DESCRIPTION: Moderate-sized tuco-tuco, with males reaching 183 mm in head and body length, 77 mm in tail length, 37 mm in hindfoot length, and 220 g in mass; equivalent female dimensions 171 mm, 61 mm, 33 mm, and 185 g, respectively. Dorsal color uniformly brown marbled with dark hairs with median black band, more noticeable on head and in specimens with worn pelage; flanks yellowish brown, becoming yellowish on venter; hands and hindfeet covered dorsally with silvery gray hairs; palmar and plantar surfaces pink in life; tail yellowish with slightly more darkened dorsal stripe. Skull moderately robust, but with gracile rostrum; broadest part of zygomatic arch at level of posterior part of orbital fossa; bullae large and easily visible from above; anterior notch of mesopterygoid fossa V-shaped and penetrates palate to level of middle of M2; orbit relatively well developed, with postorbital process of frontal blunt and poorly defined. Upper incisors nearly opisthodont, with anterior face at about a 98° angle relative to horizontal plane.

Map 427 Selected localities for *Ctenomys bonettoi* (●).

DISTRIBUTION: *Ctenomys bonettoi* occurs only from a few populations around the type locality in Chaco province, Argentina, within the *Chaco Húmedo* ecoregion. The entire distribution of this species is contained within the range of *C. argentinus*.

SELECTED LOCALITIES (Map 427; from J. R. Contreras and Berry 1982a): ARGENTINA: Chaco, Ciervo Petiso, Colonia Elisa (type locality of *Ctenomys bonettoi* J. R. Contreras and Berry), Laguna Limpia.

SUBSPECIES: *Ctenomys bonettoi* is monotypic.

NATURAL HISTORY: This is a poorly known species inhabiting sandy patches within periodically flooded humid Chaco areas.

REMARKS: The karyotype of *C. bonettoi* is $2n = 50$, $FN = 70$ (Bidau et al. 2005), one that shares many affinities to that of *C. "yolandae"* (Bidau et al. 2005; see that account, below), with which it appears closely related based on molecular sequences (Mascheretti et al. 2000). *Ctenomys bonettoi* has a simple asymmetric sperm (Bidau et al. 2005).

Ctenomys brasiliensis Blainville, 1826

Brazilian Tuco-tuco

SYNONYMS:

Ctenomys Brasiliensis Blainville, 1826:64; type locality "des parties intérieures du Brésil, de la Province de

Las Minas," Minas Gerais, Brazil; redefined herein as Minas, Lavalleya, Uruguay (see Remarks).

Spalax Brasiliensis: J. B. Fischer, 1829:304; name combination.

DESCRIPTION: Blainville's original description and measurements indicate relatively large body size. No other information on external characters, including color or craniodental attributes, have been published. Fernandes et al. (2012) compared skull of Blainville's holotype with representatives of *C. pearsoni* and *C. torquatus* using geometric morphometrics but did not provide actual linear dimensions for any craniodental attribute.

DISTRIBUTION: The range of *C. brasiliensis* is uncertain; see Remarks.

SELECTED LOCALITIES (Map 428): URUGUAY: Lavalleya, Minas (type locality of *Ctenomys Brasiliensis* Blainville).

SUBSPECIES: *Ctenomys brasiliensis* is monotypic.

NATURAL HISTORY: No data are available.

REMARKS: The name *C. brasiliensis* cannot be applied with certainty to any geographic group of tuco-tucos because Blainville's citation of Minas Gerais as the type locality is likely in error. Despite the frequent listing of this species as part of the fauna of Minas Gerais (e.g., J. A. Oliveira and Bonvicino 2006), there are no known specimens of any tuco-tuco collected from this part of Brazil, nor are subfossil specimens of the genus known from the famous Lagoa Santa caves studied by the Danish naturalist Peter Wilhelm Lund and others. It is possible that Blainville's type locality actually corresponds to the locality of Minas in present-day Uruguay, which in the early 1800s was part of the Brazilian Empire (Reig et al. 1966). In this sense, *C. minutus* (Reig et al. 1966) and *C. torquatus* (C. O. da C. Vieira 1955) have been suggested as synonyms of *C. brasiliensis*. A second possibility is that *C. brasiliensis* is one of the forms of the "pearsoni" complex of Uruguay (including *C. dorbignyi* and *C. pearsoni*), the distribution of which includes the town of Minas. However, no detailed comparisons have been made to support either of these hypotheses.

Recently, Fernandes et al. (2012) compared the skull of the holotype of Blainville's *C. brasiliensis* (collected by M. Florent Prévost and currently in the Museum National d'Histoire Naturelle, Paris; NMHNP 397) to several other species, especially those from Uruguay, with geometric morphometric methods. These data and rediscovered information on the accompanying label written as "St. Paul, prov. las Minas" support Minas, in the department of Lavalleya, Uruguay, as the type locality of *C. brasiliensis*. At the time the specimen was collected, the entire region of what is now Uruguay was dominated by the Portuguese Empire ("Provincia Cisalpina do Reino Unido de Portugal, Brasil e Algarves"), and after Brazilian independence

Map 428 Single known locality for *Ctenomys brasiliensis* (●).

in 1822, the Uruguayan territory was considered part of a new country, Brazil. It was not until after 1825 that the province that later became Uruguay gained independence. Today, the area along the southern coast of Uruguay contains only populations of *C. pearsoni* E. P. Lessa and Langguth (see that account). Although Blainville's holotype falls within the morphospace of a large sample of *C. pearsoni* from southern Uruguay but not that of *C. torquatus* from northern Uruguay, Fernandes et al. (2012) argued that additional studies were required before the taxonomic relationship of *C. brasiliensis*—and thus the possible application of Blainville's name—to the *C. pearsoni* complex of tuco-tucos can be established. Available evidence, however, supports the hypothesis that *C. brasiliensis*, the type species of *Ctenomys*, was collected in what is now Uruguay and never ranged into southeastern Brazil.

Karyotype and sperm morphology are unknown. Gerard (1862) listed two Bolivian specimens at the British Museum without exact localities as *C. brasiliensis*, but these probably belong to *C. boliviensis* (S. Anderson 1997).

Ctenomys colburni J. A. Allen, 1903

White-bellied Tuco-tuco

SYNONYM:

Ctenomys colburni J. A. Allen, 1903b:188; type locality "Arroyo Ayke, in the basalt canyons, 50 miles southeast of Lake Buenos Ayres, Patagonia," = Cañones basálticos, Arroyo Aikén, 50 miles SE Lago Buenos Aires, De-

Map 429 Selected localities for *Ctenomys colburni* (●).

partamento Lago Buenos Aires, Santa Cruz, Argentina, 46°40'S, 70°30'W, ca. 500 m.

DESCRIPTION: Small tuco-tuco, with mean head and body length 161 mm and tail length 71 mm for males, and 146 mm and 63 mm, respectively, for females (J. A. Allen 1903b; Kelt and Gallardo 1994). Dorsal color yellowish gray strongly suffused with fulvous as opposed to black; color varies among individuals, especially with respect to distinctness of dorsal tail stripe that may be absent, present only as faint trace, or present with strongly developed black stripe.

DISTRIBUTION: This species is known only from a few localities in Santa Cruz and Río Negro provinces of Argentina.

SELECTED LOCALITIES (Map 429): ARGENTINA: Río Negro, Estancia Huanuluan (Kelt and Gallardo 1994); Santa Cruz, Arroyo Aikén (type locality of *Ctenomys colburni* J. A. Allen), Casa de Piedra, Río Ecker (A. I. Medina et al. 2007), Estancia La Cantera (Kelt and Gallardo 1994), Río Deseado (Kelt and Gallardo 1994).

SUBSPECIES: *Ctenomys colburni* is monotypic.

NATURAL HISTORY: No data are available.

REMARKS: *Ctenomys colburni* is morphologically similar to the neighboring Chilean species *C. coyhaiquensis*,

although the latter appears chromosomally more similar to the *C. maulinus* group (Kelt and Gallardo 1994). J. A. Allen (1903b) also pointed to similarity with *C. sericeus* from the Argentine Patagonia. The karyotype is $2n = 34$ (M. H. Gallardo 1991). Morphology of the sperm is simple asymmetric (Kelt and Gallardo 1994).

Ctenomys coludo Thomas, 1920

Puntilla Tuco-tuco

SYNONYMS:

Ctenomys coludo Thomas, 1920d:119; type locality "La Puntilla, near Tinogasta, Catamarca," Argentina, 28°04'S, 67°34'W, 1,000 m.

Ctenomys coludo coludo: Tate, 1935:390; name combination.

Ctenomys fulvus coludo: Cabrera, 1961:548; name combination.

DESCRIPTION: Relatively large species with total length of 302 mm and tail length of 97 mm in type specimen (a male), readily recognizable by uniformly pale color, long tail (>45% of head and body length), narrow skull, and large bullae; easily differentiated from two geographically nearest species: *C. fochi*, which is more than 20% smaller, and *C. knighti*, which is much darker, has shorter tail, larger teeth, and broader frontal region.

DISTRIBUTION: *Ctenomys coludo* is known only from the type locality, which is "a few miles out from Tinogasta toward Copacabana, at an altitude of about 1000 m above sea level" (Thomas 1920d:116).

Map 430 Selected localities for *Ctenomys coludo* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 430): ARGENTINA: Catamarca, La Puntilla (type locality of *Ctenomys coludo* Thomas), Portezuelo de Pasto Ventura (FMNH 46137).

SUBSPECIES: *Ctenomys coludo* is monotypic.

NATURAL HISTORY: No ecological or other biological data are available for this species.

REMARKS: *Ctenomys coludo* is apparently related to *C. fulvus* from Chile. Karyotype and type of sperm are unknown.

Ctenomys conoveri Osgood, 1946

Chacoan Tuco-tuco

SYNONYM:

Ctenomys (Chacomys) conoveri Osgood, 1946:47; type locality "Colonia Fernheim, 16 km. west of Filadelfia, Paraguayan Chaco. Approximately Long. 60°10'W., Lat. 22°15'S.," Boquerón, Paraguay.

DESCRIPTION: Largest species in genus, with males reaching 558 mm in head and body length, 122 mm in tail length, 60 mm in hindfoot length, and mass of 1,200 g (S. Anderson 1997). Pelage long and rather coarse, color nearly uniform cinnamon rufous with light mixture of dusky and scattered white hairs above and clear below. Tail heavily haired, rufous above and pale below, with median line of white toward tip. Skull massive and angular; jugal possesses unique crescentic excavation in front of high and broad dorsal process. Upper incisors very broad and heavy, slightly proodont, and grooved on anterior surface. Some adult specimens exhibit open frontoparietal fenestrae (S. L. Gardner and Anderson 2001).

DISTRIBUTION: This species occurs through the *Chaco Boreal* ecoregion of northwestern Paraguay and southern Bolivia.

SELECTED LOCALITIES (Map 431; from S. Anderson 1997, except as noted): BOLIVIA: Chuquisaca, 9 km E of Carandaytí, 1.5 km NW of Povenir; Santa Cruz, 26 km E of Boyuibe; Tarija, 10 km S of Capirenda, Palo Mercado, Villa Montes. PARAGUAY: Boquerón, Colonia Fernheim (type locality of *Ctenomys conoveri* Osgood).

SUBSPECIES: *Ctenomys conoveri* is monotypic.

NATURAL HISTORY: No data are available on ecology, food habits, or reproduction. S. L. Gardner and Duszynski (1990) described eimerian oocysts in one specimen.

REMARKS: Because Osgood (1946:47) believed that *C. conoveri* differed "widely from any previously described species," he placed it as the sole member of his subgenus *Chacomys*. However, electrophoretic analyses do not support subgeneric rank but rather indicate a sister relationship between *C. conoveri* and both *C. frater* and *C. lewisi*, two species of the nominotypical subgenus, among those species examined (Cook and Yates 1994). A relationship to other species of a Chacoan group such as *C. argentinus*,

Map 431 Selected localities for *Ctenomys conoveri* (●). Contour line = 2,000 m.

C. boliviensis, and *C. goodfellowi* had been suggested earlier on morphological grounds (J. R. Contreras and Berry 1982b). Osgood (1946) compared the skull of *C. conoveri* to that of *C. robustus* (now = *C. fulvus* Philippi), another large species, in his description. Eisentraut (1933) misidentified specimens of this species from Villa Montes, Palo Marcado, and near Samahuate in Bolivia as *C. brasiliensis*. Later, he (Eisentraut 1983) also referred specimens from the Chaco region of Bolivia to *C. brasiliensis*, considered by S. Anderson (1997:493) as “perhaps *C. conoveri*.” Krumbiegel (1941a) also misidentified specimens of *C. conoveri* from Villa Montes, Bolivia, as *C. leucodon* (see S. Anderson 1997). Reports of the presence of *C. conoveri* in Argentina (Massoia 1977) are based on misidentified specimens of *C. argentinus* (J. R. Contreras and Berry 1982a). The karyotype for Bolivian specimens is $2n = 48$ (S. Anderson et al. 1987:15), and for Paraguayan individuals is $2n = 50$ (Ortells 1995). Sperm morphology is simple asymmetric (J. R. Contreras 1996).

Ctenomys coyhaiquensis Kelt and Gallardo, 1994
Coyhaique Tuco-tuco

SYNONYM:

Ctenomys coyhaiquensis Kelt and Gallardo, 1994:344; type locality “2 km S Chile Chico and 1 km W Chile Chico aeródromo, Provincia General Carrera, XI Región de Aisén [= Aysén], Chile. 46°33'S, 71°46'W, 330 m.”

DESCRIPTION: Small species of tuco-tuco, head and body length between 195–264 mm, tail length 60–81 mm, hindfoot length 28–34 mm, and mass 72–182 g. Pelage tawny brown washed with yellow and black. Dorsal pelage consists of two kinds of hairs, one long and black, scattered throughout, and other tricolored with dark gray base, buff median band, and black tips. Middorsal region darker, as typical of many other species of tuco-tucos; dorsal coloration fades laterally toward ventral region, where hairs are bicolored dark gray proximally and pale buff or ochraceous buff distally. Feet of adults covered dorsally with silvery-white hairs. Tail bicolored, with darker dorsal color extending ventrally along terminal one-third of tail. Skull with large orange and mildly proodont incisors; sturdy zygomatic arches; large auditory bullae; auditory meatus extending laterally just beyond zygomatic arches; nasals slightly flared anteriorly; bony capsule of incisor root protrudes from side of rostrum; pronounced lateral ridge separates dorsal and ventral zygomatic fossae; sphenoid bones large and extend posteriorly to occipital crest; infraorbital canal large and ovoid, with small dorso-posterior projection where zygomatic plate meets frontal bone; parietal bones possess small postorbital process, complementing similar process on jugal; incisive foramina never more than one-half length of diastema; alisphenoid-presphenoid bridge straight and runs perpendicular to sagittal plane; postalisphenoid canal oval; and generally single lateral foramen present in alisphenoid. Both M3 and m3 reduced. Combination of traits diagnostic for species.

DISTRIBUTION: *Ctenomys coyhaiquensis* is known only from two localities in Chile between 330 and 730 m. Kelt and Gallardo (1994) suggested that the species might extend into Argentina, because both collecting sites are within 1 km of the border between the two countries.

SELECTED LOCALITIES (Map 432): CHILE: Aysén, 2 km S Chile Chico and 1 km W of Chile Chico Aeródromo (type locality of *Ctenomys coyhaiquensis* Kelt and Gallardo), Fundo Los Flamencos, 4.5 km SE of Coyhaique Alto (Kelt and Gallardo 1994).

SUBSPECIES: *Ctenomys coyhaiquensis* is monotypic.

NATURAL HISTORY: At the type locality (Kelt and Gallardo 1994), *C. coyhaiquensis* occupied sandy or rocky soils that supported a sparse shrub and herbaceous community. Principal shrubs included *Mullinum spinosum* (Apiaceae), *Colliguaya saliscifolia* (Euphorbiaceae), *Escallonia rubra* (Escalloniaceae), and *Berberis buxifolia* (Berberidaceae). At the higher Coyhaique Alto site, these tuco-tucos inhabited a gravelly soil with bunchgrasses and a few shrubs (*B. buxifolia* and *E. rubra*; Kelt and Gallardo 1994).

REMARKS: M. H. Gallardo et al. (1996) documented the loss of genetic (electromorphic protein) variation in a population following an eruption of Volcán Hudson in

Map 432 Selected localities for *Ctenomys coyhaiquensis* (●). Contour line = 2,000m.

southern Chile in 1991. The karyotype consists of $2n = 28$, $FN = 44$ (Kelt and Gallardo 1994), and the sperm is of the simple asymmetric type (Kelt and Gallardo 1994).

Ctenomys dorbignyi J. R. Contreras and Contreras, 1984
D'Orbigny's Tuco-tuco

SYNONYMS:

Ctenomys d'orbignyi J. R. Contreras and Contreras, 1984: 131; type locality "Paraje Mbarigüü, Departamento Berón de Astrada, Provincia de Corrientes, a $27^{\circ}33'$ de latitud Sur y a $57^{\circ}31'$ de longitud oeste," Argentina, 54 m; note incorrect original spelling with apostrophe (ICZN 1999:Art. 32.5.2).

Ctenomys dorbignyi: J. R. Contreras and Scolaro, 1986:21; corrected spelling of *d'orbignyi* J. R. Contreras and Contreras.

DESCRIPTION: Relatively large tuco-tuco, with average head and body length 206 mm (range: 190–224 mm), tail length 91 mm (range: 86–99 mm), hindfoot length (including claws) 40.4 mm (range: 38.7–43.0 mm), and mass 331 g (range: 269–376 g). Dorsal color fairly uniform brown tone overall; venter pale; there no collar of differentiated color; white postauricular spots as well as white areas in axilla and inguinal regions present, although extent of latter variable. Skull robust and relatively long, with broad and slightly expanded rostrum, and moderately proodont upper incisors; width of interorbital constriction

and zygomatic breadth proportionately smaller than species of Chaco region, and tympanic bullae more developed than in that species group; frontoparietal sutures gently curved forward; line through apex of spinous processes and postorbital process of jugal slants slightly forward; free end of vomer between premaxillaries well developed and clearly visible; no visible interpremaxillary foramen; orbital expansion of maxilla extends above jugal with crescent-shaped external depression extending onto adjacent bones, which not as deep as in *C. argentinus* or *C. conoveri*, but more marked than in *C. perrensi*, with vertical, thin but well-developed sickle-shaped blade.

DISTRIBUTION: *Ctenomys dorbignyi* occurs in a series of isolated areas in Corrientes and Entre Ríos provinces within the *Esteros del Iberá* and *Pampa* ecoregions of Argentina (J. R. Contreras and Contreras 1984; J. R. Contreras and Scolaro 1986; see Remarks).

SELECTED LOCALITIES (Map 433; from J. R. Contreras and Contreras 1984, except as noted): ARGENTINA: Corrientes, Costa Grande, Mbarigüü (type locality of *Ctenomys dorbignyi* J. R. Contreras and Contreras), Tres Bocas, Esquina, Los Angeles, Laguna Itá, Arerunguá, La Tilita, Ibahay, Paraje Yabrahá, Caa Catí, Palmar Grande, Colonia Romero, Tacuaracuarendy Sarandicito (Argüelles et al. 2001); Entre Ríos, Paso Vera (Giménez et al. 2002), San Joaquín de Miraflores (Giménez et al. 2002), Tiro Federal (Giménez et al. 2002).

SUBSPECIES: *Ctenomys dorbignyi* is monotypic.

NATURAL HISTORY: *Ctenomys dorbignyi* inhabits sandy patches far from the forested islets that are frequent within the area of its distribution. Population size is strongly affected by the cycles of annual rainfall. Litter size averages 1.3 ± 0.58 , $N = 18$ (J. R. Contreras, pers. comm.). Population density is low in northern populations and much higher in the southern ones. J. R. Contreras and Contreras (1984) suggested that the species is at least semi-social, although this claim needs confirmation.

REMARKS: *Ctenomys dorbignyi* is readily distinguished from neighboring species (J. R. Contreras and Contreras 1984). From *C. perrensi*, *C. dorbignyi* differs in its color and color pattern, in less pronounced procumbency, by the reduction or obliteration of the interpremaxillary foramen, larger tympanic bullae, higher and wider rostrum, and a more convex cranium. From *C. argentinus*, *C. dorbignyi* differs in all diagnostic cranial characters. This species does show some superficial resemblance to *C. minutus* but differs in the morphology of the occipital foramen and relative zygomatic breadth. The karyotype of *C. dorbignyi* is $2n = 70$ in all the populations with minor variation in FN (80 to 84). The karyotypic similarity to *C. pearsoni* ($2n = 68-70$) reinforces other commonalities between the two taxa (Argüelles et al. 2001).

Map 433 Selected localities for *Ctenomys dorbignyi* (●).

J. R. Contreras and Scolaro (1986) compared cranial measurements among four geographically partitioned samples covering the species range in Corrientes province, noting that the eastern sample (*oriental nucleo*), centered at the locality of Contreras Cué, was substantially divergent in multivariate morphospace relative to the other three samples. Interestingly, this same population does not share the typical $2n = 70$ karyotype characteristic of *C. dorbignyi* but has diploid numbers ranging between $2n = 41$ and $2n = 47$ (Ortells et al. 1990; Giménez et al. 2002). Analyses of mtDNA suggest that this latter group is likely an undescribed species (informally called *Ctenomys* sp. by Giménez et al. 2002; see also Remarks for *C. perrensi*). Pending further field and laboratory analyses, the Contreras Cué sample is best considered as a taxon distinct from *C. dorbignyi*; it is not included in the mapped range. Sperm morphology is simple symmetric (Vitullo et al. 1988).

Ctenomys dorsalis Thomas, 1900

Black-backed Tuco-tuco

SYNONYM:

Ctenomys dorsalis Thomas, 1900g:385; type locality “Northern Chaco of Paraguay”; a more specific locality is in-

determinable at present, but presumably either in Alto Paraguay or Boquerón departments.

DESCRIPTION: Small tuco-tuco, holotype (female) 156 mm in head and body length, 46 mm in tail length, and 30 mm in hindfoot length. Fur soft and fine. General dorsal color buffy fawn with marbled black dorsal line extending from nose to rump; line sharply defined on head, about 10 mm broad, but widens to more diffuse band on back; dark lateral face markings around eye or ear lacking, but well-marked light collar present behind cheeks and chin extending to each side of ear. Throat, chest, outer edges of belly, and narrow midline stripe pale buffy with slate-colored basal hairs; remaining ventral hairs self-colored white. Dorsal surfaces of both hands and feet dirty white. Tail hairs mixed black and white. Craniodental characters have not been described, except that incisors orange above and below.

DISTRIBUTION: The geographic distribution of *C. dorsalis* is unknown, but presumably encompasses the *Chaco Boreal* ecoregion of Paraguay and perhaps adjacent Bolivia and/or Brazil (see Remarks).

SELECTED LOCALITIES (Map 434): PARAGUAY: Alto Paraguay or Boquerón, precise locality unknown.

SUBSPECIES: *Ctenomys dorsalis* is monotypic.

NATURAL HISTORY: No data are available.

REMARKS: The type, and only known specimen, was collected in 1900 and presented to the Natural History Museum (London) by J. G. Kerr; it consists of a skin and upper incisors. Because of the uncertainty of its type locality, *C. dorsalis* is another of the problematic species of tuco-tucos, although various authors have provided arguments to restrict the type locality. For example, Rusconi (1928) proposed Resistencia (in Chaco province, Argentina) as the type locality. Moojen (1952b) suggested a distribution in present-day Chaco Boreal (which was part of Bolivia in 1900, the year the holotype was collected), perhaps extending into adjacent Brazil. Cabrera (1961), Mares and Ojeda (1982), Redford and Eisenberg (1992), and Woods and Kilpatrick (2005) give a variation on “northern Paraguayan Chaco.” Redford and Eisenberg (1992:map 11.129) map two localities without documentation. However, until additional specimens matching the details of the holotype are collected, the type locality of *C. dorsalis* will remain ambiguous. A useful hint for identifying at least the general Chacoan area where the type specimen was obtained might be in the local vernacular name *Sunkum* (Thomas 1900g), possibly *sunkum*. Careful examination of the vocabularies of the various indigenous tribes in the general Chaco region may help to pinpoint a more limited area of occurrence (J. R. Contreras and Roig 1992). Karyology and sperm morphology are unknown.

Map 434 Possible range of *Ctenomys dorsalis* (?) (see Remarks).

Ctenomys emilianus Thomas and St. Leger, 1926

Emily's Tuco-tuco

SYNONYM:

Ctenomys emilianus Thomas and St. Leger, 1926b:637; type locality "Chos Malal, Prov. Neuquén. Altitude 805 m," Departamento Chos Malal, Neuquén, Argentina, 37°23'S, 70°16'W.

DESCRIPTION: Large, pale tuco-tuco, "readily distinguishable by its clear fawn color, contrasting with the whitish belly and sides, and its low flattish skull" (Thomas and St. Leger 1926b:638). External dimensions of holotype head and body length 211 mm, tail length 91 mm, and hind-foot length 39 mm. General color above pale glossy fawn, uniform on head and back, without frontal blackening; sides and venter, including chin and throat, buffy whitish, with this color extending further up sides and onto hips and thighs more than in most other species, and thus contrasting with brown color of rump. Hairs of forefeet and hindfeet and tail buffy whitish; tail lacks any blackening of its terminal tuft. Skull slender in build, flat, with zygomatic arches expanded but not convex; nasals narrow; interorbital region flattened; braincase low with masseteric ridge well defined; lambdoidal ridges well defined; vertical occipital central ridge absent; and bullae large and well inflated.

DISTRIBUTION: *Ctenomys emilianus* is only known from the type locality and neighboring areas in the Patagonian steppe of Neuquén province, Argentina.

Map 435 Selected localities for *Ctenomys emilianus* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 435): ARGENTINA: Neuquén, Chos Malal (holotype of *Ctenomys emilianus* Thomas and St. Leger), Río Quilquihue (Massoia 1988a).

SUBSPECIES: *Ctenomys emilianus* is monotypic.

NATURAL HISTORY: *Ctenomys emilianus* lives in sandy soils and dunes at elevations up to 800 m. It occurs parapatrically with a small and more darkly colored species (probably *C. haigi*) in the vicinity of the type locality of Chos Malal (Thomas and St. Leger 1926b; Pearson 1984).

REMARKS: Neither karyotype nor sperm morphology have been described.

Ctenomys famosus Thomas, 1920

Famatina Tuco-tuco

SYNONYMS:

Ctenomys famosus Thomas, 1920g:420; type locality "Potrerillo, at about 2600 m," Sierra de Famatina, Departamento Famatina, La Rioja, Argentina, 25°50'S, 67°27'W, 2,600 m.

Ctenomys fulvus famosus: Cabrera, 1961:549; name combination.

DESCRIPTION: Relatively small tuco-tuco, with holotype (female) dimensions head and body length 160 mm, tail length 74 mm, and hindfoot length 31.5 mm. Color above and below uniformly pale, similar to that of *C. coludo*, but tail considerably shorter. Skull also similar to that of *C. coludo* but overall smaller, with smaller bullae,

Map 436 Single known locality for *Ctenomys famosus* (●). Contour line = 2,000 m.

with less widely expanded zygomatic arches, and less heavy cheek teeth; supraorbital region with small ledges.

DISTRIBUTION: *Ctenomys famosus* is known from the type locality and probably nearby areas within the Sierrita de Famatina in La Rioja province, Argentina, at elevations to 3,800 m.

SELECTED LOCALITIES (Map 436): ARGENTINA: La Rioja, Potrerillo (type locality of *Ctenomys famosus* Thomas).

SUBSPECIES: *Ctenomys famosus* is monotypic.

NATURAL HISTORY: No ecological data are available.

REMARKS: Thomas (1920g) regarded *C. famosus* as morphologically similar to the geographically adjacent *C. coludo*, which he had named earlier in the same year, differing from the latter primarily by a relatively shorter tail and smaller bullae. A year later Thomas (1921g) suggested that *famosus* was only a subspecies of *coludo*. Cabrera (1961) treated *famosus* as a subspecies of *C. fulvus*. The karyotype and sperm morphology are unknown.

Ctenomys flamarioni Travi, 1981

Flamarion's Tuco-tuco

SYNONYM:

Ctenomys flamarioni Travi, 1981:123; type locality "Fazenda Caçapava, Estação Ecológica do Taim, Rio Grande, Rio Grande do Sul, Brasil," 32°52'S 52°32'W, 5–10 m.

DESCRIPTION: Medium to large-sized species, with holotype (female) measuring 289 mm in total length and

74 mm of tail length. Upper incisors orthodont (Travi 1981). Overall color sandy yellow, making *C. flamarioni* palest species of those inhabiting southern Brazil and adjacent Uruguay (Rebelato 2006). Baculum elongated (mean length 10.4 mm) and thin, with rounded tip. Glans penis with spines of various shapes (from sharp to rounded); spine density 12/mm², mean spine length 226.26 ± 32.42 μm s.d. (Rocha-Barbosa et al. 2013).

DISTRIBUTION: *Ctenomys flamarioni* occurs within the coastal dunes in Santa Catarina and Rio Grande do Sul states, Brazil.

SELECTED LOCALITIES (Map 437; from Travi 1981): BRAZIL: Rio Grande do Sul, Cidreira, Fazenda Caçapava (type locality of *Ctenomys flamarioni* Travi), Hermenegildo, Lagoa do Peixe, Tramandaí; Santa Catarina, Morro dos Conventos.

SUBSPECIES: *Ctenomys flamarioni* is monotypic.

NATURAL HISTORY: This is one of the best-known species of tuco-tucos with respect to ecology and behavior. Males occupy territories almost five times larger than females (G. P. Fernandez 2002). Tunnel systems are very long, especially in males, and constructed at a depth of about 30 cm (Bretschneider 1987). Food items are mainly species of Poaceae and Cyperaceae (Bretschneider 1987). The overall sex ratio does not differ from 1:1 in the gen-

Map 437 Selected localities for *Ctenomys flamarioni* (●).

eral population, but in adults the ratio is biased toward females (2:1–2.7:1), and the species is polygynous in mating behavior (G. P. Fernandez 2002). Gestation is about 120 days long (Bretschneider 1987), and litter size ranges between two and three (Travi 1983). Fernandez-Stolz et al. (2007) described the role of dispersal in local population bottlenecks.

