thorough evaluation of these forms. Dating estimates suggest a late Miocene divergence between the *musteloides* group and *spixii*, followed by species level divergence within the *musteloides* group in the pre-Puna of the Andes during the Pliocene (Dunnun and Salazar-Bravo 2010b). Tate (1935), Hückinghaus (1961a), Cabrera (1961), Solmsdorff et al. (2004), and Bezerra (2008) have reviewed the genus.

KEY TO THE SPECIES OF GALEA:

1. Processus alaris superior absent; second prism of the PM3, M1, and M2 extended lateroabrorally; nasals relatively short; parietals relatively long; in most cases mesopterygoid fossa relatively narrow and V-shaped anteriorly; white spot behind ear absent; occurs from the Bolivia-Brazil border west to southern Peru and south to southern Argentina. 2
- 1'. Processus alaris superior present; second prism of the PM3, M1, and M2 not extended lateroabrorally; nasals relatively long; parietals relatively short; in most cases mesopterygoid fossa broad and U-shaped anteriorly; white spot behind ear present; occurs in eastern Brazil 4
2. Distributed in the Andes of southern Peru, Bolivia, Argentina, and northern Chile 3

- 2'. Distributed in the lowlands of Bolivia, Paraguay, and Argentina *Galea leucoblephara*
 3. Range limited to southern Bolivia and northern Argentina *Galea comes*
 3'. Range limited to northern and central Bolivia, Peru, and northern Chile *Galea musteloides*
 4. Dorsal pelage blackish from the eyes to the nape
 *Galea flavidens*
 4'. Dorsal pelage not as above. *Galea spixii*

Galea comes Thomas, 1919

Southern Highland Yellow-toothed Cavy

SYNONYMS:

Kerodon boliviensis: Thomas, 1913a:143; name combination, but not *Cavia boliviensis* Waterhouse, 1848.

Galea comes Thomas, 1919f:134; type locality "Maimara, 2230 m," Jujuy, Argentina.

Galea musteloides: Thomas, 1926c:327; part; not *musteloides* Meyen.

DESCRIPTION: Dorsal coloration more mottled than *G. musteloides*, blend of olive, brown and tan; venter mix of yellow and white, with line between dorsum and venter not as distinct as in *G. musteloides*. Dorsal hairs gray at base, tan or brown at midshaft, and black at tip; ventral hairs gray at base and either buffy yellow or white at midshaft and tip. Ears covered with orange hairs; yellow ring surrounds the eyes (J. Dunnun, pers. obs.). Dimensions of holotype include head and body length 243 mm, hindfoot length 39 mm, ear length 22 mm, and greatest skull length 54 mm (Thomas 1919f).

DISTRIBUTION: *Galea comes* is known only from the Andes of southern Bolivia and northern Argentina.

SELECTED LOCALITIES (Map 375): ARGENTINA: Jujuy, Abrapampa (Thomas 1919f), Maimara (type locality of *Galea comes* Thomas), Sierra de Zenta (Thomas 1921k), 12.3 km N and 11.5 km W of San Antonio de los Cobres (Dunnun and Salazar-Bravo 2010b); La Rioja, La Invernada, ca. 35 km N of Nevada de Famatina (Thomas 1920g; not located). BOLIVIA: Tarija, Iscayachi (Dunnun and Salazar-Bravo 2010b).

SUBSPECIES: *Galea comes* is monotypic.

NATURAL HISTORY: The collector, Emilio Budin, reported this species as common in rough and brambly ground [at Maimara] and that it was harmful to cultivation (Thomas 1913a:143). In the Rio Tomayapo river valley (Tarija department, Bolivia), colonies composed of many individuals were interspersed among *Ctenomys lewisi* burrows and were observed foraging around burrows during the day (J. Dunnun, pers. obs.).

REMARKS: Thomas' (1919f) description includes specimens from Abrapampa but he designated a specimen collected from Maimara (Thomas 1913a) as the type.

Map 375 Selected localities for *Galea comes* (○) and *Galea musteloides* (●). Contour line = 2,000 m.

Thomas later (1926c:327) synonymized *comes* Thomas with *musteloides* Meyen, a decision followed by most subsequent authors (Tate 1935; Cabrera 1961, Woods and Kilpatrick 2005). Dunnun and Salazar-Bravo (2010b) considered *comes* Thomas a distinct species, a decision I follow here. The karyotype is $2n = 128$, FN = 136 (Dunnun and Salazar-Bravo 2010b).

Galea flavidens (Brandt, 1835)

Eastern Yellow-toothed Cavy

SYNONYMS:

Cavia flavidens Brandt, 1835:439; type locality "Patria Brasilia."

[*Cavia*] *bilobidens* Lund, 1839b:208; *nomen nudum*.

Cavia bilobidens Lund, 1840a:32 [1841b:248, plate 21, Fig. 6]; type locality "Rio das Velhas's Floddal" (see Lund 1841b:264–266), Lagoa Santa, Minas Gerais, Brazil (a fossil).

[*Cerodon*] *bilobidens*: Lund, 1840c:313; name combination.

Cavia (*Cerodon*) *flavidens*: Waterhouse, 1848:168; name combination.

K[erodon].flavidens: Giebel, 1855:462; name combination.

[*Cavia* (*Galea*)] *flavidens*: E.-L. Trouessart, 1880b:195; name combination.

[*Cavia* (*Kerodon*)] *flavidens*: E.-L. Trouessart, 1897:639; name combination.

[*Galea*] *flavidens*: Thomas, 1916f:303; first use of current name combination.

DESCRIPTION: Similar in appearance to *G. spixii*, but with blackish dorsal areas stretching from eyes to nape (Brandt 1835). Incisors opisthodont; lingual prisms of PM4 and M1 narrower than labial ones, and labial prism of M2 not elongated posteriorly. Skull with broad zygomatic arches; lateral profile from orbits to rostrum deeply concave; posterior palatal emargination V-shaped; and angular process of mandible short (Solmsdorff et al. 2004). Bonvicino, Lima, and Weksler (2005) provided measurements for specimens she attributed to *C. flavidens*: head and body length 205–231 mm, hindfoot 43–47 mm, ear 24–25 mm, and mass 150–330 g.

DISTRIBUTION: *Galea flavidens* is restricted to the cerrado of central Brazil (Redford and Fonseca 1986).

SELECTED LOCALITIES (Map 376): BRAZIL: Goiás, Parque Nacional da Chapada dos Veadeiros (Bonvicino, Lima, and Weksler 2005).

SUBSPECIES: *Galea flavidens* is monotypic.

NATURAL HISTORY: Little information is available for this species. Bonvicino, Lima, and Weksler (2005) reported a single pregnant female (with one embryo) collected in November in *cerrado rupestre* between 1,300 and 1,500 m in the Chapada dos Veadeiros National Park. Other rodents taken at the same time included species of *Thrichomys* and *Oligoryzomys*.

REMARKS: Solmsdorff et al. (2004) described the two historically known specimens and commented on cranial similarities with *G. spixii*. Bonvicino, Lima, and Weksler (2005) tentatively recognized the validity of this species and commented on three newly collected specimens. Bezerra

(2008) discussed the difficulty in morphologically assessing *G. flavidens* due to the lack of good diagnostic characters in the original description, lack of a holotype, and ambiguous type locality; she suggested that *flavidens* was likely a synonym of *G. spixii*. Paula Couto (1950:232) considered *bilobidens* Lund, a fossil species from Lagoa Santa, Brazil, a synonym of *spixii* Wagler. Cabrera (1961:573), on the other hand, listed *bilobidens* Lund in the synonymy of *G. flavidens*, noting that, if he was correct, then the type locality of *flavidens* Brandt could be in Minas Gerais, Brazil). Cabrera also recognized that Paula Couto could have been correct in his assignment of *bilobidens* Lund to *G. spixii*. In either case, both the taxonomic and geographic status of *G. flavidens* remains uncertain, as does the allocation of Lund's *bilobidens*.

Galea leucoblephara Burmeister (1861)

Lowland Yellow-toothed Cavy

SYNONYMS: See under Subspecies.

DESCRIPTION: General characters as for genus but more lightly colored than *M. musteloides*, in part due to paler hue of subterminal area of hair. Overall color ranges from olive to reddish dorsally and yellow on flanks; ventral areas dirty yellowish white (Cabrera 1953). Burmeister (1861) remarked on pure white eye-rings, from which his name derives.

Subspecies *G. l. littoralis* similar to nominotypical form but more finely speckled, with less yellow; hairs on back indistinctly annulated to their bases with alternating light and dark rings of gray; subterminal ring buffy; tips black. Rings around eyes lighter than head but not conspicuously so. Venter dull buffy white and not sharply defined; hairs gray at base. Upper surfaces of feet buffy. Dimensions of holotype head and body length 199 mm, hindfoot length 39 mm, ear length 18 mm, greatest skull length 47 mm (Thomas 1901c).

Specimens of *G. l. demissa* from Chuquisaca, Bolivia mottled tan dorsally and buffy cream ventrally; dorsal hair light gray at base, gradually darkening to near black, followed by subterminal tan ring, and dark tip; both gray band around neck and eye-ring present; feet light tan; ears well furred and covered with fine orange hair. Pelage of animals from Salta province, Argentina, with speckled appearance, with grayish to brownish dorsum, whitish venter, and denuded area on neck. White eyering not readily visible and some individuals have dark band around neck. Head and body length 198–235 mm, mass from 180–280 g (Mares, Ojeda, and Barquez 1989).

DISTRIBUTION: *Galea leucoblephara* occurs in the lowlands from central Bolivia through Paraguay to southern Argentina.

SELECTED LOCALITIES (Map 377): ARGENTINA: Buenos Aires, Bahía Blanca (type locality of *Cavia boliviensis littoralis* Thomas), Laguna Chasticó (J. R. Contreras 1972); La Rioja, La Rioja (Cabrera 1953); Neuquén,

Map 376 Selected localities for *Galea flavidens* (○) and *Galea spixii* (●).

Collón Curá (Thomas 1927e), Zapala (Thomas 1927d); Río Negro, Pilcaniyeu (type locality of *Galea negrensis* Thomas); Salta, La Represa, Metán (Cabrera 1953); San Juan, Angaco Sud (AMNH 41894); San Luis, 9 km N of Paso del Rey (Dunnun and Salazar-Bravo 2010b); Santiago del Estero, Suncho Corral (AMNH 41589). BOLIVIA: Chuquisaca, 12 km N and 11 km E of Tarabuco (Dunnun and Salazar-Bravo 2010b); Santa Cruz, Ascención de Guarayos (S. Anderson 1997), Campo de Guanacos (type locality of *Galea spixi campicola* Doutt), 3.5 km W of Estación El Pailón (Dunnun and Salazar-Bravo 2010b); Tarija, 2 km S and 5 km E of Palos Blancos (Dunnun and Salazar-Bravo 2010b). PARAGUAY: Alto Paraguay, Palmar de Las Islas (Dunnun and Salazar-Bravo 2010b), Estancia Tres Marias (Dunnun and Salazar-Bravo 2010b).

SUBSPECIES: I follow Dunnun and Salazar-Bravo (2010b) and recognize three subspecies.

G. l. demissa Thomas, 1921

SYNONYMS:

Galea boliviensis demissa Thomas, 1921:623; type locality “San Antonio, Parapiti, [Santa Cruz,] Bolivia. Alt. 600m.”

Galea musteloides demissa: Tate, 1935:347; name combination.

Galea spixi campicola Doutt, 1938:100; type locality “Campo de Guanacas, eastern Bolivia; altitude 450 meters,” western part of Cordillera Province, about 90 miles south of Santa Cruz de la Sierra, Santa Cruz, Bolivia.

[*Galea spixi*] *spixi*: Doutt, 1938:101; part, not *Cavia spixii* Wagler.

Galea spixii campicola: Cabrera, 1961:575; name combination.

[*Galea*]. [*leucoblephara*]. *demissa*: Dunnun and Salazar-Bravo, 2010b:251; first use of current name combination.

This subspecies occurs mainly in the Chaco ecoregion of lowland central and southern Bolivia, western Paraguay, and as far south as Santiago del Estero and Catamarca provinces in Argentina. This subspecies may also extend into the eastern slopes and valleys of the pre-Andean chains in Tucumán province, Argentina (Dunnun and Salazar-Bravo 2010b).

S. Anderson (1997) regarded *campicola* as a subspecies of *Galea spixii*, but it is included here based on morphological (Bezerra 2008) and molecular analyses (Dunnun and Salazar-Bravo 2010b).

G. l. leucoblephara (Burmeister, 1861)

SYNONYMS:

Anoema leucoblephara Burmeister, 1861:425; type locality “Die Art war häufig bei Mendoza wie bei Tucuman; sie bewohnt ohne Zweifel den ganzen Westen der La Plata-Staaten, lebt in Erdlochern an Wegen, wo Büsche

stehen und wurde in allen Altern und Geschlechtern von mir gesammelt.” Type locality restricted to Mendoza, Argentina by Yepes (1936:40); lectotype designated by Solmsdorff et al. (2004).

[*Cavia* (*Galea*)] *leucoblephara*: E.-L. Trouessart, 1880b:195; name combination.

[*Cavia* (*Kerodon*)] *leucoblephara*: E.-L. Trouessart, 1897:640; name combination.

[*Cavia* (*Cerodon*) *boliviensis*] *leucoblephara*: E.-L. Trouessart, 1904:526; name combination.

Kerodon boliviensis: Thomas, 1902c:229; part; name combination.

Kerodon leucoblepharus: Thomas, 1911c:254; name combination but incorrect gender concordance.

[*Galea*]. *leucoblephara*: Thomas, 1919b:212; name combination.

[*Cavia*]. (*Galea*) *boliviensis leucoblephara*: Osgood, 1915:195; name combination.

[*Galea*] *musteloides leucoblephara*: Tate, 1935:347; name combination.

Galea [*leucoblephara*]. *leucoblephara*: Dunnun and Salazar-Bravo, 2010b:252; first use of current name combination.

This subspecies occurs in western Argentina from southern Catamarca province in the north through La Rioja, San Juan, San Luis, Mendoza, and Córdoba provinces in the south (Cabrera 1953; Dunnun and Salazar-Bravo 2010b).

G. l. littoralis (Thomas, 1901)

SYNONYMS:

Cavia boliviensis littoralis Thomas, 1901c:195; type locality “Bahia Blanca, [Buenos Aires,] Argentina.”

[*Cavia* (*Cerodon*) *boliviensis*] *littoralis*: E.-L. Trouessart, 1904:526; name combination.

[*Galea*]. *b[oliviensis]*. *littoralis*: Thomas, 1919b:212; name combination.

Galea negrensis Thomas, 1919b:211; type locality “Pilcañeu, Upper Río Negro. 1400 m [41°S., 71°W.],” Río Negro, Argentina.

Galea littoralis: Thomas, 1929:44; name combination.

[*Galea*] *musteloides littoralis*: Tate, 1935:347; name combination.

[*Galea*] *musteloides negrensis*: Ellerman, 1940:243; name combination.

[*Galea*]. *leucoblephara littoralis*: Dunnun and Salazar-Bravo, 2010b:251; first use of current name combination.

This subspecies occurs in southern Argentina, extending from northern Chubut in the south to lower Mendoza and La Pampa in the north and from the Atlantic coast of Buenos Aires province to the base of the Andes (Cabrera 1961). Bezerra (2008) recognized *littoralis* as a distinct species based on cranial characters.

NATURAL HISTORY: This species is primarily a diurnal, terrestrial herbivore, inhabiting both mesic and xeric grasslands of lowland central and southern South America. Original studies on population biology, behavior, and reproduction were reported as *G. musteloides*. Males maintain a linear dominance hierarchy through aggression; the female hierarchy is less stable. Breeding occurs year-round and females can produce up to seven litters per year. The gestation period is about 53 days and average litter size is three (Rood 1972). Females have one inguinal and one lateral abdominal pair of mammae. The average age of first reproduction is about three months for males and two months for females, with a minimum of 11 days (Weir 1974b). Substantial work has been done on their promiscuous mating behavior, mate choice, and reproductive success (Keil et al. 1999; Sachser et al. 1999; Hohoff et al. 2003). F. Fonseca (1960) and Hopkins and Rothschild (1966) reported ectoparasites for Bolivian specimens.

REMARKS: Dunnun and Salazar-Bravo (2010b) elevated *G. leucoblephara* from within *G. musteloides* based on molecular phylogenetic analyses. These authors also

suggested that the current distribution of the *leucoblephara* group is the result of two dispersal events into the Argentinian lowlands from the pre-Puna during the late Pliocene, followed by northward expansion during the Pleistocene into the Chaco regions of Bolivia and Paraguay. The karyotype consists of $2n = 68$ and $FN = 136$ (W. George et al. 1972; Dunnun and Salazar-Bravo 2010b).

Galea musteloides Meyen, 1833

Highland Yellow-toothed Cavy

SYNONYMS: See under Subspecies.

DESCRIPTION: General hue of fur brownish with yellowish or olivaceous tinge dorsally and white ventrally. Dorsal hairs pale gray at base, with pale brownish yellow median ring, and dark tip; venter and throat whitish with distinct line demarking venter from dorsal pelage; gray band present around throat area; eyelids whitish yellow and ears clothed in yellow brown hairs. Subspecies *G. m. auceps* differs greatly from *G. m. musteloides* and *G. m. boliviensis* in pelage coloration: paler yellow, tan dorsum and sides, with hairs gray at base and tipped black, but with wide middle section of yellow tan; venter buffy white and eyelids and lashes black. Cranial and tooth characters of *G. musteloides* as for genus. This species differs from *G. spixii* in that upper surface of skull less arched when viewed from side; outline nearly straight from tip of nasals back to point just anterior to frontoparietal suture, but descends slightly between orbits and toward apex of nasals; palate between the molars nearly flat, not concave as in *G. spixii* (Waterhouse 1848).

DISTRIBUTION: *Galea musteloides* is found in the Andes of central Bolivia, southeastern Peru, and extreme northeastern Chile.

SELECTED LOCALITIES (Map 375): BOLIVIA: Cochabamba, Valle Hermoso (type locality of *Galea monasteriensis* Solmsdorff, Kock, Hohoff, and Sachser); La Paz, Achacachi (S. Anderson 1997), Irupana (S. Anderson 1997); Santa Cruz, Estancia Laja (Dunnun and Salazar-Bravo 2010b); Oruro, 7 km S and 4 km E of Cruce Ventilla (Dunnun and Salazar-Bravo 2010b). CHILE: Arica y Parinacota, Putre (Mann 1950). PERU: Puno, Pairumani, 22 mi SW of Llave on the Río Huanque (Pearson 1951), Sillustani (Dunnun and Salazar-Bravo 2010b).

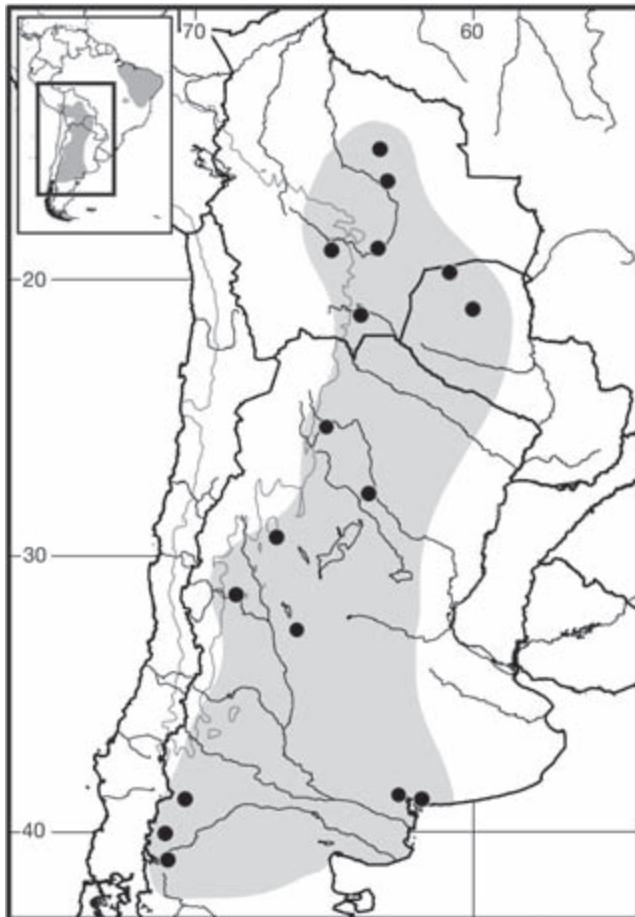

SUBSPECIES: I recognize three subspecies of *Galea musteloides*.

G. m. auceps (Thomas, 1911)

SYNONYMS:

Kerodon auceps Thomas, 1911c:255; type locality "Guarina (alt. 4000m.), near the south-east, the Bolivian, end of the lake [Titicaca]," La Paz, Bolivia.

C[avia]. (Galea) auceps: Osgood, 1915:195; name combination.

Map 377 Selected localities for *Galea leucoblephara* (●). Contour line = 2,000m.

[*Galea*] *auceps*: Thomas, 1916f:303; name combination.
G[alea]. auceps Thomas, 1919f:134; incorrect subsequent spelling of *Kerodon auceps* Thomas.

[*Galea*] *musteloides auceps*: Tate, 1935:347; first use of current name combination.

This subspecies occurs in the highland areas around the southern edge of Lake Titicaca in western La Paz department, Bolivia, and adjacent areas of Puno department, Peru.

Cabrera (1961) included *auceps* Thomas in the synonymy of *G. musteloides musteloides*. S. Anderson (1997:481) disagreed, stating “the pale and yellowish subspecies *G. m. auceps* is rather distinct in comparison to the darker nominotypical subspecies,” a decision followed by Woods and Kilpatrick (2005).

G. m. boliviensis (Waterhouse, 1848)

SYNONYMS:

Cavia boliviensis Waterhouse, 1848:175; type locality “high tableland between Cochabamba and La Paz [Bolivia]”. Thomas (1911c:255) designated a lectotype and restricted the type locality to “Paratani [= Parotani], close to Cochabamba,” Cochabamba, Bolivia.

K[erodon]. boliviensis: Giebel, 1855:463; part; name combination.

[*Cerodon*] *boliviensis*: Fitzinger, 1867b:155; part; name combination.

[*Cavia* (*Galea*)] *boliviensis*: E.-L. Trouessart, 1880b:195; part; name combination.

[*Galea*] *boliviensis*: Thomas, 1916f:302; name combination.

Cavia musteloides boliviensis: Osgood, 1916:210; name combination.

Galea musteloides musteloides: Tate, 1935:347; part; name combination.

Galea monasteriensis Trillmich, Kraus, Künkele, Asher, Clara, Dekomien, Epplen, Saralegui, and Sachser, 2004: footnote 517; *nomen nudum*.

Galea monasteriensis Solmsdorff, Kock, Hohoff, and Sachser, 2004:137–156; type locality “Valle Hermoso, 2557 m a.s.l., 66°09'W, 17°23'S, S of Cochabamba, Cordillera Oriental, Cochabamba Province, Bolivia.”

Galea musteloides boliviensis: Solmsdorff, Kock, Hohoff, and Sachser, 2004:147; first use of current name combination.

This subspecies occurs in the eastern region of the Bolivian Altiplano.

Osgood (1916:211) erroneously stated that Thomas (1911c:255) had designated Sajama, Bolivia, as the type locality of Waterhouse's *boliviensis*, based on Thomas's (1911b:255) referral of a specimen from this locality to the nominotypical subspecies. Subsequently, Thomas (1926c:327) reduced *boliviensis* Waterhouse to a synonym of *musteloides* Meyen and most subsequent authors have

followed this taxonomy (Tate 1935; Cabrera 1961; Woods 1993; Woods and Kilpatrick 2005), but recent reviews have recognized the subspecies (Solmsdorff et al. 2004; Dunnun and Salazar-Bravo 2010b). Bezerra (2008) found insufficient morphological differences to warrant separation of *monasteriensis* and *musteloides*; Dunnun and Salazar-Bravo (2010b) treated *G. monasteriensis* as a synonym of *G. m. boliviensis* based on molecular data.

G. m. musteloides Meyen, 1833

SYNONYMS:

Galea musteloides Meyen, 1833:598; type locality “Sie bewohnen die Hochebenen der westlichen Cordillerenkette, auf dem Passe von Tacna nach dem Alpen-see von Titicaca. Das Plateau von Tacora, besonders der Kamm desselben, zwischen dem Bolivianischen Indianerdorfe Morocallo, und dem Peruanischen Kirchdorfe Pisacoma [Pisacoma, 16°54'S, 69°23'W, Puno, Peru], gänzlich bestend aus trachytischer Lava und Conglomeraten, wird von ihnen bewohnt,” = Paso de Tacna, on road to Lake Titicaca, Peru.

Kerodon rupestris: Lesson, 1842:102; name combination.

K[erodon]. boliviensis: Giebel, 1855:463; part; name combination.

[*Cerodon*] *boliviensis*: Fitzinger, 1867b:155; part; name combination.

Galea musteloides musteloides: Tate, 1935:347; first use of current name combination.

Cavia musteloides musteloides: Pearson, 1951:153; name combination.

This subspecies occurs in the Andean Altiplano of southwestern Peru, western Bolivia, and extreme northeastern Chile (Dunnun and Salazar-Bravo 2010b).

NATURAL HISTORY: *Galea musteloides* is primarily a diurnal, terrestrial herbivore, inhabiting the grasslands of the central Andes. Individuals excavate their own burrow systems but also utilize abandoned burrows of other mammals, such as *Lagostomus*, *Ctenomys*, and *Chaetophractus*. They appear to respond to the alarm calls of *Ctenomys* by seeking cover (Sanborn and Pearson 1947). Muñoz-Pedreros (2000) reported their burrow systems to be shallow with grass-lined alcoves and that they cohabitate with *Ctenomys opimus*. In northern Chile, they consume the bark and leaves of *Lepidophyllum* and *Baccharis* shrubs (Asteraceae) and the grasses *Stipa* and *Festuca* (Muñoz-Pedreros 2000). Females reach sexual maturity at one month of age, males at two to three months. The gestation period averages 55.3 days (range: 50–58 days; Solmsdorff et al. 2004). Young weigh around 40 g at birth, and litter size ranges from two to seven (average of three) individuals that are suckled for three to five weeks (Muñoz-Pedreros 2000). This species exhibits low compatibility among unfamiliar adults as well

as differences in courtship and copulatory posture in comparison to *G. leucoblephara* (Trillmich et al. 2004). This is the only species of *Galea* to exhibit a monogamous mating system (Hohoff et al. 2002). F. Fonseca (1960), Hopkins and Rothschild (1966), and Smit (1987) report ectoparasites from Bolivian specimens.

REMARKS: Woods and Kilpatrick (2005) gave the date of Meyen's description as 1832; the correct publication date of Meyen's work, however, is 1833.

Dunnum and Salazar-Bravo (2010b) restricted *G. musteloides* to populations from the Altiplano of southern Peru, northern Chile, and west-central Bolivia, identifying two molecular clades within this range. One of these comprised individuals from the Lake Titicaca area in Peru and Bolivia assignable to the subspecies *G. m. musteloides* and *G. m. auceps*. The second included samples from Oruro, Cochabamba, and Santa Cruz departments, Bolivia, which they assigned to *G. m. boliviensis*. These authors suggested that diversification of the subspecies occurred about the Pliocene-Pleistocene boundary. G. I. Molina (1782:306) used *Lepus minimus* in describing a "Cuy" from Chile, which Tate (1935:344) thought likely to be *Galea* and thus included it as a subspecies of *G. musteloides*. Ellerman (1940:243) regarded Molina's *minimus* to be a valid species of *Galea*, but also noted that, if Tate were correct in his assignment to *musteloides*, Molina's name predated *musteloides* Meyen and as such Meyen's name, and all others associated with it, would become synonyms of *G. minimus* G. I. Molina. Hückinghaus (1961a) agreed with Ellerman and referred to this species as *Galea minimus*. Alternatively, Cabrera (1961) listed Molina's name in the synonymy of *Cavia porcellus*. Because the correct assignment of Molina's name remains unresolved, I follow Cabrera (1961) and regard it as a synonym of *Cavia porcellus* (Linnaeus); see Remarks under that account.

The karyotype of *G. musteloides* consists of a $2n = 68$ and $FN = 136$ (Dunnum and Salazar-Bravo 2010b).

Galea spixii (Wagler, 1831)

Spix's Yellow-toothed Cavy

SYNONYMS: See under Subspecies.

DESCRIPTION: General coloration grayish, with somewhat indistinct brownish tint on back; dorsal hair pale gray at base and dusky at tip with broad subterminal ring of pale brownish yellow; hairs on sides of body lighter at tip with subterminal ring almost whitish; throat, abdomen, and inner surfaces of limbs white; small white mark present above eye and more distinct white patch behind the ear. *Galea s. palustris* lacks postauricular spot seen in *G. s. spixii* and *G. s. wellsi* (Osgood 1915); feet nearly white. Lateral profile of skull forms gentle convex curve from base of nasals to posterior part of the parietals, where

it descends quickly to the occiput, not straight or concave between orbits as in *G. musteloides* (Waterhouse 1848). Measurements of holotype *G. s. palustris* head and body length 225 mm, hindfoot length 46 mm, ear length 25.5 mm, and greatest skull length 55 mm (Thomas 1911c), and those of *G. s. wellsi* head and body length 234 mm, hindfoot length 51 mm, and greatest skull length 57.5 mm (Osgood 1915).

DISTRIBUTION: *Galea spixii* is known from eastern Brazil (Moojen 1952b).

SELECTED LOCALITIES (Map 376): BRAZIL: Alagoas, Quebrangulo (Mares, Willig et al. 1981); Bahia, São Marcello, junction of Rio Preto and Rio Sapão (type locality of *Cavia* [*Galea*] *wellsi* Osgood); Ceará, Crato (Moojen 1943a), São Paulo (Thomas 1910c); Minas Gerais, Campos Geraes de San Felipe (Osgood 1915); Pará, Cametá, lower Rio Tocantins (type locality of *Kerodon palustris* Thomas); Pernambuco, Saltinho, Rio Formoso (Ximénez 1980).

SUBSPECIES: I recognize three subspecies.

G. s. palustris (Thomas, 1911)

SYNONYMS:

Kerodon palustris Thomas, 1911b:608; type locality "Cametá, Lower Tocantins," Pará, Brazil.

C[avia]. (*Galea*) *palustris*: Osgood, 1915:195; as subgenus, name combination.

[*Galea*] *palustris*: Thomas, 1916f:303; name combination.

[*Galea spixii*] *palustris*: Doult, 1938:101; first use of current name combination and incorrect subsequent spelling of *Cavia spixii* Wagler.

This subspecies occurs in northeastern Brazil, south of the Rio Amazonas.

G. s. spixii (Wagler, 1831)

SYNONYMS:

Cavia spixii Wagler, 1831a:512; type locality "Die Ordnung der Nager bin ich durch zwey neue Gattungen Ferkelmäuse (*Cavia*), welche Herr von Spix von seiner Reise am Amazonianstrome, zurückbrachte, und die sich daher in unserem Museum befinden, zu bereichern im Stande," = Rio Amazonas, Brazil. Osgood (1915:197) discussed and restricted the type locality to Campos Geraes de San Felipe, east of Januária, Bahia [a locality actually in Minas Gerais state], Brazil. Cabrera (1961:575) stated that the type locality was unknown but, by his inclusion of *saxatilis* Lund in the synonymy of this subspecies, he restricted the type locality to Lagoa Santa, Minas Gerais, Brazil.

[*Cavia*] *saxatilis* Lund, 1839b:208; *nomen nudum*.

C[avia]. (*Cerodon*) *saxatilis* Lund, 1840b:14 [1841c:287, plate 25, Figs. 14, 18]; type locality "Rio das Velhas's Floddal" (see Lund 1841b:292, 294), Lagoa Santa, Minas Gerais, Brazil.

- Cerodon saxatilis*: Lund, 1840c:313; name combination.
Cavia (Cerodon) spixii: Waterhouse, 1848:173; name combination.
K[erodon]. spixi Giebel, 1855:463; name combination and incorrect subsequent spelling of *Cavia spixii* Wagler.
Prea saxatilis: Liais, 1872:541; name combination.
 [*Cavia (Galea) Spixii*]: E.-L. Trouessart, 1880b:195; part; name combination.
 [*Cavia (Kerodon) spixii*]: E.-L. Trouessart, 1897:639; name combination.
 [*Cavia (Cerodon) boliviensis*] *saxatilis*: E.-L. Trouessart, 1904:526; name combination.
 C[avia]. (*Galea*) *spixi*: Osgood, 1915:195; incorrect subsequent spelling of *Cavia spixii* Wagler.
 [*Galea*] *spixi*: Thomas, 1916f:303; name combination and incorrect subsequent spelling of *Cavia spixii* Wagler.
 [*Galea*] *spixii*: Tate, 1935:347; name combination.

This subspecies occurs in eastern Brazil, but its western limits remain unclear.

G. s. wellsi (Osgood, 1915)

SYNONYMS:

- [*Cavia (Galea) Spixii*]: E.-L. Trouessart, 1880b:195; part; name combination.
 [*Cavia (Kerodon) spixii*]: E.-L. Trouessart, 1897:639; part; name combination.
Cavia spixi: Goeldi and Hagmann, 1906:74; name combination and incorrect subsequent spelling of *spixii* Wagler.
Cavia (Galea) wellsi Osgood, 1915:196; type locality “São Marcello [= São Marcelo], junction of Rio Preto and Rio Sapaõ [= Sapão], Bahia, Brazil.”
 [*Galea*] *wellsi*: Thomas, 1916f:303; name combination.
 [*Galea spixi*] *wellsi* Doutt, 1938:101; first use of current name combination and incorrect subsequent spelling of *Cavia spixii* Wagler.

This subspecies is limited to northeastern Brazil (Cabrera 1961).

NATURAL HISTORY: *Galea spixii* occupies only low-lying areas within the Caatinga ecoregion, where individuals use a network of well-worn runways. Individuals are mostly crepuscular but activity may occur at any time (Mares, Willig et al. 1981). Nest sites appeared to be temporary and were typically found under rocks or low, overhanging vegetation. Areas frequented by *G. spixii* were readily distinguished by their runways and cleared patches used for sand bathing (Streilein 1982a). *Galea spixii* exhibited a wide range of vocalizations in response to varying situations. The mating system approximated a male dominance polygyny (Lacher 1981). The gestation period ranged from 49 to 52 days and litter size averaged 2.2 (range: 1–5). Lacher (1981) and Mares, Willig et al. (1981) reported re-

production to occur in both captivity and the wild. Mares et al. (1982) described molt. This species is difficult to trap except when traps were placed along the runways. Trapped individuals frequently displayed a death-feigning behavior when handled (Streilein 1982a).

REMARKS: Emmons et al. (2006) reported *G. spixii* from the Parque Nacional Noel Kempff Mercado, but identifications need to be verified as these may be referable to *G. l. demissa*. Dunnun and Salazar-Bravo (2010b) placed *G. spixii campicola* in synonymy with *G. leucoblephara demissa*. The concept of *G. spixii* I employ here includes *wellsi* Osgood and *saxatilis* Lund (Cabrera 1961:575; Corbet and Hill 1991:201), but Hückinghaus (1961a:71) considered *wellsi* a distinct species and both Avila-Pires (1982) and Solmsdorff et al. (2004) recognized *saxatilis* as a valid species. Karyotype consists of a $2n = 64$ and FN = 118 (Maia 1984).

Genus *Microcavia* H. Gervais and Ameghino, 1880

The genus as currently recognized is composed of three species and occurs from the highlands of southwestern Bolivia and northern Chile south to Santa Cruz province in southern Argentina and likely southern Chile (Osgood 1943b; C. A. Quintana 1996; S. Anderson 1997). Fossil materials from four species are known from mid-Pliocene to Recent deposits in Argentina and Uruguay (C. A. Quintana 1996; Ubilla et al. 1999). Mountain caviids occupy a wide variety of arid and semiarid habitats from near sea level to above 4,000 m. They are medium-sized caviids, slightly smaller than *Cavia* (head and body length ranges from 170 to 250 mm, mass from 200 to 500 g, and mean condyloincisive length is 42.2 mm [range: 36–46 mm; Hückinghaus 1961a]). Individuals possess no external tail; females have four mammae; eyes are large and surrounded by a conspicuous white ring; dorsal coloration is olive gray agouti and under parts are pale gray; and the submandibular gland present in *Galea* is lacking. The skull is shortened and bowed compared to other Caviinae. The highest part of the skull occurs over the posterior zygomatic root and the orbital branch of the maxillary is continuous as a narrow strip in front of the lacrimal. The incisive foramen is larger than in *Cavia* and *Galea*, triangular in shape, and placed more closely to the toothrows. The bullae are larger and the orbit is more rounded than in either *Cavia* or *Galea*. Cheek teeth are like those of *Galea* with each tooth divided into two lobes by one inner fold. M3 has a deeper posterior fold than in *Galea*. The lower teeth are bilobed. Incisors are nonpigmented. Descriptive information is from Osgood (1915), Thomas (1916f), and Ellerman (1940).

The genus *Microcavia* is known from late Pliocene through mid Pleistocene deposits (Verzi and Quintana 2005). Cabrera (1961) recognized two subgenera, *Microcavia* containing *M. australis* and *M. shiptoni*, and *Monticavia* containing *M. niata*. C. A. Quintana (1996), however, found no support for subgeneric divisions.

SYNONYMS:

Cavia: I. Geoffroy St.-Hilaire and d'Orbigny, 1833:plate 12; not *Cavia* Pallas.

Kerodon: Bennett, 1836:190; part (description of *kingii*); not *Kerodon* F. Cuvier.

Cerodon Waterhouse, 1848:180; as a subgenus of *Cavia* (allocation of *australis*); unjustified emendation of *Kerodon*, but not *Kerodon* F. Cuvier.

Anaema Blainville, 1855:26; incorrect subsequent spelling of *Anoema*, but not *Anoema* F. Cuvier; referred to *C. aperea* but a *Microcavia* skull is figured.

Anoema: Burmeister, 1879:271; part (listing of *australis*); as a subgenus of *Cavia*, but not *Anoema* F. Cuvier.

Microcavia H. Gervais and Ameghino, 1880:50; type species *Cavia australis* I. Geoffroy St.-Hilaire and d'Orbigny, by subsequent designation (Kraglievich 1930a).

Caviella Osgood, 1915:194; as subgenus; type species *Cavia australis* I. Geoffroy St.-Hilaire and d'Orbigny, by original designation.

Monticavia Thomas, 1916f:303; type species *Monticavia niata* (= *Cavia niata* Thomas), by original designation.

Nanocavia Thomas, 1925a:419; type species *Nanocavia shiptoni* Thomas, by original designation.

Microavia Cabrera, 1953:20; incorrect subsequent spelling of *Microcavia* H. Gervais and Ameghino.

REMARKS: In the original description of the genus, H. Gervais and Ameghino (1880:50–55) did not designate a type species among the four they listed under *Microcavia*. Subsequently, Kraglievich (1930a) selected *C[avia]. australis* I. Geoffroy St.-Hilaire and d'Orbigny (1833) as the type species, a choice followed by C. A. Quintana (1996) in his review of the genus. Cabrera (1953), however, argued that the type species should be *Microcavia typus*, one of the fossil taxa described by H. Gervais and Ameghino (1880:52) under their description of their new genus and now listed as a synonym of *M. australis* (e.g., C. A. Quintana 1996). Cabrera (1961) and Tognelli et al. (2001) accepted this argument as each gave *Microcavia typus* H. Gervais and Ameghino as the type species of *Microcavia*. Both erred, however, as H. Gervais and Ameghino (1880) clearly neither explicitly nor implicitly selected *M. typus* among the four species they listed, as required by genus-level names authored prior to 1930 (ICZN 1999:Art 67.4.1). Thus, Kraglievich's (1930a) selection of *australis* I. Geoffroy St.-Hilaire and d'Orbigny is correct. Thomas (1921e), Hück-

inghaus (1961), and C. A. Quintana (1996) reviewed the genus.

KEY TO THE SPECIES OF *MICROCAVIA* (FROM TOGNETTI ET AL. 2001):

1. Incisors orthodont, lateral mandibular fossa deepened anteriorly *Microcavia australis*
- 1'. Incisors proodont, lateral mandibular fossa not deepened anteriorly 2
2. Cranial profile strongly convex, length of auditory bullae >10 mm *Microcavia niata*
- 2'. Cranial profile not strongly convex, length of auditory bullae <10 mm *Microcavia shiptoni*

Microcavia australis (I. Geoffroy St.-Hilaire and d'Orbigny, 1833)

Southern Mountain Cavy

SYNONYMS: See under Subspecies.

DESCRIPTION: Head and body length 170–245 mm, hindfoot 35–50 mm, ear 14–20 mm (Cabrera 1953), and mass 141–340 g (Mares, Ojeda, and Barquez 1989). General coloration olive-gray agouti with speckled appearance, ventrum paler gray. Eyes large and encircled by white ring. Teeth described for genus but incisors orthodont. Lateral mandibular fossa not deepened anteriorly as in *M. niata* and *M. shiptoni* (Tognelli et al. 2001). Tognelli et al. (2001) provided external and cranial measurements for each subspecies.

DISTRIBUTION: *Microcavia australis* occurs in Argentina from Jujuy province in the northwest, east to Buenos Aires province, and south to Santa Cruz province, and to southern Chile. Woods (1993) included extreme southern Bolivia in the distribution, but S. Anderson (1997) reported no known specimens from that country. Pine et al. (1979) discussed its presence in Aysén, Chile.

SELECTED LOCALITIES (Map 378; from C. A. Quintana 1996, except as noted): ARGENTINA: Buenos Aires, Copetonas, San Blas (Cabrera 1953); Catamarca, Recreo (type locality of *Caviella australis salinia* Thomas), Tinogasta, Santa María; Chubut, Lago Colhue-Huapi, Rawson; Jujuy, Yavi; La Rioja, Guandacol; Neuquén, Zapala (Thomas 1927d), Collón Curá (Thomas 1927e); San Juan, Cañada Honda (type locality of *Caviella australis joannia* Thomas); Santa Cruz, Lago San Martín (Cabrera 1953); Santa Fe, To-stado. CHILE: Aysén, Chacabuco Valley (Pine et al. 1979).

SUBSPECIES: Thomas (1921e) recognized five subspecies within *M. australis* while Cabrera (1953) recognized only three: *M. a. australis* I. Geoffroy St.-Hilaire and d'Orbigny (including *kingii* Bennett, *nigriana* Thomas, and *joannia* Thomas, as synonyms); *M. a. maenas* Thomas; and *M. a. salinia* Thomas. I follow Cabrera's (1953) treatment but note that if southern populations prove recognizable, then *kingii* Bennett is the available name. Sassi et al.

(2011) found high levels of molecular divergence between highland and lowland populations, suggesting possible cryptic taxa within *M. australis*.

M. a. australis (l. Geoffroy St.-Hilaire and d'Orbigny, 1833)

SYNONYMS:

C[*avia*]. *australis* I. Geoffroy St.-Hilaire and d'Orbigny, 1833:1 [unnumbered text for plate 12]; type locality "sur les bords du Rio Negro, vers le Quarante-unième degré," emended to "on the Lower Rio Negro," Río Negro, Argentina, by Thomas (1929:44).

Kerodon Kingii Bennett, 1836:190; type locality "apud Portum Desire dictum, ad Patagoniæ littus orientale," Puerto Deseado, Santa Cruz, Argentina.

[*Cerodon*] *Kingii*: Wagner, 1844:70; name combination.

Cavia (*Cerodon*) *australis*: Waterhouse, 1848:180; name combination.

Cavia Kingii: Waterhouse, 1848:plate 3, Fig. 2; name combination.

Anaema aperea: Blainville, 1855:26; name combination, referring to plate, but not *aperea* Erxleben.

C[*avia*]. (*Anaema*) *Aperea*: Blainville, 1855:5 of Atlas; name combination, referring to plate, but not *aperea* Erxleben.

C[*avia*]. *aperea*: Blainville, 1855:plate 2 in Atlas; name combination, but not *aperea* Erxleben; caption reads *C. aperea* but the skull figured is of *M. australis*.

K[*erodon*]. *australis*: Giebel, 1855:463; name combination.

Cavia (*Anoema*) *australis*: Burmeister, 1879:272; name combination, but not *Anoema* F. Cuvier.

[*Cavia* (*Galea*)] *australis*: E.-L. Trouessart, 1880b:195; name combination.

[*Cavia* (*Kerodon*)] *australis*: E.-L. Trouessart, 1897:639; name combination.

C[*avia*]. (*Caviella*) *australis*: Osgood, 1915:195; name combination.

[*Caviella*] *australis*: Thomas, 1916f:302; name combination.

C[*aviella*]. *australis*: Thomas, 1916f:302; name combination.

Caviella australis australis: Thomas, 1921e:445; name combination.

Caviella australis nigriana Thomas, 1921a:446; type locality "Neuquen, R. Negro," Neuquén, Argentina.

Caviella australis joannia Thomas, 1921e:446; type locality "Cañada Honda, San Juan. Alt. 500 m," Argentina.

[*Microcavia*] *australis*: Kraglievich, 1927:579; name combination.

C[*aviella*]. a[*ustralis*]. *kingi*: Thomas, 1929:44; name combination and incorrect subsequent spelling of *kingii* Bennett.

Microcavia australis australis: Yepes, 1935a:242; first use of current name combination.

M[*icrocavia*]. *australis kingii*: Yepes, 1935a:242; name combination.

M[*icrocavia*]. *australis joannia*: Yepes, 1935a:242; name combination.

Cavia (*Microcavia*) *australis*: Osgood, 1943b:142; name combination.

The nominotypical subspecies is found in Argentina from San Juan province in the west and southern Buenos Aires province in the east, south to Santa Cruz province.

M. a. maenas (Thomas, 1898)

SYNONYMS:

Cavia maenas Thomas, 1898d:284; type locality "Chilecito, Rioja, 1200 metres," La Rioja, Argentina.

[*Cavia* (*Cerodon*)] *moenas* E.-L. Trouessart, 1904:527; name combination and incorrect subsequent spelling of *maenas* Thomas.

C[*avia*]. (*Caviella*) *maenas*: Osgood, 1915:195; name combination.

[*Caviella*] *maenas*: Thomas, 1916f:302; name combination.

Caviella australis maenas: Thomas, 1921e:447; name combination.

[*Microcavia*] *moenas*: Kraglievich, 1927a:579; name combination and incorrect subsequent spelling of *maenas* Thomas.

M[*icrocavia*]. *australis maenas*: Yepes, 1935a:242; first use of current name combination.

Microcavia australis moenas: Yepes, 1936:40; incorrect subsequent spelling of *maenas* Thomas.

Microcavia australis joannia: Yepes, 1936:39; part, but not *joannia* Thomas.

This subspecies is found in the montane zones of La Rioja, Catamarca, Salta, and Jujuy provinces of northwestern Argentina at elevations up to 2,500 m.

M. a. salinia (Thomas, 1921)

SYNONYMS:

Caviella australis salinia Thomas, 1921e:447; type locality "Recreo," Catamarca, Argentina.

M[*icrocavia*]. *australis salinia*: Yepes, 1935a:242; first use of current name combination.

This subspecies occupies the saline areas of eastern Catamarca and La Rioja, the southwestern part of Santiago del Estero, and the northwestern part of Córdoba provinces, south to northern San Luis province, Argentina.

NATURAL HISTORY: Rood (1970, 1972) provided extensive information on the behavior and natural history of the species. Mountain cavies are diurnal and active all year. They are herbivores, feeding mostly on leaves, shoots, flowers, and fruits, but may gnaw on the bark of shrubs and trees when necessary (Rood 1970; Tognelli et al. 2001). They exhibit a male dominance hierarchy based upon

Map 378 Selected localities for *Microcavia australis* (●). Contour line = 2,000m.

agonistic interactions. However, cooperation among individuals in the form of group huddling, mutual grooming, and indiscriminant nursing is common. Colony size ranged from 4 to 38 individuals in the Monte Desert (J. R. Contreras and Roig 1978). Rood (1970) also reported densities of 24 individuals/ha from Buenos Aires Province. Home ranges were approximately 0.75 ha for males and half that for females. Reproduction occurred from August to April, with most litters born between September and October. The gestation period in captivity was 54 days (Rood 1970). Mean litter size was 2.8 (range: 1–5; Rood 1972). De la Barrera (1940) provided disease and parasite information.

Microcavia niata (Thomas, 1898)

Northern Mountain Cavy

SYNONYMS: See under Subspecies.

DESCRIPTION: Size small, similar to that of *M. australis*. Dorsal hair length 15–18 mm. General coloration pale

yellowish buff; face, cheeks, hairs on and around base of ears, and upper surface of feet whitish buff; venter and anal region white with slight buffy tinge, not sharply defined on sides (Thomas 1898c). General cranial characters as for genus but varies as follows: incisors more proodont than in *M. australis*, with angle of line of tooththrow about 115°; M3 less complicated, with heel a short projection without internal notch; lateral mandibular fossa not deepened anteriorly. Differs from *M. shiptoni* in that skull bowed more anteriorly (Ellerman 1940), providing strongly convex profile, and length of auditory bullae >10 mm (Tognelli et al. 2001). Auditory bullae large, with maximum diameter greater than one-third zygomatic width (Kraglievich 1930). Measurements of holotype of *M. n. niata* include head and body 190 mm, hindfoot 34 mm, and ear 13 mm (Thomas 1898c), and that of *M. n. pallidior* head and body 200 mm, hindfoot 41 mm, ear 22 mm, and greatest skull length 46.5 mm (Thomas 1902c).

DISTRIBUTION: *Microcavia niata* occupies the Altiplano of southwestern Bolivia and adjacent northern Chile.

SELECTED LOCALITIES (Map 379; from S. Anderson 1997, except as noted): BOLIVIA: La Paz, Huaraco-Antipampa, Esperanza, near Mount Sajama (type locality of *Cavia niata* Thomas); Oruro, Condo, 30 km S and 25 km E of Sajama; Potosí, Pampa de Talapaca. CHILE: Tarapacá, vicinity of Enquela (Marquet et al. 1993).

SUBSPECIES: I recognize two subspecies, following S. Anderson (1997) and Woods and Kilpatrick (2005).

M. n. niata (Thomas, 1898)

SYNONYMS:

Cavia niata Thomas, 1898c:282; type locality “Esperanza, a ‘tambo’ in the neighbourhood of Mount Sahama, Bolivia . . . at an altitude of 4000 metres in the ‘Puna’ region,” La Paz, Bolivia [see S. Anderson 1997].

[*Cavia* (*Cerodon*)] *niata*: E.-L. Trouessart, 1904:527; name combination.

Kerodon niata: Neveu-Lemaire and Grandidier, 1911:16; name combination.

C[*avia*]. (*Caviella*) *niata*: Osgood, 1915:195; name combination.

M[*onticavia*]. *niata*: Thomas, 1916f:303; name combination.

[*Monticavia*] *niata niata*: Tate, 1935:349; name combination.

Caviella [(*Monticavia*)] *niata niata*: Ellerman, 1940:246; name combination.

Cavia (*Microcavia*) *niata*: Pearson, 1951:170; name combination.

Microcavia (*Monticavia*) *niata*: Hückinghaus, 1961a:83; name combination.

Microcavia niata: Cabrera, 1961:572; name combination.

Microcavia niata niata: Cabrera, 1961:572; first use of current name combination.

The nominotypical subspecies is found in the border region of Bolivia and Chile, in extreme southwestern La Paz department, northwestern Oruro department, and the area around Colchane, Chile.

M. n. pallidior (Thomas, 1902)

SYNONYMS:

Kerodon niata pallidior Thomas, 1902c:229; type locality "Pampa Aullaga. Alt. 3700 m," west of Lago Poopó, Oruro, Bolivia (see S. Anderson 1997).

[*Cavia* (*Cerodon*) *niata*] *pallidior*: E.-L. Trouessart, 1904:527; name combination.

C[avia]. (Caviella) niata pallidior: Osgood, 1915:195; name combination.

M[onticavia]. niata pallidior: Thomas, 1916f:303; name combination.

Caviella [(Monticavia)] niata pallidior: Ellerman, 1940:246; name combination.

Microcavia (Monticavia) niata: Hückinghaus, 1961a:83; part; name combination, but did not recognize subspecies.

Microcavia niata pallidior Hückinghaus, 1961a:84; incorrect subsequent spelling of *pallidior* Thomas.

Microcavia niata pallidior: Cabrera, 1961:572; first use of current name combination.

This subspecies is found in the departments of Oruro and Potosí, Bolivia.

NATURAL HISTORY: Marquet et al. (1993) reported on populations occurring in bog areas in the Chilean highlands (3,700–4,000 m). They observed colonies in shrubby areas and in close proximity to *Ctenomys* burrows, possibly occupying the abandoned burrows as reported for *Galea musteloides* by Mann (1978). Here, the diet of *M. niata* consisted of the herbaceous genera *Eleocharis* (Cyperaceae) and *Werneria* (Asteraceae), the grasses *Distichlis* and *Deyouxia* (Poaceae), and aquatic plants such as *Liolaopsis* (Apiaceae). A single colony was composed of 5 males and 10 females, 8 were juveniles and 7 were adults, ranging in size from 81–380 g. No sexual or agonistic behavior was observed among members of the same colony. However, individuals of a colony were highly territorial and aggressive towards those of other colonies and elicited alarm calls in response to the approach of potential predators.

In the Sajama area of Bolivia (3,800 m), *M. niata* occupied small isolated salt flats located within very sandy Puna habitat dominated by Peruvian feather grass (*Stipa ichu*) and woody shrubs. Their burrows were interspersed throughout an area also occupied by *Ctenomys*; no *Microcavia* were found in the surrounding areas. Individuals were active from dawn to dusk. Most active burrows appeared to contain a

Map 379 Selected localities for *Microcavia niata* (●) and *Microcavia shiptoni* (○). Contour line = 2,000 m.

single animal, however a pregnant female with two embryos and two subsadults were observed foraging together and were eventually taken from a single tunnel system no longer than 5 m in length (J. Dunnun, pers. obs.).

Microcavia shiptoni (Thomas, 1925)

Shipton's Mountain Cavy

SYNONYMS:

Nanocavia shiptoni Thomas, 1925a:419; type locality "Laguna Blanca, Catamarca Altitude 3400 m," Argentina.

Caviella [(Nanocavia)] shiptoni: Ellerman, 1940:246; name combination.

Monticavia (Nanocavia) shiptoni: Kraglievich, 1930a:94; name combination.

Microcavia shiptoni: Cabrera, 1953:34; first use of current name combination.

DESCRIPTION: General characteristics as for genus. Dorsal color dull brownish buffy to tawny, venter buffy white or whitish with base of hairs brownish slaty (Mares, Ojeda, and Barquez 1989). Ears short and covered with fine buffy hairs. Similar in appearance to *M. australis*, but somewhat smaller. Head and body length 181–220 mm, hindfoot

36–39 mm, and mass 150–220 g. Dimensions of holotype include head and body 220 mm, hindfoot 37 mm, and greatest skull length 45 mm (Thomas 1925a). Bullae considerably smaller than in other two species, with portion appearing on occipital surface nearly uninflated (Ellerman 1940).

DISTRIBUTION: *Microcavia shiptoni* occurs in the highlands of northwestern Argentina between the elevations of 3,000 and 4,000 m in the provinces of Catamarca, Tucumán, and Salta.

SELECTED LOCALITIES (Map 379): ARGENTINA: Catamarca, Laguna Blanca (type locality of *Nanocavia shiptoni* Thomas); Salta, Chorrillos (C. A. Quintana 1996).

SUBSPECIES: *Microcavia shiptoni* is monotypic.

NATURAL HISTORY: Habits and behavior are unknown (Mares, Ojeda, and Barquez 1989).

REMARKS: Mares, Ojeda, and Barquez (1989) suggested *M. shiptoni* may be a race of *M. australis*, however, recent work utilizing molecular data supports its recognition as a distinct species (Dunnnum 2009). The phylogenetic placement of *M. shiptoni* in relation to the other *Microcavia*, however, is not fully resolved. Quintana (1996) suggested that *M. shiptoni* was most similar to *M. australis* and the extinct *M. robusta*. Based on molecular data, the best supported hypothesis is a *shiptoni*–*niata* sister relationship (Dunnnum 2009; Mahadeshwar 2010).

Subfamily Dolichotinae Pocock, 1922

The Dolichotinae comprises the single Recent genus *Dolichotis*. This subfamily appears as sister to the Hydrochoerinae in molecular phylogenetic analyses (Opazo 2005; Upham and Patterson 2012) as well as combined fossil and molecular work (M. E. Pérez and Pol 2012), with the divergence estimates for these subfamilies ranging from the early Middle Miocene (Opazo 2005; Rowe et al. 2010) to the late Miocene (M. E. Pérez and Pol 2012).

Genus *Dolichotis* Desmarest, 1819

I include both species of Mara within the genus *Dolichotis*, although many authors (Cabrera 1961; Mares and Ojeda 1982; Mares, Ojeda, and Barquez 1989; Rowe and Honeycutt 2002; Barquez, Díaz, and Ojeda 2006) have placed *D. salinicola* in the genus *Pediolagus*. The Maras are currently distributed throughout the arid and semi-arid lowlands of southern Bolivia, Paraguay, and Argentina, and are present in the fossil record from early and mid-Pleistocene deposits (McKenna and Bell 1997). Opazo (2005) estimated divergence time of the two extant species at 7.5 ± 4.8 mya, Dunnnum (2009) at 5.9 mya (95% HPD

1.8–9.9 mya), both based on molecular data but utilizing differing methods. These dates are similar to those within other caviid genera and, I argue, provide further support for the inclusion of both species within the single genus *Dolichotis*.

Maras are hare-like in appearance and are adapted for a cursorial life. The limbs are long in comparison to other caviids, with the hind limbs much longer and more muscular than the forelimbs. The radius is longer than the humerus. The hind limbs have three hoof-like digits with the central digit elongated. The forefeet have four sharply clawed digits with the middle two equally enlarged. The maras are much larger than other Caviinae, ranging from 450 mm head and body length in *D. salinicola* to 800 mm in *D. patagonum*. The hairy ears are long, with a simple supertragus. The short tail is nearly hairless. The dorsal pelage is agouti gray, and a distinct white rump band is present across the tail. Under parts are white; the flanks and chin are orange. A single pair of anal glands is present above the anus, in contrast to a position anterior to the anus in all other caviids (C. M. Campos, Tognelli, and Ojeda 2001).

Cranially, the frontals are broadened, with the orbits roofed in by expansion of the frontal bone, which is deeply notched anteriorly. The nasals are specialized and do not extend as far forward as the premaxillae. The paroccipital processes are elongated more so than in genera of Caviinae or *Kerodon*, although less than in *Hydrochoerus*. The palate is short, extending posteriorly only to about the level of M2. The jugal is broad and short. Auditory bullae are moderately large. The cheek teeth are ever-growing and unilaterally hypsodont. The upper cheek teeth are bilobed, except for M3, which is divided into three lobes by two reentrant folds. Lower cheek teeth have one labial fold dividing each tooth into two lobes (Ellerman 1940). The diastema is longer than the length of the maxillary toothrow, the nasolacrimal foramen is absent in the lateral view, and the mesopterygoid fossa is positioned at the level of the anterior and posterior prisms of the M2 (Ubilla and Rinderknecht 2003).

SYNONYMS:

Cavia: Zimmermann, 1780:328; description of *patagonum*; not *Cavia* Pallas.

Lepus: Oken, 1816:825; inclusion of *patagonicus*; unavailable name (ICZN 1956).

Dolichotis Desmarest, 1819g:211; type species *Cavia patagonica* Shaw, by original designation (= *Cavia patagonum* Zimmermann).

Dasyprocta: Desmarest, 1822:358; part (listing of *patagonica*); not *Dasyprocta* Illiger.

Chloromys: Desmoulin, 1823:47; part (listing of *patagonicus*); not *Chloromys* F. Cuvier.

Mara d'Orbigny, 1829:220; based on "La Lièvre de Patagonie."

Pediolagus Marelli, 1927:5; type species *Dolichotis centralis* Weyenbergh, by original designation (= *Dolichotis salinicola* Burmeister, 1876).

Weyenberghia Kraglievich, 1927a:578; type species *Dolichotis salinicola* Burmeister; proposed as subgenus; objective synonym of *Pediolagus* Marelli.

Paradolichotis Kraglievich, 1927b:594; replacement name for *Weyenberghia* Kraglievich, type species *Dolichotis salinicola* Burmeister (= *Dolichotis centralis* Weyenbergh).

Lagospedius Marelli, 1928:103; type species *Lagospedius centralis* (= *Dolichotis centralis* Weyenbergh).

KEY TO THE SPECIES OF *DOLICHOTIS*:

1. Size smaller, head and body length <500; legs relatively short; ulna approximately the same length as the skull or the tibia; nasal bones with the edges not projected forward; two pairs of mammae; penis with two spikes at the base of the glandular sac. . . . *Dolichotis salinicola*
- 1'. Size larger, head and body length >500; legs relatively long; ulna substantially longer than the skull or the tibia; nasal bones with the edges projected forward; four pairs of mammae; penis with no spikes at base of glandular sac *Dolichotis patagonum*

Dolichotis patagonum (Zimmermann, 1780)

Patagonian Mara

SYNONYMS: See under Subspecies.

DESCRIPTION: Second largest caviid, after capybaras total length 600–800 mm, greatest length of skull 125–133 mm, and mass 7–8 kg (C. M. Campos, Tognelli, and Ojeda 2001). Dorsal coloration agouti gray; lower portions of rump with sharply defined white patch separated from dorsal area by contrasting darker area; venter white and flanks, cheeks, chin and chest orange brown. Cranial and tooth characters as for genus.

DISTRIBUTION: *Dolichotis patagonum* occurs in lowland forest, shrub, and grasslands of Argentina, between approximately 28°S to 50°S (C. M. Campos, Tognelli, and Ojeda 2001) but locally extirpated from some regions such as Buenos Aires province (Cabrera 1953).

SELECTED LOCALITIES (Map 380): ARGENTINA: Buenos Aires, D'Orbigny (Cabrera 1953); Catamarca, Catamarca (Cabrera 1953); Córdoba, Cruz del Eje (Thomas 1902d), near border of San Luis on road between Río Cuarto and Mercedes (Cabrera 1953); La Rioja, La Rioja (Cabrera 1953); San Luis, San Luis (Cabrera 1953); Santa Cruz, Bahía del Fundo (Krumbiegel 1941); Río Negro, east of Nahuel Huapi (Krumbiegel 1941).

Map 380 Selected localities for *Dolichotis patagonum* (●). Contour line = 2,000 m.

SUBSPECIES: I follow Cabrera (1953) and C. M. Campos, Tognelli, and Ojeda (2001) and recognize two subspecies.

D. p. patagonum (Zimmermann, 1780)

SYNONYMS:

Cavia patagonum Zimmermann, 1780:328; type locality unknown. Tate (1935:355) stated that Zimmermann "alluded to Pennant's knowledge of the animal, but no mention of it by Pennant appears until his second edition of 'History of Quadrepeds.'" Tate (1935) listed the type locality as "Patagonia."

Cavia magellanica Kerr, 1792:220; type locality "inhabits the country about Port Desire in Patagonia," Argentina, based on the Patagonian Cavy of Pennant (1781).

Cavia Patachonica Shaw, 1801:226; type locality "Patagonia," Argentina, based on the Patagonian Cavy of Pennant (1781).

- Lepus patagonicus* Oken, 1816:825; name combination and incorrect subsequent spelling of *patagonum* Zimmermann, 1780; unavailable name (ICZN 1956).
- Dasyprocta patagonum*: Illiger, 1815:108; name combination.
- [*Dolichotis*] *patachonica*: Desmarest, 1819g:210; name combination.
- [*Dolichotis*] *patagonicha* Desmarest, 1819h:40; incorrect subsequent spelling of *patachonica* Shaw, 1801.
- Dolichotis* [*magellanica*]: Say, 1821:331, footnote for *Cavia magellanica*; name combination.
- Dasyprocta patachonica*: Desmarest, 1822:358; name combination; placed *Cavia patachonica* Shaw, 1801 in *Dasyprocta* Illiger [Dasyproctidae] but called attention to the genus *Dolichotis* in a footnote.
- Chloromys patagonicus*: Desmoulins, 1823:47; name combination, and incorrect subsequent spelling of *Cavia patachonica* Shaw.
- D[asyprocta]. patagonica* Gray, 1827:272; incorrect subsequent spelling of *patachonica* Shaw.
- Mara magellanica*: Lesson, 1831:113; name combination.
- Mara patagonica* Lesson, 1831:plate xlii; name combination, and incorrect subsequent spelling of *patachonica* Shaw.
- Chloromys patachonicus* Waterhouse, 1839:89; incorrect subsequent spelling of *patachonica* Shaw.
- D[olichotis]. patagonica*: Wagner, 1844:iv:66; name combination and incorrect subsequent spelling of *patachonica* Shaw.
- Dolichotis patichonica* Waterhouse, 1848:plate 3, Fig. 1; incorrect subsequent spelling of *patachonica* Shaw.
- Dolichotis patagona*: J. A. Allen, 1902a:22; argued that *patagonum* Zimmermann took precedence over *patachonica* Shaw.
- Dolichotis magellanicus*: Thomas, 1929:44; justified emendation of *magellanica* Kerr; considered *Dolichotis* a masculine noun.
- D[olichotis]. magellanica magellanica*: Yepes, 1935a:245; name combination and incorrect gender agreement.
- Dolichotis australis*: Cabrera and Yepes, 1940:233; name combination.
- Dolichotis* [(*Dolichotis*)] *patagona patagona*: Ellerman, 1940:248; name combination and incorrect gender agreement.
- Dolichotis patagonum*: Krumbiegel 1941:21; name combination.
- Dolichotis patagonum patagonum*: Krumbiegel, 1941b:24; first use of current name combination.

The nominotypical subspecies is known from central Buenos Aires province west to Córdoba, San Luis and Mendoza provinces, and south to Santa Cruz province in Argentina (Cabrera 1953).

D. p. centricola (Thomas, 1902)

SYNONYMS:

- Dolichotis magellanicus centricola* Thomas, 1902d:242; type locality "Cruz del Eje, Central Cordova," Córdoba Province, Argentina.
- D[olichotis]. salinicola*: Thomas, 1902d:243; part; not *salinicola* Burmeister.
- Dolichotis* [(*Dolichotis*)] *patagona centricola*: Ellerman, 1940; name combination and incorrect gender agreement of *patagonum* Zimmermann.
- Dolichotis australis centricola*: Cabrera and Yepes, 1940:233; name combination.
- Dolichotis patagonum centricola*: Krumbiegel, 1941:24; first use of current name combination.

This subspecies occurs in Catamarca, the eastern part of La Rioja, northwestern Córdoba, and southwestern Santiago del Estero provinces, Argentina (Cabrera 1953).

Cabrera (1953) remarked on the misleading nature of the type locality "Cruz del Eje, Central Cordova," which refers to the name of a train station and not actually to central Córdoba province. The subspecies only reaches the northern portion of Córdoba province.

NATURAL HISTORY: C. M. Campos, Tognelli, and Ojeda (2001) reviewed the ecology and life history of the Patagonian Mara. This species is an herbivore, feeding predominantly on fruits and green vegetation (Bonino et al. 1997; C. M. Campos 1997; C. M. Campos and Ojeda 1997) with a preference for grasses over shrubs and forbs (Sombra and Mangione 2005). Home range size varied from 33.25 to 197.5 ha, with a mean of 97.87 ha (Taber 1987). They are strongly monogamous, with pairs remaining together until death (Genest and Dubost 1975). Breeding is either communal or solitary, with increased pup survival in dens with higher numbers. Selection of open habitats for breeding warrens resulted in significantly higher pup survival in Mara populations in Península Valdés (Baldi 2007). Breeding in southern Argentina occurred from August to December or January (Baldi 2007; Taber and MacDonald 1992). Gestation was 100 days in the wild and most females produced one litter per year (Taber, 1987). Four pairs of ventral mammae are present in females (Weir 1974b). Eisenberg (1974) described vocalizations. Rues et al. (2013) delineated trophic interactions between maras and the introduced European hare (*Lepus europaeus*) in San Juan province, Argentina. Sutton and Hugot (1987), Sutton and Durette-Desset (1995), and Porteous and Pankhurst (1998) provided information on parasites.

REMARKS: C. M. Campos, Tognelli, and Ojeda (2001) summarized the nomenclatural history and recognized two

subspecies, following Cabrera (1953). Tate (1935:355) noted that Lesson (1827) employed the combination *Lepus magellanicus*. Cabrera (1953), however, argued that Lesson's name actually referred to the European hare, *Oryctolagus cuniculus*, not *Dolichotis*. Wurster et al. (1971) described a karyotype with $2n = 64$, FN = 124, and meta-centric sex chromosomes.

Dolichotis salinicola Burmeister, 1876

Chacoan Mara

SYNONYMS:

Dolichotis salinicola Burmeister, 1876a:635; type locality "Central Argentine Railway . . . near the stations Totora-lejo and Recreo, about lat. 29° S and long. 65° W," Catamarca, Argentina.

Dolichotis centralis Weyenbergh, 1877:247; type locality "der Sierra de Cerdoba (*sic*) . . . die tusschen de dorpen Perchal en Quilpolos," Sierra de Córdoba, presumably between the pueblos of Perchal and Quilpo, Córdoba province, Argentina.

Dolichotis salinica Weyenbergh, 1877:247; incorrect subsequent spelling of *salinicola* Burmeister.

Dolichotis patagonica: Burmeister, 1879:260; part (see Berg 1898:24); not *patachonica* Shaw [= *patagonum* Zimmerman].

[*Dolichotis patagonica*] *salinicola*: E.-L. Trouessart, 1880b: 196–197; name combination, and incorrect subsequent spelling of *patachonica* Shaw.

[*Dolichotis*] *centralis*: E.-L. Trouessart, 1904:528; name combination.

Pediolagus centralis: Marelli, 1927:plates 1, 2, and 5; name combination.

Weyenberghia salinicola: Kraglievich, 1927a:578; name combination as subgenus.

[*Dolichotis*] (*Paradolichotis*) *salinicola*: Kraglievich, 1927b: 594; name combination.

Pediolagus salinicola: Yepes, 1935a:245; name combination.

Dolichotis [(*Paradolichotis*)] *salinicola*: Ellerman, 1940: 248; name combination.

Dolichotis salinicola ballivianensis Krumbiegel, 1941:22; type locality "Fortin Ballivian am Pilcomayo," Río Pilcomayo, Salta, Argentina.

Dolichotis salinicola salinicola: Krumbiegel, 1941:23; first use of current name combination.

Pediolagus salinicola cyniclus Cabrera, 1953:75; type locality "La Florencia, Formosa," Argentina.

DESCRIPTION: General appearance similar to *D. patagonum* but overall size smaller and pelage coloration duller with less orange. Total length 439–515 mm, hindfoot length 91–101 mm, ear length 58–64 mm, and mass 1,800–

2,300 g (Mares, Ojeda, and Barquez 1989). Dorsum agouti brown, extending onto sides and throat; sides somewhat lighter and venter white and tan; cheeks and chin washed with tan; white patches occur in front of and behind eyes. Limbs shorter than in *D. patagonum*; ulna approximately same length as skull or tibia. Two pairs of mammae present and penis contains two spikes at base of glandular sac. Cranial characters as for genus but, in contrast to *D. patagonum*, lower anterior prolongation of nasals rudimentary or absent (Ellerman 1940).

DISTRIBUTION: *Dolichotis salinicola* occurs in the Chaco ecoregions of extreme southern Bolivia, Paraguay and northwestern Argentina as far south as Córdoba province.