REMARKS: *Ctenomys flamarioni* is distinguished from the neighboring species *C. torquatus*, *C. minutus*, and *C. lami* by its whitish-yellow color and zygomatic region. The karyotype of *C. flamarioni* is $2n = 48$, $FN = 50-78$, partly associated with geographic variation in whole-arm constitutive heterochromatin. G-banding suggests a close cytogenetic relationship between *C. flamarioni* and species of the Argentinian “*mendocinus*-group,” such as *C. australis*, *C. mendocinus*, and *C. porteousi* (T. R. O. Freitas 1994; Massarini and Freitas 2005), a hypothesis strongly supported by mtDNA sequence analysis (Parada et al. 2011). Sperm morphology is the simple asymmetric type (T. R. O. Freitas 1995a).

Ctenomys fochi Thomas, 1919

Foch's Tuco-tuco

SYNONYMS:

Ctenomys fochi Thomas, 1919a:117; type locality “Chumbicha, Catamarca,” Departamento Capayán, Catamarca, Argentina, 28°52'S, 66°14'W, 415 m.

Ctenomys mendocinus fochi: Cabrera, 1961:552; name combination; considered a valid subspecies of a polytypic *C. mendocinus* Philippi.

C[tenomys]. fochi Redford and Eisenberg, 1992:374; incorrect subsequent spelling of *Ctenomys fochi* Thomas.

DESCRIPTION: Small species, with external dimensions of holotype (young adult male) head and body length 162 mm, tail length 76 mm, and hindfoot length 30 mm. General body color drab buffy brown with hairs of venter washed with paler tones; hairs throughout slaty at base; muzzle and crown nearly black. Skull similar to that of *C. bergi*, but with bullae uniformly more inflated and line connecting anterointernal angle with meatal tube more distinctly convex forward.

DISTRIBUTION: *Ctenomys fochi* is known only from the vicinity of the type locality in Catamarca province, Argentina.

SELECTED LOCALITIES (Map 438): ARGENTINA: Catamarca, Chumbicha (type locality of *Ctenomys fochi* Thomas).

SUBSPECIES: *Ctenomys fochi* is monotypic.

NATURAL HISTORY: No ecological data are available. According to the collector, Emilio Budin, the species “lives in very dry red earth” (Thomas 1919a:119).

REMARKS: *Ctenomys fochi* is apparently closely related to *C. bergi* from Córdoba province (Thomas 1919a),

Map 438 Single known locality *Ctenomys fochi* (●). Contour line = 2,000 m.

but is distinguishable in aspects of color, particularly the nearly black muzzle and crown, and by the more greatly inflated bullae. The karyotype and sperm morphology are unknown.

Ctenomys fodax Thomas, 1910

Lago Blanco Tuco-tuco

SYNONYMS:

Ctenomys fodax Thomas, 1910a:243; type locality “Valle del Lago Blanco, Cordillera region of Southern Chubut, Patagonia (about 46°S., 71°W.)”; restricted to Estancia Valle Huemules, Departamento Río Senguerr, Chubut, Argentina (45°57'S, 71°31'W, 575 m) by Pardiñas et al. (2007).

Ctenomys talarum fodax: Rusconi, 1928:243; name combination.

DESCRIPTION: One of larger species in genus, with dimensions of holotype (adult male) head and body length 260 mm, tail length 98 mm, and hindfoot length (without claw) 40.4 mm. Fur soft; dorsal color generally cinnamon. Skull large and bowed, with nasals broad in front giving entire rostrum broad appearance; nasals extend posteriorly to frontopremaxillary processes; auditory bullae sufficiently expanded to be visible when braincase is viewed from above; interparietal longer than broad, commonly divided by median suture.

DISTRIBUTION: *Ctenomys fodax* is restricted to the vicinity of the type locality in the Patagonian steppe of Chubut province, Argentina.

Map 439 Selected localities for *Ctenomys fodax* (●).

SELECTED LOCALITIES (Map 439): ARGENTINA: Chubut, Estancia Valle Huemules, Lago Blanco (type locality of *Ctenomys fodax* Thomas, as restricted by Pardiñas et al. 2007), Lago Musters (A. I. Medina et al. 2007), Valle del Lago Blanco (FMNH 18191).

SUBSPECIES: *Ctenomys fodax* is monotypic.

NATURAL HISTORY: No ecological data are available.

REMARKS: Considered by Thomas (1910a) to be most closely related to *C. osgoodi* J. A. Allen (now *C. magellanicus osgoodi*; see that account), but larger in body size and with distinctive cranial differences. Listed by Osgood (1943b) and Cabrera (1961) as a synonym of *C. magellanicus osgoodi* J. A. Allen. The karyotype is $2n = 28$, FN = 38, and sperm morphology is of the simple asymmetric type (Montes et al. 2001).

Ctenomys frater Thomas, 1902

Forest Tuco-tuco, Red Tuco-tuco

SYNONYMS:

Ctenomys frater Thomas, 1902c:228; type locality “Potosí, 4300 m,” Potosí, Bolivia, 19°35’S, 65°45’W, ca. 4,300 m.

Ctenomys budini Thomas, 1913a:141; type locality “Cerro de Lagunita, E. of Maimara. 4500m,” Jujuy, Argentina.

Ctenomys sylvanus Thomas, 1919g:155; type locality “Tartagal, 600 m”; Salta, Argentina.

Ctenomys sylvanus utibilis Thomas, 1920a:193; type locality “Yuto, Rio San Francisco. Alt. 500 m.”; about 70 km N Villa Carolina, Jujuy, Argentina.

Ctenomys budini barbarus Thomas, 1921d:185; type locality “Sierra Santa Barbara, S. E. Jujuy. Type from Sunchal, alt. 1200 m”; Jujuy, Argentina.

Ctenomys budini budini: Thomas, 1921d:186; name combination.

Ctenomys budini sylvanus: Thomas, 1921d:186; name combination.

Ctenomys budini utibilis: Thomas, 1921d:186; name combination.

Ctenomys sylvanus mordosus Thomas, 1926c:325; type locality “Tambo, 2200 m,” Tarija, Bolivia; considered by Cabrera (1961:548) to be a valid subspecies of a polytypic *C. frater* Thomas.

[*Ctenomys*] *sylvanus sylvanus*: Tate, 1935:390; name combination.

Ctenomys frater barbarus: Cabrera, 1961:547; name combination.

Ctenomys frater budini: Cabrera, 1961:548; name combination.

Ctenomys frater frater: Cabrera, 1961:548; name combination.

Ctenomys frater mordosus: Cabrera, 1961:548; name combination.

Ctenomys frater sylvanus: Cabrera, 1961:548; name combination.

DESCRIPTION: Small to medium-sized species; specimens of *C. f. mordosus* from Bolivia with total length 229–272 mm, tail length 55–76 mm (S. Anderson 1997); those from Jujuy, Argentina, larger, with total length 230–300 mm, tail length 50–85 mm (M. M. Díaz and Barquez 2002). General color of nominotypical subspecies and *C. f. mordosus* brownish fawn with dull buffy undersurface without inguinal white patches (Thomas 1902c; S. Anderson 1997). Specimens from Salta province, Argentina, dark russet to black (M. M. Díaz et al. 1997), and those from Jujuy Province reddish or coppery (hence, common name “*tuco colorado*” [red tuco-tuco]; M. M. Díaz and Barquez 2002). Skull greatly vaulted. Thomas (1926c:325–326) characterized *C. s. mordosus* as having “size and general external appearance quite as in true *sylvanus*,” but with much broader and heavier incisors, “their combined breadth attaining 7 mm in old specimens as compared with 5.5 mm. in equally aged specimens of *sylvanus*.” Upper incisors nearly orthodont, with angle of anterior face 98° of horizontal plane. Rostrum of *mordosus* thickened, in a manner seen “to a still greater extent in *C. boliviensis*” and in *C. steinbachi*. “An allied species, with equally broad incisors, is the *Ctenomys frater* of Potosi, but that has peculiarly narrowed bullae and is of a decidedly lighter colour.”

DISTRIBUTION: *Ctenomys frater* occurs in southern Bolivia (Potosí and Tarija departments) and northwestern Argentina (Salta and Jujuy provinces).

SELECTED LOCALITIES (Map 440): ARGENTINA: Jujuy, Caimancito (FMNH 29048), Calilegua (FMNH 23235), Cerro de la Lagunita (type locality of *Ctenomys budini* Thomas), mountains W of Yala (FMNH 23241), San Rafael (FMNH 29053), Sunchal (type locality of *Ctenomys budini barbarus* Thomas), Yuto, Río San Francisco (type locality of *Ctenomys sylvanus utibilis* Thomas); Salta, Aguaray (CML 80), Tartagal (type locality of *Ctenomys sylvanus* Thomas). BOLIVIA: Potosí, Potosí (type locality of *Ctenomys frater* Thomas); Tarija, Caraparí (Anderson 1997), 3 km SE of Cuyambuyo (S. Anderson 1997), Tambo (type locality of *Ctenomys sylvanus mordosus* Thomas), Yacuiba (S. Anderson 1997).

SUBSPECIES: *Ctenomys frater* currently includes five subspecies (synonymies listed here under the species): *Ctenomys f. frater* Thomas, an isolated population in eastern Potosí, Bolivia; *Ctenomys f. barbarus* Thomas, from the mountains in southern Jujuy and adjacent Salta, Argentina; *Ctenomys f. budini* Thomas, from the high elevations in Jujuy and adjacent west-central Salta, Argentina; *Ctenomys f. mordosus* Thomas, from southern Tarija, Bolivia, and perhaps extreme northern Jujuy, Argentina; and *Ctenomys f. sylvanus* Thomas, from the base of the Andes in eastern Jujuy and western Salta, Argentina.

NATURAL HISTORY: In Argentina, *Ctenomys frater* has been captured in moist forests and grassy meadows between 2,000 and 4,500 m in Jujuy Province, and in flat areas with deep soils near creeks in Salta Province (Mares, Ojeda, and Kosco 1981; see also Thomas 1919g). In Bolivia, the subspecies *C. f. mordosus* occurs at elevations from 600 to 2,700 m, and *C. f. frater* at 4,300 m. No detailed data on habitat, habits, behavior, food, or reproduction is known for Bolivian populations (S. Anderson 1997). S. L. Gardner and Duszynski (1990) describe eimerian oocysts in the feces of three specimens of *C. f. mordosus*.

REMARKS: Woods (1993) erroneously gave the type locality of *C. frater* Thomas as in Argentina. In 1921, Thomas (p. 186) argued that *sylvanus* Thomas and *sylvanus utibilis* Thomas, along with *budini* Thomas and a new form he described in that paper (*budini barbarus*) “should be united specifically, and be considered as four subspecies of one species” (i.e., *C. b. budini*, *C. b. sylvanus*, *C. b. utibilis*, and *C. b. barbarus*). In 1926, ignoring his earlier view that *sylvanus* was only a subspecies of *budini*, Thomas (p. 325) described *Ctenomys sylvanus mordosus* but noted that it was allied to *Ctenomys frater*. Cabrera (1961) grouped each of these names, in various combinations, into five subspecies of *C. frater*: *C. f. barbarus*, *C. f. budini*, *C. f. frater*, *C. f. mordosus*, and *C. f. sylvanus* (with *utibilis* Thomas as a synonym). Woods and Kilpatrick (2005:1562) listed *budini* Thomas as a

Map 440 Selected localities for *Ctenomys frater* (●). Contour line = 2,000 m.

species distinct from *C. frater*, with *barbarus* Thomas as a valid subspecies. These authors listed *sylvanus* Thomas both in the synonymy of *C. frater* (p. 1564, with an incorrect year of publication of 1925) and as a separate species, *C. sylvanus* (p. 1569, citing the correct publication year of 1919).

Cook et al. (1990) compared *C. f. frater* and *C. f. mordosus* to other Bolivian species in external and craniodental characters. Cook and Yates (1994) regarded *C. frater* (as represented by *C. f. mordosus*) and *C. lewisi* to be more closely related to each other, based on electrophoretic analyses, than to any other Bolivian species these authors examined. Cook et al. (1990) described a karyotype consisting of $2n = 52$, $FN = 78$ for *C. f. mordosus*, and Ruedas et al. (1993) reported on genome size and other karyological details of this same subspecies. The sperm is the simple symmetric morphological type (Vitulo and Cook 1991; Bidau 2006).

Ctenomys fulvus Philippi, 1860

Long-tailed Tuco-tuco

SYNONYMS:

Ctenomys fulvus Philippi, 1860:157, Zool. tab. L; type locality “Reise durch die Wüste Atacama,” or vicinity of Pingo-Pingo, Atacama desert, Chile, 2,700 to 3,300 m, 24°00'S 69°00'W (Osgood 1943b:127).

Ctenomys atacamensis Philippi, 1860:158, Zool. Table II, Fig. 1; type locality “Reise durch die Wüste Atacama,”

or Tilopozo, about lat. 23°20'S, Atacama Desert, Chile (Osgood 1943b:127).

Ctenomys robustus Philippi, 1896:11, plate 4, Fig. 2, and plate 5, Fig. 1a–d; type locality “la provincia de Tarapacá, cerca de Pica, en los lugares llamados ‘canchones’ en una elevacion de cerda de 12200 m,” Chile; Canchones (20°15'S 69°20'W) is on the open plain between Pica and Noria (Osgood 1943).

Ctenomys pallidus Philippi, 1896:13:plate 4, Fig. 1 and plate 5, Fig. 3a–c; type locality “Breas, en el desierto de Atacama,” southwest of Antofagasta de la Sierra, about 26°3'S and 67°56'W, alt. 9,000–10,000 ft (Osgood 1943b:127; the coordinates, however, place the locality in Catamarca, Argentina).

Ctenomys pernix Philippi, 1896:15, plate 5, Fig. 5 and plate 6, Fig. 2; type locality “Aguas Calientes,” near Socaire, east of Salar de Atacama, about lat. 23°S., long. 68°16'W., Chile (Osgood 1943b:127).

Ctenomys chilensis Philippi, 1896:16, plate 6, Fig. 1; type locality “la cordillera de Linares” but probably from Atacama Desert (Osgood 1943b:127).

Ctenomys fulvus robustus: Mann, 1978:292; name combination.

DESCRIPTION: Very large species, with total length 280–350 mm; samples assignable to *robustus* may exceed 350 mm (Mann 1978). Upper parts slightly grizzled clay color with sides considerably paler than back; forehead and narrow line around mouth darkened or even slightly blackish; under parts uniform, clear cinnamon buff; tail blackish brown above and terminates in light pencil; feet whitish buff with some darkening medially and proximally. Skull large and heavily ridged with swollen auditory bullae and broad, wedge-shaped nasals.

DISTRIBUTION: *Ctenomys fulvus* occurs in northern Chile at elevations above 2,700 m.

SELECTED LOCALITIES (Map 441): CHILE: Antofagasta, Aguas Calientes (type locality of *Ctenomys pernix* Philippi), Pingo-Pingo; (type locality of *Ctenomys fulvus* Philippi), Salar de Atacama (Slamovitz et al. 2001), San Pedro de Atacama (Feito and Gallardo 1982), 20 mi E of San Pedro de Atacama (Osgood 1943b), Tilopozo (type locality of *Ctenomys atacamensis* Philippi); Tarapacá, Canchones, La Huayca (Feito and Gallardo 1982), near Pica (type locality of *Ctenomys robustus* Philippi).

SUBSPECIES: Two subspecies of *Ctenomys fulvus* are currently recognized: *C. f. fulvus* (with *atacamensis* Philippi, *pallidus* Philippi, *pernix* Philippi, and *chilensis* Philippi as synonyms) and *C. f. robustus* Philippi (see Mann 1978; Woods and Kilpatrick 2005). The nominotypical form occurs in western Antofagasta and *C. f. robustus* is restricted to the Oasis de Pica in the desert of Tarapacá. The two ranges are separated by four degrees of latitude.

Map 441 Selected localities for *Ctenomys fulvus* (●). Contour line = 2,000 m.

NATURAL HISTORY: *Ctenomys fulvus* inhabits sandy soils in desert flats with creosote bush (*Larrea*, Zygophyllaceae) or other desert shrubs, and riparian forests along dry gullies. Burrow systems are deep (more than 25 cm below the surface), and burrow temperature is maintained between 19° and 25°C while the outside temperature may vary between 6° and 62°C. Individuals are active early in the morning (5:00 to 7:00 AM) and especially in the dry season. They are known to eat *Larrea* leaves (Rosenmann 1959; Mann 1978). Hickman (1985, 1988) described mound-building behavior and swimming ability, and Cortés, Miranda et al. (2000) described thermal biology.

REMARKS: Cabrera (1961) included both *C. coludo* Thomas and *C. famosus* Thomas as valid subspecies of *C. fulvus*. Both of these taxa are considered separate species herein. The two subspecies of *C. fulvus* share the same $2n = 26$ karyotype (M. H. Gallardo 1979). Sperm morphology is symmetric in both subspecies (Feito and Gallardo 1982).

Ctenomys goodfellowi Thomas, 1921

Goodfellow's Tuco-tuco

SYNONYMS:

Ctenomys goodfellowi Thomas, 1921a:136; type locality “Esperanza, near Concepcion, Prov. Nuflo de Chaves, E. Bolivia,” Santa Cruz, Bolivia, 16°15'S 62°04'W, 400 m.

Ctenomys boliviensis goodfellowi: Cabrera, 1961:546; name combination.

DESCRIPTION: Large tuco-tuco, slightly smaller than related *C. boliviensis*; total length of females 257–288 mm, tail length 71–79 mm; for males, total length >330 mm and tail length >93 mm (S. Anderson 1997). Colors also very similar to those of *C. boliviensis*, although “the dark dorsal line is heavier and the white of the undersurface is reduced to inconspicuous axillary and inguinal patches” (Thomas 1921a:136). Broad, heavy orange incisors and very large premolars characteristics of both species. In general, cranium of *C. goodfellowi* smaller, less ridged, with less thickened zygomata, and smaller and less inflated bullae than *C. boliviensis* (Thomas 1921a).

DISTRIBUTION: *Ctenomys goodfellowi* is known only from two localities in north-central Santa Cruz department, Bolivia (see S. Anderson 1997).

SELECTED LOCALITIES (Map 442): BOLIVIA: Santa Cruz, Esperanza (type locality of *Ctenomys goodfellowi* Thomas), 10 km N of San Ramón, La Laguna (S. Anderson 1997).

SUBSPECIES: *Ctenomys goodfellowi* is monotypic.

NATURAL HISTORY: No data are available on ecology, habitat, behavior, or food. A single pregnant female was trapped in June (S. Anderson 1997). S. L. Gardner and Duszynski (1990) report eimerian oocysts in the feces.

REMARKS: Listed as a subspecies of *C. boliviensis* by Cabrera (1961) and S. Anderson et al. (1987), but electrophoretic data (Cook and Yates 1994) support *C. good-*

fellowi as a distinct species. Mitochondrial DNA sequence data (E. P. Lessa and Cook 1998), however indicate that *C. boliviensis* and *C. goodfellowi* are sister species, at least among the limited set of taxa these authors examined. The karyotype is $2n = 46$, FN= 68 (S. Anderson et al. 1987), and the sperm is symmetric in its morphology.

Ctenomys haigi Thomas, 1919

Patagonian Tuco-tuco

SYNONYMS:

Ctenomys haigi Thomas, 1919b:210; type locality “Maitén, W. Chubut. 700 m,” El Maitén, Departamento Cushamen, Chubut, Argentina, 42°03’S, 71°10’W, 700 m.

Ctenomys haigi lentulus Thomas, 1919b:211; type locality “Pilcañeu, Upper Rio Negro, 1400 m,” Pilcaniyeu, Departamento Pilcaniyeu, Provincia de Rio Negro, Argentina, 41°13’S, 70°61’W.

Ctenomys haigi haigi: Thomas, 1919b:211; name combination.

Ctenomys mendocinus haigi: Thomas, 1927e:201; name combination.

Ctenomys haigi luteolus Rusconi, 1928:245; incorrect subsequent spelling of *lentulus* Thomas; not *luteolus* Thomas.

Ctenomys haigii: Pearson, 1995:116; inadvertent spelling error.

DESCRIPTION: Medium-sized and short-tailed species (mean body measurements from five specimens of females and males, respectively, in MVZ collection: head and body length, 172 and 194 mm; tail length, 81 and 88 mm; hindfoot length, 34 and 36 mm; mass, 152 and 229 g). Dorsal color grayish brown, without median line on crown or rump; top of nose dark brown; sides clearer gray and flanks and venter light to washed buffy. Mandible lacks deep channel. About 56% of adult specimens show open frontoparietal fenestrae (S. L. Gardner and Anderson 2001).

DISTRIBUTION: *Ctenomys haigi* occurs in the Neuquén, Rio Negro and Chubut provinces, Argentina in Patagonian steppe and the *Monte de Llanuras y Mesetas* ecoregions.

SELECTED LOCALITIES (Map 443; from Pearson and Christie 1985, except as noted): ARGENTINA: Chubut, El Maitén (type locality of *Ctenomys haigi* Thomas); Neuquén, 37 km SW of Chos Malal, Collón Cura (Thomas 1927e), Collón Cura, 16 SE of La Rinconada, 1 km W of Confluencia, Estancia Alicurá, Parque Nacional Laguna Blanca, Paso del Cordoba (MVZ 183291); Río Negro, 10 km S of Comallo (MVZ 185053), 19 km SE of Bariloche, 43 km SSW of Bariloche, Campo Viejo, Estancia San Ramón (MVZ 186062), 7.5 km N and 8 km E of Cerro Ñireco (MVZ 183295), 5 km W of Comico, Lago Steffen (MVZ 162284), Laguna Tromen (MVZ 193693), Pilcaniyeu (type

Map 442 Selected localities for *Ctenomys goodfellowi* (●). Contour line = 2,000 m.

locality of *Ctenomys haigi lentulus* Thomas), 5 km W of Sierra Grande.

SUBSPECIES: *Ctenomys haigi* is monotypic.

NATURAL HISTORY (from Pearson 1984, except as noted): As is characteristic of all tuco-tucos, *C. haigi* is restricted to self-dug underground burrows where it may be active day or night. It is rarely seen above ground, but occasional emergence is indicated by its frequent occurrence in owl pellets as well as the toothmarks on the small-sized, above-ground shrubs upon which it feeds. Individuals are vocal, uttering a single, short syllable and with as many as 30 such “calls” in a single bout. The species inhabits treeless steppe vegetation. Litter size ranges between two and four (mean 2.6). Lacey et al. (1998) described solitary burrow use by adults of both sexes. Hambuch and Lacey (2002) and Lacey (2001) contrasted patterns of variation at both MHC and microsatellite loci, respectively, between the asocial *C. haigi* and the geographically adjacent but social *C. sociabilis*.

REMARKS: Thomas (1919b) considered *C. haigi* to be allied to *C. colburni*, although smaller and with less pronounced bullae. Subsequently, Thomas and St. Leger (1926b:639) thought that *haigi* “will be found to grade into” *C. mendocinus*. And, finally, Thomas (1927e) formalized this earlier suggestion by stating that his subspecies *lentulus* was indistinguishable from typical *haigi*, which he then placed as a subspecies of *C. mendocinus*.

Map 443 Selected localities for *Ctenomys haigi* (●). Contour line = 2,000 m.

Pearson (1984) argued that *C. haigi* was a species distinct from *C. mendocinus* on the basis of their different karyotypes, a position supported by substantial divergence in electromorphic and mtDNA sequence data (Sage et al. 1986; E. P. Lessa and Cook 1998). Pearson (1984) also regarded specimens from Chos Malal, Neuquén Province, Argentina, in the Natural History Museum, London, that Thomas identified as *C. mendocinus* were best assigned to *C. haigi* on the basis of size and coloration. The karyotype of *C. haigi* is $2n = 50$, $FN = 66$ (Pearson 1984; M. H. Gallardo 1991). Sperm morphology is of the simple asymmetric type (M. H. Gallardo et al. 2002; Bidau 2006).

Ctenomys ibicuiensis T. R. O. Freitas, Fernandes, Fornel, and Roratto, 2012

Ibicuí Tuco-tuco

SYNONYMS:

Ctenomys ibicuiensis T. R. O. Freitas, Fernandes, Fornel, and Roratto, 2012:1358: type locality “Manoel Viana, in central-western Rio Grande do Sul, southern Brazil, 29°23’37”S, 55°25’43”W.”

DESCRIPTION: Species defined primarily by chromosomal and mtDNA cytochrome-*b* sequence differences relative to other species of “*torquatus*-group” from southwestern Brazil and adjacent parts of Argentina and Uruguay; few data available for external characteristics, including pelage color and color pattern, although species moderate in body size (head and body length 159 mm, tail length 75 mm, hindfoot length 37 mm, and mass 200 g; T. R. O. Freitas et al. 2012). Cranially, *C. ibicuiensis* most similar to geographically adjacent populations of *C. torquatus*, but differs with shorter skull, less robust zygomatic arches, and more compact cranium. Multivariate analyses of dorsal, ventral, and lateral landmarks of skull separate *C. ibicuiensis* from six other species, including *C. lami*, *C. minutus*, *C. pearsoni*, *C. perrensi*, *C. roigi*, and *C. torquatus*.

DISTRIBUTION: *Ctenomys ibicuiensis* is known from only six closely adjacent localities in the municipalities of Manoel Viana and Macambará in Rio Grande do Sul state, Brazil, at an elevation approximately 200 m.

SELECTED LOCALITIES (Map 444; from T. R. O. Freitas et al. 2012): BRAZIL: Rio Grande do Sul, BR 176, Manoel Viana, Piraju, Manoel Viana (type locality of *Ctenomys ibicuiensis* T. R. O. Freitas et al.), Passo do Narciso, Maçambará.

SUBSPECIES: *Ctenomys ibicuiensis* is monotypic.

NATURAL HISTORY: No data ecology, reproduction, behavior, or other aspects of the population biology of this species have been reported. T. R. O. Freitas et al. (2012:1359) recorded the habitat as “sand dunes and grasslands, disturbed by agricultural activities and desertification.”

Map 444 Selected localities for *Ctenomys ibicuiensis* (●).

Map 445 Single known locality for *Ctenomys johannis* (●). Contour line = 2,000 m.

REMARKS: The karyotype consists of $2n = 50$, $FN = 68$, with 10 biarmed and 14 acrocentric autosomal pairs and a biarmed X chromosome (T. R. O. Freitas et al. 2012). A distinctly large pair of biarmed autosomes is diagnostic. In their phylogenetic analysis of mtDNA cytochrome-*b* sequences (T. R. O. Freitas et al. 2012), *C. ibicuiensis* was sister to a clade comprised of *C. lami*, *C. minutus*, and *C. torquatus*.

Ctenomys johannis Thomas, 1921

San Juan Tuco-tuco

SYNONYMS:

Ctenomys coludo johannis Thomas, 1921g:523; type locality “Department of San Juan. Type from Cañada Honda. Alt. 500 m,” Departamento Sarmiento, San Juan, Argentina, 31°59’S 68°33’W, 600 m.

Ctenomys fulvus johannis: Cabrera, 1961:549; name combination.

Ctenomys johannis: J. R. Contreras, Roig, and Suzarte, 1977: 162; first use of current name combination but inadvertent misspelling of *johannis* Thomas.

DESCRIPTION: Similar in body size and other characters to *C. coludo* from Catamarca province, Argentina, but color of *C. johannis* less strongly buffy (termed “drab-gray”), with nape, foreback, and sides of head gray; nasal patch present, more strongly marked than in *C. coludo*. Ventral hairs with whitish tips, faintly tinged buffy. Caudal crest blackened terminally, darkening essentially absent in

C. coludo. Skull similar to that of *C. coludo*, but zygomatic arches less widely spread so that breadth across arches distinctly less than across opening of auditory tubes; interparietal sutures barely perceptible, or not at all. External dimension of holotype, head and body length 199 mm, tail length 97 mm, and hindfoot length 36 mm.

DISTRIBUTION: *Ctenomys johannis* is only known from the type locality in the *Monte de Llanuras y Mesetas* ecoregion of San Juan province, Argentina.

SELECTED LOCALITIES (Map 445): ARGENTINA: San Juan, Cañada Honda (type locality of *Ctenomys coludo johannis* Thomas).

SUBSPECIES: *Ctenomys johannis* is monotypic.

NATURAL HISTORY: According to Emilio Budin, the collector, this species was found “under trees; holes made in naked soil” (Thomas 1921g:524).

REMARKS: The karyotype and sperm morphology are unknown.

Ctenomys juris Thomas, 1920

Jujuy Tuco-tuco

SYNONYMS:

Ctenomys juris Thomas, 1920a:194; type locality “El Chaguaral, between San Pedro and Villa Carolina. Alt. 500 m,” Departamento San Pedro, Jujuy, Argentina, 24°16’S, 64°48’W, 500 m (see J. R. Contreras 1984b:239).

Ctenomys mendocinus juris: Cabrera, 1961:552; name combination.

DESCRIPTION: Small species, resembling *C. fochi* but with much smaller bullae (Thomas 1920a; A. I. Medina et al. 2007). General color uniformly pale brown with buffy or whitish half-collar extending to ear on side of neck; as with *C. fochi*, marked darkening on top of muzzle; inner sides of forelimbs whitish, paler than venter; hands and feet white above; tail dull buffy whitish, with dark brown terminal crest. Skull with broad nasals, slightly narrowed posteriorly; zygomatic arches widely expanded, anterior breadth often greater than posterior; mesopterygoid fossa penetrates palate to level of middle of M2; bullae small and narrow but smoothly contoured, not compressed, and markedly smaller than those of *C. fochi*. Upper incisors particularly proodont, reaching angle of 108°, more so than either *C. bergi* (100°) or *C. fochi* (94°). External measurements of holotype, head and body length 177 mm, tail length 72 mm, and hindfoot length 29 mm.

DISTRIBUTION: *Ctenomys juris* is known only from the type locality in the *Chaco Seco* ecoregion of Jujuy province, Argentina.

SELECTED LOCALITIES (Map 446): ARGENTINA: Jujuy, El Chaguaral (type locality of *Ctenomys juris* Thomas).

SUBSPECIES: *Ctenomys juris* is monotypic.

NATURAL HISTORY: According to Emilio Budin (Thomas 1920a:194), this tuco-tuco was found “in stony ground in ravines running down to the river.”

REMARKS: Cabrera (1961) treated this species as a subspecies of *C. mendocinus* Philippi, a position main-

tained by Redford and Eisenberg (1992) and Woods (1993). Galliari et al. (1996) listed *C. juris* as a species, without comment. The diploid number of *C. juris* is $2n = 26$ (C. J. Bidau, unpubl. data). Sperm morphology is the simple asymmetric type (Bidau 2006).

Ctenomys knighti Thomas, 1919

Catamarca Tuco-tuco

SYNONYMS:

Ctenomys knighti Thomas, 1919d:498; type locality “Otro Cerro, North-eastern Rioja”; an abandoned ranch at the southern end of Sierra de Ambato, NE Chumbicha, Departamento Capayán, Catamarca, Argentina, 28°45'S, 66°17'W, 2,023 m (see Pardiñas et al. 2007).

Ctenomys knighti knighti: Cabrera, 1961:549; name combination.

DESCRIPTION: Small to medium-sized species; dimensions of holotype (adult male) head and body length 203 mm, tail length 82 mm, and hindfoot length 36 mm. Dorsal color dark brown; flanks, especially over thighs, buffy; venter uniformly ochraceous with cinnamon-buff hair tips; no collar present around the throat; muzzle, both on top and sides of mouth and tip of chin, distinctly blackish. Skull elongated with narrow nasals; parietal region lacks any trace of separate interparietal, even in the youngest specimens; incisive foramina elongated; bullae large and, when viewed from behind, have conspicuously smooth posterosuperior portion not covered by plastering bones of occipital series.

DISTRIBUTION: *Ctenomys knighti* is found in Catamarca and La Rioja provinces of Argentina within the *Chaco Seco* and *Monte de Sierras y Bolsones* ecoregions, at elevations from 770 to 2,025 m.

SELECTED LOCALITIES (Map 447): ARGENTINA: Catamarca, Otro Cerro (type locality of *Ctenomys knighti* Thomas); La Rioja, Machigasta (Llanos 1947).

SUBSPECIES: *Ctenomys knighti* is monotypic.

NATURAL HISTORY: No ecological data are available. Emilio Budin, the collector, found the species “on stony ground” (Thomas 1919d: 499).

REMARKS: The location of Otro Cerro has been debatable since Thomas (1919d) first described specimens from this locality (see Thomas 1920b; Pearson 1958; Cabrera 1961; and Myers et al. 1990 for varying opinions). Pardiñas et al. (2007:399–400 and Fig. 4, p. 403) reviewed this history and provided detailed information that placed this site at the southern end of the Sierra de Ambato in Catamarca, not Rioja, province. Fortunately, the resolution of this issue by Pardiñas et al. (2007) fixes the type locality for *C. knighti* and several other mammal species described by Thomas.

Thomas (1919d) believed *C. knighti* allied to *C. budini* (= *C. frater budini* herein) from Jujuy Province, but distin-

Map 446 Single known locality for *Ctenomys juris* (●). Contour line = 2,000 m.

Map 447 Selected localities for *Ctenomys knighti* (●). Contour line = 2,000m.

Map 448 Selected localities for *Ctenomys lami* (●).

guishable from that species by its dark muzzle, more buffy sides, absence of a collar, and cranially notably by the absence of a separate interparietal. Sperm morphology and karyotype are unknown.

Ctenomys lami T. R. O. Freitas, 2001

Lami Tuco-tuco

SYNONYM:

Ctenomys lami T. R. O. Freitas, 2001:2; type locality “Beco dos Cegos, Lami Beach in the Guaiba river, near Porto Alegre, at 30°51’S, 51°10’W,” Rio Grande do Sul, Brazil.

DESCRIPTION: Quite variable in size, total length 231–310mm, tail length 67–92mm, hindfoot length 31–42mm, and mass 170–307g. Dorsal color dark brownish, with each hair dark grayish basally and brownish near tip; ventral pelage paler. Cranially, nasal bones wide anteriorly and taper posteriorly; frontal region flat from interorbital region posteriorly; frontoparietal suture round; braincase oval-shaped, with length about one-third length of skull; zygomatic arches squared and robust; incisive foramina small; mesopterygoid fossa wide posteriorly and flared anteriorly; auditory bullae large and ventrally inflated. Mandible with long and narrow coronoid process, heavy condyloid process, and large angular process. All molariform teeth kidney-shaped, with M3 and m3 much reduced in size. Upper incisors large, orthodont, and faced with orange enamel.

DISTRIBUTION: *Ctenomys lami* is known from multiple localities in Rio Grande do Sul state, Brazil, in the

small area south and east of Porto Alegre between the Rio Guaiba and Lago Barros.

SELECTED LOCALITIES (Map 448; from T. R. O. Freitas 2001): BRAZIL: Rio Grande do Sul, Beco dos Cegos (type locality of *Ctenomys lami* T. R. O. Freitas), Chico Lomã, Parque de Itapuã.

SUBSPECIES: *Ctenomys lami* is monotypic.

NATURAL HISTORY: T. R. O. Freitas (2001) recorded pregnant females of *C. lami* in the months of June and December. Litter size was one to three embryos (mean = 2.04 ± 0.73; N = 25).

REMARKS: T. R. O. Freitas (2001) distinguished this species from the parapatric *C. minutus* primarily by its unique but highly variable karyotype. At least seven karyotypes are known, with diploid number ranging from $2n = 54$ to 58 with fusion/fission and pericentric inversion systems described in detail (T. R. O. Freitas 2007). El Jundi and Freitas (2004) provided details on genetic and demographic structure.

Ctenomys latro Thomas, 1918

Mottled Tuco-tuco

SYNONYM:

Ctenomys latro Thomas, 1918a:38; type locality “Tapia, about 20 miles north of Tucuman City. Alt. 600m,” Departamento Trancas, Tucumán, Argentina, 26°36’ S, 65°18’ W, 689m.

DESCRIPTION: Small to medium-sized species, head and body length 161–172mm (A. I. Medina et al. 2007).

Overall color buffy fawn on sides of head, back, and flanks; crown and middle of face dark brown; venter pale buff with throat white and darker chest patch present; colors of the upper and under surfaces sharply differentiated; light buffy patch behind ear that runs downward and backward onto side of neck; tail dark brown along entire length of dorsal surface but pale buffy on sides and below. Skull low and flattened, with narrow braincase; rostrum unusually broadened, due to thickening of bone outside anterior half of incisor alveolus; nasals broad, abruptly and squarely truncated behind, considerably surpassed by premaxillary processes, and with sides forming straight converging lines; zygomatic arches widely expanded, but distinctly short anteroposteriorly; temporal ridges unite to form low median sagittal crest rather than remaining separated; supraoccipital smooth, without median ridge; bullae small but smooth and well inflated. Cheek teeth small and appear rather delicate; PM4 exceeds molars in diagonal diameter.

DISTRIBUTION: *Ctenomys latro* is known only from Tucumán province, Argentina, in the *Chaco Seco* ecoregion.

SELECTED LOCALITIES (Map 449): ARGENTINA: Tucumán, Burreyacu, E Cerro Campo (Thomas 1926d), Río Choromoro (A. I. Medina et al. 2007), Tapia (type locality of *Ctenomys latro* Thomas), Ticucho (Ipucha et al. 2008).

SUBSPECIES: *Ctenomys latro* is monotypic.

NATURAL HISTORY: No data on ecology are available. Specimens have been collected in areas of open Chacoan forest with extremely stony soils.

Map 449 Selected localities for *Ctenomys latro* (●). Contour line = 2,000 m.

REMARKS: Cabrera (1961:553) synonymized *C. latro* with *C. mendocinus*, listing the name as a synonym under the subspecies *C. m. tucumanus* Thomas, part of his concept of a polytypic *C. mendocinus*. Reig and Kiblicky (1969) and Roig and Reig (1969) considered both *C. latro* and *C. tucumanus* to be distinct species based on karyotypic differences, a conclusion followed both by subsequent authors and as viewed herein. *Ctenomys latro* is closely allied to *C. pilarensis*, *C. occultus*, and *C. argentinus* in mtDNA sequence analyses, with this clade apparently sister to *C. tucumanus* (Mascheretti et al. 2000; Parada et al. 2011; see also J. R. Contreras and Bidau 1999). Contrary to Cabrera's (1961) hypothesis, *C. latro* shares no molecular relationship with *C. mendocinus* (Parada et al. 2011). Several related karyotypes have been reported for the species, including $2n = 42$, FN = 50 (Reig and Kiblicky 1968a), $2n = 40$, FN = 44 (Ortells 1995) and $2n = 40-42$, FN = 48 (Ipucha 2002; Ipucha et al. 2008).

Ctenomys leucodon Waterhouse, 1848

White-toothed Tuco-tuco

SYNONYMS:

Ctenomys leucodon Waterhouse, 1848:281; type locality "San Andrés de Machaca, . . . south of the Lake Titicaca, Department of La Paz, Bolivia"; ca. 4,000 m, $16^{\circ}44'S$ $69^{\circ}01'W$. Thomas, 1927b:552.

Ctenomys (Haptomys) leucodon Thomas, 1916g:305; designation as type species of new subgenus *Haptomys*.

DESCRIPTION: Medium sized with total length of adults 200–278 mm, tail length 79–85 mm, and hindfoot length averaging 34 mm (Sanborn and Pearson 1947; S. Anderson 1997). Back clay colored with base of hairs slate gray followed by either broad or narrow clay band and tipped with black; head darker and sides of muzzle and cheeks buckthorn brown; undersurface near tawny-olive overall but with reddish tinge on chest; tail dark brown above and faintly lighter beneath, not dirty white as given in Waterhouse's description, and without crest of long whitish hairs (Sanborn and Pearson 1947). Upper incisors strongly procumbent and almost unique within genus with white or pale yellowish white enamel (Waterhouse 1848; Pearson 1959).

DISTRIBUTION: *Ctenomys leucodon* occurs in the Altiplano highlands surrounding Lake Titicaca, extending from La Paz, Bolivia, to southern Puno, Peru (Pearson 1959).

SELECTED LOCALITIES (Map 450): BOLIVIA: La Paz, Chilalaya (Cook et al. 1990), Comauchi (S. Anderson 1997), San Andrés de Machaca (type locality of *Ctenomys leucodon* Waterhouse). PERU: 10 km SW of Huacullani (Pearson 1959), Río Ccallacami, near Huacullani (Sanborn and Pearson 1947).

SUBSPECIES: *Ctenomys leucodon* is monotypic.

Map 450 Selected localities for *Ctenomys leucodon* (●). Contour line = 2,000 m.

NATURAL HISTORY: Few data on ecology are available. A single pregnant female has been recorded in the month of August in Bolivia (S. Anderson 1997). In one local Peruvian population, Pearson (1959) noted that individuals were nonvocal, made large earthen mounds in sloping grassland, and occurred at slightly lower elevation than adjacent populations of *C. opimus*. S. L. Gardner and Duszynski (1990) examined feces of this species but found no eimerian oocysts.

REMARKS: Thomas (1916g) placed *C. leucodon* into the monotypic subgenus *Haptomys*, a position that has mixed support from molecular markers. Cook et al. (1990) compared this species to others they recognized as occurring in Bolivia. Phylogenetic analyses of electromorphic allozymes (Cook and Yates 1994) placed *C. leucodon* in a near basal-polytomy with species of the nominotypical subgenus, whereas mtDNA sequences positioned *C. leucodon* in a near-basal polytomy, excluding *C. sociabilis* (Parada et al. 2011). Cook et al. (1990) described a karyotype with $2n = 36$, $FN = 68$. Sperm morphology is unknown.

Ctenomys lewisi Thomas, 1926

Lewis's Tuco-tuco

SYNONYM:

Ctenomys lewisi Thomas, 1926c: 323; type locality "Sama, 4000 m," 50 km W Tarija, Tarija, Bolivia, 21°3'S 65°10'W.

DESCRIPTION: Relatively large, reddish-brown tuco-tuco with unusually procumbent incisors, similar to those of *C. leucodon* but more robust. Head and body length 204–219 mm, tail length 68–71 mm, and hindfoot length averages 37 mm. General color of upper parts uniform dark cinnamon brown without special markings; muzzle only slightly washed with black; under surfaces brighter cinnamon, often very bright, sometimes throughout but always in inguinal region; throat with slight, darker collar; forefeet and hindfeet dull whitish above; tail thinly haired, blackish above at base but whitish otherwise. Skull large, long, but neither broad nor robust; nasals rather short and broad; interorbital region broad, without projecting supraorbital ledges; lambdoidal crest strongly developed, with well-marked median forwardly directed angle; zygoma with simple angular projection above, not broadened at its tip; concave groove on outer upper side of malar absent; bullae appear somewhat compressed. Upper incisors very large and heavy, flattened and strongly pigmented orange in front, very proodont (incisive angle of holotype 117°), and readily visible in front of premaxilla when viewed from above. About 33% of adult specimens show open frontoparietal fenestrae (S. L. Gardner and Anderson 2001).

DISTRIBUTION: *Ctenomys lewisi* is known from two closely adjacent localities in northwestern Tarija, Bolivia (S. Anderson 1997:492, Fig. 770).

Map 451 Selected localities for *Ctenomys lewisi* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 451): BOLIVIA: Tarija: 1 km E of Iscayachi, Río Tomayapo (S. Anderson 1997), Sama (type locality of *Ctenomys lewisi* Thomas).

SUBSPECIES: *Ctenomys lewisi* is monotypic.

NATURAL HISTORY: *Ctenomys lewisi* inhabits deep soils of the Tomayapo Valley and Sama between 3,450 and 4,000 m. Thomas (1926c) inferred a semiaquatic habit based on captures in holes in wet stream banks, but more recent captures have not confirmed this suggestion (S. Anderson 1997). Pregnant females have been recorded in the month of July. S. L. Gardner and Duszynski (1990) reported eimerian oocysts from feces.

REMARKS: Both electromorphic (Cook and Yates 1994) and mtDNA sequence (E. P. Lessa and Cook 1998; Parada et al. 2011) analyses suggest a close sister relationship between *C. lewisi* and *C. frater*, and then with *C. conoveri* and an apparently undescribed species from Llathu, Cochabamba, Bolivia (Parada et al. 2011). Cook et al. (1990) described a karyotype with $2n = 56$ and FN = 74; Ruedas et al. (1993) reported on genome size and other karyological attributes. Sperm morphology is the simple symmetric type (Vitullo and Cook 1991).

Ctenomys magellanicus Bennett, 1836

Magellanic Tuco-tuco

SYNONYMS:

Ctenomys magellanicus Bennett, 1836:190, type locality "Port Gregory [= Bahía San Gregorio], near eastern end of north side of Straits of Magellan, Chile," Aysén, 52°25'S, 69°45'W, 0 m (see J. A. Allen 1905:35; Rusconi 1928:238; Osgood 1943b).

Ctenomys fueginus Philippi, 1880:276, type locality "östlichen Insel," eastern island or Isla Grande, Tierra del Fuego, Magallanes y Antártica Chilena, Chile (Osgood 1943b).

Ctenomys neglectus Nehring, 1900b:535; type locality "Patagonien."

Ctenomys robustus J. A. Allen, 1903b:185; type locality "Río Chico de Santa Cruz, near the Cordilleras," Santa Cruz, Argentina; restricted by Pardiñas (2013) as "río Tucu Tucu, ca. 8 km aguas abajo desde su nacimiento (48.47°S, 71.87°W, departamento Río Chico, Santa Cruz, Argentina)." Preoccupied by *Ctenomys robustus* Philippi (1896), although not the same species (see account for *C. fulvus*).

Ctenomys osgoodi J. A. Allen, 1905:191; substitute name for *C. robustus* J. A. Allen.

Ctenomys magellanicus fueginus: Osgood, 1943b:119; name combination.

Ctenomys magellanicus osgoodi: Osgood, 1943b:120; name combination.

Ctenomys magellanicus dicki Osgood, 1943b:123; type locality "Estancia Ponsonby, east end of Riesco Island, Ma-

gallanes, Chile," Isla de Riesco, Provincia de Magallanes, Magallanes y Antártica Chilena region, ca. 52°50'S 71°45'W.

Ctenomys magellanicus obscurus Texera, 1975: 163; type locality "Estancia Lago Escondido, 20 km S de la Sección Río Grande, cerca de Lago Blanco, Tierra Del Fuego, Magallanes y Antártica Chilena, Chile, ca. 500 m," 53°53'S 68°52'W.

DESCRIPTION: Relatively large species with total length from 267 mm in *C. m. magellanicus* to 304 mm in *C. m. fueginus*. Generally pale-colored, with pale grizzled grayish buff upper parts and clear cinnamon buff under parts in *C. m. magellanicus* and *C. m. fueginus*; prevailing color of populations allocated to *C. m. osgoodi*; much darker, brownish ochraceous rather than grayish buff; color of *C. m. dicki* wholly mixed blackish and buffy smoke gray both above and below; that of *C. m. obscurus* homogeneously darker than other subspecies (Texera 1975). Skull notably angular with many sharp ridges and pointed processes, particularly so in specimens of nominotypical race. Skull of *C. m. fueginus* similar to that of *C. m. magellanicus* but with slightly more swollen and bulbous auditory bullae, broader interorbital region, and broader rostral or antemolar part. Skull of *C. m. osgoodi* also similar but with narrower and more laterally compressed auditory bullae. Skull of *C. m. dicki* essentially as that of *C. m. fueginus*, except that auditory bullae slightly smaller and shorter and interorbital region wide, as in *C. m. magellanicus*.

DISTRIBUTION: *Ctenomys magellanicus* is distributed in extreme southern Chile and southern Argentina, including Tierra del Fuego.

SELECTED LOCALITIES (Map 452): ARGENTINA: Santa Cruz, Cordilleras, west of upper Río Chico (type locality of *Ctenomys osgoodi* J. A. Allen), 30 mi S of Santa Cruz (Osgood 1943b); Tierra del Fuego, Estancia San Martín, Bahía San Sebastián (MVZ 164145), Estancia Vi-amonte (Osgood 1943b), Lago Fagnano (Osgood 1943b), near east end of Lake Fagnano (Osgood 1943b). CHILE: Aysén, Río Ñirehuao (Osgood 1943b); Magallanes y Antártica Chilena, Bahía Felipe (USNM 398541), Estancia Lago Escondido (*Ctenomys magellanicus obscurus* Texera), Estancia Ponsonby, east end of Riesco Island (type locality of *Ctenomys magellanicus dicki* Osgood), La Cumbre, Bagaules (Feito and Gallardo 1982), Port Gregory (type locality of *Ctenomys magellanicus* Bennett), Punta Arenas (AMNH 17444).

SUBSPECIES: Both Osgood (1943b) and Cabrera (1961) considered *C. magellanicus* to be a polytypic species with four subspecies (*dicki* Osgood, *magellanicus* Bennett, *fueginus* Philippi, and *osgoodi* Allen). Texera (1975) later described a fifth subspecies (*obscurus*).

NATURAL HISTORY: An inhabitant of the Patagonian steppe, *C. magellanicus* lives usually in open meadows with dense grass cover. Burrow systems are constructed 30cm or more below the surface. Individuals feed on the roots of grasses and shrubs (Mann 1978). Native Americans from Tierra del Fuego called these tuco-tucos *cururu*, a name also applied to other medium-sized rodents in the area, and at least the indigenous Selk'nam included them in their diet (Pepa 2001; Pardo 2007).

REMARKS: Thomas (1898h) recorded a specimen of this species from Tombo Point (Punta Tombo), Chubut, Argentina, without justification. This tuco-tuco is very likely not *C. magellanicus*, given the large expanse of Patagonian steppe separating this locality from the main distribution of the species. Osgood (1943b:122) referred a topotype of *C. fodax* in the Field Museum collection to *C. m. osgoodi*; *C. fodax* is herein considered a species distinct from *C. magellanicus* (see that account).

The type locality of J. A. Allen's *C. robustus* (subsequently renamed *C. osgoodi*) was given in the original description as "Rio Chico de Santa Cruz, near the Cordilleras (J. A. Allen 1903b:185). Subsequently, Allen (1905:40) gave additional information to narrow the exact locality, stating first "in the alluvial river valley of the upper Rio Chico, at the eastern base of the Andes" and then a few sentences later "most specimens of this species appear to have been taken in Mayer Basin, at the edge of the Cordilleras." Earlier in the same report, Allen (1905:2) had written about the route taken by the field party who "then followed a continuous journey of some 259 miles up the Rio Chico de Santa Cruz, to the mouth of the Rio Belgrano" with mammal specimens taken "north from the Rio Belgrado to the vicinity of Lake Buenos Aires." Allen (1905:footnote 2) further wrote "most specimens are labeled 'Arroyo Eche' (= Aike)." Lago Buenos Aires (= Lago General Carrera) is about 180km north of the mouth of the Río Belgrano where it joins the Río Chico (at about 48.24°S, 71.24°W). The type locality of *osgoodi* J. A. Allen is thus likely at a point between these two places. I have been unable to locate either "Mayer Basin" or "Arroyo Eche," although present-day RN 40 crosses the Río Ecker about 60km south of Perito Moreno, which is just east of Lago Buenos Aires.

Ctenomys magellanicus is chromosomally polytypic. Reig and Kiblicky (1969) recorded diploid numbers of 36 and 38 for *C. m. fueginus*, and M. H. Gallardo (1979) described a diploid number of 34 for *C. m. magellanicus*. Lizarralde et al. (2003) examined telomeric sequence localization in the $2n = 34$ and $2n = 36$ cytotypes. Sperm morphology is the simple asymmetric type (Feito and Gallardo 1982). Fasanella et al. (2013) reported on historical demography and spatial structure in mtDNA sequences

Map 452 Selected localities for *Ctenomys magellanicus* (●).

and nuclear microsatellite loci for population samples on Tierra del Fuego that encompassed the two cytotypes.

Ctenomys "mariafarelli" Azurduy, 2005

Maria Farrell's Tuco-tuco

SYNONYM:

Ctenomys mariafarelli Azurduy, 2005b:70; type locality "5.5 Km al noreste de la localidad de Vallegrande (18°28'S, 64°08'O; 1800 m), provincia Florida, del Departamento de Santa Cruz, Bolivia"; *nomen nudum* (see Remarks).

DESCRIPTION: Relatively large tuco-tuco, with total length of males (N = 2) 291–295 mm, tail length 74–85 mm, hindfoot length 39–41 mm, and mass 307–364 g; females (N = 3) smaller, total length 254–273 mm; tail length 73–81 mm; hindfoot length 33–38 mm, and mass 173–227 g. Dorsal color brownish with poorly defined median blackish stripe, lacking half-collar typical of *C. boliviensis*, purportedly its closest relative; flanks paler brown or ochraceous; venter yellowish with white inguinal and axillary spots. Skull elongated and narrow with respect to expansion of zygomatic arches; nasal bones wide posteriorly and taper anteriorly; frontal region narrow; zygomatic arches slightly square; tympanic bullae moderately large and inflated. Upper incisors conspicuously proodont, large, and faced with orange enamel.

DISTRIBUTION: *Ctenomys "mariafarelli"* is known only from the type locality in Santa Cruz department, Bolivia.

Map 453 Single known locality for *Ctenomys* "mariafarelli" (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 453): **BOLIVIA:** Santa Cruz: Vallegrande (type locality of *Ctenomys mariafarelli* Azurduy).

SUBSPECIES: *Ctenomys* "mariafarelli" is monotypic.

NATURAL HISTORY: No data are available on ecology, behavior, reproduction, or food preferences.

REMARKS: According to Azurduy (2005b), the species is closely allied to *C. boliviensis*. Neither the karyotype nor sperm morphology is known. The name *Ctenomys mariafarelli* was published in the electronic journal *Kempffiana*, and thus at the time of publication did not meet the requirements of Article 8.6 of the International Code for Zoological Nomenclature (ICZN 1999). The recently amended Code (International Commission on Zoological Nomenclature 2012) accepts electronic publication of new names, but only if (a) the date of issue is subsequent to 2011, (b) the publication date is included in the work itself, and (c) the publication is registered in the *Official Register of Zoological Nomenclature* (ZooBank). Since none of these requirements apply to Azurduy's name, *mariafarelli* Azurduy is a *nomen nudum*.

Ctenomys maulinus Philippi, 1872

Maule Tuco-tuco

SYNONYMS:

Ctenomys maulinus Philippi, 1872: 442; type locality "D. Toribio Medina, hat diese Art im Januar und Februar d.J. in der hohen Cordillere der Prov. Maule gefunden und zwar in der Höhe des Sees laguna de Maule, aus

welchem der bie Talca vorbeifliessende und bei Consti-tucion Mündende Fluss gleichen Namens entspringt," given as Laguna de Maule, Talca province, Chile, ca. 36°00'S, 70°30'W" by Osgood (1943b:125).

Ctenomys mendocinus maulinus: Thomas, 1927d:657; name combination.

Ctenomys maulinus maulinus: Osgood, 1943b:24; name combination.

Ctenomys maulinus brunneus Osgood, 1943b:125; type locality "Rio Colorado, Province of Malleco, Chile. Alt. 3,000 ft," 38°27'S, 71°22'W, 900 m.

DESCRIPTION: Medium sized, total length varying from 275 mm in nominotypical subspecies to 305 mm in *C. m. brunneus*. Dorsal color of *C. m. maulinus* uniformly light brown and tail typically with short, white pencil at tip. Color of *C. m. brunneus* richer and darker brown (Mann 1978); feet dull buffy white; tail brown above, pale buffy below with buffy white pencil at the tip. Skull with persistent frontoparietal fontanelle; wide flat interorbital space; imperceptible postorbital processes; auditory bullae relatively short and swollen in nominotypical subspecies but narrower and more elongate in *C. m. brunneus*.

DISTRIBUTION: The nominotypical subspecies *C. m. maulinus* occurs only in Talca province, Chile, whereas *C. m. brunneus* is distributed in the provinces of Cautín and Malleco between 1,000 and 2,000 m (Osgood 1943b; Greer 1965). Yepes (1935a) and Pearson (1984, 1995) extended the range of this species into Neuquén and Río Negro provinces of Argentina, but without comments on subspecies allocation.

SELECTED LOCALITIES (Map 454): **ARGENTINA:** Neuquén, Aeropuerto Caviahue (MVZ 183299), 2 km E and 1 km N of Caviahue (MVZ 183298), Chapelco (MVZ 183304), 1 km E of Copahue, Las Maquinitas (MVZ 183310), Lago Epulafquen (MVZ 185055), Lago Lolog, NE coast, 5 km W of Rio Quilquihue (MVZ 183312), near Estancia Los Helechos, 2.5 km W and 5 km S of Cerro Colorado (MVZ 163462); Río Negro, ridge above Refugio Neumeyer (MVZ 163823). **CHILE:** Araucanía, Río Colorado (type locality of *C. maulinus brunneus* Osgood), Lonquimay, Río Colorado (MVZ 154132); Maule, Arroyo del Valle, Río Maule (FMNH 50731), Río Maule, 14 km above Curillanque (FMNH 50733), Laguna del Maule (type locality of *Ctenomys maulinus* Philippi).

SUBSPECIES: Both Osgood (1943b) and Cabrera (1961) recognized two subspecies, the paler nominotypical form in Talca province, Chile, and the darker *C. m. brunneus* from Malleco and Cautín provinces, Chile. Specimens from Neuquén and Río Negro provinces in Argentina are, as yet, unassigned to subspecies (see Pearson and Christie 1985).

Map 454 Selected localities for *Ctenomys maulinus* (●). Contour line = 2,000 m.

NATURAL HISTORY: *Ctenomys maulinus* inhabits widely divergent habitats such as *Nothofagus* (Nothofagaceae) – *Araucaria* (Araucariaceae) woodlands and open volcanic sands from 900 to 2,000 m elevation (Redford and Eisenberg 1992). M. H. Gallardo and Anrique (1991) describe population parameters and burrow systems, and M. H. Gallardo and Kohler (1994) document demographic changes and loss of genetic variation in a local population following a volcanic eruption.

REMARKS: Skins and skulls of Argentinean specimens are indistinguishable from *C. m. maulinus* from Chile (Pearson 1995). Numerous large tuco-tucos, probably *C. maulinus*, have been recovered from owl pellets more than 5,000 years old at Cueva Trafal, near Confluencia, Neuquén province, Argentina (Pearson 1984). Both subspecies of *C. maulinus* share the same $2n = 26$, $FN = 48$, karyotype (M. H. Gallardo 1979) and an asymmetrical simple sperm morphology (Feito and Gallardo 1976, 1982).

Ctenomys mendocinus Philippi, 1869

Mendoza Tuco-tuco

SYNONYMS:

Ctenomys mendocina Philippi, 1869:38; type locality “Mendoza,” = Mendoza Province, Argentina, Departamento Capital, 32°53’S, 68°49’W, 980 m.

Ctenomys mendocinus: Philippi, 1896:17; correction of gender agreement.

Ctenomys eremophilus J. R. Contreras and Roig, 1975:19; unavailable (ICZN 1999:Art. 13; see Parada et al. 2012).

Ctenomys eremicus J. R. Contreras, 1979a:45; *nomen nudum*.
Ctenomys eremophilus J. R. Contreras, 1981:22; *nomen nudum*.