SELECTED LOCALITIES (Map 381): ARGENTINA: Córdoba, Cruz del Eje (Thomas 1902d); Formosa, La Florencia (Cabrera 1953); La Rioja, La Rioja (Cabrera 1953); Salta, Fortín Ballivian (*Dolichotis salinicola ballivianensis*), Macapillo (Cabrera 1953). BOLIVIA: Santa Cruz, San José Chiquitos (S. Anderson 1997); Tarija, Pilcomayo (S. Anderson 1997). PARAGUAY: Alto Paraguay, Estancia 3 Marias (TTU 79838); Presidente Hayes, Estancia Samaklay (TTU 80407).

SUBSPECIES: *Dolichotis salinicola* is monotypic.

NATURAL HISTORY: The ecology of *D. salinicola* is similar to that of *D. patagonum*. It occupies the dry, low, thorny scrub of the arid Chaco. The species is diurnal and social, often found in pairs or groups, living in self-constructed burrows or those abandoned by viscachas. Females have two pairs of mammae. Gestation period is about 77 days, with one to two young per litter (Weir 1974b), although, Mares, Ojeda, and Barquez (1989) reported a gestation of two months and litter sizes ranging from two to five.

REMARKS: Burmeister's (1876a) original description of *D. salinicola* was based on young individuals about half adult size; he subsequently (1876b) elaborated on the external characteristics of this species based on his observations of two living adults. Cabrera (1961) included *D. salinicola* in the genus *Pediolagus* and recognized three subspecies, *ballivianensis* Krumbiegel, *cyniclus* Cabrera, and *salinicola* Burmeister. Woods (1984, 1993) followed Ellerman (1940) and regarded *Pediolagus* as a subgenus of *Dolichotis*. Verzi and Quintana (2005) recorded this species from the San Andrés Formation of the late Pliocene of coastal Buenos Aires province, Argentina.

Kraglievich (1927a:578) proposed *Weyenberghia* as a subgenus; however, later in the same volume of *Physis* (Kraglievich 1927b:594), he proposed the replacement name *Paradolichotis*, stating that *Weyenberghia* had been previously applied to an insect and was thus unavailable

Map 381 Selected localities for *Dolichotis salinicola* (●). Contour line = 2,000 m.

as a homonym. I am unable to find generic use of *Weyenberghia* predating Kraglievich's publication. Kraglievich may have been mistaken in thinking the name was preoccupied by *Lasiadora weijenberghii* Thorell, 1894 (an arachnid). This tarantula species was subsequently included within *Weyenberghia* Mello-Leitao 1941. Cabrera (1961) was not sure if *Weyenberghia* was indeed preoccupied and followed it with a question mark ("Preocupado?").

Subfamily Hydrochoerinae Gray, 1825

Kerodon is included within this subfamily due to the consistently observed sister taxon relationship between *Hydrochoerus* and *Kerodon* in both morphological and molecular sequence analyses (Woods 1984; Rowe and Honeycutt 2002; Opazo 2005; Upham and Patterson 2012). Divergence between the two genera occurred in the mid-Miocene, from between 8 mya (M. E. Pérez and Pol 2012) and 12.28 ± 2.3 mya (Opazo 2005; see also Upham and Patterson 2012). Several distinct lineages of the Hydrochoerinae are known in the fossil record and some fossil forms extended into North America during the late Pliocene and Pleistocene (Mones and Ojasti 1986; Woods 1984; Mones 1991; Walton 1997; Vucetich et al. 2005, 2013; Deschamps et al. 2012). A complete

review of virtually all aspects of the evolution and ecology of capybara is available in J. R. Moreira et al. (2013).

Genus *Hydrochoerus* Brisson, 1762

Two species are recognized, *H. hydrochaeris* and *H. isthmius*. The genus is found in the fossil record from the Pleistocene in North America and the early or mid-Pleistocene in South America (McKenna and Bell 1997).

Capybaras are the largest living rodent, similar in appearance to *Cavia* only much larger with a head and body length varying from 100 to 130 cm and mass from 27 to 79 kg. The tail is vestigial. The pelage is sparse, long, and coarse, reddish brown to grayish dorsally and yellow brown ventrally. Mature males possess enlarged sebaceous glands on the snout. The forefoot has four digits and hindfoot has three, as in the other Caviids. The digits are arranged in a radial pattern and are partially webbed. Females have six pairs of ventral mammae. The limbs are short, the head is broad and large, and the muzzle is heavy and truncate. The eyes are located dorsally and far back on the head. Toothrows converge anteriorly. The incisors are white, with shallow grooves on their anterior surfaces. Cheek teeth are evergrowing and more complex than the other caviids, composed of multiple plates or lophs. M3 is enormously enlarged, exceeding the length of the other three molariform teeth combined (Ellerman 1940; Woods 1984).

SYNONYMS:

- Mus*: Linnaeus, 1758:59; part (description of *porcellus*); not *Mus porcellus* Linnaeus.
- Hydrochoerus* Brisson, 1762:80; type species *Sus hydrochaeris* Linnaeus, by subsequent designation (ICZN 1998).
- Cavia*: Pallas, 1766:31; part (description of *capybara*); not *Cavia* Pallas.
- Sus*: Linnaeus, 1766:102; part (description of *hydrochaeris*); not *Sus* Linnaeus.
- Hydrochaeris* Brännich, 1771:44; incorrect subsequent spelling of *Hydrochoerus* Brisson.
- Hydrochaerus* Erxleben, 1777:191; part (description of *capybara*); incorrect subsequent spelling of *Hydrochoerus* Brisson.
- Calva* Gmelin, 1788:120; part (listing of *capybara*); incorrect subsequent spelling of *Cavia* Pallas.
- Savia* Treviranus, 1802:211; part (listing of *capybara*); unjustified emendation of *Cavia* Pallas.
- Hydrochoenus* Gray, 1821:304; incorrect subsequent spelling of *Hydrochoerus* Brisson.
- Hydrocharus* Gray, 1825; incorrect subsequent spelling of *Hydrochoerus* Brisson.
- Hydrocherus* F. Cuvier, 1829a:492; incorrect subsequent spelling of *Hydrochoerus* Brisson.

Capibara Moussy, 1860:13; *nomen nudum*.
Capiguara Liais, 1872:545; new name for *Hydrochoerus* Brisson.
Hydrochoeris J. A. Allen, 1916d:568; incorrect subsequent spelling of *Hydrochoerus* Brisson.
Xenohydrochoerus Rusconi, 1934a:21; type species *Xenohydrochoerus ballesterensis* Rusconi, by original designation.
Hydrocheirus Hollande and Batisse, 1959:1; incorrect subsequent spelling of *Hydrochoerus* Brisson.
 REMARKS: Husson (1978:456) discussed the spelling of the generic name and concluded that *Hydrochoerus* Brisson was not valid because Brisson's (1762) work was not consistently binominal. The International Commission on Zoological Nomenclature (ICZN 1998) subsequently ruled that Brisson's names, including *Hydrochoerus* Brisson, were valid. Moussy (1860) is a summary of the wild and domestic animals occurring in Argentina and includes no descriptions. His *Capibara* (based on Marcgraf 1648) is listed in the synonymy for the capybara and should be regarded as a *nomen nudum*. Mones (1991) reviewed the genus.

KEY TO THE SPECIES OF *HYDROCHOERUS*:

1. Size large, head and body length >1 m; premaxillae with posteriorly extended portions ending well in front of posterior plane of incisive foramina; $2n = 66$, FN = 102
 *Hydrochoerus hydrochaeris*
- 1'. Size small, head and body length <1 m; premaxillae with posteriorly extended portions reaching to near posterior plane of incisive foramina; $2n = 64$, FN = 104
 *Hydrochoerus isthmius*

Hydrochoerus cololoi Berro, in Francis and Mones, 1968:46; *nomen nudum*.

Hydrochoerus hydrochaeris uruguayensis: Barlow, 1969: 44; name combination.

DESCRIPTION: General characteristics as for genus; body large and heavy, limbs short, and forefeet and hindfeet mesaxonic and webbed. Larger of two species, with length over 1,300 mm and mass over 75 kg. Hair course, from dark brown and reddish to light brown and yellowish. Hair length 30–120 mm. Skull with strong zygomatic, broad jugal, and extremely elongated paroccipital process. Palate long, reaching posterior part of M3. Bullae proportionally smaller than in other Caviidae. Pterygoid fossa deep but not perforated. Angular process of mandible not everted as in typical Hystricognath rodents. First three upper cheek teeth composed of two Y-shaped prisms; M3 11 to 14 prisms, first Y-shaped, others comprised of single plates, except posterior ones, which may vary. Lower cheek teeth composed of three prisms, which may be separated into up to six plates in m3. Prisms on upper and lower teeth separated by thick cement lamina. Description based on Mones and Ojasti (1986).

DISTRIBUTION: *Hydrochoerus hydrochaeris* occurs east of the Andes in eastern Colombia through Venezuela, the Guyanas, Ecuador, and Peru, south through Brazil, Bolivia, Paraguay, northwestern and eastern Argentina, and Uruguay.

SELECTED LOCALITIES (Map 382): **ARGENTINA:** Entre Ríos, islands of the lower Río Paraná delta (R. D. Quintana 2002), Jujuy, Agua Salada (M. M. Díaz and Barquez 2007), Paraná (type locality of *Hydrochoerus irroratus* Ameghino). **BOLIVIA:** Beni, camino San Borja to Trinidad (S. Anderson 1997); Santa Cruz, Buena Vista (S. Anderson 1997). **BRAZIL:** Ceará, Lagoa do Catu (Feijó and Langguth 2013); Maranhão, Miritiba (Mones 1991); Pará, 52 km SSW of Altamira, right bank Rio Xingu, (Voss and Emmons 1996), Ilha de Marajó, Fazenda Eco-Búfalos (J. R. Moreira et al. 1997); Paraíba, Rio Cuiá, bairro Valentina (Feijó and Langguth 2013); Rio de Janeiro, Vale do Paraíba, Itatiaia (Avila-Pires 1977); Sergipe, Rio São Francisco, 2 km SW of Penedo (Feijó and Langguth 2013). **COLOMBIA:** Arauca, Campo Petrolero de Caño Limón (Forero-Montana et al. 2003). **ECUADOR:** Pastaza, Mera (Rageot and Albuja 1994). **FRENCH GUIANA:** Cayenne, Les Nouragues (Voss and Emmons 1996). **GUYANA:** Mazaruni-Potaro, Kartabo (Voss and Emmons 1996). **PARAGUAY:** Boquerón, Fortín Juan de Zalazar (Wetzel and Lovett 1974). **PERU:** Amazonas, Huampami, Río Cenepa (Patton et al. 1982); Madre de Dios, Cocha Cashu Biological Station (Voss and Emmons 1996). **SURINAM:** Wanica, Kwatta (Husson 1978). **URUGUAY:** Canelones, Arroyo Tropa Vieja (Barlow 1969); Trienta Tres, 16 km SSW of Boca del Río Tacuari (Barlow 1969). **VENEZUELA:** Apure, Río Cinaruco, 65 km NW of Pto. Páez (Hand-

ley 1976); Aragua, Lake Valencia (Osgood 1910); Bolívar, Río Supamo, 50 km SE of El Manteco (Handley 1976); Monagas, Hato Mata de Bejucu (Handley 1976).

SUBSPECIES: Cabrera (1961) recognized three subspecies (*dabbenei* Rovereto from Paraguay and northeastern Argentina, *uruguayensis* Ameghino and Rovereto from Uruguay and eastern Argentina, and the nominotypical form from the remainder of the range). Mones and Ojasti (1986:1), however, noted that populations exhibited a latitudinal cline in body size and mass, and that subspecies recognition could only be “based on extreme populations and arbitrary limits.” They chose to view *H. hydrochaeris* as monotypic although highly variable geographically.

NATURAL HISTORY: Mones and Ojasti (1986) reviewed the ecology, behavior, reproduction, and other aspects of population biology, including parasites. Capybaras occupy a wide variety of mesic lowland habitats including forested riverbanks, mangrove swamps, and brackish wetlands. Regarded as a semiamphibious mammal, it requires water for drinking, wallowing, and protection. They are diurnal herbivores and feed on grasses, sedges, and semi-aquatic plants. They live in herds typically ranging in size from two to 30 animals controlled by a dominant male. During drought periods, temporary herds of up to a hundred animals may aggregate around remaining waterholes. Home range size varies from 10 ha in high-density populations to over 200 ha. Capybara breed throughout the year but mating frequency appears to increase at the onset of the rainy season. The gestation period is 150 days and females normally breed once per year, twice if conditions remain favorable. Litter size ranges from one to seven, and averaged four in Venezuelan populations. Over 80 parasites are listed in the specialized literature. Borges-Landáez et al. (2012) examined potential gene flow effects generated by hunting pressure, and thus the preservation of genetic diversity, in populations of capybara in the llanos of western Venezuela. Moriera et al. (2013) reviewed capybara biology, evolution, and ecology.

REMARKS: Marcgraf (1648:230) was the first to describe and illustrate a capybara in Willem Piso’s *Historia naturalis Brasiliae*, a description upon which Linnaeus (1766:103) subsequently based his *Sus hydrochaeris*. Hollister (1914) mentioned Surinam as the type locality of the capybara, following the statement by Linnaeus (1766) of “habitat in Surinamo.” Tate (1935:355), however, gave the type locality as “Brazil,” acknowledging that, while Linnaeus wrote Surinam, he had based his *Sus hydrochaeris* wholly upon Marcgraf’s description and his own examination of a young animal, apparently without a stated locality of origin. Marcgraf’s travels and observations were confined to northeastern Brazil. In concert with Tate (1935), Cabrera (1961:583) gave the type locality as “Pernambuco, Brazil,”

Map 382 Selected localities for *Hydrochoerus hydrochaeris* (●). Contour line = 2,000m.

Carvalho (1965) cited it as “banks of the São Francisco river, in the State of Alagoas,” and Mones (1975) listed it as “Río São Francisco en la frontera entre los estados de Alagoas y Sergipe, Brasil.” Husson (1978:451) selected the juvenile specimen apparently seen by Linnaeus as the lectotype and restricted the type locality to Surinam. Most recently, Feijó and Langguth (2013:103–107) designated a neotype for *Sus hydrochaeris* Linnaeus, with its precise locality of “Río São Francisco, 2km suboeste da cidade de Penedo, estado de Sergipe, Brasil,” because (1) the type locality of *Sus hydrochaeris* Linnaeus remained uncertain, (2) Husson’s choice of a lectotype did not by itself define Surinam as the type locality since the origin of Linnaeus’s specimen was uncertain, (3) there was no specimen corresponding to the lectotype, and (4) *Sus hydrochaeris* Linnaeus was polytypic, with multiple subspecies subsequently named.

The karyotype consists of a $2n = 66$ and $FN = 102$ (Wurster et al. 1971).

Hydrochoerus isthmius Goldman, 1912

Lesser Capybara

SYNONYMS:

Hydrochaerus hydrochaeris: J. A. Allen, 1904c:444; listing of a specimen from Mamatoca, Magdalena, Colombia.

Hydrochoerus hydrochaeris: Osgood, 1912:56; listing of specimens from El Panorama, Río Aurare, Zulia, Venezuela.

Hydrochoerus isthmius Goldman, 1912b:11; type locality “Marragantí, near the head of tide-water on the Río Tuyra, eastern Panama,” Darién.

Hydrochaeris isthmius: Hall and Kelson, 1959:785; name combination.

Hydrochaeris hydrochaeris isthmius: Cabrera, 1961:584; name combination.

Hydrochaeris hydrochaeris: Handley, 1966:785; name combination.

Hydrochoerus hydrochaeris isthmius: D. Heinemann, 1975: 446; name combination.

DESCRIPTION: Smaller than *H. hydrochaeris*, with total length approximating 100 cm and greatest skull length of holotype 200 mm. Pelage color ranges from dark reddish to dull clay color, usually darker above than below, and blackish in some specimens on middle of face, cheeks, lower part of rump, and outer sides of hind legs. Eyerings, sides of muzzle, and spots at base of ears paler. The ears and feet brownish (Goldman 1912b). Measurements of holotype include head and body length 1,025 mm and hindfoot length 200 mm (Goldman 1912b). Skull with pterygoid processes shorter, thicker, and more rounded, less produced posteriorly.

DISTRIBUTION: *Hydrochoerus isthmius* occurs in Panama, western Colombia, and northwestern Venezuela.

SELECTED LOCALITIES (Map 383; South America only): COLOMBIA: Magdalena, Santa Marta, Mamatoco

Map 383 Selected localities for *Hydrochoerus isthmius* (●). Range in Panama from Hall (1981). Contour line = 2,000m.

(J. A. Allen 1904c); Valle del Cauca, Río Frio (J. A. Allen 1916b). VENEZUELA: Zulia, El Panorama (Osgood 1912).

SUBSPECIES: *Hydrochoerus isthmius* is monotypic.

NATURAL HISTORY: Little is known about the population biology and ecology of this species. Populations in Panama are scarce and shy and although small groups can be seen at dusk or dawn around Gamboa pond and on the shores of islands in the Panama Canal, in other areas they are mostly nocturnal (F. A. Reid 1997). The gestation period ranges from 104 to 111 days (Weir 1974b). In northwestern Colombia in Córdoba department, Lesser Capybara's were abundant where they used stream edges, swamps, and permanent lagoons (Ballesteros Correa and Jorgenson 2009). Herd sizes averaged 4.9 individuals, with the threat of local populations resulting from hunting and habitat destruction. Principal predators included domestic dogs, *Boa constrictor*, the crocodilians *Caiman crocodiles* and *Crocodilus acutus*, and the Crested Eagle (*Morphnus guianensis*).

REMARKS: Handley (1966:785) and Mendez (1993) regarded *H. isthmius* as a subspecies of *H. hydrochaeris*, but Mones (1991) in his systematic and phylogenetic review recognized it as a distinct species. The karyotype is $2n = 64$ and FN = 104 (Peceño 1983).

Genus *Kerodon* F. Cuvier, 1823

The genus *Kerodon* contains two species, *K. acrobata* and *K. rupestris*, distributed in eastern and central Brazil, from the state of Piauí to the northern part of Minas Gerais (Cabrera 1961; Moojen et al. 1997). Both are rock specialists that inhabit the semiarid Caatinga region. The genus dates from the late Pleistocene (McKenna and Bell 1997).

Mocos, or rock cavies, are gray-agouti dorsally and light brown on the venter. Typical adult weight can reach 1 kg and body size is equal to or larger than that of *Cavia*. The genus is similar in body form to members of the Caviinae but differs in a number of unique characteristics, including clawless toes of the manus and pes covered with a thick leather-like epidermis, and all digits with subcutaneous nails except the innermost digit of the pes, which has a small grooming claw. A tail is absent or only a vestigial projection. The sternum is narrow and rounded, not broad and flat as in the Caviinae. The skull, especially the rostrum, is much narrower and longer than that of the Caviinae and the length of the diastema is proportionately larger as well (Lacher 1981; Moojen 1952b). The infraorbital foramen lacks a canal for nerve transmission. The incisive foramen is excessively narrowed (Ellerman 1940). G. Lessa et al. (2005) reported on geographic variation in cranial

characters among populations of *K. rupestris* and between this species and *K. acrobata*.

Traditionally the genus *Kerodon* has been placed within the Caviinae (Ellerman 1940; Cabrera 1961; Woods 1993; McKenna and Bell 1997) although behavioral and reproductive data suggested the genus was distinct from the other caviines (Lacher 1981). Woods (1984) placed *Kerodon* within the Dolichotinae based on morphological characters but molecular phylogenetic analyses strongly support a sister relationship between *Kerodon* and *Hydrochoerus* (Rowe and Honeycutt 2002; Opazo 2005; M. E. Pérez and Pol 2013).

SYNONYMS:

Cavia Wied-Neuwied, 1820:43; type species *Cavia rupestris* Wied-Neuwied, by original designation; not *Cavia* Pallas.

Kerodon F. Cuvier, 1823b:151; type species the "Moco" of É. Geoffroy St.-Hilaire (= *Kerodon moco* Lesson, = *Cavia rupestris* Wied-Neuwied), by monotypy.

Kerodons F. Cuvier, 1829a:493; incorrect subsequent spelling of *Kerodon* F. Cuvier.

Cerodon Wagler, 1830:18, footnote; unjustified emendation of *Kerodon* F. Cuvier.

Ceratodon Wagler, 1830:18 footnote; preoccupied by *Ceratodon* Brisson [= *Monodon* Linnaeus; Cetacea: Monodontidae].

Prea Liais, 1872:541; part (listing of *rupestris*); new name for *Kerodon* F. Cuvier.

Ceredon Parsons, 1894:252; incorrect subsequent spelling of *Kerodon* F. Cuvier.

REMARKS: Many authors have used the year 1825 for F. Cuvier's description of *Kerodon*, however, his *Des Dents des Mammifères* was published from 1821 to 1825 in parts, with the rodent section appearing in 1823. Isidore Geoffroy St.-Hilaire and d'Orbigny (1833:plate 1 of unnumbered text for *Cavia australis*) designated the type species *Cavia rupestris* "elle est devenue le type d'un petit groupe a part, le genre *Kerodon*." Osgood (1915) restricted *Kerodon* to include only *K. rupestris*, to which Thomas (1916f) concurred, indicating the genus was monotypic. Moojen et al. (1997) more recently described the second species currently recognized.

KEY TO THE SPECIES OF *KERODON*:

1. Size large, mean adult weight 1,040 g, mean head and body length 384 mm, mean hindfoot length 72 mm, mean greatest length of skull 87.6 mm mean incisive foramina length 9.6 mm; rostrum long, ratio of diastema to width of braincase 91.8%; dorsal pelage darker gray, dorsal coloration of feet dark-brown ferruginous, hip pelage not conspicuously colored. Known only from NE Goiás, Brazil. *Kerodon acrobata*

1'. Size small, mean weight 612g, mean head and body length 297mm, mean hindfoot length 62mm, mean greatest length of skull 70.6mm; mean incisive foramina length 4.3mm; rostrum short, ratio of diastema to width of braincase 68.8%; dorsal pelage lighter gray, dorsal coloration of feet light-brown with a white band in the internal half, hip pelage brilliant ferruginous color. *Kerodon rupestris*

Kerodon acrobata Moojen, Locks, and Langguth, 1997
Acrobatic Moco

SYNONYMS:

Kerodon acrobata Mares and Ojeda, 1982:394; *nomen nudum*.

Kerodon acrobata Moojen, Locks, and Langguth, 1997:1; type locality "Fazenda Santa Helena, at Rio São Mateus, about 72 km from São Domingos and 60 km from Posse (by road), 13°50'S, 46°50'W, Goiás, Brazil."

DESCRIPTION: General characteristics as for genus. Overall color of upperparts dark gray to light brown agouti. Dorsal pelage formed by long, dark guard hairs (30–35 mm), with no light bands, and shorter overhairs (22–25 mm), with subterminal buffy ring and dark tip; all hairs gray at base; sides same color as dorsum although paler; hairs on lower rump and outer sides of legs have light ferruginous colored ring; venter gray with buffy wash, mainly at midline hairs; feet brown-orange dorsally with darker band up middle, with forefeet more lightly colored than hindfeet. Mystacial vibrissae long (up to 105 mm).

Skull with flat profile in middorsal region; rostrum is conspicuously stretched forward; posterior half of frontal not inflated and supraorbital ridges slightly beaded; palatal bridge short and mesopterygoid fossa V-shaped, reaching second prism of M2; pterygoid bones well developed; occiput concave with medial posterior crest; orbital branch of zygomatic process of maxilla not interrupted by lacrimal; occipital foramen as tall as wide, with short, blunt median process projecting ventrally. Mandible with long symphysis, and the angular process is wide at the base; crista masseterica well developed on anterior part and fossa masseterica shallow on posterior part. Incisors orthodont or opisthodont, with white enamel. Upper molars with two cordiform prisms except in PM4, with three that diminish in size posteriorly, and M3, with additional distal extension of posterior prism. Labial face of upper molars with obsolete sulcus, more developed in anterior prism of PM4; sulcus deeper in lower molars. Anterior prism of PM4 smaller than second; second largest in molar series. Moojen et al. (1997) provided descriptive characters of pelage and skull, and Bezerra et al. (2010) compared cranial variation for both sexes and described and figured the glans penis and baculum.

DISTRIBUTION: *Kerodon acrobata* is known from a small region in central Brazil in northeastern Goiás state and adjacent Tocantins state, west of the Espigão Mestre, Serra Geral de Goiás (Moojen et al. 1997; Bezerra et al. 2010).

SELECTED LOCALITIES (Map 384): BRAZIL: Goiás, Fazenda Cana Brava, Nova Roma (Moojen et al. 1997), Fazenda Canadá (Bezerra et al. 2010), Fazenda Santa Helena, Rio São Mateo (type locality of *Kerodon acrobata* Moojen, Locks, and Langguth); Tocantins, Dianópolis (Bezerra et al. 2010).

SUBSPECIES: *Kerodon acrobata* is monotypic.

NATURAL HISTORY: The Acrobatic Moco inhabits seasonally dry tropical forest west of the Serra Geral de Goiás and appears to be restricted to Cerrado habitat. This species is similar in ecology to *K. rupestris*. It is a terrestrial herbivore, well adapted for climbing on rocks and nesting in crevices within the rocks and feeding on Cactaceae, manioc and leaves of the local vegetation. It is extremely agile and able to spring from branch to branch within the tallest bushes (Moojen et al. 1997; Bezerra et al. 2010).

REMARKS: Mares and Ojeda (1982:394) used the name *Kerodon acrobata* for a second species from Brazil but never provided a formal description (Woods 1993:780). Moojen et al. (1997:4) thus correctly regarded *acrobata* Mares and Ojeda a *nomen nudum* and provided the necessary description to establish the validity of the name.

Map 384 Selected localities for *Kerodon acrobata* (○) and *Kerodon rupestris* (●).

Kerodon rupestris (Wied-Neuwied, 1820)

Moco, Rock Cavy

SYNONYMS:

Cavia rupestris Wied-Neuwied, 1820:43; type locality “Rio Grande de Belmonte, am Rio Pardo, am S. Francisco,” Bahia, Brazil.

[*Kerodon*] *moco* F. Cuvier, 1823b:151, plate 48; “Nous ne connaissons encore dans ce genre que l’espèce qui nous a donné ce système de dentition et qui recoit au Brésil, suivant M. de Saint Hilaire, le nom de moco.”

Kerodon sciureus I. Geoffroy St.-Hilaire, 1826:120; type locality “L’Amérique meridionale est la patrie de cette espèce.”

Kerodon rupestris: Rengger, 1830:274, footnote; first use of current name combination.

Kerodon rupestre Lund, 1838:50, footnote; incorrect subsequent spelling of *rupestris* Wied-Neuwied.

Cerodon rupestris: Lund, 1840b:13 [1841c:285]; name combination.

Cavia (*Cerodon*) *rupestris*: Waterhouse, 1848:164; name combination.

Prea rupestris: Liais, 1872:541; name combination.

Cavia (*Kerodon*) *ruspestris* E.-L. Trouessart, 1880b:196; name combination, and incorrect subsequent spelling of *rupestris* Wied-Neuwied.

Ceredon rupestris: Parsons, 1894:252; name combination.

Cavia sciurus Tate, 1935:337; name combination, and incorrect subsequent spelling of *sciureus* I. Geoffroy St.-Hilaire.

Kerodon aciureus Cabrera, 1961:580; incorrect subsequent spelling of *Kerodon sciureus* I. Geoffroy St.-Hilaire.

DESCRIPTION: General characteristics as for genus. Size large (mass 700–1,000g), although smaller than *K. acrobata*. Dorsal coloration gray-agouti with black and white mottling; dorsal hairs gray-brown at roots, annulated with grayish white near tip, and black at tip; black prevails onto crown of head but on back dark and pale colors nearly equal; hind part of back assumes brownish color due to pale subterminal ring of each hair having rufous white hue; rump and hinder part of hind legs red chestnut color; throat white, suffused with pale ochraceous yellow; abdomen sometimes white, and chest tinted with rufous in some individuals and yellowish in others; dorsal portions of tarsi whitish and suffused with rufous or pale rust color; ears clothed in pale yellowish hairs. Mystacial hairs black and very long (Waterhouse 1848).

Skull, especially rostrum, narrow and long, with length of diastema also proportionately larger than in caviine taxa (Lacher 1981; Moojen 1952b). Infraorbital foramen lacks canal for nerve transmission; incisive foramen excessively narrowed (Ellerman 1940); occipital surface with round convex area as opposed to concave with median posterior crest as in *K. acrobata*. Masseteric fossa reaches anteriorly

only to end of m2. External crest of angle of mandible well developed (Moojen et al. 1997). Upper cheek teeth bilobed with M3 possessing weak, backwardly projecting heel. Lower pm4 with well-marked extra anterior projection and talonid of lower m3 poorly defined (Ellerman 1940). Mean condyloincisive length of skull 73 mm (range: 59–65.9 mm; Hückinghaus 1961a).

DISTRIBUTION: Northeastern Brazil from the state of Minas Gerais in the southwest to Ceará in the northeast.

SELECTED LOCALITIES (Map 384): BRAZIL: Alagoas, Santana do Ipanema, Sítio Goiabeira (Mares, Willig et al. 1981); Bahia, Juazeiro (Mares, Willig et al. 1981); Ceará, Itapajé (Mares 1981), Juá (Moojen et al. 1997); Minas Gerais, Riacho da Cruz (Mares, Willig et al. 1981); Paraíba, Mulungú (Moojen 1943a); Pernambuco, Bodocó (Moojen et al. 1997), Pernambuco, Bonito (USNM 14761).

SUBSPECIES: *Kerodon rupestris* is monotypic.

NATURAL HISTORY: *Kerodon rupestris* is a terrestrial herbivore and an extreme habitat specialist, restricted to rocky outcrops that occur throughout the Caatinga bioregion of northeastern Brazil. Sexual and agonistic data suggested that they exhibit resource defense polygyny in relation to these outcrops (Lacher 1981). This species exhibited a longer gestation period (75 days) and smaller litter size (mean = 1.4) than any species of the Caviinae. Reproduction occurred year round in the laboratory (Streilen 1982c). As is typical of caviids, juveniles are born precocious and the growth rate is very rapid. Animals can weigh 500g and are reproductively mature by three months (Lacher 1979). Despite the lack of a tail and claws, individuals are very adept climbers, venturing out of rock outcrops both day and night to forage in adjacent trees and shrubs (Lacher 1981). Streilein (1982a) reported that they gain the majority of their sustenance from treetop foraging. Mares et al. (1982) described molting patterns in relation to two other genera of caviids in the Caatinga. Lacher (1979) suggested that *Kerodon* could be domesticated for use as a supplemental protein source due to their rapid growth rate, early maturation, and ease of reproduction in captivity.

REMARKS: Moojen (1952b:126) listed the type locality as “Rio Grande de Belmonte, Rio Pardo, rio São Francisco,” following Wied-Neuwied’s (1820) original designation. Cabrera (1961:580) simply listed the type locality as “Rio Belmonte, estado de Bahía.” The karyotype is $2n = 52$, with variation in FN from 92 to 94 (Maia 1984; G. Lessa et al. 2013).

Family Cuniculidae G. S. Miller and Gidley, 1918

James L. Patton

The pacas include two living species within a single genus that together are among the largest of the extant cavi-

morph rodents (mass reaching 12–13 kg; Collett 1981; E. M. Pérez 1992; Emmons and Feer 1997). Males are typically larger than females. Both species have moderately robust and stout bodies, a large head, swollen cheeks, thick and fleshy lips, large nares, prominent and stiff vibrissae, short and rounded ears, a large rump, and a tail reduced to a small stump. The eyes are large, dorsally positioned, and widely spaced. The limbs are short; forefeet have four subequal toes with a small pollex bearing a claw, hindfeet have three large toes with both a short hallux and fifth digit, neither of which typically contact the ground. The claws are extremely thick, almost hoof-like. The pelage is coarse, without distinct underfur, varying from short and shiny in appearance in *C. paca* to thick, long, and relatively soft in *C. taczanowskii*. In both species, lines of large white spots that sometimes coalesce into stripes mark the dorsal and lateral pelage. Females have one inguinal and one axillary pair of mammae. External genitalia are hidden within an anal sac in both sexes; there is no scrotum in males.

The skull is massive and broad, with short nasals but long and broad frontals, and uniquely notable for a greatly inflated zygomatic region modified by outgrowths of the maxilla and jugal to form large, internally hollowed cheekplates, the surface of which are highly rugose in males but less so in females. The cheekplates develop quickly from the more typical slender and smooth zygoma of post-natal young (T. W. Nelson and Shump 1978). Both external and internal cheek pouches are associated with the expanded zygoma (A. B. Howell 1940) and, along with the cheekplate, may serve for amplification of vocalizations and tooth-grinding sounds (Herskovitz 1955a). The jugal does not approach the lacrimal and lacks a jugal fossa. The lacrimal canal is large and positioned on the side of the rostrum. The infraorbital foramen is rather small, in part because of the anterior expansion of the zygoma, and with a distinct canal for nerve transmission on its floor. A sagittal crest is present in adults and postorbital processes are present but at the very rear of the orbit. The auditory bullae are small and the paroccipital processes are narrow, recurved in distal aspect, and extend vertically below the occiput. The lower jaw is hypsignathous with a rounded angular process only moderately displaced laterally.

Upper incisors are moderately small and narrow, especially in comparison to the size of the skull, and have an orange enamel layer. Cheek teeth are hypsodont, semi-rooted, flat-crowned, and have a complex re-entrant fold pattern. Three labial and two lingual folds characterize PM4 through M2 of the maxillary toothrow; M3 typically has three labial and three lingual folds. All mandibular cheek teeth usually have one labial and three lingual folds. Shortly after eruption in all teeth, most folds isolate into narrow, transverse islands with wear (Friant 1968).

F. S. Oliveira et al. (2006) detailed dental characteristics and tooth dimensions during ontogeny using radiographic methods.

The genus is known only from the Recent from Mexico, Central America, and South America (McKenna and Bell 1997).

Phylogenetic affinities of the pacas have been somewhat problematic historically, but an understanding of their position within the New World caviomorphs has stabilized markedly in the past decade. Landry (1957) placed the Cuniculidae within the superfamily Octodontoidea and Wood (1965) listed it within the superfamily Chinchilloidea. Virtually all other authors, however, have consistently allied the pacas with the cavies, capybara, and, especially, the agoutis in the superfamily Caviioidea, a placement solidified by molecular phylogenetic analyses (Rowe and Honeycutt 2003; Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012; P.-H. Fabre et al. 2012). Classifications have also varyingly treated the pacas as a distinct family (Cabrera 1961; Wood 1965; Husson 1978; Woods 1982, 1984a, 1993) or as a subfamily within a group that also included the dasyproctids (Simpson 1945 [Dasyproctidae, Cuniculinae]; McKenna and Bell 1997 [Agoutidae, Agoutinae]). Both mitochondrial and nuclear gene sequences support the Cuniculidae as sister to the Caviidae (Rowe and Honeycutt 2003; Opazo 2005) or to a clade comprising both the Dasyproctidae + Caviidae (Upham and Patterson 2012; P.-H. Fabre et al. 2012). While the two extant species of *Cuniculus* share a relatively recent divergence (within the Plio-Pleistocene, estimated at 3.5 ± 1.2 mya), the family links only deeply to other members of the Caviioidea (the late Oligocene, estimated at 26.5 ± 2.5 mya by Opazo 2005).

REMARKS: Earlier use of the family name Agoutidae Gray (e.g., Cabrera 1961; McKenna and Bell 1997) instead of Cuniculidae stemmed from the unacceptability of Brisson's name *Cuniculus*, a position made moot by the explicit acceptance of Brisson's mammal names (ICZN 1998:Opinion 1894).

Genus *Cuniculus* Brisson, 1762

SYNONYMS:

Cuniculus Brisson, 1762:98; type species by subsequent designation "*Paca*, Brisson, p. 99, based on *Cuniculus major palustris, fasciis albis notatus* Barrère, 1741" = *Mus paca* Linnaeus (Hollister 1913:79); not *Cuniculus* Meyer, 1790, a synonym of *Oryctolagus* (Mammalia: Leporidae), nor *Cuniculus* Wagler, 1830, a synonym of *Dicrostonyx* (Mammalia: Cricetidae, Arvicolinae).

Mus: Linnaeus, 1766: 79; part (description of *paca*); not *Mus* Linnaeus.

Cavia: Erxleben, 1777:348; part (description of *paca*); not *Cavia* Pallas.

Agouti Lacépède, 1799:9; type species *Agouti paca* Lacépède (= *Mus paca* Linnaeus), by monotypy.

Coelogenus F. Cuvier, 1807:203; type species *Mus paca* Linnaeus, by subsequent designation (Thomas 1924g).

Coelogenys Illiger, 1811:92; emendation of *Coelogenus* F. Cuvier.

Paca G. Fischer, 1814:85; type species *C[avia]. paca* G. Fischer (= *Mus paca* Linnaeus), by original designation.

Caelogenus J. Fleming, 1822:192; incorrect subsequent spelling of *Coelogenus* F. Cuvier.

Osteopera Harlan, 1825:126; type species *Osteopera platycephala* Harlan, by monotypy.

Caelogenys Agassiz, 1842:5; incorrect subsequent spelling of *Coelogenys* Illiger.

Genyscoelus Liais, 1872:537; substitute name for *Coelogenus* F. Cuvier.

Mamcoelogenysus A. L. Herrera, 1899:26; unjustified renaming of *Coelogenys* Illiger and unavailable name because it is based on zoological formulae (ICZN 1987:318).

Stictomys Thomas, 1924b:238; type species *Stictomys taczanowskii* (Stolzmann, 1885), by original designation.

Agouti (*Coelogenys*): Krumbiegel, 1940: 236; name combination.

REMARKS: Tate (1935) and E. M. Pérez (1992) reviewed the complex nomenclatural history of this genus. Brisson (1762:98) erected the genus *Cuniculus* but did not designate a type species. The fourth species in his list (pp. 99) was “Paca,” based directly on his own “Le Pak,” initially published in the first edition of his *Regnum Animale* (1756). This description was accompanied by **, which, on the third page of the preface (1762), was explained as indicating that he had personally examined a specimen. Thus, both editions of Brisson’s *Regnum Animale* alluded to a *paca* that Brisson had personally inspected. Since Brisson’s generic bird names were accepted (ICZN 1911:Opinion 37), Tate (1935:310) argued that Brisson’s generic mammal names, which were strictly analogous to his bird names, should also be accepted. However, J. A. Allen (1910a:322) had previously argued that Brisson’s specific names, both bird and mammal, were unacceptable because they were not binomial, although they were binary. Consequently, Brisson’s “Paca” has been interpreted as an invalid technical name. Linnaeus (1776), however, formally described *Mus paca*, listing “Paca” Brisson, 1756, as the author, and thus validated the specific epithet for this taxon.

Merriam (1895b:375–376) pointed out that *Cuniculus* Brisson, 1762, was a composite genus comprised of *Cavia*, *Lemmus*, *Coelogenus*, *Dasyprocta*, *Anisonyx* [= *Spermophilus*], and *Allactaga*. He attempted to fix the type as “*alactaga* (Olivier) 1800” by the process of elimination.

Hollister (1913:79) noted that Merriam’s (1895b) designation by elimination of *alactaga* Olivier as the type of *Cuniculus* Brisson (1762) was an unacceptable method to determine a genotype and designated “Paca, Brisson, p. 99, based on *Cuniculus major palustris, fasciis albis notatus* Barrère, 1741” the type of the genus. As Tate (1935:310) documented, Brisson actually examined the animal he named “Paca” and thus it was upon that specimen that *paca* Linnaeus (1766) was based.

Thomas (1914g:285) remarked upon “*fiat*” versus “*priority*” names and advocated the retention of “*Coelogenys*” [sic] with type *Mus paca* Linnaeus instead of *Agouti* Lacépède or *Cuniculus* Brisson, both of which antedated *Coelogenus* F. Cuvier.

Lönnerberg (1921:43) remarked that the “*Paca*” of Marcgraf (1648:224), Ray (1691:226), and others be regarded to constitute the basis of *Mus paca* Linnaeus, and suggested that Pernambuco be designated the type locality. This argument had been, however, superseded by Hollister’s (1913:79) prior designation of “Paca, Brisson” as the type of the genus *Cuniculus*.

The ICZN (1925:Opinion 90) ruled against the suspension of the Rule of Priority in the case of *Coelogenys* (Illiger’s [1811] emendation of *Coelogenus* F. Cuvier, 1807).

Cabrera (1961:595) listed J. Stolzmann as the author of *Coelogenys*, which he regarded as different from *Coelogenys* Illiger (an emendation of *Coelogenus* F. Cuvier). The basis for Cabrera’s decision, however, is unclear as Stolzmann’s description (1885:161) clearly mentioned “*Coelogenys paca*,” giving the name of the *paca* in common use in the early and mid-1800s (e.g., Wied-Neuwied 1821; Renger 1830), before he went on to name *Coelogenys taczanowskii* as a new taxon.

Woods (1982, 1984a, 1993) and McKenna and Bell (1997), among others, accepted *Agouti* Lacépède, 1799, as the valid generic name for Linnaeus’s *Mus paca* on the argument that *Cuniculus* Brisson, 1762, was unavailable because his work was not consistently binomial, citing Hopwood (1947) and the International Commission (ICZN 1955a:197). However, and finally, the International Commission (ICZN 1998:Opinion 1894) removed the nomenclatural instability of the generic name for the *pacas* by explicitly ruling to conserve *Cuniculus* Brisson.

Thomas (1905a:590) noted that the *pacas* fell into two groups, one characteristic of lowland forests and the other with a montane distribution, groups that are now regarded as the two species recognized in the current literature.

KEY TO THE SPECIES OF *CUNICULUS*:

1. Pelage short and sparse; spots aligned in rows largely on sides; plantar surfaces smooth; zygoma more greatly expanded laterally, compressing the infraorbital foramen

as viewed from the front; nasals short; incisive foramina shallow and narrow; foramen ovale large

- *Cuniculus paca*
1'. Pelage long and dense; spots aligned in rows on sides, neck and mid-back; plantar surfaces granulated; zygomata less expanded laterally so that infraorbital foramen as viewed from the front is broader; nasals longer and more robust; postorbital process more conspicuous; foramen ovale small *Cuniculus taczanowskii*

Cuniculus paca (Linnaeus, 1766)

Paca

SYNONYMS:

- [*Mus*] *paca* Linnaeus, 1766:81; type locality "Brasilia [= Brazil], Guiana"; restricted to "French Guiana" by Hollister (1913:79; see Tate 1935:315) and to Pernambuco, Brazil, by Lönnberg (1921:43).
[*Cavia*] *paca* Erxleben, 1777:356; = *Mus paca* Linnaeus.
Agouti paca Lacépède, 1799:9; = *Mus paca* Linnaeus.
C[*avia*] *paca alba* Kerr, 1792:216; type locality "environs of the river St. Francis in South America," Rio São Francisco, Minas Gerais, Brazil.
Coelogenys subniger F. Cuvier, 1807:206; type locality "Tobago," Trinidad and Tobago.
Coelogenys fulvus F. Cuvier, 1807:207; based on Brisson (1762), Buffon (1763), and É. Geoffroy St.-Hilaire (1803) and, therefore, with type locality "Cayenne, French Guiana."
[*Paca*] *maculata* G. Fischer, 1814:87; type locality "Guiana, Brasilia [= Brazil]."
[*Coelogenys*] *rufa* Olfers, 1818:213; type locality "South America."
Coelogenys paca: Wied-Neuwied, 1821:254; name combination.
Osteopera platycephala Harlan, 1825:126; based on a skull of unknown origin found on "the shore of the river Delaware," United States.
C[*oelogenys*]. *fulvus*: Wied-Neuwied, 1926:247; name combination.
Coelogenys subniger: Wied-Neuwied, 1826:457, name combination.
Coelogenys paca: Rengger, 1830: 251; name combination.
Coelogenys laticeps Lund, 1839c [Lund, 1841a:102]; type locality "Rio das Velhas Floddal" (see Lund 1841a: 133–134), Lagoa Santa, Minas Gerais, Brazil; a fossil taxon considered a synonym of *C. paca* by Paula Couto (1950:169).
Coelogenys rugiceps Lund, 1839c [Lund, 1841a:102]; type locality "Rio das Velhas Floddal" (see Lund 1841a: 133–134), Lagoa Santa, Minas Gerais, Brazil; a fossil taxon considered a synonym of *C. paca* by Paula Couto (1950:169), following Winge (1887).

Coelogenys fuscus Lesson, 1842:103; type locality "Guyane; Brésil."

Coelogenys sublaevis P. Gervais, 1854:326; type locality "Colombie."

Paca americana Liais, 1872:538; type locality "le Brésil, la Guyane et le Paraguay."

Agouti paca virgatus Bangs, 1902:47; type locality "Divala," Chiriquí, Panama.

Coelogenys paca mexianae Haggmann, 1908:25; type locality "Insel Mexiana [= Ilha Mexiana]," Ilha Mexiana, Pará, Brazil.

Agouti paca nelsoni Goldman, 1913:9; type locality "Catemaco, southern Vera Cruz, Mexico."

Cuniculus paca nelsoni: Hollister, 1913:79; name combination.

Cuniculus paca paca: Hollister, 1913:79; name combination.

Cuniculus paca virgatus: Hollister, 1913:79; name combination.

Cuniculus paca sublaevis: Hollister, 1913:79; name combination.

C[*oelogenys*]. *p[aca]. virgata*: Lönnberg, 1921:45; name combination.

Coelogenys paca guanta Lönnberg, 1921:45; type locality "Gualea, 5,000 feet," Pichincha, Ecuador.

[*Coelogenys*] *guanta*: Thomas, 1924b:239; name combination.

[*Cuniculus*] *paca alba*: Tate, 1935:316; name combination.

[*Cuniculus*] *subniger*: Tate, 1935:316; name combination.

[*Cuniculus*] *fulvus*: Tate, 1935:316; name combination.

[*Cuniculus*] *sublaevis*: Tate, 1935:316; name combination.

[*Cuniculus*] *paca mexianae*: Tate, 1935:316; name combination.

[*Cuniculus*] *paca guanta*: Tate, 1935:316; name combination.

A[*gouti*]. *p[aca]. mexiannae*: Krumbiegel, 1940:233; name combination.

Agouti paca venezuelica Krumbiegel, 1940:233; type locality "Maracay," Aragua, Venezuela.

[*Agouti paca*] *guanta*: Krumbiegel, 1940:237; name combination.

Cuniculus paca laticeps: Paula Couto, 1950:169; name combination.

[*Agouti paca*] *mexicanae* Woods, 1993:783; incorrect subsequent spelling of *mexianae* Haggmann.

[*Cuniculus paca*] *mexicanae*: Woods and Kilpatrick, 2005: 1559; incorrect subsequent spelling of *mexianae* Haggmann.

DESCRIPTION: Chestnut red to dark brown upperparts with three or four lines of large white spots, often coalescing into stripes, from sides of neck to rump; lower cheeks, throat, chest, and venter white. Hair coarse, sparse, and short over entire body (Emmons and Feer 1997). Soles of feet generally smooth, not granular (Thomas 1905a).

Cranially, cheekplates more greatly expanded, constricting infraorbital foreman to greater degree than in Mountain Paca, shorter nasal bones, less conspicuous postorbital processes, narrower and more shallow incisive foramina, and larger foramina ovale (Ríos-Uzeda et al. 2004). Otherwise, two species of paca similar in all other attributes that diagnose genus *Cuniculus*.

DISTRIBUTION: *Cuniculus paca* occurs throughout the Neotropical lowland forests from eastern and southern Mexico south through Central America and in the South American countries of Colombia, Venezuela, the Guianas, Ecuador, Peru, Bolivia, Paraguay, and most of Brazil, and has been introduced into Cuba and the Lesser Antilles. The elevational range is from sea level to 1,600m (Hall 1981; E. M. Pérez 1992) or to 2,000m (Cuervo Díaz et al. 1986).

SELECTED LOCALITIES (Map 385): ARGENTINA: Misiones, Parque Nacional Iguazú (Crespo 1982b). BOLIVIA: Cochabamba, San Antonio (S. Anderson 1997); La Paz, 8 km SE of Caranavi (S. Anderson 1997); Santa Cruz, 10 km N of San Ramón (S. Anderson 1997), Santa Cruz, Buena Vista (S. Anderson 1997). BRAZIL: Bahia, Santo Amaro (FMNH 20435); Ceará, Serra do Covão (Feijó and Langguth 2013); Goiás, Anápolis (AMNH 134086); Pará, Belem (MCZ 31700), Ilha Mexiana (type locality of *Coelogenys paca mexianae* Hagmann); Pernambuco, Pernambuco (type locality of [*Mus*] *paca* Linnaeus, as restricted by Lönnberg 1921:43); Rio de Janeiro, Bemposta (AMNH 134098); Santa Catarina, Ilha de Santa Catarina (Graipel et al. 2001). COLOMBIA: Antioquia, Río Currulao, 20 km SE of Turbo (FMNH 69635); Cauca, El Payapo (FMNH 90067); La Guajira, Villanueva, Sierra Negra (USNM 281824); Magdalena, Buritaca (AMNH 23470); Nariño, near Guayabetal (MSU 29484); Sucre, Las Campanas (FMNH 72413). ECUADOR: El Oro, Portovelo (AMNH 46547); Esmeraldas, La Bocana (MSU 9513); Santa Elena, near Manglaralto, Cordillera de Colconche (UMMZ 80186). FRENCH GUIANA: Paracou (Voss et al. 2001). GUYANA: Barima-Waini, Baramita (ROM 100935); Demerara-Mahaica, 1 mi E of Buxton (FMNH 46223). PARAGUAY: Canindeyú, Mbaracayu Reserve (UAM 46601); Misiones, 5 km ENE of Ayolas (UMMZ 125719). PERU: Amazonas, Huampami, Río Cenepa (Patton et al. 1982); Cusco, Kiteni (LSUMZ 19344); Huánuco, Hacienda Exito (FMNH 41144); Junín, Chanchamayo (FMNH 65791); Puno, San Juan (Sanborn 1953). SURINAM: Paramaribo, Paramaribo (USNM 13311). TRINIDAD AND TOBAGO: Princetown (AMNH 6041). VENEZUELA: Falcón, near La Pastora, 11 km ENE of Mirimiri (Handley 1976); Mérida, Mérida (AMNH 21645); Miranda, 1 km S of Río Chico (Handley 1976); Monagas, Hato Mata de Bejuco (Handley 1976); Zulia, Kasmera (Handley 1976).

SUBSPECIES: Ellerman (1940) recognized seven subspecies, including four from South America in addition to the nominotypical form (*alba* Kerr, *mexianae* Hagmann, *guanta* Lönnberg, and *sublaevis* P. Gervais). Cabrera (1961) recognized only three, including *guanta* Lönnberg and *mexianae* Hagmann in addition to the nominotypical form. Both E. M. Pérez (1992) and Woods and Kilpatrick (2005) recognized four subspecies in addition to the nominotypical form, only two with South American distributions (*guanta* Lönnberg, and *mexianae* Hagmann [incorrectly spelled *mexicanae* by Woods and Kilpatrick, 2005]). However, no review of geographic variation that would adequately diagnose and delineate the geographic range of any of these taxa has yet been accomplished.

NATURAL HISTORY: E. M. Pérez (1992) reviewed published data on reproduction, population ecology, and behavior. These large rodents inhabit primarily tropical rainforest, including a wide range of forest types, from mangrove swamps, riparian communities, and dense upland scrub. They prefer areas near water (Collett 1981). Mostly frugivorous, pacas are opportunistic feeders that also feed on leaves, buds, and flowers, and are considered to play a major role in seed predation and dispersal (Beck-King et al. 1999; Dubost and Henry 2006). Population densities, measured in quite different habitats in Venezuela, Colombia, Panama, and Costa Rica ranged from 25 to >70 adults per square kilometer (Eisenberg et al. 1979; Collett 1981; Smythe et al. 1983; Glanz 1983; Beck-King et al. 1999). These are important members of tropical forest communities, representing up to 16% of the biomass of nonvolant mammals (Eisenberg and Thorington 1973; Eisenberg et al. 1979). Collett (1981) reported on age structure in natural populations in Colombia, noting that animals can live up to 13 years. Although fecundity is low, survivorship of adults is high. Primary mammalian predators are all species of cats (Felidae) and both coyotes and bush dogs; non-mammalian predators include crocodiles and the boa constrictor (Ramdial 1972; Deutsch 1983). Pacas are hunted extensively for food, with the meat preferred by many local people, including indigenous communities where it may constitute as much as 8% of wild meat consumed (Ojasti 1983). Smythe (1987, 1991) advocated captive breeding for the potential of paca as a domestic protein source in lowland forest communities; Emmons (1987a) presented counter-arguments.

Pacas are a nocturnal, solitary animal that seeks refuge in burrows, hollows at the base of trees, or among rocks; their burrows are modified from those originally dug by armadillos (Lander 1974). Extensive camera-trap surveys in northern Mato Grosso state, Brazil, documented activity from dusk to dawn, with activity levels unaffected by the

lunar cycle, except for the onset of dusk, season, temperature, or rainfall (Michalski and Norris 2011). A. Link et al. (2012) also used camera traps to establish an important year-round use of mineral licks by paca in eastern Ecuador. Individuals use fixed trails during nightly foraging or other travel purposes. They breed year-round, with no indication of seasonal clustering of births or significant age-specific variation in fecundity (Collett 1981; Dubost et al. 2005). Females reach reproductive maturity at about nine months of age, males at one year. Litter size is a single young with individual females breeding from one to three times per year (Mondolfi 1972; Matamoros 1981). Gestation ranges from 114 to 119 days in the laboratory, with an interbirth interval of 191 days (Lander 1974; Collett 1981; Matamoros and Pashov 1984). Neonates are precocial, with eyes open, well-developed pelage, and erupted incisors and cheek teeth; weaning occurs at about 12 weeks (Matamoros 1981).

An extensive array of organisms parasitize pacas, including nematode, cestode, and protozoan endoparasites (González and Espino 1974; Guerrero 1985; Naiff et al. 1985; S. L. Gardner et al. 1988; Sato et al. 1988; A. Q. Gonçalves et al. 2006; S. L. Gardner et al. 2013) and ectoparasitic ticks and fleas (Darskaya and Malygin 1996; Barros-Battesti and Knysak 1999). Pacas also serve as a reservoir for important tropical diseases, such as leishmania (F. T. Silveira et al. 1991) and trypanosomiasis (Loyola et al. 1987).

REMARKS: As Tate (1935:315) noted in his treatment of the taxonomy of caviomorph rodents, there has been some debate as to what *Mus paca* Linnaeus was, including its type locality. Linnaeus (1766) cited under *paca* the descriptions of Marcgraf (1648), Ray (1691), and Brisson (1762), among others, and gave the habitat as “Brasilia, Guiana.” Brisson cited Marcgraf and Ray, among others, but his description was marked by a double **, indicating that he had examined the specimen himself. Except for Brisson, all citations ultimately focused on the work of Marcgraf. Hence, as Tate stated (p. 315) “the question then remains whether *paca* Linnaeus must be held founded upon Marcgraf’s *paca* of Brazil or upon Brisson’s *paca* from ‘Guiana and Brazil.’” Tate used the Determination of the First Reviser (ICZN 1999:Art. 24.2) to decide between the two alternatives, noting that Hollister (1913), who had selected *paca* Linnaeus as the type of *Cuniculus*, selected as type for the species “*Paca*, Brisson, p. 99, based on *Cuniculus major palustris, fasciis albis notatus* Barrère, 1741.” Tate then argued that Barrère’s *paca* “was undoubtedly from French Guiana” and thus that “Hollister may be considered as having fixed the type locality of *paca* as French Guiana.” Lönnberg (1921:43) subsequently, and incorrectly, restricted the type locality to Pernambuco, Brazil. Moojen (1952b:119) also cited Pernambuco for

Map 385 Selected locality for *Cuniculus paca* (●). Contour line = 2,000m.

the type locality, but other reviewers (Cabrera 1961:595; Woods and Kilpatrick 2005:1559) have followed Tate’s argument by listing the type locality of *paca* Linnaeus as Cayenne, French Guiana. Thomas (1905a) initially thought that *sublaevis* P. Gervais could be either *C. paca* or *C. taczanowskii*, but later both he (Thomas 1924b) and Lönnberg (1921) treated it as a female *Cuniculus paca*.

The karyotype consists of a $2n = 74$ and FN of 56 (Fredga 1966). Van Vuuren et al. (2004) examined population genetic structure in French Guiana using molecular sequence markers, with a signature characteristic of recently expanded populations.

Cuniculus taczanowskii (Stolzmann, 1885)

Mountain Paca

SYNONYMS:

Coelogenys taczanowskii Stolzmann, 1885:161; type locality “habite les montagnes de l’Equateur entre 6000 et 10,000 pieds au dessus de niveau de la mer. Elle n’est pas très rare dans les forêts des deux versants des Andes,” Pichincha, Ecuador.

A[gouti]. taczanowskii: Thomas, 1905a:589; name combination.

Agouti sierrae Thomas, 1905a:589; type locality “Pedregosa Montañas, Sierra de Merida, Alt. 2000m,” Mérida, Venezuela.

Cuniculus taczanowskii: Hollister, 1913:79; first use of current name combination.

- Cuniculus sierrae*: Hollister, 1913:79; name combination.
- Agouti* [*Coelogenys*] *sierrae andina* Lönnberg, 1913:28; type locality “rocks of Pichincha . . . altitude of 9 to 12,000 feet.” Pichincha, Ecuador.
- Agouti paca taczanowskii*: J. A. Allen, 1916b:205; name combination.
- Agouti thomasi* Eaton, 1916:89; type locality “small kitchen-midden near eastern limit of the city,” Machu Picchu, Cusco, Peru.
- Coelogenys taczanowskii andina*: Lönnberg, 1921:48; name combination.
- [*Stictomys*]. *taczanowskii*: Thomas, 1924b:238; name combination.
- [*Stictomys*] *andina*: Thomas, 1924b:238; name combination.
- [*Stictomys*] *sierrae*: Thomas, 1924b:238; name combination.
- Coelogenys sierrae*: Pittier and Tate, 1932:265; name combination.
- [*Stictomys*] *taczanowskii taczanowskii*: Tate, 1935:317; name combination.
- [*Stictomys*] *taczanowskii andina*: Tate, 1935:317; name combination.
- Stictomys taczanowskii*: Tate, 1939:184; name combination.
- Cuniculus taczanowskii taczanowskii*: Ellerman, 1940:225; name combination.
- Cuniculus taczanowskii andina*: Ellerman, 1940:225; name combination.
- Cuniculus taczanowskii sierrae*: Ellerman, 1940:225; name combination.
- Stictomys taczanowskii andina*: Cabrera, 1961: 595; name combination.
- Stictomys taczanowskii sierrae*: Cabrera, 1961:596; name combination.
- Stictomys taczanowskii taczanowskii*: Cabrera, 1961:596; name combination.
- Cuniculus hernandezii* Castro, López, and Becerra, 2010: 130; *nomen nudum*; no type locality designated, but inferred from text to be “Cordillera Central, Colombia.”
- DESCRIPTION:** Same general body size and conformation as Common Paca, but differs externally by having much longer, thicker, and softer dorsal fur, spots on top of back as well as on sides, and distinctly granulated soles of feet. General color also darker, with blackish brown tones rather than reddish brown, and venter pale but washed terminally with pale brown. Cranial character differences documented by Ríos-Uzeda et al. (2004) include longer and more robust nasals, less expanded cheekplates resulting in broader and more open infraorbital foramen, more conspicuous postorbital processes, broader and deeper incisive foramina, and much smaller foramen ovale.
- DISTRIBUTION:** *Cuniculus taczanowskii* is known from forested slopes of the Andes of northwestern Venezu-

ela, Colombia, Ecuador, Peru, and Bolivia, at an elevational range from approximately 2,000 to 4,000 m (Cuervo Díaz et al. 1986; Ríos-Uzeda et al. 2004; J. Castro et al. 2010).

SELECTED LOCALITIES (Map 386): COLOMBIA: Antioquia, El Cedro, Caicedo (FMNH 70801), Paramillo (AMNH 37795); Cauca, La Florida (J. A. Allen 1916b); Cundinamarca, Río Balcones (FMNH 70803); Huila, Río Ovejeras (FMNH 70802); Nariño, Barbaças (J. A. Allen 1916b); Quindío, La Guneta (J. A. Allen 1916b). ECUADOR: Napo, Río Ansu (YPM, no number); Azuay, Molleturo (AMNH 61877); Pichincha, Pichincha (type locality of *Agouti* [*Coelogenys*] *sierrae andina* Lönnberg) San Ignacio (AMNH 66727). PERU: Ayacucho, Yuraccyacu (LSUMZ 14436); Cusco, Machu Picchu (type locality of *Agouti thomasi* Eaton), Marcapata (FMNH 75125), Puesto de Vigilancia Acjanaco (B. D. Patterson et al. 2006); Huánuco, Cordillera Carpish (A. L. Gardner 1971); Piura, Tambo (FMNH 80974); Puno, Sandia (FMNH 79917); San Martín, Puerta del Monde (LSUMZ 27383). BOLIVIA: La Paz, San Juanito (Ríos-Uzeda et al. 2004). VENEZUELA: Lara, Paramo de los Rosas (J. A. Allen 1911); Mérida, Paramito (Handley 1976); Tachira, Buena Vista (Handley 1976).

SUBSPECIES: Cabrera (1961) recognized three subspecies (*andina* Lönnberg, from the central Andes of Ecuador; *sierrae* Thomas, from the northern Andes of Colombia and the Sierra de Mérida of northwestern Venezuela; and the nominotypical form from the Andes of Ecuador and southern Colombia). Woods and Kilpatrick (2005:1560) regarded *C. taczanowskii* to be monotypic. No adequate review of the few available specimens has been attempted. See Remarks for comments about the uniqueness of southern Peruvian specimens.

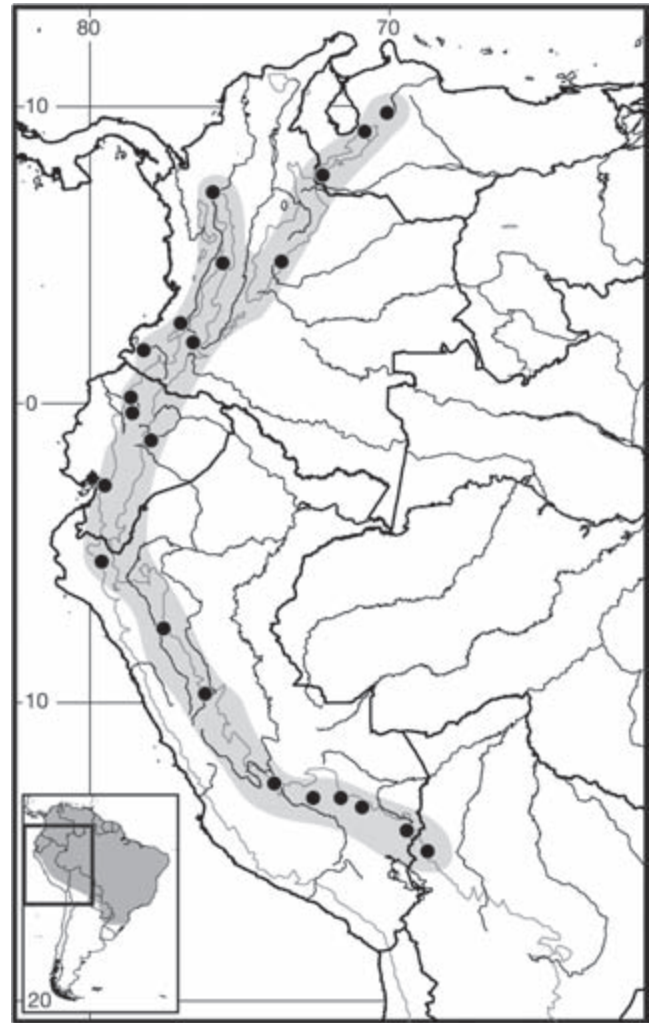

NATURAL HISTORY: The mountain paca has not been studied in the field, and little information on life history, ecology, or behavior is known. The single known specimen from Bolivia (Ríos-Uzeda et al. 2004) was collected in montane forest dominated by bamboo (*Chusquea* and *Neurolepis* [Poaceae]) and upland trees (*Clusia* [Clusiaceae] and *Podocarpus* [Podocarpaceae]). In Ecuador, the species was taken in subtropical forest on the edge of páramo (I. Castro and Román 2000).

REMARKS: Both Cabrera (1961:596, but not on p. 595) and Woods and Kilpatrick (2005:2560) incorrectly gave the citation for Stolzmann’s description of *Coelogenys taczanowskii* as 1865, not 1885.

Tate (1935:314) suggested that *Agouti thomasi* Eaton was a *nomen nudum*, as he had not discovered a published description of this taxon. The name, however, stems from Eaton (1916:89, plates 38, Figs. 6–8, and 39, Figs. 1–3) who described *thomasi* based on partial skulls from the archaeological site at Machu Picchu in southern Peru. While Edmund Heller, the collector of modern mammals

during the 1915 Yale Peruvian Expedition of which Eaton was a part, failed to obtain representatives of this species, Thomas (1920h:220) concluded that “closely allied to living Andean forms, [*thomasi*] will perhaps be found still to exist in the neighborhood [of Machu Picchu].” Sanborn (1953:7) wrote “a subspecies, *thomasi*, was described from Machu Picchu by Eaton (1916) from skulls found in burial caves. The validity of this race can not be established however until complete specimens are collected.” Thomas (1924b:239) linked the Peruvian *thomasi* to the Ecuador *guanta* Lönnberg and *sublaevis* P. Gervais, two names currently listed as synonyms of the lowland *C. paca*, not to the montane *C. taczanowskii* despite the high elevation of and cloud forest habitat at the type locality of Machu Picchu. The expanded nasals, less protrusive cheekplates, prominent postorbital processes, and small foramina ovale depicted in the drawings of the holotype (Eaton 1916:plate 39) are all characteristics of *C. taczanowskii* (Ríos-Uzeda et al. 2004). While Ellerman (1940) simply repeated Tate’s (1935) suggestion that *Agouti thomasi* Eaton was a *nomen nudum*, neither Cabrera (1961) nor Woods and Kilpatrick (2005) listed the name in their respective taxonomic compilations of *Cuniculus*.

The karyotype is variable, ranging from $2n = 78$, FN = 82 for individuals from the Cordillera Oriental and $2n = 72$, FN = 82 for those from the Cordillera Central, both in Colombia (J. Castro et al. 2010) to $2n = 42$, FN = 80 (A. L. Gardner 1971), based on a specimen from Junín department in Peru. J. Castro et al. (2010) designated the $2n = 72$ karyotypic form as a distinct species, *Cuniculus hernandezii*, an action supported by limited molecular and morphometric data. However, *hernandezii* is a *nomen nudum*; the proposed name does not conform to the requirements of the Code of Nomenclature (ICZN 1999), neither Article 13.1.1 (the need for an explicit description or definition that clearly differentiates a new species from other taxa) nor Article 16.4 (the need to designate a name-bearing type specimen). The authors of *hernandezii* also did not follow either Recommendation 16C (to deposit a type specimen in a research collection that meets the requirements of Recommendation 72F) or Recommendation 16F (that the type be illustrated). Furthermore, since the type locality of *taczanowskii* Stolzmann is from Ecuador, and no comparisons were made to Stolzmann’s description or to specimens from at or near to the type locality, it is unclear why J. Castro et al. (2010) allocated specimens with $2n = 78$ from the Cordillera Oriental to *taczanowskii* and not those they called *hernandezii*. While *Cuniculus taczanowskii* appears to be polytypic as currently understood, adequate geographic analyses of multiple character sets are required to delineate taxon boundaries and apply appropriate names to each.

Map 386 Selected localities for *Cuniculus taczanowskii* (●). Contour line = 2,000m.

Family Dasyproctidae Bonaparte, 1838

James L. Patton and Louise H. Emmons

Agoutis (*Dasyprocta*) and acouchys (*Myoprocta*) are largely diurnal, rabbit-like denizens of lowland to mid-elevation tropical forests, dry forests, savanna edge, and human-disturbed habitats including cultivated land. *Dasyprocta* ranges from southern Mexico to western Ecuador on the west side of the Andes and east of the Andes throughout the Guianas to the mouth of the Amazon and south to northern Argentina and southern Brazil, as well as on several islands of the Greater and Lesser Antilles. *Myoprocta* is limited to the Guianan region and Amazon Basin. The bodies of members of both genera are relatively slender; the forelimbs and hindlimbs are elongated and thin, with a decreased femoral robustness indicative of speed specialization (Elissamburu and Vizcaíno 2004). The eyes are large,

ears are short but conspicuous and sparsely haired, and the tail is either short (*Myoprocta*) or almost vestigial (*Dasyprocta*). The forefeet have five digits, the middle three well developed with digit III elongated; the pollex is reduced to a knob-like structure, and digit V is short but still obvious to the eye. The hindfeet have only three digits, again the digit III elongated. All digits have sharp, hoof-like claws. The soles for forefeet and hindfeet are naked and smooth; large plantar pads are present. The mesaxonic and digitigrade foot structure coupled with elongated limbs and a vestigial clavicle (Rocha-Barbosa et al. 2002) signal cursorial locomotion with a quadrupedal, saltatorial gait; individuals can run and jump well. Body size ranges from 6 kg in the largest species of *Dasyprocta* to a maximum of 1.5 kg in species of *Myoprocta*.

The pelage is thick and coarse, with hairs appearing glossy. Long and coarse mystacial, superciliary, and genal vibrissae are present, with the mystacial reaching past the ear when laid back against the side of the head. Overall color varies greatly from black, brown, or reddish to yellowish with individual hairs having multiple, alternating eumelanic and pheomelanic color bands. The rump may have elongated hair often contrasting in color with mid-back and thighs; these hairs are erected to flash contrasting pale bases when individuals are alarmed. The under parts are generally paler, with sparse hair. Forefeet and hindfeet may be colored as the legs or have a contrastingly darker, typically black, tone.

The skull is elongate and smooth, lacking heavy ridging, although a slight sagittal crest over the posterior portion of the braincase is present in adults. The premaxillae and nasals, of approximately equal length, project beyond the upper incisors. The rostrum is deep and heavy. The zygomatic arches are short and weak in appearance, the jugal being especially thin and not in contact with an expanded lacrimal. There is no jugal fossa present. The lacrimal canal opens on the side of the rostrum above and slightly forward of the root of PM4. The infraorbital foramen is moderate in size and lacks a distinct groove or canal on its floor for nerve passage. The incisive foramina are small with the opening nearly occluded by an expanded medial septum. The anterior border of the mesopterygoid fossa is rounded and extends at least to the posterior margin of M2. Elongated but narrow sphenopalatine foramina are present on the bony roof of the fossa. The auditory bullae are moderately inflated; the external auditory meatus is noticeably small; the paroccipital process is short but distinct in *Dasyprocta*, nearly vestigial in *Myoprocta*. The supraoccipital lacks a lateral process but a distinct vertical median ridge is present. Blood supply to the brain is via the vertebral and external carotid arteries; both the internal carotid artery

and stapedia artery are missing (Bugge 1971, 1974). The dentary lacks a ridge or groove on its lateral surface; the angular process is extremely deflected; the condyloid process has a prominent postcondyloid process; and the triangular-shaped coronoid process is only weakly developed.

The upper toothrows are approximately parallel. The molariform teeth are strongly hypsodont, semirooted, and have flat occlusal surfaces. The single premolar (PM4) is preceded by a deciduous precursor (dPM4). Each tooth has a single lingual and four labial reentrant folds forming five crests, the pentalophodont pattern regarded as primitive for caviomorphs (Reig 1986; Vucetich and Verzi 1993). The folds isolate quickly into lakes with wear; these lakes may subdivide into as many as eight elements in transverse lines. Upper and lower incisors are thin and laterally compressed, with the enamel pigmented yellow or orange. Both extant genera share a combination of dental traits that include the lingual separation of the metaloph from the posteroloph in early stages of wear and the presence of a spur on the posteroloph; the posterior projection of the paracone; the early union of the lingual ends of the mesolophs, metalophs, and posterolophs; bulbous enamel on the occlusal surface; separation of the mesoloph from the mure, at least in unworn teeth; and a posteroloph that is separated from the hypocone in early stages of wear (Vucetich and Verzi 2002). F. S. Oliveira et al. (2012) detailed the macrostructure of the cheek teeth of *Dasyprocta azarae* using radiography and histological sections.

Pocock (1922), Hooper (1961), Iack-Ximenes (1999), and Menezes et al. (2001, 2003) describe morphology of the phallus, which is similar to that of the paca (*Cuniculus paca*) with the characteristic intromittent sac, epidermis on both inside and out covered by dense comb-like spines, and a pair of elongated spikes on the floor that extend distally beyond the remainder of the glans when the intromittent sac is everted. The baculum is a subcylindrical bony rod expanded laterally at the base, deeply concave ventrally and convex dorsally, with a truncate and angular tip capped by a mass of cartilage. In the female, the genital and urinary openings are visible externally as distinct apertures, with the prepuce, containing the urinary orifice, and clitoris separate from the sphincter surrounding the anus (Pocock 1922). A pair of anal glands is present, represented externally by small pouches opening on each side of and within the sphincter musculature of the anus. M. A. M. Carvalho et al. (2008) described the arterial supply to the penis of *Dasyprocta prymnolopha*; Mollineau et al. (2006, 2009) described the male reproductive system, including the position and both gross and microanatomy of the accessory glands.

Females have four pairs of mammae, all in a ventral position (Weir 1974b). Ovulation is generally spontaneous, with a mean estrous cycle length of 34 to 42 days, and seasonally structured. A postpartum estrous occurs within 50 days if young are present, and within 16 days if lost (in *Myoprocta*; Weir 1974b). As with other caviomorphs, dasyproctids have small litters (one to three offspring), with young precocial at birth following a long gestation period (99 to 120 days). The lactation period is short (about 20 days), and puberty is reached at an average age of 6 months (*Dasyprocta*) or up to 12 months (*Myoprocta*; Weir 1974b). The precocial nature of neonates is reflected by a large ratio of newborn to adult brain weight (Pilleri 1959). Miglino et al. (2002, 2004) and R. F. Rodrigues et al. (2006) provided details of placentation in *Dasyprocta*. The eyes of agoutis are well adapted for their diurnal lifestyle, with a high proportion of cones relative to rods in the retina (Farias Rocha et al. 2009).

Agoutis and acouchys have been traditionally placed within the Cavoidea, either as a family unto themselves (Winge 1887; Tullberg 1899; Wood 1965) or one that also included the pacas (Pocock 1922; Simpson 1945; Landry 1957; and McKenna and Bell 1997; see comment in Woods 1993). Molecular analyses are completely concordant in documenting the Dasyproctidae as part of the Cavoidea, but support a basal position of either the Dasyproctidae (Rowe and Honeycutt 2002; Opazo 2005; Rowe et al. 2010) or the Cuniculidae (Upham and Patterson 2012). Divergence dates for the base of the family are estimated to be as recent as 27.9 ± 2.4 mya in the Late Oligocene (Opazo 2005) or as old as 31 mya (95% posterior probability range: 28–47 mya; Rowe et al. 2010), in the Late Eocene. The earliest fossils are recorded from the early Oligocene (B. Patterson and Wood 1982; McKenna and Bell 1996). However, as posited by B. Patterson and Wood (1982), Vucetich (1984), and Walton (1997), these early, now extinct forms are a clade apart from the two extant genera. Divergence estimates based on molecular sequences (Opazo 2005) suggest a split between *Dasyprocta* and *Myoprocta* in the early part of the Late Miocene, at about 10.7 ± 2.3 mya. Both extant genera have been restricted to tropical and subtropical forested regions throughout their histories, although at least one extinct member of their lineage (*Plesiaguti tototi*) extended to coastal Buenos Aires province in Argentina during a warm period of the lower-middle Pleistocene (Ensendadan) (Vucetich and Verzi 2002).

KEY TO THE GENERA OF DASYPROCTIDAE:

1. Size large (2–6 kg); tail minute, inconspicuous, and naked; teeth large with toothrow >17 mm in length
 *Dasyprocta*

- 1'. Size smaller (<1.5 kg); tail short but conspicuous, and hairy; teeth small, with toothrow <14 mm in length . . .

. *Myoprocta*

REMARKS: The skulls of both *Dasyprocta* and *Myoprocta* share the same cranial conformation and general set of qualitative features, with most obvious differences between them associated with overall size. Ellerman (1940) believed the two genera sufficiently similar to be considered as subgenera of a single genus-group taxon.

Genus *Dasyprocta* Illiger, 1811

Members of the genus *Dasyprocta*, or agoutis, are among the most recognizable rodents of the Neotropical forests, ranging from southern Mexico through Central America to Ecuador on the west side of the Andes and from the north coast of South America, including Trinidad and Tobago and several islands of the Lesser Antilles, to northern Argentina and coastal Brazil east of the Andes. The genus can be generally characterized by the set of external and cranial characters described above for the family.

The ubiquity and easy recognition of an agouti, however, belie the rather chaotic current taxonomy of the genus. The number of species, their respective morphological boundaries, and thus their geographic ranges are poorly understood, with substantive conflicts in both names applied and mapped or described ranges among modern syntheses (Eisenberg 1989; Eisenberg and Redford 1999; Emmons and Feer 1990, 1997; Woods and Kilpatrick 2005; Bonvicino, Oliveira, and D'Andrea 2008). As nearly every modern author has lamented, the genus is in critical need of revision.

The 10 species we recognize, their distributions, and their morphological characters are based primarily on four sources: (1) the descriptions of external characters and mapped ranges of species recognized by Emmons and Feer (1990, 1997), which, while not documented by referenced specimens, were based on the senior author's examination of specimens in U.S., European, and Brazilian collections, her access to the notes of Charles O. Handley Jr. at the National Museum of Natural History, and her personal field experiences; (2) the evaluation of Venezuelan species by Ojasti (1972), a study that detailed character differences of morphological and taxonomic groups from throughout that country; (3) the reconstruction of part of the convoluted nomenclatural history of the genus by Husson (1978) and, especially, Voss et al. (2001) in their respective reviews of agoutis of the Guianan region; and (4) the unpublished masters thesis of Iack-Ximenes (1999), who reviewed Brazilian species based primarily on specimens housed in collections of that country. Iack-Ximenes detailed trends in color and color pattern and provided a hypothesis of

species relationships derived from cladistic analysis of those characters. He also emphasized the general allopatric nature of populations with different color patterns, using this criterion as a major basis for the species he delimited. Our review here is clearly provisional and will undoubtedly be modified substantively as even regional units are studied in appropriate detail. Indeed, as this book was in the final stages of production, Feijó and Langguth (2013) described *Dasyprocta iacki* from northeastern Brazil and reviewed the taxonomy of the red-rumped agoutis from south of the Amazon herein considered as *D. leporina*. Readers should examine Feijó and Langguth (2013) for the details of their arguments.

SYNONYMS:

Mus: Linnaeus, 1758:58; part (description of *leporinus*, based on *Lepus javensis* of Catesby); not *Mus* Linnaeus.

Calva Gmelin, 1788:120; part; incorrect subsequent spelling of *Cavia* Pallas [*Calva* written in text although *Cavia* is on page headers].

Cavia: Erxleben, 1777:353; part (listing of *aguti* and *leporina*); not *Cavia* Pallas.

Agouti: Daudin, 1802:166; part (description of *cayanus*); not *Agouti* Lacépède.

Dasyprocta Illiger, 1811:93; part; included species *Cavia aguti* (= *Mus aguti* Linnaeus) and *Cavia acouschy* [*sic*] Erxleben; type species *Mus aguti* Linnaeus, by subsequent designation (Thomas 1903d:464, who erected *Myoprocta* to contain *Dasyprocta acouschy* [Linnaeus]).

Platygyga Illiger, 1811:93; included in the synonymy of *Dasyprocta*; *nomen nudum*.

Cloromis F. Cuvier, 1812:290, plate 15, Fig. 10; no type species given.

Chloromys Rafinesque, 1815:56; incorrect subsequent spelling of *Cloromis* F. Cuvier.

Platygyga Desmarest, 1816:210; incorrect subsequent spelling of *Platygyga* Illiger.

Chloromys G. Cuvier, 1817:214; incorrect subsequent spelling of *Cloromis* F. Cuvier; included species *Cavia acuti* (= *Mus aguti* Linnaeus) and *Cavia acuchi* (= *Myoprocta acouschy* [Erxleben]).

Chloromys Lesson, 1827:300; inclusion of *acuti* (= *Mus aguti* Linnaeus) and *cristatus*; not *Chloromys* Schlosser, 1884, a subgenus of *Steneofiber* (see McKenna and Bell 1997:197); year incorrectly given as 1927 in Woods and Kilpatrick (2005).

Cutia Liais, 1872:534; part; type species *Mus aguti* Linnaeus; *nomen oblitum*.

Mamdasyproctaus A. L. Herrera, 1899:29; unavailable name because it is based on zoological formulae (ICZN 1987:318).

REMARKS: Illiger (1811), when he erected *Dasyprocta*, included both *Cavia aguti* [= *Mus aguti* Linnaeus] and

Cavia acouschy (*sic* = *Cavia acouchy* Erxleben) without selecting either as the type of his new genus. Thomas's (1903d:464) erection of *Myoprocta* to contain "the long-tailed Agouti, '*Dasyprocta*' *acouchy*, Linn,'" resulted in the de facto selection of *Mus aguti* Linnaeus as the type species of Illiger's *Dasyprocta*.

Emmons and Feer (1990, 1997) recognized seven species in the genus, six with ranges at least in part of South America and five within Brazil alone. They only treated, however, those South American species that occurred in lowland rain or dry forest areas. Iack-Ximenes (1999) delineated 12 species in Brazil, including three that as yet have no available name; many of these have been included in the recent guides of Brazilian mammals (N. R. Reis et al. 2006; Bonvicino, Oliveira, and D'Andrea 2008; Paglia et al. 2011). Herein, we take a somewhat intermediate approach, recognizing all of the taxa shared in common by Emmons and Feer and Iack-Ximenes plus additional taxa not considered by either of these authors. Not all of those taxa recognized by Iack-Ximenes seem worthy of recognition in our opinion, given geographic variation in color and color pattern in the widespread species, although we comment on each in the various accounts that follow. Although Iack-Ximenes (1999) and Voss et al. (2001) provided linear measurements of cranial dimensions for samples of Brazilian and Guianan taxa, as yet no treatise has adequately reviewed geographic variation in these characters within species or delineated the differences among them. Nor has anyone yet described the qualitative cranial characters of use in defining species or any geographic units. Rather, our current understanding of species boundaries stems almost exclusively from pelage color and color pattern, supplemented limitedly by overall body size and, to a lesser extent, the apparent lack of true sympatry among species. What we provide here is best viewed as a simple set of hypotheses waiting to be tested by an adequate integration of external and craniodental morphology, especially with molecular phylogeographic and phylogenetic data and methods.

A word of further caution: the poorly delineated ranges and different taxonomies employed by authors over the past decades make the allocation of ecological or life history data to the species recognized herein difficult. Thus, for the information summarized for each species in the natural history notes, we have excluded references citing a particular species name unless the locality of field studies is identified and clearly falls within that part of a species' range where no other agouti might be present.

Contrary to so many Neotropical rodent genera, there is substantial karyotypic stability among the species of *Dasyprocta*. All literature reports to date give a diploid number of 64 and FN = 122 or 124, regardless of the species named or the geographic locality identified.

KEY TO THE SOUTH AMERICAN SPECIES OF *DASYPROCTA* (BECAUSE OF EXTENSIVE GEOGRAPHIC VARIATION IN COLOR, SOME INDIVIDUALS MIGHT FAIL TO BE DISTINGUISHED BY THIS KEY; CONSULT BOTH THE DETAILED DESCRIPTIONS AND RANGE MAPS IN THE ACCOUNTS THAT FOLLOW):

1. Body size smallish, typically <3 kg in mass 2
- 1'. Body size larger, typically >3 kg in mass 3
2. Overall color grayish with yellow to orange tones, hairs finely banded by five to seven phaeomelanin alternating with an equal number of eumelanin bands; mid-back and rump darker than sides but of same tone
. *Dasyprocta azarae*
- 2'. Forequarters gray, rump and flanks bright, pale orange; flanks with few dark bands on hairs; distribution limited to eastern Amazonia south of the Rio Amazonas
. *Dasyprocta croconota*
3. Dorsal and lateral color a mixture of black and white, without reddish or yellow pigments 4
- 3'. Dorsal and lateral color contains reddish or yellowish pigments 6
4. Head, back, and rump uniformly blackish flecked with white tipped hairs; fore and hind limbs and feet black
. *Dasyprocta fuliginosa*
- 4'. Head, back, and rump not blackish flecked with white tipped hairs; forelimbs and hindlimbs not black but forefeet and hindfeet either brown or black 5
5. Head and back blackish flecked with yellow to rufous tipped hairs; long hairs overhanging rump entirely white basally, with black tips; feet blackish.
. *Dasyprocta kalinowskii*
- 5'. Head, back, and rump uniform reddish brown or blackish with yellowish hairs; mid-body and rump with long, black; pale-tipped hairs overhanging rump; feet brown or blackish *Dasyprocta punctata*
6. Rump orange to red with a wide black dorsal stripe from mid-back across rump to tail; flanks of thighs orange
. *Dasyprocta prymnolopha*
- 6'. No blackish dorsal stripe present over mid-back or rump; flanks of thighs vary in color expression. 7
7. Head and forequarters grizzled olivaceous; rump and flanks orange; fore and hind limbs blackish 8
- 7'. Head and upper back grizzled olivaceous, black flecked with reddish, yellowish, brownish, whitish; rump and flanks not yellow-orange. 9
8. Broadly distributed from the Guianan region in the north to the south-central coast of Brazil, except for the northeastern region. *Dasyprocta leporina*
- 8'. Restricted to the coastal margin of northeastern Brazil
. *Dasyprocta iacki*
9. Head, mid-back, and rump uniformly finely grizzled black and tawny yellow, brown and yellowish, or black

and orange; midline of back usually darker than sides but of same color tone; feet brown, with hindfeet relatively short (in comparison to skull length).

- *Dasyprocta variegata*
- 9'. Head, mid-back, and rump uniformly blackish with or without yellowish or reddish bands dominating the black tones; hindfoot relatively long (in comparison to length of skull) *Dasyprocta guamara*

Dasyprocta azarae Lichtenstein, 1823

Azara's Agouti

SYNONYMS:

Dasyprocta Azarae Lichtenstein, 1823:3; based on Felix d'Azara's (1801:26) "*l'acuti*," but type locality given as "E provincia San. Paulo [= São Paulo] Brasil."

Chloromys Acuti: Rengger, 1830:259; name combination.

Dasyprocta caudata Lund, 1840b:12 [1841c:287]; type locality "Rio das Velhas's Floddal" (see Lund 1841c:292, 294), Lagoa Santa, Minas Gerais, Brazil.

Cutia azarae: Liais, 1872:536; part; name combination.

Cutia azarae, var. *brasiliensis* Liais, 1872:536; part; no type locality mentioned; implied type locality Minas Gerais, Brazil.

[*Cutia azarae*] var. *paraguayensis* Liais, 1872:536; based on Felix d'Azara's (1801:26) "*à tort l'acuti*"; therefore, the type locality is near Asunción, Paraguay.

Dasyprocta aurea Cope, 1889:138; type locality "Chapada" [= Chapada dos Guimarães], Mato Grosso, Brazil.

D[asyprocta]. rarea: Cope, 1989:139; typographical error.

Dasyprocta variegata yungarum Thomas, 1910d:505; type locality "Chimosi [= Chimasi], alt. 1700m. Yungas, [La Paz,] Bolivia."

Dasyprocta azarai Miranda-Ribeiro, 1914:45, table; name combination and incorrect subsequent spelling of *azarae* Lichtenstein.

Dasyprocta variegata urucuma J. A. Allen, 1915b:634; type locality "Urucum (near Curumbá [= Corumbá]) Matto Grosso [= Mato Grosso do Sul], Brazil."

Dasyprocta felicia Thomas, 1917f:310; type locality "near Concepcion, [Concepción department,] Paraguay."

Dasyprocta variegata boliviae Thomas, 1917f:312; type locality "Yacuiba, [Tarija,] southern Bolivia, on Argentine boundary south of Caiza."

Dasyprocta azarae catrinae Thomas, 1917f:311; type locality "Santa Catharina, [Santa Catarina,] S. Brazil."

Dasyprocta paraguayensis: Osgood, 1921:39; name combination.

Dasyprocta azarae azarae: Ellerman, 1940:194; name combination.

Dasyprocta azarae aurea: C. O. da C. Vieira, 1945:396; name combination.

[*Dasyprocta azarae*] *azarae*: C. O. da C. Vieira, 1945:425; name combination.

Dasyprocta azarae paraguayensis: Cabrera, 1961:587; name combination.

Dasyprocta punctata urucuma: Cabrera, 1961:590; name combination.

DESCRIPTION: One of smallest members of genus, head and body length 430–575 mm, tail length 10–35 mm, hindfoot length 100–120 mm, ear length 25–45 mm, and mass 2.4–3.4 kg (Emmons and Feer 1997; Iack-Ximenes 1999). Dorsal color overall gray washed with dull tawny yellow or olivaceous to bright orange, with hairs finely banded by multiple (5–7) white, yellowish, or orange bands interspersed with similar number of blackish ones. In sunlight, living individuals appear golden, often with black rump. Mid-body broadly washed with tawny yellow orange, rump hairs black contrasting with mid-body and sparsely speckled with white or pale orange (or gray, from frosted with white tips on hairs, and area around tail (as viewed from rear) often orange. Sides of head from nose to ear all, or partly, washed with orange or tawny; base of vibrissae pink and naked, with white patch around corner of mouth. Legs orange or tawny, extremities of feet have blackish “socks” that may extend up to heels and elbows or only to toes; posterior thighs and hind legs black. Under parts, flanks, and anterior thighs bright to pale orange; inguinal region often white. Young with same color and color pattern as adults, but with shorter rump hairs. Animals from drier regions, particularly in Argentina, Paraguay, and southwestern Brazil, tend to be mostly gray or olivaceous. *Dasyprocta azarae* easily distinguished from other species by overall homogeneous yellow-olivaceous color coupled with grayish to blackish hindquarters.

DISTRIBUTION: Azara’s Agouti ranges throughout southwestern and south-central Brazil, from Mato Grosso and Goiás states in the north to the coast in Rio Grande do Sul and São Paulo states, Bolivia south of the Río Beni, eastern Paraguay, and northeastern Argentina, at elevations ranging from near sea level to 700 m. Iack-Ximenes (1999) included a specimen (INPA 99) from a locality within a patch of cerrado vegetation in Rondônia state, Brazil, an area that otherwise has only *Dasyprocta fuliginosa*. S. Anderson (1997) did not recognize more than one Bolivian species (which he listed as *D. punctata*), but we provisionally assign all Bolivian *Dasyprocta* from Chuquisaca, La Paz, Santa Cruz, and Tarija departments to *D. azarae*. The species probably ranges north as far as the Río Beni, but northern limits require verification. L. H. Emmons (unpubl. data.) has both collected a specimen (from El Encanto, Santa Cruz; LHE 781) and obtained many photographs of *D. azarae* from the cerrado of Santa Cruz de-

partment. Iack-Ximenes (1999) included another (MNRJ 5618) of unspecified locality from this same region in Bolivia. The type locality of *D. variegata boliviae* Thomas is on the Argentina border at the western edge of the Bolivian Chaco. The species also occurs in Kaa-Iya National Park, in the Bolivian Chaco (20°03′03″S, 62°26′04″W), based on photo documentation (E. Cuellar and A. Noss, pers. comm. of photos to L. H. Emmons). Because the *Dasyprocta* of southern Bolivia and Paraguay all conform to *D. azarae*, we have provisionally grouped the neighboring populations in Argentina in this species; these samples have been assigned to *D. punctata* in previous synopses of Argentinian species (e.g., Barquez, Díaz, and Ojeda 2006; M. M. Díaz and Barquez 2007).

SELECTED LOCALITIES (Map 387): ARGENTINA: Jujuy, Mesada de la Colmenas (Heinonen and Bosso 1994), Villa Carolina (Thomas 1920a); Misiones, Parque Nacional Iguazú (Crespo 1982b); Salta, Aguaray (R. A. Ojeda and Mares 1989), Vado de Arrayazal, 20 km NW of Aguas Blancas (R. A. Ojeda and Mares 1989). BOLIVIA: Chuquisaca, Porvenir (S. Anderson 1997); La Paz, Chimosi [= Chimasí] (type locality of *Dasyprocta variegata yungarum* Thomas), Puente de Choculo (S. Anderson 1997); Santa Cruz, El Encanto, Cascades (LHE 781), Floripondio (S. Anderson 1997); Tarija, Yacuiba (type locality of *Dasyprocta variegata boliviae* Thomas), Parque Nacional Noel Kempff Mercado, El Encanto (LHE 781). BRAZIL: Bahia, Fazenda Jatobá-Floryl (UNB 1560); Goiás, Pouso Alto [= Pircanjuba] (USNM 283473), Rio São Miguel (MNRJ 2305); Mato Grosso, Chapada [= Chapada dos Guimarães] (USNM 113431), Jacaré, alto Rio Xingú (MNRJ 11974), São Domingos (MZUSP 6986), São Luiz de Cáceres (MNRJ 5833), Tapirapoan (MNRJ 904); Mato Grosso do Sul, Urucum, near Corumbá (type locality of *Dasyprocta variegata urucuma* J. A. Allen), Maracaju (MNRJ 4612); Minas Gerais, Lagoa Santa, Rio das Velhas (type locality of *Dasyprocta caudata* Lund), Lassance (MNRJ 2304); Paraná, Monte Alegre (MHNCI 485); Rio Grande do Sul, São Lorenço do Sul (MZUSP 249); Santa Catarina, Corupá (MSCJ [no number]); São Paulo, Cotia (MZUSP 25531), Serra da Bocaina (MZUSP 25792). PARAGUAY: Caaguazú, Sommerfield Colony #11 (MNRJ 43170); Concepción, near Concepción (type locality of *Dasyprocta felicia* Thomas).

SUBSPECIES: Thomas (1904a:241) remarked that he could find little tangible difference between specimens collected at localities as wide ranging as the Chapada dos Guimarães in Mato Grosso state, Brazil, eastern Paraguay, or at the type locality of São Paulo, Brazil. He commented, however, on the extensive variation among individuals taken at any one of these localities. Cabrera (1961:587)

listed three valid subspecies: the nominotypical form (with *caudata* Lund and *aurea* Cope as synonyms) from east-central Brazil in Minas Gerais, São Paulo, Paraná, and Mato Grosso states; *D. a. catrinae* Thomas from the southwestern Brazilian states of Santa Catarina and Rio Grande do Sul; and *D. a. paraguayensis* Liais (with *felicia* Thomas a synonym) from eastern Paraguay and north-eastern Argentina. S. Anderson (1997), while including all Bolivian *Dasyprocta* in his concept of *D. punctata*, listed two subspecies, *boliviae* Thomas and *yungarum* Thomas, both of which we assign herein to *D. azarae*. Iack-Ximenes (1999) regarded both *aurea* Cope and *catrinae* Thomas to be valid species (see Remarks). Given the number of available names but complete lack of any comprehensive review of character variation over the species range, it is premature to validate any of these taxa as recognizable geographic variants.

NATURAL HISTORY: Azara's Agouti occurs in forest patches within savannas (*floresta estacional semidecidual*) and lowland Atlantic Forest (*floresta ombrófila densa*). It is common in cerrado habitats in eastern Bolivia and central Brazil, especially dense in groves of *Attalea* palms that invade burned deforested areas. It feeds on seeds of these (L. B. de Almeida and Galetti 2007) and other palms and is an important disperser of palm seeds (F. R. da R. Silva et al. 2011). Individuals are active during daylight and cool temperatures just after dawn and before nightfall. This agouti adapts to human disturbance, where it is fond of mangos, avocados, cashews, and other domestic crops (L. H. Emmons, pers. comm.). It was the most abundant medium-sized mammal recorded from camera-trap surveys in Rio Grande do Sul (Kasper et al. 2007), and the major prey item of bush dogs, *Speothos venaticus*, in Paraguay (Zuecher et al. 2005). Basic physiological parameters, such as basal metabolic rate, have been measured in captive populations (H. F. Brito et al. 2010). Known internal parasites include Trichostrongyloid nematodes (Pudicinae; Cassone and Duret-Desset 1991), ciliated protozoa (*Amylophorus*; C. Pereira and Almeida 1942), and the flagellate protozoan, *Trypanosoma cruzi* (J. C. Oliveira and Pattolli 1964). Ticks of the genus *Amblyomma* were recovered from agoutis inhabiting Parque Nacional das Emas in Goiás state, Brazil (T. F. Martins et al. 2011).

REMARKS: Felix d'Azara (1801) recorded "*l'acuti*" from near Asunción, Paraguay, and subsequently Lichtenstein (1823:3) briefly described *Dasyprocta azarae*, basing it on Azara's animal, but curiously giving São Paulo, Brazil, as the locality. Liais (1872:536) described *Cutia azarae* var. *paraguayensis*, also based on Azara's "*l'acuti*." Thomas (1917f:310) argued that Lichtenstein's *azarae* from São Paulo was a different species from Azara's Paraguay ani-

mal and, apparently unaware of Liais' *paraguayensis*, proposed *Dasyprocta felicia* for Azara's animal. Subsequently, Osgood (1921:39) stated that *paraguayensis* Liais "although provisionally and somewhat irregularly proposed, this name is clearly based on Azara's '*l'acuti*.' This species, therefore, should take the name *paraguayensis* and *Dasyprocta felicia* Thomas becomes a synonym." Tate (1935), in his taxonomic history of *Dasyprocta*, neither listed Liais's *paraguayensis* nor referred to Osgood's 1921 paper discussing the topic. Ellerman (1940), however, agreed with Osgood and listed *felicia* Thomas as a synonym of *paraguayensis* Liais. Cabrera (1961) also considered *felicia* Thomas a synonym of *paraguayensis* Liais while listing the latter as a valid subspecies of *D. azarae*. The most recent published compilation of taxa in the genus, that of Woods and Kilpatrick (2005), simply regarded both *paraguayensis* Liais and *felicia* Thomas as synonyms of *azarae* Lichtenstein. Iack-Ximenes (1999), in his unpublished review of Brazilian species, expressed the same view.

Lund (1840b [1841c]) described *D. caudata* from Lagoa Santa, Minas Gerais, Brazil, recognizing his new taxon by its larger size and longer tail than the Paraguayan agouti, which he called *D. azarae*. Thomas (1917f:310) believed that *caudata* was the same as Lichtenstein's *D. azarae* from São Paulo, and Lund's name has been listed as a synonym of this species by essentially all subsequent authors, regardless of varying views as to whether Lichtenstein's *azarae* and Liais's *paraguayensis* (including *felicia* Thomas as a synonym) were the same or different forms.

Cope (1889:138) described *Dasyprocta aurea* based on a single, well-preserved skin entirely yellow-orange in color and supposedly collected at Chapada (= Chapada dos Guimarães), Mato Grosso by H. H. Smith. In comparisons to *croconota* Wagler, *prymnolopha* Wagler, and *azarae* Lichtenstein, Cope believed the relationship of his new species lay with *D. azarae*. J. A. Allen (1915b:633–634), upon examining Cope's type, suggested that the animal was a yellow albino, although "the long rump hairs indicate that *aurea* is not an albinism of *D. azarae*." On the other hand, Thomas (1917f:311), based on apparently normal-colored specimens from Chapada in the British Museum, stated that *aurea* Cope was barely distinguishable subspecifically from *D. azarae*. Two other specimens from Chapada, collected by H. H. Smith in 1883 (USNM 113430–113431), are gray-frosted dorsally and on the rump, and slightly paler but otherwise similar to *D. azarae* from Mato Grosso (Caceres, USNM 390350) and Goiás (Pouso Alto [= Piracanjuba], USNM 283473). Most subsequent authors (C. O. da C. Vieira 1945, 1951, 1953, 1955; Cabrera 1961; Woods 1993; Woods and Kilpatrick 2005) followed Thomas in listing *aurea* Cope as a synonym of

azarae Lichtenstein. Moojen (1952b), Bishop (1974), and Iack-Ximenes (1999), however, each sided with J. A. Allen (1915b) in asserting that *aurea* was a valid species separate from *azarae*. Iack-Ximenes (1999) questioned whether Chapada dos Guimarães was, in fact, the place where Smith obtained the specimen Cope described, in part because Smith's travels took him widely through central and coastal Brazil and also because none of the many other agoutis from this area in collections exhibited the unique color characters of Cope's animal. Iack-Ximenes further argued that the rarity of true sympatry among agoutis supported his belief that Cope's type was collected elsewhere. He cited a second specimen (MNRJ 2286) that matched the characters of *aurea* but that, unfortunately, lacked associated provenance or other information. Smith's locality may or not be questionable, but it is not possible at present to refute either Allen's suggestion that the animal is a yellow albino of a unique species or Thomas's, and others, conclusion that *aurea* Cope simply represents a mutant *D. azarae*.

Thomas (1910d, 1920a) concept of *Dasyprocta variegata* was rather expansive, and he described both *yungarum* from the Yungas of La Paz department, Bolivia, in 1910 and later *boliviae* from Tarija department in 1917 in this species. However, both *D. azarae* and *D. variegata* share some color characters, such as black or brown feet and finely annulated black and colored hairs, although these traits are geographically and individual variable and descriptions are ambiguous. S. Anderson (1997) recognized *yungarum* Thomas as one of two subspecies of agoutis in Bolivia, both of which he incorrectly assigned to *D. punctata*. He erred, however, on two accounts: first, by mapping *yungarum* to southern Bolivia (Santa Cruz, Chuquisaca, and Tarija departments) and, second, by listing its type locality of Chimosi (= Chimasi) in Cochabamba rather than La Paz department. We have not seen the holotype of *yungarum*, but the description could fit that of *D. azarae* as well as *D. variegata*. Because *azarae*-like agoutis extend to near the base of the Andes in the vicinity of the savannas of Ixiamas in La Paz department (photo documentation by R. Wallace, pers. comm. to L. H. Emmons), to the east of Chimasi but at lower elevation, we provisionally assign *yungarum* Thomas to *D. azarae*.

J. A. Allen (1915b) described *Dasyprocta variegata urucuma* based on single specimen collected by Leo E. Miller during the American Museum's Roosevelt Brazilian expedition. He explicitly stated that *urucuma* belonged to the "*D. variegata* group" and needed no comparison to *D. azarae* (J. A. Allen 1915b:634), but his reasoning was unstated, and his concept of *variegata* at the time included three species we recognize herein (*D. punctata* from northwestern South America, *D. azarae*, and true *D. variegata*).

On both geographic and habitat grounds, we are inclined to associate *urucuma* J. A. Allen with *D. azarae*. However, Robert S. Voss (pers. comm.), who examined Allen's holotype, noted that "all of these open-country agoutis [= *D. azarae* and *D. variegata*] look more or less the same," a comment that only highlights the need for careful revision of existing specimens of both species. This need is exemplified by Iack-Ximenes's (1999) assignment of a specimen (INPA 99) from Jaciparaná in Rondônia state, Brazil, to *D. azarae*, a locality just a few kilometers south of Porto Velho from where Osgood (1916:209) assigned specimens to *D. variegata*.

Thomas (1917f:311) described *Dasyprocta azarae catrinae* from an unspecified locality in Santa Catarina state, Brazil, "a locality further south than any place from which a *Dasyprocta* has been recorded." He regarded this animal to represent a new subspecies of *D. azarae*, distinguishing it from Lichtenstein's "true" *azarae* from São Paulo by its paler and grayer general color, with the foreback and sides "scarcely tinged at all with yellow; the rump also yellowish, not hoary grayas in the usual *azarae*." Iack-Ximenes (1999:134) believed *catrinae* to be specifically distinct from *D. azarae*, distinguishing the single specimen he examined (MZUSP 1631, from Joinville, Santa Catarina) by the same color differences noted by Thomas. Other recent authors had followed Thomas and regarded *catrinae* either as a valid subspecies of *D. azarae* (Cabrera 1961) or placed the name in a list of synonyms of that species (Woods and Kilpatrick 2005). A specimen purportedly from Santa Catarina (USNM 19691) has long, bright red rump hairs annulated with black, and is indistinguishable from an agouti from Rio de Janeiro (USNM 283472), both identifiable as *D. leporina*, and unlike *D. azarae*. However, the USNM specimen was acquired in 1891 from a Berlin dealer (August Müller), so its provenance is questionable. Given that apparently only three specimens are available from Santa Catarina state (the holotype of *catrinae* in the British Museum and those in the MZUSP and USNM), only one with provenance, we take the conservative approach and list *catrinae* Thomas as a synonym of *D. azarae* Lichtenstein.

While we believe Woods and Kilpatrick (2005) appropriately included *aurea* Cope and *catrinae* Thomas as synonyms of *D. azarae*, they also listed *acuti* F. Cuvier, 1812 as a synonym. This must be an inadvertent error because Cuvier's name is a misspelling of *aguti* Linnaeus, 1766, and is thus correctly placed in the synonymy of *Dasyprocta leporina* (see the account of that species).

Finally, Thomas (1917f:312) also described *D. variegata boliviae*, from Yacuiba, in Tarija department at the edge of the Bolivian Chaco. Because his description matches specimens we have examined from Paraguay and both the

Map 387 Selected localities for *Dasyprocta azarae* (●). Contour line = 2,000 m.

Cerrado and Chaco of Bolivia, we assign *boliviae* Thomas to *D. azarae*. As noted here, S. Anderson (1997) assigned all Bolivian agoutis to *D. punctata*, but probably all records he listed from the dry forests of eastern Santa Cruz department are *D. azarae*, although a reexamination of each of these specimens is required to confirm identifications (see Remarks for *D. variegata*). In general, the distinction between *D. azarae* and *D. variegata* is not absolute, and it will likely take an appropriate analysis using DNA methodologies to determine whether these are, in fact, separate biological entities or whether *variegata* might simply be a northern extension of *D. azarae*.

Specimens from the northern Pantanal in Mato Grosso state, Brazil, have a karyotype with $2n = 64$, $FN = 122$, one that differs in individual chromosome morphology from the complement of other species (A. L. G. Souza et al. 2007a).

Dasyprocta croconota Wagler, 1831

Orange Agouti

SYNONYMS:

Dasyprocta croconota Wagler, 1831c:618; type locality “Brasilia ad flumen Amazonum,” incorrectly restricted by J. A. Allen (1915b:628) to “the immediate vicinity of the mouth of the Rio Madeira”; emended by Lack-Ximenes (1999:142) to Santarém, Rio Tapajós, Pará, Brazil; see Remarks).

D[asyprocta]. croconota: Wagner, 1844:44, Fig. 172b; name combination.

[*Dasyprocta*] *croconota*: E.-L. Trouessart, 1897:634; name combination.

Dasyprocta croconota croconota: J. A. Allen, 1916d:568; name combination.

Dasyprocta aguti maraxica Thomas, 1923a:341; type locality “Caldeirão, Marajó Island [= Ilha de Marajó],” Pará, Brazil.

[*Dasyprocta*] *aguti maraxica*: Tate, 1935:330; name combination.

[*Dasyprocta*] *a[aguti]. mar[axica]*.: Krumbiegel, 1941:104, Fig. 8; name combination.

[*Dasyprocta*] *crocon[ota]*.: Krumbiegel, 1941:104, Fig. 8; name combination.

Dasyprocta aguti croconota: Cabrera, 1961:586; name combination.

DESCRIPTION: Another relatively small species, head and body length 465–560 mm, tail length 10–25 mm, hind-foot length 105–110 mm, ear length 40–45 mm, and mass 2.2–2.8 kg. Distinguished from other species, particularly from *D. leporina*, by bright orange coloring over hindquarters and rump and general absence of black or brown pigment on hindquarters. Rump hairs orange to ruby red with strongly faded, or even whitish, basal portion; some specimens may have rump sprinkled with flecks of black, but not to degree that these affect general monochromatic orange coloring. Dorsal streak on mid-back well demarcated and body, other than rump, sprinkled with black to clear brown and yellow to reddish hairs.

DISTRIBUTION: This species occurs in the eastern Amazon of Brazil from the lower Rio Tapajós to the left margin of the lower Rio Tocantins and on Ilha de Marajó and Ilha Mexiana at the mouth of the Rio Amazon. All known localities are between 0 and 200 m in elevation.

SELECTED LOCALITIES (Map 388): BRAZIL: Pará, Cametá, west bank of Rio Tocantins (MZUSP 5363), Curralinho, Ilha de Marajó (MNRJ 4960), Fazenda Gavinha, Ilha de Marajó (MPEG 982), Foz do Rio Curuá (MZUSP 5353), Ilha Mexiana (Krumbiegel 1941a), Monte Cristo, Rio Tapajós (MZUSP 3791), Rio Arapiuns, Santarém (MPEG 704), Rio Curuá-Tinga, affluent of Rio Curuá-Una (MNRJ 11602), Santarém, Rio Tapajós (MZUSP 3790), Sítio Calandrinho, Rio Tocantins (MPEG 8871), Urucurituba, Rio Tapajós (MZUSP 2347).

SUBSPECIES: We treat *Dasyprocta croconota* as monotypic, although Thomas (1923a) recognized specimens from Ilha de Marajó as a subspecies of *D. aguti* [= *D. leporina* herein]; see comment under Remarks.

NATURAL HISTORY: This species has apparently not been studied in the wild, as no data on ecology, population biology, life history, or behavior have been published (at

least under this species name). It inhabits lowland rainforest, including second growth and forest edge, within the *Floresta Ombrófila Densa* vegetative cover type (Iack-Ximenes 1999).

REMARKS: *Dasyprocta croconota* has usually been listed as a subspecies (E.-L. Trouessart 1880:192–193; Cabrera 1961:586) or as a simple synonym (Woods and Kilpatrick 2005) of *D. aguti* [= *D. leporina*]. Thomas (1923a:342) believed that *croconota* “may be an Amazon representative” of *D. aguti* [= *D. leporina*]. Moojen (1952b), however, regarded *D. croconota* as a species distinct from *D. aguti*, and Iack-Ximenes (1999) presented evidence of character differences between and broadly overlapping distributions of *D. croconota* and *D. aguti* south of the Rio Amazon in eastern Brazil. We follow Iack-Ximenes and recognize two species of red-rumped agoutis in east-central Brazil: *D. croconota*, characterized by its bright orange to red flanks and rump and a range limited to Pará state, and *D. leporina* with yellow-orange hindquarters sprinkled with black and a range extending from the Guianan region through eastern Amazonia and the gallery forests of the Cerrado to the forested central coast of Brazil. Appropriate future molecular analyses will determine whether Iack-Ximenes’s hypothesis is correct, or whether specimens he allocated to *D. croconota* are only part of a color polymorphism present in populations from Pará state within a single species, *D. leporina*.

Wagler gave only “Brasília ad flumen Amazonum” as the locality for his *croconota*, which was based on a specimen collected by Johann von Spix during his travels in Amazonia (see Hershkovitz 1987b:28, Fig. 5 for a map of Spix’s route). J. A. Allen (1915b:628–629) stated “specimens in the American Museum collected by Leo E. Miller (Roosevelt Brazilian Expedition) at Calama, on the lower Rio Madeira [actually upper Rio Madeira in northernmost Rondônia state; see Paynter and Traylor 1991], agree satisfactorily with Wagler’s description,” with the footnoted comment “except that the incisors are not white.” Allen thus posited, because Spix had spent considerable time on the Amazon River between the Rio Madeira and Rio Negro, ascending the lower parts of both, that “it seems not unreasonable to indicate the immediate vicinity of the mouth of the Rio Madeira as the type locality of *Dasyprocta croconota*.” Most subsequent authors (e.g., Tate 1935; Ellerman 1940; Moojen 1952b; C. O. da C. Vieira 1955; Cabrera 1961) followed Allen’s argument. Iack-Ximenes (1999:149–152), however, questioned Allen’s supposition on multiple grounds. First, only Black Agoutis are known from the lower Rio Madeira and adjacent areas of Amazonia, near where Wagner’s (1842c) holotype of *Dasyprocta nigricans* had originated, and where Allen himself had restricted the type locality of Wagler’s

Dasyprocta fuliginosa (see Remarks in the account of that species). Second, even Miller’s specimens of an obvious Red-rumped Agouti from Chalama are of questionable provenance because, once again, only Black Agoutis are known from the middle Rio Madeira in the vicinity of Chalama today. Third, although C. O. da C. Vieira (1955) followed Allen’s opinion regarding the type locality of *croconota*, the distribution of this species that he articulated was primarily that area between the lower Rio Tapajós and Rio Tocantins in Pará state, well to the east of the Rio Madeira. Finally, because Spix also traveled extensively along the lower Amazon between the Tapajós and Tocantins, Iack-Ximenes argued that a locality in this region from which a specimen of the same color characteristics as the one Spix collected, and that Wagler described, should be chosen as the type locality. He suggested Santarém, on the lower Rio Tapajós, as most appropriate. We agree with this assessment, regard Allen’s restriction of *croconota* Wagler to the lower Rio Madeira as incorrect, and accept Iack-Ximenes’s emendation to Santarém, Rio Tapajós, Pará, Brazil, as a logical alternative.

Thomas (1923a) described *Dasyprocta aguti maraxica* from Caldeirão on Ilha de Marajó at the mouth of the Amazon, discriminating it from Wagler’s *D. croconota* with its “brownish fore-back and light centre of belly” while emphasizing the “more strongly tawny colour of the anterior half of the body” of *maraxica* as a characteristic more typical of *D. aguti* (p. 342). Krumbiegel (1941) identified populations from Ilha Mexiana, on the north side of Ilha de Marajó as *Dasyprocta aguti* and *Dasyprocta*

Map 388 Selected localities for *Dasyprocta croconota* (●).

rubrata, both now synonyms of *D. leporina*. However, based on his examination of specimens from these islands in Brazilian collections, Iack-Ximenes (1999) placed *maraxica* Thomas in the synonymy of *croconota* Wagler and regarded Krumbiegel's specimens from Ilha Mexiana to be *D. croconota* as well.

The karyotype of *D. croconota* is apparently unknown.

Dasyprocta fuliginosa Wagler, 1832

Black Agouti

SYNONYMS:

D[asyprocta]. fuliginosa Wagler, 1832:1220; type locality "habitat in Brasilia versus flumen Amazonum"; restricted by J. A. Allen (1915b:626) to "Villa de Borba," Rio Madeira, Amazonas, Brazil.

Dasyprocta nigra Gray, 1842:264; type locality "South America."

Dasyprocta nigricans Wagner, 1842c:362; type locality "Von Borba, am Madeiro und vom Rio Negro oberhalb des Cocuy," based on specimens collected by Johann Natterer in part at Villa de Borba, on the lower Rio Madeira, with which Wagner (1842c:362, 1844:48) compared Wagler's type and considered it identical with Natterer's specimens.

Dasyprocta pallida Waterhouse, 1848:389; *nomen nudum* (see Husson 1978:468).

Dasyprocta variegata zamorae J. A. Allen, 1915b:627; type locality "Zamora (altitude 2000 feet), [Zamora-Chinchi], Ecuador."

Dasyprocta fuliginosa fuliginosa: J. A. Allen, 1916d:568; name combination.

Dasyprocta fuliginosa mesatia Cabrera, 1917:53; type locality "Tarapoto, en el bajo Napo, Ecuador," about 2°S latitude, Oriente, Ecuador.

Dasyprocta apurensis Delacour, 1922:198; type locality "San Fernando-de-Apure," Apure, Venezuela.

Dasyprocta fuliginosa apurensis: Ojasti, 1972:184; name combination.

D[asyprocta]. fuliginosa nigricans: Ojasti, 1972:188; name combination.

DESCRIPTION: Among largest of agoutis, with head and body length 540–760 mm, tail length 20–40 mm, hindfoot length 120–145 mm, ear length 35–50 mm, and mass 3.5–6 kg. Distinguished by entirely black upper parts, finely grizzled with white (individual hairs are black with short, white tips). Hairs over rump black, sometimes with inconspicuous white tips, and usually do not overhang the rump as distinct fringe; nape with slight crest of longer, black hairs; tail black, as are feet; throat white or strongly grizzled white; venter dark brown and more or less grizzled with white, often with belly midline white. Animals from Venezuela (Amazonas state) with long, overhanging rump

hair, with long white tips, similar to condition characteristic of *D. punctata isthmica*, perhaps indicating taxonomic distinctiveness or hybridization with contiguous populations of *D. punctata*.

Readily separable from *Dasyprocta leporina*, which ranges to immediate east, by overall dark coloring, especially black hindquarters, sprinkled with white or pale yellow; from *Dasyprocta azarae* to southeast, which possesses hairs with multiple, alternating reddish-yellow and blackish-brown bands, producing golden-hued forequarters and midbody, rather than uniform black hairs with pale tips, and is much smaller; and differs from *D. variegata* and *D. azarae*, which replaces it from central Peru south to Argentina, by larger size and overall black color rather than grizzled black with yellow, brown and yellow, or black and orange overall appearance.

DISTRIBUTION: Black Agoutis occur almost exclusively in the western Amazon Basin of Brazil west of the Rio Negro and Rio Madeira, in southern Venezuela, southeastern Colombia, eastern Ecuador, and eastern Peru north of Junín department. However, Ojasti's (1972) assignment of *apurensis* Delacour from Apure state, Venezuela, to *D. fuliginosa* extends the species' distribution into the western tributaries of the Río Orinoco (see map in O. J. Linares 1998). A specimen in the USNM (443450) from Apure is dark brown with white annulations on hairs rather than black, resembling animals from Zulia that are cataloged as *D. punctata* but is also quite like some *D. fuliginosa* from Amazonas. Its smaller size (head and body 522 mm) and browner hue cause us to provisionally retain it under *D. punctata*, but with some doubts. Elevational range extends to 1,000 m on the eastern flank of the Andes.

SELECTED LOCALITIES (Map 389): BRAZIL: Acre, Seringal do Oriente, Rio Juruá (MPEG 835); Amazonas, Borba, Rio Madeira (type locality for *Dasyprocta fuliginosa* Wagler and *Dasyprocta nigricans* Wagner), km 62 on BR 319 (INPA 94), Cucuy [= Cucuí], Rio Negro (Wagner 1842c), Codajeas (MPEG 8913), João Pessôa [= Eirunepé], Rio Juruá (MNRJ 5987); Mato Grosso, Aripuanan [= Aripuanã] (MNRJ 2307), Porto do Braço das Lontras, Rio Comemoração Floriano, alto Rio Jamarí (MNRJ 2292); Rondônia, Alvorada d'Oeste, km 87 on BR 429 (MPEG 19708), UHE Samuel, Rio Jamarí (MPEG 22576). COLOMBIA: Meta, Restrepo (AMNH 136304), San Juan de Arama, Plaza Bonita (FMNH 87891); Putumayo, Río Mecaya (FMNH 70785). ECUADOR: Chimborazo, Pallatanga (Tomes 1860a); Orellana, San José de Payamino (MVZ 170936); Zamora-Chinchi, Zamora (type locality of *Dasyprocta variegata zamorae* J. A. Allen). PERU: Amazonas, vicinity of Huampani, Río Cenepa (MVZ 155205), Chachapoyas (Thomas 1927a); Loreto, Balsapuerto (Osgood 1914b), Iquitos (Thomas 1928c), near Río Curaray

(Lönnberg 1921); Ucayali, 59 km SW of Pucallpa (USNM 499236). VENEZUELA: Amazonas, Belén, Río Cunucuma, 56 km NNW of Esmeralda (Handley 1976), Boca Mavaca, 84 km SSE of Esmeralda (Handley 1976), Cerro Yapacana (USNM 256432); Apure, Hato El Frío, 30 km W of El Samán (Ojasti 1972), San Fernando de Apure (type locality of *Dasyprocta fuliginosa apurensis* Delacour).

SUBSPECIES: Some authors (e.g., Cabrera 1961; Ojasti 1972) have recognized multiple subspecies within *D. fuliginosa*, but we allocate some of those names to other species (e.g., *candelensis* J. A. Allen and *colombiana* Bangs, both synonyms of *D. punctata*). J. A. Allen (1915b) noted the strong similarity of the large, black *D. colombiana* from Santa Marta, to those he called *D. variegata* (regarded herein as *D. punctata*) and to *D. fuliginosa*, while Ojasti (1972) remarked that Venezuelan specimens that he referred to *D. f. fuliginosa* exceeded the size of those from the type locality in Brazil, and could be separated as a valid subspecies, to which he applied the name *D. f. nigricans*. However, Wagler's *fuliginosa* and Wagner's *nigricans* both share the same type locality (Borba on the Rio Madeira). Thus, should appropriate geographic analyses eventually conclude that the southern Venezuela samples deserve recognition, another name must be coined. Ojasti also noted that *apurensis* Delacour, a name that had been ignored by previous workers, was applicable to samples of *D. fuliginosa* from Apure state in Venezuela. These populations share the same chromatic pattern as typical *D. fuliginosa* but are much smaller in all dimensions. Although the color and color pattern of *D. fuliginosa* do vary geographically, the lack of any review of this variation prevents one from delineating to any realistic degree appropriate geographic units that might be formally recognized, much less deciding on which, if any, available name might apply.

NATURAL HISTORY: Little is known about the population biology, behavior, or natural history of this species. Gorchov et al. (2004) documented *D. fuliginosa*, along with the acouchys (probably *Myoprocta pratti*), as a major disperser of the seeds of *Hymenaea courbaril* (Fabaceae) in logged rainforest in eastern Peru. Similarly, Tuck Haugaasen et al. (2012) found Black Agoutis to be both major predators and dispersers of Brazil nut (*Bertholletia excelsa* [Lecythidaceae]) seeds on the lower Rio Purus in central Amazonian Brazil. Munari et al. (2011), using both line transects and camera traps, determined that Black Agoutis were primarily diurnal, a characteristic of other agouti species where studied, and present in both *várzea* and *terra firme* forests along the Rio Juruá in western Amazonian Brazil. Reproduction and pregnancy was homogeneously distributed in every month of the year in the Peruvian Amazon, with the same pregnancy rate in both wet and dry seasons (Mayor et al. 2011). Mean ovu-

lation rate was 2.5 follicles, and litter sizes were 2.1 per pregnancy. Reproductive potential in this area is believed adequate to sustain density despite intense hunting pressure of the local indigenous people (Mayor et al. 2011). Goff and Brennan (1978) described ectoparasitic mites (family Trombiculidae), and both Durette-Desset et al. (2006) and A. Q. Gonçalves et al. (2006) have identified internal nematode (*Trichostrongylina* and *Helminthoxys*) and cestode (*Raillietina*) parasites in animals they attribute to this species.

REMARKS: The type locality of Wagler's *fuliginosa* was not explicitly specified in the original publication. The type specimen is another one of those that had been obtained by Johann von Spix during his travels along the central and lower Rio Amazon in the early 1800s (see Hershkovitz 1987b:28, Fig. 5). Wagner (1842c:362; see also 1844:48) described *Dasyprocta nigricans* based on specimens collected by Johann Natterer, also from the central Amazon of Brazil, stating that Spix's type had come from the same region as his *nigricans*, for which he gave the type locality as Villa de Borba, on the lower Rio Madeira. Wagner (1842c, 1844) compared Wagler's type and considered it identical with Natterer's specimens, but he chose not to use Wagler's earlier name. Because *fuliginosa* and *nigricans* are the same taxon, and because both are based on specimens collected in the same general region, J. A. Allen (1915b:626) restricted the type locality of Wagler's *fuliginosa* to Borba, lower Rio Madeira, the same locality as that of Wagner's *nigricans*.

Iack-Ximenes (1999) argued that the Black Agouti should properly bear the name *Dasyprocta cristata* (É. Geoffroy St.-Hilaire, 1803), a concept he also extended to include Tschudi's *Dasyprocta variegata*, or the Brown Agouti, as envisioned by Emmons and Feer (1990, 1997) and herein. His reasoning was based primarily on the supposition that the specimen examined by Geoffroy St.-Hilaire was one of those collected by the Brazilian naturalist Alexandre Rodrigues Ferreira but subsequently stolen from the Museu Real d'Ajuda in Lisbon by Napoleon's army during its invasion of Portugal in 1808, and then sent to the Muséum National d'Histoire Naturelle in Paris. Because Ferreira collected through central Amazonia, Iack-Ximenes (1999:68) corrected the type locality of *cristata* from "découvert a la Guyane hollandaise" [= Surinam], as originally given, to Igarapé Grande on the Rio Juruá, Amazonas, Brazil. Although É. Geoffroy St.-Hilaire as well as A.-G. Desmarest did base descriptions of some South American mammals on the purloined Ferreira collection (e.g., *Mesomys hispidus*, see that account and Orlando et al. 2003; see also Hershkovitz 1987b), Geoffroy St.-Hilaire's *cristata* cannot be one of those as he named the taxon five years before Napoleon's army plundered

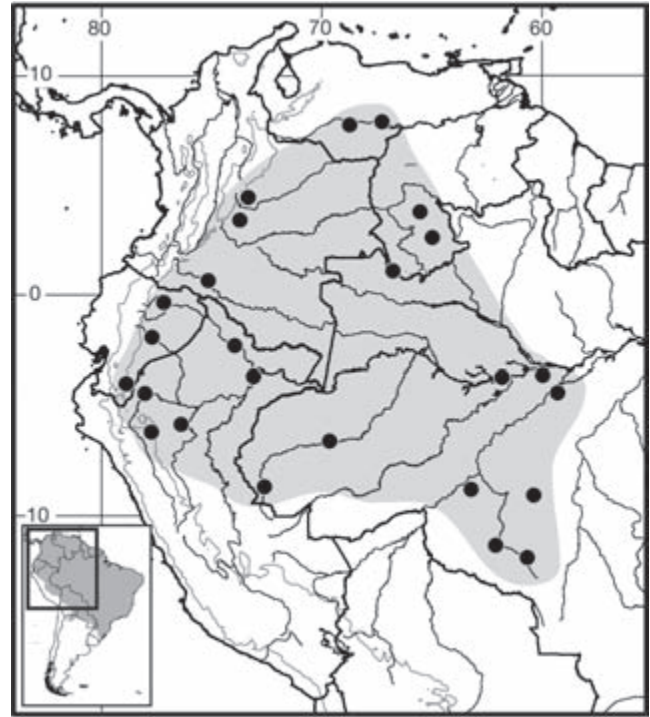

Lisbon. For further details regarding *crinata* É. Geoffroy St.-Hilaire, see Remarks in the account for *D. leporina*.

Cabrera (1961) listed *nigra* Gray (1842) as a synonym of *D. fuliginosa* Wagler, but Woods and Kilpatrick (2005) ignored Gray's name. Despite Gray's (p. 264) unhelpful type locality of "South America," the description he gave ("black, grizzled with white; shoulder and haunches blacker; legs black") associates *nigra* with Wagler's *fuliginosa* (but see Remarks under *D. kalinowskii*).

Contrary to Cabrera (1961), who regarded *zamorae* J. A. Allen, 1915, as a valid subspecies of *Dasyprocta punctata*, or Woods and Kilpatrick (2005), who followed Cabrera but simply included Allen's name as a synonym of *D. punctata*, we regard *zamorae* J. A. Allen a synonym of *D. fuliginosa* Wagler. Our belief is based on the hypothesis that the agoutis on both sides of the northern Andes (e.g., *punctata* on the western and *fuliginosa* on the eastern versant) represent separate species, despite similarities that some samples may share in color and color pattern. Allen's description (p. 627) highlighted a reddish ("deep ochraceous tawny") overall tone of *zamorae* rather than the blackish tones typical of *fuliginosa*, although he did note the rump hairs had rather long, white tips, a characteristic of some specimens of *fuliginosa*. He believed, however, that *zamorae* was closely related to *chocoensis* (which Allen described in the same paper from the Chocó of western Colombia) and *colombiana* Bangs (from the Santa Marta region, both of which are now regarded as representatives of *D. punctata* (see their account)).

Husson's (1978:466–468) inclusion of *D. fuliginosa* in the fauna of Surinam is based on a single specimen labeled as from that country but without additional details as to locality, collector, or even date of collection (see Voss et al. 2001). Husson assigned the specimen to this species, and not to the widespread and common agouti of the country, *D. leporina*, because of its dark blackish brown dorsal surface and the lack of even a trace of rufous on the rump. Whether this specimen (RMNH 23963) is a mutant, or local color variant of *D. leporina*, or something truly different, without additional specimens from anywhere in the Guianan region of unquestionable provenance, we do not include Surinam within the currently understood geographic range of *D. fuliginosa*.

The specimens that Tomes (1860a:216) referred to *Dasyprocta caudata* Lund from Pallatanga, Ecuador, are listed here as *D. fuliginosa*, but those that Lönnberg (1921) called *D. fuliginosa* from Guala (on the western slope of the Andes in Pichincha department), Ecuador, are either best attributed to *D. punctata* or the locality may be erroneous (as is the case for Lönnberg's specimen of *Pattonomys occasius* [Thomas 1921f], also said to have come from Guala, although this species is restricted to the Amazon

Map 389 Selected localities for *Dasyprocta fuliginosa* (●). Contour line = 2,000 m.

lowlands [Emmons 2005]). We have not examined any of these specimens.

The karyotype of *D. fuliginosa* is $2n = 64$, $FM = 122$ (J. F. S. Lima and Langguth 1998; R. S. L. Ramos et al. 2003).

Dasyprocta guamara Ojasti, 1972

Guamara Agouti

SYNONYM:

Dasyprocta guamara Ojasti, 1972:176; type locality "Caño Araguabisi, Territorio Delta Amacuro, Venezuela."

DESCRIPTION: Medium-sized agouti, equivalent in total length (513–604 mm) to some of larger species in genus but with smaller mass, 3–4.4 kg. Remarkable characteristic are proportionally elongated hindfeet, which average about 130% of greatest skull length in comparison, for example, to <115% among geographically proximate samples of *D. leporina*. Dorsal coloration brown to black finely mixed with ochraceous and without any chromatic separation between rump and rest of dorsal surface. Skull notable for its relatively wide and short proportions (condylobasilar length <2 times zygomatic width), conical contour of zygomatic arches when viewed from above, and well-developed lateral crests on jugal.

DISTRIBUTION: *Dasyprocta guamara* is known only from two localities in the Orinoco delta of northeastern Venezuela.

Map 390 Selected localities for *Dasyprocta guamara* (●).

SELECTED LOCALITIES (Map 390): VENEZUELA: Delta Amacuro, Cañō Araguabisi (type locality of *Dasyprocta guamara* Ojasti), Cañō Guiniquina (Ojasti 1972).

SUBSPECIES: *Dasyprocta guamara* is monotypic.

NATURAL HISTORY: Little is known of the natural history and ecology of this species. It inhabits the dense and marshy forests of the Orinoco delta, habitat that is always wet and partly inundated during high tide. Ojasti (1972) conjectured that the exceptionally elongated feet facilitate locomotion through the muddy substrate. Individuals seek refuge in hollow trunks of fallen trees. This is one of the most abundant mammals in the region and forms an important protein source for local peoples. Two of five adult females collected in the month of November were pregnant, each with two embryos.

REMARKS: The karyotype of *D. guamara* is unknown.

Dasyprocta iacki Feijó and Langguth, 2013

Iack's Red-rumped Agouti

SYNONYM:

Dasyprocta iacki Feijó and Langguth, 2013:112 [English version], 115 [Portuguese version]; type locality "Biological Reserve Guaribas (60°[sic, should be 6°] 44'S, 35°9'W), municipality of Mamanguape, state of Paraíba, Brazil."

DESCRIPTION: Medium-sized species (head and body 479 mm); dorsal part of head brown speckled with yellow-orange; cheeks more yellowish in color than crown; mystacial vibrissae long and black, some reading posteriorly

to ears; chin, circumbucal, and intermandibular regions with white hairs; ventral region of neck yellow with basal white bands; ears average 43 mm in length, covered with sparse hairs; innerside of pinna with yellow-orange hairs with brown base; hairs on back of body gradually increase in length caudally; general color of body agouti, mid-dorsal region with wide but subtle stripe of darker brown speckled with orange that becomes gradually paler on the sides; general color of rump dark brown speckled with orange; sides orange; venter with yellow patch in thoracic region that narrows caudally, becoming grayish agouti over belly; limbs brown speckled with orange on outer side and yellow on inner side; forefeet and hindfeet covered dorsally with short brown hairs speckled with orange.

DISTRIBUTION: *Dasyprocta iacki* is known for certain from only the littoral zone in Paraíba and Pernambuco states, Brazil. As noted by Feijó and Langguth (2013), however, this is probably the same species as that identified by Iack-Ximenes (1999) as *Dasyprocta aguti* from south of the lower Rio Amazonas between the Madeira and Tocantins rivers (and different from *D. leporina*, which Iack-Ximenes restricted to the red-rumped agoutis from the left bank of the lower Rio Amazonas north to the Guianan region; see account for *Dasyprocta leporina*, particularly the Remarks section).

SELECTED LOCALITIES (Map 391): BRAZIL: Paraíba, Reserva Biológica Guaribas, Mamanguape (type

Map 391 Selected localities for *Dasyprocta iacki* (○) and *Dasyprocta leporina* (●). Contour line = 2,000m.

locality of *Dasyprocta iacki* Feijó and Langguth); Pernambuco, Mata de Dois Irmãos (Feijó and Langguth 2013).

SUBSPECIES: *Dasyprocta iacki* is monotypic.

NATURAL HISTORY: No information on ecology is available; the two known localities are within the Atlantic Forest domain.

REMARKS: Feijó and Langguth (2013) suggested that *D. iacki* would likely apply to other red-rumped agoutis from the right (south) bank of the Rio Amazonas south to the Rio São Franciaco, should they be recognized as a separate species, as posited by Iack-Ximenes (1999); see account for *D. leporina*.

Specimens referred to *D. aguti* by J. F. S. Lima and Langguth (1998) with $2n = 64$, FN = 122 or 124 represent this species (see Feijó and Langguth 2013:114).

Dasyprocta kalinowskii Thomas, 1897

Kalinowski's Agouti

SYNONYM:

Dasyprocta kalinowskii Thomas, 1897e:219; type locality "Idma, Valley of Santa Ana, Cuzco, Peru. Alt. 4600 feet."

DESCRIPTION: Thomas (1897e:219) wrote that this species was of large size, giving head and body length of holotype as 630 mm, hindfoot length as 125 mm, and tail length about 24 mm. Upper parts of body colored with hairs banded in black and yellowish rufous, with elongated hairs overhanging rump uniquely white with black tips. Area at base of tail black and abruptly defined from elongated and white rump hairs. Under parts yellowish, grizzled with brown, and feet blackish. White rump hairs tipped black readily distinguish this species from *D. fuliginosa*, with its all black rump and hairs tipped in white, as well as from *D. variegata*, which occurs lower on same slopes in southern Peru, and which is colored grizzled black and tawny yellow, brown and yellowish, or black and orange. Black feet of *D. kalinowskii* also differ from the brown feet and legs of *D. variegata*.

DISTRIBUTION: *Dasyprocta kalinowskii* is an endemic species of southern Peru known only from the eastern slopes of the Andes in the Urubamba and Marcapata drainages, at an elevational range between 1,000 and 2,000 m.

SELECTED LOCALITIES (Map 392): PERU: Cusco, Aymaibanba [= Amaybamba], Urubamba Valley (MCZ 58244), Hacienda Cadena, Río Marcapata (FMNH 78664), Idma, Santa Ana Valley (type locality of *Dasyprocta kalinowskii* Thomas).

SUBSPECIES: *Dasyprocta kalinowskii* is monotypic.

NATURAL HISTORY: No information is available on local ecology, behavior, or life history traits of this species. The species occupies upper tropical forest (*yungas* ecoregion; Brack-Egg 1986; Pacheco et al. 2009) on the steep slopes of the eastern Andes.

REMARKS: In keeping with most previous authors (e.g., Cabrera 1961; Pacheco 2002; Woods and Kilpatrick 2005; Pacheco et al. 2009), we list *Dasyprocta kalinowskii* as a species distinct from the neighboring *D. variegata*, which occurs at lower elevations in the eastern Andes and lowlands throughout southern Peru. Emmons and Feer (1990, 1997) made no mention of this species, although their mapped range of *D. variegata* encompassed the limited range of *D. kalinowskii*. Eisenberg and Redford (1999) also regarded *D. kalinowskii* as a species, but noted that its status was uncertain and that careful comparisons to both *D. variegata* and *D. fuliginosa* were warranted. Gray (1842:264) described *D. nigra* as "black, grizzled with white; shoulder and haunches blacker; legs black; throat gray; belly rather grayer; hair of the back elongated, flattened, white at the base. *Hab.* South America." This description is suspiciously like *D. kalinowskii*, but Thomas did not mention Gray's earlier species, although Alston (1876) placed *nigra* in synonymy with *D. fuliginosa*, and redescribed it as with "rump hoary, the very long and soft hairs beige broadly tipped and often ringed at the base with white." Specimens of *D. fuliginosa* do not usually have rump hairs annulated with white to the base, although a specimen from Venezuela (USNM 388224) has very narrow white bands alternating with brown along the entire length of its rump hairs.

Thomas (1897e:219), in his description of *D. kalinowskii*, stated "this handsome Aguti may be readily distinguished from any species hitherto described by the peculiar

Map 392 Selected localities for *Dasyprocta kalinowskii* (●). Contour line = 2,000 m.

coloration of its long rump-hairs, which, white with black tips, are quite unlike those of any other species." This color pattern of the rump hairs is opposite that typical for *D. variegata*, as Thomas himself noted (1910d:506) when he remarked that Peruvian specimens had yellowish light tips and that Tschudi, in his description of *variegata*, had noted that the tips were whitish.

The karyotype of *D. kalinowskii* is unknown.

Dasyprocta leporina (Linnaeus, 1758)

Red-rumped Agouti

SYNONYMS:

[*Mus*] *leporinus* Linnaeus, 1758:80; based on *Lepus javensis* of Catesby (1754:18, plate 18); type locality fixed by neotype selection to "forest near the boarding-school Peninika, near the confluence of the Peninika Creek and the upper Commewijnw River," Commewijnw District, Surinam (Husson 1978:457, 463).

[*Mus*] *aguti* Linnaeus, 1766:80; type locality "Brasilia, Surinamo, Guiania"; based on "*Aguti vel acuti Brasiliensibus*" of Marcgraf (1648:224); restricted to Brazil by Thomas (1898f:272) and given incorrectly as "Pernambuco" by Cabrera (1961).

Cavia aguti: Erxleben, 1777:353; name combination.

Cavia leporina: Erxleben, 1777:355; name combination.

[*Cavia*] *bicolor* Boddaert, 1784:103; type locality "Habitat in Americae meridionalis Calidiora," listed as equivalent to *leporinus* Linnaeus.

Calva Aguti: Gmelin, 1788:121; name combination.

Cavia Agouti Brongniart, 1792:115; name combination and incorrect subsequent spelling of *aguti* Linnaeus.

C[*avia*]. *aguti leporina*: Kerr, 1792:217; name combination.

C[*avia*]. *aguti cumicularis* Kerr, 1792:217; part; type locality "Brasil, Giana, Cayenne e Índias Occidentalis."

Agouti Cayanus Daudin, 1802:166; type locality "Cayenne," French Guiana.

Cavia cristata É. Geoffroy St.-Hilaire, 1803:catalog; type locality "Patrie. Surinam.

[*Dasyprocta*] *aguti*: Illiger, 1811:93; name combination.

Dasyprocta acuti Illiger, 1815:114; name combination and incorrect subsequent spelling of *aguti* Linnaeus, 1766.

[*Dasyprocta*] *S. acuty* Oken, 1816:823; [*S.* = *Savia*?]; incorrect subsequent spelling of *aguti* Linnaeus.

Chloromys acuti G. Cuvier, 1817:214; name combination and incorrect subsequent spelling of *aguti* Linnaeus, 1766.

[*Dasyprocta aguti*] *leporina* B. Olfers, 1818:214; part; name combination.

D[*asyprocta*]. *aguti*: Olfers, 1818:214; part; name combination.

Dasyprocta acuti Desmarest, 1822:357; part; name combination and incorrect subsequent spelling of *aguti* Linnaeus, 1766.

Dasyprocta cristata: Desmarest, 1822:358; name combination.

Dasyprocta aguti: Lichtenstein, 1823:5; name combination.

[*Dasyprocta*] *Agouti*: Minding, 1829:91; name combination, and incorrect subsequent spelling of *aguti* Linnaeus, 1766.

Dasyprocta agutti C. O. da C. Vieira, 1953:158; incorrect subsequent spelling of *aguti* Linnaeus, 1766.

Dasyprocta leporina leporina: Husson, 1978:373; name combination.

Dasyprocta a[aguti]. aguti: Tribe, Leher, Doglio, Rebello, Mello, and Guimarães, 1985:296; name combination.

Dasyprocta leporina aguti: Hershkovitz, 1987b:37; name combination.

[*Dasyprocta leporina*] (*aguti*): Corbet and Hill, 1991:202; name combination.

DESCRIPTION: One of more variable species in body size although typically in moderate to large size range for genus; head and body length 470–650 mm, tail length 10–30 mm, hindfoot length 118–148 mm, ear length 40–50 mm, and mass 2.1–5.9 kg (Emmons and Feer 1997; Lack-Ximenes 1999). Color variable geographically but generally characterized by finely grizzled olivaceous head and forequarters; rump dark red to yellowish-orange, covered by long, straight hairs, which overhang rump in fringe, usually paler yellow or orange at base (color visible when hairs are erect). Individual rump hairs with yellow-orange bands, beginning with base and ending at tips, alternating with two to five brown or black bands. Top of head, neck, and mid-back between shoulders sometimes blackish or with crest of longer, pure blackish hairs. Vibrissae stiff, black, and reach to base of ear. Chin naked. Ears short, rounded, and mostly naked. Eyes large. Tail tiny, inconspicuous, and naked stub. Both forefeet and hindfeet dark brown. Under parts grizzled brownish orange or orange with white midline. Individuals range in color from dull brown-olivaceous to bright orange-olivaceous forequarters; specimens from Trinidad and Tobago smaller than mainland representatives of species and generally colored dark brown. Populations north of Rio Amazonas larger in size and have narrower skull (Lack-Ximenes 1999). Distinguished from *D. croconota* by bright orange rump and flanks of latter, from *D. fuliginosa* by yellowish-red instead of black rump, from *D. prymnolopha* by lacking black mid-dorsal stripe over rump, and from *D. azarae* by larger size and brownish overall color with red to yellow-orange rump contrasting with tawny gray washed with orange tones of latter.