DESCRIPTION: Medium sized (mean total body length 247.3 mm in females and 262.12 mm in males; tail length 77.4 mm females and 82.2 mm males; Rosi et al. 2002, 2005; A. I. Medina et al. 2007). Dorsal pelage light brown to grayish red with transverse waves of blackish hair that disappear in paler ventral region; tail whitish with median dorsal stripe of longer hairs; feet covered with sparse white hair. Cranial features include broad rostrum, prominently ridged parietals without sagittal crest, well-developed lambdoid crest, jugals with prominent dorsally projected processes, enlarged infraorbital foramina with no canal for nerve transmission, and large bullae with flat and closely appressed paroccipital processes. Mandible with moderately developed coronoid process and wide angular process that flares outward. Upper and lower third molars vestigial. Upper incisors nearly orthodont, with roots extending to anterior edge of cheek teeth; enamel colored dark orange.

DISTRIBUTION: *Ctenomys mendocinus* is distributed along the eastern base of the Andes of west-central Argentinean provinces of Mendoza, San Luis, San Juan, and La Pampa provinces (Braggio et al. 1999; Rosi et al. 2002). Most populations occupy the *Monte de Llanuras y Mesetas* ecoregion between 174 and 3,400 m (Rosi et al. 2002; Bidau 2006).

SELECTED LOCALITIES (Map 455): ARGENTINA: La Plata, Estancia la Pastoril (Braggio et al. 1999), Lihuel-Calel (Wilkins and Cunningham 1993), Naicó (Braggio et al. 1999), Río Salado (Braggio et al. 1999), Santa Rosa (Braggio et al. 1999); Mendoza, Desaguadero (Wilkins and Cunningham 1993), 3 km S of Laguna Diamante (Sage et al. 1986), La Paz (Wilkins and Cunningham 1993), Las Higueras (Rosi, Cona et al. 1996), Las lajas (Rosi, Cona et al. 1996), Lavalle (Wilkins and Cunningham 1993), Mendoza (type locality of *Ctenomys mendocinus* Philippi), Papagallos (Roig and Reig 1969), Tambillos (Rosi et al. 2002), Tupungato (Slamovitz et al. 2001), 25 de Mayo (Pearson and Lagiglia 1992); San Luí, Villa Mercedes (Rosi et al. 1992).

SUBSPECIES: *Ctenomys mendocinus* today is considered monotypic.

NATURAL HISTORY: *Ctenomys mendocinus* is one of the best-studied tuco-tuco species and one with the largest known geographic distribution (see Rosi et al. 2005). Albanese et al. (2010) described resource use and distribution and Camin (2010) reviewed gestation, maternal behavior, and growth and development. This species constructs burrows of the linear type with those of males significantly longer (mean 51 m) than those of females (22 m; Camin

et al. 1995; Rosi, Cona et al. 1996). As is true for most tuco-tucos, *C. mendocinus* has solitary habits even in the reproductive season and is strongly territorial (Puig et al. 1992; Rosi et al. 2000). Reproduction occurs from July to March; gonadal activity of females begins in the winter, but male testes seem to be active throughout the year (Dacar et al. 1998). Gestation lasts three months, and the annual mean litter size is 2.8 (range: 1–4; Rosi, Puig et al. 1996). Camin (1999) described mating behavior. Dietary habitats of *C. mendocinus* are also well known, with specialization primarily on the above ground parts of grasses and shrubs (Camin and Madoery 1994; Madoery et al. 1997; Puig et al. 1999; Tort et al. 2004).

REMARKS: Cabrera (1961:551) included *C. bergi*, *C. fochi*, *C. haigi*, *C. juris*, *C. occultus*, *C. recessus* (= *C. talarum recessus*), and *C. tucumanus* as subspecies of *C. mendocinus*. He also included *C. azarae* and *C. latro* in the synonymy of *C. m. mendocinus* and *C. m. tucumanus*, respectively. Herein, each of these taxa is considered good species (Bidau 2006). M. M. Díaz et al. (2000) cited *C. mendocinus* for Salta province, Argentina, but those specimens are more appropriately assigned to *C. fochi*. *Ctenomys mendocinus* has its closest affinities (based on morphological, chromosomal, and molecular data) with other species in central Argentina that collectively comprise a “mendocinus” group, namely *C. azarae*, *C. porteousi*, and *C. australis* (J. R. Contreras and Bidau 1999; Mascheretti et al. 2000), which has been expanded more recently to include *C. flamarioni* and *C. rionegrensis* (Parada et al. 2011) based on mtDNA sequences.

J. R. Contreras and Roig (1975) coined the name *Ctenomys eremophilus* for a new species they proposed from the Ñacuñán Biosphere Reserve in Mendoza province, Argentina, in the abstracts of a scientific meeting. J. R. Contreras (1979a, 1981) subsequently referred to the same sample as *C. eremicus* or *C. eremophilus*, respectively. Parada et al. (2012), however, documented that *eremophilus* J. R. Contreras and Roig was unavailable, as it did not meet the requirements for publication (ICZN 1999:Art. 13). And, Galliari et al. (1996) concluded that both *eremicus* J. R. Contreras and *eremophilus* J. R. Contreras were *nomina nuda* as neither name was accompanied by a description, illustration, or reference to such (ICZN 1999:Art.12). Unfortunately, *eremophilus* has been used in the subsequent literature as though it were a valid species (Giannoni et al. 1996; Borruel et al. 1998; Rosi et al. 2009). Bidau (2006) regarded *eremophilus* as a synonym of *C. pontifex* Thomas, without comment (see Parada et al. 2012).

The karyotype of *C. mendocinus* is polymorphic, with diploid numbers of 48 or 50 and number of autosomal arms varying between 68 and 80, mostly due to variation in short-arm heterochromatin (Massarini, Barros, Ortells,

Map 455 Selected localities for *Ctenomys mendocinus* (●). Contour line = 2,000m.

and Reig 1991; Massarini, Barros, Roig, and Reig 1991; Braggio et al. 1999; Parada et al. 2012). Individuals with both $2n = 48$ and 50 were present in the Ñacuñán Biosphere Reserve, with these samples sharing high similarity to other samples of *C. mendocinus* in mtDNA cytochrome-*b* sequences (Parada et al. 2012). It has a simple asymmetrical type of sperm (Vitullo et al. 1988).

Ctenomys minutus Nehring, 1887

Minute Tuco-tuco

SYNONYMS:

Ctenomys minutus Nehring, 1887:47; type locality “stammen aus den ‘Campos’, welche sich östlich von Mundo Novo (also ziemlich weit nördlich in der Provinz Rio Grando do Sul),” Brazil (= Taquara do Mundo Novo, Reig, et al. 1965; or = Taquara, Belton 1985), ca. 10m, 29°39’S 50°47’W; restricted by Langguth and Abella (1970:18), following Nehring (1900c:206), to the oceanic coast at a resort near the mouth of the Rio Tramandahy, 98 km E of Porto Alegre, Rio Grande do Sul, Brazil.

Ctenomys minimus S. Anderson, 1985:14; incorrect subsequent spelling of *Ctenomys minutus* Nehring.

DESCRIPTION: Described from three skulls sent to Alfred Nehring by Th. Bischoff. Nehring’s original description included only a few dimensions of each skull (approximate total lengths 41.5, 39, and 35.5 mm, respectively; basilar lengths 34, 32.3, and 28.5 mm; widths of

upper incisors, 4.6, 4.0, and 3.8 mm; and lengths of upper toothrow, 31.5, 27.0 [?], and 27.6 mm). Nehring noted that all three skulls were of adult animals, because all teeth had erupted and were worn, although smallest of three was younger than largest. Other features apparent from illustrations provided in Nehring (1887, 1900c) include slightly proodont upper incisors, enlarged but anterior-posteriorly constricted auditory bullae, proportionally broad interorbital region, braincase with weakly developed parasagittal ridged, approximately equal distances across zygomatic arches and auditory tubes, and vertically directed postorbital spine of the jugal. Overall dimensions, contrary to implication of species epithet, place *C. minutus* among medium-sized species of tuco-tucos, with total length averaging 250 mm (Reig et al. 1966). Overall color medium to dark brown dorsally and light brown ventrally; young individuals usually paler than adults (Rebelato 2006). Baculum paddle shaped, mean length 9.34 mm, with V-shaped proximal tip. Glans penis with dense (12/mm²), single-tipped epidermal spines averaging $245.14 \pm 49.81 \mu\text{m}$ s.d. in length (Rocha-Barbosa et al. 2013).

DISTRIBUTION: *Ctenomys minutus* is known from the southern Brazilian states of Santa Catarina and Rio Grande do Sul.

SELECTED LOCALITIES (Map 456; from T. R. O. Freitas 1997, except as noted): BRAZIL: Rio Grande do Sul, Capão Novo, Cidreira, Mostardas, Osório, Palmares do Sul, Palmital, Passinhos, Taquara (type locality of *Ctenomys minutus* Nehring), Tavares, Tôrres; Santa Catarina, Jaguaruna, Morro dos Conventos.

SUBSPECIES: Cabrera (1961:553) recognized two subspecies, *C. m. minutus* and *C. m. bicolor*, the latter corresponding to *C. bicolor* (Miranda-Ribeiro 1914), herein regarded as a separate species. Consequently, *C. minutus* is monotypic.

NATURAL HISTORY: This species usually occupies the highest parts of sandy and dry fields and pastures not far from water bodies along the coastal plain of southern Brazil. This is a solitary and territorial species, with low vagility and sedentary behavior and sexual size dimorphism in favor of males (Marinho and Freitas 2006). Population densities may vary from 7 to 42 individuals per hectare (Gastal 1994; M. B. Fonseca 2003). Sex ratio is 1:1 in juveniles and subadults but biased toward females in adults, with 1.3 times more females in general and 1.26:1 females in the adult cohort (M. B. Fonseca 2003; Marinho and Freitas 2006). Gestation time is about 90 days, and sexual maturity is reached within 6–7 months (M. B. Fonseca 2003).

REMARKS: Thomas (1898d:285) believed that the original series of three skulls upon which Nehring (1887)

based his *C. minutus* were immatures, “so much so, indeed, that I doubt if the full-grown animal is any smaller than the Uruguayan *Ct. torquatus*, Licht.” Nehring (1900a,c), however, rebutted Thomas’s assertion in great detail and provided line-drawings as well as a photograph of the largest of three skulls he used in his original description to emphasize its “adult” features, including well-developed ridging, broad zygomatic arches, and almost complete fusion of the sphenobasilar suture.

S. Anderson (1997:497; see also S. Anderson et al. 1987) tentatively assigned Bolivian specimens from Santa Cruz department to *C. minutus* “on the basis of size and geographic occurrence.” This assignment, however, is probably in error. Anderson’s “geographic occurrence” rationale was based on Cabrera’s (1961) unjustified consideration of *C. bicolor* from Mato Grosso (or Rôndônia; see account of that species), Brazil, as a valid subspecies of *C. minutus*. Moreover, the holotype, and only known specimen of *C. bicolor* is large, not small in size, making the linkage of this taxon to either the Bolivian specimens or to true *C. minutus* from southeastern Brazil untenable, and thereby negating a geographic connection between the small Bolivian specimens and *C. minutus*. Indeed, E. P. Lessa and Cook (1998) referred to these Bolivian specimens as “*Ctenomys* sp. ‘minut,’” thus suggesting that

Map 456 Selected localities for *Ctenomys minutus* (●).

they had been incorrectly assigned to *C. minutus*. Whether or not these Bolivian specimens belong to another of those species that have been described or represent an as yet unnamed taxon must await further revisionary work on the genus.

Populations of *C. minutus* from Brazil are very polymorphic for Robertsonian and tandem fusions, resulting in a variation of diploid number from 42 to 50 (T. R. O. Freitas 1997, 2005; Freygang et al. 2004). Marinho and Freitas (2000) and Gava and Freitas (2002, 2004) characterized contact zones between different cytotypes. The sperm has the symmetric morphology (T. R. O. Freitas 1995).

Ctenomys nattereri Wagner, 1848

Natterer's Tuco-tuco

SYNONYMS:

Ctenomys Nattereri Wagner, 1848:72; type locality "Caissora (Provinz Matogrosso)" (= Caiçara, Nehring 1900b: 537 and Cabrera 1961:553, or = Cáceres, S. Anderson et al. 1987:1), Mato Grosso, Brazil, ca. 200 m, 16°00'S 57°45'W.

Ctenomys boliviensis nattereri: S. Anderson et al., 1987:11; name combination.

DESCRIPTION: Moderately large, head and body length about 245 mm, tail length 71 mm, ear length 11 mm, and hindfoot length (including claw) 54 mm. Head and particularly muzzle very broad and flat, rhinarium nearly naked, eyes small, and incisors very broad and ungrooved; ear opening very small, within small pinna. Claws on forefeet especially long (medial claw about 16 mm), and typical tuco-tuco comb-like hairs extend from sides of hindfeet. Overall dorsal color uniform brownish and shiny, flecked with black that vaguely defines a dorsal stripe passing from middle of head along back, gradually disappearing toward rump. Under surface all black but with light shading, interrupted by white spotting, particularly in axillary and inguinal areas. Upper incisors faced with "vivid saffron-red" enamel. A third known specimen, from José Bonifácio, Rondônia state, Brazil, smaller, with head and body 218 mm and tail 72 mm (J. A. Allen 1916d).

DISTRIBUTION: *Ctenomys nattereri* is known only from three localities, one each in Santa Cruz department, Bolivia, and both Mato Grosso and Rôndônia states in west-central Brazil.

SELECTED LOCALITIES (Map 457): BOLIVIA: Santa Cruz, Santa Cruz de la Sierra (Parada et al. 2011). BRAZIL: Rondônia, José Bonifácio (J. A. Allen 1916d); Mato Grosso, Cáceres (probable type locality of *Ctenomys nattereri* Wagner).

SUBSPECIES: *Ctenomys nattereri* is monotypic.

NATURAL HISTORY: No data are available ecological characteristics of *C. nattereri* except for the account of the specimen that Leo E. Miller collected on February 24, 1914, during the Roosevelt-Rondon Expedition (J. A. Allen 1916d; L. E. Miller 1918). According to L. E. Miller (1918:239), the single excavated burrow "measured fifteen feet [4.60 m] long, eight feet [2.45 m] deep and three feet [0.92 m] wide, and it required half a day for the Indians to complete the work." This is a fairly deep system for tuco-tucos. The burrow, however, was simple because "at the end [of the 15 feet long tunnel] was a small cavity, but no nest. Small bunches of grass were found in the gallery which had been pulled down by the roots." The local Nhambiquara, who helped Miller collect the specimen, were very fond of the animal's flesh "and often dig them out to eat" (L. E. Miller 1918:238). Although "the animal seemed bewildered above ground and could not run fast" (L. E. Miller 1918:239), Theodore Roosevelt, who was watching the whole procedure, wrote that "the animal dug hard to escape, but when taken and put on the surface of the ground it moved slowly and awkwardly," but "it showed vicious courage" (Roosevelt 1914:246). In his field notes, L. E. Miller (in J. A. Allen, 1916d:595) calls this tuco-tuco "cururu," probably mistaking this with "curu-curu," a common name given to tuco-tucos in parts of Brazil (A. B. de H. Ferreira 1986:513). Interestingly, *cururu* or *cururú* was the name given by indigenous Fueguians to *C. magellanicus* (see that account).

REMARKS: The true geographic distribution of *C. nattereri* is almost completely unknown. Nehring (1900b) described and figured the skull upon which Wagner based his name *C. nattereri*, giving the locality as "Caiçara in Matto Grosso." Cabrera (1961:553) also restated Wagner's (1848) type locality of "Caissora" as "Caicara (= Caiçara)." S. Anderson et al. (1987:11), however, equated "Caissora" with "Cáceres" in the Brazilian state of Mato Grosso (16°00'S 57°45'W). No locality named "Caissora" occurs in Brazil, and of the six Caiçara localities found in maps and gazetteers, none relates geographically to the probable type locality of *C. nattereri*. Thus, "Cáceres" is the most probable geographic location of the type of *C. nattereri*.

J. A. Allen (1916d:569) reported finding one specimen of *C. nattereri* at 12°19'S 60°30'W near the community of José Bonifácio (misspelled as José Bonefascio [pp. 560, 595] and José Bonesfascio [p. 569]) in the Brazilian state of Rondônia, although he gave no reason for this assignment. This locality is, however, quite distant from Cáceres, and separated from it by the high Chapada dos Parecís, suggesting an atypically (for a tuco-tuco) large distribution. Moreover, L. E. Miller (in J. A. Allen 1916d:595)

detected the sporadic presence of *Ctenomys* mounds from “Tapiropan” (= Tapirapoñ or Tapirapuã) at 14°51’S and 57°45’W, up to José Bonifácio. S. Anderson et al. (1987) compared the skull of this specimen with those of *C. boliviensis* and found a number of small but insignificant differences. These authors thus concluded that *nattereri* Wagner was a subspecies of *C. boliviensis* Waterhouse, which they (as first reviewers) selected as having date priority. Their action thus expanded the range of this tuco-tuco species even more. A further complication is the description of *C. rondoni* by Miranda-Ribeiro (1914), also from Mato Grosso but with the imprecise locality of Maria de Molina and Rio Juruena (see the account of *C. rondoni*). Again without justification, Cabrera (1961:553) synonymized *C. rondoni* with *C. nattereri*, a decision followed most recently by Woods and Kilpatrick (2005:1561). Herein, these two are treated as separate species. Clearly, detailed surveys for tuco-tucos in the Brazilian states of Mato Grosso and Rôndônia and the adjacent Bolivian province of Santa Cruz are required to determine the current biological boundaries of these various “species” and map their distributions correctly.

Both karyotype and sperm morphology is unknown. MtDNA cytochrome-*b* sequence analysis (Parada et al. 2011) places *C. nattereri* as a member of the “*boliviensis*” group, along with *C. boliviensis* and *C. goodfellowi*, a well-supported monophyletic clade identified as the

“Boliviano-Matogrossense” group by J. R. Contreras and Bidau (1999).

Ctenomys occultus Thomas, 1920

Furtive Tuco-tuco, Oculito

SYNONYMS:

Ctenomys occultus Thomas, 1920e:243; type locality “Monteagudo, about 80 km. S.E. of Tucumán City,” San Miguel de Tucumán, Departamento Simoca, Tucumán, Argentina, 27°31’S, 65°17’W, 296 m.

Ctenomys mendocinus occultus: Cabrera, 1961:552; name combination.

DESCRIPTION: Small species, head and body length 1380–151 mm (A. I. Medina et al. 2007). Overall color warm brown, with upper surfaces glossy cinnamon brown with some vague darkening on crown, but without blackish forehead; under surfaces washed with pale drabby, chin and throat more sharply drab. Specimens range from whitish to drab below. Skull similar to that of *C. juris* with small bullae, proodont incisors, and presence of small sharp-edged ledges projecting over orbital fossae, which are short and more abruptly cut; zygomata widely spaced with middle region markedly convex outward; often small medial additional foramen present anterior to incisive foramina; mesopterygoid fossa extends forward to middle of M2. Anterior face of the proodont incisors angled at 102° to 104° of horizontal plane.

DISTRIBUTION: *Ctenomys occultus* is known from only a few localities in Tucumán province in the *Chaco Seco* ecoregion.

SELECTED LOCALITIES (Map 458): ARGENTINA: Tucumán, Alberdi (J. R. Contreras, pers. comm.), La Cocha (J. R. Contreras, pers. comm.), Lamadrid (Thomas 1920e), Monteagudo (type locality of *Ctenomys occultus* Thomas), Simoca (Parada et al. 2011).

SUBSPECIES: *Ctenomys occultus* is monotypic.

NATURAL HISTORY: No data on ecology are available; Redford and Eisenberg (1992) stated that individuals live in areas of xeric vegetation, but without documentation.

REMARKS: Thomas (1920e:244) regarded *C. occultus* to be closely allied to *C. juris* from Jujuy province, differing from it “by so many little characters that it seems to deserve a special name, and also to *C. latro* from Tucumán province, despite their differences in size.” Reig and Kiblicky (1968a) used the unique karyotype of $2n = 20$, FN = 40, of *C. occultus* to validate it as a species distinct from *C. mendocinus*. This species belongs to the “*tucumanus* group,” along with *C. argentinus*, *C. latro*, and *C. tucumanus*, based on mtDNA sequence analyses (Parada et al. 2011). The sperm is the simple asymmetric type (Bidau 2006).

Map 457 Selected localities for *Ctenomys nattereri* (●). Contour line = 2,000 m.

Map 458 Selected localities for *Ctenomys occultus* (●). Contour line = 2,000m.

Ctenomys opimus Wagner, 1848

Andean Tuco-tuco

SYNONYMS:

Ctenomys opimus Wagner, 1848:75; type locality: "Bolivia," restricted by Thomas (1900g:383) to "Sahama," Mount Sahama, Oruro, Bolivia, ca. 17°49'S, 67°28'W, 3,000–4,000m.

Ctenomys opimus nigriceps Thomas, 1900g:383; type locality "Tetiri, about 40 miles [64 km] W. of Puno, on the Puno-Moquegua road. Altitude 16,000 feet [4,880 m]," Pampa de Titiré, Puno, Peru.

Ctenomys opimus luteolus Thomas, 1900g:384; type locality "Cordilleras of Jujuy, [Jujuy,] Argentina Republic."

Ctenomys opimus opimus: Yepes, 1930:325; name combination.

Ctenomys luteolus: Yepes, 1935a:252; name combination.

Ctenomys optimus S. L. Gardner and Anderson, 2001:12; incorrect subsequent spelling of *Ctenomys opimus* Wagner.

DESCRIPTION: Large, total length of Bolivian and Peruvian specimens 270–340mm and those from Argentina (Salta and Jujuy provinces) 275–300mm (Pearson 1959; Cook et al. 1990; S. Anderson 1997; M. M. Díaz and Barquez 2002; A. I. Medina et al. 2007). Pelage long, lax, and soft in texture, with dorsal color uniformly pale yellowish, tending to become darker as tips of hairs wear, sometimes in patches, as on top of head. Majority of adult specimens show open frontoparietal fenestrae (S. L. Gardner and Anderson 2001).

DISTRIBUTION: *Ctenomys opimus* occurs widely across the Altiplano from southern Peru to northwestern Argentina, northern Chile, and southwestern Bolivia, all at elevations above 3,200m.

SELECTED LOCALITIES (Map 459): ARGENTINA: Catamarca, Antofagasta de la Sierra (R. A. Ojeda 1985); Jujuy, Tres Cruces (A. I. Medina et al. 2007); Salta, Chorrillos (Yepes 1930), La Poma (Mares, Ojeda, and Barquez 1989), Los Cardones (Ipucha et al. 2008), Salar Pastos Grandes (M. M. Díaz et al. 2000), Tolar Grande (M. M. Díaz et al. 2000), Vega Cortadera (M. M. Díaz et al. 2000). BOLIVIA: La Paz, Esperanza, near Mount Sahama (Cook et al. 1990), Huaraco-Antipampa (Cook et al. 1990); Oruro, Challapata (Thomas 1902c), Cruce Ventilla (Cook et al. 1990), Huancaroma (Cook et al. 1990), Mount Sajama (type locality of *Ctenomys opimus* Wagner), Oruro (Cook et al. 1990); Potosí, Livichuco (Thomas 1902c), Potosí (Thomas 1902c), Uyuni (Cook et al. 1990). CHILE: Arica y Parinacota, Choquelimpie (Sanborn and Pearson 1947), Lagho Chungara (Feito and Gallardo 1982). PERU: Puno, Caccachara (Sanborn and Pearson 1947; Pearson 1951), Lago Loriscota (MVZ 139609), Pampa de Ancomarca (MVZ 115976), Pampa de Tetirí (type locality of *Ctenomys opimus nigriceps* Thomas), 25 km SW of Pisacoma (MVZ 115981), Río Santa Rosa, 8 mi W of Mazocruz (MVZ 115982); Tacna, Lago Suche (Pearson 1959).

SUBSPECIES: Three subspecies are recognized in the current literature (e.g., Cabrera 1961; Woods and Kilpatrick 2005): *nigriceps* Thomas, from Moquegua, Tacna, and Puno departments in southern Peru; *opimus* Wagner, from northern Chile and throughout the highlands of Bolivia; and *luteolus* Thomas, from the mountains of northwestern Argentina in Jujuy, Catamarca, and Salta provinces. These taxa differ primarily by differences in color pattern.

NATURAL HISTORY: This species occurs at elevations up to 5,000m, where it can be very abundant in areas of sparse vegetation and loose sandy, gravelly, or cindery soils. Pearson (1951, 1959) described burrow systems, food habits, digging behavior, parasites and associates, reproductive biology, sexual dimorphism, and population densities at several study sites in southern Peru. Bennett (1846:8) found animals on sandy slopes and valleys "at no great distance from water" where "large patches of land were completely undermined by its workings." He believed that animals ate below ground bulbs and grass roots, rarely leaving their burrows to feet on grass stems. Their burrowing activity was heightened in the morning. S. Anderson (1997) recorded reproduction season in Bolivia. C. R. Lambert et al. (1988) and S. L. Gardner and Duszyński (1990) reported on eimerian oocysts in the feces of Bolivian specimens. This species is

Map 459 Selected localities for *Ctenomys opimus* (●). Contour line = 2,000m.

the type host of a species of sucking louse (Durdén and Musser 1994).

REMARKS: George R. Waterhouse (in Bennett 1846:8) referred to specimens from Potosí, Bolivia recorded by Bennett (1946:8–9) as *C. brasiliensis*; these, however, most likely represent *C. opimus*. Feito and Gallardo 1982) regarded *C. opimus* to be closely allied to *C. fulvus* based on sperm morphology; molecular analyses either place *C. opimus* in a basal position (electrophoretic characters; Cook and Yates 1994), within a group of Bolivian species with respect to those from geopolitical areas outside of Bolivia (mtDNA sequences; E. P. Lessa and Cook 1998), or within a “*opimus* group” that also included *C. fulvus*, *C. scagliai*, and *C. saltarius* (mtDNA sequences; Parada et al. 2011). All analyzed subspecies have the same karyotype of $2n = 26$ metacentric chromosomes, or $FN = 48$ (M. H. Gallardo 1979; Cook et al. 1990; Toloza et al. 2004; Ipucha et al. 2008). Ruedas et al. (1993) provided data on genome size. The sperm type is simple symmetric (Feito and Gallardo 1982; Vitullo and Cook 1991).

Ctenomys osvaldoreigi J. R. Contreras, 1995

Oswaldo Reig's Tuco-tuco

SYNONYM:

Ctenomys osvaldoreigi J. R. Contreras, 1995a:1; type locality “Estancia San Luis, Ruta Provincial 20, 10 kiló-

Map 460 Single known locality for *Ctenomys osvaldoreigi* (●). Contour line = 2,000m.

metros al oeste del Río Yuspe, en el extremo sudeste del Departamento Cruz del Eje, Provincia de Córdoba, 31°24’S, 64°48’W, aproximadamente a 2000 metros,” Argentina.

DESCRIPTION: Medium sized, total body length of male holotype 275 mm with mass, 244 g; equivalent data for female paratype 254 mm and 203.2 g, respectively; and for female topotypic series, body length 235–254 mm, mass 176–279 g (J. R. Contreras 1995a; A. I. Medina et al. 2007). General color uniformly ochraceous brown dorsally (corresponding to “antique brown” in Smithe’s [1975] atlas) with tawny tips to hairs; venter ochraceous (“cinnamon”) and lacking inguinal and axillary white spots common in many species in genus; white collar that characterizes most Bolivian and Chacoan species is lacking; tail bicolored, brown above and cream below; dorsal surfaces of feet same general color as body. Skull gracile with elongated rostrum that exhibits little evidence of lateral widening; weakly developed temporal crests; slender zygomatic arches, with breadth across them significantly greater than that across external auditory tubes; interparietalscarcely visible or fused with parietal and squamosal bones; bregmatic fontanelles lacking in adults; auditory bullae small and uninflated. Small fossa that characterizes most Chacoan species absent.

DISTRIBUTION: *Ctenomys osvaldoreigi* is only known from its type locality in Córdoba province, Argentina.

SELECTED LOCALITIES (Map 460): ARGENTINA: Córdoba, Estancia San Luis (type locality of *Ctenomys osvaldoreigi* J. R. Contreras).

SUBSPECIES: *Ctenomys osvaldoreigi* is monotypic.

NATURAL HISTORY: No data on behavior, ecology, reproduction, or food preferences are available.

REMARKS: Giménez et al. (1999) described a karyotype with $2n = 52$, FN = 56 (see also Ipucha et al. 2008), and simple, asymmetric sperm morphology.

Ctenomys paraguayensis J. R. Contreras, 2000
Paraguayan Tuco-tuco

SYNONYM:

Ctenomys paraguayensis J. R. Contreras, 2000:62; type locality “Corate-í, 12 kilómetros al oeste de la ciudad de Ayolas, departamento Misiones, República del Paraguay, aproximadamente en las coordenadas: 27°24’S–57°01’W.”

DESCRIPTION: Medium sized with head and body length of three known specimens 166–174 mm, tail length 73–80 mm, hindfoot (with claw) 34.8–37 mm, and mass 146–187 g. General color very similar to that of *C. pilarensis*, the other tuco-tuco species from eastern Paraguay, including presence of prominent, pale semicollar that passes obliquely from below ear around back of head, reaching base of neck; cheeks of *C. paraguayensis*, however, paler with face lacking any blackish coloration. Ventral coloration clear creamy gray without white spots in inguinal or axillary regions; tail only slightly bicolored. Skull graceful in overall appearance; width across zygomatic arches always greater than width across auditory tubes; postorbital spine of jugal rises almost perpendicular to occlusal plane of cheek teeth rather than obliquely; rim of zygomatic arch lacks foramen that may be present in other species; superior placement of auditory meatus relative to cheek teeth, a characteristic shared with species in northeastern Argentina and adjacent Uruguay, one of most notable features; two lateral openings through which alisphenoid-presphenoid bridge is visible present both sides of mesopterygoid fossa; this bridge is thin, with medial posterolateral expansion shaped like sharp stylus about 4 mm in length.

J. R. Contreras (2000) provided detailed comparisons, particularly of cranial features, between *C. paraguayensis*, *C. dorbignyi*, and *C. pilarensis*, and somewhat less so to *C. argentinus*.