DISTRIBUTION: *Dasyprocta leporina* occurs throughout the Guianan region, from northern Venezuela (east of

Lake Maracaibo) to French Guiana and Brazil north of the Amazon and east of the Rio Negro, then south of the Amazon east of the Rio Madeira to central coastal Brazil.

A. Allen 1911); Falcón, near Mirimire (Handley 1976); Lara, Antoátequi, W of Guarico (J. A. Allen 1911); Monagas, Caripe, Cumaná (*Dasyprocta rubrata flavescens* Thomas); Zulia, El Panorama, Río Aurare (Osgood 1912).

SUBSPECIES: There is considerable geographic variation in color over the back and flanks of *D. leporina*, and multiple subspecies have been recognized in limited geographic parts of the species range. For example, Cabrera (1961) and Ojasti (1972) each recognized several subspecies, and O. J. Linares (1998) mapped the ranges of two subspecies in Venezuela (*cayana* Daudin to the south of the Río Orinoco, at elevations ranging between 10 and 860 m, and *flavescens* Thomas from north of the Río Orinoco in the Cordillera Central, Cordillera Oriental, east side of Lago de Maracaibo, and throughout the llanos, at an

elevation range from 10 to 1,450m). We agree, however, with Voss et al. (2001:142), who argued “the necessity for a trinomial classification remains to be convincingly established by a comprehensive study of geographic variation.” These authors also noted (p. 142) that “for future revisionary work, a large series of specimens collected by H. A. Beatty in the Wilhelmina Mountains of Surinam . . . provides a useful sample of individual variation from a single local population of this nomenclaturally important species.”

NATURAL HISTORY: *Dasyprocta leporina* has been studied extensively, mostly in the Guianan region but also in parts of both eastern Amazonian and Atlantic forests of Brazil. In French Guiana (e.g., Dubost 1988), the species can occur in all available vegetation types but primarily in open forest, usually distant from both water and dense vegetation. Density may vary with forest type, with greater numbers in fragmented patches than in continuous forest (Jorge 2008). The basic social unit of this agouti is the family, comprising a breeding pair with their young of the year. Subadult and juvenile males are either solitary or may group into small units of two to three individuals. Each group occupies areas about 200m in diameter with groups separated from one another by 50m or less, although there is intergroup territorial defense. This distributional pattern is clumped, as a result of the aggregation of individual home ranges. Home range, or site, fidelity is nearly permanent over time. Individuals frequently use well-worn trails and often travel in pairs or as the entire family group. Consistent with the longevity of family groups and a clumped distribution, several separate mitochondrial maternal lineages may overlap within an area, even over relatively small geographic regions such as French Guiana (van Vurren et al. 2004).

Both diurnal and nocturnal resting places are used by single individuals, with the number varying by individual not by sex or age (Dubost 1988). As is characteristic of all others in the genus, this species is primarily diurnal but with a bimodal activity pattern concentrated in the early morning and late evening when a second phase of foraging occurs (Norris et al. 2010), with foraging activity varying in response to available resources and temperature (Jorge and Peres 2005). Foraging time depends upon forest age and tree structure, both of which affect resource availability. Adult sex ratio is skewed in favor of females because of high juvenile male mortality. Females typically reproduce once per year, and while births may occur year-round most are concentrated in the dry season (Henry 1994). In French Guianan forests, pregnancy peaks between November and April, beginning with the early rainy season and coincidental with an increase in the number of fruiting trees (Dubost et al. 2005). The gestation period is 110–112 days, and litter size ranges from one to three (Weir 1971b; Henry 1997;

Dubost et al. 2005). Neonates are precocial, well furred, and with eyes open at birth (Henry 1994).

Considerable research has been directed to the role this species plays in the removal, dispersal, and survival of the seeds of many rainforest trees (Forget 1990; Forget and Cuiljpers 2008), particularly those large-seeded species (Galetti et al. 2010), including important cash crops such as Brazil nuts (Peres and Baider 1997; Scoles and Gribel 2012) and palms (Pires and Galetti 2012). Seed dispersal is over short distances, given the average size of home ranges (3 to 8.5 ha in eastern Brazil; Silvius and Fagoso 2003, Jorge and Peres 2005). Henry (1999), Dubost and Henry (2006), and Silvius and Fragoso (2003) documented the importance of frugivory, including both pulp and seeds, in a diet that was broadened with the use of other plant parts (e.g., cotyledons, leaves, flowers) and even animal materials under varying rainfall and fruit production seasonal schedules. Henry (1997) detailed the interplay between diet and seasonal reproduction in French Guiana, also including the seasonal use of invertebrates by pregnant females. Ghilardi and Alho (1991) described seasonal dietary trends in eastern Amazonian Brazil. Individuals scatter hoard seeds that they later retrieve and consume (Jorge and Howe 2009) and also the pilfered caches of others (P. R. Guimarães et al. 2005). They avoid plant species whose seeds accumulate toxic secondary compounds, such as quinolizidine alkaloids (P. R. Guimarães et al. 2003).

A wide range of endoparasites may infect individual agoutis, including nematodes (Cameron and Reesal 1951; Hugot 1986; A. Q. Gonçalves et al. 2006), apicomplexans of the genus *Eimeria* (Lainson et al. 2007), tapeworms (Cameron and Reesal 1951; Zimmerman et al. 2009), and round worms (Cameron and Reesal 1951). This species is also an important reservoir for *Trypanosoma cruzi*, the parasitic euglenoid trypanosome associated with Chagas disease (Deane 1967; R. D. Ribeiro and Barretto 1977).

REMARKS: The technical name applied to the Red-rumped Agouti has varied among authors for more than a century, with *Mus aguti* Linnaeus (1766) initially almost universally applied (Tate 1935; Ellerman 1940; Cabrera 1961; Handley 1976; Corbet and Hill 1980) but *Mus leporinus* Linnaeus (1758) used in more recent synopses (Woods 1993; Woods and Kilpatrick 2005). Part of the variance in name application has been taxonomic (the number of species recognized) and part as been nomenclatural (the correct name applied to those species recognized, and why). What follows is a temporal summary of the major players in this debate.

Thomas (1898f:272–273) believed that the red- and yellow-rumped agoutis of the Guianas and Brazil (presumably including that portion of Brazil south of the Amazon River), while superficially similar, were different from one

another. Hence, he argued that fixing Linnaeus's "*Mus aguti*" to either of these geographic groups was difficult because, while Linnaeus had included Surinam and Guiana along with Brazil in the locality of his *Mus aguti* (Linnaeus 1766:80, geographic range given as "Brasilia, Surinamo, Guiana"), he had based his name on the description provided by Marcgraf (1648) of a Brazilian animal, specifically that part of Brazil where Marcgraf's geographical work was centered. Consequently, Thomas (p. 272) assigned *Mus aguti* Linnaeus to "the true Brazilian species" (i.e., the red- and yellow-rumped form that occurs south of the Amazon River). Thomas (p. 273) then proposed the name *Dasyprocta rubrata* to represent the red- and yellow-rumped agoutis inhabiting Trinidad and the Guianas.

Husson (1978:462–463) reviewed the nomenclatural history of the Guianan agouti and, contrary to Thomas (1898f), stated that *Dasyprocta aguti* (Linnaeus, 1766) has been generally used for that species. He noted, however, that *Mus leporinus* Linnaeus, 1758 (based on the description and color plate of "*Lepus javensis*" of Catesby [1754:18, plate 18]), was older and thus had priority. Husson also noted that, although some authors had accepted this synonymy, others had not because Linnaeus had stated that Catesby's animal had originated from "Java and Sumatra." However, Pennant (1781:366) had recognized that this geographic provenance was in error and remarked that the "Javan Cavy" inhabited "Surinam and the hotter parts of South America, where it is a common food." Shaw (1801:26) also stated that Catesby's animal was a "native of Surinam, and other parts of South America. It is altogether an American animal . . . notwithstanding its common title of the Java Hare." He correctly regarded *Mus leporinus* as an agouti and treated it as a variety of *Mus aguti*. Gray (1843b:124) incorrectly identified *Mus leporinus* as an acouchy (now *Myoprocta acouchi* [Erxleben, 1777]). Waterhouse (1848:391–392, footnote 1) corrected Gray's error, but, although he agreed that *Mus leporinus* was undoubtedly an agouti, he did not use the name for any species in the genus *Dasyprocta*. Thomas (1911d:146) and Tate (1935:329, 331) had also assigned *Mus leporinus* to *Dasyprocta*, but while neither of these authors believed the species to be identifiable, Tate did suggest that it might be referable to one of the Central American agoutis. Finally, Husson (1978) argued that Surinam was the probable origin of Catesby's animal, and, to stabilize nomenclature, he selected a neotype from that country (RMNH 20752) for *Mus leporinus* Linnaeus, as Catesby's specimen was no longer extant. This action thus made *Dasyprocta leporinus* (Linnaeus) the oldest available name for the Guianan red- and yellow-rumped species.

Hershkovitz (1969:23) used the name *Dasyprocta leporina* in discussing South American mammals that had ex-

panded into Middle America after the closure of the Panamanian isthmus but did not identify the geographic scope of his concept. Eisenberg (1989) did use *Dasyprocta leporina* to apply to the Guianan agouti, basing his decision on Husson (1978). Later (in Eisenberg and Redford 1999), he extended his concept of *Dasyprocta leporina* to include Brazil on both sides of the lower Amazon ranging south to the Atlantic coast, and specifically mentioned that his *D. leporina* included *D. agouti* [sic]. Emmons and Feer (1990, 1997) continued in the same vein, mapping a single species of red-rumped agouti from the Guianas south to coastal Brazil, but used the name *D. agouti* [sic] rather than *D. leporina*, commenting only that "some recent works use the species name *D. leporina*" (Emmons and Feer 1997:226). Iack-Ximenes (1999) followed Thomas (1898f) and regarded red- and yellow-rumped agoutis in the Guianan region as a species distinct from those in Brazil south of the Amazon. He applied *Dasyprocta leporina* (Linnaeus) to the former and *Dasyprocta aguti* (Linnaeus) to the latter. He also argued that samples south of the Rio São Francisco in southern Brazil were distinct from those north of that river to the right (= south) bank of the lower Amazon.

We follow Eisenberg (1989), Emmons and Feer (1990, 1997), Eisenberg and Redford 1999), and Voss et al. (2001) and recognize a single, broadly distributed species of red-rumped agouti, *Dasyprocta leporina*. Should future analyses of morphological and molecular characters support Iack-Ximenes's (1999) hypothesis that this single species is actually divisible into three, one north of the Rio Amazonas and two south of that river and divided by the Rio São Francisco, the name *D. aguti* (Linnaeus) can no longer apply to either, as argued by Thomas (1898f) and used by Iack-Ximenes (1999). Voss et al. (2001) selected as neotype of Linnaeus's *Mus aguti* the same specimen that Husson (1978) had selected as neotype of *Mus leporinus* Linnaeus, thus unequivocally making *Mus aguti* a junior subjective synonym of *Mus leporinus* with both having the same type locality in Surinam (see Voss et al. 2001:143–144 for details). Feijó and Langguth (2013) suggested that their newly described *D. iacki* might apply to those samples distributed between the right (= south) bank of the lower Rio Amazonas and the left (= north) bank of the Rio São Francisco, and it is also conceivable that Wagler's earlier *croconota* might apply, as Iack-Ximenes's (1999) separation of this taxon as a species has yet to be tested (see Remarks under *D. croconota*). There is no currently available name for the red-rumped agouti distributed between the Rio São Francisco and the Atlantic coast of Brazil should those samples eventually be recognized as specifically distinct.

The name *Agouti cayanus* is usually credited to Lacépède, 1802 (e.g., Tate 1935; Cabrera 1961; Woods and Kilpatrick 2005), but, as noted by Sherborn (1899:409 and

1924b:1154; see also Husson 1978:483), F. M. Daudin is the author of those species names that first appeared in the 1802 (*Didot*) edition of Lacépède's *Tableau des divisions*.

The status of *Cavia cristata* É. Geoffroy St.-Hilaire, 1803, with its type locality given as "Surinam," is uncertain. Tate (1935:331) listed it questionably in his "Dark gray agouti" group; Ellerman (1940), Cabrera (1961), and Husson (1978) each regarded *cristata* as a species distinct from the widespread *D. leporina* in the Guianan region, although Husson (p. 466) acknowledged its "uncertain status." Hershkovitz (1972:329), minimizing the value of color differences alone in such variable organisms as agoutis, regarded those variants as belonging to a single species. Voss et al. (2001:142) suggested, because neither the holotype nor a second specimen in the Leiden Museum mentioned by Husson (1978) were "accompanied by names of collectors, dates of collection, or any additional geographic information," that "we assume that these old and poorly documented Surinamse records are erroneous." Lack-Ximenes (1999) argued that *Cavia cristata* É. Geoffroy St.-Hilaire was the correct name for the Black Agouti, to which herein we refer as *D. fuliginosa* (see that account). Because of the uncertainty in the provenance of Geoffroy St.-Hilaire's *cristata* (Voss et al. 2001) and the inability, at present, to document levels of both within and among population variation, even within the limited region of the Guianas, we provisionally list *cristata* É. Geoffroy St.-Hilaire as a synonym of *D. leporina*.

Fredga (1966), Hsu and Benirschke (1968a) and R. S. L. Ramos et al. (2003) described the karyotype of *D. leporina* (as *D. aguti*) with $2n = 64$, FN = 122 or 124.

Dasyprocta prymnolopha Wagler, 1831

Black-rumped Agouti

SYNONYMS:

Dasyprocta prymnolopha Wagler, 1831c:619; type locality "Habitat in Guiana," but corrected to "foz do Amazonas, Pará, Brazil" by Goeldi and Hagmann (1904:73) and further restricted to "Belém, Pará, Brazil" by Lack-Ximenes (1999).

Dasyprocta croconota prymnolopha: J. A. Allen, 1915b:629; name combination.

Dasyprocta nigriclunis Osgood, 1915:192; type locality "São Marcello [= São Marcelo], upper Rio Preto, Bahia, Brazil."

DESCRIPTION: Another relatively small species, head and body length 450–525 mm, tail length 18–30 mm, hind-foot length 95–115 mm, and ear length 36–43 mm. Emmons and Feer (1990, 1997) characterized general color and color pattern as yellow-orange grizzled with black foreparts that become red-orange from midback over outer

thighs, with top of rump covered by contrasting wedge of long, completely black hairs that are often pale yellow at base and may be visible when rump hairs are erect. Crown of head blackish, and neck with crest of longer, black hairs. Both forefeet and hindfeet dark brown. Under parts pale orange sprinkled with white hairs down midline. Young share same color and color pattern as adults but are generally duller overall. Combination of black stripe from mid-back over rump and sharply demarcated rusty-red upper thighs make this species one of more recognizable in genus.

DISTRIBUTION: This species is limited to northeastern Brazil from eastern Pará state south of the Rio Amazonas along the coast to Alagoas and Bahia states, and inland into Minas Gerais and Tocantins states. The elevational range is from sea level to 900 m (Lack-Ximenes 1999).

SELECTED LOCALITIES (Map 393): BRAZIL: Alagoas, Fazenda Canoas (MZUSP 7371); Bahia, Fazenda Jatobá-Floryl (UNB 1599), Lamarão (Thomas 1917e), São Marcelo, upper Rio Preto (type locality of *Dasyprocta nigriclunis* Osgood); Ceará, Sítio Camará, Milarges (MNRJ 43146), Sítio Piraguara, São Benedito (MNRJ 43144); Maranhão, Fazenda Pé de Coco, Estreito (MPEG 22683), Ilha de São Luis do Maranhão (MZUSP 7984), Palmeiral, Cantanhede (MPEG 23175), Pedra Chata, Rio Gurupi, Carutapera (MPEG 10947); Minas Gerais, Mocambinho, Manga (MNRJ 29059); Pará, Parará do Sumaúma, mouth of Rio Tocantins (MZUSP 25516), Vila Brabo, right bank of Rio Tocantins (MPEG 11874), Vista Alegre, Praia do Rio Camará (MPEG 10202); Pernambuco, Recife (MNRH 7637); Tocantins, Cana Brava (MZUSP 3963).

SUBSPECIES: As currently understood, *D. prymnolopha* is monotypic, although the inclusion of *nigriclunis* Osgood within this species may signal a regional color variant in the southwestern portion of the range worthy of recognition (see Remarks).

NATURAL HISTORY: This species can be found within a wide diversity of phytogeographic assemblages in eastern Brazil, from *Floresta Ombrófila Densa* to *Savana* and *Savana Estépica*. It is the only agouti of the Caatinga biome. As with other species in the genus, *D. prymnolopha* is a seed predator and plays a central role in the dispersal and survival of rainforest trees (Melo and Tabarelli 2003). No other aspects of the natural history of this species have been published based on field studies of natural populations, but components of the reproductive biology are known from captive animals. For example, D. A. Guimarães et al. (1997) documented a 30-day estrus period and an average gestation length of 104 days, D. A. Guimarães et al. (2009) reported on the importance of the presence of a male to stimulate the onset of puberty in females, and D. A. Guimarães et al. (2011) described sterol concentrations during the estrous cycle.

REMARKS: *Dasyprocta prymnolopha* has been rather uniformly regarded as a valid species of agouti throughout the past century (E.-L. Trouessart 1904; Tate 1935; Moojen 1952b; Cabrera 1961; Emmons and Feer 1990, 1997; Woods 1993; Woods and Kilpatrick 2005), although Ojasti (1972) suggested that its status was uncertain. J. A. Allen (1915b:628–629) applied *prymnolopha* Wagler to the red-rumped agoutis of the Guianan region, based on the errant locality “Guianas” given by Wagler (1831c) in his description, listing *prymnolopha* as the Guianan subspecies of the red or orange-rumped agoutis, to which he applied the name *D. croconota* (see Remarks for that species). Thomas (1917e:260–261) corrected Allen’s use of both *croconota* Wagler and *prymnolopha* Wagler for the red-rumped agoutis because *prymnolopha* was so easily distinguished from all other agoutis by its distinctly black rump.

Osgood (1915), in his description of *D. nigriclunus*, believed it to be distinct from but with a general relationship to *D. prymnolopha*. Both forms were acknowledged to have the characteristic black nape and rump, but Osgood differentiated his new species by the banded (grizzled) rather than monochromatic (clear) orange hairs on the thighs and sides of the rump. Thomas (1917e:259), however, doubted whether *nigriclunus* Osgood was separable from *prymnolopha*, citing variability among specimens from Bahia in the grizzled versus clear color of the thighs and rump sides in support of his argument. These opinions were followed by virtually all subsequent authors (Cabrera 1961; Emmons and Feer 1990, 1997; Woods 1993; Woods and Kilpatrick 2005). Iack-Ximenes (1999), however, regarded *nigriclunus* a valid species closer in relationship to *D. fuliginosa*, with its range limited to southern Tocantins and northern Bahia states.

The type locality of “Guianas” given by Wagler (1831c) is clearly in error, as noted by Goeldi and Hagmann (1904:73), who believed the type must have been collected near the mouth of the Amazon River in Pará state, Brazil (see also Voss et al. 2001:142). J. A. Allen (1915b:629), in accepting Wagler’s “Guiana” locality, suggested that “it would be necessary to designate a definite type locality . . . , which may or may not have come from Cayenne.” Thomas (1917e:260), however, agreed with Goeldi and Hagmann’s assessment, as have all subsequent authors (Cabrera 1961; Woods 1993; Woods and Kilpatrick 2005). Iack-Ximenes (1999:182) proposed to restrict the type locality of *D. prymnolopha* Wagler to Belém, Pará state, Brazil. A specimen of *prymnolopha* in the USNM (no. 19645) has as its locality “Guyana.” It was acquired in 1891 from the dealer E. Gerrard Jr. in a mixed lot including specimens from Rio Grande do Sul (Brazil), Argentina, Costa Rica, Ecuador, Medellín (Colombia), and British Guiana (Guyana). The clearly erroneous locality can be attributed

Map 393 Selected localities for *Dasyprocta prymnolopha* (●). Contour line = 2,000 m.

to poor record keeping by the dealer. A similar occurrence may have involved Wagler’s type, as traders, both then and now, travel up the coast from Brazil to the Guianas.

The karyotype of *D. prymnolopha* is $2n = 64$, $FN = 122$ (J. F. S. Lima and Langguth 1998; R. S. L. Ramos et al. 2003).

Dasyprocta punctata Gray, 1842

Central American Agouti

SYNONYMS (South American only; see Hall 1981 for names applied to Mexican and Central American forms):

Dasyprocta punctata Gray, 1842:264; type locality “South America,” restricted to Realejo, Nicaragua by Goodwin (1946:417).

Dasyprocta colombiana Bangs, 1898a:163; type locality “Santa Marta, Colombia.”

Dasyprocta variegata colombiana: Osgood, 1910:28; name combination.

Dasyprocta fuliginosa candelensis J. A. Allen, 1915b:625; type locality “La Candela (altitude 6500 feet), Huila, Colombia.”

Dasyprocta variegata chocoensis J. A. Allen, 1915b:627; type locality “Los Cisneros (altitude 600 feet), Chocó district, Colombia.”

Dasyprocta fuliginosa colombiana: J. A. Allen, 1916b:205; name combination.

Dasyprocta pandora Thomas, 1917f:313; type locality “Gorgona Island, off west coast of Colombia.”

Dasyprocta punctata colombiana: Cabrera, 1961:589; name combination.

Dasyprocta punctata chocoensis: Cabrera, 1961:589; name combination.

Dasyprocta punctata pandora: Cabrera, 1961:590; name combination.

Dasyprocta punctata zuliae Ojasti, 1972:190; type locality “Matera Cusare, Cuenca del río Negro en la sierra de Perijá, Edo. Zulia, Venezuela.”

DESCRIPTION: Somewhat intermediate in size relative to small species, such as *D. azarae*, and larger ones, such as *D. fuliginosa*, head and body length 480–600 mm, tail length 20–55 mm, hindfoot length 120–156 mm, ear length 36–37 mm, and mass 3.2–4.2 kg (Emmons and Feer 1997). Two basic color patterns largely, but not completely, separable on geographic grounds: Populations from Pacific slope from southern Mexico to Panama, Colombia, and Ecuador with upper parts uniformly warm red-brown, yellow-brown, or gray-yellow; fur banded with fine black striations throughout when viewed closely; nape and rump hairs not different from remainder of upper parts; chin and inguinal region either clear orange or white in gray-yellow individuals; chest grizzled like back. Samples from along Atlantic slope from Costa Rica, Panama, and northern Colombia, foreparts brown to blackish, finely grizzled with tawny or olivaceous; crown and nape often blackish, midbody forward of rump with band of brighter orange-banded hairs, and rump hairs long, black, and with long yellow to white tips; long hairs overhang rump in fringe; chin and inguinal region whitish, belly brown. Some animals from western Colombia and Ecuador generally exhibit second pattern but have pale yellow frosting on rump, tawny foreparts, and necks with grayish sides. Extreme individuals with brown to black color phase may resemble overall color of *D. fuliginosa* while less extreme specimens are similar to *D. variegata*, both of which occur east of Andes (see Remarks for both *D. fuliginosa* and *D. variegata*).

DISTRIBUTION (South America only): This species is largely cis-Andean, ranging from northern Colombia east to northwestern Venezuela in the Sierra de Perijá and western slopes of the Sierra de Mérida (Ojasti 1972; O. J. Linares 1998; Prieto-Torres et al. 2011) and south along the Pacific coast of Colombia (including Isla Gorgona) and Ecuador. It apparently extends onto the eastern slope of the eastern Andes in Colombia and into the headwaters of the Río Sarare, a tributary of the Río Orinoco in Venezuela. Elevation in Colombia extends from sea level to 1,600 m (Alberico et al. 2000; Castaño et al. 2003).

SELECTED LOCALITIES (Map 394): COLOMBIA: Antioquia, Río Currulao, 20 km SE of Turbo (FMNH 69556); Arauca, Fátima, Río Cobaría (FMNH 92628); Bolívar, San Juan Nepomuceno (FMNH 68907); Cauca, Gorgona Island (type locality of *Dasyprocta pandora*

Thomas), Río Mechengue (FMNH 86764); Chocó, Baudo (J. A. Allen 1912), Unguía (FMNH 69553); Córdoba, Catival, upper Río San Jorge (FMNH 68913); Huila, La Candela (type locality of *Dasyprocta fuliginosa candelensis* J. A. Allen), Río Aguas Claras, Río Suaza (FMNH 70794); Magdalena, Santa Marta (type locality of *Dasyprocta colombiana* Bangs); Nariño, Guayacana (FMNH 89512); Tolima, Quebrada Aico between Coyaima and Chaparral (MVZ 104956); Valle de Cauca, Los Cisneros (type locality of *Dasyprocta variegata chocoensis* J. A. Allen). ECUADOR: Bolívar, San José, 12 mi SW of Huigra (MVZ 184026); Esmeraldas, Rosa Zarate, near Río Quininde (FMNH 44326); Guayas, Naranjo [= Naranjito] (J. A. Allen 1915b); Pichincha, Guala (Lönnberg 1921). VENEZUELA: Apure, Nuitla, Selvas de San Camilo, 29 km SSW of Santo Domingo (USNM 443450); Táchira, Orope (Osgood 1910); Zulia, El Rosario, 45 to 51 km WNW of Encontrados (Handley 1976), Río Limón (FMNH 18767).

SUBSPECIES: Hall (1981) recognized 11 subspecies in Central America and Cabrera (1961) eight for South America, although only three of these (*colombiana* Bangs, *chocoensis* J. A. Allen, and *pandora* Thomas) are included herein in the synonymy of *D. punctata*. Cabrera (1961:587) regarded *candelensis* J. A. Allen to be a valid subspecies of *D. fuliginosa* rather than of *D. punctata*, as we do herein. Agoutis from the type locality in Nicaragua are uniform reddish in color, with short, undifferentiated rump hairs banded throughout their length. The earliest name for the form with long, pale-tipped rump hairs is *D. isthmica* Alston, 1876, from Colón in Panama. The reddish forms in coastal Ecuador and Colombia seem to resemble *isthmica*, with variations in color (e.g., *chocoensis* J. A. Allen) whereas those extending east into central and northern Colombia and northwestern Venezuela are darker, brown or blackish, but also with long, pale-tipped rump hairs (e.g., *colombiana* Bangs, 1898; *dariensis* Goldman, 1913). J. A. Allen (1915b) discussed these forms at length. See Remarks for *D. variegata*.

Pending an adequate review of geographic trends in color and cranial characters, it is premature to validate any of forms as subspecies, although the regional differences in color may well argue for such. If so, Bang's name *colombiana* would apply to the form along the Caribbean coast, with *zuliae* Ojasti either a synonym or a localized valid taxon in the Sierra de Perijá and adjacent areas of northwestern Venezuela (but see comment by Ojasti in the addendum to his 1972 paper). Allen's *candelensis* would be the earliest name applicable to a Pacific coast animal (by page priority over *chocoensis* J. A. Allen), unless *isthmica* Alston, 1876, proves applicable to the agoutis of the Chocó. We regard the remainder of the South American forms listed by Cabrera (1961) as subspecies

of his *D. punctata* to be more appropriately linked to *D. azarae* (*boliviana* Thomas and *urucuma* J. A. Allen), *D. fuliginosa* (*zamorae* J. A. Allen), or *D. variegata* (*yungarum* Thomas).

NATURAL HISTORY: Populations of *D. punctata* in Costa Rica and Panama have been well studied, with numerous publications on topics ranging from general natural history to details on density, social organization, group membership, spacing behavior, and foraging ecology (Smythe 1978). Additional studies include those on scatter hoarding and cache-finding behavior (J. O. Murie 1977; Galves et al. 2009), home range (Aliaga-Rossel et al. 2008), predators (Aliaga-Rossel et al. 2006), reproductive biology (Merritt 1983), diel activity pattern (T. D. Lambert et al. 2009), and role in seed predation and dispersal (Smythe 1970; Hallwachs 1986; Forget 1992; Forget et al. 1994). Few data are available from populations of this species within its South American range, as mapped here, but presumably these would display the same kinds of characteristics detailed for those in Central America as well as the basic ones typical of all agouti species.

REMARKS: Following Emmons and Feer (1990, 1997), we restrict *D. punctata* to those agoutis with a cis-Andean

distribution on the Pacific coast of Ecuador and Colombia, Caribbean coast of Colombia and extreme northwestern Venezuela, and inter-Andean valleys west of the Cordillera Oriental. This species name has been commonly applied, including recently, to agoutis on the eastern side of the Andes, especially in Peru (Pacheco et al. 1995), Bolivia (S. Anderson 1997), and northwestern Argentina (R. A. Ojeda and Mares 1989; Barquez, Díaz, and Ojeda 2006; M. M. Díaz and Barquez 2007), all records that we consider to represent *D. azarae* or *D. variegata* (see those accounts).

Matson and Shump (1981), in one of the few such papers available for any species of agouti, described sex and age-related variation in a large sample of skulls of *D. punctata* from a single locality in northwestern Ecuador.

The karyotype is apparently unknown.

Dasyprocta variegata Tschudi, 1845

Brown Agouti

SYNONYMS:

D[asyprocta]. variegata Tschudi, 1845:plate XVI; type locality “hingegen höher hinauf bis an die Gränze der obern Wald und Ceja-region dis zu 6000' ü. M.,” [= “the boundary of the upper forest- and Ceja region, 6000 feet,”] Chanchamayo region, Junín, Peru.

Dasyprocta variegata variegata: J. A. Allen, 1912:76; name combination.

DESCRIPTION: Somewhat smallish but heavy-bodied species, with head and body length 445–540 mm, tail length 11–38 mm, hindfoot length 94–120 mm, ear length 41–45 mm, and mass 3.0–5.2 kg (Emmons and Feer 1990, 1997). Upper parts finely grizzled black and tawny yellow, brown and yellowish, or black and orange, giving overall appearance blackish washed with tawny, plain brown, or orange from distance. Hairs of rump not elongated into overhanging fringe, and finely banded like hairs on rest of upper parts, from which they little differentiated. Head often blackish, and midline of back usually darker than sides. Feet dark brown, except in orange animals, colored like back. Chin and throat, and often midline of venter, white. Rest of under parts brownish yellow in brown individuals to bright pale orange in orange animals. The Brown Agouti becomes progressively paler and more orange from north to south and east to west. Those from northwestern part of range in Peru (Junín department, near likely type locality) blackish speckled with white and yellow, and successively to south, those from Río Urubamba plain brown, and those from Madre de Dios yellowish to reddish brown.

DISTRIBUTION: This species occurs in the lowland rainforest in the western Amazon Basin from central Peru (Junín department) and western Brazil (upper Rio Purus and Rio Madeira drainages) to extreme northern Bolivia.

Map 394 Selected localities for *Dasyprocta punctata* (●). Distribution in Panama from Hall (1981). Contour line = 2,000 m.

The southern limits of *D. variegata* and the northern boundary of *D. azarae* are unclear; we map it at about the Río Beni in northern Bolivia.

SELECTED LOCALITIES (Map 395): BOLIVIA: Beni, Riberalta (S. Anderson 1997); Pando, Independencia (S. Anderson 1997). BRAZIL: Rondônia, Porto Velho, Rio Madeira (Osgood 1916). PERU: Cusco, Río Urubamba, 50 mi NE of Cusco (MVZ 116712); Junín, Chanchamayo (type locality of *Dasyprocta variegata* Tschudi); Puno, Bella Pampa, 16 mi N and 2 mi E of Limbani (MVZ 116711); Ucayali, Balta, Río Curanja (MVZ 136642).

SUBSPECIES: We regard *D. variegata* as monotypic, pending an adequate review of geographic variation.

NATURAL HISTORY: The ecology of this species is poorly known throughout its range, although Enrique Ortiz (pers. comm. to L. H. Emmons) has studied its role as a disperser of Brazil nuts (*Bertholletia excelsa* [Lecythidaceae]) in Peru. The species apparently maintains dense populations wherever there are Brazil nuts, as do other taxa of agoutis (e.g., *D. leporina*, Peres and Baider 1997) as they can open the giant, hard exterior shell. *Dasyprocta variegata* also eats and caches nuts of the palm genera *Attelya* and *Astrocaryum*, with their idiosyncratic behavior as a seed disperser an important contributor to spatial association and genetic structure in the tree species (Choo et al. 2012). They sleep at night under fallen brush and in hollow logs (L. H. Emmons, pers. comm.). H. Gómez et al. (2005), using camera traps, determined a primarily diurnal activity pattern but one extending into the twilight hours at localities in Madidi National Park in Amazonian Bolivia.

REMARKS: Tschudi's description and illustration of the type of *variegata* indicate a blackish animal with entirely black neck and rump hairs (Tschudi 1845; Alston 1876), speckled with some yellow-banded and white-tipped hairs. Although this color combination is reminiscent of *D. fuliginosa*, a specimen from Chanchamayo, Peru (USNM 255135), nearly matches the description, but has dark-brown overtones caused by narrow ochraceous bands on most hairs, which produce speckles throughout the mid-body and sides. This animal likewise lacks the long, pale-tipped rump hairs characteristic of South American *D. punctata*.

Thomas (1899a:40) used the name *Dasyprocta isthmica* Alston to refer to specimens collected by Otto Garlepp in the "district of Cuzco," southern Peru. This is clearly an error, as *isthmica* was the name Alston (1876b, 1880a) gave to agoutis from Central America (see *D. punctata* account). Specimens from Beni and Pando departments, Bolivia, that S. Anderson (1997) included under his concept of *D. punctata* we refer herein to *D. variegata*, pending a thorough review of the boundaries between *D. varie-*

Map 395 Selected localities for *Dasyprocta variegata* (●). Contour lines = 2,000 m.

gata and *D. azarae* (as noted in the account of the latter species).

Hungerford and Snyder (1964) provided the karyotype of a live animal they obtained from the Philadelphia Zoological Garden and identified as *Dasyprocta variegata*. The diploid number was 64; the entire complement, including sex chromosomes, was composed of entirely biarmed elements (FN = 124).

Genus *Myoprocta* Thomas, 1903

Acouchys are a smaller version of the agouti, about one-third the mass on average and with a conspicuous, but still short, tail. Other than overall size and length and hairiness of the tail, the two genera share the same body form with large hindquarters and humped back, elongated, thin limbs, digitigrade foot structure, cursorial gait, general conformation of the skull, and even details of tooth and cranial structures.

SYNONYMS:

- Cavia*: Erxleben, 1777:353; part (description of *acouchy*); not *Cavia* Pallas.
- Agouti*: Daudin, 1802:166; part (listing of *acuschy*); not *Agouti* Lacépède.
- Dasyprocta*: Illiger, 1811:93; part; included *Cavia acouchy* [sic] Erxleben.
- Chloromys* G. Cuvier, 1817:214; part; included *Cavia acouchy* [sic] Erxleben; incorrect subsequent spelling of *Cloromis* F. Cuvier.

Cutia Liais, 1872:534; part (listing of *acuchy*); *nomen oblitum*.

Myoprocta Thomas, 1903d:464; type species "*Dasyprocta*" *acouchy* Linnaeus (= *Cavia acouchy* Erxleben 1777), by original designation.

REMARKS: Tate (1939), Cabrera (1961), Woods (1993), Voss et al. (2001), and Woods and Kilpatrick (2005) each recognize two species of acouchys, generally the "red" (or "reddish") eastern Amazonian and "green" (or "greenish") western Amazonian forms, although the names applied to each differ among these authors. Iack-Ximenes (1999) recognized three species, which do not conform exactly to the "red" and "green" types. Herein, I follow Voss et al. (2001), who provided characters that, in combination, unambiguously distinguished specimens of "red" (*M. acouchy*) and "green" (*M. pratti*) acouchys they examined in the major European and U.S. museums.

Voss et al. (2001) stated that all *M. acouchy* specimens they examined closely resembled one another and found no compelling evidence that more than a single species was represented. Alternatively, these authors noted but did not document significant geographic variation among populations of *M. pratti* that may suggest this taxon is a complex of closely related species. Both species are in need of appropriate revisionary analyses.

KEY TO THE SPECIES OF *MYOPROCTA*:

1. Color reddish-brown dorsally, with uniformly orange or reddish under parts; distinct rump patch of very long (60–80 m) and highly polished hairs more heavily pigmented than those of sides, middle back, or forequarters, and that form a blackish to deep mahogany brown, glossy fringe extending to the base of the tail; cranial dimensions average larger (see Voss et al. 2001:Table 41); sphenopalatine vacuities narrow slits *Myoprocta acouchy*
- 1'. Color drab yellowish- or grayish-brown dorsally with yellowish under parts (usually with a distinct white midventral streak); distinct rump patch never present, with fur over hindquarters similar in length, color, and texture to the rest of the dorsal pelage; cranial dimensions average smaller; sphenopalatine vacuities wide and teardrop in shape. *Myoprocta pratti*

Myoprocta acouchy (Erxleben, 1777)

Red *Acouchy*

SYNONYMS:

[*Cavia*] *acouchy* Erxleben, 1777:354; type locality fixed by neotype selection to "Paracou, French Guiana" (Voss et al. 2001:148).

Cavia akouchi Zimmermann, 1777:508; different spelling for the same animal upon which Erxleben's name was

based (see J. A. Allen [1902a] for the preferential use of Erxleben's name).

Calva Acuschy Gmelin, 1788:121: name combination and incorrect subsequent spelling of *acouchy* Erxleben.

Agouti acuschy Daudin, 1802:166; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

Cavia acuschi É. Geoffroy St.-Hilaire, 1803:166; type locality "l'Amérique méridionale."

Dasyprocta acuchi Illiger, 1811:93; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

Dasyprocta acouchy Illiger, 1815:108; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

[*Dasyprocta*] *S. Acuchy* Oken, 1816:823; [*S.* = *Savia*?]; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

Cavia Akuchi Desmarest, 1816:212; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

Cavia acuchi G. Cuvier, 1817:214; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

Dasyprocta acuschy Desmarest, 1822:358; name combination and incorrect subsequent spelling of *acouchy* Erxleben.

[*Dasyprocta*] *Acouchy*: Minding, 1829:91; name combination.

Cavia exilis Wagler, 1831c:620; type locality "Habitat in Brasilia ad flumen Amazonum," restricted to "near the mouth of Rio Negro," Amazonas, Brazil (J. A. Allen 1916b:205).

D[asyprocta]. leptura Wagner, 1844:49; type locality "Die Heimath ist am Rio negro, einem der nördlichen hauptzuflüsse des Amazonenstroms," possibly at Barra do Rio Negro [= Manaus], Amazonas, Brazil (see Pelzeln 1883; Voss et al. 2001).

Cutia acuchy: Liais, 1872:536; based on "*l'Akouchy de Buffon*" from "la Guyane et le nord de l'Amérique du Sud" [= *Cavia acouchy* Erxleben].

Myoprocta acouchy: Thomas, 1903d:464; first use of current name combination.

Dasyprocta acouchy: Goeldi and Hagmann, 1904:73; name combination.

Dasyprocta (Myoprocta) exilis exilis: J. A. Allen, 1916d:569; name combination.

Dasyprocta exilis: Thomas, 1920f:278; name combination.

D[asyprocta]. exilis: Thomas, 1920f:280; name combination.

[*Myoprocta*] *exilis exilis*: Tate, 1935:335; name combination.

[*Myoprocta*] *leptura*: Tate, 1935:335; name combination.

Myoprocta exilis demararae Tate, 1939:182; type locality "Bonasica, Essequibo River, British Guiana."

M[yo]procta. e[xilis]. lepture Tate, 1939:182; incorrect subsequent spelling of *leptura* Wagner.

DESCRIPTION: Small bodied, head and body length 335–390 mm, tail length 51–78 mm, hindfoot length 90–104 mm, ear length 25–40 mm, mass 1.05–1.45 kg. Upper parts colored dark chestnut red or orange on sides and legs, grizzled with black and some yellow on crown and neck. Mid-back and rump glossy black or very dark red. Rump hairs long, straight, and overhang rear of body in straight fringe; hairs entirely dark, not banded. Eyes large; ears quite large, naked, with tips well above crown; areas behind ears, around mouth and eyes, and under chin almost naked. Vibrissae well developed, black, and reach to behind ear. Tail short and slender, white below and with small white tuft at tip. Behaviorally, tail often wagged or tipped straight up, exposing white underside. Legs long and thin; sole of feet black. Under parts thinly haired, pale to dark rust-red or orange. Some individuals grizzled with yellow and appear olivaceous, but these retain long, dark rump hairs otherwise characteristic of *M. acouchy* (Emmons and Feer 1997).

Skull averages larger than that of *M. pratti* (Voss et al. 2001), with noticeably longer toothrows (mean 13.8 mm, range: 12.4–15.5 mm) and bullae (mean 16.1 mm, range: 14.5–18.5 mm), broader interorbit (mean 22.5 mm, range: 20.9–24.2 mm), and longer nasals (mean 27.3 mm, range: 25.0–31.8 mm). Of four qualitative traits identified by Tate (1939) in his distinction between red and green acouchys, Voss et al. (2001) confirmed that size of sphenopalatine vacuities that perforate the bony roof of the mesopterygoid fossa (“palatal foramina” of Tate) were most useful; very narrow slits (<1 mm wide) in *M. acouchy* while in most *M. pratti* both larger (>1 mm wide) and openings teardrop shaped.

DISTRIBUTION: Lowland rainforest in Guyana, Surinam, and French Guiana, and that part of northeastern Brazil east of the Rio Branco and north of the Rio Amazonas. Voss et al. (2001:145) noted two records outside of this domain, both substantiated by vouchered specimens: one in the AMNH from the “Lower Solimões” believed to be Manacapuru on the north (= left) bank of the Solimões just west of the mouth of the Rio Negro; and two from the south (= right) bank of the Amazon between the Rio Madeira and Rio Tapajós. Emmons and Feer (1997) extended the mapped range of their Red Acouchi to the region between the lower Rio Xingu and Rio Tocantins, presumably based on unvouchered reports (e.g., T. K. George et al. 1988; Voss and Emmons 1996). Apparently no Brazilian collection contains specimens of any acouchy from the Rio Xingu or Rio Tocantins basins (Iack-Ximenes 1999).

SELECTED LOCALITIES (Map 396): BRAZIL: Amapá, Rio Vila Nova, Mazagão (MPEG 411), Terezinha, Rio Amapari, Serra do Navio (MNRJ 43207), Vila Velha do Cassiporé (MPEG 6601); Amazonas, Lago do Baptista

(FMNH 50895), Lago do Serpa (FMNH 50897), Manaus (type locality of *Dasyprocta leptura* Wagner; Voss et al. 2001), Rio Apuaú, left bank Rio Negro (MPEG 7148), Rio Pitinga, left bank Rio Uatumã (MVZ 194289), Villa Bella da Imperatriz, south bank Amazon River (AMNH 93044); Pará, Monte Alegre (MPEG 2285), Lago Cuiteua, Rio Amazonas (MCZ 32356); Roraima, Conceição, Rio Branco (FMNH 20007). FRENCH GUIANA: Cayenne, Paracou (type locality of *Cavia acouchy* Erxleben). GUYANA: Essequibo Islands–West Demerara, Bonasika River (type locality of *Myoprocta exilis demararae* Tate); Upper Demerara–Berbice, Potaro River (ROM 29120); Upper Takutu–Upper Essequibo, Nappi Creek, foot of Kanuku Mountain (ROM 31539). SURINAM: Paramaribo, Paramaribo (USNM 13309).

SUBSPECIES: Cabrera (1961) listed three subspecies, the nominotypical form (with *demararae* Tate as a synonym) from the Guianan region and eastern Amazonian Brazil north of the Rio Amazonas, *exilis* Wagler (with *leptura* Wagner as a synonym) from the lower Rio Negro to the lower Rio Tapajós in the central Amazonian Brazil, and *parva* Lönnberg, from east of the Andes in southern Colombia, Ecuador, and northern Peru. This latter name has been applied to the Green Acouchy, *Myoprocta pratti*, by more recent authors (see Remarks under that species). The validity of *M. a. acouchy* versus *M. a. exilis* has yet to be tested by rigorous analyses of any type of character set.

NATURAL HISTORY: Acouchys of both species share similar life history, ecology, and behavior to those attributes of agoutis. In French Guiana (Dubost 1988), Red acouchys frequented all forest habitats except disturbed areas. Individuals were strictly diurnal, with most activity confined to morning hours. The family, with an adult male and female plus their immediate offspring, comprised the basic social unit, although each member lived alone within individual home ranges that, while clumped, exhibited little overlap. These small home ranges had multiple heavily frequented areas and many resting sites, often located in hollow logs, that consisted of a single nest in current use and several older leaf-heaps. Males preferred open forests, females more closed habitats. The size of home ranges and the level of individual activity decreased in the dry season when food resources are most scarce. Familial units were widely separated, so intergroup interactions were rare. Food was not stored in or adjacent to nests but buried in small caches through the entire home range. Reproduction is strongly seasonal, with more than half of all births concentrated between November and January during the period when the number of fruiting tree species and individuals of each begins their annual increase; no births occurred from August to October, when fruit availability is at its lowest (Dubost et al. 2005). Litter size ranged from one to three, with a

median of two young per pregnancy. The juvenile sex ratio was skewed in favor of males, but the adult sex ratio was near one, resulting from increased risks taken by juvenile males when dispersing. Red acouchys eat primarily fruits, predominantly pulp followed by seeds and exocarp; other food types, including insects, comprised less than 1% of the diet (Dubost and Henry 2006). Diet varies seasonally, depending upon both the number of fruiting plant species and overall fruit production and nutritional needs associated with reproduction. Seeds were collected and scatterhoarded by burying, with caches often more than 100 m distant from the tree that dropped them (Jansen et al. 2004), both important components of tree dispersal and regeneration (see also Forget 1990, 1991). Red acouchys will hoard rapidly germinating seeds, such as from the tree *Carapa procera* (in the mahogany family Meliaceae), but manipulate the seed by removing the protruding radicle and epicotyl to stop seed development and thus to prolong storage life in the cache (Jansen et al. 2006). In central Amazonian Brazil where the forest has been modified into patches of varying size, scatter hoarding and seed removal was inversely related to patch size (Jorge and Howe 2009), and population density dropped nearly an order of magnitude from continuous forest to patches of about 1 ha in size (Jorge 2008).

REMARKS: Thomas (1926f:639), Cabrera (1961:591), and Emmons and Feer (1990, 1997) applied Erxleben's *acouchy* to the Red Agouti while Tate (1939), Husson (1978), Woods (1993), Alberico et al. (2000), and Iack-Ximenes (1999) used this name for the Green Acouchy. Voss et al. (2001), however, noted that this disagreement in usage stemmed from whether geography or color was viewed as the determining factor in how Erxleben's name should be applied. These authors favored geography, as the type locality for Erxleben's animal could be unambiguously established as French Guiana ("Cayenne"). They then (p. 148) stabilized the nomenclature of species-name assignments by selecting a neotype for *Cavia acouchy* Erxleben from Paracou, French Guiana. For further details, see Voss et al. (2001:144–151).

Wagler's (1831c) description of *exilis* clearly identifies a reddish animal ("*notaeo toto castaneo-fuscescente*") and thus aligns Wagler's name with *Myoprocta acouchy*. Similarly, the "*ferrugineo-rufa*" color given by Wagner (1844) to his *leptura* solidifies this name as a synonym of *M. acouchy* as well. Both original specimens came from the lower Rio Negro, as specified by Wagner in his paper describing *leptura* and by J. A. Allen (1916b:205) in his restriction of the locality of Wagler's *exilis*. Voss et al. (2001:151, footnote *d*) noted that Wagner's type series was collected by Johann Natterer and possibly at "Barra do Rio Negro" (= Manaus), which was the only definite local-

Map 396 Selected localities for *Myoprocta acouchy* (●).

ity where Natterer apparently obtained acouchys (Pelzeln 1883).

Emmons and Feer (1997) suggested that *milleri* J. A. Allen represented an isolated population of *M. acouchy* in the upper Río Vaupés of Colombia, where some hybridization with *M. pratti* might occur. These authors also noted that both red and green acouchys may co-occur in the Serranía de la Macarena in eastern Colombia, presumably based on the list of Colombian mammals assembled by Cuervo Díaz et al. (1986). However, Voss et al. (2001:151), who actually examined Allen's holotype, unambiguously regarded *milleri* as a green acouchy.

Fredga (1966) and Hsu and Benirschke (1968b) described a karyotype with $2n = 62$, $FN = 118$ for specimens they called *Myoprocta acouchy* but that lacked provenance data.

Myoprocta pratti Pocock, 1913

Green Acouchy

SYNONYMS:

Myoprocta pratti Pocock, 1913:110; type locality "Amazonas," Peru; restricted to Pongo de Rentema, Río Marañón, Amazonas, about 78°20' by Thomas (1920f:279).

Myoprocta milleri J. A. Allen, 1913a:477; type locality "La Murelia, Caquetá, altitude 600 feet," Colombia.

Dasyprocta (Myoprocta) exilis milleri: J. A. Allen, 1916b:205; name combination.

Myoprocta pratti limanus Thomas, 1920f:279; type locality "Acajutuba, near mouth of Rio Negro, above Manaus [= Manaus]," Amazonas, Brazil.

M[yoprocta]. p[ratti]. milleri: Thomas, 1920f:279; name combination.

Myoprocta exilis parva Lönnberg, 1921:41; type locality “near Rio Curaray, El Oriente, Ecuador.”

Myoprocta pratti archidonae Lönnberg, 1925:274; type locality “Archidona on the eastern side of the Andes [Napo province] in Ecuador, 2400 feet above sea level.”

Myoprocta pratti limana: Thomas, 1926f:638; corrected gender concordance.

Myoprocta pratti caymanum Thomas, 1926f:638; type locality “Canabouca, Parana do Jacaré, south side of the Solimoens [= Rio Solimões], about 120 km. to the southwest of Manaus [= Manaus]”; = Paraná do Jacaré, Lago Canabouca, Amazonas, Brazil (Vanzolini 1992).

Myoprocta pratti puralis Thomas, 1926f:639; type locality “Ayapua [Aiapuá], about 300 km. S.W. of Manaus [= Manaus]”; an island on west side of the lower Rio Purus below Arumã, Amazonas, Brazil (Paynter and Traylor 1991).

[Myoprocta] pratti pratti: Tate, 1935:335; name combination.

M[yoprocta]. a[couchy]. milleri: Tate, 1939:182; name combination.

M[yoprocta]. a[couchy]. pratti: Tate, 1939:182; name combination.

M[yoprocta]. a[couchy]. limanus: Tate, 1939:182; name combination.

M[yoprocta]. a[couchy]. archidonae: Tate, 1939:182; name combination.

M[yoprocta]. a[couchy]. caymanum: Tate, 1939:182; name combination.

M[yoprocta]. a[couchy]. puralis: Tate, 1939:182; name combination.

DESCRIPTION: Slightly smaller in external dimensions than *M. acouchy*, head and body length 298–383 mm; tail length 40–58 mm, hindfoot length 74–98 mm, ear length 31–37 mm, and mass 0.8–1.2 kg (Emmons and Feer 1997). Color on upper parts and legs finely grizzled olivaceous, with each hair possessing multiple alternating narrow bands of black and yellow; back and sides usually uniformly colored, sometimes washed with reddish tone, and rump may occasionally be darker, almost blackish, but with hairs always banded. Rump hairs long but usually do not overhang as fringe. Sides of muzzle, cheeks, and postauricular patch rusty orange; chin and area around eyes almost naked. Under parts pale orange, thinly haired over yellowish skin; throat, chest, and midline of belly often white. Young animals colored as adults but often with stronger orange tints. Overall body shape and proportions, including tail length and color, like those of *M. acouchy*. Green acouchys from Venezuelan Amazon more typically gray-brown on sides, thighs grizzled with white hairs.

Cranially the two species share most features, although skull of *M. pratti* somewhat smaller in most dimensions, notably so in maxillary toothrow length (mean 13.2 mm, range: 12.4–14.2), interorbital breadth (mean 20.0 mm, range: 18.4–22.0), and bullar length (mean 14.7 mm, range: 13.7–15.6; Voss et al. 2001:Table 41). In contrast to condition in *M. acouchy*, sphenopalatine vacuities in bony roof of mesopterygoid fossa of *M. pratti* are teardrop-shaped apertures, rather than narrow slits, >1 mm in width (Tate 1939; Voss et al. 2001).

DISTRIBUTION: *Myoprocta pratti* ranges from the eastern foothills of the Andes to west of the lower Rio Negro, north of the Amazon in southern Venezuela, Brazil, Colombia, Ecuador, and Peru, and south of the Amazon River in Peru, Bolivia, and Brazil to at least the Rio Madeira. S. Anderson (1997) mapped two additional localities in Pando department, Bolivia, citing an unpublished report by L. H. Emmons. Elevational range extends from the floor of the Amazon Basin at about 50 to 1,200 m on the Andean slopes.

SELECTED LOCALITIES (Map 397): **BOLIVIA:** Pando, Luz de América, Reserva Nacional de Vida Silvestre Amazónica Manuripi (Miserendino and Azurduy 2005). **BRAZIL:** Acre, Seringal Santo Antônio (MZUSP 11234); Amazonas, Acajutuba, lower Rio Negro (type locality of *Myoprocta pratti limanus* Thomas), Ayapua [= Aiapuá] (type locality of *Myoprocta pratti puralis* Thomas), Canabouca, Paraná do Jacaré (type locality of *Myoprocta pratti caymanum* Thomas), Carvoeiro (MZUSP 20187), Foz do Rio Castanhas (MNRJ 2316), São João, Aripuanan (MNRJ 2313), Tauá, Rio Uaupés (AMNH 78599), Umarituba, Rio Negro (AMNH 78598); Rondônia, Calama (AMNH 37122). **COLOMBIA:** Meta, La Macarena Parque, Río Guapaya (FMNH 88023); Putumayo, Río Mecaya (FMNH 71133). **ECUADOR:** Napo, 12 km NE of Lago Agrio (FMNH 125085); Pastaza, Río Capahuari (FMNH 43191), Río Pindo Yacu (FMNH 43186). **PERU:** Amazonas, Pongo de Rentema, Río Marañón (type locality of *Myoprocta pratti* Pocock), Tseasim, Río Huampami of Río Cenepa (MVZ 153579); Cusco, Quincemil (FMNH 75195); Loreto, Sarayacu, Ucayali River (AMNH 76277); Madre de Dios, Cocha Cashu Biological Station (B. D. Patterson et al. 2006); Pasco, Cumbre de Ollon, ca. 12 km E of Oxapampa (LSUMZ 25891); Ucayali, Lagarto, upper Ucayali River (AMNH 76621), 59 km SW of Pucallpa (USNM 499237). **VENEZUELA:** Amazonas, Belén, 56 km NNW of Esmeralda, Río Cunucunuma (USNM 388222), Boca Mavaca, 84 km SSE of Esmeralda (USNM 406522).

SUBSPECIES: Cabrera (1961) recognized six subspecies: *parva* Lönnberg (which he considered a form of *M. acouchy*) from eastern Ecuador and probably southern Colombia and northern Peru; *caymanum* Thomas from

south of the Amazon River in the lower Rio Purus drainage in Brazil; *limana* Thomas from the Rio Negro drainage in central Brazil and southern Venezuela; *milleri* J. A. Allen from south Colombia and northeastern Ecuador; *pratti* Pocock from south of the Río Marañón to at least Cusco department, Peru; and *puralis* Thomas in the region south of the Rio Solimões and west of the Rio Purus. As noted by Voss et al. (2001), there is considerable variation in color and mensural characteristics over the range of the species, but the degree to which the available names map on to coherent geographic units must wait for appropriate character analyses. As these authors also noted, *M. pratti* as currently envisioned may be a complex of closely related taxa worthy of recognition at the species level.

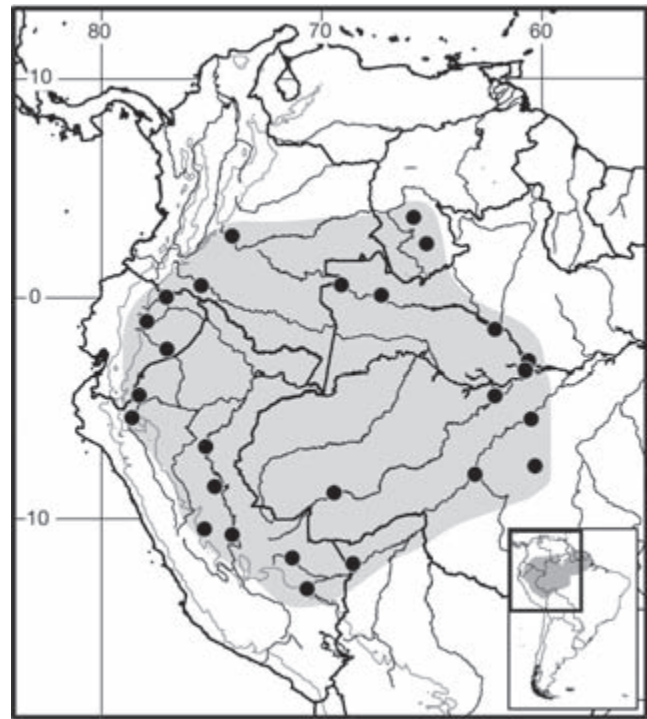

NATURAL HISTORY: The Green Acouchy has not been extensively studied in the field, with most information available anecdotal or based on captive observations. In general, these animals are diurnal and feed on fallen seeds (that they scatter hoard, as do other dasyproctids; Morris 1967) and fruits, and can den in abandoned armadillo burrows (L. H. Emmons, pers. comm.). J. A. Allen (1916d:595) noted, “In the Caquetá I found them [*milleri*] apparently living in colonies, in wet forests. They were out and about in the mornings, and took refuge in holes in the riverbank. The flesh is white and possesses a delicious flavor.” Using both line transect and camera traps, Munari et al. (2011) demonstrated that Green Acouchys along the Rio Juruá in western Amazonian Brazil were active only during daylight hours and specialized in upland, *terra firme* forest without venturing into flooded, or *várzea* forest. Kleiman (1970) and Weir (1971a) described an estrous cycle lasting about 40 days and a gestation length of 99 days in captive females. Under these conditions, sexual maturity was reached within 8 to 12 months. Breeding success was greatest when the female was housed with a single male, which suggests the importance of paired adult family groups similar to the basic social unit described for the Red Acouchy in French Guiana (e.g., Dubost 1988). Kleiman (1971, 1972) summarized courtship, copulatory, and maternal behaviors in her captive population.

REMARKS: Both *pratti* Pocock and *milleri* J. A. Allen were named in 1913; Pocock’s name has date priority, however, as his paper was published in July of that year while Allen’s appeared in September.

J. A. Allen (1916d:569) believed that Pocock’s *Myoprocta pratti* agreed well with Wagler’s description of *exilis* and with a specimen he had from Calama (from the middle Rio Madeira) in central Brazil. He also regarded the type locality of *pratti* as “indefinite as the type locality of *exilis*” and continued with “it seems perfectly safe to assume that both came from that portion of the Amazon drainage which includes the lower Rio Negro and the lower Rio Madeira.” Allen thus

assigned *pratti* as a synonym of *Dasyprocta* (*Myoprocta*) *exilis exilis*. Thomas (1920f:279), however, found it “impossible to accept Dr. Allen’s identification of [*Dasyprocta exilis* Wagler] with one of the greenish-coloured *pratti* group.” Thomas also reported that, although Pocock did not record the exact locality of his *pratti*, Thomas had learned from Mr. A. E. Pratt that the specimen had been obtained at the Pongo de Rentema on the Río Marañón, which is just east of the boundary between the regions of Cajamarca and Amazonas on that river, at about 78°20’W latitude.

Lönnerberg (1921) assigned his *parva* to *Myoprocta exilis* and subsequently in his description of *archidonae* (Lönnerberg 1925) contrasted the two as representing “red” (*parva*) and “green” (*archidonae*) acouchys, respectively. Both Tate (1939) and Cabrera (1961) followed Lönnerberg, listing *parva* as a subspecies of the Red Acouchy (Tate under the name *M. exilis*, Cabrera as *M. acouchy*). Lönnerberg (1921:41–42) contrasted his *parva* with J. A. Allen’s *milleri* from nearby in southern Colombia as not having the pale olivaceous yellow washed with black characteristic of *milleri*. Rather, he described *parva* as dark grizzled brownish overall color, the back “with only a little sprinkling of pale yellow,” the top of the head blackish brown sprinkled with orange yellow, and the under parts “yellowish buff.” He made no mention of the distinctive long fringe of hairs on the rump that characterize *M. acouchy* (as envisioned by Voss et al. 2001 and herein) but did note the small dimen-

Map 397 Selected localities for *Myoprocta pratti* (●). Contour line = 2,000m.

sions of the skull, giving a measurement of 11 mm for the length of the upper toothrow for both a male and female specimen. Although the specimens Lönnberg had may be darker than other *M. pratti* from the western Amazon, the characteristics given are clearly within the range expressed among populations and even individuals from single localities of that species. There seems every reason, therefore, to associate Lönnberg's *parva* with the Green Acouchy *M. pratti*, a conclusion also reached by Voss et al. (2001) and Woods and Kilpatrick (2005).

As currently understood, Green and Red acouchys, like so many other species in the west-central Amazon, are apparently allopatric and separated by the lower Rio Negro (*M. pratti* to the west and *M. acouchy* to the east). Their ranges closely approach near the mouth of the Rio Negro in the vicinity of Manaus, a limited area with the respective type localities of Thomas's *limanus* (a Green Acouchy; see Voss et al. 2001:151, Table 41) and Wagler's *exilis* and Wagner's *leptura*, both Red acouchys.

The karyotype of *Myoprocta pratti* is apparently unknown.

Superfamily Chinchilloidea Bennett, 1833

Angel E. Spotorno and James L. Patton

This superfamily includes only the Chinchillidae (which, in turn is composed of the subfamilies Chinchillinae and Lagostominae) plus Dinomyidae. The sister relationship between these two family-group taxa has become well established in all molecular phylogenetic analyses (Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012; P.-H. Fabre et al. 2012), with the divergence between the two lineages beginning in the Early Miocene, at about 10.1 ± 2.7 mya (Opazo 2005). Among others, Woods (1982) and McKenna and Bell (1997) placed the Dinomyidae within the Caviioidea.

Family Chinchillidae Bennett, 1833

This family comprises the chinchillas (*Chinchilla*), mountain viscachas (*Lagidium*), and plains viscachas (*Lagostomus*), mostly limited to the drier regions of western and southern South America from the highlands of Ecuador through the Andes of Peru and Bolivia to the coastal mountains of Chile and Patagonian steppe of Argentina.

These are rabbit-like rodents with short forelimbs and elongated hindlimbs, large eyes and ears, and with size varying from a head and body length of nearly 400 mm and average mass of 500 g (*Chinchilla*) to 700 mm body length and mass of 5 kg or greater (*Lagostomus*). Sexual dimorphism can be extreme, with females nearly twice the mass

of males in *Chinchilla* but with males larger than females in *Lagostomus*. The tail varies in length, but is always less than half of the length of the total length, proportionally shortest in *Lagostomus* (about 33% of head and body length) and longest in *Lagidium* (about 75% of head and body length). It is always well furred, with a distinctly brushlike appearance in species of both *Chinchilla* and *Lagidium*. The tail of *Lagostomus* breaks easily at the 4th caudal vertebrae and is thus often lost. Both forefeet and hindfeet have fleshy plantar pads; the distal toe pads are enlarged and obscure, with small, curved claws in *Chinchilla* and *Lagidium*. Elongated and nearly straight claws on both forefeet and hindfeet dwarf small toe pads in *Lagostomus*. The pollex (digit I) is lacking (*Lagidium* and *Lagostomus*) or severely reduced in size (*Chinchilla*), so the forefeet have only four functional digits in all three genera. Both *Chinchilla* and *Lagidium* have four digits on the hindfeet (lacking the hallux, digit I); *Lagostomus* has only three (lacking digits I and V). Digit II of the hindfeet in both *Chinchilla* and *Lagidium* has a cluster of stiffened hairs on one side of the claw; a similar cluster is present on the central digit (III) of *Lagostomus* (drawings in Pocock 1922:Figs. 14, 15). Mystacial vibrissae in all three genera are coarse, stiff, and long, extending to the tip of the ear when laid back. Superciliary and genal vibrissae are soft and fine in *Chinchilla* and *Lagidium*, but longer and coarser in *Lagostomus*. This latter genus also has an extensive, thick mat of short bristles on the cheek below the eye. Overall dorsal coloration varies from gray to bluish black with yellowish white under parts in *Chinchilla* and *Lagidium* and brownish or grayish black with strikingly bold black and white facial bands in *Lagostomus*. The pelage is especially soft and dense, notably so in both *Chinchilla* and *Lagidium*. *Chinchilla* has been nearly exterminated in the wild because of the value of their fur (Spotorno, Zuleta et al. 2004).

The skull is elongated and relatively narrow, with a broad interorbital region, long and narrowed rostrum, and a braincase varying in shape from slightly rounded (in *Lagidium*) to triangular (in *Chinchilla*, due to the enlarged mastoid bullae), to squared (in *Lagostomus*), which is especially robust in appearance. A postorbital process on the frontal is weakly developed in *Chinchilla* and *Lagidium* but expanded, flat, and triangular in shape in *Lagostomus*. The lacrimal canal is positioned on the side of the rostrum just in front of the infraorbital foramen, which itself is large and with a deep canal for nerve passage in *Lagostomus* but not in *Chinchilla* or *Lagidium*. The zygomatic arch is horizontally thin but deep, with a well-developed jugal contacting the lacrimal in *Lagidium* and *Lagostomus* but not in *Chinchilla*, and a moderate postorbital spine comprised solely by the jugal. The upper zygomatic root is positioned far behind the lower root,

over the posterior molars. Both the tympanic and mastoid portions of the auditory bullae are greatly inflated in *Chinchilla*, less so in *Lagidium*, and only weakly inflated in *Lagostomus*, with the mastoid portion visible on the dorsal surface of the cranium in *Chinchilla* and *Lagidium*. The auditory tube is directed dorsally rather than laterally. The incisive foramina are long and narrow, encompassing more than half the length of the diastema in *Chinchilla* and *Lagidium* but only about one-third that distance in *Lagostomus*. The maxillary toothrows of all three genera diverge posteriorly, so the minimum distance between the fourth premolars is only about 20% to 30% of the maximum distance between the third molars. The palate is short, with the anterior border of the mesopterygoid fossa reaching to M2 in all three genera. Sphenopalatine vacuities are well developed in *Chinchilla*, small and contained completely within the pterygoid in *Lagidium*, and reduced to small slits at the palatine-ptyerygoid junction in *Lagostomus*. The basisphenoid varies considerably in width in conjunction with the degree of hypertrophy of the tympanic bullae among the three genera. The paroccipital processes, both in size and relationship to the bullae, vary as well among the genera, being small and closely appressed to the bullae in *Chinchilla*, longer but free from and curved over the distal portion of the bullae in *Lagidium*, and elongated, vertical, and completely free of the bullae in *Lagostomus*.

Upper incisors are narrow with little expressed pigment in the anterior enamel, orthodont to opisthodont in *Chinchilla* and *Lagidium* but proodont in *Lagostomus*. Cheek teeth are flat crowned and hypsodont. All teeth have three transverse plates, or laminae, in *Chinchilla* and *Lagidium*; all teeth in also have three plates in *Lagostomus* except M3, which possesses only two plates. The deciduous premolars (dPM4 and dpm4) are replaced.

The lower jaw lacks a masseteric crest on the dentary in all three genera. The coronoid process is small in both *Chinchilla* and *Lagidium* but elongate in *Lagostomus*, set off from the ramus by a moderately deep depression lateral to the mandibular incisure for the insertion of the posterior masseter. The angular process is thin and elongate in both *Chinchilla* and *Lagidium*, much more robust in *Lagostomus*; it is only slightly deflected laterally to the sheath of the incisor, again except in *Lagostomus*.

Bugge (1971) described the cephalic arterial system for *Chinchilla*; that for the other two genera is unknown but presumably is similar. As is characteristic of most other hystricognaths, both the internal carotid artery and the tympanic part of the stapedia artery are lacking. The vertebral artery supplies the brain whereas the stapedia area of supply is taken over by the external carotid. The persistent parts of the stapedia artery include the distal part of

the stem, the proximal part of the supraorbital branch with the middle meningeal artery, the orbital part of the supraorbital branch, and the entire infraorbital and mandibular branches. This combination of features sets chinchillids apart from other caviomorph lineages.

Lagostomus is apparently unique among hystricognath rodents in having a narrow, cylindrical penis that lacks the intromittent sac (= *sacculus urethralis*) that is characteristic of all other members of this larger group (Pocock 1922; Hooper 1961), including *Chinchilla* (Tullberg 1899; Spotorno 1979). The phallus of *Lagidium* has not been described.

Chinchillids can be distinguished from other South American caviomorph rodents by the combination of a large lacrimal bone and lacrimal canal opening on the side of the rostrum; by the dorsally deflected auditory canal with an accessory foramina at the base; by an angular process that is delicate and not strongly hystricognathous; by the lack of a masseteric crest on the dentary; and by an occlusal pattern of the cheek teeth composed of closely packed but distinctly transverse lamellar plates, numbering three or fewer.

Chinchillids extend from the Deseadan (Oligocene) to Recent in South America. The family is commonly divided into two subfamilies, the Chinchillinae, which contains only the extant genera *Chinchilla* and *Lagidium*, and the Lagostominae, which contains at least two extinct genera that date to the Early and Middle Miocene as well as the extant *Lagostomus* (McKenna and Bell 1997). Neither *Chinchilla* nor *Lagidium* have a fossil record, but *Lagostomus* is known from the early Pleistocene, and possibly late Pliocene (Kraglievich 1926).

Wood and Patterson (1959) and Wood (1965) grouped the chinchillids with dasyproctids, dinomyids, and cuniculids into the superfamily Chinchilloidea based on similarities of dental morphology. Vucetich (1975) and B. Patterson and Wood (1982) proposed a more restricted Chinchilloidea, containing among the extant South American caviomorphs only the Chinchillidae. However, available molecular data support a strong sister relationship between the Chinchillidae and Dinomyidae (Huchon and Douzery 2001; Opazo 2005; Sallam et al. 2009; Rowe et al. 2010), with these two families comprising the Chinchilloidea as the sister group to the Octodontoidea (families Abrocomidae, Echimyidae, Ctenomyidae, Octodontidae). The stem split within a Chinchilloidea that encompasses both the Chinchillidae and Dinomyidae is placed in the Early Miocene, at an estimated age 19.1 ± 2.7 mya (Opazo 2005), at 19.2 mya (95% credibility interval 16.5–23.3; Sallam et al. 2009), or within the range of 17 to 21 mya (Huchon and Douzery 2001), which spans the Oligocene-Miocene boundary.

KEY TO THE SUBFAMILIES AND GENERA OF CHINCHILLIDAE:

1. Paroccipital processes long, separated from bulla; bullae not inflated and not visible on dorsal surface of cranium; occipital region of skull strong, prominent with enlarged lambdoidal ridge; skull more prominently ridged; postorbital processes of frontal well developed; incisors proodont; cheek teeth (except M3) bilaminate; three digits on hindfeet with heavy, prominent, and sharp claws. Lagostominae, *Lagostomus*
- 1'. Paroccipital processes small and closely aligned to bulla; bullae inflated, visible on dorsal surface of cranium; occipital region smooth, without sharply delineated lambdoidal ridge; skull without prominent ridges for muscle attachment; postorbital process of frontals weakly developed; incisors orthodont or slightly opisthodont; cheek teeth trilaminate; four digits on hindfeet with weak, blunt claws. Chinchillinae, 2
2. Bullae greatly inflated, with large exposure of mastoid portion on dorsal surface of cranium; jugal usually not in contact with lacrimal; laminae of cheek teeth straight, not curved *Chinchilla*
- 2'. Bullae less inflated, with only small exposure of mastoid portion on dorsal surface of cranium; jugal always in contact with lacrimal; laminae of cheek teeth strongly curved, not straight. *Lagidium*

Subfamily Chinchillinae Bennett, 1833

The Chinchillinae comprises two genera, *Chinchilla* and *Lagidium*, characterized by small to medium size (head and body length ranging from 300 to 650 mm; mass 400 to 1700 g), very soft and lax fur, four toes on both forefeet and hindfeet with enlarged toe pads obscuring small, curved claws, a skull with small paroccipital processes either appressed to or conforming to the curvature of inflated auditory bullae with the mastoid portion visible on the dorsal surface, and three laminae on each cheek tooth. Limited molecular sequence data confirm a sister relationship between *Chinchilla* and *Lagidium* with respect to *Lagostomus* (Spotorno, Valladares, Marín et al. 2004; Ledesma et al. 2009).

Genus *Chinchilla* Bennett, 1829

As currently understood, there are two species within the genus *Chinchilla*, the Chilean Chinchilla (*Chinchilla lanigera*) and the Short-tailed Chinchilla (*Chinchilla chinchilla* [= *C. brevicaudata*]). *Chinchilla lanigera* is smaller in body size (less than 260 mm in body length) than *C. chinchilla* (>320 mm long), with shorter and more rounded ears (<32 mm versus >45 mm), and with a longer tail (>130 mm

versus <100 mm). External characters in common to both species include very soft fur; long and narrow hindfeet with three main digits and digit V placed high on the foot and not reaching the base of digit IV, and an unguis bundle of stiff bristle hairs on digit II; short forefeet with four main digits, pollex represented by a small, clawless tubercle; and rudimentary cheek pouches (Pocock 1922).

Cranially, the rostrum is long and narrow, the interorbital region broad, but with a well-developed constriction. The postorbital processes of the frontal are very small, and the skull lacks prominent ridges of muscle attachment. The most conspicuous aspect of the skull are the greatly inflated tympanic and mastoid portions of the auditory bullae, with an expanded dorsal mastoid portion clearly visible such that the interparietal is narrow and long and the lateral portion of the supraoccipital is restricted to narrow bands of bone. The mastoid bullae extend posteriorly from the occipital region. Paroccipital processes are small and closely appressed to and dwarfed by the bullae. The floor of the infraorbital foramen is smooth, lacking a canal for nerve transmission. The jugal is especially deep but usually does not extend to reach the lacrimal. Palatal foramina are very long and narrow, occupying more than 75% of the length of the diastema. The mandible has narrow and elongated angular processes and the ridge lateral to the condylar process for the attachment of the posterior masseter is weakly developed.

The cheek teeth diverge strongly, with the distance between the anterior PM4s about 30% of the distance between the posterior M3. Each cheek tooth has three laminae, or plates, with the posterior one of M3 directed backward rather than transversely. The anterior lobe of each lower cheek tooth is reduced relative to the medial and posterior lobes. The laminae of all teeth are straighter than are those of *Lagidium*.

Delimitation of the number of valid species is constrained by a generally inadequate understanding of geographic continuity in all types of characters. Osgood (1943b) recognized a single species (*Chinchilla chinchilla*) with three subspecies: the Peruvian *C. c. chinchilla* Lichtenstein, *C. c. velligera* Prell [with *lanigera* Bennett a synonym] from Chile, and *C. c. boliviana* Brass from Bolivia and Argentina. Cabrera (1961), Woods (1993), and Woods and Kilpatrick (2005) listed two (*Chinchilla chinchilla* [= *C. brevicaudata* of other authors] and *C. lanigera*), and Bidlingmaier (1937) recognized three (*chinchilla* Lichtenstein, *boliviana* Bass, and *velligera* Prell). Waterhouse (1848) commented on differences in overall size and tail length between the Chilean and Peruvian chinchillas, describing the latter as *C. brevicaudata* in reference to its short tail. Pine et al. (1979) included *brevicaudata* in *lanigera* without comment. S. Anderson (1997:473) stated “no convincing case, based on

adequately documented specimens of known provenance, has been made for more than one species.” He went on to write (p. 474) that geographic variation “was known in a general way to the fur trade. Pelts from higher and colder regions had longer, finer, warmer fur, probably were larger, and the animals may have had shorter tails and ears. However, variation is so poorly known that the use of [even] subspecies seems more confusing than clarifying.” Alternatively, Spotorno, Valladares, Marín et al. (2004) found that samples from northern Chile (Antofagasta; which they referred to *brevicaudata*) differed from those from central Chile (Coquimbo; referred to *lanigera*) by 5.9% in mitochondrial sequence divergence, and argued that these represented separate species. However, given that only a single wild population of one (*lanigera*) and two populations of the second (*brevicaudata*) were sampled for each taxon, that these localities are nearly 1,000 km distant, and that none of the range in Peru, Bolivia, or Argentina was sampled, it is perhaps premature to use these limited data as definitive evidence for species boundaries. Unfortunately, it is unclear whether we will ever be able to delineate the number of species within the genus, as Osgood (1943b:135) noted more than 60 years ago. There are few specimens of known provenance in collections, and the local extermination of wild populations over much of the historic range due to overexploitation for their valuable fur greatly restricts the level of geographic sampling that would be necessary to adequately delimit both species and geographic ranges. Nevertheless, there is a recent record at a geographically intermediate locality (F. Valladares et al. 2012), so there is hope that additional populations will be uncovered that can help resolve taxonomic boundaries. Herein, we follow the most recent reviews (Spotorno, Valladares, Marín et al. 2004; Spotorno, Zuleta et al. 2004; Woods and Kilpatrick 2005) and provisionally recognize two species.

SYNONYMS:

- Mus*: G. I. Molina, 1782:301; part (description of *laniger*); not *Mus* Linnaeus.
Cricetus: É. Geoffroy St.-Hilaire 1803:197; part (listing of *laniger*); not *Cricetus* Leske.
Lemmus: Tiedemann, 1808:476; part (listing of *laniger*); not *Lemmus* Link.
Chinchilla Bennett, 1829:1; type species *Chinchilla lanigera* Bennett, derived from *Mus laniger* G. I. Molina, by monotypy.
Eriomys Lichtenstein, 1830:plate 28, and unnumbered text; type species *Eriomys chinchilla* Lichtenstein, by monotypy.
Callomys d’Orbigny and Geoffroy St.-Hilaire, 1830:282; part; a composite genus with no type species selected.
Lagostomus: F. Cuvier, 1830:plate 64; part (listing of *laniger*); not *Lagostomus* Brookes.

Aulacodus: Kaup, 1832:column 1211; not *Aulacodus* Temminck.

REMARKS: Bennett’s *Chinchilla* has been variously dated to 1829, 1830, and 1831, resulting in differing opinions as to the proper genus-group name applied to the chinchilla. Wiegmann (1835:205), for example, argued that *Eriomys* Lichtenstein had precedence over *Chinchilla* Bennett, although he wrote “in den *Gardens and Menagerie of the Zoological Society*. 1831. Vol. 1, p. 1., bereits [already] 1829 gedruckt [printed].”

Alternatively, as noted by Osgood (1941:410), *Chinchilla* had been given precedence historically because Bennett’s description was more complete and accurate.

The confusion over date priority likely stems from the fact that *The Gardens and Menagerie of the Zoological Society of London*, which was edited by Bennett, was published in three editions, one each in the years 1829, 1830, and 1831. Tate (1935:357) apparently had in hand the 1831 edition when he noted that Bennett’s own preface was dated June 30, 1830. Sherborn (1922) initially gave 1831 for the date of Bennett’s publication but subsequently (Sherborn 1925a:1233, 1927b:1829) listed 1829 for Bennett’s *Chinchilla* and *lanigera*, respectively. Most subsequent authors have cited 1829 as the publication date for Bennett’s name (E.-L. Trouessart 1897; Ellerman 1940; Osgood 1941; Cabrera 1961 [p. 567; on p. 566 Cabrera gave 1820, which is likely a printer’s error]). None of these authors, however, referenced the words of Bennett himself who wrote (Bennett 1833:58), “To complete the history of *Chinchilla* he [= Bennett] also gave an account of the various notices regarding it, which have appeared since September 1829, the date of his account of it in the ‘Gardens and Menagerie of the Zoological Society’” and (Bennett 1835c:45) “Dr. Rousseau translated into French my account of the *Chinchilla*, from the ‘Gardens and Menagerie of the Zoological Society’, attributing its date to 1831, which some of the later published copies of the volume bear upon the title-page, instead of 1829, when the number containing the *Chinchilla* was published.” There seems little doubt that the initial publication of Bennett’s *Chinchilla* stems from 1829, removing any question of the correct use of his name for the chinchilla, and with precedence over those proposed subsequently.

D’Orbigny and Geoffroy St.-Hilaire’s (1830) *Callomys* is a composite genus that included *Callomys viscaccia* (assigned to *Viscaccia* Schinz [1825a], a synonym of *Lagostomus* Brookes), *Callomys laniger* (= *Chinchilla lanigera*), and *Callomys aureus* (an indeterminate species based on a furrier’s skin that lacked the feet, ears, and tail). As none of these three names were specifically chosen a type species, *Callomys* d’Orbigny and Geoffroy St.-Hilaire is indeterminate as well (see J. A. Allen 1901d).

There has also been considerable confusion and debate over the type species of *Chinchilla* Bennett, originally described in a semipopular publication (Bennett 1829) but subsequently in a more technical and fully illustrated treatment (Bennett 1835c). G. I. Molina (1782:301) described “La Chinchilla, *Mus Laniger* (I. *Mus cauda mediocri, palmis tetradactylis, plantis pentadactylis, corpore cinereo lanato*)” from Chile. Bennett (1829:1) gave the type of his new genus as *Chinchilla lanigera*, using the feminine ending to Molina’s name but clearly describing an animal that he had in hand at the time; his specimen also came originally from Chile. Lichtenstein (1830:plate 28 and accompanying unnumbered text) described *Eriomys* with the type species *Eriomys chinchilla*, from Peru. Finally, Prell (1934a), who recognized that there was confusion over Molina’s *laniger*, named the Chilean chinchilla *Chinchilla velligera*, stating clearly that his name was intended to apply to the animal described by Bennett.

Osgood (1941) argued that the correct type species for Bennett’s *Chinchilla* was *Chinchilla velligera* Prell, 1934a, rather than *Mus laniger* G. I. Molina, 1782 (as used by Tate 1935:359; Ellerman 1940:227; and Cabrera 1961:566, for example) or *Chinchilla lanigera* Bennett, 1829 (as used by Woods and Kilpatrick 2005). Osgood’s reasons were fivefold: (1) *Mus laniger* G. I. Molina was clearly based on a composite because Molina “confounded the true chinchilla, the mountain viscacha, the chinchilla rat [= *Abrocoma*], and perhaps the degu (*Octodon*)” (p. 409), and thus its designation as the type of the genus “is unjustified not only because it is unidentifiable but also because it was a ‘species inquirendae’” (p. 410); (2) that *Eriomys chinchilla* Lichtenstein, 1830, while valid for the Peruvian form, was “not available as type of the genus *Chinchilla*, in spite of the tautonymy, and in spite of its priority” (p. 410) because “the type *must have a name based on the animal described by Bennett*, that is, the Chilean form as at present understood” [italic in the original] (p. 410); (3) that *Cricetus chincilla* [sic] G. Fischer, 1814, cannot be used as it was proposed only as a substitute name for *Mus laniger* G. I. Molina, which itself is unidentifiable; (4) that “*Chinchilla lanigera* as used by Bennett is, at best, also to be regarded as a substitute for *Mus laniger*, and, although it is not an exact homonym, *any attempt to give it status with Bennett as author is likely to be futile*” [italic ours] (p. 410); and (5) that the Chilean chinchilla had no other name subsequently applied to it until Prell (1934a:100) used *Chinchilla velligera* and stated plainly that the name was intended to apply to the animal described by Bennett. Osgood thus argued that Prell’s name is the only one that provided what he considered the requirements for a type for the genus if *Mus laniger* G. I. Molina was removed from consideration.

S. Anderson (1997:474) acknowledged that Molina’s *laniger* could be rejected as a dubious name of uncertain synonymy, and used *Eriomys chinchilla* Lichtenstein as the type for Bennett’s *Chinchilla*. He stated that the type locality of Lichtenstein’s taxon was actually uncertain, said to be Peru by Prell (1934a) and Osgood (1941) or to be uncertain but perhaps Chile by G. M. Allen (1942). Thus, without explicitly stating so, Anderson’s action indicated that the second objection raised by Osgood (1941; point 2, above) was invalid.

Finally, and most recently, Spotorno, Zuleta et al. (2004) gave the type species as *Mus laniger* G. I. Molina, arguing that Molina’s *laniger* was neither ambiguous nor unidentifiable and that Bennett’s emendation of *laniger* to the feminine *lanigera* was incorrect, as *laniger* “is perfectly acceptable as a noun in apposition” (p. 6). These authors then cited J. P. Valladares and Spotorno (2003:Case 3278) as a petition submitted to the International Commission on Zoological Nomenclature to conserve Molina’s name, although they stated that “the petition is not yet published, and the Commission has not rendered an opinion.” In response to this petition, however, the Secretariat answered by letter to Spotorno that it “is not necessary to refer to the Commission to resolve these problems, because the genus-group name *Chinchilla* Bennett (1829) appears to be the oldest available name for the taxon and as such is the valid name (Article 23 of the Code). Also, the different genus-group referable to it does not need to be suppressed for absolute tautonymy (Article 68.4 of the Code) or for junior subjective synonym of *Chinchilla* (Article 23 of the Code).” The logical extension of the Secretariat’s response is that, if Bennett’s *Chinchilla* is valid, then his species-group name *C. lanigera* is also valid.

KEY TO THE SPECIES OF *CHINCHILLA*:

1. Body size small (head and body length <260mm); ears short (<32mm) and more rounded; and tail long (>130mm) *Chinchilla lanigera*
- 1'. Body size larger (head and body length >320mm); ears longer (>45mm) and less rounded; and tail short (<100mm) *Chinchilla chinchilla*

Chinchilla chinchilla (Lichtenstein, 1830)

Short-tailed *Chinchilla*

SYNONYMS:

Chinchilla chinchilla chinchilla: Osgood, 1943b:136; name combination.

Chinchilla chinchilla boliviana: Osgood, 1943b:136; name combination.

Chinchilla brevicaudata boliviana: Cabrera, 1961:567; name combination.

Chinchilla brevicaudata brevicaudata: Cabrera, 1961:567; name combination.

[*Chinchilla chinchilla*] *brevicauda* Woods and Kilpatrick, 2005:1550; incorrect subsequent spelling of *Chinchilla brevicaudata* Waterhouse.

DESCRIPTION: Distinguishable from *C. lanigera* by larger size (head and body length >320 mm) and both shorter ears (<32 mm) and tail (<100 mm). Modal number of caudal vertebrae 20 (Grau 1986). Otherwise, two species apparently share same overall external and craniodental traits. Prell (1934a) stated that Peruvian (*chinchilla* or *brevicaudata*) and Bolivian (*boliviana*) forms differed only slightly in color.

DISTRIBUTION: *Chinchilla chinchilla* was historically known from the coast and Andes of central Peru (Tschudi 1845) south through the highlands of west-central Bolivia (S. Anderson 1997), northern Chile (Spotorno, Valladares, Marín et al. 2004), and adjacent northwestern Argentina (Osgood 1943b; Barquez, Díaz, and Ojeda 2006). Based on information gleaned from local informants, Cajal and Bonaventura (1998) believed that relictual populations remain in the northwestern Argentinean provinces of Catamarca, Jujuy, and Salta. M. M. Díaz and Barquez (2007) recorded specimens from the highlands of Jujuy province, but failed to find any extant populations during their five years of fieldwork, although Chebez (1994) stated that a Provincial Reserve had been established for the species. Chilean populations were thought to be extinct due to overexploitation by 1953 (J. E. Jiménez 1996), but have since been rediscovered in the highlands of Antofagasta (Spotorno, Zuleta et al. 1998; Cortes et al. 2003; Spotorno, Valladares, Marín et al. 2004). Bolivian populations may be extinct, as the most recent specimen was collected in 1939 (S. Anderson 1997). Eisenberg and Redford (1999) stated

that the last Peruvian specimens had been taken more than 50 years ago, and Pacheco (2002) considered the species to be extinct in the wild in Peru. However, the Royal Ontario Museum has a single specimen collected in 1984 at a restaurant in Cerro de Pasco east of Lima (ROM 91301; identification verified by Judith Eger, pers. comm.). It is unclear if this animal came from a nearby natural population or might have been from a captive colony, but the possibility that an extant population remains in the remote highlands of central Peru is noteworthy nevertheless. J. E. Jiménez (1996) provided a generalized map of the presumed historical distribution.

SELECTED LOCALITIES (Map 398): ARGENTINA: Jujuy, Abra Pampa (M. M. Díaz and Barquez 2007), Susques (Cajal and Bonaventura 1998); Salta, Los Andes (R. A. Ojeda and Mares 1989), Socompa (R. A. Ojeda and Mares 1989). BOLIVIA: Cochabamba, mountains near Chuquecamata (S. Anderson 1997); La Paz, Frankfurt, at border with Chile, Bolivia, and Peru (S. Anderson 1997). CHILE: Antofagasta, Calama (AMNH 137276), El Laco, 56 km SW of Socaire (Spotorno, Valladares, Marín et al. 2004), Lullaillaco (Spotorno, Valladares, Marín et al. 2004); Arica y Parinacota, Parinacota (USNM 391825); Atacama, Laguna Santa Rosa (F. Valladares et al. 2012), Quebrada Piedras Lindas, Parque Nacional Nevado Tres Cruces (F. Valladares et al. 2012). PERU: Pasco, Cerro de Pasco (ROM 91301).

SUBSPECIES: Brass (1911) distinguished populations from Bolivia and Chile as a subspecies (*boliviana*) separate from the nominal form from Peru. However, given the difficulty in establishing species boundaries, we agree with S. Anderson (1997) that delineating subspecies is probably more confusing than it is useful. Thus, we regard *C. chinchilla* to be monotypic until adequate studies of geographic variation are undertaken and published.

NATURAL HISTORY: Little information is known about the ecology or population biology of this species, with none known for Peruvian or Bolivian localities. In Peru, before most populations were exterminated by overexploitation for fur or meat, *C. chinchilla* was reported as abundant, ranging from the coast near Lima to elevations as high as 11,000 feet (Osgood 1943b:135; quoting from Tschudi 1845) and Walle (1914) made similar comments about Bolivian populations in La Paz, Oruro, and Potosí departments. Walle (1914:370), however, noted “the extinction of the species will only be a matter of time if measures are not taken to preserve it.” In Argentina, García Fernández et al. (1997) and Barquez, Díaz, and Ojeda (2006) listed conservation status as “in critical danger” due to overexploitation. In Chile as well, *C. chinchilla* is regarded as in risk of extinction (Cofré and Marquet 1999; SAG 2000), although a few populations have been

rediscovered in Antofagasta (II Región) where it lives at elevations between 3,400 and 5,000m (Muñoz-Pedreros and Yáñez 2000; Tirado et al. 2012). Tirado et al. (2012) reported that individuals in Parque Nacional Llullaillaco at 3,400m were herbivorous, consuming primarily bunch grass (*Stipa chrysophylla*) and secondarily shrubs of the genus *Adesmia* (Papilionaceae). As an adaptation to high elevations, this species has a higher hemoglobin oxygen affinity (P50 at 23.3 ± 0.06 mm Hg) than that of the coastal *C. lanigera* (27.7 ± 0.03 mm Hg; Ostojic et al. 2002). It is also well adapted to the low water and food availability at these extreme elevations, as basal metabolic rate, thermal conductance, and the energetic cost for maintenance of water balance were each lower than predicted from body size (Cortés et al. 2003). Spotorno, Zuleta et al. (1998) argued that the short ears and tail of *C. chinchilla* are external adaptations to the cold environments in which these animals occur.

Map 398 Selected localities for *Chinchilla chinchilla* (●); questionable locality in central Peru shown as disjunct from contiguous range. Contour line = 2,000m.

REMARKS: Many authors who recognized more than a single species of *Chinchilla* have used and continue to use *brevicaudata* Waterhouse, 1848 as the name for the Short-tailed Chinchilla (e.g., E.-L. Trouessart 1897, 1904; Cabrera 1961; Woods 1993; Barquez et al. 2006; M. M. Díaz and Barquez 2007). It seems clear, however, that Lichtenstein's earlier name *chinchilla*, with its type locality in Peru, has priority (see Osgood 1943b; S. Anderson 1997; Woods and Kilpatrick 2005). S. Anderson (1997:475) listed *Chinchilla intermedia* Dennler, 1939, as a synonym of *C. chinchilla*, citing Cabrera (1961) and without having seen Dennler's paper. The reference that Anderson cited (p. 529), and stated to come from Prell (1934a:103), was a paper by Dennler published in 1934 regarding the European fur trade and farm breeding of chinchillas, with no mention of the name *C. intermedia*. Rather, as noted by Prell (1934a:102–103), Dennler referred only to the common names given in the fur trade, "chinchilla cordillerana" in South America and "chinchilla Indiana" in Europe. Cabrera (1961:567) cited a second Dennler paper published in another source as "*Chinchilla intermedia* Dennler, Rev. Anim. Pelif., 2, 1939:95." We have been unable to locate either of these papers, and have not listed Dennler's apparent name in the synonymy above as a result.

The karyotype is completely biarmed, with $2n = 64$ and $FN = 128$ (Vidal-Rioja et al. 1973a, as *C. brevicaudata*).

Chinchilla lanigera Bennett, 1829

Chilean Chinchilla

SYNONYMS:

Mus Laniger G. I. Molina, 1782:301; type locality "Provincia Boreali del Chile" [= northern provinces of Chile]; given as "Coquimbo" by Osgood (1943b:134).

Cricetus laniger: É. Geoffroy St.-Hilaire, 1803:197; name combination.

L[emmus]. laniger: Tiedemann, 1808:476; name combination.

C[ricetus]. chincilla G. Fischer, 1814:55; type locality "Chile borealibus"; substitute name for *Mus laniger* G. I. Molina.

[Hypudaeus] ? laniger Illiger, 1815:108; *nomen nudum*; name given in a list of South American species and without a description.

Chinchilla lanigera Bennett, 1829:1; type locality "Coquimbo, Chile"; based on *Mus laniger* G. I. Molina.

Callomys laniger: d'Orbigny and Geoffroy St.-Hilaire, 1830:289; name combination.

Lagostomus laniger: F. Cuvier, 1830:plate 64; name combination.

Aulacodus laniger: Kaup, 1832:column 1211; name combination.

Chinchilla velligera Prell, 1934a:100; type locality “Chile-vom Rio Chuapa”; replacement name for *Mus lanigera* Bennett.

DESCRIPTION: As previously noted, *Chinchilla lanigera* differs from *C. chinchilla* by smaller body size (<260 mm), more rounded and longer ears (>45 mm), and longer tail (>130 mm; Spotorno, Zuleta et al. 2004). Modal number of caudal vertebrae 23 (Grau 1986). Otherwise, the two species share same external and cranio-dental traits that characterize genus. This species exhibits reverse sexual dimorphism, with females substantially larger than males; wild animals, but smaller and less sexually dimorphic than domestic individuals, with mass averaging 412 g in wild-caught males, 422 g in wild-caught females (J. E. Jiménez 1990a) in contrast to weights up to 600 and 800 g, respectively, for two sexes in domestic stock (Neira et al. 1989).

DISTRIBUTION: The historic distribution included the hills and low mountains of coastal Chile, between 26° and 35°S latitude (Bennett 1835c; Spotorno, Zuleta et al. 2004). By the mid-nineteenth century, however, *C. lanigera* had been exterminated from latitudes south of 32° (Río Choapa, the type locality of *Chinchilla velligera* Prell) and north of 29°S latitude (Gay 1847; J. E. Jiménez 1990a,b). The two currently known natural populations are restricted to the region between 31° and 29°S latitude (Spotorno, Zuleta et al. 2004). An earlier report (E. P. Walker 1968) of populations as far south as 52° is apparently in error (Spotorno, Zuleta et al. 2004). Both J. E. Jiménez (1996) and Spotorno, Zuleta et al. (2004) map the presumed historical distribution.

SELECTED LOCALITIES (Map 399; known extant populations only, from Spotorno, Valladares, Marín et al. 2004): CHILE: Coquimbo, Illapel, 15 mi N of Aucó, La Higuera.

SUBSPECIES: *Chinchilla lanigera* is monotypic.

NATURAL HISTORY: Spotorno, Zuleta et al. (2004) reviewed the ecology, reproductive biology, physiology, and behavior of both wild and captive *C. lanigera*. The literature on captive animals is voluminous, covering virtually all aspects of form and function but especially reproductive anatomy and physiology as well as basic husbandry. Data from natural populations are very limited. The native range is within the barren, arid, and rugged areas of the transverse mountain chains in north-central Chile that connect the coastal ranges with the Andes, at elevations from 400 to 1,650 m. Here, rainfall is seasonal and limited, and the typical habitat is rocky or sandy substrates covered by plant communities that are a matrix of typical xeric species from the northern desert and mesic southern Mediterranean zones. Individuals shelter in crevices between rocks, in holes dug below rocks, or within large bromeliads (*Puya*

beteroniana; J. E. Jiménez 1990a). This species is social, living in colonies of up to 100 individuals (Albert 1900) or greater (J. E. Jiménez 1990a) that range in extent from 1.5 to >100 ha, usually on northfacing slopes. The natural population structure is viewed as a classic metapopulation, with frequent local extinction followed by recolonization of suitable habitat patches. Population density averaged 4.37 individuals per hectare and did not fluctuate between years of low and high precipitation (J. E. Jiménez et al. 1992). Natural predators include the Culpeo (*Lycalopex culpaeus*), which take all age classes, and the Magellanic Horned Owl (*Bubo magellanicus*), which preys mostly on the young (J. E. Jiménez 1993). Chinchillas are herbivores that feed on a wide range of plant species, mostly grasses and forbs, with diet shifting both seasonally and annually (Serra 1979; Cortés et al. 2002).

Chinchillas are noted for being quiet and relatively shy but nevertheless quite active animals that ricochet across rocks with remarkable agility by use of their long hindlimbs. Individuals are highly philopatric, using conspicuous rocks within their home range for resting, as observation posts, and as latrines that advertise their presence. They keep their fur clean by sand or soil bathing (Stern and Merari 1969), repeatedly using the same small patch and thus leaving a barren circle of fine dust up to 40 cm in diameter near the entrance to their burrow.

The gestation period is 111 days (range: 105–118), based on captive animals, with litter size ranging from one to six but usually two or three (Neira et al. 1989). Lactation normally lasts six to eight weeks, and sexual maturity of both sexes is reached by eight months of age, on average (Weir 1974a). Reproduction in the wild apparently occurs during the winter (between May and November; Spotorno, Zuleta et al. 2004). The maximum recorded life span in the wild has been six years (J. E. Jiménez 1990a), but captive animals may live more than twenty years. Lammers et al. (2001) examined the ontogeny leading to sexual dimorphism in adults and Cortés, Rosenmann, and Bozinovic (2000a,b) examined the efficiency of water regulation by minimizing evaporative water loss and maximizing metabolic water production.

This species is highly endangered in the wild (Thornback and Jenkins 1982; Glade 1988), and has the second highest conservation priority among Chilean mammals (Cofré and Marquet 1999). Due to severe overharvesting for their valuable fur (Iriarte and Jaksic 1986), the species was nearly exterminated from the wild by the early 1900s (J. E. Jiménez 1996). J. E. Jiménez (1993) estimated the total wild population at only 2,500 to 11,700 individuals, with numbers apparently declining.

Chilean Chinchillas were initially domesticated for their valuable pelts but now are raised both for the pet trade

Map 399 Selected localities for *Chinchilla lanigera* (●). Contour line = 2,000 m.

(R. A. Webb 1991) and as laboratory animals, where they are used in auditory research (Heffner and Heffner 1991; L. Robles and Ruggero 2001).

REMARKS: For a discussion of whether *laniger* Molina or *lanigera* Bennett is the correct specific epithet to be applied to this species, see Remarks for the genus.

The karyotype is completely biarmed, with $2n = 64$ and $FN = 128$ (Makino 1953; Nes 1963; Hsu and Benirschke 1967).

Genus *Lagidium* Meyen, 1833

We recognize three species of *Lagidium*, one with an extensive distribution down the spine of the Andes, from southern Peru through Bolivia and northern Chile to central Argentina (*L. viscacia*, including *L. peruanum* which has been recognized by many authors as a valid species, both in the past and presently [e.g., Woods and Kilpatrick 2005; Ledesma et al. 2009]), a second from a small area in the mountains of west-central Argentina and adjacent Chile (*L. wolffsohni*), and a third, recently described from southern Ecuador (*L. abuacaense*). While multiple species names are available along the extended distribution of *L. viscacia*, hypotheses of species boundaries or geographic limits are lacking at the present time (see Remarks).

Externally, *Lagidium* is larger in body size than *Chinchilla*, with head and body length averaging 344 mm

(range: 322 to 405 mm) and mass 1.24 kg (range: 1.2 to 1.6 kg; Pearson 1948). Unlike *Chinchilla*, however, while females are slightly larger in average measurements than males, they are not significantly so. The tail is shorter than the head and body, although longer absolutely and proportionally than in *Chinchilla*, averaging about 78% of the body length. Coarse, pale hairs form a crest along the top of the tail and are sharply demarcated from the shorter, finer dark hairs along the bottom. The tip of the tail varies from black to red-brown. As with *Chinchilla*, the fur is thick and soft, comprised of dense tufts that contain a dozen or so individual hairs; the sparse guard hairs have slender shafts and stout tips. Pearson (1948) noted that adult coloration of populations from southern Peru he called *L. peruanum* was unusually variable, with specimens in the same local population ranging from creamy buff over the entire back to a dark grizzled gray. The venter is always paler than the back, gray washed with buffy yellow. Buff or orange fur usually covers the rump and upper thighs, and there may be axillary and inguinal patches of white. The palms and soles are naked and black, but the backs of both forefeet and hindfeet are furry, usually quite pale or even white. The ears are gray, or gray-brown, fringed with pale gray or white hairs. The darkest region is over the rump, and a narrow, dark, mid-dorsal line running up to the shoulder region is frequently present. The ears are large. The hindfeet are narrow with four digits, with digit V extremely short. The forefeet have four digits. All digits terminate in short, curved claws dwarfed by enlarged toe pads. The tail is longer absolutely and proportionally than in *Chinchilla*, though typically less than 50% of the head and body length, well furred, and terminates in a black tip that is characteristically curled dorsally. Females of *L. peruanum* have a single pair of mammae, located on the side of the thorax (Pearson 1949).

The skull is narrow, with a long rostrum. The interorbital region is broad, with weakly developed postorbital processes of the frontals that tend to be depressed between the orbits. The braincase is flat and rounded, with no sagittal ridge and only weakly developed parietal ridging. The bullae are enlarged, with the mastoid portion visible on the dorsal surface of the skull, but not to the degree as in *Chinchilla*, and not extending posterior to the occiput. Thus, the interparietal is wider than it is long, in contrast to the condition in *Chinchilla*. The paroccipital processes are longer than in *Chinchilla*, not in intimate contact with the bullae but curved to conform to the shape of the tympanic portion. The jugal is broad and in contact with the lacrimal anteriorly. The floor of the infraorbital foramen is smooth, lacking a canal indicative of nerve passage. Incisive foramina are long and narrow, but occupy only about 60% of the diastemal length. The anterior palate is greatly

restricted between the premolars, with the horizontal distance less than 25% of that between the last molars. The mandible is similar to that of *Chinchilla*, with elongated and narrowed angular processes and a weakly developed ridge lateral to the reduced coronoid process for muscle attachment.

The cheek teeth each have three, distinctly curved rather than straight, laminae, particularly so in M3. In the maxillary series the third plate of each tooth is shorter than the other two, with that of M3 forming a posteriorly pointed heel. In the mandibular series, the first plate of each tooth is reduced relative to the median and posterior plates.

SYNONYMS:

Lepus: G. I. Molina, 1782:307; part (description of *viscacia*); not *Lepus* Linnaeus.

Viscaccia Oken, 1816:835; part (a composite based on *Lepus chilensis* Oken, the “*le vizcache*” of Azara [1801], and *Mus laniger* G. I. Molina [see J. A. Allen 1902c:196]); ruled a synonym of *Lagidium* Meyen (ICZN 1925) and an unavailable name (ICZN 1956).

Callomys d’Orbigny and Geoffroy St.-Hilaire, 1830:282; part (description of *aureus*); a composite genus with no type species selected.

Lagidium Meyen, 1833:576; type species *Lagidium peruanum* Meyen, by monotypy (recommended for legalization by fiat, instead of *Viscaccia* Oken, by Thomas [1914g:285; see also Thomas 1924g:347], with *Lagidium* Meyen officially adopted in preference to *Viscaccia* Oken [ICZN 1925:Opinion 90; ICZN 1929:Opinion 110]).

Lagotis Bennett, 1833:58; type species *Lagotis Cuvieri* Bennett, by monotypy; not *Lagotis* Desmarest, a junior synonym of *Pedetes* Illiger (Palmer 1904).

REMARKS: Oken (1816:835) erected *Viscaccia*, based both on *Lepus chilensis* (a replacement name for Molina’s *Lepus viscacia*) and *Mus laniger* G. I. Molina, a composite but a name that is associated with *Chinchilla* (see Remarks for that genus). *Viscaccia* Oken has often been associated with the mountain viscachas (e.g., E.-L. Trouessart 1897; Thomas 1907a). J. A. Allen (1902c), however, argued that, because Molina’s *Lepus chilensis* was based wholly on “*le vizcache*” of Azara (1801), which is the Plains Viscacha, *Lagostomus* (see that account), Oken’s *Viscaccia* applied to *Lagostomus* rather than *Lagidium*. Initially the International Commission (ICZN 1925:Opinion 90) ruled “*Lagidium* Meyen, 1833, type species *Lagidium peruanum* Meyen, is adopted in preference to *Viscaccia* Oken, 1816, genotype ‘*Lepus chilensis* G. I. Molina.’” Subsequently, the ICZN (1929:Opinion 110) suppressed *Viscaccia* for the purpose of Priority but not of Homonymy and then, in Opinion 417 (ICZN 1956), rejected Oken’s entire *Lehrbuch* (Vol.

3) for nomenclatural purposes, and thus making the generic association of his *Viscaccia* moot.

Lagidium Meyen and *Lagotis* Bennett were both proposed in 1833, the former in March of that year and the latter initially read before the Zoological Society of London in May. Bennett, however, asserted (1835a:492; 1835c:492) that his *Lagotis* should have priority as it was “characterized by me . . . at a Meeting of the Committee of Science and Correspondence [of the Zoological Society of London] in June 1832, and the name then given was affixed, through the life of the individual, to the cage in which the Society’s animal was kept.” Despite Bennett’s protestations to the contrary, however, *Lagotis* as a valid name stems from its first appearance in the published literature, two months after Meyen’s *Lagidium* (see Wiegmann 1835:204). Furthermore, *Lagotis* Bennett is preoccupied by *Lagotis* Desmarest (based on a manuscript name of M. de Blainville), a junior synonym of *Pedetes* Illiger (Tate 1935:361).

Callomys d’Orbigny and Geoffroy St.-Hilaire is a composite genus clearly based on species now placed in both *Lagostomus* (*Callomys viscacia*) and *Chinchilla* (*Callomys laniger*), but also a third species, *Callomys aureus*, based on furrer’s skins without feet, ears, or tail that Bennett (1833:59) considered a questionable synonym of *Chinchilla lanigera* and Tate (1935:360) thought might well represent a *Lagidium*. E.-L. Trouessart (1897:627) listed *aureus* as a synonym of *Lagidium peruanum* Meyen. Even so, *Callomys* as a genus is indeterminate and *C. aureus* as a species is as well.

The genus *Lagidium* is in need of a revision that incorporates analyses of adequate geographic samples for both morphological and molecular character variation. The poorly delineated species boundaries are highlighted by the various published opinions, all of which lack substantive character analyses.

Thomas (1907a:441) reviewed the characters and distribution of the species named during the nineteenth century, referring all to the genus *Viscaccia*, as follows: *viscacia* G. I. Molina, a “large deep gray animal from the Chilean Andes,” *cuvieri* Bennett and *pallipes* Bennett, both “referable to a strongly yellowish form found in Northern Chile,” and *peruana* Meyen, which “I cannot certainly identify.” He then described 10 additional species as new. In 1914, Thomas (p. 285) reversed his earlier opinion and advocated use of *Lagidium* over *Viscaccia*. He subsequently described seven additional species between 1919 and 1926 (*lockwoodi* [1919d], *vulcani* [1919f], *famatinae* [1920g], *boxi* [1921c], *tontalis* and *viatorum* [1921i], and *sarae* [Thomas and St. Leger 1926b]), each largely known only from one or a few specimens and from their respective type localities. Ellerman (1940:230–231) cited R. W. Hayman, who examined all specimens in the British Museum and believed that the

21 named forms could be grouped readily into four species: *L. viscacia* (with *lutea*, *cuscus*, *perlutea*, *vulcani*, *tucumana*, *lockwoodi*, *famatiniae*, *tontalis*, *viatorum*, and *moreni* synonyms), *L. peruanum* (including *pallipes*, *inca*, *subrosea*, *saturata*, *punensis*, and *arequipae*); *L. boxi* (including *sarae*); and *L. wolffsohni*, which he stated (p. 231) “differs clearly in colour pattern from all the remainder.” Osgood (1943b) placed all Chilean and Argentinean taxa within a polytypic *L. viscacia*, but did not comment on those taxa described from Bolivia or Peru. Cabrera (1961) recognized three species, the polytypic and broadly ranging *L. peruanum* and *L. viscacia* and the monotypic *L. wolffsohni* with a limited range in Santa Cruz, Argentina. S. Anderson (1997) recognized a single species in Bolivia (*L. viscacia*) even though he mapped localities only minimally distant from those of *L. peruanum* from the adjacent Altiplano of Peru. Similarly, Pacheco et al. (2009) applied *L. viscacia* to Peruvian records, noting the imprecise definition of this species and difficulty in delimiting *L. peruanum*. Woods and Kilpatrick (2005) followed Cabrera in their recent taxonomic compilation of the genus, and recognized three species (*L. peruanum*, *L. viscacia*, and *L. wolffsohni*). Finally, Ledesma et al. (2009) described a new species, unexpectedly encountered in southern Ecuador (see Werner et al. 2006).

It is impossible at the present time to either effectively diagnose species or to map their ranges with any certainty, much less to sort the plethora of available names to one “species” or another, except by the geographic proximity of their respective type localities. Only Thomas (1907a), when he described 10 new “species,” and R. W. Hayman, when he “looked through the considerable British Museum material with a view of getting the twenty-one ‘distinct species’ in this genus into some sort of revision” (in Ellerman 1940:230), had examined a broad spectrum of specimens and named forms at one time. Hayman placed considerable weight on overall size and coloration, particularly the distinctness of the dorsal stripe, in establishing his groups. However, as Pearson (1948:346) noted, “the color of specimens from a single locality is extremely variable [including the dorsal stripe] and changes considerably with age—facts not fully realized by Thomas when he described five full species from Peru (see especially Thomas 1907a) and three from adjacent Bolivia.” Moreover, in some cases, Hayman’s allocation of names to his “species” severely conflicted with geography (i.e., his linkage of *pallipes* to *L. peruanum*, even as a possible synonym of *L. p. peruanum* from southern Peru [Ellerman 1940:231], when the type of Bennett’s *pallipes* came from far to the south, in Mendoza province, Argentina [see Osgood 1943b:138–139]). These conflicts only highlight Pearson’s (1948) caution about intralocality variation not to mention the complete lack of any substantive geographic analyses of any kind,

for any character. Even the limited mitochondrial sequence data available (Spotorno, Valladares, Marín et al. 2004; Ledesma et al. 2009) has so far failed to resolve species boundaries although it offers hope as more samples are added. However, if the general clade structure obtained by these authors is upheld by additional work, then both the number of species and the names applied to each will substantially change, as will the geographic limits of each species so defined. For example, the recent analysis of Ledesma et al. (2009) recovered six clades that together formed a basal polytomy with nearly equivalent levels of divergence (maximum 9%). These clades included (1) the single specimen of *L. abuacaense* from Ecuador, (2) two specimens assigned to *L. viscacia perlutea* from Bolivia and northern Argentina, (3) *L. viscacia boxi* (from Neuquén, Argentina) plus *L. wolffsohni*, (4) *L. viscacia viscacia* from north-central Chile, (5) *L. peruanum* from northern Chile, and (6) *L. peruanum* from southern Peru. Only clades 5 and 6 share limited sister-group support.

Herein, we take a conservative position and recognize only a single, widely ranging and likely polytypic species, *L. viscacia* (including *L. peruanum* and *L. boxi*), and two highly localized, peripheral isolates, the southern *L. wolffsohni*, despite the fact that it is apparently nested phylogenetically within *L. viscacia*, and the northern *L. abuacaense*. As we noted earlier, with additional molecular sampling targeted both to type localities and to infill geographic lacunae, the resolution of species limits and the applicability of available names to each will certainly redefine taxonomic diversity in the genus. Fortunately, *Lagidium* has not been exploited to the degree as has *Chinchilla*, and sufficient natural populations remain that can be sampled.

KEY TO THE SPECIES OF *LAGIDIUM*:

1. Body size larger (head and body length >470 mm); dorsal coloration rich brownish slate; mid-dorsal dark stripe weakly developed; ears short with black outer and lighter inner surfaces; distribution limited to southern Argentina and adjacent Chile *Lagidium wolffsohni*
- 1'. Body size smaller (head and body length ranges from 360 to 425 mm); dorsal coloration highly variable, from creamy buff to dark gray; mid-dorsal dark stripe usually well developed; distribution from southern Ecuador to northern Argentina and Chile 2
2. Dorsal color dark gray; dorsal surface of feet blackish; ears short (ca. 60 mm) and black on both surfaces; least interorbital breadth of skull narrow (ca. 16.5 mm); rostrum broad (ca. 16.2 mm); braincase flat; known only from southern Ecuador *Lagidium abuacaense*
- 2'. Dorsal color highly variable, but typically buff to dark gray; dorsal surface of feet pale, not black; ears longer

(>65 mm, on average); broader interorbital breadth (>16.8 mm); narrower rostrum (<14 mm); braincase more elevated; broad range from central Peru to central Chile and Argentina *Lagidium viscacia*

Lagidium ahuaense Ledesma, Werner, Spotorno, and Albuja, 2009

Ecuadorean Viscacha

SYNONYM:

Lagidium ahuaense Ledesma, Werner, Spotorno, and Albuja, 2009:47; type locality “Cerro El Ahuaca, Parroquia Cariamanga, Canton Calvas, Loja Province, Ecuador (04°18'2"S, 79°32'47"W).”

DESCRIPTION: Medium sized for genus, head and body length of holotype 403 mm. Dorsal color brownish-gray dorsal; ventral color yellowish gray; ears blackish with cream-colored fringes; forefeet and hindfeet bear black hairs dorsally; palms and soles naked and blackish in color. Dorsally, tail with long and coarse hairs, maroon with some cream in color; ventral surface of tail clothed in short, blackish-brown hairs; tail tip clothed in long hairs. Vibrissae mostly black, with mystacial vibrissae thick and long (up to nearly 150 mm), superciliary vibrissae scarce but thick, and single genal vibrissa present.

In comparison with other species, *L. ahuaense* darker than average specimen of *L. viscacia* and of *L. wolffsohni*. Skull, in dorsal view, with more pronounced convex premaxillofrontal sutures, wider rostrum and narrower interorbital constriction, less arched braincase, more robust jugal; in ventral view, mesopterygoid fossa with more parallel sides and somewhat narrower basioccipital, constricting space between bullae.

DISTRIBUTION: *Lagidium ahuaense* is known only from the type locality in the Cerro El Ahuaca, a steep granite peak about 1 km from the town of Cariamanga. Here, the species inhabits the full elevational extent of the peak (1,950–2,480 m).

SELECTED LOCALITIES (Map 400): ECUADOR: Loja, Cerro El Ahuaca (type locality of *Lagidium ahuaense* Ledesma, Werner, Spotorno, and Albuja).

SUBSPECIES: *Lagidium ahuaense* is monotypic.

NATURAL HISTORY (available data from Werner et al. 2006): Individuals at the type locality of Cerro Ahuaca are restricted to the immediate vicinity of extensive rocky surfaces, on a steep cliff face (varying from a 40° to 80° incline) at 2,450 m, where a small colony of individuals (at least two adults and one juvenile) was observed and photographed. The vegetation is classified as dry montane scrub (Sierra 1999), with the surrounding area heavily deforested in recent decades. Observations suggested that individuals are timid and stay close to their den entrance, which was placed in a deep rock crevice on

Map 400 Single known locality for *Lagidium ahuaense* (●). Contour line = 2,000 m.

an 80° slope. The viscacha at Cerro Ahuaca was unknown to the local people.

REMARKS: This species is known only from the holotype as a preserved specimen. Werner et al. (2006) published a color photograph of a living individual.

Lagidium viscacia (G. I. Molina, 1782)

Mountain Viscacha

SYNONYMS:

Lepus viscacia G. I. Molina, 1782:307; no type locality given; restricted to “Chilean Andes; cordillera of Santiago” (Osgood 1943b:137).

Lepus viscaccica Brandis, 1786:272; unjustified emendation of *viscacia* G. I. Molina.

Callomys aureus d’Orbigny and Geoffroy St.-Hilaire, 1830:291; no type locality given; *nomen dubium* (Bennett 1833; Tate 1935).

Lagidium peruanum Meyen, 1833:578; type locality “Es lebt auf den Hoch-ebenen Perus, stets über die Höhe von 12 bis 13000 Fuss hinaus” (= high plateau, Peru, altitude, 12,000 to 13,000 feet), probably Pisacoma, Puno, Peru (Pearson 1948:346, citing pers. comm. from C. C. Sanborn).

Lagotis Cuvieri Bennett, 1833:59; no type locality given; “purchased, in June 1832, from a dealer, who was completely ignorant of the locality from which it was originally obtained” (Bennett 1833:59).

Lagotis pallipes Bennett, 1835b:67–68; type locality “in Chiliae montosis,” actually from Mendoza province,

- Argentina, "at an elevation of 4000 to 5000 feet, between Villavicencia [= Villavicencio] and Uspallata" (Bridges 1843:132; see also Osgood 1943b:138–139).
- Lagidium Cuvieri*: Wagner, 1843a:306; name combination.
- Lagidium pallipes*: Wagner, 1843a:308; name combination.
- Lagidium lutescens* Philippi, 1896:8, plate II, Fig. 2, plate III, Fig. 5; type locality "provincia Tarapacá inter Copacoya et Inocaliri, nec non ad Socaire prope oppidum Atacama," Chile.
- Lagidium crassidens* Philippi, 1896:10; no type locality given.
- Lagidium crinigerum* Philippi, 1896:10, plate III, Fig. 2; no type locality given.
- [*Lagidium*] *pallipes*: E.-L. Trouessart, 1897:627; name combination.
- Lagidium Moreni* Thomas, 1897b:467; type locality "Chubut, Patagonia," (stated [p. 466] to have been obtained "in the hills near Chubut Eastern Patagonia," but subsequently considered as "unknown, as 'Chubut' is a province of considerable size, and there is no evidence as to where in it the specimen was obtained" [Thomas 1921c:181]), Argentina.
- Viscaccia viscaccia* Thomas, 1907a:441; name combination and incorrect subsequent spelling of *viscacia* G. I. Molina.
- V[*iscaccia*]. *Cuvieri*: Thomas, 1907a:441; name combination.
- V[*iscaccia*]. *pallipes*: Thomas, 1907a:441; name combination.
- V[*iscaccia*]. *peruana*: Thomas, 1907a:441; name combination.
- Viscaccia inca* Thomas, 1907a:442; type locality "Incapirca, Zeziro," Junín, Peru.
- Viscaccia arequipae* Thomas, 1907a:442; type locality "Sumbay, near Arequipa. Alt. 4000 m," Arequipa, Peru.
- Viscaccia subrosea* Thomas, 1907a:442; type locality "Galera, W. of Oroya, Dept. Lima. Alt. 4800 m," Peru.
- Viscaccia saturata* Thomas, 1907a:442; type locality "Limbane [= Limbani], Inambari, Dept. Puno. Alt. 3500 m," Peru.
- Viscaccia punensis* Thomas, 1907a:443; type locality "Puno, Lake Titicaca. Alt. 3800 m," Puno, Peru.
- Viscaccia cuscus* Thomas, 1907a:443; type locality "Paratani, [Cochabamba,] Bolivia (about 66° W., 17° 5' S.). Alt. 2600 m."
- Viscaccia lutea* Thomas, 1907a:443; type locality "Esperanza, [near Mt.] Sahama, [La Paz,] Bolivia. Alt. 4000 m."
- Viscaccia perlutea* Thomas, 1907a:443; type locality "Pampa Aulliaga, [Oruro,] Bolivia (67°W., 19° 30' S.). Alt. 3800 m."
- Viscaccia tucumana* Thomas, 1907a:444; type locality "Cumbre de Mala-Mala, Sierra de Tucuman. Alt. 3000 m," Tucumán, Argentina.
- Lagidium lockwoodi* Thomas, 1919d:499; type locality "Otro Cerro, North-eastern Rioja," a ranch at the southern end of the Sierra de Ambato, Catamarca, Argentina (Pardiñas et al. 2007).
- Lagidium tucumanum*: Thomas, 1919f:133; name combination.
- Lagidium vulcani* Thomas, 1919f:133; type locality "Cerro Casabindo, 4800 m," Jujuy, Argentina.
- Lagidium famatinae* Thomas, 1920g:421; type locality "La Invernada, in the northern half of the chain, about 35 km. north of the mountain 'Nevada de Famatina,' and situated at an altitude of about 3800 m," La Rioja, Argentina.

Lagidium viscaccia sumuncurensis Crespo, 1963:61; type locality "Campana Mahuida, depot. Valcheta, Río Negro, Argentina, 700 m."

DESCRIPTION: As for genus, and as distinguished from *L. abuacaense* and *L. wolffsohni* in those accounts.

DISTRIBUTION: *Lagidium viscaccia* occurs along the spine of the Andes from central and southern Peru, western Bolivia, northern to central Chile, and northwestern and western Argentina as far south as Chubut province (42°S latitude). Osgood (1943b) considered the Mountain Viscacha to be the only Chilean mammal definitively characteristic of his Puna Zone, that region above timberline and below snowline. The species ranges from 700 m in Río Negro province, Argentina, to above 4,800 m in the mountains from central Peru through Bolivia, Chile, and northwestern Argentina. Pearson (1951) recorded the species as confined almost entirely to the Altiplano in Peru, but subsequently (Pearson 1957) described a population in the fog-shrouded hills (*lomas*) near Lima in central Peru at an elevation of 2,200 ft elevation (ca. 670 m). In northwestern Argentina, the species is restricted to Puna habitat, but at middle and southern latitudes within the country it is found in pre-Puna and Patagonian steppe (R. A. Ojeda and Mares 1989; Barquez, Díaz, and Ojeda 2006).

SELECTED LOCALITIES (Map 401): ARGENTINA: Catamarca, Otro Cerro (type locality of *Lagidium lockwoodi* Thomas); Chubut, El Hoyo (LACM 59595); Jujuy, Cerro Casabindo (type locality of *Lagidium vulcani* Thomas); La Rioja, La Invernada (type locality of *Lagidium famatinae* Thomas); Mendoza, between Villavicencio and Uspallata (type locality of *Lagotis pallipes* Bennett), Puesto El Peralito, Malargüe (R. A. Ojeda and Mares 1989); Neuquén, Piño Hachado (type locality of *Lagidium sarae* Thomas and St. Leger); Río Negro, Campana Mahuida (type locality of *Lagidium viscaccia sumuncurensis* Crespo), 40 mi S of Maquinchao (MCZ 19222), Pilcaniyeu (type locality of *Lagidium boxi* Thomas); Salta, Chorrillos (R. A. Ojeda and Mares 1989); San Juan, Los Sombreros, Sierra Tontal (type locality of *Lagidium tontalis* Thomas); Tucumán, Cumbre de Mala-Mala, Sierra de Tucumán (type locality of *Viscaccia tucumana* Thomas). BOLIVIA: Chuquisaca, 6 mi NE of Tarabuquillo (CAS 14848); Cochabamba, Altamachi (USNM 271426), 9.5 km by road SE of Rodeo (AMNH 260946); La Paz, 10–15 km N of Achacachi (USNM 271392), 1 km W of pass between Antequilla and Pelehuco (MVZ 164778), border of Chile, Bolivia, and Peru (S. Anderson 1997), Esperanza (type locality of *Viscaccia lutea* Thomas), La Paz (S. Anderson 1997); Oruro, Pampa Auliaga (type locality of *Viscaccia perlutea* Thomas); Potosí, 9 km W of Villa Alota (S. Anderson 1997), Llica (S. Anderson 1997); Tarija, Tambo

(S. Anderson 1997). CHILE: Antofagasta, near Copacoya (type locality of *Lagidium lutescens* Philippi), 20 mi E of San Pedro (Osgood 1943b), Talabre (Spotorno, Valladares, Marín et al. 2004); Arica y Parinacota, Timar (USNM 391824); Atacama, Santa Rosa (Spotorno, Valladares, Marín et al. 2004); Coquimbo, Vicuña (Spotorno, Valladares, Marín et al. 2004); O'Higgins, Sewell (Osgood 1943b). PERU: Apurímac, Grau, Virundo (MUSM 2212); Arequipa, Sumbay (type locality of *Viscaccia arequipae* Thomas); Ayacucho, 15 mi WNE of Puquio (MVZ 138147); Cusco, Laguna Sibinacocha (MUSM 17553), Ocobamba Pass (USNM 194467); Junín, 20 km E of Lurin (MVZ 137762); Lima, Naña (Pearson 1957); Pasco, Chipa (AMNH 60576); Puno, Limbani (type locality of *Viscaccia saturata* Thomas), Pisacoma (type locality of *Lagidium peruanum* Meyen); San Martín, Pampa de Cuy, Parque Nacional Río Abiseo (MUSM 7889).

SUBSPECIES: Osgood (1943b) recognized seven subspecies that occurred, or might occur, in Chile; Crespo (1963) recognized five subspecies (including *wolffsohni*) in central and southern Argentina; and S. Anderson (1997) mapped the ranges of three subspecies in Bolivia. *Lagidium viscacia* is highly variable in color, body size, and tail length over its large range, as exemplified by the large number of “species” that were described in the early 1900s. Although variation can be extensive within populations and no assessment of geographic patterns has been made, it is highly likely that geographic units can and should be formally recognized as subspecies. At the moment, however, it is not possible to do so, as even the question as to whether the single species recognized here is composite or not remains an open issue. As a consequence, we make no effort to delineate infraspecific taxa within *L. viscacia* at the present time.

NATURAL HISTORY: This species has been studied extensively in the field in the Altiplano of southern Peru (as *L. peruanum*; Pearson 1948, 1949) and in the Patagonian step of Argentina (as *L. viscacia*; R. S. Walker et al. 2000, 2003, 2007, 2008; Galende and Raffaele 2012). In southern Peru the habitat is dry, mountainous country above 3,800 m, with sparse vegetative cover composed mostly of bunch grasses (*Stipa* and *Festuca*) and short *tola* shrubs (predominantly *Lepidophyllum*, *Baccharis*, and *Senecio* [Asteraceae]), and where viscachas “may make his home any place . . . where there are rocks, water, and food—no rocks, no viscachas” (Pearson 1948:346). Preferred habitat was vast tumbles of boulders where crevices provide ready-made burrows, but animals were also found on steeply vertical cliffs or other rock faces as long as there are adequate crevices or narrow, stony tunnels to provide nesting sites. Animals are highly gregarious, living in colonies that may range widely in size (from 4 to 75 individuals), at an over-

all density of 0.4 individuals per acre (0.162 ha) because of the highly clumped distribution of occupied boulder fields. Each colony is composed of smaller groups consisting usually of two to five individuals; these groups appear to be families, although their composition does not remain constant throughout the year. Each “family” contains a mature male and female (presumably the parents) and one, two, or occasionally three young of different ages. The oldest male offspring may be sexually mature yet still living with the family. There is no defense of individual or family territories, and the entrances of different “family” dens may be only a few feet apart within the same colony. Individual viscachas occupy the same burrow for long periods. Wariness is a group as well as individual characteristic, and all individuals pay attention to the sharp alarm whistles of a single individual. They appear to rely most heavily on vision as the dominant sense. Lucherini et al. (2009) estimated relative abundance of Mountain Viscachas at multiple sites in northwestern Argentina using direct observations, pellet counts, and photographic camera “traps.”

Mountain viscachas are poor diggers with only small claws, so dens are within natural crevices or under boulder piles. The rare self-dug burrows, typically found under boulders in loose gravel or soil, probably require multiple individuals and perhaps multiple generations to construct. The presence of viscachas is readily detected by distinctive and copious fecal pellets that can be found throughout the colony, on top of rocks or in sheltered crannies. There is a tendency to use certain latrine areas where multiple generations may “build” fecal piles that occupy several square feet. Presence is also evident by occasional tufts of fur lodged in plants or among rocks, by *tola* bushes stripped of bark, and by the presence of beaten pathways between outcrops within the larger home range of a colony.

Unlike either Chinchillas or Plains Viscachas, *Lagidium* are diurnal, up by sunrise, often spending the initial hours of the day perched on sentinel boulders where they dress their fur and soak up heat from the morning sun. In the evening, they typically feed until dark or shortly thereafter, before returning to their shared burrows. They are herbivorous, specializing on green leaves, flowers, fruits, stems, and bark rather than dried plant materials, but eat a wide variety of plants in the local environment, so the range of plants available will differ considerably from one geographic region to another. They do not cache green vegetation for future use, but actively forage daily. Individuals descend from their boulder field or rocky cliff colonies to feed on the green vegetation where pools of melt water accumulate.

Predators detected by Pearson (1948) in Peru included the Culpeo (*Lycalopex culpaeus*), Lesser Grison (*Galictis cuja*), Puma (*Puma concolor*), and Andean Mountain Cat

(*Leopardus jacobitus*) as well as various avian raptors. Napolitano et al. (2008) found the remains of *L. viscacia* in the feces of both the Pampas Cat (*Leopardus colocolo*) and Andean Mountain Cat (*L. jacobitus*) in northern Chile. Mountain Viscachas are agile, quadrupedal bounders, like rabbits, with propulsion provided by their long hindfeet and limbs. Their “reckless, carefree bounds from rock to rock, or ledge to ledge” (Pearson 1948:360) and long stride of up to six feet makes them difficult to capture. Individuals are very vigilant and vocalize warning with a series of very high-pitched whistles. Both sexes whistle, and all individuals within the group will respond to the calls of a single animal. Different whistles may be given for aerial and terrestrial potential predators.

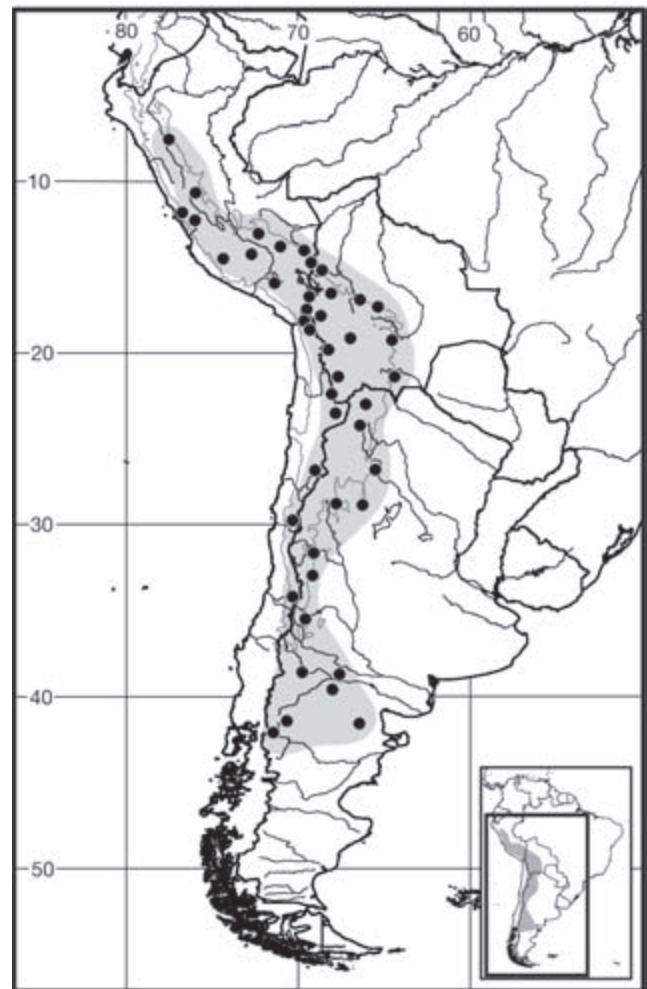

In southern Peru, the reproductive season begins in late October and extends through the “summer” months, with pregnant females taken in October, November, and December as well as July and August, but not in September or most of October. Females breed after they reach approximately 1 kg in mass and thus may have their first estrous the year that they are born. Males reach breeding condition at the same mass, or at about seven months of age; they are capable of breeding at all seasons thereafter and for the remainder of their life. A large vaginal plug is formed in the female tract after copulation. Ovulation occurs near the time of copulation, is almost always from the right ovary, with implantation thus nearly always in the right uterine horn. Gestation is approximately three months with a single, precocial young born at a birth weight of about 225 g. A postpartum estrus and pregnancy is possible, and a single female may have two to three litters per year. Lactation is limited in temporal duration to about one month, as the young are born alert, fully furred, and with open eyes at birth, and are capable of feeding on green vegetation immediately. Pearson (1948) described the ontogenetic molt and color change with age; there is no season molting pattern in adults, so that molting is likely continuous. Life expectancy of both sexes is equal, maximally two to three years.

Mountain Viscachas overlap with grazing/browsing artiodactyls, such as vicuñas, guanacos, and huemuls as well as with a number of small rodents, predominantly the sigmodontine genera *Abrothrix*, *Auliscomys*, *Chinchillula*, *Phyllotis*, and *Punomys*. Individuals typically host roundworms and tapeworms of the genus *Cittotania*, and ectoparasites such as lice of the genera *Gyropus* and *Philandesia*. Their use of dust-baths and the bristle-like combs on their hind toes help dislodge troublesome “boarders.”

Indigenous peoples of the Andes mixed viscacha hair with that of alpaca, vicuña, or other fibers to spin yarn for making exceedingly fine cloth, with viscacha hair provid-

ing color variety to the finished product. The use of viscacha fur or pelts for clothing, however, has been largely discontinued throughout their range. This species is, however, still used for food. Historically, however, Mountain Viscachas have not been persecuted by humans with the same fervor as have chinchillas, and as a result natural populations are still reasonably abundant throughout the long latitudinal range of the species. Current IUCN (2011) conservation status is in the “Least Concern” category.

Pearson (1957) recorded a colony at Naña, 2,200 ft [= 670 m] in the fog belt, or *lomas*, of the coastal desert in Lima department, Peru. These *lomas* are hilltops that support only clumps of fog-nourished *Tillandsia* (Bromeliaceae), where no vegetation occurs on the lower slopes but where irrigated fields are present on valley floors. The single individual Pearson observed “appeared to be similar to the Mountain viscachas of southern Peru but with more than average buffy color” (p. 5).

Map 401 Selected localities for *Lagidium viscacia* (●). Contour line = 2,000 m.

REMARKS: The specific epithet *viscacia* has been spelled with either one second *c* (*viscacia*: Tate 1935; Osgood 1943b; Cabrera 1961; Woods and Kilpatrick 2005) or two (*viscaccia*: Thomas 1907a; Ellerman 1940). Because the name stems from G. I. Molina (1782), who spelled it with a single second *c*, *viscacia* is the correct spelling (ICZN 1999:Art. 32.3). Molina described *Lepus viscacia* in 1782. As pointed out by Lahille (1906), there is little doubt that Molina had reference to a *Lagidium*, although Bennett (1835a) showed that Molina confused the habits of the lowland (*Lagostomus*) and mountain viscachas (*Lagidium*). Bennett (1835d) elaborated on his earlier (1835b) description of *Lagotis pallipes*, providing a beautiful color illustration of this taxon.

The karyotype of specimens referred to both *peruanum* Meyen and to *boxi* Thomas is $2n = 64$, FN = 126 (W. George and Weir 1974).

Lagidium wolffsohni (Thomas, 1907)

Wolffsohn's Mountain Viscacha

SYNONYMS:

Viscaccia Wolffsohni Thomas, 1907a:440; type locality "Sierra de los Baguales y de las Vizcachas, lat. 50°50'S., long. 72°20' W., [Santa Cruz] on the boundary between Chili [= Chile] and Argentina."

Lagidium peruanum: Burmeister, 1879:253; part (*wolffsohni* as a synonym of *peruanum* Meyen).

[*Lagidium*] *wolffsohni*: Tate, 1935:363; name combination.

Lagidium viscacia wolffsohni: Osgood, 1943b:142; name combination.

[*Lagidium*]. *v[iscacia]*. *wolffsohni*: Crespo, 1963:63; name combination.

DESCRIPTION: Large species with long fur strongly suffused with orange and very bushy tail. Head and body length of holotype 470 mm, tail length 305 mm, hindfoot length 107 mm, and ear length 65 mm. Size appears even larger because of very long and rich fur, with wool hairs exceeding 35 mm in length. General color of head and body clay gray, but brownish slate wool hairs give overall darker tone to fur; only a hint of dark dorsal stripe characteristic of other species; lower cheeks, throat, chest, and belly color richer and redder, almost tawny; distinctive white spots present on each axilla and on each side of inguinal region; ears comparatively short, thickly and closely haired, outside surface black but inner surface clothed with whitish hairs, and with marked line of creamy-tipped hairs along base; forelimbs tawny or yellowish to tips of toes; hind limbs duller, more brownish clay colored. Hindfeet large and heavy. Tail stated as "finer" than any other taxon, immensely bushy with hairs forming dorsal crest over 150 mm long; color of upper, crested side mixed black and buff or ochraceous buff; un-

derside of tail black, finely grizzled with glossy ochraceous buff. Skull comparatively large and heavy, with expanded nasals, short incisive foramina, and less swollen bullae than other forms.

DISTRIBUTION: *Lagidium wolffsohni* is known from the Sierra de los Baguales on both sides of the border between Argentina (Santa Cruz province; Barquez, Díaz, and Ojeda 2006) and Chile (Magallanes y Antártica Chilena; Osgood 1943b; Mann 1978) and from a single locality in Aysén province, Chile (Ledesma et al. 2009).

SELECTED LOCALITIES (Map 402): ARGENTINA: Santa Cruz, Sierra de los Baguales y de las Vizcachas (type locality of *Viscaccia Wolffsohni* Thomas). CHILE: Aysén, Estancia Chacabuco, Cochrane (Ledesma et al. 2009); Magallanes y Antártica Chilena, Sierra Baguales, Última Esperanza (Spotorno, Valladares, Marín et al. 2004).

SUBSPECIES: *Lagidium wolffsohni* is monotypic.

NATURAL HISTORY: Nothing is known about the natural history or ecology of this species, although its conservation status in Argentina is considered "En Peligro," in part because of its extremely restricted range (Barquez, Díaz, and Ojeda 2006).

Map 402 Selected localities for *Lagidium wolffsohni* (●). Contour line = 2,000 m.

REMARKS: Thomas (1907a:441) stated that *L. wolffsohni* “is readily distinguishable from all other members of the genus by its large size, rich colour, long fur, immensely bushy tail, and short black ears.” Alternatively, Osgood (1943b:142), in listing this taxon as a valid subspecies of *L. viscacia* noted that “its published measurements indicate the size to be about the same as in *moreni* and *boxi*, and the description of the skull offers no unusual characters, but the color is distinctive.” Mann (1978:244), however, followed Thomas and differentiated *wolffsohni* at the species level from *viscacia* by virtue of its larger size and short, black ears.

The karyotype of *L. wolffsohni* is unknown. As noted above, the specific status of this taxon is questionable, especially given the molecular evidence of its nested phyletic position within other samples of *L. viscacia* (Ledesma et al. 2009). Osgood (1943b) and Crespo (1963) regarded *wolffsohni* as a subspecies of *L. viscacia*.

Subfamily Lagostominae Wiegmann, 1835

This subfamily comprises the single Recent genus *Lagostomus*, with two described species. One of these, *L. crassus*, is known only from a single skull found buried in the sand at a locality in southern Peru (Thomas 1910a). The second, *L. maximus* or the Plains Viscacha, occurs from the dry lowlands of south-central Bolivia, western Paraguay, south through chaco, pampas, and steppe habitats of central Argentina as far south as the provinces of Neuquén and Río Negro. McKenna and Bell (1997) regarded *Pliolagostomus* Ameghino, 1887 and *Prolagostomus* Ameghino, 1887, both from the Early to Middle Miocene, to be extinct representatives of the subfamily. *Lagostomopsis*, described by Kraglievich (1926) as a subgenus of *Lagostomus*, is known from the Pliocene and Pleistocene of Argentina.

REMARKS: McKenna and Bell (1997:210) dated the subfamily name Lagostominae to Wiegmann, 1832 (*Lagostomi*, used as a family name), which is in error. Wiegmann’s paper was published in 1835, in the inaugural year of his new journal *Archiv für Naturgeschichte* (see Bauer and Adler 2001).

Genus *Lagostomus* Brookes, 1829

Lagostomus differs chiefly from members of the Chinchilinae externally by much larger size, with total length averaging 641 mm for females (range: 530 to 735 mm) and 753 mm for males (range: 685 to 820); tail length 160 mm (range: 135 to 173 mm) and 181 mm (range: 154 to 205 mm), respectively; and mass 4.0 kg (range: 3.5 to 5.0) and 6.3 (range: 5.0 to 8.8), respectively. The dorsal and lateral coloration is gray-brown with bold black and white

markings on the face, and fur that is less soft to the touch. A patch of short and stiff bristles is positioned below the eyes. The tail is short, proportionately much more so than in other genera (about 33% of head and body length). The forefeet possess four digits, with digit I missing entirely. The hindfeet are notably long and narrow, with only three digits due to complete loss of digits I and V. Each digit possesses only a very small terminal toe pad and stout and distinctly thick and sharp claws. Females have two pairs of mammae located laterally on the thorax.

The skull is flat, with broad frontals that bear well-marked and triangular-shaped postorbital processes, and heavy parasagittal ridging for muscle attachment. In comparison with the other genera in the family, the rostrum appears robust, but the nasals remain relatively long and narrow. The jugal is deep and thick, extending upward to meet an expanded lacrimal, and has a moderately developed post-orbital process. The floor of the infraorbital foramen has a deep groove bordered by a lateral flange for nerve passage. The tympanic portion of each bulla is expanded ventrally, but not to the degree in the other genera. The mastoid portion is not inflated and, while visible on the occiput when viewed from behind, is not visible on the dorsal surface of the cranium. Paroccipital processes are lengthened, vertical, and both extend well below and are free from contact with the bullae. The incisive foramina are short, occupying less than half the length of the diastema. The palate is strongly constricted anteriorly, with the distance between the upper premolars only about 20% of that between the last molars.

The mandible is thick and stout, with a reduced angular process that flares laterally more so than in the other genera, a low but conspicuous coronoid process, and a well-developed ridge lateral to the condyle for the attachment of the posterior masseter muscle.