DISTRIBUTION: *Ctenomys paraguayensis* is known only from the type locality in Misiones department, Paraguay.

SELECTED LOCALITIES (Map 461): PARAGUAY: Misiones: Corate-í (type locality of *Ctenomys paraguayensis* J. R. Contreras).

SUBSPECIES: *Ctenomys paraguayensis* is monotypic.

NATURAL HISTORY: No ecological data are available.

REMARKS: *Ctenomys paraguayensis* was described based on three specimens secured at the type locality. The species is distinct in both cytogenetic and morphological characters relative to all other known species in the genus. The karyotype is $2n = 52$ (J. R. Contreras 2000), more similar to species occurring in northern Corrientes province, Argentina (see accounts of *C. perrensi* and allies), and not to the neighboring *C. pilarensis* from Ñeembucú department, Paraguay. Comparative analysis of morphometric, osteological, and general somatic characteristics indicated a clear differentiation of this species with *C. pilarensis* as well as no close affinity with those species from the northeastern Argentinean provinces of Corrientes and Entre Ríos, such as *C. dorbignyi*. *Ctenomys paraguayensis* may represent Brants (1827) *Ratton tucotuco* Brants, a bibliographical species based on Azara’s (1802) “el tucutuco” from Paraguay, but definitive evidence for this hypothesis is lacking (see Langguth 1966, 1978). Brant’s *tucotuco*, however, was ruled (ICZN 1982:Opinion 1232) to be a vernacular name and unavailable for use in zoological nomenclature. Because of the great environmental change resulting from the construction of the Yacyretá dam, *C. paraguayensis* is very likely reduced in numbers if it has not already vanished from its very restricted geographic range in extreme eastern Paraguay. Sperm morphology is unknown.

Map 461 Single known locality for *Ctenomys paraguayensis* (●).

Ctenomys pearsoni E. P. Lessa and Langguth, 1983

Pearson's Tuco-tuco

SYNONYM:

Ctenomys pearsoni E. P. Lessa and Langguth, 1983:86; type locality "Arroyo Limetas, 25 km SE de Carmelo, Dep. Colonia, Uruguay."

DESCRIPTION: Medium sized, total length 245–277 mm, tail length 72–82 mm, and mass 165–300 g (E. P. Lessa and Langguth 1983; E. M. González 2001). Body color similar to that of *C. torquatus*, and both species possess same clear half-collar. Skull depressed and elongated; dorsal surface of frontals almost flat from level of interorbital constriction toward rear; frontoparietal sutures straight and almost transverse; parietals show anterior medial elongated zone limited by temporal crests, in same plane as frontals; rostrum narrow and elongated, with markedly proodont incisors; frontals narrowed because of very limited interorbital constriction; braincase relatively narrow; interpremaxillary and incisive foramina enlarged and highly visible; palate narrow and excavated between molariform teeth, with thin bony septum present in sagittal plane; auditory bullae elongated and project from behind occipital condyles; paroccipital processes well developed; preorbital foramina high and elongated; mandibular apophyses of jugals triangular and moderately robust. Coronoid process of mandible subtriangular, with wide base; posterior border elevated toward front relative to plane of molariform teeth. E. P. Lessa and Langguth (1983) detailed number of small but clear cranial differences that distinguish this taxon from both geographically neighboring (such as *C. torquatus*, which it strongly resembles) and distant species. Penile morphology distinctive feature of *C. pearsoni*, with paddle-shaped, single-tipped baculum wider, shorter, and better defined than in other tuco-tucos (Altuna and Lessa 1985).

DISTRIBUTION: *Ctenomys pearsoni* occurs along the coast of Uruguay from Rocha department in the east to Colonia in the west, and in adjacent Entre Ríos province in Argentina.

SELECTED LOCALITIES (Map 462): ARGENTINA: Entre Ríos, Médanos (Reig et al. 1966). URUGUAY: Canelones, Cuchilla Alta (Tomasco and Lessa 2007); Colonia Arroyo Limetas (type locality of *Ctenomys pearsoni* E. P. Lessa and Langguth), Estanzuela (E. P. Lessa and Langguth 1983); Maldonado, Chihuahua (Tomasco and Lessa 2007), José Ignacio (Tomasco and Lessa 2007), Solís (Tomasco and Lessa 2007); Montevideo, Carrasco (Tomasco and Lessa 2007); Rocha, Laguna de Rocha (Tomasco and Lessa 2007), Laguna Negra (Tomasco and Lessa 2007), Valizas (Tomasco and Lessa 2007); San José, Arazatí (E. P. Lessa and Langguth 1983), Río Santa Lucía (E. P. Lessa and Langguth 1983); Soriano, 1 km N of Nueva Palmira (E. P. Lessa and Langguth 1983).

SUBSPECIES: *Ctenomys pearsoni* is monotypic.

NATURAL HISTORY: *Ctenomys pearsoni* inhabits coastal sandy soils along the edge or near river mouths (Altuna et al. 1999). Altuna (1985) described details of the burrow microclimate. This is a solitary, highly territorial, and aggressive species, typical of most tuco-tucos. Females are sexually mature and mate within their first year, but males do not. The baculum and other reproductive structures of males are not fully developed until an age of one year (Altuna and Lessa 1985). The mating system is polygynous. Reproduction occurs during the winter months, and litter sizes range between two and four. As in other tuco-tucos, young are weaned after 30–40 days and are fully independent at about 2 months' age. Maternal behavior is highly developed in this species, as is probably true for most other tuco-tucos (Altuna et al. 1999). Vocal signals in pups and geographic variation in vocalizations have been studied by Francescoli (2001, 2002). As for other well-studied tuco-tucos, *C. pearsoni* is an herbivorous generalist preferring grasses such as *Cynodon dactylon* and *Panicum racemosum*, the more abundant species in its habitat (Altuna et al. 1999). Feeding behavior of these tuco-tucos has been well studied; individuals are autocoprophagic (Altuna et al. 1998, 1999). The caecum is unique, weighing 30% of total mass, thus making it the (relatively) largest among all hystricognaths for which this feature has been measured (Altuna et al. 1998).

REMARKS: *Ctenomys pearsoni* shares a pair of spiny bulbs on the male phallus with *C. dorbignyi*, *C. perrensi*, and *C. roigi* from Argentina (Altuna and Lessa 1985). The karyotype of *C. pearsoni* is distinctive but highly variable, with diploid numbers ranging from 56 and 70 in Uruguayan populations (A. Novello and Altuna 2002; A. F. Novello and Lessa 1986) with the chromosome morphology of the $2n = 70$ form almost the same as the karyotype of *C. dorbignyi* (Argüelles et al. 2001). In Uruguay, a series of chromosomally differentiated populations extending from Montevideo to Punta del Este (east of the Santa Lucia river in the departments of Carrasco, Salinas, and Maldonado) are included in the "*pearsoni* complex" (E. P. Lessa and Langguth 1983; E. M. González 2001; A. Novello and Altuna 2002). The Argentinean Médanos population of *C. pearsoni* has $2n = 68$ (Reig et al. 1966; originally assigned to *C. torquatus*), but differences from the $2n = 70$ *pearsoni-dorbignyi* pattern are minimal. The morphologically very similar *C. torquatus* has a completely different karyotype (see below). However, populations of the "*pearsoni*-complex," that is, those populations morphologically close to typical *C. pearsoni*, are karyotypically distinct ($2n = 56$ – 64 ; A. F. Novello and Lessa 1986). Sperm type is symmetrical. Tomasco and Lessa (2007) described the molecular phylogeography of the chromosomally variable

Map 462 Selected localities for *Ctenomys pearsoni* (●).

populations ($2n = 56, 58, 64, 66,$ and 70) along the coast of Uruguay and discussed the role of chromosomal diversification in speciation within with species and tuco-tucos more generally. D'Anatro and D'Elía (2011) detailed morphometric variation among populations representing all karyotypic forms. With a single exception, all populations were indistinguishable, supporting their view that not all fixations of chromosomal rearrangements define independent evolutionary units that would warrant species recognition.

Ctenomys perrensi Thomas, 1896

Perrensi's Tuco-tuco

SYNONYMS:

Ctenomys Perrensi Thomas, 1896:311; type locality "Goya, Corrientes, Argentina," Departamento Goya, Corrientes, Argentina, $29^{\circ}08'S, 59^{\circ}16'W, 37m$.

Ctenomys perrensis Cabrera, 1961:554; incorrect subsequent spelling of *Ctenomys perrensi* Thomas repeated by several subsequent authors (e.g., Redford and Eisenberg 1992; Woods 1993; Nowak 1999).

DESCRIPTION: Medium sized, total length 230–270 mm (A. I. Medina et al. 2007). General color dark buff or clay, heavily mixed with black along median line from face extending down back; eye to ear and below is lighter patch; cheeks brownish. Under surfaces from throat to belly rich buff, but patches of pure and sharply

contrasting white occur in axillary and inguinal regions. Upper surfaces of hands and feet thinly haired white. Skull short, broad, and rounded, not heavily ridged; zygomatic arches broader than breadth across posterior skull as measured at auditory meatus; nasals short, tapering backward, unusually broad and truncated behind; interorbital region short and very broad, postorbital process and ledges of limited development; frontoparietal suture almost directly transverse, little bowed backward; bullae small and little inflated, especially anteriorly. Upper incisors distinctly opisthodont, forming arc of smaller circle than in most tuco-tucos.

DISTRIBUTION: *Ctenomys perrensi* occurs in west-central Corrientes province, Argentina (see detailed map in J. R. Contreras et al. 1985, and Remarks).

SELECTED LOCALITIES (Map 463; from Giménez et al. 2002, except as noted): *Ctenomys perrensi* (*sensu stricto*): ARGENTINA: Corrientes, Colonia 3 de Abril, Goya (type locality of *Ctenomys perrensi* Thomas). *Ctenomys perrensi* complex: ARGENTINA: Corrientes, Arroyo Pegujó (Mirol et al. 2010), Chavarría, Contreras Cué, Curuzú Laurel, Estancia Tacuarita (Mirol et al. 2010), Loma Alta, Loreto, Manantiales, Pago Alegre, Paraje Angostura (Mirol et al. 2010), Paraje Caiman, Saladas, San Miguel (Parada et al. 2011).

SUBSPECIES: *Ctenomys perrensi* is monotypic.

NATURAL HISTORY: Very little ecological data are available. Mean litter size is 2.45 ± 0.89 s.d. ($N = 11$; J. R. Contreras, pers. comm.).

REMARKS: Both Cabrera (1961:554) and Woods and Kilpatrick (2005:1567) incorrectly cited the year of publication of Thomas's description as 1898. However, the issue of the *Annals and Magazine of Natural History* in which Thomas proposed *Ctenomys perrensi* (series 6, volume 18) appeared in 1896.

Ctenomys perrensi is closely allied at the molecular level to all other *Ctenomys* inhabiting Corrientes Province, including *C. roigi*, *C. dorbignyi*, and unnamed chromosomally distinct taxa inhabiting central and northwestern Corrientes (referred to as *Ctenomys* sp. and *Ctenomys* sp. in Giménez et al. 2002), and also to *C. pearsoni* from Entre Ríos province, Argentina, and Uruguay (J. R. Contreras and Bidau 1999; Mascheretti et al. 2000; Giménez et al. 2002). Parada et al. (2011) have named this assemblage of species the "*torquatus*" group (equivalent to the "Corrientes" group of J. R. Contreras and Bidau, 1999) on molecular evidence. However, none of the five taxa from Corrientes form reciprocally monophyletic groups in either allozyme or mtDNA or microsatellite analyses (Ortells and Barrantes 1994; Giménez et al. 2002; Mirol et al. 2010), al-

Map 463 Selected localities for *Ctenomys perrensi* (●) and those of the *Ctenomys* “perrensi-complex” (○; see Remarks).

though each is well differentiated chromosomally, suggesting that the origin of the whole assemblage has been recent and that collectively they form a “superspecies” complex (Giménez et al. 2002; Mirol et al. 2010; Gómez Fernández et al. 2012). The karyotype of *C. perrensi* (*sensu stricto*) is $2n = 50$; however, the “perrensi-complex” (*C. perrensi* + *Ctenomys* sp. α + *Ctenomys* sp. β) members range in diploid number from $2n = 41$ to $2n = 66$ (Ortells 1995; Giménez et al. 2002). This species has a simple symmetric type of sperm (Vitullo et al. 1988).

The map of localities (Map 463) separates those records for *C. perrensi sensu stricto* from the karyotypically differentiated forms referred to as the “perrensi-complex,” which extend toward central Corrientes province. Additional karyotypically distinct populations occur in northeastern Corrientes province, but these seem more related at the molecular level to *C. dorbignyi*, despite their low chromosome numbers. All references to the presence of *C. perrensi* in Misiones province are erroneous (Yepes 1935a; Honacki et al. 1982; Redford and Eisenberg 1992; Woods 1993). Misiones is the only Argentinean province where no *Ctenomys* populations are known to exist. There are also references to the presence

of *C. perrensi* in Entre Ríos province (Woods 1993; Redford and Eisenberg 1992), but these records actually correspond to *C. pearsoni*.

Ctenomys peruanus Sanborn and Pearson, 1947

Peruvian Tuco-tuco

SYNONYM:

Ctenomys peruanus Sanborn and Pearson, 1947: 135; type locality “Pisacoma, alt. 14,000 ft., Department of Puno, southern Peru,” $16^{\circ}55'S$ $69^{\circ}22'W$, 3,965 m.

DESCRIPTION: Large, pale, dark-footed species, with broadly expanded zygomatic arches, sagittal crest, and reduced last molar. Mean head and body length 220 mm, mean tail length 88 mm, and mean hindfoot length 41 mm (A. I. Medina et al. 2007). Back, sides, and belly colored creamy-buff, heavily lined in black to give overall brown tone; nose, lips, ears, and surrounding fur dark brown; hindfeet brown above, forefeet the same color as body; tail tawny. Skull with broadened zygoma expanded anteriorly so much so that zygomatic width greater than distance between outer edges of bony auditory meatus; sagittal crest present, even in smaller females; top of skull moderately arched. Last molar above and below about one quarter size of other molars.

DISTRIBUTION: *Ctenomys peruanus* is limited to Puno department in southern Peru.

SELECTED LOCALITIES (Map 464): PERU: Puno, Pampa de Quellecota (Pearson 1959), Hacienda Pichupichuni, Río Callacame, 8 km NW of Huacullani (Pearson 1959), Quellecota (MVZ 114767), Mazocruz (Sanborn and Pearson 1947), Pisacoma (type locality of *Ctenomys peruanus* Sanborn and Pearson).

SUBSPECIES: *Ctenomys peruanus* is monotypic.

NATURAL HISTORY (from Pearson 1951, 1959): This species inhabits open, often heavily grazed pampa shrub steppe composed of thorn bushes, closely cropped grass, dwarf flowers, and occasional tufts of taller grasses in southern Peru, where its range meets that of *C. opimus*. In the sandy and gravelly soils these tuco-tucos likely compete seriously with domesticated livestock (alpaca, llama, and sheep). This is the only Peruvian species that vocalizes conspicuously, with an alarm call described as “a musical bubbling” (p. 157). They are active during the day, will sit motionless with their heads at the entrance to their tunnels, and forage above ground to a meter or more from their burrow opening. Stomach contents contained coarse vegetable matter. The breeding season begins in November and lasts at least through April, with a gestation period approximating 4 months. There is likely only one litter produced by each female in a year. Litter size varied from 1 to 5, with a mean of 3.5, although resorption rates reduce the mean litter to about three young. Young

Map 464 Selected localities for *Ctenomys peruanus* (●). Contour line = 2,000 m.

are precocial, with late-term embryos well furred and neonates well developed at birth. Sex ratio may slightly favor females (Pearson 1951) or be strongly skewed to females (Pearson 1959). Several other vertebrates (mammals, birds, reptiles, and amphibians) use abandoned burrow systems. Pearson (1959) estimated density by counting active burrow opening and observing, with binoculars, the heads of active tuco-tucos at their entrances. He also suggested that *C. peruanus* was social, living in colonies, a behavior that contrasts with other tuco-tucos except *C. sociabilis*.

REMARKS: Sanborn and Pearson (1947) believed that *C. peruanus* was closely related to *C. fulvus* from northern Chile. The karyotype and sperm type of *C. peruanus* have not been reported.

Ctenomys pilarensis J. R. Contreras, 1993

Pilar Tuco-tuco

SYNONYM:

Ctenomys pilarensis J. R. Contreras, 1993:44; type locality “Pilar, [Ñeembucú,] Paraguay.”

DESCRIPTION: Medium sized, head and body length of males 189–209 mm and that of females 169–177 mm (A. I. Medina et al. 2007). No other details published.

DISTRIBUTION: *Ctenomys pilarensis* occurs in extreme southern Paraguay.

SELECTED LOCALITIES (Map 465; from Giménez et al. 1997, except as noted): PARAGUAY: Ñeembucú, Des-

Map 465 Selected localities for *Ctenomys pilarensis* (●).

mochado, Mayor Martínez, Paso Pucú, Pilar (type locality of *Ctenomys pilarensis* J. R. Contreras).

SUBSPECIES: *Ctenomys pilarensis* is monotypic.

NATURAL HISTORY: *Ctenomys pilarensis* inhabits fine sandy soils and is often found in manioc plantations. No specific data on behavior, reproduction, or ecology are known.

REMARKS: I have been unable to locate the original description of this species, which was apparently published in the abstracts and proceedings of a scholarly meeting. If the rules of the Code were followed in this brief presentation, then the name *pilarensis* J. R. Contreras is valid. However, if eventual access to these proceedings shows that the Code requirements were not followed, then *pilarensis* J. R. Contreras will become a *nomen nudum*, and this taxon will require a new name.

Mascheretti et al. (2000) included *C. pilarensis* in a group of Chacoan species that otherwise included *C. argentines*, *C. latro*, *C. occultus*, and *C. tucumanus*, which Parada et al. (2011) called the “tucumanus group.” Both studies were based on mtDNA sequences.

This species is chromosomally polytypic with the few populations sampled either $2n = 48$ or $2n = 50$. Each karyotype, however, has an FN = 50, supporting differentiation through Robertsonian changes (Giménez et al.

1997). The sperm is the simple asymmetric morphology (Giménez et al. 1997).

Ctenomys pontifex Thomas, 1918

Brown Tuco-tuco

SYNONYM:

Ctenomys pontifex Thomas, 1918a:39; type locality “East side of the Andes near Fort San Rafael, Province of Mendoza,” Argentina; restricted to Volcán Peteroa, Malargüe department, ca. 35°26'S, 70°20'W by Pearson and Lagiglia (1992).

DESCRIPTION: Medium sized; external dimensions of holotype (adult female) head and body length 183 mm, tail length 77 mm, and hindfoot length 34 mm. Color above uniform drab-brown without darker markings; under parts paler and buffier; tail brown above, whitish below. Skull rather narrow; zygomatic arches not expanded widely and with median ascending process placed posteriorly, making orbit proportionally large compared with temporal fossa; nasals long and nearly parallel sided, slightly surpassed behind by premaxillary processes; braincase lacks strong ridges; mesopterygoid fossa narrow; bullae long and narrow, in marked contrast with those of nearby *C. mendocinus*.

DISTRIBUTION: *Ctenomys pontifex* is known only from Mendoza province, Argentina.

SELECTED LOCALITIES (Map 466): ARGENTINA: Mendoza, Ñacuñán (J. R. Contreras 1979a), Volcán Peteroa (type locality of *Ctenomys pontifex* Thomas).

SUBSPECIES: *Ctenomys pontifex* is monotypic.

NATURAL HISTORY: Giannoni et al. (1996) described the burrowing behavior of *C. pontifex* (under the *nomen nudum* *C. eremophilus*; see Remarks). No other ecological data are available.

REMARKS: *Ctenomys pontifex* is another tuco-tuco species for which the type locality is uncertain and (as in the case of *C. knighti* discussed previously) where other rodent species share the same type locality. Thomas (1918a:40) gave this locality as “East side of the Andes near Fort San Rafael, Province of Mendoza”; Cabrera (1961:555) listed it simply as “San Rafael, Mendoza” and not, as Rusconi (1928:244) had thought, to “Fuerte de San Rafael, Provincia de Mendoza.” This locality is within the Department of 25 de Mayo of Mendoza province. Pearson and Lagiglia (1992:35) assigned to *C. mendocinus* tuco-tucos collected in the vicinity of the presumed type locality of *C. pontifex*, and suggested that Thomas Bridges had likely collected the type specimen of *pontifex* in the neighbourhood of the Peteroa volcano, near the border between Argentina and Chile. This locality is in the Department of Malargüe, Mendoza, about 200 km WSW of San Rafael

Map 466 Selected localities for *Ctenomys pontifex* (●). Contour line = 2,000 m.

between 2,400 and 3,000 m elevation (Pearson and Lagiglia 1992).

Bidau (2006) regarded *eremophilus* J. R. Contreras and Roig as a synonym of *C. pontifex*, but Parada et al. (2012) clearly linked this unavailable name to *C. mendocinus* (see that account).

The diploid number is 50 (M. O. Ortells, pers. comm.), but the sperm type is unknown.

Ctenomys porteousi Thomas, 1916

Cinnamon Tuco-tuco

SYNONYMS:

Ctenomys porteousi Thomas, 1916g:304; type locality “Bonifacio, S.W. Buenos Ayres Province, about 36°40'S, 62°W,” Departamento Guaminí, Buenos Aires, Argentina, 36°49'S, 62°13'W, 100 m.

Ctenomys porteousi porteousi: Yepes, 1935a:252; name combination.

DESCRIPTION: Medium sized with mean head and body length 186 mm (range: 174–205), tail length 77 mm (range: 68–89), hindfoot 30 mm (range: 28–33), and mass 192 g (range: 115–240; J. R. Contreras and Reig 1965). General color above cinnamon-brown lined with black; mid-dorsal area darkened, sometimes black, but dark area not sharply defined; top of muzzle and crown also blackish; under parts near vinaceous buff or drabby, bases of hairs

dark slaty; upper surfaces of hands and feet buffy whitish; tail dull whitish or pale brown, with darker, often blackish, terminal crest. Skull large but with smooth crown, parietal ridges imperceptible even in oldest individuals; incisive foramina medium in size; foramen magnum placed unusually high, with either one or two projections downward on its upper edge; bullae large. Upper incisors proodont, angled in comparison to toothrows between 97° and 100°; their enameled surfaces dark orange.

DISTRIBUTION: *Ctenomys porteousi* is found in the *Pampas* ecoregion of southeastern Buenos Aires province, Argentina.

SELECTED LOCALITIES (Map 467; J. R. Contreras and Reig 1965, except as noted): ARGENTINA: Buenos Aires, Álamos, Bonifacio (type locality of *Ctenomys porteousi* Thomas), Daireaux, Papín (Thomas 1916g), Pirovano.

SUBSPECIES: *Ctenomys porteousi* is monotypic.

NATURAL HISTORY: No information on ecology is available.

REMARK: *Ctenomys porteousi* is a member of the “mendocinus” group based on mtDNA sequences, along with *C. australis*, *C. flamarioni*, *C. mendocinus*, and *C. rionegrensis* (Parada et al. 2011). It has the typical “mendocinus” karyotype of $2n=46$, 47, or 48 (Massarini, Barros, Ortells, and Reig 1991). Massarini et al. (1992) described the genetic structure of populations of this species based on electromorphic markers. The sperm is sim-

Map 467 Selected localities for *Ctenomys porteousi* (●). Contour line = 2,000 m.

ple asymmetric in morphology (Vitulo et al. 1988). Apfelbaum et al. (1991) compared levels of electromorphic variation within and between *C. porteousi* and *C. australis*, and Mapelli et al. (2012) detailed phylogeography and posited Late and post-Pleistocene population history based on mtDNA sequences.

Ctenomys pundti Nehring, 1900

Pundt's Tuco-tuco, Small Tuco-tuco

SYNONYMS:

Ctenomys Pundti Nehring, 1900a:420; type locality “Alejo Ledesma im Süden der Provinz Cordoba,” Departamento Marcos Juárez, Córdoba, Argentina, 33°38'S, 62°37'W, 113 m.

Ctenomys mendocinus pundti: Cabrera, 1961:553; name combination.

DESCRIPTION: One of smallest species; overall head and body length of specimen used by Nehring in his description 170 mm, tail 43 mm, and hindfoot (including claws) only 20 mm. Color of upper parts yellowish-brown; under parts whitish-gray; both forefeet and hindfeet whitish above; tail bicolored, blackish above and whitish below. Dorsal hairs with yellow-brown tips and dark blue-gray bases. A. I. Medina et al. (2007) collected fully mature specimens with head and body length ranging between 133 and 138 mm in females, and 144 and 157 mm in males; some specimens weighed less than 100 g. Skull likewise small, with dimensions given by Nehring of total length 31.3 mm, basilar length 25.5 mm, zygomatic breadth 19.5 mm, width across auditory meatus 19.6 mm, least interorbital constriction 6.6 mm, nasal length 10.2 mm, diastema length 8.0 mm, upper toothrow length 6.9 mm, and width across both lower incisors 3.2 mm. Nehring noted, in particular, that occiput was not sharp-edged but founded, reflecting weakly developed lambdaoidal crest. Other cranial features apparent in illustrations provided by Nehring (1900a,c) include proodont upper incisors, greatly expanded and ventrally rounded auditory bullae, auditory meatus set on same plane as upper cheek teeth, and weakly developed but verticalpostorbital process of jugal. Many of these characters are attributes of small size.

DISTRIBUTION: *Ctenomys pundti* occurs in the provinces of Córdoba and San Luis in north-central Argentina within the *Pampa* and *Espinal* ecoregions.

SELECTED LOCALITIES (Map 468, from A. I. Medina et al. 2007, except as noted): ARGENTINA: Córdoba, Alejo Ledesma (type locality of *Ctenomys pundti* Nehring), La Carlota, Manantiales, Puente Olmos; San Luis, Eleodoro Lobos (J. R. Contreras, pers. comm.)

SUBSPECIES: *Ctenomys pundti* is monotypic.

NATURAL HISTORY: No ecological data are available.

Map 468 Selected localities for *Ctenomys pundti* (●). Contour line = 2,000 m.

REMARKS: The karyotype of *C. pundti* includes a $2n = 50$ and $FN = 84$ (Ipucha et al. 2008). Tiranti et al. (2005) discussed the morphological and karyological relationships of this species to other tuco-tucos, concluding that *C. pundti* is closest to *C. talarum*. The sperm morphology is the simple symmetric type (Bidau 2006).

Ctenomys rionegrensis Langguth and Abella, 1970

Río Negro Tuco-tuco

SYNONYMS:

Ctenomys minutus rionegrensis Langguth and Abella, 1970: 13; type locality “Balneario Las Cañas, boca del Arroyo Las Cañas, 7 km al Sudoeste de Fray Bentos, Río Negro, Uruguay,” ca. 100 m, 33°06'S 58°20'W.

Ctenomys rionegrensis: Altuna and Lessa, 1985:483; first use of current name combination.

DESCRIPTION: Relatively small tuco-tuco; external and cranial measurements for both sexes separately: males, head and body length 178–190 mm, tail length 71–83 mm, hindfoot length 30–33 mm, greatest skull length 45.9–47.9 mm, condylobasilar length 41–42.8 mm; females, head and body length 162–190 mm, tail length 65–83 mm, hindfoot length 29–33 mm, greatest skull length 41–44.6 mm, condylobasilar length 37.1–40.0 mm. Dorsal color varies extensively, with individuals either clear brownish-orange, dark-backed, or melanic (D'Elía et al. 1998; Wlasiuk et al. 2003); “agouti” individuals with small, yellow parauricular spots and yellowish venters; no inguinal or axillary

spots present; base of all body hairs, above and below, dark gray; tail bicolored with dorsal dark brown line along length. Skull with sides of rostrum parallel when viewed from above; temporal crests of parietal run almost parallel getting more near posteriorly; dorsal face of frontals and parietals flat. In comparison with *C. torquatus*, skull more rectilinear in shape; nasals flat or slightly convex longitudinally; dorsal border of foramen magnum with wide medial indentation; lateral processes seen in *C. torquatus* barely conspicuous; dorsal radius of upper incisors shorter such that incisors more opisthodont; most external point of zygomatic arch near its posterior end; zygoma dorsoventrally narrow with respect to *C. torquatus*; vertex of mandibular process of zygoma more rostral with respect to vertex of frontal process; longitudinal crest running along the external surface of the zygomatic bone is almost straight. The ventral root of zygomatic process of maxillary, at its origin, projected backward forming open angle; rostral edge of dorsal root of zygomatic arch projected forward and upward with respect to plane that passes to masticatory surface; Hill's (1935) interpremaxillary foramen very small.

DISTRIBUTION: *Ctenomys rionegrensis* inhabits the southeastern most part of the Río Negro department in Uruguay, between the Río Negro and Río Uruguay, and the coast of the Río Uruguay in Entre Ríos province, Argentina.

SELECTED LOCALITIES (Map 469): ARGENTINA: Entre Ríos, Concordia (Langguth and Abella 1970), Colonia Yerua (Langguth and Abella 1970), Paranacito (Reig et al. 1966), Parque Nacional El Palmar (Reig et al. 1966), Ubajay (Reig et al. 1966), Victoria (Reig et al. 1966). URUGUAY: Río Negro, Arrayanes (Wlasiuk et al. 2003), Balneario Las Cañas (type locality of *Ctenomys minutus rionegrensis* Langguth and Abella), La Guarida (Wlasiuk et al. 2003), La Tabaré (Wlasiuk et al. 2003), Mafalda (Wlasiuk et al. 2003).

SUBSPECIES: *Ctenomys rionegrensis* is monotypic.