The upper incisors are distinctly proodont, with weakly pigmented enamel (if at all), and their surfaces covered with faint longitudinal grooves. Each maxillary cheek tooth has only two straight and rather thick laminae, except M3 that has three, with the last plate essentially lacking a posteriorly directed heel. All mandibular teeth have only two laminae.

The male phallus is elongated and thin, and is unique among all other hystricognath genera, including *Chinchilla*, in lacking the intromittent sac (Pocock 1922).

Fossils of *Lagostomus* are known from the Late Miocene (Salicas Formation; Tauber 2005), Pliocene (Chapadmalal Formation; Kraglievich 1926; J. L. Prado et al. 1998), and late Pleistocene-Holocene (G. Gómez et al. 1999) in Argentina.

SYNONYMS:

Viscacia Rafinesque, 1815:56; *nomen nudum* (Tate 1935:365).

Viscaccia Oken, 1816:835; part (a composite based on *Lepus chilensis* Oken, the “*le vizcache*” of Azara [1801], and *Mus laniger* G. I. Molina [see J. A. Allen 1902c:196]); unavailable name (ICZN 1956).

Dipus: Desmarest, 1817d:117; part (description of *maximus*); not *Dipus* Zimmermann, 1780.

Viscaccia Schinz, 1825a:429; type species *Viscaccia Americana* Schinz (= *Dipus maximus* Desmarest, 1817); a homonym of *Viscaccia* Oken.

Vizcacia Schinz, 1825b [or 1826; see Palmer 1897a]:117; variant spelling of *Viscaccia* Schinz.

Lagostomus Brookes, 1828:134; *nomen nudum*.

Lagostomus Brookes, 1829:96; type species *Lagostomus trichodactylus* Brookes (= *Dipus maximus* Desmarest), by monotypy.

Chinchilla C. H. Smith, 1842:309, plate 26; no type locality given; based on an engraving (facing p. 171) in Griffith et al. (1827) *The Animal Kingdom*, the English translation of G. Cuvier’s *Le règne animal*.

Callomys d’Orbigny and Geoffroy St.-Hilaire, 1830:282; part (inclusion of *viscacia* [= *Dipus maximus* Desmarest]); a composite genus with no type species selected.

Viscacia Rengger, 1830:272, footnote; incorrect subsequent spelling of *Viscaccia* Schinz (a homonym of *Viscaccia* Oken, which is unavailable [ICZN 1956]).

Lagostomopsis Kraglievich, 1926:45; an extinct taxon proposed as a subgenus of *Lagostomus* Brookes.

REMARKS: Félix de Azara (1801) observed and described “*le vizcache*,” an animal that could only have been the Plains Viscacha based on the geographic area of his travels (the La Plata river basin of present day Paraguay, Argentina, Brazil, and Uruguay). The nomenclatural history of the Plains Viscacha is complicated, but not to the same degree as that of either *Chinchilla* or *Lagidium* (see Palmer 1897a; J. A. Allen 1900b, 1905; Tate 1935). As with the latter two genera, much of this contorted history revolves around the common name “*viscacha*” (in its various spellings) and the formalization of that common name as *Viscacia*, *Vizcacia*, or *Viscaccia* by early nineteenth century authors, compounded by the often unclear application of these names to one or more of the three genera of chinchillids currently recognized. Fortunately, both the non-overlapping geographic ranges of each of these genera and the specimen(s) or authority upon which each early name was based help unravel the historical confusion in the applicability of names to these three taxa.

Joshua Brookes (1828) first used the name *Lagostomus* in a paper read before the Zoological Club of the Linnaean Society on May 27 of that year, with a two-sentence synopsis published in the *Zoological Journal* in July 1828 (Sherborn 1927a). Here he proposed to designate *Lagostomus trichodactylus* for Desmarest’s *Dipus maxi-*

mus (= *Lagostomus maximus*). Brookes subsequently read a considerably more detailed paper before the Zoological Club on both June 3 and 17, 1828, although the issue of the *Transactions of the Linnaean Society* in which his paper was published did not appear until 1829. In this second paper, Brookes (1829) detailed characteristics of the skin and skeleton of his *Lagostomus*, again proposed *trichodactylus* for Desmarest’s *maximus*, and documented similarities and differences of the specimen he had at his disposal with the descriptions given of a living specimen by F. Cuvier and M. de Blainville that had been summarized by Desmarest (1817d).

Brookes’s (1829) *Lagostomus* thus became the name applied to the Plain’s Viscacha for most of the nineteenth century (Bennett 1833, 1835c; Waterhouse 1848; Burmeister 1879; E.-L. Trouessart 1897). However, J. A. Allen (1902b:375; 1905:31) argued that Azara’s “*le vizcache*” formed the basis of Oken’s (1816) *Viscaccia*, because Oken included within his *Viscaccia* both *Lepus chilensis* Oken, which he wrote was based wholly on “*le vizcache*,” and *Mus laniger* G. I. Molina, a name that is now associated with *Chinchilla*. Furthermore, because Oken diagnosed his *Viscaccia* by the possession of four toes on the fore and three toes on the hindfeet (“*Zehen vorn 4, hinten 3*”), *Mus laniger*, with four toes on both forefeet and hindfeet, was excluded as the type for his genus. Thus, J. A. Allen (1905) used *Viscaccia* Oken for the Plains Viscacha, with *Lagostomus* Brookes considered a junior synonym. The year previously E.-L. Trouessart (1904) employed *Viscacia* [sic] Schinz (1825a) for the Plains Viscacha. Oken’s *Viscaccia* is unavailable, first because his name was initially ruled a synonym of Bennett’s *Lagidium* (ICZN 1925:Opinion 90), then suppressed under the Plenary Powers of the International Commission in Opinion 110 (ICZN 1929; see also ICZN 1955b:Direction 24), and finally because his entire *Lehrbuch* (Vol. 3) was rejected for nomenclatural purposes (ICZN 1956:Opinion 417). A year before Oken, Rafinesque (1815:56) had used the name *Viscacia* in a list, but as he did not provide a description his name is a *nomen nudum* (Palmer 1897a). Both *Viscaccia* Schinz, 1825a (with type species *Viscaccia Americana* Schinz) and *Vizcacia* Schinz, 1825b (variant spelling of *Viscaccia* Schinz; year of publication uncertain, see Palmer 1897a:22; unfortunately, C. D. Sherborn, in his multivolume *Index Animalium*, made no reference to either *Vizcacia* Schinz or *pamparam* Schinz) have been historically considered homonyms of Oken’s earlier *Viscaccia*, and remain so even after Oken’s names were declared unavailable (as per ICZN 1929:Opinion 110). Thus, *Lagostomus* Brookes is the earliest valid name for the Plains Viscacha (see also Cabrera 1961:559). D’Orbigny and Geoffroy St.-Hilaire (1830) erected *Callomys*, a composite

genus that probably included species in each of the three chinchillid genera recognized today, but certainly those of *Lagostomus* and *Chinchilla* (see Tate 1935:358, 360, and 365). Tate (1935:364–368) provided a detailed summary of this complicated history.

KEY TO THE SPECIES OF *LAGOSTOMUS*:

1. Distribution southern Peru; skull large (condylobasilar length = 122 mm) *Lagostomus crassus*
1. ' Distribution southern Bolivia, Paraguay, and Argentina; skull smaller (condylobasilar length <110 mm, on average) *Lagostomus maximus*

Lagostomus crassus Thomas, 1910

Peruvian Plains Viscacha

SYNONYM:

Lagostomus crassus Thomas, 1910a:246; type locality "Santa Ana, District of Cuzco, Peru."

DESCRIPTION: Larger in size and stouter in form than *L. maximus*, with stout and heavy skull larger in all di-

mensions than largest specimen of *L. maximus* in the British Museum collections (Thomas 1910a). Anterior frontal region particularly broad and convex upward; breadth across antorbital foramina greatly exceeds that of *L. maximus*; incisive foramina minute in size and palatal foramina large.

DISTRIBUTION: *Lagostomus crassus* is known only from the type locality.

SELECTED LOCALITIES (Map 403): PERU: Cusco; Santa Ana (type locality of *Lagostomus crassus* Thomas).

SUBSPECIES: *Lagostomus crassus* is monotypic.

NATURAL HISTORY: This species is known from only a single skull found by J. Kalinowski "buried in sand" (Thomas 1910a:245). Thomas stated further "no viscachas of this genus are known to live in Peru, and the animal is probably now extinct, but the skull is in no way fossilized, and indicates that these animals lived in Peru at a very recent date." No specimens of *Lagostomus* have been collected in the adjoining Altiplano regions of Bolivia (S. Anderson 1997). Given the lack of any additional specimens in the modern or archaeological record of such an obvious rodent in the Altiplano of Peru or Bolivia, we agree with Jackson et al. (1996) that the single skull of *L. crassus*, which is at the upper end of the size range of *L. maximus*, probably represents a Plains Viscacha that was taken to Peru.

Lagostomus maximus (Desmarest, 1817)

Plains Viscacha

SYNONYMS:

Lepus chilensis Oken, 1816:835; based on Azara's (1801) "le vizcache" (J. A. Allen 1902c:196); unavailable name (ICZN 1956).

Dipus maximus Desmarest, 1817d:117; no type locality given; based on a live animal observed and described in 1814 by M. de Blainville in England, stated to have originated in "Nouvelle-Hollande" [= Java, Indonesia]. *V[iscaccia]. Americana* Schinz, 1825a:429; no type locality designated.

Vizcacia pamparum Schinz, 1825b [circa 1825 or 1826; see Palmer 1897a]:244; no type locality designated.

Lagostomus trichodactylus Brookes, 1828:134; *nomen nudum*.

Lagostomus trichodactylus Brookes, 1829:102; no type locality designated.

Callomys viscacia: d'Orbigny and Geoffroy St.-Hilaire, 1830:291; = *Dipus maximus* Desmarest, not *Lepus viscacia* G. I. Molina; name combination.

Lagostomus viscacha: Meyen, 1833:584; name combination.

Lagotis criniger Lesson, 1842:105; *nomen nudum*; stated to be from "Plata" and thus likely referable to *Lagostomus* rather than *Lagotis* Bennett [= *Lagidium* Meyen].

Map 403 Selected localities for *Lagostomus crassus* (○) and *Lagostomus maximus* (●). Contour line = 2,000 m.

Chinchilla Diana C. H. Smith, 1842:309; no type locality designated.

Lagostomus tricodactylus Waterhouse, 1848:448; incorrect subsequent spelling of *trichodactylus* Brookes.

Vizcaccia maxima: Palmer, 1897a:21; name combination.

Viscaccia maxima: Berg, 1900:221; name combination.

Viscaccia chilensis: J. A. Allen, 1902c:196; name combination.

Viscaccia viscacia: E.-L. Trouessart, 1904:517; name combination.

Viscaccia chilensis: J. A. Allen, 1905: 32; name combination.

Lagostomus maximus: Thomas, 1910a:245; first use of current name combination.

Lagostomus maximus immollis Thomas, 1910a:245; type locality "Tapia, Tucuman. Alt. 700m," Tucumán, Argentina.

Lagostomus maximus petilidens Hollister, 1914a:58; type locality "8 miles north of Carmen de Patagones, [Buenos Aires,] Argentina" (not "8 miles south of Carmen de Patagones" as given by Tate [1935:368] and Ellerman [1940:236]).

[*Lagostomus*] *maximus maximus*: Tate, 1935:368; name combination.

[*Lagostomus*] *maximus immollis*: Tate, 1935:368; name combination.

[*Lagostomus*] *maximus petilidens*: Tate, 1935:368; name combination.

Lagidium chilensis: Devincenzi, 1935:75; name combination.

Lagostomus maximus maximus: Ellerman, 1940:236; name combination.

Viscaccia americana: Osgood, 1943b:238; name combination.

DESCRIPTION: As for genus, except as distinguishable from *L. crassus*.

DISTRIBUTION: *Lagostomus maximus* is distributed in the pampas and adjoining semiarid Monte and Chaqueñan regions of South America, from southeastern Bolivia, western Paraguay, and northern, eastern, and central Argentina. As an agricultural pest, the Plains Viscacha has been extirpated from a substantial portion of its native range, but it has also expanded this historic range in areas due to anthropogenic modification of natural habitats. Detailed data on current distribution are lacking (Jackson et al. 1996).

SELECTED LOCALITIES (Map 403): ARGENTINA: Buenos Aires, Bahia Blanca (KU 3023), Buenos Aires (MCZ 5040), 8 mi N of Carmen de Patagones (type locality of *Lagostomus maximus petilidens* Hollister), Punta Blanca (UWBM 73509), Necochea (USNM 172825); Entre Ríos, Arroyo Perucho Verne (Udrizar Sauthier, Abba et al. 2008); La Pampa, Estancia Los Ranqueles (MVZ 177626) Tello (USNM 172849); Mendoza, Ñacuñán (OMNH 15158); Salta, El Breal (R. A. Ojeda and Mares

1989), Las Lajitas (R. A. Ojeda and Mares 1989), Rearte Norte, Rosario de la Frontera (R. A. Ojeda and Mares 1989); Santa Fé, Esperanza (USNM 118480); Santiago del Estero, Buena Vista (OMNH 23723); Tucumán, Río Colorado (USNM 172822). BOLIVIA: Chuquisaca, 1 km W of Sargento Rodriguez [Paraguay] (S. Anderson 1997); Santa Cruz, Com. Guirapembi (S. Anderson 1997), Parapeti (S. Anderson 1997); Tarija, ca. 35 km by road SE of Villa Montes (UMMZ 155896).

SUBSPECIES: Three subspecies are recognized in the literature (Llanos and Crespo 1952; Jackson et al. 1996) based on coat color, skull morphology, and incisor width: *L. m. immollis* Thomas from Bolivia, Paraguay, and north-central Argentina; *L. m. maximus* Desmarest from central Argentina; and *L. m. petilidens* Hollister from southern Buenos Aires, La Pampa, and Río Negro provinces, Argentina. However, as noted by Jackson et al. (1996), the ranges of the three subspecies are uncertain, and, in the absence of an adequate review of morphological and/or molecular variation over this range, the validity of each remains to be determined.

NATURAL HISTORY: Jackson et al. (1996) reviewed aspects of the natural history, ecology, reproduction, and conservation of this species. This species lives in lowland habitats that include subtropical, humid grasslands in northeastern Argentina, dry thorn scrub in Bolivia, Paraguay, and north-central Argentina, and desert scrub in the southwestern part of its range. These are colonial animals, with one to three adult males, two to four times as many females, and immatures living in a communal burrow system called a "vizcachera" (Llanos and Crespo 1952). The burrow system is complex, with multiple entrances and branching underground tunnels. Sticks, bones, dry cow dung, and other materials may be placed around the entrances; males use these items for scent marking (Branch 1993b).

In the semiarid scrub of La Pampa in central Argentina, groups of Plains Viscachas live in vizcacheras that range in number of burrows from 18 to 93, with satellite burrows scattered among them (Branch, Villarreal, Sosa et al. 1994). These satellites are used for escaping high-risk situations during the nonbreeding season (winter months) but serve as residences and display sites for adult males during the breeding season (spring to fall months). All viscachas from a single vizcachera share a common home range, which averages 1.29 ha (Branch 1993a), with minimal overlap between the home ranges of adjacent vizcacheras. Home range boundaries are not defended, but all members of a group will defend the vizcachera from intruders of either sex or age class. Mutual grooming by members of a vizcachera is common, and all individuals used a communal dust bath. All individuals of the vizcachera also have access to all burrows in the system (Branch 1993b). Aban-

doned burrows serve as important refuges for burrowing owls (*Athene cunicularia*; Machicote et al. 2004) and as breeding sites for various reptiles and amphibian species (J. M. Gallardo 1970).

Plains Viscachas are nocturnal and active year-round, emerging from their burrows shortly before dusk (Branch 1993c). In winter, adult males forage with both females and immatures, but during the remainder of the year they forage alone. Groups of up to 30 individuals may be observed foraging together (Llanos and Crespo 1952; Branch 1993b), and individuals may forage at distances considerably beyond the boundaries of the home range.

Breeding is seasonal in the wild, with most females reproductively active in the autumn and young born in the spring (Llanos and Crespo 1952; Jackson 1989; Weir 1971c; Branch et al. 1993). The estrous cycle is forty days long. Females hyperovulate, producing 200 to 800 ova per estrous event (Jensen et al. 2006, 2008); following a delayed implantation, up to five blastocysts implant in each uterine horn (Weir 1971c,d). The gestation day period is long: 154 days, including the delay of implantation of 18 days. Young are precocial at birth. Lactation lasts two to three months (Jackson 1989). Average litter size in natural populations is about 1.9 young (Llanos and Crespo 1952; Jackson 1989). Females reach sexual maturity earlier than do males, with a mean time to first conception of 214 days and first birth of 368 days (Jackson 1989). Males reach sexual maturity at 12 to 16 months (Llanos and Crespo 1952; Jackson 1989). The testicular cycle in males is highly seasonal, with peak conception rates and male fertility in March and April, at which time 91% of males in the population were fertile.

The sex ratio at birth in the wild is approximately 1:1 (Jackson 1990a), or slightly skewed in favor of females (Branch et al. 1993). Females are recruited into their natal vizcacheras and may breed at eight months of age. Males, on the other hand, typically disperse although they may continue to reside in their natal vizcachera when environmental conditions are poor. There is usually a complete turnover of adult males each year, with resident males replaced by immigrants from other vizcacheras. Individuals may live seven to eight years in the wild (Llanos and Crespo 1952). Branch, Villarreal, and Fowler (1994) summarized factors affecting population dynamics.

Plains Viscachas are herbivorous and coprophagous (Jackson 1985a; Kufner et al. 1992; Puig et al. 1998; Kufner and Monge 1998), foraging on a wide range of plant species. In the grasslands of central Argentina, not surprisingly the majority of forage comprises species of grasses, but in dry scrub habitats, viscachas eat the leaves of a variety of forbs and shrubs as well as grasses (Branch, Villarreal, Sbriller, and Sosa 1994). By selective grazing, viscachas al-

ter the species composition, cover, and vegetative structure around their burrow systems (Branch, Villarreal et al. 1996; Branch et al. 1999; Arias et al. 2003; Villarreal et al. 2008).

Predators comprise a variety of mammalian carnivores, including pumas (*Puma concolor*), Geoffroy's Cat (*Leopardus geoffroyi*), Pampas Fox (*Lycalopex gymnocercus*), Crab-eating Fox (*Cerdocyon thous*), and Lesser Grison (*Galictis cuja*; Branch 1995; Branch, Pessino, and Villarreal 1996; Jackson et al. 1996; Pessino et al. 2001). The boa (*Boa constrictor*) may have been an important predator in the northern part of the range in Argentina in earlier periods (Llanos and Crespo 1952). Individuals give a loud, two-syllable antipredator call (Branch 1993a). The call is given by adult males most frequently and is similar to the call these individual use in response to male intruders.

A variety of nematode and cestode helminthes (Sutton and Durette-Desset 1995; G. W. Foster et al. 2002) and protozoans of the family Eimeriidae parasitize Plains Viscachas (Couch et al. 2001). Ectoparasites include ticks of the genus *Amblyomma* (Guglielmona et al. 1990).

This species is of considerable economic interest in Argentina both because of its status as an agricultural pest and commercial value of its meat and pelt. Substantial numbers of skins are exported annually.

REMARKS: Both *Dipus maximus* Desmarest and *Lagostomus trichodactylus* Brookes are based on the same animal. Desmarest's name came directly from a manuscript description, provided to him by M. de Blainville, of a live animal seen in England (Waterhouse 1848:213). And, as Brookes had detailed (1829:95), his own description was based on an individual obtained "from Mr. Cross, in whose Vivarium at Exeter Change it had been seen while living, and especially noticed, both by M. de Blainville and by M. F. Cuvier. Each of these distinguished naturalists has described its general characters and habits."

The karyotype is $2n = 56$, FN = 110 (Hsu and Benirschke 1971; Wurster et al. 1971; Vidal-Rioja et al. 1973b; W. George and Weir 1974).

Family Dinomyidae Alston, 1876

James L. Patton

The single living species is among the largest of extant caviomorph rodents, with a head and body length up to 800 mm and a mass reaching 15 kg. The ears are short and rounded; the upper lip has a deep cleft; the vibrissae are long; the tail is short, thick, and well furred; the limbs are short and stout; the feet are plantigrade, relatively short and broad, with four digits, each with a long claw. The palmar and plantar surfaces are naked with pads containing the remaining skeletal elements of the pollex and hallux. The animal walks with only the heel of the hindfoot raised

above the ground, which results in a waddling gait (Goeldi 1904; Pocock 1926). Webbing extends from the plantar pad to about half way to the tips of the small digital pads (Grand and Eisenberg 1982; Pocock 1926). Overall color is black or dark brown (Lönnerberg [1921] suggested that the sexes are dichromatic, with adult males black and adult females brown), typically with two discontinuous white stripes down the back beginning from the shoulders and two or more shorter rows of white spots down each side. The under parts are paler than the dorsum and lack any marks. The pelage itself is coarse, with the hairs of varied length. Females have two lateral-thoracic and two lateral-abdominal pairs of mammae (Weir 1974b).

The skull is massive and blocky, but only slightly ridged, and nearly flat in dorsal profile. The zygoma is deep and heavy and lacks a jugal fossa; the jugal does not touch the lacrimal. The lacrimal canal does not open on the side of the rostrum. The infraorbital foramen is large but does not exhibit a ventral groove for nerve passage. The lacrimal bone lacks a descending flange, and there are no lateral processes of the supraoccipital. The paroccipital processes are short and vertically directed; the bullae are of medium size. The angular process of the dentary is strongly deflected, and the coronoid process is vestigial.

The upper incisors are broad and thick, their width greater than that of the cheek teeth. The cheek teeth are tetralophodont, have flat occlusal surfaces and high crowns, are rootless, and grow continuously throughout life (or euhypsodont, following the terminology of Mones [1968]). The two anterior laminae of the maxillary teeth are isolated and the posterior two laminae are united; the mandibular teeth exhibit a reversed pattern, with the anterior two laminae connected and the posterior two isolated. Deciduous premolars are replaced by permanent teeth, as in most mammals but not all hystrocimorph rodents. The maxillary toothrows converge strongly anteriorly.

The second and third cervical vertebrae are fused (Ray 1958). Mones (1997) provided a thorough description of the postcranial skeleton of *Dinomys*.

A monotypic genus, *Dinomys*, is present in the Recent fauna of South America, although the family has a rich and deep historical record in the Cenozoic (McKenna and Bell 1997; Woods 1984a). Either living populations of *D. branickii* or fossil taxa are known from every country except Chile, Paraguay, and the Guianas. Earliest fossils are recorded from the Deseadan Oligocene of Bolivia (B. Patterson and Wood 1982). Mones (1981), in his revision of the group, recognized four subfamilies, three of which are now extinct. The Dinomyinae is composed of two tribes, one now extinct and the Dinomyini containing the single Recent genus and species. The two largest known rodents (*Phoberomys* from the Late Miocene of Venezuela, estimated to be 700 kg in

mass [Sánchez-Villagra et al. 2003; Horovitz et al. 2006], and *Josephoartigasia* from Plio-Pleistocene of Uruguay, estimated at nearly 1000 kg [Mones 2007; Rinderknecht and Blanco 2008]) are members of this family.

At one time or another the Dinomyidae have been placed within each of the three caviomorph superfamilies recognized herein: the Erethizontoidea (Grand and Eisenberg 1982), the Caviioidea (Simpson 1945; Fields 1957; Woods 1982; B. Patterson and Wood 1982; McKenna and Bell 1997), and Octodontoidea (Landry 1957), or even within a superfamily (Dinomyoidea) of its own (see White and Alberico 1992). Tate (1935) went so far as to include *Dinomys* as a genus within the Caviidae. The limited molecular sequence data available (Spotorno, Valladares, Marín et al. 2004; Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012) clearly support *Dinomys* (and thus the Dinomyidae) as the sister to a clade containing the chinchillid genera *Chinchilla*, *Lagidium*, and *Lagostomus* and well separated from erethizontids, caviids, or octodontids. Alternatively, cladistics analyses of craniodental, chromosomal, and reproductive and gestation patterns of caviomorphs supported a sister-group relationship between *Dinomys* and the prehensile-tailed porcupine *Coendou* (Lidia Nasef 2010).

REMARKS: Simpson (1945), Starrett (1967), and Woods (1984a), among others, attributed the family name Dinomyidae to Alston (1876a) whereas S. Anderson (1997) and Woods (1993) attributed authorship to Troschel (1874). However, Mones (1995) clearly documented that the name properly stems from Peters (1873a:552; see also Peters 1873b:233), with Alston's name only an emendation and Troschel's an incorrect emendation. McKenna and Bell (1997) and Woods and Kilpatrick (2005) followed Mones's position.

Genus *Dinomys* Peters, 1873

As the single Recent genus in a monotypic family, *Dinomys* is characterized by the same set of features that diagnose the family.

SYNONYM:

Dinomys Peters, 1873a:551; type species *Dinomys branickii* Peters, 1873, by original designation.

Dinomys branickii Peters, 1873

Pacarana

SYNONYMS:

Dinomys branickii Peters, 1873a:551; type locality "der Colonia Amable Maria, in der Montaña de Vitoc, in den Hochgebrigen Perus erlegt." Junín, Peru.

Dinomys pacarana Miranda-Ribeiro, 1919:13; type locality "precedente do Amazonas," Brazil, "probably came from Río Purús region" (Sanborn 1931a:151).

Dinomys branickii occidentalis Lönnberg, 1921:49; type locality “road to Guala, about 6,000 feet; . . . llambo near Guala, about 5,000 feet,” ca. 1,500 to 1,800 m, Pichincha, Ecuador (White and Alberico 1992).

Dinomys gigas Anthony, 1921a:6; type locality “La Candela, Huila, Colombia, altitude, 6,500 ft.”

DESCRIPTION: As for the family.

DISTRIBUTION: *Dinomys branickii* is known from the Mérida Andes of northwestern Venezuela, all three Andean cordilleras in Colombia, south along both Andean slopes of Ecuador, the eastern Andean slope and western Amazon Basin of Peru and Bolivia, and western Brazil in the upper Purus and Juruá drainages. Gottdenker et al. (2001) mapped the known localities in Bolivia. The elevational range is approximately 250 to 3,200 m, spanning the western margins of lowland Amazonian rainforest to upper montane tropical forest on the Andean slopes.

SELECTED LOCALITIES (Map 404): BOLIVIA: Cochabamba, El Palmar (S. Anderson 1997); La Paz, Yolo-cito (S. Anderson 1997); Santa Cruz, San Rafael de Amboró (Rumiz and Eulert 1996). BRAZIL: Acre, Iquiri [= Rio Ituxi, near Rio Branco; Paynter and Traylor 1991] (C. O. da C. Vieira 1952), Paraná do Natal, Rio Juruá (C. O. da C. Vieira 1955), Parque Nacional da Serra do Divisor (Calouro 1999). COLOMBIA: Antioquia, Sierra Santa Elena (Nicéforo-María 1923), 9 km S of Valdivia (FMNH 69593); Boyacá, Páramo de Toquilla (White and Alberico 1992); Caldas, Bosque de Florencia (Castaño et al. 2003); Cauca, Inza (AMNH 149283); Huila, La Candela (type locality of *Dinomys gigas* Anthony). ECUADOR: Pichincha, Guala (type locality of *Dinomys branickii occidentalis* Lönnberg), Santo Domingo de los Colorados (Lönnberg 1921). PERU: Amazonas, Kagka, Río Kagka (MVZ 153246); Cusco, Consuelo, 15.9 km SW of Pilcopata (Solari et al. 2006), Marcapata (FMNH 57186); Huánuco, Hacienda Buena Vista, Río Chinchao (FMNH 34408); Junín, Colonia Amable Maria (type locality of *Dinomys branickii* Peters); Loreto, Iquitos (AMNH 98576); Madre de Dios, Cocha Cashu (Pacheco et al. 1993); Pasco, Pozuzo (FMNH 34702); Puno, Sandia (FMNH 78430); Ucayali, Balta, Río Curanja (LSUMZ 16768). VENEZUELA: Táchira, El Caimito (Boher et al. 1988).

SUBSPECIES: In the absence of any review of geographic trends in any character set, it is premature to judge the taxonomic value of the names now available. I thus treat *Dinomys branickii* as monotypic.

NATURAL HISTORY: White and Alberico (1992) reviewed the ecology, behavior, and reproductive biology of *Dinomys branickii*. Most of what is known comes from captive animals (Mohr 1937; Collins and Eisenberg 1972; Merritt 1984; Iwata 1989), with few studies available on natural populations. Their calm, gentle nature in captiv-

ity (Goeldi 1904; Edmund Heller, in Sanborn 1931a) belies their generic name *Dinomys*, which means “terror mouse.”

Alho (1982:Table 1) gave the preferred habitat as seasonally flooded tropical evergreen rainforest (or *várzea*), but this habitat occurs only limitedly along the Amazonian margins of the species range. Nearly every specimen obtained to date has come from upland rainforest, typically on the middle to lower slopes of the Andes or outlier ridges (Grimwood 1969). These animals are herbivorous, eating palm and other fruits, tender stems, and leaves. They apparently nest in rock crevices, hollow logs, or self-dug burrows, either as solitary individuals or in small groups ranging from two to five individuals (Boher and Marín 1988). The most extensive field study on pacaranas is that of Saavedra-Rodríguez et al. (2012), who examined habitat and space use in the central Colombian Andes. Here, animals occupied patches of primary and secondary forest as well as disturbed areas near streams, but where tree cover was always >20%. Only the largest patches were occupied. Individuals lived in groups of four to five composed of two adults (presumably a male and female) and two to three young. Each group occupied a den in deep caves found on sloping rocky outcrops, and had an average home range of 2.45 ha around the den. Population density varied between 5.5 and 9.9 groups per km², with those estimates based on sign from footprints and group latrines (see also Osbahr 2010). Animals fed on a wide variety of plants, mostly consuming leaves and stems but also fruits, nuts, and roots. These authors concluded that while pacaranas can survive in forest fragments, the main factor limiting distribution and abundance was the availability of adequate dens. Individuals are parasitized by ascarid and nematod worms (Merritt 1984) as well as cestodes and protozoans (Boher and Marín 1988).

Osbahr et al. (2009) and Osbahr and Azumendi (2009) examined the relationship between limb structure and movement and the functional ecology of habitat use, specifically comparing the slow walking cursorial gait characteristic of this species with the more fossorial activity of the sympatric mountain paca *Cuniculus taczanowskii*.

REMARKS: This rare, large, and extremely unique rodent was completely unknown to science until Peters's 1873 brief description, and few specimens have been collected since. Goeldi (1904) gave the first description of living animals, and Preller (1907) provided the first complete description of the skull, based on Goeldi's specimens. Miranda-Ribeiro (1919), Anthony (1921a), and Lönnberg (1921) in sequence described three additional taxa based on differences in dorsal coloration (black versus brown) and stripe-spot patterns. Nicéforo-María (1923) described a specimen from the Sierra Santa Elena, near Medellín, Colombia, which he thought might represent a distinct species

based on its yellow instead of white lines and spots. Sanborn (1931a) reviewed available specimens and concluded that all named forms were only geographic or age variants of the single species *D. branickii*. All subsequent authors (Cabrera 1961; Ellerman 1940; Tate 1935; Woods 1993; Woods and Kilpatrick 2005) have followed this taxonomy.

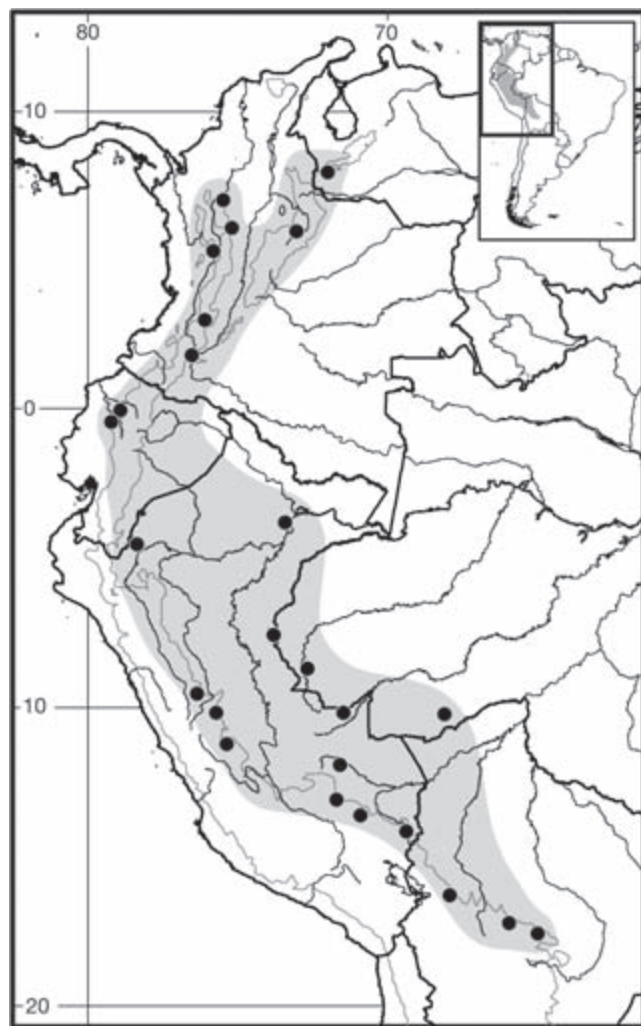

Verified records of this species in Brazil are limited to the headwaters of the Rio Juruá and Rio Purus in Acre state (Miranda-Ribeiro 1919; C. O. da C. Vieira 1952, 1955; Whitney et al. 1996 [cited in Vriesendorp et al. 2006]; Calouro 1999), although the precise locality is unknown for several of these. The locality in Amazonas state cited by C. O. da C. Vieira (1955; Paran  do Natal, Rio Juru ) is most likely in Acre, as the Rio Paran  do Natal is in the municipality of Porto Walter, with the community of Natal approximately 7 km up river from that town. The locality of a single specimen of *D. branickii* in the mammal collection of the Fun a o Universidade de Rond nia (UFROM 038)

is unknown, but certainly from Brazil (Y. L. R. Leite, pers. comm.). As that collection primarily houses voucher specimens from the hydroelectric plants at Santo Ant nio and Jirau along the Rio Madeira, this species likely extends into the extreme northern part of Rond nia state. Eisenberg and Redford (1999:map 16.151) plotted two Brazilian localities, one in the mid-Rio Pur s (Amazonas) and the second in the mid-Rio Madeira (Rond nia), but did not identify vouchers or provide references. Alho (1982:Table 2) suggested that the range extended to Par  state in eastern Amazonia, likely an error based on Goeldi's (1904) report.

Superfamily Erethizontoidea Bonaparte, 1845

Family Erethizontidae Bonaparte, 1845

Robert S. Voss

Map 404 Selected localities for *Dinomys branickii* (●). Contour line = 2,000 m.

Members of the family Erethizontidae, commonly known as New World porcupines, comprise three genera in two subfamilies that collectively range from boreal North America (Alaska and northern Canada) to subtropical South America (Uruguay and northern Argentina). Whereas the subfamily Chaetomyiinae contains a single species (*Chaetomys subspinosus*) that is endemic to the Atlantic Forest of southeastern Brazil, the subfamily Erethizontinae contains the North American porcupine (*Erethizon dorsatum*) and at least 13 Neotropical species, all of which are here referred to the genus *Coendou* (including *Echinoprocta* and *Sphiggurus*; Voss 2011, Voss et al. 2013). Although several fossil genera have been referred to the family Erethizontidae (McKenna and Bell 1997), few exhibit diagnostic familial synapomorphies, so their relationships to Recent taxa are correspondingly ambiguous.

Insofar as known, Neotropical erethizontids are nocturnal, arboreal, and herbivorous, consuming leaves, bark, fruit, and immature seeds (Gaumer 1917; Goldman 1920; Enders 1935; Montgomery and Lubin 1978; Charles-Dominique et al. 1981; Janzen 1983; Armond and Chagas 1990). At least two species routinely den in hollow trees or tree cavities, which accumulate piles of feces and have a strong odor (Miles et al. 1981; Janzen, 1983); other recorded diurnal retreats are in vine tangles, tree forks, and palm crowns. Most reports suggest that erethizontids normally give birth to a single largeprecocial offspring after a long gestation (Shadle 1948; Roberts et al. 1985; Roze 1989; Armond and Chagas 1990; Pasamanni 2009; but see Gaumer, 1917). Evidence of predation on Neotropical porcupines is scarce, but they are known to be eaten, at least occasionally, by harpy eagles (Izor 1985; Piana 2007), ocelots (Emmons 1987b; R. S. Moreno et al. 2006;

R. C. Bianchi and Mendes 2007), pumas (Chinchilla 1997; Novack et al. 2005; R. J. Foster et al. 2010), and large snakes (M. R. Duarte 2003). Although the ectoparasites of erethizontids have not been reviewed in the literature, chewing lice of the trichodectid genus *Eutrichophilus* and the ixodid tick *Amblyomma longirostre* seem to be consistently associated with these rodents (Timm and Price 1994; Nava et al. 2010). South American erethizontids inhabit a wide variety of forested landscapes from sea level to about 3,500 m, including lowland and montane rain forests, deciduous (dry) forests, and gallery forests surrounded by savannas.

Erethizontids are relatively large rodents, but they nevertheless exhibit substantial taxonomic variation in size. The adult weight of the smallest known species (*Coendou rosmalenorum*) is probably in the range of 500–1,000 g (Voss and da Silva 2001), whereas the largest living species (the North American porcupine, *Erethizon dorsatum*) is said to exceed 10 kg in some populations (Roze 1989). In general aspect, porcupines are stoutly built, with short limbs, blunt heads, small eyes and pinnae, spiny pelage, and prehensile feet. In the absence of any adequate published account of erethizontid comparative morphology, the following paragraphs provide a brief summary of essential characters and descriptive terminology.

Porcupine vibrissae include most of the usual mammalian complement of tactile hairs (Pocock 1914; J. C. Brown 1971; J. C. Brown and Yalden 1973) and others of more restricted taxonomic occurrence. All porcupines have mystacial, superciliary, and genal vibrissae on the face, and a small tuft of short submental vibrissae on the chin, but interramal vibrissae are apparently absent (Pocock 1922). The mystacial hairs are the most abundant and obvious of the facial vibrissae; in *Erethizon* these are short, scarcely reaching the base of the ear when laid back against the face, but the mystacial vibrissae of *Chaetomys* and *Coendou* are long and extend well behind the ear. Postcranial vibrissae are apparently absent in *Erethizon*, but are prominent in the other two genera. In *Chaetomys* and *Coendou*, the forelimb is provided with vibrissae between the elbow and wrist, and vibrissae also occur on the hindlimb from the upper leg to the ankle. Bilaterally paired vibrissae distributed along the ventral surface of the thorax and abdomen in *Chaetomys* and *Coendou* appear to be unique among hystricognath rodents, although similar tactile hairs occur in tree squirrels (Hyvärinen et al. 1977).

Soft fur that is long enough to completely or partially conceal the quills is always part of the pelage of juvenile porcupines. A sparse covering of short hairs hidden among the bases of the quills is invariably retained in species that appear to lack any soft pelage as adults (e.g., *Coendou pre-*

hensilis). Long or short, most porcupine fur is composed of wavy wool hairs, but the emergent fur of some species also contains distinctively stiffer and coarser guard hairs. Unlike wool hairs, guard hairs are straight (not wavy), but they are flexible enough to be tied in loose knots without kinking or breaking (unlike spines or bristles). In *Erethizon*, wool hairs are shed seasonally en masse, whereas guard hairs are lost and replaced individually throughout the year (Po-Chedley and Shadle 1955). Unfortunately, molting phenomena have not been studied in any Neotropical erethizontid species.

Erethizontid quills are stiff spines that are normally round in cross-section; cut transversely and viewed under low magnification, quills can be seen to consist of a thin but tough outer cortex surrounding a spongy pith (Chernova 2002:Fig. 1a); they cannot be bent double without kinking. Two types of quills are usefully distinguished. Defensive quills are effective weapons capable of inflicting painful, sometimes crippling and even fatal wounds; easily detached from the owner's skin, they have sharp, hard tips with microscopic barbs (Vincent and Owers 1986:plate VIIc; Chernova 2002:Fig. 1b). Bristle-quills, by contrast, are nondefensive spines; firmly rooted in the skin, they have soft, flexible tips (Voss and da Silva 2001:Fig. 1C). Both *Erethizon* and *Coendou* have ordinary (defensive) quills, but bristle-quills are found only in a few species of the latter genus (comprising the "*Coendou vestitus* group" of Voss and da Silva 2001). Erethizontid quills come in two basic color patterns: bicolored quills are whitish or yellowish basally and blackish distally, whereas tricolored quills have whitish or yellowish bases, blackish middle bands, and paler (whitish, yellowish, reddish, or pale-brown) tips. The black-and-white (or black-and-yellow) motif of porcupine quills is an often-cited example of aposematic coloration, which is also associated with dangerous spines in other animal groups (Inbar and Lev-Yadun 2005; Speed and Ruxton 2005; Caro 2009).

Most of the dorsal body pelage of *Chaetomys* consists of another distinctive pelage structure that could be called broomstraw-spines. Firmly rooted in the skin (like bristle-quills), they are distinctively kinked or wavy, somewhat resemble broomstraws or phocid vibrissae (Voss and Angermann 1997:Fig. 8). Nothing like these unusual hairs is known from the pelage of any other rodent.

The underside of the basal part of the tail in all erethizontids is densely covered with stiff bristles that point toward the tail tip. These distinctive hairs are round in cross-section and have no hollow or spongy pith; they lack barbed points and are very difficult to detach from the skin. In some taxa, caudal bristles are restricted to the underside of the tail, but in others they extend onto the lateral and dorsal surfaces as well. These bristles probably function to

brace the animal from slipping backward on inclined surfaces when the tail is pressed against the substrate.

The ventral pelage of some species of *Coendou* includes another distinctive hair type in the form of soft spines that are flattened in cross-section and are much thicker, stiffer, and straighter than the wool hairs with which they are usually mixed. Although spinous in form, they have soft, flexible tips. They can be bent double without kinking or breaking in some species, but not in others.

Erethizontids are distinctive in several other external features. Unlike most rodents, they do not have a naked glandular rhinarium surrounding the nostrils, and they also lack a naked philtrum dividing the upper lip into left and right halves (see J. C. Brown 1971, for facial anatomical terminology). Instead, the entire muzzle, including the nostril margins, is densely covered with short, velvety hairs, and the upper lip is undivided.

The small but distinct pinna of *Erethizon* (illustrated by Pocock 1922:Fig. 6C) is densely furred and has an evenly convex free margin; the simple fleshy structure of the external ear in this genus is unremarkable, broadly resembling the morphology seen in other hystricognaths (op. cit.). By contrast, the pinna in *Chaetomys* and *Coendou* is reduced to an angular ridge of almost naked skin that can apparently be closed by folds of the internal cartilaginous structure to protect the external auditory canal (Pocock 1922:Fig. 6D); the antitragus is much enlarged and bears a small but distinct tuft of soft spines. The essential characters of the pinna can usually be determined from properly prepared dry skins.

Erethizontids are plantigrade climbers whose feet are conspicuously modified for prehension. The manus and pes of all species have naked soles densely covered with small undifferentiated tubercles, none of which can be homologized with the large plantar pads (thenar, hypothenar, and interdigitals; J. C. Brown and Yalden 1973) that are present in most rodents and in all other nonaquatic plantigrade hystricognaths (Pocock 1922). All erethizontids likewise have strong, curved claws that can be powerfully closed over the plantar surface. Unlike most rodents, in which the pollex is small but distinct and provided with a nail, no external trace of a thumb is normally present in any erethizontid. In other respects, however, the external morphology of the feet differs among erethizontid genera.

The manus of *Erethizon* is about as broad across the metacarpal-phalangeal articulations as it is at the wrist, and it has short subequal digits; the stout claws of this genus are laterally compressed by comparison with those of many other hystricognaths, but the sides of the claws are not joined ventrally at the base, so the subunguis is exposed from the digital pad to the tip. By contrast, the manus of *Chaetomys* and *Coendou* is conspicuously broad-

ened proximally by a fleshy pad projecting from the inner (medial) side, and the forefoot is narrowed distally by elongation of the digits, of which the middle two (III and IV) much exceed the outer pair (II and IV); the claws are much elongated and more laterally compressed than in *Erethizon*, with the result that the sides are often joined at the base, concealing the subunguis.

The short pes of *Erethizon* has five clawed digits, of which the hallux is smallest and the rest are subequal in length. The digits are set side by side, without special separations among them, and together oppose a fleshy expansion of the inner margin of the sole, but the shape of the foot is not otherwise unusual. In *Chaetomys* and *Coendou*, however, the hallux lacks any external vestige and the remaining pedal digits are elongated. These digits oppose a large prehensile pad (supported internally by metatarsal I and a greatly expanded medial sesamoid; Candela and Picasso 2008:Fig. 22) on the medial side of the foot; this grasping structure, easily recognizable even on dried skins, is unique in Mammalia.

The tail of *Erethizon* is a stubby organ, somewhat less than half the length of the head and body, covered with defensive quills above and with stiff bristles below; there is no naked prehensile tip. The tail of the North American porcupine functions importantly in defense (tail-slaps drive quills deep into the skin of would-be attackers) and, pressed against tree bark, as a brace that prevents climbing animals from slipping backward (Roze 1989).

By contrast, the tail of most *Coendou* species is substantially longer than the head and body and has a naked prehensile surface near the tip. Whereas most other prehensile-tailed mammals grasp arboreal supports using the ventral caudal surface, porcupine tails are dorsally prehensile. The very short tail (somewhat less than half the length of head and body) of *C. rufescens* has been described as nonprehensile by authors who probably never saw a living example (e.g., Ellerman 1940), but most specimens have sparsely-haired tail-tips that are worn and calloused dorsally, suggesting that this organ retains some prehensile function (Alberico et al. 1999). The basal part of the tail in *Coendou* is always covered dorsally with body pelage (easily detached defensive quills with or without emergent fur, depending on the species), but the ventral surface, sides, and at least some of the caudal dorsum proximal to the naked prehensile surface is densely covered with stiff backward-pointing bristles that probably have a mechanical bracing function like that described above for *Erethizon*. The tail of *Chaetomys* has stiff, backward-pointing bristles on the ventral surface near the base, and the dorsal surface near the tip is more sparsely haired than the ventral surface, suggesting that it is dorsally prehensile.

Female erethizontids have four mammae in two thoracic-abdominal pairs on the ventral surface (well away from the quills), each surrounded by a small hairless areola. Males sometimes also have well-developed mammae, however, so skins cannot be confidently sexed by the presence of teats.

In general aspect, erethizontid skulls have a short, blunt rostrum; broad interorbital region; strong, laterally projecting zygomatic arches; and prominent auditory bullae. As in other caviomorph rodents, the infraorbital foramen is very large (transmitting the anterior part of the medial masseter; Woods 1972) and the pterygoid fossae are perforated (communicating with the orbital fossae). The lacrimal bone is usually absent (or very small and indistinguishably fused to the frontal or to the maxilla); it is seldom visible as a separate ossification even in juvenile skulls. The paroccipital process, highly developed in many other caviomorphs, is comparatively small in erethizontids and never projects ventrally below the auditory bulla. Well-developed postorbital processes and bony auditory tubes (surrounding the external auditory meatus on the lateral aspect of each bulla) are present in *Chaetomys* but not in any other Recent erethizontid. Three species of *Coendou* have highly inflated nasofrontal sinuses, possibly a defensive adaptation that provides increased cranial surface area for quill deployment and allows erected quills to point forward and sideways, thus protecting otherwise vulnerable soft tissues from attacking predators (Voss et al. 2013).

The upper cheek tooth rows are parallel or weakly convergent anteriorly in Neotropical porcupines, never strongly convergent as in some large sympatric caviomorphs (e.g., caviids and *Dinomys*). The coronoid process of the mandible is small but distinct in most species (*Coendou vestitus* is an exception; Voss and da Silva 2001), and the lower incisor root does not extend posteriorly beyond m3. The cheek teeth are rooted and have either four or five transverse crests. The deciduous fourth premolars (dP4/dp4) are replaced in all erethizontids (including *Chaetomys*; G. A. S. Carvalho 2000).

Gupta (1966) described the axial postcranial skeleton of erethizontids, and Candela and Picasso (2008) have described the appendicular skeleton.

KEY TO THE NEOTROPICAL GENERA OF ERETHIZONTIDAE:

1. Quills wavy, without hard, sharp points (except on head); tail without a well-developed hairless prehensile surface; skull with well-developed postorbital processes, bony auditory tubes, and ontogenetically persistent sutures; upper cheek teeth longer than wide, high-crowned, and essentially laminar in occlusal design, without connecting median crests. *Chaetomys*

- 1'. Quills straight or gently curved but never wavy, with hard, sharp points on head, rump, and usually over the rest of the dorsal surface from nose to tail base; tail with a well-developed hairless dorsal prehensile surface (except in a few specimens of *Coendou rufescens*); skull without well-developed postorbital processes or bony auditory tubes; cranial sutures tending to disappear with age; upper cheek teeth wider than long, low-crowned, always with a median crest linking second and third transverse lophs. *Coendou*

Genus *Chaetomys* Gray, 1843

The monotypic genus *Chaetomys* is a small (ca. 1 kg) erethizontid with a tail that is shorter than the combined length of its head and body (the ratio of tail to head and body length is about 70% in the only examined adult specimen with external measurements). Its visible dorsal pelage consists of thin, wavy, dull-brown spines; except on the head, most of the spines are nondefensive because they lack hard, sharp points. The tail is slender and lacks a well-developed prehensile surface, although the dorsal surface is hairless near the tip in some specimens. The skull is very heavily built, with well-developed postorbital processes of the frontal bones that almost contact correspondingly well-developed postorbital processes of the jugals, and each auditory bulla is provided with a bony tube that surrounds the external auditory meatus. Cranial sutures are ontogenetically persistent, remaining visible even in adult specimens. The frontal sinuses are never inflated. The upper cheek teeth are longer than they are wide, high-crowned, and laminar in occlusal design, consisting of transverse plates without connecting median crests. Illustrations of external and/or craniodental characters are in Ellerman (1940), Oliver and Santos (1991), and Voss and Angermann (1997).

SYNONYMS:

- Chaetomys* Gray, 1843b:123; type species *Hystrix subspinosa* Olfers, by monotypy.
Plectrochoerus Pictet, 1843b:227; type species *Plectrochoerus moricandi* Pictet, by monotypy.

REMARKS: Although G. S. Miller and Gidley (1918), Stehlin and Schaub (1951), and B. Patterson and Wood (1982) all referred *Chaetomys* to the family Echimyidae, there is no compelling evidence that it is anything other than a porcupine. The only morphological trait cited as evidence for a close phylogenetic relationship between *Chaetomys* and echimyids was the alleged retention of the deciduous premolars (dP4/dp4) throughout adult life (B. Patterson and Wood 1982: 394). However, the milk dentition of *Chaetomys* is, in fact, shed and replaced by P4/p4 as in all other nonechimyid hystricognaths (G. A. S. Carvalho 2000).

Furthermore, *Chaetomys* lacks the derived enamel ultrastructural traits of Octodontoidea (the higher-level clade to which Echimyidae belongs; T. Martin 1994), and it shares with other erethizontids the derived presence of a posterior carotid foramen (T. Martin 1994; Bryant and McKenna 1995; G. A. S. Carvalho 2000). These arguments, together with the identical prehensile structure of the manus and pes that *Chaetomys* uniquely shares with *Coendou* (see above) strongly support the traditional placement of *Chaetomys* with other New World porcupines (Thomas 1897a; Ellerman 1941; Landry 1957). Recent molecular analyses (R. do V. Vilela et al. 2009; Voss et al. 2013) provide additional compelling evidence that Erethizontidae, in the sense herein understood, is monophyletic.

Chaetomys subspinosus Olfers, 1818

Broomstraw-spined Porcupine

SYNONYMS:

H[ystrix]. subspinosus Olfers, 1818:211; type locality Salvador, Bahia, Brazil (Voss and Angermann 1997).

H[ystrix]. tortilis Olfers, 1818:211; type locality Salvador, Bahia, Brazil (Voss and Angermann 1997).

H[ystrix]. Subspinosus Kuhl, 1820; a junior synonym based on the same ZMB material in Berlin previously named by Olfers (Voss and Angermann 1997).

Chaetomys subspinosus: Gray, 1843b:21; first use of current name combination.

Plectrochoerus moricandi Pictet, 1843b:227; type locality "Bahia" (= Salvador), Bahia, Brazil (Voss and Angermann 1997).

C[ercolabes]. subspinosus: Wagner, 1844:35; name combination.

Chaetomys tortilis: Moojen, 1952b:100; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Chaetomys subspinosus* occurs in the humid Atlantic coastal lowlands and mountains (to at least 650 m) of southeastern Brazil, formerly from Sergipe to northern Rio de Janeiro (roughly between 11° and 22° S latitude; including easternmost Minas Gerais), but many local populations are now extinct due to widespread deforestation (I. B. Santos et al. 1987; Oliver and Santos 1991).

SELECTED LOCALITIES (Map 405; from Oliver and Santos 1991): BRAZIL: Bahia, Araçás, Cravolândia, Firmino Alves; Espírito Santo, Jirau, Nova Lombardia Biological Reserve; Minas Gerais, Bandeira; Rio de Janeiro, Fazenda São Pedro; Sergipe, Arauá.

SUBSPECIES: I treat *Chaetomys subspinosus* as monotypic.

NATURAL HISTORY: This species is said to occur in primary and secondary rainforest, gallery forest, *restinga* forest (a low-canopy coastal formation including palms

and mangroves), macega scrub (severely degraded thickets without large trees), and cabruca plantations (cacao orchards with an intact canopy of native trees). In all of these habitats of the Atlantic coastal region, *Chaetomys subspinosus* co-occurs with, but is less common than, another small erethizontid, *Coendou insidiosus* (see I. B. Santos et al. 1987; Oliver and Santos 1991).

A radio-collared adult male observed by Chiarello et al. (1997) was active only at night and moved through the forest at an average height of about 10 m above the ground, descending only to defecate; collected feces appeared to be composed of finely ground leaves, and tree leaves were the only items that the animal was seen eating. Observed movements were sluggish, and the animal spent most of each night resting. Most observed locomotion was on small-diameter (<2 cm) substrates, and the animal's tail was usually seen coiled around branches and twigs. Subsequent field studies, also based on radio-collared animals (Souto Lima et al. 2010; Giné et al. 2010, 2011; Zortéa and de Brito 2010; Giné et al. 2011; P. A. Oliveira et al. 2011), have confirmed that this species is nocturnal, arboreal, and solitary. Several unusual behaviors, such as using concealed latrines and leaving offspring alone most of the time, suggest that *Chaetomys* is highly vulnerable to predation and survives by being highly cryptic (Giné et al. 2011). *Chaetomys* is a specialized herbivore, perhaps more so than other erethizontids (Souto Lima et al. 2010). The diet of four radio-collared individuals studied by Giné et al. (2010) included leaves of 17 species of trees, but only three species of Fabacea with protein-rich leaves accounted for 78% of recorded feeding observations. The anatomically simple stomach of this species, its long large intestine, and its sacculated caecum suggest that *Chaetomys* is a hindgut fermenter with typical erethizontid adaptations for a high-fiber diet and water conservation (no individuals were observed to drink water in >900 hours of observation; Giné et al. 2010). The screwworm, *Chochliomyia hominivorax*, may infest the skin of *C. subspinosus* (Kuniy and Santos 2003), and helminth endoparasites of the genera *Hymenolepis* and *Trichuris* are known endoparasites (Kuniy and Brasileiros 2006). Molecular genetic diversity is mostly contained within local populations (C. G. Oliveira et al. 2011).

REMARKS: Voss and Angermann (1997) discussed the complex taxonomic history of this species (the original authorship of which is often misattributed) and redescribed Olfers' (1818) type material. Other useful descriptions of the external and/or craniodental characters of *Chaetomys semispinosus* are in Waterhouse (1848), Ellerman (1940), Emmons and Feer (1997), T. Martin (1994), and G. A. S. Carvalho (2000). The karyotype is $2n = 52$, $FN = 76$ (R. do V. Vilela et al. 2009).

Map 405 Selected localities for *Chaetomys subspinosus* (●).

Genus *Coendou* Lacépède, 1799

The 13 living species of *Coendou* (including *Echinoprocta* and *Sphiggurus*; see Voss 2011; Voss et al. 2013) collectively range from Mexico to Uruguay and northern Argentina. Twelve species occur in South America (only *C. mexicanus* does not), where they inhabit tropical and subtropical moist and dry forests from sea level to about 3,500 m. Although many fossils have been referred to *Coendou*, assignments of extinct species to this genus (versus *Erethizon*) are sometimes controversial (Sussman 2011).

Recent species of *Coendou* are small to large (ca. 500 g to 5 kg) erethizontids with tails that vary in relative length from about 40% to >100% of the combined length of the head and body (Voss 2011). The visible dorsal pelage is completely spiny in some species, but in other species the quills may be partially or completely concealed by long fur. Whether concealed by fur or not, the quills of *Coendou* are straight or gently curving, never wavy. At least on the rump, the quills of all species are defensive spines with hard, sharp, microscopically barbed points. The tail of most species is a robust, muscular organ with a well-developed dorsal prehensile surface. The skull lacks well-developed postorbital processes and bony auditory tubes. The usual sutures among adjacent cranial bones are visible in juvenile and in many subadult skulls, but most cranial sutures disappear with age (only the sutures surrounding

the premaxillae and the auditory bullae persist in old adult specimens). The frontal sinuses are conspicuously inflated in some species, but not in others. The roof of the external auditory meatus is smooth and featureless in some species, but in others it is provided with a transverse bony ridge (Voss et al. 2001:Fig. 70A) and is said to be keeled. The upper cheek teeth are low-crowned and wider than they are long; a median crest connecting the second and third transverse lophs is always present. Citations to published illustrations of external and craniodental morphology are provided in the species accounts that follow.

Several long-furred species of *Coendou* were previously referred to the genus *Sphiggurus* (e.g., by Husson 1978; Woods and Kilpatrick 2005), and the short-tailed species *C. rufescens* was previously referred to the monotypic genus *Echinoprocta*. As traditionally recognized, however, these taxa are not reciprocally monophyletic, and allegedly diagnostic “generic” characters (e.g., size, long versus short fur, cranial sinus inflation) appear to have evolved homoplastically in the course of erethizontid phylogeny (Voss et al. 2013). Contradictory results (mtDNA sequence analyses interpreted as supporting the reciprocal monophyly of *Sphiggurus* and *Coendou*; Bonvicino, Penna-Firme, and Braggio 2002) were based on misidentified specimens (Voss 2011:9, footnote 2).

SYNONYMS:

- Coendou* Lacépède, 1799:11; type species *Hystrix prehensilis* Linnaeus, by monotypy.
- Coendus* E. Geoffroy, 1803:157; incorrect subsequent spelling of *Coendou* Lacépède.
- Coandu* G. Fischer, 1814:102; incorrect subsequent spelling of *Coendou* Lacépède.
- Sinethere* F. Cuvier, 1823a:427; type species *S. prehensilis* (Linnaeus), by original designation.
- Sphiggure* F. Cuvier, 1823a:427; type species *S. spinosa* F. Cuvier, by original designation.
- Sinoetherus* F. Cuvier, 1823c:256; incorrect subsequent spelling of *Sinethere* F. Cuvier.
- Sphiggurus* F. Cuvier, 1823c:256; incorrect subsequent spelling of *Sphiggure* F. Cuvier (but to be maintained due to prevailing subsequent usage; Voss 2011:6).
- Coendu* Lesson, 1827:290; incorrect subsequent spelling of *Coendou* Lacépède.
- Synethere* Lesson, 1827:291; incorrect subsequent spelling of *Sinethere* F. Cuvier.
- Sinetheres* J. B. Fischer, 1829:369; incorrect subsequent spelling of *Sinethere* F. Cuvier.
- Cercolabes* Brandt, 1835:391; type species *Hystrix prehensilis* Linnaeus (proposed as a replacement name for *Coendou* Lacépède).
- Synoetheres* Lund, 1839a:227; incorrect subsequent spelling of *Sinethere* F. Cuvier.

- Sphingurus* Tschudi, 1844:185; incorrect subsequent spelling of *Sphiggure* F. Cuvier.
Echinoprocta Gray, 1865: 321; type species *Erethizon (Echinoprocta) rufescens* Gray, by monotypy.
Cryptosphingurus Miranda-Ribeiro, 1936:975; type species *C. villosus* (F. Cuvier), by original designation.

KEY TO THE SOUTH AMERICAN SPECIES
 OF *COENDOU*:

1. Size small (adult head and body length <400 mm; adult condyloincisive length of skull <70 mm); dorsal pelage includes defensive quills (with hard, sharp, microscopically barbed points) intermingled with bristle-quills (with long, flexible, wiry tips; see Voss and da Silva 2001: Fig. 1) except on head, rump, and base of tail (which have only defensive quills); tail always shorter than the combined length of head and body; frontal sinuses not inflated 2
- 1'. Size small or large; dorsal pelage does not include bristle-quills intermingled with defensive quills; tail longer or shorter than head and body; frontal sinuses inflated or not 5
2. Tail very short (about 50% of head and body length); dorsal pelage includes long blackish fur that partially or completely conceals defensive quills; bristle-quills bicolored (whitish or yellowish basally and dark brown or blackish distally); buccinator-masticatory foramen and foramen ovale confluent (Voss and da Silva 2001: Fig. 6A); mandible lacks a distinct coronoid process (op. cit.:Fig. 4) *Coendou vestitus*
- 2'. Tail >50% of head and body length (except, perhaps, in high-montane populations of *C. pruinusos*); dorsal pelage with or without long fur; bristle-quills tricolored (with pale tips); buccinator-masticatory foramen and foramen ovale separate; mandible with distinct coronoid process 3
3. Tail usually <70% of head and body length (never much longer); dorsal pelage always includes long fur that partially or completely conceals defensive quills; auditory bullae small, uninflated, not contacting paraoccipital processes. *Coendou pruinusos*
- 3'. Tail usually >75% of head and body length (never much shorter); dorsal pelage with or without long fur; auditory bullae large and inflated, contacting paraoccipital processes. 4
4. Dorsal pelage appears completely spiny (long fur absent); at least some quills on head tricolored (with pale tips); postcranial defensive quills one-third to one-half black; ventral pelage includes clusters of soft spines mixed with sparse wool hairs *Coendou ichillus*
- 4'. Dorsal pelage includes long fur that partially or completely conceals defensive quills; no pale-tipped quills on head; postcranial defensive quills mostly pale (only tips dark brown or blackish); ventral pelage consists of guard hairs and sparse wool *Coendou roosmalenorum*
5. Tail very short (usually <50% of head and body length); dorsal body pelage without long fur; postcranial quills with hard, sharp, microscopically barbed points only on rump (the remainder nondefensive, with soft points) *Coendou rufescens*
- 5'. Tail consistently longer (>50% of head and body except in highland populations of *C. quichua*); dorsal body pelage with or without long fur; all postcranial quills with hard, sharp, microscopically barbed points 6
6. Large (combined length of adult head and body >400 mm; condylo incisive length of adult skull >77 mm; adult maxillary tooththrow >18 mm); dorsal body pelage appears completely spiny (long fur absent); frontal sinuses inflated in most fully adult specimens 7
- 6'. Usually smaller (combined length of adult head and body usually <400 mm; condyloincisive length of adult skull usually <77 mm; adult maxillary tooththrow usually <18 mm); dorsal body pelage with or without long fur; frontal sinuses seldom inflated 8
7. Quills uniformly bicolored and abruptly shorter on lower back and rump than on shoulders and upper back (resulting in a visually conspicuous cape or mantle of long quills); mesopterygoid fossa usually extends anteriorly between second upper molars *Coendou bicolor*
- 7'. Long tricolored quills (with white tips) intermingled with shorter bicolored quills over most of the dorsal surface, including the rump (except in specimens from the southern Maracaibo Basin, which have uniformly bicolored quills); dorsal quills decrease gradually in length from upper back to rump, without abrupt transition; mesopterygoid fossa usually extends anteriorly between third molars *Coendou prehensilis*
8. Dorsal pelage does not include long fur (appearing completely spiny) 9
- 8'. Dorsal pelage usually includes long fur that partially or completely conceals the quills. 11
9. Occurs in northern and western Colombia and western Ecuador; roof of external auditory meatus usually strongly keeled *Coendou quichua*
- 9'. Occurs in Brazil; roof of external auditory meatus smooth or weakly keeled 10
10. Occurs along south bank of the Amazon east of the Rio Madeira to Maranhão (on the Atlantic coast); dorsal body quills mostly bicolored (whitish or yellowish basally with black tips), but at least a few lateral quills usually with pale (usually whitish but sometimes brownish) tips; ventral pelage consists of soft spines;

- dorsal surface of tail covered with blackish bristles . . .
 *Coendou nycthemera*
- 10'. Occurs in extreme E Brazil (Pernambuco and Alagoas); most dorsal body quills tricolored, with long reddish tips; ventral pelage consists of soft fur; dorsal surface of tail covered with brownish or reddish bristles . . .
 *Coendou speratus*
11. Occurs north of Amazon and east of the Rio Negro-Casiquire-Orinoco; tail about as long as combined length of head and body; dorsal fur blackish streaked with long yellowish guard hairs; quills all bicolored; roof of external auditory meatus smooth
 *Coendou melanurus*
- 11'. Occurs in southeastern Brazil; tail substantially shorter than combined length of head and body; dorsal fur dark or pale but not streaked with long yellowish guard hairs; quills all bicolored or some quills tricolored; roof of external auditory meatus smooth 12
12. Long dorsal fur (when present) dark basally with pale hair tips (except in some northern specimens which have pale-gray fur); at least some of the longer quills tricolored (with yellowish, orange, or reddish tips); vibrissae and caudal bristles bicolored (dark basally with yellowish or orange tips); adult maxillary tooththrow >15 mm
 *Coendou spinosus*
- 12'. Long dorsal fur uniformly pale (white, yellowish, or grayish), or pale basally with darker (brownish) hair tips; vibrissae and caudal bristles all-dark (without pale tips); adult maxillary tooththrow <15 mm
 *Coendou insidiosus*

Coendou bicolor (Tschudi, 1844)

Bicolor-spined Porcupine

SYNONYMS:

Sphingurus bicolor Tschudi, 1844:186; type locality "in den Urwäldern zwischen den Flüssen Tullumayo und Chanchamayo," Junín, Peru.

Coendou simonsi Thomas, 1902b:141; type locality "Charuplaya, 1400 m," Cochabamba, Bolivia.

Coendou (Coendou) bicolor: Tate, 1935:306; name combination.

Coendou (Coendou) simonsi: Tate, 1935:306; name combination.

Coendou [(Coendou)] bicolor bicolor: Ellerman, 1940:187; name combination.

Coendou [(Coendou)] bicolor simonsi: Ellerman, 1940:187; name combination.

DESCRIPTION: Length of adult head and body 405–500 mm; ratio of tail to head and body 90% to 105% (varies geographically); condyloincisive length of adult skull 85–95 mm; length of adult maxillary tooththrow 19–22 mm; long dorsal fur absent (appears completely spiny); defen-

sive quills bicolored, very long over shoulders and upper back but abruptly shorter on lower back and rump; bristle-quills absent; frontal sinuses usually inflated; roof of external auditory meatus smooth.

DISTRIBUTION: *Coendou bicolor* occurs along the eastern Andean foothills and in adjacent Amazonian lowland forest from San Martín in northeastern Peru southward to northeastern Bolivia (Beni). An apparently isolated population occurs in relictual montane forest on the west side of the Andes in northern Peru (Cajamarca), and the species is also credibly reported from northwestern Argentina (M. M. Lucero 1987). By contrast, published reports of *C. bicolor* from Amazonas in northern Peru (Patton et al. 1982), Brazil (Lara et al. 1996), Ecuador (Tirira 1999), Colombia (Alberico et al. 1999), and Venezuela (O. J. Linares 1998) appear to be based on misidentifications (Voss 2011).

SELECTED LOCALITIES (Map 406): ARGENTINA: Jujuy, Yuto (M. M. Lucero 1987). BOLIVIA: Beni, Puerto Caballo (AMNH 214615), Yucumo (AMNH 262271); Cochabamba, Charuplaya (BM 2.1.1.103). PERU: Cajamarca, 2.5 km N of Monte Seco (MUSM 9398); Huánuco, Tingo María (FMNH 91303); Junín, Chanchamayo (FMNH 65799); Madre de Dios, Reserva Cuzco Amazónico (KU 144560); San Martín, Área de Conservación Municipal Mishquiyacu-Rumiyacu y Almendra (FMNH 203679); Ucayali, Río Alto Ucayali (AMNH 147500).

SUBSPECIES: No subspecies of *Coendou bicolor* are recognized (see Remarks).

NATURAL HISTORY: Nothing has been recorded in the literature about the natural history of this species, but specimens have been collected in both montane and lowland rainforest. The relictual montane rainforest in which *Coendou bicolor* occurs the west side of the Andes, for example, was described by Koepcke and Koepcke (1958), and the lowland habitat of the species east of the Andes was described by Duellman and Koechlin (1991).

REMARKS: Cabrera (1961) treated several nominal taxa as subspecies of *Coendou bicolor*, including *quichua* (herein recognized as a valid species), *richardsoni* (a synonym of *quichua*), and *sanctaemartae* (a synonym of *prehensilis*). Cabrera's concept of *C. bicolor* and other classifications based on it (e.g., Woods 1993; Woods and Kilpatrick 2005) were discussed by Voss (2003, 2011) and Voss et al. (2013), whose recommended usage is followed here. Recent phylogenetic analyses of cytochrome-*b* sequence data suggest that *C. bicolor* is the sister species of *C. nycthemera*, a much smaller congener from eastern Amazonia (Voss et al. 2013). As discussed by Voss (2011), mtDNA cytochrome-*b* sequences previously attributed to *C. bicolor* by Bonvicino, Penna-Firme, and Braggio (2002), R. do V. Vilela et al. (2009), and Y. L. R. Leite et al. (2011) were obtained by Lara et al. (1996) from misidentified specimens of *C. prehensilis*.

Map 406 Selected localities for *Coendou bicolor* (●). Contour line = 2,000 m.

Coendou ichillus Voss and da Silva, 2001
Western Amazonian Dwarf Porcupine

SYNONYMS:

Coendou ichillus Voss and da Silva, 2001:17; type locality “Río Pastaza,” Pastaza, Ecuador (exact locality unknown; see Voss and da Silva 2001:footnote, p. 7).

Sphiggurus ichillus: Woods and Kilpatrick, 2005:1548; name combination.

DESCRIPTION: Length of adult head and body ca. 260–290 mm (estimated values from only two specimens); average ratio of tail to head and body ca. 85%; condyloincisive length of adult skull 58–65 mm; length of adult maxillary toothrow 14–16 mm; long dorsal fur absent (appears completely spiny); defensive quills bicolored (except on head where some quills are tricolored); bristle-quills present (tricolored); frontal sinuses not inflated; roof of external auditory meatus smooth.

DISTRIBUTION: All known specimens and reliable sight records of *Coendou ichillus* are from the rainforested lowlands of eastern Ecuador and northeastern Peru (Voss and da Silva 2001), but it would be reasonable to expect this species to occur throughout most of northwestern Amazonia (north of the Amazon and west of the Rio Negro).

SELECTED LOCALITIES (Map 407): ECUADOR: Napo, La Selva Jungle Lodge (Voss and da Silva 2001); Pastaza, Río Conambo (EPN 807), Río Yana Rumi (FMNH 43289). PERU, Loreto, Iquitos (FMNH 112565).

Map 407 Selected localities for *Coendou ichillus* (●). Contour line = 2,000 m.

SUBSPECIES: No subspecies of *Coendou ichillus* are recognized.

NATURAL HISTORY: No museum specimen of *Coendou ichillus* is accompanied by habitat information, but all of them come from landscapes dominated by lowland rainforest. Two sight records, however, one of which is vouchered by a photograph (Voss and da Silva 2001:Fig. 12), are from lowland rainforest in a white-water river floodplain; both observations suggest that, like other erethizontids, *C. ichillus* is nocturnal and arboreal.

REMARKS: This species appears to be closely related to *Coendou pruinosis*, *C. roosmalenorum*, and *C. vestitus*, all of which also have bristle-quills in addition to ordinary defensive quills and soft fur in their dorsal pelage (Voss et al. 2013). Voss and da Silva (2001) provided a detailed morphological description of *C. ichillus*, photographs, measurements, and relevant comparisons with congeneric taxa. A recently published photograph of the skin of an Ecuadorian porcupine in the Gothenburg Museum of Natural History (Johansson and Högström 2008) is captioned as “*Sphiggurus ichillus*,” but the specimen in question is unambiguously identifiable by its very short tail and reddish quills as *Coendou rufescens*.

Coendou insidiosus (Olfers, 1818)

Bahian Hairy Dwarf Porcupine

SYNONYMS:

H[ystrix]. insidiosa Olfers, 1818:211; type locality “Brazil,” probably in or near the city of Salvador in northern Bahia (Voss and Angermann 1997).

Cercolabes pallidus Waterhouse, 1848:434; type locality unknown (originally said to be from the West Indies, but presumably from southeastern Brazil; Voss and Angermann 1997).

Syntheres (Sphiggurus) pallidus: E.-L. Trouessart, 1880b: 184; name combination.

Coendu pallidus: E.-L. Trouessart, 1897:622; name combination.

Coendu insidiosus: E.-L. Trouessart, 1897:623; name combination.

Coendou (Sphiggurus) insidiosus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) pallidus: Tate, 1935:307; name combination.

Coendou [(Sphiggurus)] pallidum Ellerman, 1940:187; incorrect subsequent spelling of *pallidus* Waterhouse, 1848).

Coendou (Sphiggurus) insidiosus insidiosus: Cabrera, 1961: 600; name combination.

Sphiggurus insidiosus: Husson, 1978:484; part (not including referred Surinam specimens); name combination.

Sphiggurus pallidus: Woods, 1993:776; name combination.

DESCRIPTION: Length of adult head and body ca. 310–350 mm; average ratio of tail to head and body approximately 65%; condyloincisive length of adult skull 61–71 mm; length of adult maxillary toothrow 13–15 mm; long dorsal fur present (uniformly pale or pale basally with darker hair tips); defensive quills bicolored; bristle-quills absent; frontal sinuses not inflated; roof of external auditory meatus smooth.

DISTRIBUTION: I have only examined specimens of *Coendou insidiosus* from the southeastern Brazilian state of Bahia, but the species is said to occur in moist forests from southern Sergipe to northern Rio de Janeiro (roughly between 11° and 22° S latitude), including easternmost Minas Gerais (I. B. Santos et al. 1987; Oliver and Santos 1991). Pale-gray-furred individuals of another southeastern Brazilian species, *C. spinosus*, however, are superficially similar to *C. insidiosus*, so unvouchered sightings are perhaps unreliable where both species could be expected (e.g., in Espírito Santo, northeastern Minas Gerais, and northern Rio de Janeiro states).

SELECTED LOCALITIES (Map 408; from Oliver and Santos 1991, except as noted): BRAZIL: Bahia, Itanhem, Itirussu (AMNH 76838), Ponto do Pitu, Salvador (ZMB 1298), Trancoso); Espírito Santo, Anchieta, Ecoporanga, 1 km S of São Mateus; Minas Gerais, Jordania; Sergipe, Arauá.

SUBSPECIES: No subspecies of *Coendou insidiosus* are recognized.

NATURAL HISTORY: This species is said to be nocturnal, arboreal, and to occur in primary and mature-secondary rainforest, gallery forest, *restinga* forest (a

low-canopy coastal formation including palms and mangroves), macega scrub (severely degraded thickets without large trees), cabruca plantations (cacao orchards with an intact canopy of native trees), and capoeira (dense young secondary growth); in all but the last of these habitats *Coendou insidiosus* co-occurs with and appears to be more numerous than *Chaetomys subspinosus* (see Oliver and Santos 1991). The species is hunted for food and for its quills, which are thought to have medicinal properties (Oliver and Santos 1991).

REMARKS: The name *insidiosus* has often been used for several other valid species of *Coendou*, including *C. melanurus* and *C. spinosus*. For a review of the complex taxonomic history of *C. insidiosus* (the authorship of which is often misattributed), see Voss and Angermann (1997), who also provided measurements, photographs, and a detailed description of Olfers' (1818) type material. Diagnostic comparisons with *C. melanurus* are in Voss et al. (2001), and color photographs of living animals are in Oliver and Santos (1991). *Coendou insidiosus* can be distinguished from superficially similar pale-gray-furred specimens of *C. spinosus* by their unicolored-dark vibrissae and caudal bristles (the vibrissae and caudal bristles of *C. spinosus* are dark basally and orange or yellowish

Map 408 Selected localities for *Coendou insidiosus* (●) and *Coendou speratus* (○). Contour line = 2,000 m.

distally), consistently bicolored quills (at least some cranial and postcranial quills are always tricolored in *C. spinosus*), and shorter tooththrows (maxillary tooththrow length is >15 mm in *C. spinosus*). Although this species was not included in their sequencing study, Voss et al. (2013) hypothesized that *Coendou insidiosus* is most closely related to *C. spinosus*, another southeastern Brazilian species.

F. S. Lima (1994) reported the karyotype of a specimen identified as *Coendou insidiosus* to be $2n = 62$, $FN = 76$.

Coendou melanurus (Wagner, 1842)

Black-tailed Porcupine

SYNONYMS:

Cercolabes melanurus Wagner, 1842c:360; type locality “Rio Negro [Barra]” (= Manaus), Amazonas, Brazil.

Sphiggurus melanurus Gray, 1842:262; type locality “Brazil.”

Syntheres (Sphiggurus) melanurus: E.-L. Trouessart, 1880b: 184; name combination.

Coendou melanurus: E.-L. Trouessart, 1897:622; name combination.

Coendou (Sphiggurus) melanurus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) insidiosus melanurus: Cabrera, 1961: 601; name combination.

Sphiggurus melanura: Bonvicino, Penna-Firme, and Braggio, 2002:1071; epithet spelled with incorrect gender.

DESCRIPTION: Length of adult head and body 330–435 mm; average ratio of tail to head and body approximately 95%; condyloincisive length of adult skull 69–80 mm; length of adult maxillary tooththrow 15–20 mm; long dorsal fur present (blackish streaked with long yellow-tipped guard hairs); defensive quills bicolored; bristle-quills absent; frontal sinuses seldom inflated; roof of external auditory meatus with well-developed transverse bony ridge.

DISTRIBUTION: *Coendou melanurus* apparently occurs throughout the northeastern Amazonian lowlands (north of the Amazon and east of the Orinoco–Rio Negro), including eastern Venezuela, Guyana, Surinam, French Guiana, and northern Brazil.

SELECTED LOCALITIES (Map 409): BRAZIL: Amapá, Serra do Navio (USNM 394732); Amazonas, Manaus (NMW 42010); Pará, Faro (AMNH 94174). FRENCH GUIANA: Paracou (AMNH 266565), St.-Laurent du Maroni (MNHN 1909–242). GUYANA: Cuyuni-Mazaruni, Kartabo (AMNH 70120); Demerara-Mahaica, Georgetown (FMNH 17762); Upper Takutu–Upper Essequibo, Nappi Creek near Letham (ROM 31683). SURINAM: Brokopondo, Afobaka (Husson 1978); Paramaribo, Paramaribo (RMNH 23982). VENEZUELA: Amazonas, Sierra Parima (O. J. Linares 1998); Bolívar, Imataca (Ochoa 1995).

SUBSPECIES: No subspecies of *Coendou melanurus* are recognized.

NATURAL HISTORY: Most specimens of *Coendou melanurus* are unaccompanied by habitat information, but the known range of this species is mostly covered by lowland rainforest, in which some individuals are definitely known to have been collected. One specimen was shot at night as it fed on the leaves of a subcanopy tree about 15–20 m above the ground in well-drained primary forest (Voss et al. 2001). Although this species is rarely seen, large numbers recovered by faunal rescue teams during hydroelectric dam construction (e.g., at Petit Saut, French Guiana; Vié 1999) suggest that it can be locally abundant. Throughout its range, *C. melanurus* is sympatric with the much larger and more commonly collected *C. prehensilis*.

REMARKS: Photographs, measurements, detailed descriptions of external and craniodental morphology, and diagnostic comparisons with other long-furred species of *Coendou* are in Voss et al. (2001). Husson (1978) misidentified this species as *C. insidiosus*, as did others who based their porcupine classifications on his work (Honacki et al. 1982; Woods 1993). A recent maximum-likelihood analysis of cytochrome-*b* sequence data (Voss et al. 2013) recovered *C. melanurus* as the sister taxon of a clade that included *C. vestitus*, *C. pruinusosus*, and *C. ichillus*.

Bonvicino, Penna-Firme, and Braggio (2002) described the karyotype of a specimen (UFPB 3001) identified as *Coendou melanurus* from Roraima state, Brazil, with $2n = 72$, $FN = 76$.

Map 409 Selected localities for *Coendou melanurus* (●). Contour line = 2,000 m.

Coendou nycthemera (Olfers, 1818)

Eastern Amazonian Dwarf Porcupine

SYNONYMS:

H[ystrix]. nycthemera Olfers, 1818:211; type locality “Brazil,” probably somewhere on the south (right) bank of the Amazon below Óbidos (Voss and Angermann 1997).

Cercolabes nycthemera: Waterhouse, 1848:417; name combination.

Syntheres (Syntheres) nycthemera: E.-L. Trouessart, 1880b:183; name combination.

Coendu nycthemera: E.-L. Trouessart, 1897:622; name combination.

Coendou (Sphiggurus) nycthemera: Tate, 1935:307; name combination.

Coendou [(Coendou)] nycthemera: Ellerman, 1940:187; name combination.

Coendou koopmani Handley and Pine, 1992:238; type locality “Belém, Pará, Brazil.”

Coendou nycthemerae Eisenberg and Redford, 1999:450; incorrect subsequent spelling of *nycthemera* Olfers.

DESCRIPTION: Length of adult head and body 290–380 mm; average ratio of tail to head and body about 90%; condyloincisive length of adult skull 61–78 mm; length of adult maxillary toothrow 14–17 mm; long dorsal fur absent (appears completely spiny); defensive quills mostly bicolor (skins appear predominantly blackish), but some tricolored quills present on many specimens; bristle-quills absent; frontal sinuses not inflated; roof of external auditory meatus smooth.

DISTRIBUTION: Specimens of *Coendou nycthemera* have been collected from the Rio Madeira eastward along the right (south) bank of the Amazon to Ilha de Marajó in the Brazilian states of Amazonas and Pará (Handley and Pine 1992). Interviews with indigenous hunters suggest that the range of this species also extends into the adjacent Atlantic coastal watershed of Maranhão (T. G. Oliveira et al. 2007).

SELECTED LOCALITIES (Map 410): BRAZIL: Amazonas, Auará Igarapé (AMNH 91726), Villa Bella da Imperatriz (AMNH 92898); Pará, Belém (USNM 394733), Cametá (AMNH 96316), Currálinho (AMNH 134074), Mocajuba (AMNH 96330), Muaná (USNM 105527).

SUBSPECIES: No subspecies of *Coendou nycthemera* are recognized.

NATURAL HISTORY: Nothing has been recorded in the literature about the natural history of this species, but all known specimens are from landscapes dominated by lowland rainforest. Throughout its geographic range *Coendou nycthemera* probably occurs sympatrically with the much larger species *C. prehensilis* (see Handley and Pine 1992). *Coendou nycthemera* is one of two small porcupines (the other is *C. roosmalenorum*) that inhabits the right (eastern) bank of the Rio Madeira, but known collecting localities

Map 410 Selected localities for *Coendou nycthemera* (●).

for these species are widely separated, and it is not known whether their ranges overlap (Voss and da Silva 2001).

REMARKS: Detailed descriptions of external and craniodental morphology are in Handley and Pine (1992) and Voss and Angermann (1997); the latter authors additionally provided black-and-white photographs of the holotype skin and skull. Recent analyses of cytochrome-*b* sequence data recovered *Coendou nycthemera* as the sister taxon of *C. bicolor*, a much larger western Amazonian species (Voss et al. 2013).

Coendou prehensilis (Linnaeus, 1758)

Brazilian Porcupine

SYNONYMS:

Hystrix prehensilis Linnaeus, 1758:57; type locality “Mata Xanguá, Usina Trapiche, municipality of Sirihaém, state of Pernambuco, Brazil, 8°38′50″S, 35°10′15″W, elevation 100 m” (fixed by neotype selection; Y. L. R. Leite et al. 2011).

Coendou prehensilis: Lacépède, 1799:11; first use of current name combination.

Coendou longicaudatus Daudin, 1802:172; type locality Cayenne, French Guiana (based on the “Coendou à longue queue” of Buffon).

Hystrix cuandu Desmarest, 1822:346; type locality “Le Brésil, la Guyane, l’île de la Trinité.”

S[inethere]. prehensilis: F. Cuvier, 1823a:433; name combination.

Cercolabes (Syntheres) prehensilis: Brandt, 1835:396; name combination.

Cercolabes (Syntheres) platycentrotus Brandt, 1835:399; type locality “America australis?” (see Remarks).

Cercolabes prehensilis: Wagner, 1844:29; name combination.

Cercolabes boliviensis Gray, 1850:380; type locality “Bolivia,” apparently near Santa Cruz de la Sierra (Voss 2011).

Cercolabes tricolor Gray, 1850:381; type locality unknown (Voss 2011).

Hystrix brandtii Jentink, 1879a:96; type locality “Surinam” (fixed by lectotype selection; Husson 1978).

Syntheres (Syntheres) boliviensis: E.-L. Trouessart, 1880b:183; name combination.

Syntheres (Syntheres) prehensilis: E.-L. Trouessart, 1880b:183; name combination.

Syntheres (Syntheres) Brandtii: E.-L. Trouessart, 1880b:183; name combination.

Coendu brandtii: E.-L. Trouessart, 1897:621; name combination.

Coendu tricolor: E.-L. Trouessart, 1897:622; name combination.

Coendu boliviensis: E.-L. Trouessart, 1897:622; name combination.

Coendou centralis Thomas, 1904a:240; type locality “Chapada [= Chapada dos Guimarães],” Mato Grosso, Brazil.

Coendou sanctaemartae J. A. Allen, 1904c:411; type locality “Bonda, Santa Marta district, Colombia.”

Coendou (Coendou) prehensilis: Tate, 1935:306; name combination.

Coendou (Coendou) boliviensis: Tate, 1935:306; name combination.

Coendou (Coendou) brandtii: Tate, 1935:306; name combination.

Coendou (Coendou) sanctaemartae: Tate, 1935:306; name combination.

Coendou (Coendou) tricolor: Tate, 1935:306; name combination.

Coendou (Coendou) centralis: Tate, 1935:306; name combination.

Coendou (Coendou) platycentrotus: Tate, 1935:306; name combination.

Coendou [(Coendou)] prehensilis prehensilis: Ellerman, 1940:187; name combination.

Coendou [(Coendou)] prehensilis boliviensis: Ellerman, 1940:187; name combination.

Coendou prehensilis platycentrotus: Miranda-Ribeiro, 1936:971; name combination.

Coendou (Coendou) baturitensis Feijó and Langguth, 2013:124; type locality “Community Sitio Barreiros, municipality of Aratuba, Baturite Range, Ceará, Brazil.”

DESCRIPTION: Length of adult head and body 400–530 mm; average ratio of tail to head and body about 100%;

condyloincisive length of adult skull 77–103 mm; length of adult maxillary toothrow 18–24 mm; long dorsal fur absent (appears completely spiny); defensive quills bicolored and tricolored (most skins appear heavily speckled or streaked with white); bristle-quills absent; frontal sinuses highly inflated; roof of external auditory meatus weakly keeled.

DISTRIBUTION: *Coendou prehensilis* occurs from northern Colombia (Magdalena, Cesar, Bolívar departments) eastward across northern South America (including Venezuela and the Guianas) and southward throughout most of the forested cis-Andean lowlands of Ecuador, Peru, and Brazil to eastern Bolivia (Beni, Cochabamba, La Paz, Santa Cruz departments), eastern Paraguay, and northwestern Argentina (Salta province).

SELECTED LOCALITIES (Map 411): ARGENTINA: Salta, Tartagal (Olrog 1976). BOLIVIA: Beni, 8 km N of Exaltación (AMNH 214613); Cochabamba, Campamento Yuquí (Anderson 1997); La Paz, Río Madidi (MSB 56078); Santa Cruz, Buena Vista (FMNH 21396). BRAZIL: Bahia, Barra (FMNH 21709); Goiás, Anápolis (AMNH 134062); Mato Grosso, Acurizal (Schaller 1983); Mato Grosso do Sul, Maracaju (AMNH 134073); Minas Gerais, Lagoa Santa (CN 520); Pará, Igarapé Assu (BM 4.7.4.82), Marajó (USNM 519688); Pernambuco, Mata Xanguá (Y. L. R. Leite et al. 2011); Rio Grande do Sul, Venâncio Aires (Scheibler and Christoff 2007). COLOMBIA: Magdalena, Bonda (AMNH 15459); Meta, Villavicencio (AMNH 73680). ECUADOR: Sucumbíos, Limoncocha (USNM 528360). FRENCH GUIANA: Paracou (Voss et al. 2001). GUYANA: Upper Takutu–Upper Essequibo, 20 mi E Dadanawa (USNM 362242). PARAGUAY: Concepción, Yby-Yaú (UMMZ 146507); Paraguari, Parque Nacional Ybycuí (Yahnke et al. 1998). PERU: Amazonas, Huampami (MVZ 153571); Pasco, Pozuzo (ZMB, uncataloged). SURINAM: Paramaribo, Paramaribo (FMNH 95783). TRINIDAD AND TOBAGO: Trinidad, Caparo (AMNH 24202). VENEZUELA: Apure, Nulita (USNM 442610); Falcón, Mirimire (USNM 406750); Sucre, Manacal (USNM 406748); Táchira, Las Mesas (USNM 443409); Vargas, Los Venados (USNM 371277).

SUBSPECIES: I do not recognize any subspecies of *Coendou prehensilis*.

NATURAL HISTORY: *Coendou prehensilis* occurs in lowland rainforest, dry (deciduous) forests, and riparian woodlands in savanna landscapes. Arboreal, nocturnal, and solitary, these large porcupines seem to be less folivorous than smaller erethizontids (e.g., *C. spinosus*; see below), apparently feeding mostly on fruit, immature seeds, and sometimes bark (Charles-Dominique et al. 1981; Emmons and Feer 1997). Diurnal retreats are in hollow trees (Miles et al. 1981) or in shady places in the subcanopy (Montgomery and Lubin 1978). Captive females give birth aseasonally to a single precocial offspring after a gestation of about 200

days; despite their advanced state of development at birth, young *C. prehensilis* are not nutritionally independent until about 15 weeks after birth (Roberts et al. 1985). Three animals radio-collared in the Venezuelan llanos moved 50–700 m each night and used a different sleeping site each day; at least some nocturnal travel must have been on the ground because trees were widely spaced in this habitat; the largest home range recorded over the course of a two-month study period was 38 hectares (Montgomery and Lubin 1978). Large numbers of this species have been recovered by faunal rescue projects after hydroelectric dam construction, suggesting that it can be locally abundant in some situations.

REMARKS: Illustrations and descriptions of the external and craniodental morphology of *Coendou prehensilis* are in Husson (1978) and Leite et al. (2011); summary tabulations of measurement data are in Voss (2011). Specimens of *C. prehensilis* misidentified as *C. bicolor* were sequenced by Lara et al. (1996), whose molecular data were subsequently analyzed by Bonvicino et al. (2002), Vilela et al. (2009), and Leite et al. (2011). Husson (1978), Leite et al. (2011), and Voss (2011) discussed the nomenclature of this very widespread species. Mitochondrial DNA sequence data suggest that the nominotypical Pernambuco population is the most divergent among the 19 samples analyzed, whereas other specimens (from northern South America, Amazonia, and the Cerrado) exhibit very little genetic variation (Voss et al. 2013). The oldest available name that applies to the latter clade is *longicaudatus* Daudin, 1802, from French Guiana. Sequence data are,

unfortunately, unavailable from the Ceará population that Feijó and Langguth (2013) named as *C. baturitensis*, the phenotypic characteristics of which do not seem to fall outside the range of variation among material that I refer to *C. prehensilis*. Surprisingly, *C. prehensilis* appears to be most closely related to a clade of trans-Andean and Andean species that includes *C. mexicanus*, *C. quichua*, and *C. rufescens* (see Voss et al. 2013).

F. S. Lima (1994) described the karyotype of this species as $2n = 74$, $FN = 82$.

Coendou pruinosus Thomas, 1905

Frosted Porcupine

SYNONYMS:

Coendou pruinosus Thomas, 1905b:310; type locality “Montañas de la Pedregosa,” Mérida, Venezuela.

Coendou (Sphiggurus) pruinosus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) vestitus pruinosus: Cabrera, 1961:602; name combination.

Sphiggurus vestitus: Honacki et al., 1982:572; name combination, part.

Sphiggurus pruinosus: Woods and Kilpatrick, 2005:1549; name combination.

DESCRIPTION: Length of adult head and body 320–380 mm; ratio of tail to head and body about 50–70% (varies geographically); condyloincisive length of adult skull 61–71 mm; length of adult maxillary tooththrow 14–16 mm; long dorsal fur present (usually frosted-blackish in fresh highland specimens); defensive quills bicolored (except on head, which has some tricolored quills); bristle-quills present (tricolored); frontal sinuses not inflated; roof of external auditory meatus weakly keeled.

DISTRIBUTION: This species is known from mountains, foothills, and adjacent lowlands (from 54 to 2,600 m) in northern Colombia (Meta, Norte de Santander departments) and northern Venezuela (Aragua, Vargas, Mérida, and Zulia states).

SELECTED LOCALITIES (Map 412): COLOMBIA: Meta, Villavicencio (AMNH 136312); Norte de Santander, Alturas de Pamplona (FMNH 140260). VENEZUELA: Aragua, Colonia Tovar (EBRG 20243), Rancho Grande (EBRG 126); Mérida, Mérida (AMNH 21350); Zulia, El Rosario (USNM 496172); Vargas, Caracas (BM 26.11.4.11); Zulia, Misión Tukuko (MHNLS 7692).

SUBSPECIES: No subspecies of *Coendou pruinosus* are recognized.

NATURAL HISTORY: Most specimens are unaccompanied by habitat information, but two are known to have been shot from trees at night; recorded habitats include lowland rainforest and cloud forest (Handley 1976; Concepción and Molinari 1991; Voss and da Silva 2001).

Map 411 Selected localities for *Coendou prehensilis* (●). Contour line = 2,000 m.

Map 412 Selected localities for *Coendou pruinusos* (●). Contour line = 2,000 m.

REMARKS: Voss and da Silva (2001) provided a detailed morphological description of this species and compared it with other congeneric taxa. Recent phylogenetic analyses of cytochrome-*b* sequence data (Voss et al. 2013) suggest that *Coendou pruinusos* may be closely related to *C. ichillus*, *C. roosmalenorum*, and *C. vestitus*, all of which also have bristle-quills in addition to ordinary defensive quills and soft fur in their dorsal pelage.

Concepción and Molinari (1991) reported the karyotype of this species as $2n = 42$, $FN = 76$, based on a specimen from Mérida state, Venezuela (CVULA I-3030).

Coendou quichua Thomas, 1899

Quichua Porcupine

SYNONYMS:

Coendou quichua Thomas, 1899c:283; type locality “Puembo, Upper Guallabamba River, Province of Pichincha, Ecuador; altitude about 2500 metres.”

Coendou rothschildi Thomas, 1902e:169; type locality allegedly “Sevilla Island, off Chiriquí, Panama,” but this information is fraudulent according to Olson (2008), who claimed that the type was probably collected near Boquerón on the adjacent mainland of Chiriquí province, Panama.

Coendou quichua richardsoni J. A. Allen, 1913a:478; type locality “Esmeraldas (near sea level), Ecuador.”

Coendou (Coendou) quichua quichua: Tate, 1935:306; name combination.

Coendou (Coendou) quichua richardsoni: Tate, 1935:306; name combination.

Coendou (Coendou) rothschildi: Tate, 1935:306; name combination.

Coendou (Coendou) bicolor quichua: Cabrera, 1961:598; name combination.

Coendou (Coendou) bicolor richardsoni: Cabrera, 1961:598; name combination.

DESCRIPTION: Length of adult head and body 330–440 mm; ratio of tail to head and body about 55–90% (varies geographically); condyloincisive length of adult skull 69–87 mm; length of adult maxillary tooththrow 16–19 mm; long dorsal fur absent (appears completely spiny); defensive quills bicolored and tricolored; bristle-quills absent; frontal sinuses seldom inflated; roof of external auditory meatus strongly keeled in most specimens.

DISTRIBUTION: *Coendou quichua* is known from Panama, trans-Andean Colombia, and western Ecuador. Elevations recorded on specimen labels suggest that the species ranges from sea level to about 3,300 m.

SELECTED LOCALITIES (Map 413): COLOMBIA: Cesar, San Alberto (LACM 27376); Chocó, Acandí (Alberico et al. 1999); Cundinamarca, San Juan de Río Seco (AMNH 73679); Santander, San Vicente de Chucurí (Alberico et al. 1999). ECUADOR: Cotopaxi, Otonga (Jarrín-V. 2001); Esmeraldas, Esmeraldas (AMNH 33242); Pichincha, Mindo (BM 34.9.10.186), Puembo (BM 99.2.18.17), Tablón (NRM A58/2822).

Map 413 Selected localities for *Coendou quichua* (●). Contour line = 2,000 m.

SUBSPECIES: I do not recognize any subspecies of *Coendou quichua*.

NATURAL HISTORY: Panamanian specimens have been observed in trees at night and are said to conceal themselves among matted vines in the forest canopy; anecdotes suggest that they feed on leaves and fruits, and that they are attacked by ocelots (*Leopardus pardalis*) on occasion (Goldman 1920; Enders 1935).

REMARKS: For a discussion of the taxonomic status of this species, formerly regarded as a subspecies of *Coendou bicolor*, see Voss (2003, 2011). Panamanian populations of *C. quichua* were traditionally identified as *C. rothschildi* (e.g., by; Emmons and Feer 1997; F. A. Reid 1997; Woods and Kilpatrick 2005), but these nominal taxa seem to be part of a single widespread trans-Andean species (Voss 2011). Phylogenetic analyses of cytochrome-*b* sequence data (Voss et al. 2013) recover *C. quichua* (represented by Panamanian, Colombian, and Ecuadorean samples) as a member of a clade that also includes *C. mexicanus* and *C. rufescens*.

W. George and Weir (1974) described a karyotype with $2n = 74$, $FN = 82$, from a Panamanian specimen of *Coendou rothschildi*.

Coendou rosmalenorum Voss and da Silva, 2001

Roosmalens's Porcupine

SYNONYMS:

Coendou rosmalenorum Voss and da Silva, 2001:24; type locality "Novo Jerusalem [= Nova Jerusalem] near the left bank of the middle Rio Madeira in the Brazilian state of Amazonas."

Sphiggurus rosmalenorum: Woods and Kilpatrick, 2005: 1549; name combination.

DESCRIPTION: Length of adult head and body 290 mm (the only two specimens accompanied by measurements have identical values for this dimension); average ratio of tail to head and body about 85%; condyloincisive length of adult skull 59–65 mm; length of adult maxillary toothrow 12–14 mm; long dorsal fur present (brownish or grayish); defensive quills bicolored; bristle-quills present (tricolored); frontal sinuses not inflated; roof of external auditory meatus weakly keeled.

DISTRIBUTION: *Coendou rosmalenorum* is currently known from just three localities on the Rio Madeira, but it is likely to be widely distributed south of the Amazon in western Amazonia.

SELECTED LOCALITIES (Map 414): BRAZIL: Amazonas, Nova Jerusalem (INPA 2586); Rondônia, 49 km E of Porto Velho (INPA 677).

SUBSPECIES: No subspecies of *Coendou rosmalenorum* are recognized.

Map 414 Selected localities for *Coendou rosmalenorum* (●). Contour line = 2,000 m.

NATURAL HISTORY: Of the three known specimens, the holotype was captured as it emerged from a felled tree, one paratype was shot on the ground at night, and another paratype was taken during faunal rescue operations at a hydroelectric dam site; all three capture sites were in lowland rainforest. Kept alive as a pet for several months, one individual was only active at night and ate a variety of seeds and fruit (Voss and da Silva 2001).

REMARKS: This species may be closely related to *Coendou ichillus*, *C. pruinusosus*, and *C. vestitus*, all of which also have bristle-quills in addition to ordinary defensive quills and soft fur in their dorsal pelage (Voss et al. 2013). Voss and da Silva (2001) provided a detailed morphological description of *C. rosmalenorum*, photographs, measurements, and relevant comparisons with congeneric taxa.

Coendou rufescens (Gray, 1865)

Stump-tailed Porcupine

SYNONYMS:

Erethizon (Echinoprocta) rufescens Gray, 1865:321; type locality "Columbia" [= Colombia].

Coendou prehensilis rufescens: E.-L. Trouessart, 1897:621; name combination.

Echinoprocta rufescens: Cabrera, 1901:159; name combination.

Coendou sneiderni Lönnberg, 1937:17; type locality “Munchique, Cauca” in the Cordillera Occidental (western Andes) of Colombia.

Coendou rufescens: Alberico et al., 1999:606; first use of current name combination.

DESCRIPTION: Length of adult head and body 340–410 mm; average ratio of tail to head and body about 40%; condyloincisive length of adult skull 65–78 mm; length of adult maxillary tooththrow 16–19 mm; long dorsal fur absent (appears completely spiny); most quills tricolored (with brownish or reddish tips), but defensive quills on rump and base of tail bicolored; bristle-quills absent; frontal sinuses not inflated; roof of external auditory meatus smooth.

DISTRIBUTION: *Coendou rufescens* occurs in all three Andean cordilleras of Colombia, on both slopes of the Ecuadorian Andes, in northern Peru (Lambayeque), and in northern Bolivia (Cochabamba). Elevations recorded on specimen tags and in the literature document an elevational range from about 800 to 3,500 m, but most records are clustered in the interval from 1,500 to 3,000 m (Voss 2011).

SELECTED LOCALITIES (Map 415): BOLIVIA: Cochabamba, Incachaca (CM 5255). COLOMBIA: Antioquia, Concordia (Alberico 1999), Reserva San Sebastián-La Castellana (Delgado-V. 2009); Caldas, Reserva Río Blanco (F. Sánchez et al. 2004); Cauca, Munchique (FMNH 88524), Paispamba (ROM 57254); Cundinamarca, Fómeque (AMNH 150028), La Aguadita (AMNH 73678); Huila, Meremberg (Alberico et al. 1999); Nariño, Reserva Natural La Planada (Alberico et al. 1999); Valle del Cauca, 4 km NW of San Antonio (MVZ 124088). ECUADOR: Azuay, Valle de Yunguilla (QCAZ 7591); Carchi, Reserva Biológica Guandera (C. Hice, pers. comm. 2005); Napo, Río Napo (Alberico et al. 1999); Tungurahua, Baños (MCZ 36327). PERU: Lambayeque, Reserva Ecológica Chaparri (Pacheco et al. 2009).

SUBSPECIES: *Coendou rufescens* is monotypic.

NATURAL HISTORY: Although the natural vegetation throughout most of the known range of this species is wet montane (“cloud”) forest, specimens have also been collected in seasonally dry forest in northwestern Peru (Linares-Palomino and Ponce-Alvarez 2009; Pacheco et al. 2009). Virtually nothing is known about the behavior or natural diet of this species, but I have seen a photograph of an individual eating leaves in the wild, and Orcés and Albuja (2004) reported a captive animal to have eaten bananas.

REMARKS: Morphological descriptions of *Coendou rufescens* are in Cabrera (1901), M. E. Trouessart (1920), Lönnberg (1937), Emmons and Feer (1997), and Alberico et al. (1999). See Voss (2011) for measurement data and

Map 415 Selected localities for *Coendou rufescens* (●); disjunct population in Bolivia mapped separately from continuous range. Contour line = 2,000 m.

comments on the taxonomy and geographic distribution of this species. Phylogenetic analyses of cytochrome-*b* sequence data (Voss et al. 2013) suggest that this species belongs to a clade that also includes *C. quichua* and *C. mexicanus*. Voss (2011) speculated that the Bolivian population might have descended from animals transported by the Inca.

Coendou speratus Mendes Pontes, Gadelha, Melo, de Sá, Loss, Caldara Junior, Costa, and Leite, 2013

Pernambuco Dwarf Porcupine

SYNONYM:

Coendou speratus Mendes Pontes et al., 2013:424; type locality “Mata Tauá, Usina Trapiche, municipality of Sirinhaém, state of Pernambuco, Brazil.”

Coendou (Sphiggurus) speratus: Feijó and Langguth, 2013: 131; name combination.

DESCRIPTION: Length of adult head and body 330–440 mm; average ratio of tail to head and body about 85%; condyloincisive length of adult skull 62–76 mm; length of adult maxillary tooththrow 14–16 mm; long dorsal fur absent (appears completely spiny); defensive quills mostly tricolored (skins appear heavily streaked with red); bristle-quills absent; frontal sinuses not inflated; roof of external auditory meatus smooth or weakly keeled.

DISTRIBUTION: Specimens of *Coendou speratus* are only known from the eastern Brazilian states of Pernambuco and Alagoas (Mendes Pontes et al. 2013).

SELECTED LOCALITIES (Map 408): BRAZIL: Alagoas, near Viçosa (Mendes Pontes et al. 2013); Pernambuco, Mata Tauá (type locality of *Coendou speratus* Mendes Pontes et al.).

SUBSPECIES: *Coendou speratus* is monotypic.

NATURAL HISTORY: This recently described species is only known to occur in remnant patches of submontane Atlantic Forest, where it occurs sympatrically with the much larger *Coendou prehensilis*. All recorded observations of *C. speratus* were of solitary individuals or pairs encountered at night while perched 10–20 m above the ground in trees. Dens are said to be in hollow trees (all natural history information from Mendes Pontes et al. 2013).

REMARKS: Phylogenetic analyses of mtDNA cytochrome-*b* sequence data (in Mendes Pontes et al. 2013) suggest that *Coendou speratus* is closely related to other Brazilian dwarf porcupines with geographically adjacent ranges (*C. insidiosus*, *C. nycthemera*, and *C. spinosus*). Unfortunately, these analyses did not include sequence data from *C. bicolor*, a much larger western Amazonian species that was found to be closely related to *C. nycthemera* in another phylogenetic study (Voss et al. 2013).

Coendou spinosus (F. Cuvier, 1823)

Paraguayan Hairy Dwarf Porcupine

SYNONYMS:

Hystrix couiy Desmarest, 1822:345; part; type locality “Le Mexique et sans doute le Brésil; le Paraguay.”

Sphiggure spinosa F. Cuvier, 1823a:433; type locality Sapucaí, Paraguarí, Paraguay (fixed by neotype selection; Voss 2011).

Sphiggure villosa F. Cuvier, 1823a:434; type locality unknown (Voss 2011).

Cercolabes (Sphiggurus) nigricans Brandt, 1835:403; type locality “Brasilia” (= Brazil).

Cercolabes (Sphiggurus) affinis Brandt, 1835:412; type locality “Brasilia” (= Brazil).

Sphingurus sericeus Cope, 1889:136; type locality São João do Monte Negro, Rio Grande do Sul, Brazil (Koopman 1976).

Syntheres (Syntheres) spinosus: E.-L. Trouessart, 1880b:183; name combination.

Syntheres (Sphiggurus) villosus: E.-L. Trouessart, 1880b:184; name combination.

Coendu affinis: E.-L. Trouessart, 1897:623; name combination.

Coendu spinosus: E.-L. Trouessart, 1897:622; name combination.

Coendu sericeus: E.-L. Trouessart, 1897:623; name combination.

Coendu villosus: E.-L. Trouessart, 1897:622; name combination.

Coendou Roberti Thomas, 1902a:63; type locality “Roça Nova, Serra do Mar of the Province of Paraná,” Brazil.

Coendou (Sphiggurus) spinosus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) villosus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) nigricans: Tate, 1935:307; name combination.

Coendou (Sphiggurus) affinis: Tate, 1935:307; name combination.

Coendou (Sphiggurus) sericeus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) roberti: Tate, 1935:307; name combination.

Coendou (Sphiggurus) spinosus nigricans: Cabrera, 1961:601; name combination.

Coendou (Sphiggurus) spinosus roberti: Cabrera, 1961:602; name combination.

Coendou (Sphiggurus) spinosus spinosus: Cabrera, 1961:602; name combination.

DESCRIPTION: Length of adult head and body 285–470 mm; average ratio of tail to head and body about 75%; condyloincisive length of adult skull 59–76 mm; length of adult maxillary toothrow 15–17 mm; long dorsal fur usually present (geographically variable in color); defensive quills bicolored and tricolored; bristle-quills absent; frontal sinuses not inflated; roof of external auditory meatus smooth.

DISTRIBUTION: *Coendou spinosus* occurs in humid tropical and subtropical forests of the Mata Atlântica of southeastern Brazil (from Espírito Santo southward to Rio Grande do Sul) and in similar contiguous habitats of northeastern Argentina (Misiones), eastern Paraguay (Caazapá, Concepción, Guaira, Itapúa, Paraguarí, San Pedro), and northern Uruguay (Artigas, Rivera, Salto, Tacuarembó). Examined specimens document an elevational range from near sea level to at least 900 m.

SELECTED LOCALITIES (Map 416): ARGENTINA: Misiones, Profundidad (Crespo 1974), Tobunas (Crespo 1974). BRAZIL: Espírito Santo, Engenheiro Reeve (BM 3.9.4.87); Minas Gerais, Lagoa Santa (UZM 501); Paraná, Roça Nova (BM 3.7.1.97); Rio de Janeiro, Nova Friburgo (USNM 259793); Rio Grande do Sul, São João do Monte Negro (ANSP 4804); Santa Catarina, Colônia Hansa (BM 28.10.11.48); São Paulo, Butantan (ZMB 35529), São Sebastião (BM 2.11.8.14). PARAGUAY: Caazapá, Estancia Dos Mariás (UMMZ 174975); Concepción, Horqueta

(UMMZ 68132); Itapúa, El Tirol (MSB 54078); Paraguari, Sapucay (USNM 115122). URUGUAY: Artigas, Paso del Campamento (Ximénez et al. 1972); Tacuarembó, near Pueblo Ansina (Ximénez et al. 1972).

SUBSPECIES: I do not recognize any subspecies of *Coendou spinosus*.

NATURAL HISTORY: The only published information about the natural history of this species was obtained by following a radio-collared adult female for one year in an Atlantic Forest fragment in Espírito Santo, Brazil (Passamani 2010). The animal was only active at night, but it spent about 50% of its time resting between episodes of moving and feeding from dusk to dawn. Diurnal retreats were in dense lianas or tree forks, at an average height of 4.5 m above the ground. The average height at which the animal was active at night was 8 m, and the only time it was observed to descend to the ground was when it defecated. The average distance travelled per night was 280 m, and the total home range was 6.3 ha. The only observed food eaten by this animal was new leaves of six tree species. A single young was born in December.

REMARKS: The external morphology of Brazilian and Paraguayan specimens (referred to "*Sphiggurus villosus*" and "*S. paraguayensis*," respectively) was described by Emons and Feer (1997). See Voss (2011) for measurement data and a discussion of the complex taxonomic history of this species. Recent analyses of cytochrome-*b* sequences (Voss et al. 2013) recovered *Coendou spinosus* as the sister taxon of a clade that included *C. bicolor* and *C. nycthem-*

era, but *C. insidiosus* (not sequenced by Voss et al. 2013) is probably a close relative.

Bonvicino et al. (2000) described a karyotype with $2n = 42$, $FN = 76$, from two male specimens (MNRJ 46937 and 46938) collected in Rio de Janeiro state, Brazil.

Coendou vestitus Thomas, 1899

Blackish Hairy Dwarf Porcupine

SYNONYMS:

Coendou vestitus Thomas, 1899c:284; type locality "Colombia."

Coendou (Sphiggurus) vestitus: Tate, 1935:307; name combination.

Coendou (Sphiggurus) vestitus vestitus: Cabrera, 1961:603; name combination.

Sphiggurus vestitus: Honacki et al., 1982:572; name combination.

DESCRIPTION: Length of adult head and body about 330–370 mm; average ratio of tail to head and body about 50%; condyloincisive length of adult skull 65–69 mm; length of adult maxillary toothrow 14–17 mm; long dorsal fur present (blackish); defensive quills bicolored; bristle-quills present (bicolored); frontal sinuses not inflated; roof of external auditory meatus weakly keeled.

DISTRIBUTION: *Coendou vestitus* is currently known from only two definitely identifiable localities, both of which are in the western foothills of the eastern Andean cordillera in the Colombian department of Cundinamarca (but see Remarks).

SELECTED LOCALITIES (Map 417): COLOMBIA: Cundinamarca, Quipile (AMNH 70529), San Juan de Río Seco (AMNH 70596).

SUBSPECIES: No subspecies of *Coendou vestitus* are recognized.

NATURAL HISTORY: Nothing has been recorded about the natural history of this species.

REMARKS: Voss and da Silva (2001) provided a detailed morphological description of this species, together with photographs, measurements, and comparisons with congeneric taxa. Recent analyses of cytochrome-*b* sequence data (Voss et al. 2013) recovered *Coendou vestitus* as part of a clade that also included *C. ichillus* and *C. pruinus*; together with *C. roosmalenorum* (not sequenced by Voss et al. 2013), all of these species have bristle-quills in addition to ordinary defensive quills and soft fur in their dorsal pelage.

Alberico et al. (1999) reported a skin that they identified as *Coendou vestitus* in the Instituto de Ciencias Naturales (Universidad Nacional, Bogotá) from Villavicencio, on the eastern side of the Andes in the Colombian department of Meta, but the only specimen of *Coendou* that I have seen from that locality (AMNH 136312) is referable to *C. pruinus*. Although it is possible that two closely

Map 416 Selected localities for *Coendou spinosus* (●). Contour line = 2,000 m.

Map 417 Selected localities for *Coendou vestitus* (●). Contour line = 2,000 m.

related species of small porcupines are sympatric near Villavicencio, the identification of the ICN specimen remains to be confirmed by cranial characters (illustrated by Voss and da Silva 2001).

Superfamily Octodontoidea *Waterhouse, 1839*

James L. Patton

The most taxonomically diverse group of hystricognaths, the Octodontoidea comprise 70% of extant genera and more than 75% of extant species of the infraorder, with species density concentrated within the tropical rainforests of Amazonia and Atlantic Forest (Upham and Patterson 2012). As recognized herein, the superfamily within South America comprises four family-group taxa, the Abrocomidae, Echimyidae, Ctenomyidae, and Octodontidae. Most molecular phylogenetic analyses support the coupling of these families as a monophyletic assemblage, and with the same pattern of relationships (Abrocomidae (Echimyidae (Ctenomyidae + Octodontidae))); Rowe and Honeycutt 2003; Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012; P.-H. Fabre et al. 2012). These analyses place the divergence of the extant lineages as early as the Late Oligocene (26.8 mya, confidence interval 24.8–28.9; Up-

ham and Patterson 2012) and as late as the Early Miocene (20.6 ± 2.4 mya), with divergence between Echimyidae versus Ctenomyidae + Octodontidae at 17.5 ± 2.2 mya, and that between the Ctenomyidae and Octodontidae at 15.0 ± 2.1 mya (Opazo 2005). Estimates derived by Upham and Patterson (2012) from a larger dataset of taxa and gene sequences are somewhat older: Echimyidae vs. Ctenomyidae + Octodontidae at 25.3 mya (24.6–26.7 mya confidence interval) and Ctenomyidae vs. Octodontidae, 19.1, 14.3–23.5 mya.

Family Abrocomidae G. S. Miller and *Gidley, 1918*

James L. Patton and Louise H. Emmons

Members of this family are called “chinchilla rats” because their soft and luxuriant fur resembles that of true chinchillas (Chinchillidae). They are similar in cranial morphology to the Octodontidae but differ in a number of readily observable characters, namely, having the lacrimal canal opening on the rostrum just above the root of the zygoma; nearly parallel maxillary tooththrows that curve slightly outward posteriorly; hypselodont and flat-crowned cheek teeth in a general figure-8 occlusal pattern, the maxillary teeth with single lingual and labial folds (except for M3, which has an extra labial fold) and the mandibular teeth with two lingual and one labial fold; narrowed lower incisors and anterior part of dentaries; narrow and elongate incisive foramina; no groove on the medioventral floor of the infraorbital canal indicative of nerve passage; a delicate zygoma with the anterior ascending process of the maxilla reduced to a slender strut, the jugal reduced to the ventral base of the bridge and thus well separated from the lacrimal, and no posterior jugal extension beyond the curvature at the base of the arch; enlarged bullae with mastoids that appear dorsally on the skull between the parietal, squamosal, and occipital bones (mastoid “islands”), and thus with correspondingly reduced supraoccipital processes; a narrowed, elongated, and delicate angular process of the dentary turned medially close to the axis of the alveolus of the incisor (referred to as subhystricognathus); a wide semilunar notch between the condyloid and angular processes; and a reduced coronoid process.

In general, these are rat-like animals of moderate (*Abrocoma*, head and body length 200 to 250 mm; skull length <55 mm) to large (*Cuscomys*, head and body length >300 mm; skull length >63 mm) size with short forelimbs and hindlimbs; a large head with blunt snout; large eyes; large and rounded ear pinnae; long and soft dorsal pelage and dense underfur, with the feet and under parts paler than the typically gray or brown dorsum; a tail of moderate to short length and well furred; forefeet with four digits

and hindfeet with five; both forefeet and hindfeet short and broad with short toes; claws weakly developed and hollow beneath, with stiff hairs projecting over claws of the middle three digits of hindfeet (*Abrocoma*) or strong and curved and with less developed comb-like hairs over digits II–IV (*Cuscomys*); and soles of feet naked but covered with small tubercles except for larger terminal toe pads beneath each claw.

Glanz and Anderson (1990) and McKenna and Bell (1997) considered abrocomids members of the Chinchilloidea. Virtually all other authors have, however, consistently placed them within the superfamily Octodontoidea, either as a distinct family (e.g., Simpson 1945; Wood 1955, 1965; Cabrera 1961; S. Anderson and Jones 1967; B. Patterson and Wood 1982; Woods 1982; Reig 1986) or subfamily of the Echimyidae (Ellerman 1940) or Octodontidae (Landry 1957). Molecular analyses using allozymes (Köhler et al. 2000), DNA-DNA hybridization (M. H. Gallardo and Kirsch 2001), and both mitochondrial and nuclear DNA sequences (Huchon and Douzery 2001; Opazo 2005; Opazo et al. 2005) have confirmed a phyletic link of abrocomids with the echimyids and octodontids, as opposed to chinchillids, and as the basal lineage within the Octodontoidea. Opazo (2005) estimated the basal split between the Abrocomidae and Echimyidae + Octodontidae to be 20.6 ± 2.4 mya, during the end of the Early Miocene, slightly older than the estimate given by Huchon and Douzery (2001; 15–18 mya) but younger than that of M. H. Gallardo and Kirsch (2001; 25–30 mya).

Until the last decade, the family contained the single genus *Abrocoma* with just two recognized species. Active systematic analyses of existing museum specimens as well as sustained fieldwork in critically important geographic areas has doubled the number of genera and increased the number of recognized species fivefold (Braun and Mares 2002; Emmons 1999a). Given that members of the family range primarily along the high-elevation spine of the central Andes, much of which is difficult to access and remains biologically unexplored, the discovery of additional diversity is likely. As five taxa of Abrocomidae are known only from their type localities, mostly from only their holotypes, the family is among the most poorly known and potentially at risk in the Neotropics.

The family Abrocomidae includes the extinct genus *Protabrocoma* from the Late Miocene of Argentina and Bolivia (Cione et al. 2000; V. H. Contreras 1991; Kraglievich 1927b; Rovereto 1914; Verzi and Quintana 2005) and the extant genera *Abrocoma* and *Cuscomys*. Pliocene fossils of *Abrocoma* are known from the coastal plain of Argentina, well east of the Andes where all extant taxa range today (Verzi and Quintana 2005).

Among the Recent genera, *Abrocoma* comprises *A. bennettii*, *A. boliviensis*, and the six closely related species within the *A. cinerea* complex (Braun and Mares 2002); *Cuscomys* contains the two species, *C. ashaninka* and *C. oblativus* (Emmons 1999a), the latter originally known from the archaeological record but rediscovered in 2009 with a recent sighting and photos (Julio G. Ochoa, pers. comm. to L. H. Emmons). Verzi and Quintana (2005) assigned *Abrocoma boliviensis* Glanz and Anderson to *Cuscomys*, based on similar features of the cheek teeth (broad anteroposterior lophs with the anterior loph nearly triangular in shape [*Cuscomys*] versus narrow anteroposterior lophs with the anterior loph both subrectangular in shape and slightly concave on its anterior face [*Abrocoma*]) and size of the coronoid process (moderate in *Abrocoma*, reduced in *Cuscomys*). However, *A. boliviensis* does not share the other dramatic characters of hindfoot and cranium detailed by Emmons (1999a:2) as diagnostic for her new genus *Cuscomys*. For the moment, therefore, we follow Glanz and Anderson (1990) and Emmons (1999a) in retaining *boliviensis* within *Abrocoma* until more thorough comparisons, perhaps including molecular markers, have been undertaken.

KEY TO THE GENERA OF ABROCOMIDAE:

1. Body size medium (condylobasilar length of skull <55 mm); tail short, less than 75% of head and body length (except *A. boliviensis*); hallux short, not reaching beyond base of second toe, and stout; claws short and nail-like; frontals behind postorbital process broad; mastoid islands medium to large and inflated; face uniformly colored; tail dorsoventrally bicolored *Abrocoma*
- 1'. Body size larger (condylobasilar length of skull >60 mm); tail long, greater than 75% of head and body length; hallux stout but longer, reaching beyond base of 2nd toe; claws strong and curved; frontals behind postorbital process noticeably constricted; mastoid island small and not inflated; face with pure white blaze down center; tail anteroposteriorly bicolored dark basally, white distally *Cuscomys*

Genus *Abrocoma* Waterhouse, 1837

These are moderately sized rats with long, soft, and dense fur, large and readily visible ear pinnae, moderate to short tails (typically <75% of the head and body length, with *A. boliviensis* an exception), and short but broad feet. The toes are short; the claws weak and small, almost nail-like. Four digits are present on the forefoot, five on the hindfoot. The hallux is reduced, barely reaching the base of the digit II, and the digit IV is shortened. Stiff bristles of hair extend

distally above the claws of the hindfoot, except the hallux, and hide the claws when viewed from above. The claw of digit I of the hindfoot is wide and hollow ventrally. Palmar and plantar surfaces of the feet, including the bottoms of the digits, are unhaired and covered with well-developed tubercles; large pads are present at the base of the digits, and a terminal pad is present beneath each claw. Overall coloration ranges from grayish to brownish-gray, the venter is typically paler than the dorsum, and the well-furred tail is weakly bicolored above and below.

The skull is moderate in length (condylobasilar length <55 mm), somewhat delicate in appearance, with a narrowed and elongated rostrum and an arched dorsal profile in lateral view. The nasals are evenly narrow for most of their length, tapering to a point posteriorly. The frontals are not constricted posterior to the postorbital process so that the frontal width at this point is greater than that of the interorbital region. The braincase is rounded, and both parietal ridges and the supraoccipital crest are only weakly developed, even in old specimens. Mastoid islands that are sandwiched between the occipitals and parietals are medium to large in size. The lateral processes of the supraoccipital are narrow and elongated. Paroccipital processes are short, broad, and closely adhered to the posterior surface of the bullae.

SYNONYMS:

Abrocoma Waterhouse, 1837:30; type species *Abrocoma bennettii* Waterhouse, fixed by Tate (1935:384).

Habrocoma Wagner, 1842a:5; unjustified emendation of *Abrocoma* Waterhouse.

REMARKS: Waterhouse (1837) described two species in his new genus *Abrocoma*, *A. bennettii* and *A. cuvieri*. Tate (1935:384) selected the former as the genotype, stating (footnote on p. 384) "I cannot find that the type of *Abrocoma* has previously been designated." Prell (1934b) regarded G. I. Molina's (1782) *Mus laniger* to represent a chinchilla rat (*Abrocoma*) and not a chinchilla (*Chinchilla*, Chinchillidae) where Molina's name has most commonly been associated (see Osgood 1941:409).

The seven species of *Abrocoma* recognized herein fall into three groups. Two contain single taxa: *A. bennettii* from the western Andean slope and coastal region of north-central Chile, and *A. boliviensis* from the east-central Andes of Bolivia. The third group includes the five remaining species that together comprise the *cinerea* complex (*A. cinerea*, *A. budini*, *A. famatina*, *A. schistacea*, *A. uspillata*, and *A. vaccarum*). These are distributed along the spine of the Andes from southern Peru through Bolivia, northeastern Chile, and northwestern Argentina, and extend onto isolated ranges to the immediate east of the Andes in Argentina (Braun and Mares 2002). All species of the *cinerea* complex are considered specialized for life in rocky cliff

faces, with many saxicolous adaptations (Braun and Mares 1996; Mares, 1997). The rock fissures these species typically inhabit accumulate crystalline fecal and urine piles (middens), which as with the North American woodrats of the genus *Neotoma* offer opportunities to examine temporal changes in paleoenvironments through macrofossil analysis and dating (Betancourt and Saavedra 2002; Holmgren et al. 2001; Kuch et al. 2002; Latorre et al. 2002; F. P. Díaz et al. 2012). Braun and Mares (2002) argued that speciation in the genus has been allopatric due to low dispersal abilities coupled with a very patchy habitat and the dietary specialization necessary to cope with unique vegetation components encountered. These authors also suggest that the most basal species in the *cinerea* complex is that which has the least affinity for saxicolous habitats, namely, the more broadly distributed *A. cinerea*. Hypotheses of both allopatric speciation and the basal position of *A. cinerea* require testing with molecular phylogenetic methods.

Verzi and Quintana (2005) assigned fossils from Santa Isabel of the San Andrés Formation (along coastal Buenos Aires Province, Argentina, south of Punta San Andrés), dated at between 2.58 and 2.14 mya, to *Abrocoma*. This locality is substantially distant both geographically and ecologically from the Chilean coastal and Andean region where species in this genus are currently distributed (Osgood 1943b; Braun and Mares 2002:Fig. 2).

Tarifa et al. (2009) detailed the habitat and behavior of a putative undescribed species from the *Polylepis* forests in Cochabamba department, Bolivia, which shares an external morphology similar to *A. boliviensis* and may represent geographic variants of this species. Tarifa et al. watched individuals use their long tail for balance, climb well, and move easily among branches, and suggested that both this animal and *A. boliviensis* are suited for arboreal activity in contrast the more terrestrial oriented *A. bennettii*, *A. cinerea*, and *A. vaccarum* (Glanz and Anderson 1990; Braun and Mares 1996). These observations highlight the potential increased diversity in this genus, both taxonomic and biological, awaiting detailed field studies in remote parts of the range.

KEY TO THE SPECIES OF ABROCOMA:

1. Body size medium (head and body length ca. 175 mm); tail proportionately long (approximately 81% of head and body length); dorsal color dark (brownish); ventral color pale (whitish); mastoid islands distinctly small (<16% of mastoid breadth) *Abrocoma boliviensis*
- 1'. Body size medium to large; tail not long (<75 head and body length); dorsal color dark or pale (grayish); ventral color drab (dark grayish) to pale; mastoid islands medium to large (>20% of mastoid breadth) 2

2. Body size large (head and body length >200 mm); tail moderately long (ca. 71% head and body length); hindfoot long (>32 mm); dorsal color dark (brownish); ventral color dark (brownish); interorbital region broad (breadth >8 mm); bullae small (width <23% condylobasilar length) *Abrocoma bennettii*
- 2'. Body large to medium (head and body length <200 m); tail moderate in length (60–70% of head and body length) or short (<55%); hindfoot length shorter (<31 mm); dorsal color paler brownish gray to gray; ventral color dark to pale gray; interorbital region narrow to medium (breadth <7.8 mm); bullae medium to large (width >27% of condylobasilar length) 3
3. Dorsal color pale gray; tail very short (35–42% of head and body length); tail weakly bicolored above and below; interorbital region broad (breadth >7.5 mm); mastoid bullae inflated (width >27% of condylobasilar length) *Abrocoma cinerea*
- 3'. Dorsal color gray with brownish overtones; tail of medium proportions (53–68% head and body length); tail moderately to strongly bicolored; interorbital region narrow (breadth <7.0 mm); mastoid bullae moderately to well inflated (width 25–29% of condylobasilar length) 4
4. Hindfeet long (>30 mm); mastoid islands large (>23% of mastoid breadth) 5
- 4'. Hindfeet smaller (<30 mm, on average); mastoid islands medium (<23% of mastoid breadth) 6
5. Body size large (head and body length ca. 200 mm); dorsal color darker (brownish gray); tail moderately bicolored; maxillary tooththrow proportionately short (<22% condylobasilar length); posterior border of palate pointed; upper incisors large and broad *Abrocoma budini*
- 5'. Body size medium (head and body length <180 m); dorsal color paler (grayish brown); tail strongly bicolored; maxillary tooththrow proportionately long (24% of condylobasilar length); posterior border of palate rounded; upper incisors small and narrow *Abrocoma uspillata*
6. Tail relatively short (<53% of head and body length, on average); upper incisors small and narrow; bullar inflation great (width >28% condylobasilar length) *Abrocoma famatina*
- 6'. Tail relatively longer (>58% of head and body length); upper incisors large and broad; bullar inflation medium (width <27% condylobasilar length) 7
7. Dorsal color grayish drab; mesopterygoid fossa wide; upper incisors orthodont *Abrocoma schistacea*
- 7'. Dorsal color gray; mesopterygoid fossa narrow; upper incisors opisthodont *Abrocoma vaccarum*

Abrocoma bennettii Waterhouse, 1837

Bennett's Chinchilla Rat

SYNONYMS:

Abrocoma Bennettii Waterhouse, 1837:31; type locality "Chile," refined to "flanks of the Cordillera, near Aconcagua" [near old village of Aconcagua, = Plaza Vieja, ca. 5 km W Los Andes] by C. Darwin (in Waterhouse 1839:85), Valparaíso, Chile.

Abrocoma Cuvieri Waterhouse, 1837:32; type locality "Valparaíso," refined to "dry hills near Valparaíso, Chile" by C. Darwin (in Waterhouse 1839:86).

Habrocoma helvina Wagner, 1842a:7; type locality "Die Heimath des von mir beschriebenen Exemplars ist, wie schon erwähnt, Chile."

H[abrocoma]. Bennettii: Wagner, 1842a:7; name combination.

Habrocoma Bennettii: Wagner, 1842b:288; name combination.

[*Habrocoma*] *Cuvieri*: Wagner, 1842b:288; name combination.

Habrocoma cuvieri: Schinz, 1845:100; name combination.

Abrocoma Murrayi Wolffsohn, 1916:6; type locality "Valleñar, Alt. 600 m," Atacama, Chile.

Abrocoma laniger: Prell, 1934b:208; considered to be *Mus laniger* G. I. Molina, 1782 (a *nomen dubium*, based on a composite [Osgood 1941; see also G. M. Allen 1942:390]).

Abrocoma bennetti bennetti Ellerman, 1940:154, Figs. 32–34; name combination, and incorrect subsequent spelling of *bennettii* Waterhouse.

Abrocoma bennetti murrayi: Ellerman, 1940:154; name combination.

DESCRIPTION: Largest species in genus (mean head and body length 206 mm); tail absolutely and proportionately long (length averaging 81% of head and body length, range: 74–88%), long hindfeet (length \geq 35 mm), and large ears (pinna length >28 mm). Dorsal fur dark brownish, with gray overtones, becoming slightly paler on sides; ventral fur very dark gray basally tipped with pale gray and thus dark, lightly frosted appearance that contrasts with pale venters of other species (Glanz and Anderson 1990:Fig. 19). Tail uniformly colored around, or only slightly paler below; well haired, but not as densely so as either *A. boliviensis* or members of *A. cinerea* complex. Dorsal surfaces of both forefeet and hindfeet clothed in whitish hairs with palmar and plantar surfaces naked but darkly pigmented. Sternal gland present, demarcated by line of whitish hairs over chest in some specimens.

Intermediate between *A. boliviensis* and members of *A. cinerea* complex in most cranial dimensions (Glanz and Anderson 1990:Table 2), although closer and typically

overlapping with former species. Skull averages shorter overall (mean condylobasal length 48–49 mm) than that of *A. cinerea* (ca. 50 mm), but is considerably longer than that of *A. boliviensis* (ca. 40 mm). Tympanic and posterior mastoid bullae also intermediate in size between those of *A. boliviensis* and the *A. cinerea* complex, even including variation present in comparing near sea level to high-elevation populations. Interorbital region of *A. bennettii* averages broader (>8 mm) than in other species; equivalent to *A. boliviensis* in nasal length (19–20 mm), but considerably longer than nasals of *A. cinerea* complex (13–14 mm).

DISTRIBUTION: *Abrocoma bennettii* is restricted to the western Andean slopes of north-central Chile, from Antofagasta in the north to O'Higgins in the south, and from sea level to 4,000 m (Osgood 1943b; Mann 1978; Guzmán and Siefeld 2011).

SELECTED LOCALITIES (Map 418): CHILE: Antofagasta, Paposo (Guzmán and Siefeld 2011); Atacama, Altamira, coastal mountains of Vallenar (USNM 391845), Domeyko (Osgood 1943b), Piedra Colgada (P. Valladares and Campos 2012), Ramadilla (Osgood 1943b), Vallenar (type locality of *Abrocoma Murrayi* Wolffsohn); Coquimbo, Paihuano (Osgood 1943b), Parque Nacional Fray Jorge (MVZ 118668), Romero (Osgood 1943b); O'Higgins, Banos de Cauquenes (Osgood 1943b); Santiago, Fundo Santa Laura (MVZ 150113); Valparaíso, Aconcagua (type locality of *Abrocoma Bennettii* Waterhouse), La Lingua, Papudo (Osgood 1943b), Limache (Osgood 1943b).

SUBSPECIES: *Abrocoma bennettii* is polytypic, with two subspecies recognized by recent authors (Ellerman 1940; Cabrera 1960; Woods and Kilpatrick 2005): The darker and larger nominotypical subspecies distributed in the central Chilean regions of Aconcagua, Valparaíso, Santiago, and O'Higgins, and the paler and smaller *A. b. murrayi* Wolffsohn known from the northern Chilean regions of Antofagasta, Atacama, and Coquimbo. Osgood (1943b:107) regarded these two taxa to intergrade based on the specimens available to him, thus confirming Ellerman's (1940) earlier decision to list both as valid subspecies of a polytypic *A. bennettii*.

NATURAL HISTORY: Charles Darwin (in Waterhouse 1839:86) noted that his specimen "was caught amongst some thickets in a valley on the flanks of the Cordillera, near Aconcagua. On the elevated plain, near the town of Santa Rosa, in front of the same part of the Andes, I saw two others, which were crawling up an acacia tree, with so much facility, that this practice must be, I should think, habitual with them." Subsequent field observers have confirmed the partial arboreal habitus of *A. bennettii* (E. C. Reed 1877). Darwin (in Waterhouse 1839:87) also stated

that "the species is abundant on the dry hills, partly covered with bushes, near Valparaíso," a reference to the characteristic Mediterranean habitat of Chile (see also Cofré et al. 2007). Fulk (1976) observed *A. bennettii* using the burrows of the degu (*Octodon degu*).

This species is part of a small mammal community that has been intensively studied in the Mediterranean habitat of central Chile. It inhabits rocky matorral and shrublands from sea level and coastal canyon to 2,000 m in the Andes. In the coastal desert zones in northern Chile, it occurs in local habitats influenced by fog and dominated by cacti and large, succulent shrubs (Guzmán and Siefeld 2011), but habitats include agricultural, wetland, and riparian shrublands (P. Valladares and Campos 2012). Data are available on population ecology, including the interplay between biotic and abiotic factors (Meserve et al. 1999), species assemblage (Iriarte, Contreras, and Jaksic 1989), patterns of temporal abundance and persistence (Jaksic et al. 1981; J. E. Jiménez et al. 1992), demographic responses to an El Niño Southern Oscillation (ENSO) event (Meserve et al. 1995), trophic relationships (Meserve 1981a), feeding ecology (Meserve 1983), and resource partitioning (Meserve 1981b), primarily but not exclusively on populations within Parque Nacional Fray Jorge. This species is also a prey item of the grison (*Galictis cuja*) and two species of local foxes (*Lycalopex culpaeus* and *L. griseus*) as well as the Barn Owl (*Tyto alba*) (Durán et al. 1987; Ebensberger et al. 1991; Iriarte, Jimenez et al. 1989; Jaksic et al. 1980; Meserve et al. 1987). Beaucournu et al. (2011) described a species of flea in the genus *Delostichus* and M. S. Gómez (1998) described the louse *Eulinognathus chilensis*, both taken from Chilean specimens.

Durden and Webb (1999), Gomez (1998), Moreno Salas et al. (2005), described ectoparasites.

REMARKS: Wolffsohn (1916:6) noted that skins of this species were "frequently offered for sale as true chinchilla [= *Chinchilla*] skins." Thomas (1927b:553) regarded *A. cuvieri* Waterhouse to be "unquestionably the young of *A. bennettii*," certainly true since the third molar has yet to erupt in the maxilla and mandible figured by Waterhouse (1839:plate 33, Fig. 1e,f). Osgood (1943b:107) noted that the old village of Aconcagua (the type locality) "has now disappeared and is represented only by a 'fundo' called Plaza Vieja. This is some five kilometers west of the present town of Los Andes." L. C. Contreras et al. (1993) described the soft anatomy of the glans penis and baculum. M. H. Gallardo et al. (2002) detailed sperm morphology. Spotorno et al. (1988) described the karyotype as $2n = 64$, $FN = 110$; M. H. Gallardo (1992) illustrated the C-banded karyotype; and Spotorno et al. (1995) discussed chromosomal divergence within the Octodontoidea. The species

Map 418 Selected localities for *Abrocoma bennettii* (●), *Abrocoma budini* (△), *Abrocoma famatina* (▼), *Abrocoma schistacea* (○), *Abrocoma uspillata* (▲), and *Abrocoma vaccarum* (▽). Contour line = 2,000 m.

has been recovered from Holocene deposits spanning the last 8,000 years in central Chile (Simonetti 1994).

Abrocoma boliviensis Glanz and Anderson, 1990
Bolivian Chinchilla Rat

SYNONYMS:

Abrocoma boliviensis Glanz and Anderson, 1990:23; type locality “Comarapa, 2500 m, province of Manuel M. Caballero, department of Santa Cruz, Bolivia; 17°54’S and 64°29’W.”

Cuscomys boliviensis: Verzi and Quintana, 2005:310; name combination.

DESCRIPTION: Medium sized, head and body length 170–178 mm, with relatively small hindfeet (length 30 mm), moderately long tail (132–150 mm), and short ears (22–

25 mm). Tail well furred, more so than in either *A. bennettii* or members of *A. cinerea* complex. Dorsal fur short and not as soft as in other species. Overall dorsal coloration dark gray-brown, contrasting strongly with gray-based but white-tipped hairs of venter; patches of hair on chest and inguinal areas white to their base; dark throat patch present in both known specimens, more distinctly obvious in holotype; narrow midline white streak on chest may indicate presence of a sternal gland. Tail indistinctly bicolored, paler below. Dorsal surfaces of forefeet and hindfeet clothed with whitish hairs, palmar and plantar surfaces naked and less pigmented than other species.

Skull smaller than in other species, with condylobasal length averaging 40.1 mm (range: 39.0–41.1 mm) as opposed to >48 mm. Nasals relatively shorter and do not extend posterior to anterior edge of the orbit. Tympanic and mastoid portions of bullae notably less inflated, although more similar to bullae of low elevation populations of *A. bennettii* in coastal Chile.

DISTRIBUTION: *Abrocoma boliviensis* is known only from the vicinity of the type locality.

SELECTED LOCALITIES (Map 419): BOLIVIA: Santa Cruz, Comarapa (type locality of *Abrocoma boliviensis* Glanz and Anderson).

SUBSPECIES: *Abrocoma boliviensis* is monotypic.

NATURAL HISTORY: Nothing is known about the behavior, ecology, or other aspects of the population biology of this species. O. P. Pearson (field notes, MVZ archives) collected the second known specimen in a trap set “along a ridge with rock outcrops plus bushes, grass, and many succulents, plus a few orchids . . . and ferns” in an area otherwise characterized as brushy vegetation with patches of cloud forest.

REMARKS: As noted by Glanz and Anderson (1990:24) there is some uncertainty about the place of origin of the holotype, and thus details about the exact type locality. The town of Comarapa is at 1,815 m (Atlas Censal de Bolivia), but the terrain around the town reaches 2,500 m within a few kilometers to the north, west, and south. The specimen thus likely came not from the town of Comarapa itself, but from the surrounding high country. The second, and only other specimen known of this species, was collected 8 km west of Comarapa, by road, at an elevation of 7,500 ft (ca. 2,270 m; O. P. Pearson field notes, MVZ archives). The area where the MVZ specimen was collected in 1955 had been greatly altered by the mid-1980s when S. Anderson (AMNH) visited the region, by increased intensity of human use, notably heavy grazing and cultivation (Glanz and Anderson 1990:26). Possibly this presumably rare species has either gone locally extinct or its abundance has been severely impacted. Additional fieldwork is critically needed in the vicinity of the type locality and other areas in the

Map 419 Selected localities for *Abrocoma boliviensis* (○) and *Abrocoma cinerea* (●). Contour line = 2,000 m.

diverse “valles” region of central Bolivia (Glanz and Anderson 1990:26). Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

Verzi and Quintana (2005) referred *boliviensis* to *Cuscomys*, based on shared features of the molar teeth and similar small coronoid processes. Pending future phylogenetic analyses that should include both morphological and molecular traits, we retain *boliviensis* within *Abrocoma* because the species possesses none of the diagnostic characters of *Cuscomys* presented by Emmons (1999a) in her description of this genus. Interestingly, Emmons (1999a) considered *A. boliviensis* along with *Cuscomys* to be the morphologically least specialized Abrocomidae.

Abrocoma budini Thomas, 1920

Budin's Chinchilla Rat

SYNONYMS:

Abrocoma budini Thomas, 1920b:476; type locality “Otro Cerro, Catamarca. Alt. 3000 m” (about 18 km NNW Chumbicha), now considered an abandoned ranch at the southern end of Sierra de Ambato, NE Chumbicha, Capayán, Catamarca, Argentina, 28°45'S, 66°17'W, 2,023 m (Pardiñas et al. 2007).