NATURAL HISTORY: *Ctenomys rionegrensis* inhabits sand dunes between the Río Negro and Río Uruguay in Uruguay and in adjacent Argentina, where it has undergone recent demographic expansion (E. P. Lessa et al. 2005). Population densities are high, up to 40 adults per hectare (Tassino 2006), with multiple animals, including multiple adults, sometimes captured at the same burrow entrance (E. P. Lessa et al. 2005). These data suggested that *C. rionegrensis* might exhibit a level of sociality beyond that of the typical tuco-tuco solitary habits. However, radio telemetric studies (Tassino et al. 2011) documented that *C. rionegrensis* is not social, as individuals neither exhibited the extensive spatial overlap nor sharing of nest sites characteristic of the group-living *C. sociabilis* (Lacey et al. 1997; Lacey 2000). Nevertheless, overlap in areas occupied

Map 469 Selected localities for *Ctenomys rionegrensis* (●).

by adults was detected, suggesting an intermediate pattern of space use between the extremes of complete solitariness and group living. Breeding is highly seasonal, with activity beginning in the late austral autumn with initial births occurring in the early spring (Tassino and Passos 2010).

REMARKS: *Ctenomys rionegrensis* shows a remarkable variation in pelage color with three primary morphs: melanic, agouti, and dark-backed (D'Elía et al. 1998; Wlasiuk et al. 2003). These authors also described population genetic structure and gene flow rates using molecular markers (see also E. P. Lessa et al. 2005). Altuna and Lessa (1985) established that *C. rionegrensis* is a species distinct from *C. minutus* from nearby Rio Grande do Sul in Brazil based on characters of the male phallus. The karyotype of this species is both polymorphic with populations and polytypic among them. At the type locality, specimens show $2n = 50$ (Kibliskey et al. 1977), but diploid numbers ranging from 48 to 56 have been reported for other Argentinean and Uruguayan populations (Bidau 2006). Sperm morphology is the simple asymmetric type (Altuna et al. 1985).

Ctenomys roigi J. R. Contreras, 1988

Roig's Tuco-tuco

SYNONYM:

Ctenomys roigi J. R. Contreras, 1988:53; type locality "Procedente de Costa Mansión, 10km. al sur de Em-

pedrado, Departamento Empedrado, Provincia de Corrientes, a 28°02'S, 58°49'W, 60 m," Argentina.

DESCRIPTION: Relatively large tuco-tuco, mean total length 277.8 mm (range: 260–299 mm), head and body length 198.1 mm (176–200 mm), tail length 88.7 mm (76–99 mm), hindfoot (with claw) length 38.6 mm (34.5–43.8), and mass 231.1 g (175.5–278.8 g). Sexually dimorphic, with males averaging 105% larger in head and body length and 131% heavier than females. Dorsal color brownish hues, more tawny on back, clay on flanks, and lightening progressively from head to rump; head in particular with dark area extending from nose to neck, more accentuated in worn than newly molted pelage; many specimens with small tufts of white hairs on head dispersed within normal coat; light collar typical of other species distributed nearby (*C. argentinus*, *C. pearsoni*, *C. torquatus*, or *C. validus*) not present; pale zone surrounds pinna and area of white rostral vibrissae. Ventral color cinnamon with pale creamy wash; ventral white spots present in majority of specimens in both axillary and inguinal regions. Legs and feet pale, with hair almost white, even unguis combs. Tail sparsely covered with hair, moderately bicolored in fresh specimens, but blackens evenly after skin dries in preserved material; tip with short pencil of hairs.

Skull robust, solid, and strong, endowed with only moderately expanded tympanic bullae not visible in dorsal view; zygomatic arch strong with greatest breadth across arches wider than that across external auditory canals; rostrum short, robust, and with very broad nasal bones anteriorly that taper and truncate before leading edge of orbit; premaxillary bones extend to posterior limit of nasals or only slightly beyond; frontal bones slightly concave above; interorbital constriction broad, terminating in well-marked postorbital process; bregmatic fenestra, conspicuous in *C. dorbignyi* and *C. perrensi*, is rarely present; temporal crests well developed, so squamosal does not extend onto dorsal surface of skull, although degree of development is both age and sex dependent; well-developed lambdoidal crests present, with interparietal barely developed or not apparent at all. Ventrally, paroccipital processes broad, covering nearly half of posterolateral surface of auditory bullae, greater extent than in other species (such as *C. argentinus* and *C. bonettoi*); fossa for insertion of masseter superficialis muscle shallow, appearing in some older specimens simply as an ossification of terminal tendon of insertion; mesopterygoid fossa V-shaped notch. Upper incisors distinctly proodont, with their anterior face at angle of 109° relative to horizontal plane formed by upper cheek teeth, much more so than other closely adjacent species, such as *C. dorbignyi*, *C. bonettoi*, *C. perrensi*, or *C. argentinus*. Upper molariform teeth medium in size; the anterior prism of PM4 very enlarged and with

visible inner groove; M3 small and either circular or sub-circular in shape.

Baculum small, spatulate-shaped bone, with ventral face flattened and more rugose and slightly convex dorsal face, usually with slight depression of varying length along median axis. Average bacular length 6.74 mm (range: 5.7–7.6 mm), average maximum width 1.85 mm (range: 1.4–2.4 mm).

DISTRIBUTION: *Ctenomys roigi* inhabits a very limited area no more than 12 km long and 3 km wide along the coast of the Río Paraná in Corrientes province, Argentina.

SELECTED LOCALITIES (Map 470): ARGENTINA: Corrientes, Colonia Brougues (Giménez et al. 2002), Costa Mansión (type locality of *Ctenomys roigi* J. R. Contreras), Empedrado (Parada et al. 2011), Estancia Yacyretá (A. I. Medina et al. 2007).

SUBSPECIES: *Ctenomys roigi* is monotypic.

NATURAL HISTORY: Little is known about the population biology or ecology of this species. As summarized by J. R. Contreras (1988), individuals are solitary living in individually exclusive but closely adjacent burrow systems. Breeding takes place during the spring-summer. Fully 50% of females were either obviously pregnant or lactating in October, with 11% young of the year, while two months later, in December, 40% of the population were young of the year with pregnant and lactating individuals comprising only

10% and 30%, respectively. Litter size is low, with seven of eight females with a single fetus, and one female with two, for an overall average of 1.124 young per pregnancy.

This species occupies sandy loam soils in prairie habitats covered by herbaceous plants, particularly invasive Solanaceae, in areas strongly subject to overgrazing by cattle. These areas are not seasonally inundated. Individuals feed from within their burrows, either harvesting tubers and roots of plants such as *Rhynchosia pallida*, *Ipomoea bonariensis*, *Senecio grisebachii*, or *Byrtia mutabilis*, or the basal stems of the dominant grasses. Individuals also access above-ground plant materials by pulling whole plant into their tunnels from below rather than by venturing onto the ground surface.

REMARKS: The karyotype of *C. roigi* is $2n = 48$, FN = 76 (Giménez et al. 2001, 2002), and the sperm is the simple symmetric type (Bidau 2006). Ortells et al. (1990) reported the FN as 80 (and cited as such by Woods and Kilpatrick 2005:1568), but their calculation included the sex chromosomes. In *C. roigi*, both X and Y chromosomes are biarmed, thus increasing the autosomal FN by four.

Ctenomys rondoni Miranda-Ribeiro, 1914

Rondon's Tuco-tuco

SYNONYMS:

Ctenomys rondoni Miranda-Ribeiro, 1914:39, plates 20 and 23, Figs. 1–1a', 3, and 5; type locality (based on the lectotype chosen by Moojen, in Miranda-Ribeiro 1955:415) "Maria de Molina," = Campos dos Palmares de Maria de Molina, Vilhena, Rondônia, Brazil, 12°07'12" S 60°28'56" W.

Stenomys rondoni: Avila-Pires, 1968:162; inadvertent misspelling of genus name.

DESCRIPTION: Medium sized with head and body length about 230 mm and tail length 80 mm. Dorsal pelage comprises pale hairs at base but turning to sepia at tips; head and especially venter slightly rufous; tail uniformly brownish. Skull robust and depressed, approximately 54 mm in total length and 34 mm across zygomatic arches (Miranda-Ribeiro 1914). Intermaxillaries robust with lateral protruding expansion that decreases toward front and projects past incisors; supraorbital process protrudes; interparietal contacts frontals along narrow zone; transverse occipital-temporal crest straight; tympanic bullae inflated; occipital foramen round anteriorly and square posteriorly; maxillaries narrow; body of ethmoid bones very narrow, pterygoids small but thick. Mandible particularly strong and wide.

DISTRIBUTION: *Ctenomys rondoni* is known only from two specimens, one each from localities in Mato Grosso and Rondônia states in western Brazil.

SELECTED LOCALITIES (Map 471): BRAZIL: Mato Grosso, Juruena (Miranda-Ribeiro 1914); Rondônia,

Map 470 Selected localities for *Ctenomys roigi* (●).

Campos dos Palmares de Maria de Molina (type locality of *Ctenomys rondoni* Miranda-Ribeiro).

SUBSPECIES: *Ctenomys rondoni* is monotypic.

NATURAL HISTORY: No ecological data are available.

REMARKS: The type locality of *C. rondoni* has been varying given as Rio Juruena (S. Anderson et al. 1987) or Juruena (Avila-Pires 1968). Miranda-Ribeiro (1914) did not select a holotype and based his description on both the skin and partial cranium of the single specimen from Juruena as well as on the more complete cranium of the specimen from Maria de Molina. João Moojen (in Miranda-Ribeiro 1955:415) designated the Maria de Molina specimen as lectotype (MNRJ 2051) while MNRJ 2050 from Juruena remained as paralectotype. However, in a catalog of type specimens at the Museo Nacional, Avila-Pires (1968:183) incorrectly switched the specimen numbers. Thus, Maria de Molina and not Juruena should be considered the type locality of *Ctenomys rondoni*. Subsequently, MNRJ 2051 was corrected in the museum records, and the cranium received the same number as the skin, MNRJ 2048 (see Langguth et al. 1997).

Despite clarification of the locality and catalog number of the lectotype, both known localities remain troublesome. Maria de Molina does not exist on maps or in gazetteers of Brazil, either old or new. In fact, the 1909 expedition led

by Coronel Cândido Rondon (when the specimens of *C. rondoni* [as well as those of *C. bicolor*] were collected) established camp in an unpopulated site near José Bonifácio. Rondon (in Viveiros 1958:298) named the place “Campos dos Palmares de Maria de Molina,” which establishes the coordinates given herein.

Although all recent authors have regarded *C. rondoni* as a synonym of *C. nattereri* (e.g., Cabrera 1961:553) or as a valid subspecies of *C. boliviensis* (e.g., Woods and Kilpatrick 2005:1561), I believe these decisions are unjustified given the ambiguous geographic status of both *boliviensis* and *nattereri*.

No data are available on either karyotype or sperm morphology.

Ctenomys rosendopascuali J. R. Contreras, 1995

Rosendo Pascual's Tuco-tuco

SYNONYM:

Ctenomys rosendopascuali J. R. Contreras, 1995b:1; type locality “Mar Chiquita, Departamento San Justo, provincia de Córdoba, Argentina, 30°48'S, 62°53'W, 65 m”; *nomen nudum?* (see Remarks).

DESCRIPTION: Relatively small with head and body length of males ranging from 160–177 mm, and 159–166 mm for females (A. I. Medina et al. 2007). Few other character data published.

DISTRIBUTION: *Ctenomys rosendopascuali* is only known from a few localities in Córdoba province, Argentina, in the *Chaco Seco* ecoregion.

SELECTED LOCALITIES (Map 472): ARGENTINA: Córdoba, Candelaria (Giménez et al. 1999), Los Mistoles (Mascheretti et al. 2000), Mar Chiquita (type locality of *Ctenomys rosendopascuali* J. R. Contreras).

SUBSPECIES: *Ctenomys rosendopascuali* is monotypic.

NATURAL HISTORY: No data on ecology, behavior, or reproduction are available.

REMARKS: Giménez et al. (1999:91) described a polytypic chromosome complement of $2n = 52$ with a variable FN of 62, 64, and 66 (see also Ipuca et al. 2008). The sperm is the simple asymmetric type (Giménez et al. 1999). Mascheretti et al. (2000) concluded that *C. rosendopascuali* was part of a lineage that also included *C. azarae*, *C. bergi*, *C. bonettoi*, *C. mendocinus*, and *C. “yolandae”* based on mtDNA sequences.

It is unclear whether the issue of *Nótulas Faunísticas* (volume 86, pp. 1–6) in which J. R. Contreras (1995b) described *C. rosendopascuali* was actually published (Yolanda Davies, daughter of Julio R. Contreras, pers. comm. to U. F. J. Pardiñas, Oct. 25, 2012). If not, then the taxon to which subsequent authors have referred under this name will require a formal description.

Map 471 Selected localities for *Ctenomys rondoni* (●). Contour line = 2,000 m.

Map 472 Selected localities for *Ctenomys rosendopascuali* (●). Contour line = 2,000 m.

Ctenomys saltarius Thomas, 1912

Salta Tuco-tuco

SYNONYMS:

Ctenomys saltarius Thomas, 1912c:639; type locality “Salta, [Salta,] N Argentina.”

Ctenomys talarum saltarius: Yepes, 1935a:252; name combination.

DESCRIPTION: Fairly large with head and body length (of holotype, adult female) 200 mm, tail length 90 mm, and hindfoot length 33 mm. Fur short and overall dull in tone, having neither length nor glossiness of neighboring species (e.g., *C. opimus luteolus* Thomas and *C. tucumanus* Thomas). Upper parts dull raw umber, browner along dorsal midline, paler on sides; under parts dull buffy whitish; area around snout whitish with inconspicuous dark collar further behind; feet dull white above; tail markedly bicolored, blackish above and dull white below. Skull very narrow, with zygomatic arches less spread than distance from front of incisors to back of toothrow, a condition that contrasts with other species; frontal region also very narrow, with interorbital breadth less than length of molar series; postorbital processes practically absent.

DISTRIBUTION: *Ctenomys saltarius* is known only from a few localities in Salta province, Argentina, all within either the *Yungas* or *Chaco Seco* ecoregions (J. R. Contreras 1984a).

SELECTED LOCALITIES (Map 473): ARGENTINA: Salta, Cafayate (CML 854), Salta (holotype of *Ctenomys saltarius* Thomas), Tolombón (A. I. Medina et al. 2007).

Map 473 Selected localities for *Ctenomys saltarius* (●). Contour line = 2,000 m.

SUBSPECIES: *Ctenomys saltarius* is monotypic.

NATURAL HISTORY: *Ctenomys saltarius* inhabits hillsides and valleys of the Monte Desert, and is especially common in *Larrea* (Zygophyllaceae) flats and areas with *Prosopis* (Fabaceae) where it feeds on creosote and other shrubs (Mares, Ojeda, and Kosco 1981).

REMARKS: Both karyotype and sperm are unknown.

Ctenomys scagliai J. R. Contreras, 1999

Scaglia's Tuco-tuco

SYNONYMS:

C[tenomys]. scagliai J. R. Contreras and Bidau, 1999:3; *nomen nudum*.

C[tenomys]. scagliai J. R. Contreras, Castro, and Cicchino, 1999:5; *nomen nudum*.

Ctenomys scagliai J. R. Contreras, 1999:10; type locality: “Los Cardones, sobre la Ruta Nacional N° 307, Kilómetro 101, entre las localidades tucumanas de El Infiernillo y Amaicha del Valley, aproximadamente a 2.500 metros sobre el nivel del mar (26°38'S–65°49'W),” Tucumán, Argentina.

DESCRIPTION: Medium sized with external measurements of holotype including head and body length 195 mm, tail length 85 mm, hindfoot length (with claw) 37.0 mm, ear length 10 mm, and mass 270 g. General color clear ochraceous brown on back to yellow-brown (straw) on flanks and venter; hairs long, silky, and strongly bicolored, with black basal part for two-fifths length of dorsal hairs and about half the length of ventral hairs; top of

muzzle and head black, extending back as dorsal stripe; both vibrissae and supra-ungual combs white; area surrounding vibrissae same color as rest of face; tail covered by short and sparsely distributed hairs, bicolored, with proximal part dirty white becoming progressively darker until distal third, which is black; ears very small, with creamy white subauricular areas that suggest pale collar; no white spots in either axillary or inguinal regions; legs covered with sparse coat of fur colored similar to that of belly.

Skull robust but looks more delicate than those of many other species; nasal bones short and relatively narrow, tapering only slightly posteriorly, with premaxilla and incisors in clear view from above and broadened premaxillary and maxillary wings on either side; posterior border of frontal bones convex; interorbital region relatively broad with weakly developed postorbital processes; frontals extend laterally to form part of overhanging roof that forms part of orbit; squamosal forms part of dorsal roof of skull, with well-developed post-tympanic projections; pair of sesamoid bones in front of lambdoidal crest between parietals and post-tympanic process of squamosal gives latter spatulate shape; interparietal enlarged and V-shaped, both uncommon features for genus; distance across external meatus on both sides typically greater than greatest width across zygomatic arches; laterally, alveoli of upper incisors positioned in common depression located posterior to proximal edge of vomer; no interpremaxillary opening, which is apomorphic condition for species; external auditory meatus positioned high on side of skull, with its lower border above plane formed by occlusal surface of upper toothrow; zygomatic arch relatively delicate, with zygomatic process of maxilla forming moderately obtuse angle; bullae appear inflated and evenly rounded in lateral view, but transversely compressed in ventral view, with expanded paroccipital process appressed only to very posterior margins; palate relatively short, with acutely V-shaped mesopterygoid fossa extending anteriorly to middle of M2; openings in alisphenoid asymmetrical, with one on right side and two on left; foramen ovale wide and within it alisphenoid-presphenoid bridge runs anteromedially from alisphenoid to become trapezoidal plate linked by short isthmus to presphenoid. Upper incisors orthodont.

DISTRIBUTION: *Ctenomys scagliai* is only known from the vicinity of the type locality in Tucumán province, Argentina.

SELECTED LOCALITIES (Map 474): ARGENTINA: Tucumán, Los Cardones (type locality of *Ctenomys scagliai* J. R. Contreras), Km 95 of Hwy 307 near Tafí del Valle (A. I. Medina et al. 2007).

SUBSPECIES: *Ctenomys scagliai* is monotypic.

Map 474 Selected localities for *Ctenomys scagliai* (●). Contour line = 2,000 m.

NATURAL HISTORY: Ecology, reproduction, behavior, or other aspects of the population biology are unknown.

REMARKS: The karyotype is $2n = 36$, $FN = 64$ (Ortells 1995, as *C. knighti*; see J. R. Contreras 1999). Sperm morphology is symmetrical, the plesiomorphic condition for the genus (J. R. Contreras 1999).

Ctenomys sericeus J. A. Allen, 1903

Silky Tuco-tuco

SYNONYMS:

Ctenomys sericeus J. A. Allen, 1903b:187; type locality "Cordilleras, upper Rio Chico de Santa Cruz, Patagonia"; restricted to "confluencia de los ríos Belgrano y Chico (~48.26°S, 71.20°W, departamento Río Chico, Santa Cruz, Argentina" (Pardiñas 2013).

Ctenomys seriseus Rusconi, 1928:243; incorrect subsequent spelling of *sericeus* J. A. Allen.

DESCRIPTION: Small with total length of males averaging 200 mm (range: 195–208 mm), tail length 56.6 mm (51–62 mm), and hindfoot length 26.2 mm (25–28 mm; A. I. Medina et al. 2007). Pelage short, soft, and glossy. General color above yellowish-gray strongly varied with black, hairs being plumbeous on basal three-fourths, then banded narrowly with pale yellowish brown, and tipped with black; flanks and ventral surface buff; sides of nose yellowish-brown; top of nose and top of head like mid-back; ears small and blackish, upper surfaces of feet dingy gray with slight yellowish cast; tail pale yellowish, with

Map 475 Selected localities for *Ctenomys sericeus* (●).

median dusky stripe along apical half of upper surface. Skull with interparietal either lacking or greatly reduced in size.

DISTRIBUTION: *Ctenomys sericeus* is only known from two localities in Santa Cruz province, Argentina.

SELECTED LOCALITIES (Map 475): ARGENTINA: Santa Cruz, La Porteña, Río Vista (Parada et al. 2011), confluence of Río Chico and Río Belgrano (J. A. Allen 1905).

SUBSPECIES: *Ctenomys sericeus* is monotypic.

NATURAL HISTORY: J. A. Allen (1905:41) stated that *Ctenomys sericeus* was parapatric to *C. osgoodi*. No other data are available.

REMARKS: J. A. Allen (1903b) compared *C. sericeus* to both *C. pundti* Nehring and *C. bergi* Thomas, two species from nearby Córdoba province and from both of which it differs in coloration. Subsequently, J. A. Allen (1905:40) narrowed the type locality of the confluence of the Chico and Belgrano rivers in Santa Cruz province. This species has a karyotype of $2n = 28-30$ chromosomes and a simple asymmetric sperm type (Montes et al. 2001; Bidau 2006).

Ctenomys sociabilis Pearson and Christie, 1985

Colonial Tuco-tuco

SYNONYM:

Ctenomys sociabilis Pearson and Christie, 1985:338; type locality "Estancia Fortín Chacabuco, 1075 m, 3 km S y 2 km W Cerro Puntudo, 71°11'40"W, 40°58'00"S," Departamento Los Lagos, Neuquén, Argentina.

DESCRIPTION: Medium sized with head and body length averaging 192 mm (range: 168–247 mm), tail 68 mm (range: 67–80) mm, hindfoot length 34 mm (range: 32–36 mm), and mass 182 g (range: 180–234 g). Color overall ochraceous-tawny above mottled with black hairs, especially in frontal region of head; ventral color similar, but lacks black hairs; diagnostic ochraceous-orange spot on both sides of nose and conspicuous black and white moustache uniformly present. Claws large, relatively narrow, and only slightly curved. Cranially, rostrum elongated, arc of upper incisors wide, and auditory bullae uninflated and exceptionally narrow.

DISTRIBUTION: *Ctenomys sociabilis* has a narrow range between the Río Trafal and Lago Nahuel Huapi, west of the Río Limay in the Reserva Nacional Nahuel Huapi in Neuquén province, Argentina (Pearson 1995).

SELECTED LOCALITIES (Map 476): ARGENTINA: Neuquén, Estancia Fortín Chacabuco (type locality of *Ctenomys sociabilis* Pearson and Christie); Estancia La Primavera, 11 km NW of Confluencia (MVZ 179310), 4 km N and 4 km E of Estancia Paso Coihue (MVZ 184869), Estancia Rincon Grande (MVZ 186111).

SUBSPECIES: *Ctenomys sociabilis* is monotypic.

NATURAL HISTORY: *Ctenomys sociabilis* is one of the more thoroughly studied tuco-tuco species in the field. It is the only clearly documented social tuco-tuco (although *C. peruanus* is suspected to be social; see Pearson 1959). Their populations consist of aggregates of collective burrows at the margins of *mallines*, the local name for the moist meadows in the Andean-Patagonian steppe, where somewhat lush vegetation grows (Pearson and Christie 1985). The majority of active burrow systems surveyed across the species range, however, were in non-*mallín* habitats (Tammone et al. 2012). It inhabits black, wet, and fine soils. It is also the only tuco-tuco that does not maintain a burrow with the mouth permanently closed and exhibits a substantial level of above-ground activity. The grass *Poa* is a main food item. Reproduction occurs in the winter, with young typically born in November. Gestation is about three months, and litter size varies from two to six young. Populations of this species may contact those of *C. haigi* and *C. maulinus* (Pearson and Christie 1985). Lacey et al. (1997) studied burrow sharing by multiple individuals; Lacey and Wiczorek (2004) described kinship patterns and group composition; Lacey (2004) documented that sociality reduces direct individual fitness; Woodruff et al. (2010) examined stress physiology and social biology in wild and captive populations; and Schwanz and Lacey (2003) showed that individuals have the capacity to discriminate gender by olfactory cues. Hambuch and Lacey (2002) and Lacey (2001) contrasted patterns of variation at both MHC and microsatellite loci, respectively, between the colonial *C. sociabilis*

Map 476 Selected localities for *Ctenomys sociabilis* (●). Contour line = 2,000 m.

and the geographically adjacent but asocial *C. haigi*. Chan et al. (2005) and Chan and Hadly (2011) documented a substantial loss of genetic diversity in modern population samples of *C. sociabilis* over the past 10,000 years.

REMARKS: The chromosome complement of *C. sociabilis* has $2n = 56$, $FN = 72$ (M. H. Gallardo 1991); its sperm is the simple asymmetric type (Pearson and Christie 1985; M. H. Gallardo et al. 2002). Mason (2004) described the middle ear apparatus.

Ctenomys steinbachi Thomas, 1907

Steinbach's Tuco-tuco

SYNONYM:

Ctenomys Steinbachi Thomas, 1907b:164; type locality "Campo of Province Sara, near Santa Cruz de la Sierra, Bolivia"; restricted to 6 km N of Buen Retiro, $17^{\circ}13'S$ $63^{\circ}38'W$ by S. Anderson et al. (1987:13).

DESCRIPTION: Very large with males reaching at least 350 mm in body length, and with males and females of equivalent size (S. Anderson et al. 1987). Measurements of holotype (an adult male) head and body length 245 mm, tail length 86 mm; hindfoot length (with claw) 45 mm. Fur straight, fine, and glossy, with hairs of back about 13 mm in length. General color unusual dark drabby-gray-brown or coppery, quite unlike that of any other *Ctenomys* known to Thomas when he described this species. Color uniform over entire head, upper surface, and sides; under surface creamy white, hairs dull slaty for their basal two-thirds; line of demarcation

on sides sharply defined; vibrissae white; chin and band across lower neck in front of arms brown, separated by broad whitish patch running across interramal region and narrowing on sides to point below ear; arms and legs pale-colored, except for narrow band running down front of forelimbs; hands and feet almost naked above, pale brown, with lateral fringes whitish; tail very thinly clothed, with dull white, sparse hairs.

DISTRIBUTION: *Ctenomys steinbachi* occurs in west-central Santa Cruz province, Bolivia.

SELECTED LOCALITIES (Map 477, from S. Anderson 1997, except as noted): **BOLIVIA:** Santa Cruz, 6 km N of Buen Retiro (type locality of *Ctenomys steinbachi* Thomas), 2 mi S of Caranda, Río Surutó, San Rafael de Amboró, 10 km S of Zanja Honda.

SUBSPECIES: *Ctenomys steinbachi* is monotypic.

NATURAL HISTORY: No published data on the autecology available. A pregnant female was collected in August with a single embryo (S. Anderson 1997).

REMARKS: Molecular analyses support a close phylogenetic relationship with the geographically adjacent *C. boliviensis* and *C. goodfellowi* (Cook and Yates 1994; E. P. Lessa and Cook 1998). Parada et al. (2011) placed this species in their "*boliviensis*" group, along with *C. boliviensis*, *C. goodfellowi*, *C. nattereri*, and *C. robo*, based on mtDNA sequences. *Ctenomys steinbachi* has a karyotype with $2n = 10$ and $FN = 18$ (S. Anderson et al. 1987), the lowest chromosome number known for a rodent, shared

Map 477 Selected localities for *Ctenomys steinbachi* (●). Contour line = 2,000 m.

only with the grass mouse *Akodon* sp. $2n = 10$. Vitullo and Cook (1991) described a simple symmetric type of sperm morphology.

Ctenomys talarum Thomas, 1898

Talas Tuco-tuco

SYNONYMS:

Ctenomys talarum Thomas, 1898d:285; type locality “‘Las Talas,’ Ensenada, La Plata,” on the Río de la Plata, east of La Plata, Partido de Berisso, Buenos Aires, Argentina, $34^{\circ}52'S$, $57^{\circ}53'W$, 10 m.

Ctenomys talarum antonii Thomas, 1910a:240; type locality “Los Yngleses, in the eastern part of the Province of Buenos Ayres,” Argentina.

Ctenomys talarum recessus Thomas, 1912a:241; type locality “Bahía Blanca,” Buenos Aires, Argentina.

Ctenomys talarum anthonii: Rusconi, 1928:243; inadvertent misspelling of *antonii* Thomas.

Ctenomys mendocinus talarum: Thomas, 1929:44; name combination.

Ctenomys mendocinus recessus: Thomas, 1929:44; name combination.

Ctenomys talarum talarum: Tate, 1935:391; name combination.

Ctenomys talarum occidentalis Justo, 1992:35; type locality “Luan Toro [= Luán Toro],” La Pampa, Argentina.

DESCRIPTION: Small with three subspecies currently recognized similar in size and degree of sexual dimorphism (A. I. Medina et al. 2007). Mean body length (both sexes combined) of nominotypical subspecies 233.4 mm, range: 212–254 mm, and tail 66.7 mm, range: 56.0–75.0 mm (Reig et al. 1966). Tail short (<39% of head and body length). Overall color dark hazel grayish red with prominent axillary white patches; conspicuous white patch occurs at lower edge of ears (Justo et al., 2003). Distinctive cranial characteristics include mastoid breadth less than zygomatic breadth, and conspicuous interpremaxillary foramen (Justo et al. 2003). Baculum short, narrow, and not very expanded at either end; mean length 6.4 mm, proximal width 1.32 mm, distal width 0.9 mm ($N = 12$; Justo et al. 2003).

DISTRIBUTION: The nominotypical subspecies, now extirpated from the type locality, extends along coastal Buenos Aires province, Argentina, from Magdalena to Santa Clara del Mar; *C. t. recessus* occupies the second or third line of sand dunes from Necochea to Punta Alta, also in Buenos Aires province; and *C. t. occidentalis* is limited to two localities in La Pampa province. Sparse populations of unknown subspecific status occur in northwestern Buenos Aires province, possibly entering La Pampa province close to the range of *occidentalis*.

SELECTED LOCALITIES (Map 478): ARGENTINA: Buenos Aires, Bahía Blanca (type locality of *Ctenomys ta-*

larum recessus Thomas), Cerro de la Gloria (Bidau et al. 2000), Ciudad de Lincoln (J. R. Contreras 1972), Ciudad de Pehuajó (J. R. Contreras 1972), Fortín Olavarría (J. R. Contreras 1972), Laguna Las Encadenadas (J. R. Contreras 1972), Las Talas (type locality of *Ctenomys talarum* Thomas), Mar Chiquita (Bó et al. 2002), Monte Hermosa (A. I. Medina et al. 2007), Necochea (Vasallo 1998), Pechuén-có (J. R. Contreras 1972), Punta Médanos (Bidau et al. 2000), Quiroga (Massoia 1988a), Saladillo (Parada et al. 2011), San Clemente del Tuyú (Bidau et al. 2000), Sierra de la Ventana (J. R. Contreras 1972); La Pampa, El Guanaco (A. I. Medina et al. 2007), La Florida (A. I. Medina et al. 2007), Luán Toro (type locality of *Ctenomys talarum occidentalis* Justo).