Abrocoma cinerea budini: Ellerman, 1940:155; name combination.

DESCRIPTION: Largest species in *A. cinerea* complex, total length >320 mm, head and body length >130 mm, hindfoot length >30 mm; darker both dorsally and ventrally than other species in complex. Coloration uniformly brownish gray, back slightly darker than sides, venter grayish drab, with hairs dark grayish or slate for about three-fourths of their length and with pale drab tips. Hairs of sternal gland white to base, thus forming white patch contrasting strongly with surrounding ventral coloration; chin grayish white, underside of neck darker than other ventral areas; hairs surrounding perianal region with buffy or whitish tips. Like *A. famatina*, drab throat patch present. Forefeet and hindfeet covered dorsally with whitish hairs. Tail dark drab to grayish above contrasting with grayish white to whitish below. Cranially, nasals evenly narrow for about half to two-thirds of length, becoming markedly convergent posteriorly, ending in a point. Dorsal edge of zygoma slanted outward such that medial edge is visible from above; anterior ascending maxillary portion of zygoma thin. Zygomatic arches expanded laterally; frontals noticeably constricted. Ventrally, posterior border of palate pointed, mesopterygoid fossa wide, mastoid islands large, and bullae slightly inflated. Upper incisors broad, large, and opisthodont. Hypoflexus and metaflexus of upper molars about equal in size and positioned more or less horizontally. Major cusps of upper cheek teeth more rounded and less anteroposteriorly compressed than in other species; all teeth subequal in size and shape. The overall length of upper tooththrow short in relation to length of skull, similar in proportional length to that of *A. famatina* and *A. vaccarum*, smaller than that of *A. cinerea* and *A. schistacea*, and much smaller than that of *A. uspallata*. In comparison to other species in complex, *A. budini* significantly larger in cranial length, diastema length, nasal length (except *A. schistacea*), and mandible length (except *A. schistacea*). Tooththrows and palate significantly longer, and wider zygomatic arches, than *A. famatina*, but interorbital breadth significantly narrower than *A. cinerea*.

DISTRIBUTION: *Abrocoma budini* is known only from the Sierra de Ambato in Catamarca province, Argentina.

SELECTED LOCALITIES (Map 418): ARGENTINA: Catamarca, Cerro Ambato (Glanz and Anderson 1990), Otro Cerro (type locality of *budini* Thomas).

SUBSPECIES: *Abrocoma budini* is monotypic.

NATURAL HISTORY: No data on ecology, behavior, or any aspect of life history are known for this species, although Barquez et al. (1991) stated that the species (regarded as a subspecies of *A. cinerea*) lives in rocks and is apparently colonial. Thomas (1920b:476), in his description of this taxon, noted that the collector, Emilio Budin, found it “among rocks, in the clefts of which it lives.”

REMARKS: As with other species in the *Abrocoma cinerea* complex, *A. budini* is a geographic outlier to the broad range of *A. cinerea* and, as such, was considered only sub-specifically distinct from that species by Ellerman (1940) and Cabrera (1961). Braun and Mares (2002) elevated *A. budini* to species status. The karyotype is unknown.

Abrocoma cinerea Thomas, 1919

Ashy Chinchilla Rat

SYNONYMS:

Abrocoma cinerea Thomas, 1919f:132; type locality “Cerro Casabindo, 4800 m,” Jujuy, Argentina.

Abrocoma cinerea cinerea: Ellerman, 1940:154; name combination.

DESCRIPTION: Medium sized, total length <286 mm, head and body length <196 mm, tail length <96 mm, hind-foot length typically ≤ 27 mm). Tail notable absolutely shorter than any other species, total length and hindfoot length less than those of *A. budini*, *A. famatina*, and *A. schistacea* (note, however, that the measurements given by Braun and Mares [2002:Table 1] include very small dimensions [lower range: 15.6 mm], likely from either juvenile specimens or those measured without the claw; Glanz and Anderson [1990:Table 1] give the range for nine specimens as 23–30 mm, mean 27.8 mm). Mean ratio of tail length to body length less than that for other species. Overall dorsal coloration pale gray, with ventral hairs gray basally with whitish tips, giving under parts whitish appearance. Sternal gland covered with white hairs, but does not contrast with very pale venter; hairs of perianal region white to the base. Both forefeet and hindfeet covered with whitish hairs. Tail indistinctly bicolored, pale gray above and whitish or grayish-white below. Two pairs of mammae in adult females, one axillary, other placed laterally on abdomen.

Skull smaller than that of *A. budini* but larger than *A. famatina*. Interorbital width greater than that of other species in group; nasals broad at midlength, tapering gradually posteriorly; zygomatic arches moderately expanded; frontals not constricted; mastoid islands only of medium size; posterior border of palate terminates in sharp point; mesopterygoid fossa wide, paroccipital processes narrow and not flattened; bullae inflated. Upper incisors broad, large, and opisthodont. Hypoflexi appear slightly narrower than in other species. Length of maxillary toothrow medium in relation to skull length, about equal to that of *A. schistacea*, larger than that of *A. budini*, *A. famatina*, and *A. vaccarum*, but much smaller than that of *A. uspillata*.

DISTRIBUTION: *Abrocoma cinerea* is distributed throughout the high Andes (above 3,700 m) from Arequipa in southern Peru, south through Bolivia, northwestern Ar-

gentina (Catamarca), and northeastern Chile (Antofagasta and Tarapacá). Late Pleistocene fossils from 1,562 m in Catamarca, Argentina, support a lower elevational and likely broader range, at least at the end of the last glacial maxima (P. E. Ortiz et al. 2011a).

SELECTED LOCALITIES (Map 418): ARGENTINA: Jujuy, Cerro Casabindo (type locality of *Abrocoma cinerea* Thomas), Sierra de Zenta (Thomas 1919f); Catamarca, Pasto alto (Braun and Mares 2002); Salta, Los Andes (Braun and Mares 2002); Tucumán, Concepción (Braun and Mares 2002). BOLIVIA: La Paz, Copacabana (S. Anderson 1997), Tembladerani (S. Anderson 1997); Oruro, Huancaroma (S. Anderson 1997); Tarija, Sama (S. Anderson 1997). CHILE: Antofagasta, Tocone (MVZ 116801); Arica y Parinacota, Arica (FMNH 134301). PERU: Arequipa, 2 km W of Sumbay (MVZ 174291); Puno, Caccachara (Pearson 1951); Tacna, 2 km N of Nevado Livine (Pearson 1951).

SUBSPECIES: As currently understood (Braun and Mares 2002), *A. cinerea* is monotypic.

NATURAL HISTORY: Emilio Budin collected the type specimen “among the rocks on the Volcano of Casabindo” (Thomas, 1919f:133) and specimens from the Sierra de Zenta “among the rocky volcanic mountains” (Thomas, 1921i:216). In northern Chile, Koford (1955) collected specimens “in their track ways or at the mouths of their open burrows [2 inches in diameter] at the bases of boulders or low resinous *tola* shrubs. On dry sandy slopes between low bushes and tufts of fescue, the round footprints, usually placed alternately as if the animal most often moved by running rather than by hopping, were followed for a distance as great as 200 yards.” He also noted that captive individuals readily ate the flowers and branch tips of the three most common shrubs (*Lepidophyllum rigidum*, *L. quadrangulare*, and *Baccharis microphylla* [Asteraceae]). The shrub *Baccharis tola* was the main plant consumed in the Parque Nacional Lullailaco in northern Chile, with the bunch grass *Stipa chrysophylla* of secondary importance (Tirado et al. 2012). Mann (1978), also in northern Chile, found this species inhabiting large rocks and carpets of yareta (*Laretia* [Apiaceae]). Pearson (1951) collected the species in the Puno department, southern Peru, at burrows dug at the edge of shale outcroppings or at the base of shrubs, and J. L. Patton (field notes, MVZ archives) obtained a single specimen in Arequipa department, Peru, among weathered granite boulders in the Altiplano. S. Anderson (1997) stated that this species was widely distributed in the Altiplano of Bolivia, where often it could be found in stonewalls. Both Pearson (1951) and Mann (1978) suggested that *A. cinerea* lives in colonies, where they feed primarily on shrubs in the family Asteraceae (*Senecio* and *Parastrephia* [Chile] and *Senecio*

or *Lepidophyllum* [Peru]). Gut morphology, in particular a long, convoluted caecum and a thick intestine with tight flexures, suggests a diet high in cellulose. Reproductively active females (pregnant or lactating) have been taken in the months of August, November, and December in both Chile and Peru (Pearson 1951; Mann 1978). Litter size in the few pregnant females collected was two or three. For populations in Salta Province, Argentina, Mares, Ojeda, and Barquez (1989) stated that the species was diurnal, herbivorous, and an excellent climber that lived in rock fissures or in burrows under rocks. These authors also suggested that the species is colonial. Cortes et al. (2002) described food habits of populations in northern Chile. Hugot and Gardner (2000) describe endoparasitic nematodes, based on specimens from Bolivia.

REMARKS: The locality record for the Santiago region in Chile (10 km W Tiltil) in Braun and Mares (2002:9 and map, pg. 7) continues an error in identification originally given by Glanz and Anderson (1990:9, caption to Fig. 3). The specimen in question (MVZ 150117) is an *Abrocoma bennettii*, not *A. cinerea* as stated. L. C. Contreras et al. (1993) described and figured the morphology of the glans penis and baculum, based on specimens from southern Bolivia. M. H. Gallardo et al. (2007) gave the diploid number as 64.

Abrocoma famatina Thomas, 1920

Famatina Chinchilla Rat

SYNONYMS:

Abrocoma famatina Thomas, 1920g:419; type locality "La Invernada, Famatina Range [= Sierra de Famatina], Rioja, 3800 m," Argentina.

Abrocoma cinerea famatina: Ellerman, 1940:155; name combination.

DESCRIPTION: Medium sized for genus, head and body length 164–182 mm, tail length 108–117 mm, hindfoot length 28–30 mm. Ratio of tail length body length similar to that of *A. budini*, but *budini* considerably larger in overall size. Dorsal color overall grayish with brownish tints along midline and across rump. Hairs of venter gray basally with whitish or pale drab tips; hairs of throat dark drab; hairs of sternal gland white to base, forming distinct white patch on mid-venter; hairs of perianal region whitish. Forefeet and hindfeet covered with white or whitish hairs. Tail bicolored, grayish above and whitish below. In color, *A. famatina* somewhat darker than *A. cinerea*, similar to *A. vaccarum*, but paler than both *A. budini* and *A. schistacea*. Presence of drab throat patch in common only with *A. budini*. Cranially, nasals slightly wider at midlength and taper posteriorly; dorsal edges of zygoma slanted outward such that medial edges easily visible in dorsal view; ascending maxillary portions of zygoma thin; zygomatic arches expanded, as in other species in this group; frontals noticeably

constricted and mastoid islands medium in size. Ventrally, posterior border of palate rounded; mesopterygoid fossa wide; bullae inflated. Upper incisors narrow, small, and opisthodont to orthodont. Length of maxillary toothrow medium in relation to skull length, about equal to that of *A. budini* and *A. vaccarum*, smaller than for *A. cinerea* and *A. schistacea*, and much smaller than for *A. usspallata*.

DISTRIBUTION: *Abrocoma famatina* is known only from the Sierra de Famatina in Rioja, Argentina. Cabrera (1961) suggested that the species extends to the Sierra del Valle Fertil and Sierra Pie de Palo in eastern San Juan province, but this is unlikely due to geographic barriers separating these ranges from the Sierra de Famatina (Braun and Mares 2002).

SELECTED LOCALITIES (Map 418): ARGENTINA: Rioja, Famatina (Braun and Mares 2002), La Invernada (type locality of *Abrocoma famatina* Thomas).

SUBSPECIES: *Abrocoma famatina* is monotypic.

NATURAL HISTORY: No data are available on the behavior or ecology of this species.

REMARKS: As with other members of the *A. cinerea* complex, *A. famatina* is limited to an isolated extension of the Andes in northwestern Argentina, and is thus a geographic outlier to the broad range of *A. cinerea*. Thomas (1920g) regarded this species as closest to *A. budini*. Considered a subspecies of *A. cinerea* by Ellerman (1940) and Cabrera (1961), *A. famatina* was raised to species status by Braun and Mares (2002). The karyotype is unknown.

Abrocoma schistacea Thomas, 1921

Sierra Tontal Chinchilla Rat

SYNONYMS:

Abrocoma schistacea Thomas, 1921i:216; type locality "Los Sombreros, Sierra Tontal. Alt. 2700 m," San Juan, Argentina.

Abrocoma cinerea schistacea: Ellerman, 1940:155; name combination.

DESCRIPTION: Medium-sized rat, head and body length 160–196 mm, tail length 96–120 mm, hindfoot length 25–30 mm. Overall dorsal color grayish drab, slightly darker along midline, with under parts similar but slightly paler to dorsum. Drab throat patch lacking; sternal gland present, covered by hairs white to their base; whitish hairs surround perianal region. Tail bicolored, similar to dorsal body color above but whitish yellow below. Forefeet and hindfeet covered dorsally with whitish hairs. All other species in genus, except *A. budini*, paler in both dorsal and ventral coloration. External measurements significantly smaller than those of *A. budini*, significantly larger than *A. cinerea*, but similar to *A. famatina* except for its smaller hindfoot. Mean ratios of tail to body length similar to values for *A. usspallata* and *A. vaccarum*. Cranially,

characterized by nasals wider at midlength and taper posteriorly; dorsal edge of zygoma slanted laterally such that medial edge easily visible in ventral view; anterior ascending maxillary portion of zygoma thin; zygomatic arches expanded; frontals noticeably constricted; mastoid islands of medium size. Ventrally, posterior border of palate rounded; mesopterygoid fossa wide; bullae only slightly inflated. Upper incisors broad, large, and more orthodont than in other species. Molariform teeth appear broad, but length of maxillary toothrow medium in relation to length of skull about equal to that of *A. cinerea*, longer than *A. budini*, *A. famatina*, and *A. vaccarum*, but much shorter than that of *A. uspallata*. Hypoflexus narrower in breadth than in other species. Taraborelli et al. (2011) noted, in particular, presence of buccal epidermal denticles (or “false teeth”) on midline of palate and tongue with horny pad.

DISTRIBUTION: *Abrocoma schistacea* is known from three localities in southern San Juan province, Argentina (Thomas 1921i; Braun and Mares 2002; Taraborelli et al. 2011), all within the Monte Desert biome at elevations between 1,100 and 2,900 m.

SELECTED LOCALITIES (Map 418): ARGENTINA: San Juan, Los Sombreros (type locality of *Abrocoma schistacea* Thomas), Parque Nacional El Leoncito (Taraborelli et al. 2011), Pedernal (Thomas 1921i).

SUBSPECIES: *Abrocoma schistacea* is monotypic.

NATURAL HISTORY: Few data on behavior, ecology, or reproduction are available. Taraborelli et al. (2011) found the species in shrub habitats dominated by *Larrea nitida* and *L. divaricata* (Zygophyllaceae) in the Parque Nacional El Leoncito, San Juan province, Argentina. Individuals occupied burrow systems within crevices on hill-sides with rocky flagstone walls. Animals lived in groups of three to four, consisting of a single male and two females or two of each sex; density averaged 0.15 individuals per ha⁻¹. They used readily identifiable latrine sites composed of piles of fecal pellets. Animals were active primarily in the early morning. Feeding was selective, rather than in relation to plant availability, with *Larrea* being the dominant food plant, especially in summer and autumn.

REMARKS: A geographic outlier to the broadly distributed *A. cinerea*, this taxon was regarded as a subspecies of *A. cinerea* by Ellerman (1940) and Cabrera (1961) but raised to species status by Braun and Mares (2002) based on comparative morphometrics analyses. The karyotype is unknown.

Abrocoma uspallata Braun and Mares, 2002

Uspallata Chinchilla Rat

SYNONYM:

Abrocoma uspallata Braun and Mares, 2002:9; type locality “Argentina: Mendoza Province: Quebrada de la Vena,

ca. 7 km SSE of the village of Uspallata, 32°39.405'S, 69°20.970'W, 1,880 ± 150 m.”

DESCRIPTION: Medium sized, mean head and body length 175.3 mm, tail length 118.7 mm, hindfoot length 29.2 mm, and mass 157.3 g; hindfeet and ears large relative to body size. The dorsal fur grayish brown with lighter tones at tips on some hairs but black on others; under parts gray basally with creamish tips, and thus an overall appearance of lightly colored venter; sternal gland and area surrounding the perianal region covered with hairs white to base and not contrasting with overall ventral color. Forefeet and hindfeet covered with white hairs. Skull with nasals evenly narrow along entire length, tapering only at posterior end; frontals constricted; mastoid islands large; zygomatic arches moderately expanded but do not extend beyond greatest width of skull; zygomata delicate, with anterior ascending processes of maxillae reduced to slender struts; jugal parts of zygomatic bridges reduced to ventral bases of bridges and, thus jugals well separated from lacrimals; incisive foramina elongated and narrow, broadening slightly posteriorly; palate short and narrow, extending posteriorly to about posterior margins of M2, with rounded posterior border; posterior palatal foramina present as two small, separate entities; pterygoids delicate and adjacent foramina large; mesopterygoid fossa narrow; bullae inflated, covering middle lacerate foramina, and large relative to cranial length; paroccipital processes broad, flattened, and fused to bullae posteroventrally. Upper incisors small, narrow, short, opisthodont, with orange enamel. Upper toothrows converge only slightly anteriorly. Lophes of cheek teeth transverse in orientation with cusps of upper molars opposite and compressed anteroposteriorly.

Distinguished from other species in genus by grayer dorsal and whiter ventral coloration (except *A. cinerea*), longer tail (except *A. budini*, which is longer, and *A. famatina*, about equal), larger hindfoot, larger ears, narrower nasals, moderately expanded zygomatic arches (except *A. cinerea*), larger mastoid islands (except *A. budini*), narrower mesopterygoid fossa (except *A. vaccarum*), relatively larger bullae, wide and flattened paroccipital processes, smaller incisors (except *A. famatina*), and relatively longer toothrows. Braun and Mares (2002) provided additional characters explicitly separating this species from other members of the *A. cinerea* complex.

DISTRIBUTION: *Abrocoma uspallata* is known from two localities in the Sierra de Uspallata, northwestern Mendoza Province, Argentina (Braun and Mares 2002; Taraborelli et al. 2011), within the Monte Desert biome at elevations between 1,850 and 2,150 m.

SELECTED LOCALITIES (Map 418): ARGENTINA: Mendoza, Quebrada de la Vena (type locality of *Abrocoma*

uspallata Braun and Mares), *Uspallata* (Taraborelli et al. 2011).

SUBSPECIES: *Abrocoma uspallata* is monotypic.

NATURAL HISTORY: This species occurs at the lowest elevation of any in the genus, with the holotype collected in a rock outcrop within the precordilleran Monte Desert characterized by creosote bush, palo verde, and various cacti (Braun and Mares 2002; Taraborelli et al. 2011). Burrows were found in crevices among rock blocks or flagstones on steep slopes, where vegetation was dominated by bunch grasses (*Stipa* sp.) and shrubs (*Larrea divaricata* and *Atriplex lampa* [Zygophyllaceae]; Taraborelli et al. 2011). Braun and Mares (2002) argued that the species was a specialist on creosote bush, which suggested a long association with the Monte Desert because of the need to evolve necessary adaptations to cope with the toxic compounds characterizing this plant. Taraborelli et al. (2011), however, found *Larrea* to comprise only 30% of the diet, with shrubs of the genera *Lycium* (Solanaceae) and *Schinus* (Anacardiaceae) taken in nearly equal proportions. Individuals are diurnal, being most active in the morning hours, and use common latrines near their burrow systems.

REMARKS: This species is known from a single specimen, the holotype, so aspects of individual variation are unknown. The karyotype has a diploid number of 66; the fundamental number could not be determined, but the majority of the chromosomes are apparently biarmed (Braun and Mares 2002).

Abrocoma vaccarum Thomas, 1921

Mendozan Chinchilla Rat

SYNONYMS:

Abrocoma vaccarum Thomas, 1921i:217; type locality "Punta de Vacas, Altitude 3000 m, North-western Mendoza," Argentina.

Abrocoma cinerea vaccarum: Ellerman, 1940:155; name combination.

DESCRIPTION: Medium sized, head and body length 165–191 mm, tail length 108–117 mm, hindfoot length 25–27 mm). Overall dorsal tones grayish, with some brownish tints, especially along midline and over rump. Hairs of venter gray basally for most of length, with whitish tips; sternal gland and perianal area covered with hairs white to base, contrasting sharply with generally gray under parts. The forefeet and hindfeet are covered with whitish hairs. Tail bicolored, grayish above and whitish below. In other species, except *A. cinerea*, tail darker dorsally and somewhat darker below, although all species share generally bicolored tail. Drab throat patch present, as in *A. budini* and *A. famatina*. Skull with nasals slightly wider at midlength and tapering posteriorly; dorsal edge of zygoma slanted outward such that medial edge easily visible in dorsal view;

anterior ascending maxillary portion of zygoma thin; frontals well constricted, as in other species of group; mastoid islands medium in size; posterior border of palate rounded; mesopterygoid fossa narrow; bullae only slightly inflated. Upper incisors broad, large, opisthodont to orthodont, with white to very pale orange enamel. Molariform teeth appear slightly broader than those of other species, except *A. schistacea*. Length of maxillary toothrow in relation to cranial length about equal to that of *A. budini* and *A. famatina*, shorter than that of *A. cinerea* and *A. schistacea*, and much shorter than that of *A. uspallata*.

DISTRIBUTION: *Abrocoma vaccarum* is known only from the type locality in Mendoza Province, Argentina. Cabrera (1961) extended the range to include southwestern San Juan, but no specimens are known from that region.

SELECTED LOCALITIES (Map 418): ARGENTINA: Mendoza, Punta de Vacas (type locality of *Abrocoma vaccarum* Thomas).

SUBSPECIES: *Abrocoma vaccarum* is monotypic.

NATURAL HISTORY: No data on are available on ecology, behavior, or other aspects of the biology of *Abrocoma vaccarum*. The habitat at the type locality consists of the short grass and low shrub vegetation characteristic of the Puna-like high Andean vegetation (Braun and Mares 2002). Beaucournu and Gallardo (2005) described ectoparasitic fleas.

REMARKS: *Abrocoma vaccarum* is another geographic outlier from the range of the broadly distributed and presumably closely related species, *A. cinerea* (Braun and Mares 2002:7). Considered a subspecies of *A. cinerea* by Ellerman (1940) and Cabrera (1961), *A. vaccarum* was raised to species status by Braun and Mares (2002). The karyotype is unknown.

Genus *Cuscomys* Emmons, 1999

The genus contains the largest species in the family (*C. ashaninka*), with the second known species (*C. oblativus*) only slightly smaller. Because the latter is only known from osteological remains, little external morphology was included in Emmons's (1999a) diagnosis of the genus. However, many of the very distinctive external morphological features of the genotype, detailed below, may also be diagnostic of the genus. In 2009 a living *Cuscomys* specimen was captured and later released about 3 km from the type locality of *C. oblativus*. Based on a series of photos (Julio G. Ochoa, pers. comm., with photographs, to L. H. Emmons), this animal showed few differences from *C. ashaninka*. We presume this individual to have been *C. oblativus*, and describe its external morphology as such, pending collection of a complete specimen for definitive comparison.

Emmons (1999a:2) diagnosed *Cuscomys* as the largest known living abrocomid rodent and the only genus morphologically adapted for an arboreal habitus. It has a long tail, greater than 75% of the head and body length; broad feet, with strong curved claws; and a stout and long hal-lux, reaching beyond the base of the second toe. The skull is large (condylobasal length >60 mm), with a robust and long rostrum nearly as broad as the interorbital region. It may be either flat or arched in dorsal profile when viewed laterally. The nasals are inflated distally, and are either blunt posteriorly (*C. ashaninka*) or separated (*C. oblativus*). The frontals are constricted behind the postorbital process such that the width at this point is equal to or less than the interorbital breadth. The palate between the upper toothrows is only slightly concave, with a prominent ridge along the median suture of the palatine bones. A temporal foramen is present posterior to the postglenoid vacuity. The dorsal extension of the mastoid between the occipitals and parietals is small and not inflated (it does not bulge dorsally). The sigmoid notch of the mandible is long and the medial condyloid ridge does not approach or meet the posterior edge of the mandible. The head has a pure white blaze from crown to chin, and the tail is sharply bicolored dark for the basal half, white for the distal half.

SYNONYM:

Cuscomys Emmons, 1999a:2; type species, *Cuscomys ashaninka* Emmons, by original designation.

REMARKS: Woods and Kilpatrick (2005:1575) incorrectly cited *A. oblativus* Eaton as the type species. These authors also used the feminine ending for the species epithet despite the fact that Emmons (1999a:2) clearly stated “the generic name is masculine.” Verzi and Quintana (2005) included *Abrocoma boliviensis* within this genus, based on shared features of the maxillary teeth and small coronoid process. But, as noted in that account, *A. boliviensis* shares none of the diagnostic characters of *Cuscomys* detailed by Emmons (1999a) in her description of the genus. We thus leave *boliviensis* within *Abrocoma*, pending the necessary phylogenetic analyses of either, or preferably both, morphological and molecular characters.

KEY TO THE SPECIES OF *CUSCOMYS* (SKULL CHARACTERS ONLY, BECAUSE EXTERNAL FEATURES ARE KNOWN ONLY FOR ONE OF THE TWO KNOWN SPECIES):

1. Larger skull (greatest skull length >66 mm); skull flat in dorsal profile; foramen magnum much wider than high; premaxillae narrow posteriorly; posterior loph of M3 directed labially, posterior border straight *Cuscomys ashaninka*
- 1'. Smaller skull (greatest skull length >64 mm); skull arched in dorsal profile; foramen magnum subcircular,

slightly higher than wide; premaxillae widening distinctly posteriorly; posterior loph of M3 directed posteriorly, posterior border strongly concave *Cuscomys oblativus*

Cuscomys ashaninka Emmons, 1999

Ashaninka Arboreal Chinchilla Rat

SYNONYM:

Cuscomys ashaninka Emmons, 1999a:2; type locality “Peru: Departamento de Cusco, northern Cordillera de Vilcabamba, 11°39'36”S; 73°40'02”W (by GPS, map datum WGS-84); elevation 3370 m,” corrected to Junín department by Quintana Navarrete (2011).

DESCRIPTION: Large (mass >900 g; head and body length >300 mm), with long tail (tail length >200 mm), and long but wide hindfeet (length >60 mm). Fur dense and long, pale gray dorsally with abundant black guard hairs 40 mm long extending 20–25 mm beyond underfur in mid-dorsum, and giving blackish coloration along midback; sides paler, sprinkled with mixture of white and dusky overhairs; dorsal underfur pale gray, soft, and somewhat wavy. Head with narrow white blaze from nose to crown; lips and chin white. Venter gray, with lightly frosted hairs, and not contrasting with sides; midline of chest between forelegs with streak of short hairs, probably associated with a sternal gland. Mystacial vibrissae dense, stiff, and either white or dusky, and extend behind shoulder when flattened against body. Three superciliary vibrissae present but no genal vibrissae evident; single vibrissa present on mid-forelimb of holotype, and only known specimen. Ear pinnae nearly naked, with fur at base sufficiently long to reach ear tips. Tail robust and long (76% of head and body length), clothed with stiff hairs that nearly hide underlying scales, and sharply bicolored dark for basal half and white for distal half. Forefeet have four toes, without evidence of a pollex; hindfeet with hallux without ungual tuft, other four digits with long, dusky tufts reaching beyond tips of stout, strongly curved claws. Feet thinly clothed with dusky hairs; broad with soles pigmented proximally but not distally (white in fresh specimen), covered with tiny tubercles; palmar and plantar pads soft and poorly defined. Only single pair of inguinal mammae was discovered, but specimen was primiparous, and its nipples small.

Skull large and robust (greatest skull length >65 mm), dorsal profile flat, and rostrum deep and broad. Nasal bones broad and slightly inflated distally, two posterior tips meet in straight line with no intercalation of the frontals; premaxillary bones of rostrum do not widen posteriorly; frontals widest anterior to postorbital process and constricted posteriorly; dorsal projections of mastoid bones small and uninflated; parietal ridges and supraoccipital crest strongly developed. Incisors large and robust; upper incisors proodont. Maxillary toothrows slightly divergent posteriorly. Man-

dible robust in comparison to species of *Abrocoma*, with angular and condyloid processes dorsoventrally deep; medial condyloid ridge passing midway up center of process, not approaching its posterior edge; external tip of condyloid process with well-defined, short medial crest; and low coronoid process. Occlusal pattern of cheek teeth similar to other species in family, but with lingual flexi at shallow angle and nearly equal in length with labial flexi such that mid-tooth mure short and nearly parallel to tooth axis.

DISTRIBUTION: *Cuscomys ashaninka* is known only from the type locality.

SELECTED LOCALITIES (Map 420): PERU: Junín, Cordillera de Vilcabamba (type locality of *Cuscomys ashaninka* Emmons).

SUBSPECIES: *Cuscomys ashaninka* is monotypic.

NATURAL HISTORY: The holotype, and single known specimen, was found dead, probably killed by a long-tailed weasel (*Mustela frenata*). The specimen was found on a steep slope in tall, wet, mossy cloud forest dominated by *Weinmannia fagaroides/microphylla* (Cunoniaceae) and *Polylepis* cf. *pauta* (Rosaceae) trees with abundant *Chusquea* sp. scandent bamboo. Alonso et al. (1999) provided details of the vegetation and other fauna at the type locality. The stomach of the holotype was greatly expanded with 140 cc of finely triturated plant material, including fruit and unidentified plant tissue. When collected 15 June, it contained a single 8 × 5 mm embryo.

Map 420 Selected localities for species of *Cuscomys ashaninka* (●) and *Cuscomys oblativus* (○). Contour line = 2,000 m.

REMARKS: The type locality is the northernmost recorded for the family, about 200 km north of the Inca burials at Machu Picchu, where *C. oblativus* was found. Between these two localities are the deep canyons of the Urubamba and Apurimac rivers and the 5,000 m snow-capped peaks of the Nevado de Sacsarayoc. Upper elevations of the northern Vilcabamba ridge are essentially a habitat island. Other mammals collected at the type locality show relationships to those to the south from the Machu Picchu area, but the area is likely to have a high local mammalian endemism because of its size and degree of isolation (Emmons 1999a).

Price and Timm (2002) described two genera of chewing lice (Phthiraptera, Grypidae), one new, from the holotype of *C. ashaninka*.

Cuscomys oblativus (Eaton, 1916)

Machu Picchu Arboreal Chinchilla Rat

SYNONYMS:

Abrocoma oblativa Eaton, 1916:87; type locality "Machu Picchu," Cusco, Peru.

Cuscomys oblativus: Emmons, 1999a:2; first use of current name combination.

DESCRIPTION: See Emmons (1999a:6–8, Figs. 7–9, Table 1) for detailed descriptions and figures of two nearly complete skulls of *C. oblativus* recovered at Machu Picchu. Specimens slightly smaller than *C. ashaninka* in both cranial length and breadth, with much longer tympanic bullae; incisors slightly larger in width; toothrow length larger; interorbital constriction is broader. One specimen with M3 unerupted and is immature. Skull more strongly arched in dorsal profile, much like that of *Abrocoma*; upper incisors opisthodont rather than proodont; tympanic bullae much less inflated; bony auditory tubes are shorter, with their openings more laterally, as opposed to upwardly, directed. Maxillary process of superior zygomatic root broader anteroposteriorly, and canted such that superior root is anterior to inferior root. Narrower zygomatic process of *C. ashaninka* slants in opposite direction. Nasals also separated posteriorly by projection from frontal bones, and premaxillae of rostrum widen posteriorly when viewed dorsally. Foramen magnum subcircular and slightly higher than wide, contrasting with much wider than high condition of *C. ashaninka*. Finally, maxillary toothrows more nearly parallel for entire length, with less posterior divergence; posterior loph of M3 directed posteriorly rather than laterally, and with strongly concave posterior border in contrast to nearly flat border. Medial loph of M3 broad and square, not tapered as in *C. ashaninka*.

A living specimen captured near Machu Picchu (J. G. Ochoa E., pers. comm. to L. E. Emmons, with photographs) very like *C. ashaninka*, but with ears relatively

longer, paler, and more pointed than round ears of *C. ashaninka*; smaller area of pure white on upper lips and base of vibrissae, and much paler head, apparently lacking black guard hairs on crown that border white blaze of *C. ashaninka*. Sex and age of this individual undocumented, but it shows a molt-line on rump, suggesting that it is subadult.

DISTRIBUTION: *Cuscomys oblativus* is known only from the type locality. A living rat presumably of this species was recently found and photographed on the Inca Trail near Wiñay Huayna about 3 km (airline) south of Machu Picchu (J. G. Ochoa E., pers. comm. to L. H. Emmons).

SELECTED LOCALITIES (Map 420): PERU: Cusco, Machu Picchu (type locality of *Abrocoma oblativus* Eaton).

SUBSPECIES: *Cuscomys oblativus* is monotypic.

NATURAL HISTORY: No data on behavior, ecology, or reproductive biology are known for *Cuscomys oblativus*.

REMARKS: For nearly a century this species was known only from the archaeological record at Machu Picchu, the famous Incan redoubt on the alto Río Urubamba. The tombs from which the original specimens were obtained date from between 1450 and 1532 AD (R. Burger, cited as pers. comm. in Emmons 1999a). Thomas (1920h:220) had concluded that the species was probably extinct “judging by the fact that . . . relatives are no longer found in this faunal area, but only far south in Chile and Argentina.” With the discovery of *C. ashaninka*, however, to the north in the Cordillera de Vilcabamba, Thomas’s statement regarding geographically distant relatives is no longer valid. A living individual was found and photographed near the type locality at Wiñay Huayna (J. G. Ochoa E., pers. comm. to L. H. Emmons), but no recent specimen exists for further comparison with *C. ashaninka*. Emmons (1999a:13) surmised that individuals of this species might have been kept as pets, or even domesticated as food or amusement because parts of individuals were found alongside four human burials, including a complete animal in a ceramic pot. One had elongated incisors, as if it has been maintained in captivity.

Family Ctenomyidae Lesson, 1842

Claudio J. Bidau

The family Ctenomyidae consists of the single Recent genus *Ctenomys* and four to six extinct genera (McKenna and Bell 1997), including *Actenomys* Burmeister (Pliocene), *Eucelophorus* Ameghino (Pliocene- Pleistocene), *Megactenomys* Rusconi (Pliocene), *Praectenomys* Villarroel (Pliocene), *Paractenomys* Ameghino (Pliocene), and *Xenodontomys* Kraglievich (Late Miocene). Both *Megactenomys* and *Paractenomys* are now viewed as either subgenera or synonyms of *Ctenomys* (Verzi and Lezcano

1996; Verzi 2002, 2008). Molecular phylogenetic analyses, both DNA sequences (e.g., A. H. Castillo et al. 2005; Cook and Lessa 1998; D’Elía et al. 1999; E. P. Lessa and Cook 1998; Opazo et al. 2005; Parada et al. 2011) and DNA-DNA hybridization (M. H. Gallardo and Kirsch 2001), strongly support a sister group relationship between the ctenomyids and the family Octodontidae. Authors, however, have differed as to whether these two taxa should be recognized at the level of the family (e.g., Simpson 1945; Woods and Kilpatrick 2005) or subfamily (e.g., McKenna and Bell 1997). The family is known only from southern South America, where much of its history has been arguably tied directly to the profound cooling and drying that began in the Miocene, especially with the Late Pliocene pulse detected worldwide at about 2.5 mya (Verzi 2002; Verzi and Quintana 2005). Earliest known fossils of *Ctenomys* date from the Late Miocene (Verzi 2002, 2008; Verzi and Quintana 2005; Reguero et al. 2007; Vieytes et al. 2007; Verzi et al. 2010).

The differentiation of the ctenomyids involved diverse adaptations to open habitats, especially those related to digging and life underground (Reig and Quintana 1992; Verzi 2002; Verzi and Olivares 2006). These adaptations included (1) acquisition of molar euhypsodonty and associated changes (occlusal simplification, secondary acquisition of radial enamel on the molar leading edge), (2) acquisition of a crescent-shaped occlusal morphology adapted to an oblique mastication, and (3) subterranean specializations of the external body and limbs, skull, and skeleton (Verzi 2002). Verzi (2008) hypothesized phyletic relationships among fossil and extant ctenomyid genera based on cladistic analysis of craniodental characters. Unambiguous synapomorphies for a monophyletic Ctenomyidae include an anterior extension of the maxillary (maxillary extended anterodorsally with respect to premaxillary septum, constraining the incisive foramen posteriad), a dorsal position of the rostral masseteric fossa (which provides attachment for the origin of the *M. masseter medialis anterior* muscle; its depth indicates strong development of this muscle), a protruding external auditory meatus with the anterodorsal and anterior margin oriented anteriorly, molars with flexi(id)s vestigial or absent, and a reduced M3, with the posterior or posterolingual face flat and anterior lobe protruding. Synapomorphies of the genus *Ctenomys* (including *Paractenomys*) include a rostral masseteric fossa positioned dorsal to the alveolar sheath of the upper incisor, deep, and ending in a curved crest slightly anterior to or level with the premaxillomaxillary suture; the bottom of the alveolar sheath of the upper incisor lodged in a cavity of the maxillary, positioned anterior to the alveolar sheath of M1; an external auditory meatus forming a protruding tube with its anterior wall moderately to very concave,

and with the ectotympanic recess forming a horizontal flat surface; a well-developed postcondyloid process, with a strong lateral apophysis on its ventral margin, and a crescent-shaped occlusal design of dpm4–m2 with a weak labial fold and a wider lingual concavity, with the posterior lobe of each molar more lingually oriented (Verzi 2008; Verzi et al. 2010).

Genus *Ctenomys* Blainville, 1826

The genus *Ctenomys* is the most speciose of any South American rodent with 63 species recognized herein (J. R. Contreras et al. 2000; Azurduy 2005a). However, as noted by Woods and Kilpatrick (2005), some 85 names have been applied to this genus, and many taxa remain to be adequately delimited geographically or systematically. It is thus clear that the number of species will increase with the combination of much needed additional field collections and revisionary work. In fact, within the past 20 years alone, eight new Recent species have been described (summary in Reeder et al. 2007; T. R. O. Freitas et al. 2012) along with several known only from the fossil record (Verzi et al. 2004; Azurduy 2005a; S. O. Lucero et al. 2008; see also Mones 1986). Additional species await description (Montes et al. 2001; Parada et al. 2011).

The earliest naturalists who explored southern South America made the initial observations and collections of *Ctenomys*. Rusconi (1931b) stated that Alcide d'Orbigny was the first one to collect a *Ctenomys* fossil, which formed the basis of *C. bonariensis* (= *C. bonaerenses*). Charles Darwin (1839, 1845) made observations on living tuco-tucos and also collected fossil mandibular fragments at Monte Hermoso in Buenos Aires province, Argentina, that Sir Richard Owen used to describe *Ctenomys priscus*, later transferred to the genus *Actenomys* (Villarroel 1975).

Living *Ctenomys* have been divided into three subgenera, based on morphological criteria: *Chacomys*, to include the single species *C. conoveri* (Osgood 1946); *Haptomys* to include *C. leucodon* (Thomas 1916g); and the nominotypical *Ctenomys* for all other species (Rusconi 1928). However, molecular evidence fails to support the validity of these subgenera, as both *C. conoveri* and *C. leucodon* are either deeply nested with the complex of species comprising the nominotypical subgenus (Cook and Yates 1994) or form part of a large basal polytomy (E. P. Lessa and Cook 1998; A. H. Castillo et al. 2005; Parada et al. 2011).

The genus is distributed from the Peruvian highlands, at approximately 15° south latitude, to Tierra del Fuego, with representative species in Bolivia, Chile, Argentina, Paraguay, Uruguay, and southwestern Brazil. The majority of species occur in Argentina where they are found in all provinces except Misiones (Bidau 2006), and where they occupy

a great diversity of habitats from sea level to an elevation of almost 5,000m. Tuco-tucos are also one of the mammal groups with highest karyotypic diversification, including species with diploid numbers ranging from $2n = 10$ to $2n = 70$ (Bidau 2006). The oldest fossils of *Ctenomys* are from the Uquía Formation in northwestern Argentina, providing a minimum age for the genus at about 3.5 mya (Reguero et al. 2007; Verzi et al. 2010), with the central Andes suggested as the possible area of origin. The molecular estimate of the time to the most recent common ancestor of extant *Ctenomys* species is considerably older, estimated at 9.2 mya (range: 6.4–12.6 mya), although most species groups stem from within the past 3 mya (Parada et al. 2011).

All species of tuco-tucos are of similar external morphology, each adapted for subterranean existence. However, there is considerable diversity in body size, ranging from the very small species such as *C. pundti*, *C. talarum*, or *C. sericeus* at less than 100g and 140mm head and body length (A. I. Medina et al. 2007) to very large ones, like the Chacoan species *C. conoveri*, where males can reach 1,200g and 558mm in head and body length (S. Anderson 1997). All species are sexually size dimorphic, with males the larger of the two sexes, but the degree of dimorphism increases with general body size (A. I. Medina and Bidau 2007; Bidau and Medina 2013; Steiner-Souza et al. 2010). The pelage ranges from short to long, is typically very thick, and general color varies extensively from gray or creamy buff to black on the upper surface (Nowak 1999). As in the North American pocket gophers (Geomyidae), which tuco-tucos resemble in external appearance and habits, fringes of hair are present on both forefeet and hindfeet. In tuco-tucos, however, the hairs on the hindfeet are stiffened and form comb like bristles that are the origin of the generic (and familial) names *Ctenomys* and Ctenomyidae (Greek root *ktenos* = comb; Blainville 1826).

The body is stout and cylindrical, the tail is short, and the limbs and neck are both short and very stout. All digits on both forefeet and hindfeet have very strong claws. The ears are very small, and the eyes are small but not as reduced as in other subterranean mammals. The incisors usually have bright orange enamel (except for *C. leucodon*, as per the name, where it is white or pale yellow). The molars are kidney-shaped, and the last one is reduced in size.

Data on reproduction are available only for a few species. Females typically produce one litter per year but some species can produce two (i.e., *C. talarum*; Malizia and Busch 1991). Species may reproduce in the dry (*C. opimus* in Peru) or the wet season (*C. torquatus* in Uruguay; Nowak 1999). Average gestation is 120 days, and litter size varies between one and three young in *C. opimus* to one to seven in *C. talarum*. Bidau and Medina (2013)

investigated testis size allometry and its relationship to sperm competition.

Males (and to a lesser degree, females) vocalize underground to mark territory, maintain social groups, or express fear. Burrow systems vary between species and type of soil but usually consist of a main tunnel up to 30 cm underground and of varying diameter, with several lateral ones with either blind ends or connecting to food sources on the surface, and a nest chamber. External openings are usually plugged when the burrow is occupied. Apparently, only *C. sociabilis* maintains burrows that are permanently open. Internal microclimatic conditions (temperature and humidity) are remarkably constant (20–22° C) in *C. torquatus* and *C. talarum* (A. I. Medina et al. 2007). Digging is typically a daylight activity. To dig, the substrate is loosened with the forefeet and removed with the hindfeet while incisors are used for cutting through roots (Weir 1974a). Tuco-tucos are completely herbivorous, eating roots and aerial parts of available plants, especially grasses (Barlow 1969).

Vieytes et al. (2007; see also Justo et al. 1995) investigated the ultrastructure of the incisor enamel and delineated morphofunctional traits among octodontoid genera with disparate digging adaptations. Those taxa that use their teeth in digging have a higher inclination of the Hunter-Schreger bands, higher relative thickness of the external index, and a higher enamel zone, traits which uniquely or in combination provide for enamel reinforcement to withstand the higher tension forces encountered while digging in hard soils. Vassallo and Mora (2007) examined scaling and growth trajectories in craniomandibular traits relevant to tooth digging, including the development of the mandibular angle and masseteric crest and the robustness of the incisors, and documented significant shape differences between ctenomyid and octodontid genera. And Steiner-Souza et al. (2010) documented shape diversity in the humerus with respect to digging adaptations. Within *Ctenomys*, these traits scale allometrically, such that large and small species do not differ in their respective ontogenetic trajectories. As a consequence, morphological diversification within this genus follows simple allometric scaling laws but changes in development resulting in departures from ontogenetic scaling underlie differentiation among genera within the superfamily. Similarly, Mora et al. (2003) examined cranial morphological attributes of tooth digging within *Ctenomys* and noted that incisor procumbency (a generalized character of tooth-digging) scales with rostral length but not overall size, but that incisor width and thickness do exhibit positive allometry such that larger species have proportionally more powerful incisors to resist greater bending forces.

The phylogenetic relationships within *Ctenomys* using molecular markers have only recently begun (E. P. Lessa and

Cook 1998; J. R. Contreras and Bidau 1999; D'Elía et al. 1999; Mascheretti et al. 2000; Montes et al. 2001; Slamovits et al. 2001; Giménez et al. 2002; A. H. Castillo et al. 2005; Parada et al. 2011). Interestingly, the substitution rate in the mtDNA cytochrome-*b* gene, which is the most common gene examined today, is elevated in comparison to above-ground octodontid relatives (C. C. Da Silva et al. 2009). Although results of these studies tend to be concordant, especially when considered jointly with morphological, chromosomal, parasitological, and biogeographic data (J. R. Contreras and Bidau 1999), species boundaries and phylogenetic relationships within the genus remain complex and incompletely understood. In this account, I recognize 64 species, 56 of which are monotypic and eight polytypic (with a combined 24 subspecies, including the nominotypical races of each). Two of these species (*C. "yolandae"* and *C. "mariafarelli"*) have yet to be properly described, but an account is provided for both because these names have been employed in the literature as though they were valid (e.g., Mascheretti et al. 2000; Woods and Kilpatrick 2005). Multiple other taxa defined by chromosomal or molecular sequences, each probably valid species, await formal description (see, for example, Parada et al. 2011). I include data on diploid number ($2n$), autosomal fundamental number (FN), presence of chromosomal polymorphism, and sperm morphology (J. R. Contreras 1996; Bidau 2006) in each species account for which such data are available.

SYNONYMS:

Orycteromys Blainville, 1826:63; used in the French form "*Oryctéromes*" for *Ctenomys* Blainville (see Palmer 1897b).

Ctenomys Blainville, 1826:64; type species *Ctenomys brasiliensis* Blainville, by monotypy.

Ratton Brants, 1827:187; part; inclusion of *Ratton tucotuco* Brants (1827:187), based on Azara's (1802:69) "*el tucotuco*"; suppressed for the purpose of Principle of Priority (but not Homonymy) by the International Commission (ICZN 1982:Opinion 1232).

Georychus: Lichtenstein, 1830:plate 31; part; not *Georychus* Illiger, 1811.

Haptomys Thomas, 1916g:305; as a subgenus of *Ctenomys*; type species *Ctenomys leucodon* Waterhouse, by original designation.

Chacomys Osgood, 1946:47; as a subgenus of *Ctenomys*; type species *Ctenomys conoveri* Osgood, by original designation.

Stenomys Avila-Pires, 1968:162; incorrect subsequent spelling of *Ctenomys* Blainville.

Both Cook et al. (1990:4–5) and S. Anderson (1997:58–59) provided illustrated keys to Bolivian species known

to them at that time, but, as documented in the accounts herein, I do not follow all of their taxonomic conclusions. Unfortunately, the production of a key for all 64 species herein covered is impossible at present. Species boundaries are both poorly defined morphologically and delimited geographically for too many taxa, 11 of which are known only from their type localities. The few specimens available preclude an adequate assessment of morphological variation and thus delineation of geographic trends for all but very few species. Moreover, while each species is described based on the available literature in the accounts here, these descriptions are uneven, incomplete, and all too often superficial in their coverage of the morphological characters provided. A thorough review of virtually every species, necessarily accompanied by widespread additional collecting, is critical to advance the current state of species-level systematics in the genus.

Recently, Parada et al. (2011) recognized eight polytypic species groups of *Ctenomys* plus seven additional apparently monophyletic species lineages using mtDNA sequences. These groups are almost coincident with those proposed by J. R. Contreras and Bidau (1999) on the basis of morphological, biogeographic, chromosomal, and incipient molecular data. The polytypic groups include (from Parada et al. 2011, followed by that by J. R. Contreras and Bidau 1999): (1) “boliviensis” or Boliviano-Matogrossense, including *C. boliviensis*, *C. goodfellowi*, *C. nattereri*, *C. robo*, and *C. steinbachi*; (2) “frater” or Bolivian-Paraguayan, including *C. conoveri*, *C. frater*, *C. lewisi*, and an undescribed species from Llathu, Cochabamba, Bolivia; (3) “magellanicus” or Patagonian (in part), including *C. colburni*, *C. coyhaiquensis*, *C. fodax*, *C. haigi*, *C. magellanicus*, and *C. sericeus*; (4) “mendocinus” or *C. mendocinus* complex plus Eastern Lineage, including *C. australis*, *C. flamarioni*, *C. mendocinus*, *C. porteousi*, and *C. rionegrensis*; (5) “opimus” or Chacoan, including *C. fulvus*, *C. opimus*, *C. saltarius*, and *C. scagliai*; (6) “talarum” or Ancestral, including *C. pundti* and *C. talarum*; (7) “torquatus” or Corrientes and Eastern, including *C. lami*, *C. minutus*, *C. pearsoni*, *C. perrensi*, *C. roigi*, and *C. torquatus*; and (8) “tucumanus” or Chacoan, including *C. argentinus*, *C. latro*, *C. occultus*, and *C. tucumanus*. Single species lineages, those that lacked supported relationships to any other taxa, included *C. maullinus*, *C. leucodon*, *C. tuconax*, and *C. sociabilis*. J. R. Contreras and Bidau (1999) either regarded these unique, single species lineages as of uncertain position (*C. leucodon* and *C. tuconax*) or did not include them in their study (*C. sociabilis*). T. R. O. Freitas et al. (2012) placed their newly described species *C. ibicuiensis* within the “torquatus” clade, also based on mtDNA sequences.

The phylogenetic hypothesis posited by Parada et al. (2011) and T. R. O. Freitas et al. (2012) is a remarkable

development, linking species that share biogeographic as well as biological characteristics. Unfortunately, however, these studies include only 40 of the 64 species recognized in the accounts that follow. Thus, the degree to which a relationship between clade membership and both distributional as well as other characters will remain robust must await the future inclusion of all known species into an enlarged analysis.

Note added in proof: After this book went into production, S. L. Gardner et al. (2014) characterized each of the 12 Bolivian species they recognized, describing four as new (*C. andersoni*, *C. erikacuellarae*, *C. lessai*, and *C. yatesi*).

Ctenomys argentinus J. R. Contreras and Berry, 1982

Argentine Tuco-tuco

SYNONYM:

Ctenomys argentinus J. R. Contreras and Berry, 1982b:166; type locality “Establecimiento Invernizzi, Campo Aráos, legua 2, 27km norte de General San Martín, Departamento Libertador General San Martín, Provincia del Chaco, a 26°36' de latitud sur y 59°15' de longitud oeste,” Argentina.

DESCRIPTION: Medium sized (mean total length 257.5 mm in females and 260.5 mm in males; mean tail length 78.0 mm in females and 84.3 mm in males). Color very characteristic, as all specimens exhibit black dorsal band that starts on muzzle, passes between eyes to become enlarged on crown, and then narrower again to extend along dorsal surface onto tail; remainder dorsal region brown, becoming paler toward flanks where hair becomes yellowish brown and then pale grayish-brown ventrally. Light-colored collar between ears and throat another conspicuous character (J. R. Contreras and Berry 1982b). Skull robust with strong crests in adult specimens and notably allometric in growth, resulting in “exaggerated” rostrum described by Thomas (1921a) for *C. boliviensis*. Tympanic bullae small and not very inflated; zygomatic arches strong with emergence of anterior apophysis of jugal, with greatest transverse width at junction of third and four sections; visible end of vomer well developed; interpremaxillary foramen, conspicuously separate in many species (Reig et al. 1966), not separable from incisive foramina; dorsal surface of nasals anteriorly flattened, much more than in *C. validus*; orbit relatively small but with postorbital apophysis of frontal and parorbital apophysis of jugal, well developed; frontosquamosal suture coincides with internal margin of temporal crest; frontals become narrow behind postorbital apophyses; in old individuals, temporal crests increasingly closer to midline and may even make contact. Upper molari-form teeth moderate to large. Upper incisors moderately proodont with anterior surface at about 105° relative to

horizontal plane. Baculum laminar and well ossified with enlarged proximal end and convex dorsal surface; length about 7 mm.

DISTRIBUTION: This species is known only from northern Argentina (Chaco, Formosa, Santiago del Estero, and possibly Santa Fe provinces; J. R. Contreras and Berry 1982b, 1985; Bidau et al. 2005; Bidau 2006).

SELECTED LOCALITIES (Map 421; from J. R. Contreras and Berry 1982b, except as noted): ARGENTINA: Chaco, Campo Aráos (type locality of *Ctenomys argentinus* J. R. Contreras and Berry), Campo Bermejo, Colonia Benítez, General Pinedo, Las Breñas Pinedo, Pampa Chica, Presidencia Roca, Tres Isletas Pinedo; Formosa, Pozo del Tigre (Massoia 1970), San Martín Número Uno; Santa Fe, Tostado; Santiago del Estero, Bandera.

SUBSPECIES: *Ctenomys argentinus* is monotypic.

NATURAL HISTORY: *Ctenomys argentinus* is widely but sparsely distributed within its range, probably because it inhabits sandy soil patches separated by ample extensions of noncolonizable lands subjected to periodic floods that cause temporal cycles of contraction and expansion of tuco-tuco populations. Populations extend across the *Chaco Húmedo* and *Chaco Seco* ecoregions (Burkart et al. 1999).

REMARKS: Previous to its formal description by J. R. Contreras and Berry (1982b) specimens of Formosa province had been assigned to *C. boliviensis* and *C. conoveri*

(Massoia 1970, 1977). *Ctenomys argentinus* is closely allied to the species of the “Chacoan lineage” of J. R. Contreras and Bidau (1999) such as *C. occultus*, *C. tucumanus*, *C. latro*, and *C. pilarensis* of Paraguay. The karyotype is $2n = 44$ with the FN = 50, 51, or 52, due to pericentric inversion polymorphism (Ortells et al. 1990; Ortells 1995; Bidau et al. 2005). Morphology of the sperm is simple symmetric (Bidau et al. 2005).

Ctenomys australis Rusconi, 1934

Dune Tuco-tuco

SYNONYMS:

Ctenomys porteousi australis Rusconi, 1934b:108; type locality “Necochea (F.C.S.), Provincia de Buenos Aires,” Partido de Necochea, Buenos Aires, Argentina, 38°33'S, 58°45'W, 10 m.

Ctenomys australis: J. R. Contreras and Reig, 1965:165; first use of current name combination.

DESCRIPTION: Medium-sized to moderately large species with total length approximately 300 mm, mean range in head and body length 212–215 mm, tail length 96–103 mm, hind foot length 41–43 mm, and mass 349–366 g (J. R. Contreras and Reig 1965:175, 180). Skull longer and broader than that of *C. brasiliensis* but zygomatic and interorbital widths smaller; rostrum robust, especially transversally, and mandible very robust with very narrow incisors.

DISTRIBUTION: *Ctenomys australis* is distributed along the Atlantic coast of southern Buenos Aires province, Argentina, within the *Pampa* ecoregion. J. R. Contreras and Reig (1965:171) provided a detailed map of localities showing the juxtaposition of the range of this species with those of the adjacent *C. talarum* and *C. porteousi*.

SELECTED LOCALITIES (Map 422): ARGENTINA: Buenos Aires, Claromecó (Slamovitz et al. 2001), Cristiano Muerto (J. R. Contreras 1972), Monte Hermosa (A. I. Medina et al. 2007), Necochea (type locality of *Ctenomys porteousi australis* Rusconi), Punta Alta (J. R. Contreras and Reig 1965), Río Quequén Salado (J. R. Contreras and Reig 1965).

SUBSPECIES: *Ctenomys australis* is monotypic.

NATURAL HISTORY: *Ctenomys australis* is an exclusive inhabitant of the first line of vegetated dunes immediately behind the beach. In some parts of its range, this species is parapatric or sympatric with *Ctenomys talarum recessus*, which occupies the second line of dunes (see that account, and Comparatore et al. 1992). This is one of the more thoroughly studied species with regard to behavior, life history, and ecology of natural populations (Zenuto and Busch 1995; C. Busch et al. 2000). Mora, Kittlein et al. (2013) documented craniodental variation within and among populations, attributing interpopulation differences to demo-

Map 422 Selected localities for *Ctenomys australis* (●). Contour line = 2,000 m.

graphic characteristics delineated by phylogeographic analyses (see Mora et al. 2010) and local adaptation.

REMARKS: Although it was initially described as a subspecies of *C. porteousi*, J. R. Contreras and Reig (1965) and Roig and Reig (1969) established the specific status of this taxon. The species is closely related to the Argentinean species of the “mendocinus” group, including *C. azarae*, *C. mendocinus*, and *C. porteousi* (Mascheretti et al. 2000), as well as to *C. flamarioni*, the most divergent “mendocinus” species from southern Brazil (Massarini, Barros, Ortells, and Reig 1991; D’Elía et al. 1999; J. R. Contreras et al. 2000; Parada et al. 2011). The karyotype is $2n = 48$, FN = 80 (Massarini, Barros, Ortells, and Reig 1991), similar to that of other “mendocinus” group species, but especially to *C. flamarioni* (see Massarini and Freitas 2005). Sperm morphology is simple asymmetric (Vitullo et al. 1988). Mora et al. (2006) examined phylogeographic structure using mtDNA sequences and Apfelbaum et al. (1991) compared levels of electromorphic variation within and between *C. australis* and *C. porteousi*.

Ctenomys azarae Thomas, 1903

Azara’s Tuco-tuco

SYNONYM:

Ctenomys azarae Thomas, 1903a:228; type locality “Sapucay, Paraguay”; corrected to “Province of Buenos Ayres, on the central pampas, lat. 37°45’, long. 65°W, 780 kilometers south-west of the Capital” by Thomas

(1903c), which now equals General Acha, Departamento Utracán, La Pampa, Argentina, 216 m.

DESCRIPTION: Relatively small species (external dimensions of holotype head and body length, 158 mm, tail length, 77 mm, hindfoot length (with claw), 35 mm). Dorsal color uniformly brown; venter pale buff, with darker markings on upper surface or white patches below; top of muzzle slightly darker than rest of body. Skull with same general shape as that of *C. mendocinus*, comparatively narrow and slender, not flattened and squared; nasals short and narrow; interorbital region ridged, with rudimentary postorbital processes; parietal ridges more marked than in similar species; zygomatic arches slope backward gradually to broadest point instead of being evenly rounded or square shouldered; mesopterygoid fossa penetrates to posterior edge of m2 instead of center of this tooth, as is more common in other species; bullae more swollen than those of *C. mendocinus*. Cheek teeth comparatively small, broad, and rounded in section, almost completely circumscribed by enamel and with only very small gap, at best, at their enteroexternal and posterointernal corners.

DISTRIBUTION: *Ctenomys azarae* inhabits central Argentinean provinces of La Pampa, Mendoza, and San Luis, within the *Espinal*, *Monte de Llanuras*, *Mesetas*, and *Pampa* ecoregions.

SELECTED LOCALITIES (Map 423; from J. R. Contreras and Reig 1965, except as noted): ARGENTINA: La Pampa, Algarrobo del Aguila, Colonia 25 de Mayo, General Acha (type locality of *Ctenomys azarae* Thomas), 5 km S of Santa Rosa, Naicó, Utracán, Victorica; Mendoza, General Alvear (Braggio et al. 1999); San Luis, Arizona.

SUBSPECIES: *Ctenomys azarae* is monotypic.

NATURAL HISTORY: This species of tuco-tuco constructs burrows in sandy soils, in zones of low and open forest, and also on hills with psammophytic vegetation. Kin and Justo (1995) provided data on diet in natural and laboratory settings.

REMARKS: Thomas (1903a:229) erroneously gave the type locality as “Sapucay, Paraguay” in his original description of this species, but corrected his mistake in a second publication that same year (Thomas 1903c:243) to “Province of Buenos Ayres, on the central pampas, lat. 37°45’S, long. 65°W, 780 kilometers south-west of the Capital, a region from which no examples of *Ctenomys* have been recorded.” This region is now recognized as General Acha in La Pampa Province. *Ctenomys azarae* is related to the “mendocinus-porteousi-australis” assemblage, and both Cabrera (1961) and J. R. Contreras and Reig (1965) regarded *azarae* as a subspecies of *C. mendocinus*. The karyotype is very similar to that of *C. mendocinus* ($2n = 46, 47, 48$), with the two species share the same chromosomal polymorphisms (Massarini, Barros, Ortells, and

Map 423 Selected localities for *Ctenomys azarae* (●). Contour line = 2,000 m.

Reig 1991; Massarini et al. 1998; Braggio et al. 1999). The sperm is of the simple asymmetric type (M. H. Gallardo 1979; Vitullo et al. 1988). De Santis et al. (2001) described enamel microstructure.

Ctenomys bergi Thomas, 1902

Córdoba Tuco-tuco

SYNONYMS:

Ctenomys bergi Thomas, 1902d:241; type locality “Cruz del Eje,” Departamento Cruz del Eje, Córdoba, Argentina, 30°44’S, 64°48’W, 449 m.

Ctenomys mendocinus bergi: Cabrera, 1961:551; name combination.

DESCRIPTION: Small to medium-sized species; external dimensions of holotype, a male, head and body length 190 mm, tail length 74 mm; head and body ranges (from A. I. Medina et al. 2007) in males 157–163 mm and females 132–144 mm. General color above uniform sandy fawn while sides and ventral surfaces pale fawn; center of face from muzzle to between ears dark brown and conspicuously different from rest of body. Skull small, narrow, and not flattened in lateral profile but rather slightly and evenly convex; nasals parallel-sided or evenly narrowing posteriorly; posterior width across auditory meatus broader than zygomatic breadth; bullae large and inflated; mesopterygoid fossa extends to level of M2.

DISTRIBUTION: This species is restricted to the *Chaco Seco* ecoregion of Córdoba province, Argentina, extending northwest from the type locality along the course of the Río Cruz del Eje. Populations at Salinas Grandes reach almost 1,000 m. Contrary to Cabrera (1961), there are no confirmed records of this species from La Rioja Province.

Map 424 Selected localities for *Ctenomys bergi* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 424; from A. I. Medina et al. 2007, except as noted): ARGENTINA: Córdoba, Cruz del Eje (type locality of *Ctenomys bergi* Thomas, 1902), Guanaco Muerto, Las Toscas, Salinas Grandes.

SUBSPECIES: *Ctenomys bergi* is monotypic.

NATURAL HISTORY: This is a poorly known species sparsely distributed in low-density populations.

REMARKS: Although Cabrera (1961:552) considered *Ctenomys bergi* a subspecies of *C. mendocinus*, the species is well differentiated from the latter by the possession of a unique karyotype ($2n = 50$, FN = 90; Giménez et al. 1999) and through mtDNA phylogenetic analyses (Mascheretti et al. 2000). The sperm has the simple asymmetric morphology (Giménez et al. 1999).

Ctenomys bicolor Miranda-Ribeiro, 1914

Bicolored Tuco-tuco

SYNONYMS:

Ctenomys bicolor Miranda-Ribeiro, 1914:41, plates 20 and 23, Figs. 2–2a’, 4, and 6; type locality “Mato Grosso” (Avila-Pires 1968:182); restricted by Bidau and Avila-Pires (2009) to Rôndonia (Brazil) between 11°50’10’’S and 12°00’00’’S, and 60°51’35’’W and 61°19’29’’W.

Ctenomys minutus bicolor: Cabrera, 1961:553; name combination.

DESCRIPTION: The holotype and only known specimen (sex unknown) large; head and body length 230 mm, tail length 95 mm. Skull relatively short (length 46 mm) but wide (zygomatic breadth 31 mm). Miranda-Ribeiro (1914)

compared his single specimen to *C. minutus* and recorded a number of cranial differences, including zygomatic breadth and curvature, which are larger and more pronounced, respectively; presence of postocular process of frontals in *C. bicolor* but not in *C. minutus*; and general shape of cranium different. Dorsal color blackish gray flanks similar but hairs with ochraceous tips, limbs whitish-ochraceous, and tail whitish (Miranda-Ribeiro 1914; Avila-Pires 1968).

DISTRIBUTION: This species is known only from its rather ambiguous type locality.

SELECTED LOCALITIES (Map 425): BRAZIL: Rondônia, no more precise locality is known (see above; type locality of *Ctenomys bicolor* Miranda-Ribeiro).

SUBSPECIES: *Ctenomys bicolor* is monotypic.

NATURAL HISTORY: No ecological or other biological data are known for *Ctenomys bicolor*.

REMARKS: The only known specimen of *C. bicolor* was collected on October 9, 1912, by the Comissão Rondon although this information was not cited in the original description (Miranda-Ribeiro 1914). The specimen is deposited in the collection of the Museu Nacional (Rio de Janeiro) as MNRJ 2052 (Langguth et al. 1997), erroneously cited as MNRJ 2025 by João Moojen (in Miranda-Ribeiro 1955). The only information about the locality is “Matto Grosso,” which at the time of collection comprised vast territories in the present-day state of Rondônia, Brazil. Avila-Pires (1968: 182), who redescribed the holotype,

gave the same information. However, Bidau and Avila-Pires (2009), based on the memoirs of Colonel Cândido Rondon who led the expedition during which the single specimen was collected (Viveiros 1958), restricted the type locality to a 1,000 km² area of Rondônia state between Primavera de Rondônia and the Rio Barão de Melgaço (possibly on the banks of Rio Pimenta Bueno) between the coordinates 11°50'10"S and 12°00'00"S, and 60°51'35"W and 61°19'29"W.

Cabrera (1961) listed *C. bicolor* as a valid subspecies of *C. minutus*, without justification.

Ctenomys boliviensis Waterhouse, 1848

Bolivian Tuco-tuco

SYNONYMS:

Ctenomys boliviensis Waterhouse, 1848:278; type locality “Plains of Santa Cruz de la Sierra”; Thomas (1921a:136) selected as lectotype (BM 46.7.28.57, an adult male) the cotype of which the skull was figured by Waterhouse, and refined the type locality to “Santa Cruz de la Sierra,” Santa Cruz, Bolivia, 480m, 17°48'S 63°10'W.

Ctenomys boliviensis boliviensis: Cabrera, 1961:546; name combination.

DESCRIPTION: Large species, with total length of males reaching 356 mm, tail length 80 mm, and mass up to 650g; females smaller, total length 316 mm, tail length 95 mm, and mass 420 g (S. Anderson et al. 1987; S. Anderson 1997). Fur soft, very glossy, and rather short; general hue bright, rufous brown; upper surface of head and muzzle blackish brown, with same color continuing as broad but poorly defined band along back of neck to fore part of back; under parts bright rusty yellow color, with exception of space between hind legs, and large patch covering fore part of abdomen, where hairs are entirely white; tail dark brown above, pale brown beneath; fur tinged gray next skin on under parts, but dark slate gray at base on upper parts; sides of body rufous brown; back darker shade of same color, becoming gradually deeper toward head, where dark color contracted into band which runs along neck, and joins black-brown color of upper surface of head; broad mark of somewhat paler hue descends from behind ears to sides of body. Vibrissae dirty white. Feet sparsely clothed with pale brown hairs, with whitish hairs on sides. Tail clothed with dirty white color, very short hairs, except at base where they may be 10 mm in length. Upper incisors notably very broad, proportionally more so than in *C. brasiliensis*. Skull remarkable for its narrowed middle part of rostrum; nasal bones broader at their extremities than in *C. brasiliensis*; auditory bullae narrow with portion that extends onto occipital plane considerably less extended in vertical direction; ridge traversing outer surface of malar bone very well developed. Cheek teeth broader relative to

Map 425 Approximate position of the single known locality for *Ctenomys bicolor* (●) (see Remarks). Contour line = 2,000m.

length, with length of first molar shorter than in *C. brasiliensis*. About 20% of adult specimens show an open frontoparietal fenestrae (S. L. Gardner and Anderson 2001).

DISTRIBUTION: *Ctenomys boliviensis* is distributed in south-central Santa Cruz, Bolivia. Massoia's (1970) report of *C. boliviensis* for Argentina is in error; these specimens are *C. argentinus* (J. R. Contreras, pers. comm.).

SELECTED LOCALITIES (Map 426; from S. Anderson 1997, except as noted): **BOLIVIA:** Santa Cruz, 2 km SE of Cotoca, Escatia Cachuela Esperanza, 3.5 km W of Estación Pailón, 4 km SW of La Bélgica, 5 km S of Mineros, Palmar de Osorio, 1 km SE of Puerto Pacay, San Miguel Rincón, Santa Cruz de la Sierra (type locality of *Ctenomys boliviensis* Waterhouse), ca. 55 km SE of Santa Cruz at Brecha.

SUBSPECIES: Cabrera (1961) recognized two subspecies, *C. b. boliviensis* and *C. b. goodfellowi*. The latter was originally described as a full species (Thomas 1921d) based on his comparisons with *C. boliviensis* that established many clear differences. S. Anderson et al. (1987) maintained the subspecific status of *C. goodfellowi*, but also cited a number of characters to suggest its specific condition, a position later taken formally by Cook and Yates (1994) and S. Anderson (1997). Anderson et al. (1987) also considered *Ctenomys nattereri* (from Mato Grosso, Brasil) to be a subspecies of *C. boliviensis*, although knowledge of this taxon is extremely limited. Thus, in this account, I treat *C. boliviensis* as monotypic and regard both *C. goodfellowi* and *C. nattereri* as full species.

NATURAL HISTORY: *Ctenomys boliviensis* inhabits friable soils in areas not frequently flooded where food consists mainly of underground tubers and roots (S. Anderson 1997). As is characteristic of other species of tuco-tucos that have been studied in the field, this one eats primarily underground tubers and roots. Mean litter size is 1.7 (range: 1–5; N = 55; S. Anderson 1997). S. L. Gardner and Duszynski (1990) described eimerian parasites.

REMARKS: *Ctenomys boliviensis* belongs to the Chacoan lineage of *Ctenomys* (J. R. Contreras and Bidau 1999) along with *C. argentinus*, *C. conoveri*, *C. latro*, *C. goodfellowi*, *C. steinbachi*, *C. pilarensis*, and possibly *C. nattereri* (J. R. Contreras and Berry 1982a; S. Anderson et al. 1987). This species exhibits substantial karyotypic diversity over its limited geographic range, with $2n$ ranging from 36 to 46 (S. Anderson et al. 1987; Cook et al. 1990). Vitullo and Cook (1991) described sperm morphology with a symmetric head; Biknevicius (1993) provided data on functional anatomy; Ruedas et al. (1993) gave data on genome size estimates; and Cook and Yates (1994) evaluated species boundaries and relationships based on electro-morphic characters.

Map 426 Selected localities for *Ctenomys boliviensis* (●). Contour line = 2,000 m.

Ctenomys bonettoi J. R. Contreras and Berry, 1982

Bonetto's Tuco-tuco

SYNONYM:

Ctenomys bonettoi J. R. Contreras and Berry, 1982a: 123; type locality "7.5 kilómetros al sudeste de Capitán Solari, Departamento Sargento Cabral, Provincia del Chaco, a 26°48' de latitud sur y a 59°33' de longitud oeste," = Colonia Elisa, Argentina.