SUBSPECIES: *Ctenomys talarum* includes three recognized subspecies (Justo et al. 2003): *C. t. talarum* Thomas, *C. t. antonii* Thomas, and *C. t. occidentalis* Justo. Reig et al. (1966:299) incorrectly considered *antonii* Thomas to be a synonym of *recessus* Thomas. However, *antonii* Thomas has date priority, so the southern subspecies of *C. talarum* is properly named *C. talarum antonii*, with *recessus* Thomas a subjective junior synonym (ICZN 1999:Art. 23.1).

NATURAL HISTORY: *Ctenomys t. antonii* occurs in partial sympatry with the larger *C. australis* in Buenos Aires province (J. R. Contreras and Reig 1965) and *C. t. occidentalis* overlaps with *C. azarae* in La Pampa province (Justo et al. 2003). Comparatore et al. (1992) examined the juxtaposition of *C. talarum* and *C. australis* in relation to edaphic and plant composition in the Necochea district, also in Buenos Aires province. Justo et al. (2003) provided a thorough summary of life history, ecology, behavior, and other attributes of this species. These data are perhaps more extensive than for any other species of tuco-tuco, and include information on social structure, spatial distribution, and age composition (Pearson et al. 1968); burrow structure (Antinuchi and Busch 1992); home range and activity patterns (A. P. Cutrera, Antinuchi et al. 2006; A. P. Cutrera, Mora et al. 2010); chemical communication (Zenuto et al. 2004); vocal communication (Schleich and Busch 2002a,b); social transmission (Vassallo 2006); energetics (Schleich and Busch 2004; Antinuchi et al. 2007; Perissinotti et al. 2009), thermoregulation (C. Busch 1989; F. Luna and Antinuchi 2007a,b), including its ontogeny (A. P. Cutrera et al. 2003); foraging costs (F. Luna and Antinuchi 2006, 2007a, b), food preferences, feeding selectivity, and digestive strategies (del Valle et al. 2001; del Valle and Lopez Mananes 2008, 2011); predation (Baladron et al. 2009); parasitism (Rossin 2004); reproductive biology, including seasonality and litter size (Malizia and Busch 1991; Fanjul et al. 2006); population ecology and behavior (Vasallo 1998; C. Busch et al. 2000); polygynous mating system (Zenuto et al. 1999), with expected

low sperm production (Zenuto et al. 2003); and various aspects of population genetic structure based on molecular markers, including effective population size (A. P. Cutrera, Lacey, and Busch 2006), kinship and dispersal (A. P. Cutrera et al. 2005), and demographic influences on selection (A. P. Cutrera and Lacey 2006, 2007; A. P. Cutrera, Lacey et al. 2010). Incisor procumbency is not the determinant factor during excavation, because the *masseter superficialis*, *masseter lateralis profundus*, *masseter medialis*, *temporalis*, *pterygoideus internus*, *pterygoideus externus*, *digastricus*, *acromiotrapezius*, *cleidomastoideus*, and *sternomastoideus* muscles assist the forelimbs in construction and compaction of tunnels (De Santis et al. 1998). Microstructure of incisor enamel indicates that incisors may assist in excavation and transportation and movement of obstacles in tunnels (Justo et al. 1995).

REMARKS: The nominotypical subspecies exhibits a polymorphic karyotype with diploid number varying from 44 to 48 (Kiblicky and Reig 1966; Bidau et al. 2000; Massarini et al. 2002). Populations of *C. t. antonii* have karyotypes of $2n = 48$ to 50 (Massarini et al. 1995; under the name *recessus*), and those of *C. t. occidentalis* are uniform at $2n = 48$ (Braggio et al. 1999). Sperm morphology is the simple symmetric type (Vitullo et al. 1988; Zenuto et al. 2003). De Santis et al. (2001) described enamel microstructure; Garcia Esponda et al. (2009) examined craniometric variation; and Mora, Cutrera et al. (2013) delineated his-

Map 478 Selected localities for *Ctenomys talarum* (●). Contour line = 2,000m.

torical demography through phylogeographic and population genetic analyses of mtDNA gene sequences.

It is possible that *C. talarum* is present in northeastern Buenos Aires province at Lima farther north than the type locality (Agnolín et al. 2010), but this claim needs confirmation.

Ctenomys torquatus Lichtenstein, 1830

Collared Tuco-tuco

SYNONYM:

Ctenomys torquatus Lichtenstein, 1830:plate 31, Fig. 1; type locality “Das Vaterland dieses Thiers sind die Südlichen Provinzen Brasiliens und die Ufer des Uruguay, wo es malwurfartig unter der Erde lebt” (see Remarks).

DESCRIPTION: Small; external measurements for males, head and body 167–230 mm, tail length 55–85 mm, hindfoot length 28–35 mm; for females, head and body 152–200 mm, tail length 60–83 mm, hindfoot length 29–33 mm (data for two Uruguayan samples; Langguth and Abella 1970). Dorsal color brownish-orange becoming clearer toward sides; whitish spots always present below and behind ears; ventral color pale brownish-orange, with whitish spots present in both inguinal and axillary regions; collar of pale brownish-orange present; basal portion of brown hairs dark gray, and that of whitish ones, white. Melanistic individuals reported for some populations (Fernandes et al. 2007). Skull much more curvilinear than that of *C. minutus*, with dorsal surface of frontal and parietal bones with small bulges and with temporal crests that converge near midline posteriorly without forming sagittal crest; nasals dorsally and longitudinally convex; dorsal border of foramen magnum with two processes, occasionally fused into single one; zygomatic arch dorsoventrally wider than in *C. minutus*; longitudinal crest on exterior face of zygomatic arch curvilinear with inferior concavity; ventral root of zygomatic process of maxilla almost perpendicular to major axis of skull; dorsal root approximately vertical; interpremaxillary foramen (J. E[ric]. Hill 1935) inconspicuous. Radius of arch described by incisors wider than in *C. minutus* such that incisors more proodont. Baculum relatively short (mean length 6.4 mm), broad, with proximal and distal tips rounded. Glans penis with sharp and convex dorsal spines, rounded and concave ventral spines; spine density 17.5/mm²; mean spine length 189.0 ± 23.9 μm s.d. (Rocha-Barbosa et al. 2013).

DISTRIBUTION: *Ctenomys torquatus* is distributed from southwestern Brazil in the state Rio Grande do Sul into neighboring Uruguay, in lowlands with fields and gallery forests termed *campos sulinos* (T. R. O. Freitas 1995b, 2006, Fernandes et al. 2007, 2009).

SELECTED LOCALITIES (Map 479): BRAZIL: Rio Grande do Sul, Alegrete (Fernandes et al. 2009), Butiá

(J. da Silva, Freitas, Heuser et al. 2000), Cachoeira do Sul (Fernandes et al. 2007), Candiota (J. da Silva, Freitas, Marinho et al. 2000), Dom Pedrito (Fernandes et al. 2009), General Câmara (Fernandes et al. 2009), Itaqui (Fernandes et al. 2009), Pelotas (J. da Silva, Freitas, Marinho et al. 2000), Quaraí (Fernandes et al. 2009), Rio Grande (Fernandes et al. 2009), Santa Maria (Fernandes et al. 2009), Taim (T. R. O. Freitas and Lessa 1984), Uruguaiiana (Fernandes et al. 2009). URUGUAY: Paysandú, Guabiyú (T. R. O. Freitas and Lessa 1984); Rivera, Cuñapirú (T. R. O. Freitas and Lessa 1984); Taquarembó, Ansina (T. R. O. Freitas and Lessa 1984).

SUBSPECIES: *Ctenomys torquatus* is monotypic, although it is chromosomally polytypic (see Remarks).

NATURAL HISTORY: Individuals of this species always construct burrows in sandy soils in open fields (Travi 1983), with the species found in cultivated fields, pastures, and vacant lots within the city of Montevideo (Barlow 1969). Burrow temperature is maintained constantly at 20–22°C (Weir 1974a). Gestation lasts 107 days on average (Weir 1974b), and litter size is 2–3 young (Nowak 1999). This species has been used as a native rodent monitor for environmental toxicity (J. da Silva, Freitas, Marinho et al. 2000; J. da Silva, Freitas, Heuser et al. 2000).

REMARKS: The type locality of *C. torquatus* is uncertain. Lichtenstein (1830) wrote that the animal came from “the southern provinces of Brazil on the shores of the Uruguay [River].” Moojen (1952b:188) repeated this same generalized locality as “margens do rio Uruguai, e estados do sul do Brasil.” Reig and Kibliskey (1969) regarded Maldonado, Uruguay, as the type locality, presumably based on the skull of “*Ctenomys torquatus*” from this locality illustrated by Nehring (1900c:203). However, only *C. pearsoni*, and not *C. torquatus*, occurs along the coast of Uruguay. And, finally, Langguth and Abella (1970) suggested that the type specimen came from southern Brazil near Lages, on the Alto Rio Pelotas in Santa Catarina state, but *C. torquatus*, as defined herein, does not occur in that area (see T. R. O. Freitas 1995, 2006).

T. R. O. Freitas and colleagues (T. R. O. Freitas and Lessa 1984; T. R. O. Freitas 1995, 2006; Fernandes et al. 2007, 2009) restricted *C. torquatus* to those populations in northern Uruguay and Rio Grande do Sul state, Brazil, with $2n = 40\text{--}46$, $FN = 72$, karyotypes. Samples allocated to this species from Entre Rios province, Argentina, and southern Uruguay with $2n = 56, 64, 68,$ and 70 (Reig et al. 1966; Reig and Kibliskey 1969; Kibliskey et al. 1977) are cranially distinct from the $2n = 40\text{--}46$ forms and were incorrectly assigned to *C. torquatus* (T. R. O. Freitas and Lessa 1984). A. F. Novello and Lessa (1986) subsequently identified the $2n = 56$ and $2n = 70$ individuals as *C. pearsoni* (see that account).

Map 479 Selected localities for *Ctenomys torquatus* (●).

Ctenomys tuconax Thomas, 1925

Robust Tuco-tuco

SYNONYM:

Ctenomys tuconax Thomas, 1925c:583; type locality “Concepción, 500 m,” Departamento Concepción, Tucumán, Argentina, 27°20’S, 63°35’W.

DESCRIPTION: Among largest and most robust species in genus; total length can reach 330 mm and mass nearly 600 g (A. I. Medina et al. 2007). Fur of medium length and rather thin. General color above uniformly dark chestnut, and back lacks darkened median line; under parts similar in color to back but paler, in some specimens approaching cinnamon; axillary white patches rarely present; head like body in color, without special markings, although top of head may be slightly darker and chin paler; hands and feet thinly haired and dull whitish above; tail pale brown. Skull very large, about equal in size to specimens of *C. opimus*, which it also resembles in shape; upper surface convex; supraorbital edges and processes, although well developed, not raised to level higher than midline of skull; nasals of medium size, not markedly narrowed posteriorly; zygomatic arches robust but not especially expanded laterally, nearly same degree as auditory meatal breadth; postorbital process of jugal of average size with small and shallow but fairly well-defined fossa on surface of bone in front of process; lambdoidal crest well developed, sharply defined, and projects forward mesially, then backward and then again forward laterally to form distinct W across skull; mesopterygoid fossa narrow and extends

forward to level of posterior third of M2; bullae not especially developed, less inflated than in *C. opimus*. Upper incisors broad, heavy, and slightly proodont, their angle about 107°. Cheek teeth strongly developed with anterior teeth proportionally larger.

DISTRIBUTION: *Ctenomys tuconax* occurs in the Yungas ecoregion of Tucumán province, Argentina. The species apparently inhabits two disjunct population nuclei in the Nevados de Aconquija, the southern extension of the Calchaquies Valleys, and the easternmost mountain range before the Chaco-Pampean flats, one at about 3,000 m elevation, and the other (including the type locality where the species may be extinct) in the lower Aconquija, between 262 and 469 m. Although Thomas (1925c) gives the elevation as 500 m, this is either an error or the species no longer occurs at low elevations.

SELECTED LOCALITIES (Map 480): ARGENTINA: Tucumán, Concepción (type locality of *Ctenomys tuconax* Thomas), El Infiernillo (MSUMMR 19212), La Calera (A. I. Medina et al. 2007).

SUBSPECIES: *Ctenomys tuconax* is monotypic.

NATURAL HISTORY: No ecological data are available.

REMARKS: Thomas (1925c:584) recognized this species on the basis of its large size and color, “being far larger than *C. tucumanus* and others of this neighbourhood, and is, indeed, but little surpassed by *C. boliviensis*. From *C. opimus* of the Bolivian plateau, which it most resembles in skull characters, it is distinguished by its uniform chestnut-

colour, widely different from that of the pale Bolivia animal.” Diploid chromosome number varies between 58 and 61, FN = 80 (Reig and Kiblicky 1968a, 1969; Slamovits et al. 2001). Sperm morphology is the simple asymmetric type (Bidau 2006).

Ctenomys tucumanus Thomas, 1900

Tucumán Tuco-tuco

SYNONYMS:

Ctenomys tucumanus Thomas, 1900f:301; type locality “Tucumán [San Miguel de Tucumán]. Altitude 450 m,” Departamento Capital, Tucumán, Argentina, 26°49’S, 65°13’W.

Ctenomys mendocinus tucumanus: Cabrera, 1961:553; name combination.

DESCRIPTION: Small to medium; external dimensions of holotype (old adult male) head and body length 172 mm, tail length 71 mm, and hindfoot length (with claw) 30.5 mm. General color above brownish fawn, with faint reddish suffusion; midline of face blackish; cheeks brownish fawn like back, with faint and lighter patch below the ear; under parts pale buffy, hairs gray basally; large white axillary and inguinal patches present, former almost extending across chest; upper surfaces of hands well haired and whitish, those of hindfeet nearly naked with few hairs white; tail practically naked, with few whitish hairs forming slight terminal crest. Near nakedness of hindfeet and tail possibly due to age and wear. Skull broad and flattened, much more so than in *C. mendocinus*; nasals evenly tapering backward, and terminating behind level of antorbital bridge; interorbital region and braincase flat, short, and broad no discernible interparietal; mesopterygoid fossa broad and open, more so than in other species.

DISTRIBUTION: *Ctenomys tucumanus* is known only from the type locality and immediate environs in Tucumán province, Argentina.

SELECTED LOCALITIES (Map 481): ARGENTINA: Tucumán, Camino Ticucho (Ortells 1995), San Miguel de Tucumán (type locality of *Ctenomys tucumanus* Thomas), Yerba Buena (J. R. Contreras 1999).

SUBSPECIES: *Ctenomys tucumanus* is monotypic.

NATURAL HISTORY: Populations occupy deep, humid soils in the piedmont and forest borders of Tucumán city (J. R. Contreras, pers. comm.). No other ecological, behavior, or other population data are known for this species.

REMARKS: Thomas (1900f) believed that *C. tucumanus* was most closely related to *C. talarum* from the coastal plain of Buenos Aires province, although it is geographically closest to *C. mendocinus*. Cabrera (1961), however, listed *tucumanus* as a valid subspecies in his concept of a polytypic *C. mendocinus*. Alternatively, Parada et al. (2011) placed this species in their “*tucuma-*

Map 480 Selected localities for *Ctenomys tuconax* (●). Contour line = 2,000 m.

Map 481 Selected localities for *Ctenomys tucumanus* (●). Contour line = 2,000 m.

Map 482 Selected localities for *Ctenomys tulduco* (●). Contour line = 2,000 m.

“*nus*” group, along with *C. argentinus*, *C. lato*, and *C. occultus*, based on mtDNA sequences. The karyotype of *C. tucumanus* is $2n = 28$ and $FN = 52$ (Reig and Kiblicky 1968a), and its sperm is of the simple symmetric type (Bidau 2006).

Ctenomys tulduco Thomas, 1921

Sierra Tontal Tuco-tuco, Tulduco

SYNONYMS:

Ctenomys tulduco Thomas, 1921i:218; type locality “Los Sombreros, Sierra Tontal, Alt. 2700 m,” Departamento Calingasta, San Juan, Argentina, $31^{\circ}33'S$, $69^{\circ}11'W$.

Ctenomys fulvus tulduco: Cabrera, 1961:549; name combination.

DESCRIPTION: Moderate sized with head and body length of holotype (adult male) 190 mm, tail length 69 mm, and hindfoot length 32.6 mm. General color above drabby gray, similar to that of *C. johannis*, and not as warm as that of *C. coludo*; ventral color strongly drabby as in *C. coludo* but unlike light undersurface of *C. johannis*; inconspicuous dull nasal patch present; tail short, with line along upper side black or blackish, varying in definition but always more pronounced than in allied species. Skull similar to that of *C. johannis*, but smaller and with rather smaller bullae, which are still far larger than those of *C. mendocinus*.

DISTRIBUTION: *Ctenomys tulduco* is known only from the vicinity of its type locality.

SELECTED LOCALITIES (Map 482): ARGENTINA: San Juan, Los Sombreros (type locality of *Ctenomys tulduco* Thomas), Pedernal (Thomas 1921i).

SUBSPECIES: *Ctenomys tulduco* is monotypic.

NATURAL HISTORY: No biological or ecological data are available for *C. tulduco*.

REMARKS: This species is similar, and possibly allied, to *C. coludo* although it is smaller (Thomas 1921i). Neither the karyotype nor sperm morphology is known.

Ctenomys validus J. R. Contreras, Roig, and Suzarte, 1977

Guaymallén Tuco-tuco

SYNONYM:

Ctenomys validus J. R. Contreras, Roig, and Suzarte, 1977: 160; type locality “El Algarrobal, Médanos del Borbollón, Departamento Guaymallén, Provincia de Mendoza,” Argentina, $32^{\circ}49'S$, $68^{\circ}46'W$, 775 m.

DESCRIPTION: Relatively large with total length and mass ranging from 281–314 mm and 187–341 g in males to 260–278 mm, 176–218 g in females (measurements of male holotype total length 296 mm, mass 312.4 g). General color grayish brown to yellowish brown, ventrally yellowish; conspicuous clear band between ears and through throat; hairs of feet and hands white, as in *C. coludo* and *C. johannis*; tail bicolored, yellowish ventrally, and with black longitudinal stripe dorsally. Skull large and robust with well-developed crests similar to those of *C. johan-*

nis; bullae large and moderately inflated; zygomatic arches strong; auditory meatus conspicuous; mesopterygoid fossa V-shaped; premaxillary bones extend posteriorly beyond nasals much more so than in *C. johannis*; interparietal sutures not visible in adult individuals; nasals widest at tips, narrowing posteriorly; skull achieves greatest depth at level of PM4; interpremaxillary foramen always visible; postorbital processes well developed, with frontal bones narrowing markedly behind. Upper cheek teeth moderately sized; occlusal surface of M3 cylindrical to subcylindrical in shape. In lower cheek teeth, pm4 similar to or smaller than m1. Baculum relatively large (length ca. 9 mm) and well ossified, ventrally flat, and slightly concave dorsally.

DISTRIBUTION: *Ctenomys validus* is only known from the type locality.

SELECTED LOCALITIES (Map 483): ARGENTINA: Mendoza, El Algarrobal (type locality of *Ctenomys validus* J. R. Contreras, Roig, and Suzarte).

SUBSPECIES: *Ctenomys validus* is monotypic.

NATURAL HISTORY: No biological or ecological data are available for *C. validus*.

REMARKS: J. R. Contreras et al. (1977) believed that *C. validus* was related to *C. johannis* Thomas, and with that species plus *C. coludo* Thomas, *C. famosus* Thomas, *C. tulduco* Thomas, and possibly *C. fulvus* Philippi formed an arc of precordilleran, inter-sierran, and Andean species that extended from Mendoza province north and west to the

Atacama of Chile. This hypothesis has yet to be tested by any character set. Karyotype and sperm type are unknown.

Ctenomys viperinus Thomas, 1926

Monte Tuco-tuco, Vipos Tuco-tuco

SYNONYMS:

Ctenomys viperinus Thomas, 1926d:605; type locality "Ñorco, near Vipos, 2500 m," Departamento Trancas, Tucumán, Argentina, 26°29'S, 65°22'W, 2,500 m.

Ctenomys knighti viperinus: Cabrera, 1961:550; name combination.

DESCRIPTION: Medium size with head and body length of holotype (adult male) 213 mm, tail length 76 mm, and hindfoot length 36 mm. General color warm brown above, paler and more drab below; many specimens with blackened muzzles and crowns, others lack these color features; majority of specimens with white axillary patches, and some have white inguinal spots. Skull somewhat small, with zygomata decidedly expanded and antorbital foramen widely open; bullae rather narrow; paroccipital processes less forwardly expanded on their lower surfaces. Upper incisors broad, enamel surfaces rather dark orange; incisive index of type 105°. PM4 considerably wider than M1.

DISTRIBUTION: *Ctenomys viperinus* is known from the type locality and neighboring areas between 320 and 2,500 m altitude in the *Yungas* ecoregion of Tucumán province, Argentina.

Map 483 Single known locality for *Ctenomys validus* (●). Contour line = 2,000 m.

Map 484 Selected localities for *Ctenomys viperinus* (●). Contour line = 2,000 m.

SELECTED LOCALITIES (Map 484): ARGENTINA: Tucumán, Ñorco (type locality of *Ctenomys viperinus* Thomas), Villa San Javier (A. I. Medina et al. 2007).

SUBSPECIES: *Ctenomys viperinus* is monotypic.

NATURAL HISTORY: No biological or ecological information is available for *C. viperinus*.

REMARKS: No data on karyotype or sperm morphology are available.

Ctenomys "yolandae" J. R. Contreras and Berry, 1984
Santa Fe Tuco-tuco, Yolanda's Tuco-tuco

SYNONYM:

Ctenomys yolandae J. R. Contreras and Berry, 1984:75; type locality, "Las Palmas, Departamento General Obligado, Provincia de Santa Fe," Argentina, 29°25'S, 59°40'W, 50 m; *nomen nudum* (see Remarks).

DESCRIPTION: Relatively small species (total length, ca. 230 mm) that has yet to be diagnosed or adequately described.

DISTRIBUTION: According to J. R. Contreras and Berry (1984), the species occurs in eastern Santa Fe province along the Paraná and San Javier rivers. This distribution is disjunct, separated by a low, floodable area unsuitable for colonization by tuco-tucos.

SELECTED LOCALITIES (Map 485; from J. R. Contreras, pers. comm., except as noted): ARGENTINA: Santa Fe, Cacique Ariacaiquín, Coronda, Helvecia, Las Palmas (J. R. Contreras and Berry 1984), Reconquista, San José del Rincón.

SUBSPECIES: *Ctenomys "yolandae"* is monotypic.

NATURAL HISTORY: No ecological data are available.

REMARKS: Woods and Kilpatrick (2005:1570) listed this taxon as a valid species. However, the name *Ctenomys "yolandae"* appeared originally only in a short abstract of presentations of a scientific meeting, and a formal designation of a holotype, diagnosis, and description has yet to be published. The name "yolandae" thus does not meet the criteria established by the International Code of Zoological Nomenclature (ICZN 1999:Art. 8) and is appropriately regarded as *nomen nudum*. Nevertheless, I list this taxon here as *C. "yolandae"* because this tuco-tuco is a distinct entity at both karyotypic (Ortells et al. 1990; Bidau et al. 2005) and molecular (Mascheretti et al. 2000) levels. In the latter case, mtDNA studies determined the phyletic proximity of *C. "yolandae"* with *C. bergi* and *C. bonettoi*, as might be expected from their morphological similarities. Furthermore, *C. "yolandae"* possesses a unique type of sperm, the complex asymmetric morphology, not found in any other tuco-tuco (Vitullo et al. 1988). The diploid number is $2n = 50$, $FN = 78$, in specimens from the type locality (Ortells et al. 1990), and $2n = 50$, $FN = 67, 70$ (Bidau et al. 2005) elsewhere. A proper description of this species is needed to validate the name.

Map 485 Selected localities for *Ctenomys "yolandae"* (●). Contour line = 2,000 m.

Family Echimyidae Gray, 1825

Louise H. Emmons, Yuri L. R. Leite, and James L. Patton

The family Echimyidae is the most diverse of the South American hystricognath rodent families, both with regard to numbers of taxa and variety of body plans (see, for example, S. I. Perez et al. 2009; Upham and Patterson 2012; P.-H. Fabre et al. 2012). The taxonomic history has been chaotic, with a number of generic names proposed, several abandoned, and the contents of both the family and genera highly unstable. Recent reviews and phylogenetic analyses (Lara et al. 1996; Y. L. R. Leite and Patton 2002; G. A. S. Carvalho and Salles 2004; Emmons 2005; Galewski et al. 2005; Iack-Ximenes et al. 2005a,b; Upham and Patterson 2012; P.-H. Fabre et al. 2012; Upham et al. 2013) have clarified relationships, and thus membership within the family, as well as both genus and species boundaries. Although great clarity has been achieved by these studies, much remains to be understood about the composition and evolutionary history of the family at all taxonomic levels.

The family Echimyidae is of ancient origin in South America, found among the oldest fossil rodents, with the earliest records from the mid-Eocene (Antoine et al. 2012) and Oligocene (B. Patterson and Wood 1982; Vucetich and Verzi 1991; Deschamps et al. 2012). Recent work documents a

diverse fauna of largely grassland (pampa) echimyids in the Miocene (Vucetich et al. 1993) as well as a rich assemblage of taxa from presumptively tropical forest habitats at the eastern base of the Andes (Frailey and Campbell 2004). Molecular-based estimates place the diversification of extant lineages in the Miocene, between 18.8 mya (95% credibility interval 20.2–17.5 mya; P.-H. Fabre et al. 2012) and 16.0 mya (21.7–11.3 mya; Upham et al. 2013).

Unfortunately, most extant taxa lack a fossil record altogether, and few of these genera can be tied phylogenetically to any of the more than 20 fossil genera currently recognized (G. A. S. Carvalho and Salles 2004; but see Candela and Rasia 2012; Deschamps et al. 2012; and Olivares et al. 2012 for current efforts to connect fossil and extant genera within a phylogenetic framework). The family is currently divided into three or four subfamilies. The living Eumysopinae (or Heteropsomyinae, see Patton and Reig 1990) includes six extant genera of terrestrial species and two of arboreal ones, with greatest generic diversity among grassland or shrubland taxa, but greatest species number in the rainforest genus *Proechimys*. There are three genera of specialized arboreal folivores in the Dactylomyinae, all denizens of lowland and montane forests. The Echimyinae contains four to nine genera of arboreal rats of forested or wooded habitats; we recognize nine genera here. Following recent molecular studies (Galewski et al. 2005; Opazo 2005; Rowe et al. 2010; Upham and Patterson 2012; P.-H. Fabre et al. 2012; Upham et al. 2013), we regard the Myocastorinae as a fourth subfamily of the Echimyidae.

Phylogenetic support for the traditional subfamily structure as well as relationships among genera within each remains uncertain. Part of this uncertainty results from the lack of inclusion of all extant genera in any character-based analysis, be it morphological or molecular, and also likely from the apparent very rapid diversification of the Recent lineages (Lara et al. 1996; Y. L. R. Leite and Patton 2002). For example, analyses of both morphological (G. A. S. Carvalho and Salles 2004; Emmons 2005; Candela and Rasia 2012) and molecular traits (Lara et al. 1996; Y. L. R. Leite and Patton 2002; Galewski et al. 2005; P.-H. Fabre et al. 2012; Upham et al. 2013) have so far failed to recover either the Eumysopinae or Echimyinae as monophyletic units. Although each of these analyses supports the monophyly of the Dactylomyinae, this group of three genera appears nested among the remaining extant echimyine genera. Furthermore, the most recent molecular analyses support the phylogenetic of the spiny tree rats *Mesomys* and *Lonchothrix*, two genera that combine echimyine and eumysopine characters (see those accounts) with the echimyine tree rats (P.-H. Fabre et al. 2012; Upham et al. 2013). Thus, the allocation of genera into phylogenetically well-supported suprageneric taxa remains a challenge for

students of echimyid rodents. Given the important representation of teeth in the fossil record, the posited occlusal character homologies proposed by Candela and Rasia (2012) are noteworthy, especially for the integration of the diverse fossil and extant taxa into a coherent set of hypothesis of relationships as well as rates and timing of lineage diversification.

The following synopsis of the nomenclatural history of the family Echimyidae is based largely on G. A. S. Carvalho and Salles (2004) and Emmons (2005). Zimmermann (1780) described the first echimyid, *Myoxus chrysurus*, placing it within a European rodent genus as was typical of that period. *Echimys* was the first echimyid genus, defined by F. Cuvier in 1809 and in which he placed the “*lérot à queue dorée*” of Allamand (= *Echimys chrysurus*) and the “*rat épineux*” of Azara (= *Euryzygomatomys spinosus*). Desmarest (1817b), crediting names to É. Geoffroy St.-Hilaire, described six new echimyids, placing these along with *Echimys chrysurus* (which he called *E. cristatus*) in the genus *Echimys*. Desmarest’s concept of *Echimys* thus included both the type species of *Echimys* and six additional species now allocated to other genera: *E. dactylinus* (a *Dactylomys*), *E. spinosus* (a *Euryzygomatomys*), *E. hispidus* (a *Mesomys*), *E. didelphoides* (a *Makalata*), *E. cayennensis* (a *Proechimys*), and *E. setosus* (a *Trinomys*). Isidore Geoffroy St.-Hilaire (1838, 1840) divided the genus *Echimys*, as viewed by Desmarest, into three genera: *Dactylomys* (including only *D. dactylinus*), *Echimys* (including *E. setosus*, *E. albispinus*, *E. myosurus* [all three *Trinomys*], *E. cayennensis* [a *Proechimys*], *E. hispidus* [a *Mesomys*], and *E. spinosus* [a *Euryzygomatomys*]), and *Nelomys* (including *N. cristatus* [= *Echimys chrysurus*] and *N. paleaceus* [an *Echimys*], *N. semivillosus* [a *Pattonomys*], *N. blainvillii* [a *Phyllomys*], and *N. armatus* and *N. didelphoides* [both *Makalata*]). In these two works, I. Geoffroy St.-Hilaire established the basis for the subsequent division of extant echimyids into the three subfamilies (Dactylomyinae, Echimyinae, and Eumysopinae) recognized in most modern classifications.

Tate (1935) sifted through 150 years of publications in a heroic review of the taxonomic history of all caviomorph rodents. He reconciled many nomenclatural discrepancies and proposed a revised generic classification, but he did not provide an extensive review of characters. His interpretation of the Echimyidae, in which he segregated the species of *Echimys* largely on the degree of hairiness of the tail, left many unresolved questions. With the major exception of Ellerman (1940), who placed nine subfamilies within his concept of the Echimyidae (including both New World [Abrocomidae, Capromyidae, Octodontidae] and Old World [Petromuridae, Thryonomyidae] groups now widely recognized as separate families), Tate’s classification

was adopted by most systematists until Cabrera (1961) again reviewed the family along with all other South American mammals and synonymized many names with little or no explanation. More recently, Emmons and Feer (1990, 1997) proposed some revisions of genera in field guide format, without explanation, including segregating *Nelomys* (now *Phyllomys*) from *Echimys*, and allocated additional species to *Makalata*. Patton and Emmons (1985) reviewed the genus *Isothrix*, from which Emmons and Vucetich (1998) subsequently segregated a new genus, *Callistomys*. Emmons, Leite et al. (2002) and Y. L. R. Leite (2003) revised the Brazilian Atlantic tree rats *Phyllomys* and documented that the name *Nelomys* had been incorrectly applied to this taxon. Emmons (1997a) presented an outline of many of the characters that diagnose the arboreal echimyines, and she later thoroughly documented both systematic and nomenclatural conclusions of that initial report (Emmons 2005), describing two new genera (*Pattonomys* and *Santamartamys*). Iack-Ximenes et al. (2005a) placed *Loncheres grandis* Wagner into the new genus *Toromys*, while commenting on characters and other taxonomic issues particularly within *Echimys*.

G. A. S. Carvalho and Salles (2004) examined all extant as well as a rich assemblage of fossil genera and delineated 50 morphological traits that they then used to provide a phylogenetic hypothesis of generic relationships. They defined and diagnosed the crown-group Echimyidae and presented a classification encompassing both Recent and extinct genera and subfamilies based on their phylogenetic hypothesis. Independently, Emmons (2005) also undertook the characterization and phylogenetic analysis of morphological characters, and reached the same set of conclusions. She also thoroughly diagnosed the subfamilies and all genera she included within the Echimyinae, which was the emphasis of her work. Lara et al. (1996), Y. L. R. Leite and Patton (2002), Galewski et al. (2005), Upham and Patterson (2012), P.-H. Fabre et al. (2012), and Upham et al. (2013) have each examined mitochondrial and nuclear gene sequence variation among 14 to 16 extant genera. A common conclusion of both morphological and most molecular analyses has been the inclusion of *Myocastor* within the Echimyidae as the monotypic subfamily Myocastorinae. Woods and Kilpatrick (2005), in their more recent classification of the Hystricomorpha, did not follow this position. Another consistent component of both morphological and molecular analyses has been a difficulty in corroborating reciprocally monophyletic assemblages of genera within both the subfamilies Echimyinae and Eumysopinae. The three genera that comprise the Dactylomyiinae (*Dactylomys*, *Kannabateomys*, and *Olallamys*) do form a monophyletic unit, but this group is otherwise nested among genera of the Echimyinae. Among the ex-

tant Eumysopinae, clades comprising *Clyomys* + *Euryzygomatomys* + *Carterodon* are consistently recovered (but see Vucetich and Verzi 1991, who do not include *Carterodon* in a sister relationship with both *Clyomys* and *Euryzygomatomys*), whereas *Proechimys* + *Hoplomys* + *Thrichomys* + *Trinomys* are linked with morphological but not always with molecular support. These two clades together lack any support as the monophyletic group that would be hypothesized by their inclusion in the same subfamily. Furthermore, while *Mesomys* + *Lonchothrix*, commonly placed within the Eumysopinae because of shared dental characters, appear to be phyletically related by molecular analyses to various echimyine and dactylomyine genera (Upham and Patterson 2012; P.-H. Fabre et al. 2012; Upham et al. 2013). Most phyletic relationships based either on morphology or gene sequences are, however, for the most part weakly supported, and a fully resolved phylogenetic hypothesis and resulting classification must await further data and analyses.

Herein, we follow G. A. S. Carvalho and Salles (2004) in their concept of the crown-group Echimyidae to include four subfamilies, two monophyletic (Dactylomyiinae and Myocastorinae), one paraphyletic (Echimyinae), and the fourth apparently either paraphyletic or polyphyletic (Eumysopinae) (see also Olivares et al. 2012). We keep these apparently nonphylogenetic groupings for convenience until a more completely resolved phylogeny is forthcoming. We exclude the Antillean Capromyidae (contra Y. L. R. Leite and Patton 2002; but see Galewski et al. 2005; Kilpatrick et al. 2012; P.-H. Fabre et al. 2012; Upham et al. 2013), which appears to be the sister to the Echimyidae (Huchon and Douzery 2001; Galewski et al. 2005; Rowe et al. 2010) or part of an unresolved polytomy at the base of the echimid radiation (P.-H. Fabre et al. 2012). We also exclude the bristle-spined porcupine *Chaetomys* (contra B. Patterson and Wood 1982; Woods 1993) because this genus unambiguously belongs to the family Erethizontidae (T. Martin 1994; G. A. S. Carvalho 2000; R. do V. Vilela et al. 2009; Voss et al. 2013). Emmons (2005) placed the three subfossorial genera (*Euryzygomatomys*, *Clyomys*, and *Carterodon*) in the tribe Euryzygomatomini within the subfamily Eumysopinae. Given the lack of documented equivalency in rank for other generic assemblages in this subfamily or others, we follow G. A. S. Carvalho and Salles (2004) and do not use tribal groupings.

The crown-group Echimyidae is diagnosed by six transformations (G. A. S. Carvalho and Salles 2004): presence of the central portion of the neolophid in dpm4; absence of the metalophid in m1–3; shallow or absent lingual opening of the mesoflexid in little-worn m1–3; shallow or absent labial opening of the mesoflexus in little-worn upper teeth;

retention of the deciduous premolar throughout life; and presence of well-developed sphenopalatine vacuities.

KEY TO THE SUBFAMILIES OF ECHIMYIDAE:

1. Large (mass >5 kg); hindfeet with interdigital webbing; pelage with long, coarse guard hairs over thick, soft underfur; maxillary teeth with two to three labial and three lingual flexi; teeth increasing in size from front to back; paroccipital process greatly elongated, vertical, and completely free from bulla Myocastorinae
- 1'. Smaller (mass <1 kg); hindfeet lack interdigital webbing; pelage soft or spiny and not divided into obvious elongated guard hairs covering dense underfur; maxillary teeth with typically only one lingual flexus with labial flexi varying from two to four; teeth either uniform or decreasing in size from front to back; paroccipital process short and curved to follow contour of bulla 2
2. Digits of forefeet and hindfeet elongate and slender; plantar surfaces without distinct pads; maxillary tooththrows diverge posteriorly; maxillary teeth with three labial and one lingual flexi Dactylomyinae
- 2'. Digits of forefeet and hindfeet not elongate and slender; plantar surfaces with distinct pads; maxillary tooththrows parallel; maxillary cheek teeth with variable number of labial and lingual flexi or with transverse laminar plates 3
3. Maxillary cheek teeth rounded in occlusal view; labial and lingual flexi do not coalesce to form transverse laminar plates Eumysopinae
- 3'. Maxillary cheek teeth rectangular in occlusal view; labial and lingual flexi combining to form variable number of transverse laminar plates Echimyinae

Subfamily Dactylomyinae Tate, 1935

Louise H. Emmons, James L. Patton, and Yuri L. R. Leite

The Dactylomyinae comprise three genera, each confined to the major tropical forest regions of South America: *Dactylomys* is distributed in elfin forests of the eastern central Andean slopes, throughout lowland rainforest of the Amazon Basin, and gallery forests in the eastern Cerrado of central Brazil; *Kannabateomys* occurs in coastal and montane Atlantic Forest of Brazil south to Argentina; and *Olallamys* has a limited range in montane forests of the northern Andes in Colombia and Venezuela. Bamboo patches form a dominant component of the habitat and, where diet is known, all taxa feed chiefly on bamboo leaves and shoots (but see Emmons 1981).

These are moderate-sized, folivorous rodents adapted to an arboreal habitus. The pelage lacks spines or bristles. The tail is typically much longer than head and body

length, and may be naked or covered with sparse fur. Both forefeet and hindfeet lack raised, smooth plantar pads; rather, the plantar skin of both manus and pes is evenly and densely covered with tiny tubercles. The toes are elongate and slender, with the middle two digits especially elongated relative to lateral ones in *Dactylomys* and *Kannabateomys*.

The skulls of all three genera share the same essential cranial and dental characters, except as noted. Rostra are short and broad; the interorbital region is broad, approximately equal to the braincase breadth, and edged with overhanging ledges that possess weak postorbital processes. Incisive foramina are small to nearly obsolete. The palate is narrow and maxillary tooththrows diverge posteriorly, more strongly so in *Dactylomys* and *Olallamys* than in *Kannabateomys*. Cheek teeth are brachydont, with four roots and with occlusal surfaces in approximately the same plane as the palate. Maxillary cheek teeth are very large, wider than the greatest palatal width, and split by three deep labial flexi and a single lingual flexus. In *Dactylomys* and *Olallamys*, the hypoflexi and mesoflexi coalesce so that the four lophi form two independent V- or Y-shaped pairs. In *Kannabateomys*, a mure connects the protoloph and metaloph so that the hypoflexi and mesoflexi do not unite, although the same general V- or Y-shaped pairs of lophi are apparent. The lower molars have two lingual flexids and one labial flexid. In *Kannabateomys*, these remain separate, but in *Dactylomys* and *Olallamys* the hypoflexids and metaflexids unite to form an anterior V-shaped loph and a single, posterior laminar loph. The alisphenoid bone has a reduced or no bony bridge extending from the foramen ovale to the basisphenoid posterior to base of parapterygoid processes. Paroccipital processes are free from bullar contact but curved over the bullae; in occipital view, these processes are angled laterally rather than vertically.

The first molecular phylogenetic study to include all three genera (Upham et al. 2013) suggests either that the Colombian *Olallamys* and the Atlantic Forest *Kannabateomys* form a sister group relative to *Dactylomys* or that the three genera are part of an unresolved trichotomy. The basal age of the radiation has been posited to be as old as 10.2 mya (Upham and Patterson 2012) or as recent as 3.5 mya (Leite and Patton 2002).

KEY TO THE GENERA OF DACTYLOMYINAE:

1. Maxillary tooththrows nearly parallel; zygomatic arches widest anteriorly; confined to Atlantic Forest *Kannabateomys*
- 1'. Maxillary tooththrows converge sharply anteriorly; zygomatic arches widest posteriorly; do not occur in Atlantic Forest 2

2. Digits 3 and 4 of forefeet and hindfeet elongated, with nails on all digits; greatest breadth across zygomatic arches >30 mm; minimum interorbital breadth >16 mm; found on east slope of central Andes, Amazon Basin, and gallery forests of Cerrado. *Dactylomys*
- 2'. Digits 3 and 4 of forefeet and hindfeet not especially elongated, with claws on all digits; greatest breadth across zygomatic arches <30 mm; minimum interorbital width <15.5 mm; range in northern Andes . . . *Olallamys*

Genus *Dactylomys* I. Geoffroy St.-Hilaire, 1838

Dactylomys are moderate-sized (mass up to 700 g) arboreal rats with nonspiny fur, long tails (typically >120% head and body length), feet with elongated central toes and pointed nails on all digits, and large, partially laminated cheek teeth that greatly restrict the anterior palate and diverge sharply posteriorly. There is a gap between the fourth and fifth toes of the hindfoot that permits the fifth toe to be used in opposition to the others to grasp thin stems, which may also be held between the middle toes. Despite their conspicuous size and morphology, their remarkable and loud vocalizations (Emmons 1981), and the strong, musky odor that permeates their living areas, *Dactylomys* are among the more poorly known and only rarely collected members of the family. They are folivores that do not readily enter traps, because of the baits commonly used or for other, unknown reasons. Their weak eye-shine and slow, methodical movements make them difficult to see at night (Emmons 1981; Emmons and Feer 1997). The vernacular name bamboo rat stems from their characteristic association with patches of bamboo, apparently a major food item, but they also occur in riverine vegetation, especially in canebrakes, and in upland forest on the rich soils of western Amazonia as well as on the intermediate slopes of the eastern Peruvian Andes. They are typically absent from black-water riverine communities.

Two or three species are recognized in the recent literature (Woods 1993; Emmons and Feer 1990, 1997; Patton et al. 2000). One of these (*D. peruanus*) occurs in the upper elevation elfin forests on the eastern slope of the Andes in Peru and Bolivia, and is unique in its fully furred tail. Two other species occur in the lowland rainforest of the Amazon Basin and gallery forests south of the Amazon, but character variation and geographic ranges of both are uncertain. Patton et al. (2000) reviewed the characters and geographic distribution of populations in western Amazonian Brazil, and recognized two species (*D. dactylinus* and *D. boliviensis*) based on concordant craniodental characters, vocal call-note, and mtDNA sequences. We follow this assessment in the accounts that follow, but the degree

of concordant color and vocal characters appears to vary geographically. The selected localities and maps we provide are based on the assignment of museum specimens by color pattern because this character can be assessed for all such specimens. It remains to be determined whether color alone is an adequate diagnosis for these two species; a complete geographic review of all characters, but especially the relationship between call structure and morphological and genetic attributes, remains an important area of future research.

SYNONYMS:

Echimys: Desmarest, 1817b:54; part (description of *dactylinus*); not *Echimys* F. Cuvier.

Dactylomys I. Geoffroy St.-Hilaire, 1838a:888; type species *Dactylomys typus* I. Geoffroy St.-Hilaire (= *Echimys dactylinus* Desmarest, 1817b:54), by original designation.

Lachnomys Thomas, 1916e:299; defined as a subgenus of *Dactylomys*; type species *Dactylomys peruanus* J. A. Allen, by original designation.

Dactylinus Anthony, 1920:83; incorrect subsequent emendation of *Dactylomys* I. Geoffroy St.-Hilaire.

REMARKS: As noted by Emmons, Leite et al. (2002), the original generic description of *Dactylomys* by Geoffroy St.-Hilaire was published in four different French journals in 1838. Following Article 24.2.1 of the International Code (ICZN 1999), Emmons, Leite et al. (2002) fixed the account in the *Comptes Rendus Hebdomadaires des Séances de L'Académie des Sciences* 6(26):884–888 as the first publication.

KEY TO THE SPECIES OF *DACTYLOMYS*:

1. Tail naked; pelage coarse. 2
- 1'. Tail furred to tip; pelage long, soft, and dense
. *Dactylomys peruanus*
2. Upper parts fairly uniform dark olivaceous, thighs and tail base little, if at all, tinged rusty, top of head with white banded hairs forming pale streaks above and below the eyes, and usually with an olivaceous-black stripe darkening from crown to nape; undercolor of back blackish *Dactylomys boliviensis*
- 2'. Top of head and muzzle pale to medium brown with unbanded hairs above eyes and to well down neck, gradually darkening to the nape; rear of thighs and tail-base rusty orange; undercolor of back black to chestnut . . .
. *Dactylomys dactylinus*

Dactylomys boliviensis Anthony, 1920

Bolivian Bamboo Rat

SYNONYM:

Dactylomys boliviensis Anthony, 1920:82; type locality "Mission San Antonio, Rio Chmore [*sic*, Chimoré], Prov. Cochabamba, Bolivia; altitude 1300 feet."

DESCRIPTION: Large olivaceous rat (head and body length about 270 mm), with very long tail (about 150% of head and body length), long hindfeet (>60 mm), and short ears (about 20 mm). Dorsal color tones more muted than in *D. dactylinus*; grizzled grayish-olivaceous streaked with black, becoming paler on sides, and gradually merging with sparsely furred, pure white venter; face distinctly grizzled gray with white banded hairs above and below eyes and with olivaceous black stripe bordered by pale-tipped hairs extends on midline from nose posteriorly between ears to nape, darkening progressively to blackish brown from above eyes to neck, but in some samples black not pronounced. Mystacial vibrissae in some samples short, extending only to one-half length of superciliary vibrissae, in contrast to much longer mystacial vibrissae of *D. dactylinus*. Tail with well-furred base that extends for about 65 mm; it is heavily scaled and naked in appearance from furred base to tip, but scales appear finer, averaging six annuli per cm near tail base and 7.5 per cm near tip, and less distinctly pentagonal than those of *D. dactylinus*; each caudal scale-hair distinctly dark brown or black over basal half, becoming completely colorless along terminal half to third of tail; median hair extends 1.5–2.0 scale rows. Tail bicolored, especially over anterior two-thirds of its length, but with broad, dark dorsal surface becoming gradually paler toward tip.

Skull large, rostrum short and broad, and supraorbital ledges proportionally broader than in other species but, with these others, form subtriangular postorbital processes. Skull differs from that of *D. dactylinus* in that paroccipital processes more anteriorly directed, following curvature of tympanic bullae, and postorbital process of zygomatic arch composed primarily of jugal. Cheek teeth of both upper and lower jaws are as in the other species.

DISTRIBUTION: Southwestern margins of the Amazon Basin, from central Peru south to central Bolivia, and east as far as the central Rio Juruá in western Brazil. This range is largely, but not exclusively, coincidental with the large area of bamboo (primarily *Guadua* spp.) dominated forest in the western Amazon (see J. M. Jacobs and von May 2012). In general, this species seems to occur at higher elevations than *D. dactylinus* or is restricted to the headwaters where the two species co-occur in the same river basin.

SELECTED LOCALITIES (Map 486): BOLIVIA: Cochabamba, Mission San Antonio, Rio Chimoré; La Paz, La Reserva (AMNH 264884). BRAZIL: Acre, Fazenda Santa Fé (= Flora), left bank Rio Juruá (Patton et al. 2000). PERU: Ayacucho, Hda. Luisiana (LSUMZ 16761); Cusco, Consuelo, 15.9 km SW of Pilcopata (FMNH 175250), Quincemil (FMNH 65680), 2 km SW of Tangoshiari (USNM 588070); Madre de Dios, Tambopata (Emmons

1981); Ucayali, Balta, Río Curanja (LSUMZ 12422), Sepahua (MVZ 173099).

SUBSPECIES: *Dactylomys boliviensis* is monotypic.

NATURAL HISTORY: Summaries of reproduction, ecology, and behavior of *D. boliviensis* are given in Emmons (1981; Peruvian animals mentioned are now assigned to this species) and Dunnum and Salazar-Bravo (2004). Habitat includes bamboo and cane thickets typically along river margins (Salazar-Bravo et al. 1994; Patton et al. 2000). Adaptations for arboreal browsing are detailed by Emmons (1981). High pulse number that ranges from a mean of 20 to 44 characterize staccato vocalizations (Emmons 1981; M. N. F. da Silva and Patton 1993). Pregnant females were recorded in July at La Reserva in Bolivia (Salazar-Bravo et al. 1994).

REMARKS: Calouro (1999) reported bamboo rats from four localities on the Brazilian side of the Serra do Divisor in the upper Rio Juruá basin of Acre state, assigning these sightings to *D. dactylinus*. These records most likely represent *D. boliviensis*, given the analyses presented by Patton et al. (2000) which were also based on specimens from the upper Rio Juruá.

Dunnum et al. (2001) described a chromosome complement with $2n = 118$ and $FN = 168$, the highest diploid number known for any mammal. Didier (1962) figured and described the baculum of a specimen from southeastern Peru, which averaged 3 mm longer than that of a specimen of *D. dactylinus* from northern Peru.

Map 486 Selected localities for *Dactylomys boliviensis* (●). Contour line = 2,000 m.

Dactylomys dactylinus (Desmarest, 1817)

Amazon Bamboo Rat

SYNONYMS:

Echimys dactylinus Desmarest, 1817b:54; type locality not given; restricted to "Upper Amazon area" (Thomas 1912d:88); see Remarks.

Dactylomys dactylinus: I. Geoffroy St.-Hilaire, 1838a:888; first use of current name combination.

Dactylomys typus I. Geoffroy St.-Hilaire, 1838a:888; type locality "l'Amérique méridionale, probablement le Brésil"; a renaming of *Echimys dactylinus* Desmarest, 1817.

D[*dactylomys*]. *dactylinus*: J. A. Allen, 1900a:221; name combination.

Dactylomys dactylinus canescens Thomas, 1912d:87; type locality "Itacoatiara, below Manaus [=Manaus], Middle Amazons," Amazonas, Brazil.

D[*dactylomys*]. *dactylomys* J. A. Allen, 1914c:389; incorrect subsequent spelling of *dactylinus* Desmarest.

Dactylomys dactylinus dactylinus: J. A. Allen, 1916b:208; name combination.

Dactylomys dactylinus modestus Lönnberg, 1921:38; type locality "on the banks of the river Curaray, El Oriente, Ecuador, 1,000ft," presumably Pastaza.

DESCRIPTION: Large olivaceous to yellowish rat; head and body length about 315 mm, with long tail (about 125% head and body length), long hindfeet (>60 mm), and short ears (about 20 mm). Face pale tannin or umber-brown, without white bands on hairs above eyes; self-colored hairs extend above and below eyes, nose, and over rostrum, gradually darkening to blackish, red, or chestnut between ears and posteriorly onto neck. This stripe contrasts sharply with grizzled yellowish to blackish dorsum, which is streaked with black hairs (see Patton et al. 2000:177, Fig. 116). Dorsal hairs chestnut or black at their bases, with subterminal black band and yellow or pale yellow tips. Sides become progressively more fulvous, with posterior thighs and sides of tail base bright burnt orange. Mid-dorsal hairs are of two types: Heavier and longer hairs bicolored, black basally with short pale yellow tip; more abundant thinner hairs blackish or reddish basally with short dark tips. Venter sparsely covered with completely white hairs. Tail base fully haired for about 60 mm, then appears naked to tip; not bicolored at base. Scales large, prominent, pentagonal, and coarse in appearance; average about five annuli per cm near base to six per cm at tip; scale hairs appear correspondingly shorter, extending less than 1.5 scale rows. All scale hairs colorless along entire length of tail distal to furred base.

Skull large, with short rostrum and broad, well-developed supraorbital ledges that form subtriangular postorbital processes; paroccipital processes more vertically oriented than

in *D. boliviensis*, and thus not following contour of bullae as closely.

DISTRIBUTION: *Dactylomys dactylinus* is distributed in the Amazon Basin from eastern Colombia south through eastern Ecuador, northern and central Peru to northeastern Bolivia and east along the Amazon River to its mouth in Brazil, extending north into the headwaters of the Río Orinoco in Venezuela and south through gallery forests along Amazonian tributaries into the eastern Cerrado of Brazil.

SELECTED LOCALITIES (Map 487): BOLIVIA: El Beni, 4 km S of Guayaramerin (AMNH 210356); Pando, Ingavi, N bank of Río Orton (USNM 579620). BRAZIL: Amazonas, Borba (AMNH 91865); Colocação Vira-Volta, left bank Rio Juruá (Patton et al. 2000), Ilha das Onças (Patton et al. 2000), right bank Rio Purus (Patton et al. 2000); Pará, 52 km SSW of Altamira, right bank Rio Xingu (USNM 549596), Fazenda Santana, Ilha Mexiana (Silva-Júnior and Nuñez 2000), Fordlândia (FMNH 92916), Reserva Biológica de Trombetas (H. Sick 31573), Serra dos Carajás (Moraes-Santos et al. 1999); Goiás, Usina Hidroelétrica Serra da Mesa (Bezerra Silva, and Marinho-Filho 2007); Maranhão, Palmeiral, Matões (Silva-Júnior and Nunes 2000); Roraima, Caracará (MPEG 6766). COLOMBIA: Meta, Serranía de La Macarena (ICN 2013), Villavicencio (J. A. Allen 1916b). ECUADOR: Pastaza, Montalvo (FMNH 41471); Sucumbios, Limoncocha (USNM 528370). PERU: Loreto, Orosa (AMNH 73771), Sarayacu (AMNH 76427); Ucayali, Yarinacocha (FMNH 55501). VENEZUELA: Amazonas, Coyowateri (C. Molina et al. 1995), Río Siapa (Ojasti et al. 1992; C. Molina et al. 1995).

SUBSPECIES: Whether both *modestus* Lönnberg and *canescens* Thomas represent valid geographic variants of *D. dactylinus* or whether other species should be segregated from the genus must await confirmation of the true locality of Desmarest's holotype and an appropriate analysis of geographic variation in both morphology, call structure, and molecules over the known range of this species. We, therefore, treat *D. dactylinus* as monotypic and list both *canescens* Thomas and *modestus* Lönnberg as synonyms.

NATURAL HISTORY: This species typically inhabits bamboo and cane thickets on the margins of seasonally inundated and upland rainforest, or in Ecuador only, the canopy of tall forests (LaVal 1976; Emmons 1981 [Ecuador material only]). Few data are available on reproductive biology, although pregnant females have been reported at the end of the rainy season in June, in the central Amazon (Patton et al. 2000). These are vocal rats, with calls composed of staccato pulses in series of 5 to 10 notes in the southwestern and central Amazon (mean = 7; Patton et al. 2000), but in Ecuador of a mean of 42 pulses was emitted

during 14-second calls (Emmons 1981). Calls of *D. boliviensis* from Peru (Manu) had longer individual pulses with longer interpulse intervals than those of *D. dactylinus* from Ecuador, but without much difference in pulse numbers (Emmons 1981). An adequate understanding of geographic variation in call structure is needed for both species.

REMARKS: Thomas's (1912d) restriction of the type locality to the upper Amazon is probably in error. Lönnberg (1921) suggested that Desmarest's holotype in the Muséum National d'Histoire Naturelle in Paris came from somewhere downriver from Iquitos in northwestern Peru. When Deville (1852) named the genus, he used both Desmarest's holotype in Paris and three additional specimens (male, female, and young) collected by the Castelnau expedition, of which Deville was a part, at "La Mission de Sarayacu, rivière de l'Ucayale, Pampa del Sacramento." He noted that the holotype was in very poor condition, and he described it as having fur varying red-brown, black, and fawn (fauve) above, with a small crest of reddish brown on the head. He described the Ucayali specimens as red, brown, and black above, tawny (fauve) red on the flanks, clear red on the outer hind thighs, and with a small crest of stiff reddish hairs on the head and nose. These specimens clearly differ in coloration from both *modestus* Lönnberg and *boliviensis* Anthony as detailed in the original descriptions of each of these taxa. We assign specimens from Limoncocha on the Río Napo in Ecuador to *D. dactylinus*, as these correspond to the description of *D. d. modestus* (Lönnberg 1921). Specimens from the Napo have black underfur and a short self-colored brown crown patch that ends at the level of the ears, with some black hairs above the ears. However, other specimens from further east along the Rio Xingu in Brazil also have

Map 487 Selected localities for *Dactylomys dactylinus* (●). Contour line = 2,000 m.

similar coloration. Aniskin (1993) described a chromosome complement of $2n=94$, $FN=144$, for specimens assigned to this species from the Loreto in northern Peru. As we have not seen these specimens, nor are they described in Aniskin's report, we cannot verify their identification. Didier (1962) described and figured the baculum based on a specimen from northern Peru. O. J. Linares (1998) tentatively assigned specimens from southern Venezuela to the subspecies *canescens* Thomas.

Dactylomys peruanus J. A. Allen, 1900

Montane Bamboo Rat

SYNONYMS:

Dactylomys peruanus J. A. Allen, 1900a:220; type locality "Juliaca, Peru, altitude 6000 feet," corrected to "Inca Mines [= Santo Domingo Mine], about 200 miles north-east of Juliaca, on the east side of the Andes, on the Inambari [Inambari] River," Puno, Peru by J. A. Allen (1901b:41).

Dactylomys [*Lachnomys*] *peruanus*: Thomas, 1927f:604; name combination.

DESCRIPTION: Smallest species in genus; head and body length of holotype 240 mm, tail length 320 mm, hindfoot length 51 mm, and ear length 14 mm. Fur distinctly soft to touch, lacking the strong bristles characteristic of both *D. boliviensis* and *D. dactylinus*. Tail longer than head and body length (about 130%); unique in being heavily furred along basal one-fifth of its length and lightly furred along distal four-fifths, instead of naked; tail hairs long, brownish-black in color; tail terminates in dark tufted tip; scale annuli remain visible even though tail is hairy. Dorsal color uniformly warm yellowish brown (olivaceous), slightly more gray-brown to clear gray on muzzle and forehead, but without stripe on top of head. Dorsal hairs bicolored, grayish black beneath and buffy at tip, with distal light band increasing in length over rump and flanks. Ventral hairs white to base, with some tipped in gray; overall ventral color whitish, or midventer may be dusky washed with some buff. Forelegs and hindlegs thickly furred with long hair to wrists and heels. Color of thighs and adjacent lateral tail base ranges from indistinct to bright orange. Vibrissae long, when appressed extending back to shoulders, predominantly black in color with pale tips. Ears small and do not protrude above hair on top of head.

Skull smaller than that of other species in genus, but conforms to them in most details of cranium and teeth; paroccipital processes curve forward following bulbar contour, as in *D. boliviensis*. Species distinguishable primarily by its uniform olivaceous coloration, dense and softer pelage, and furry tail, rather than by cranial characters.

DISTRIBUTION: *Dactylomys peruanus* occurs in the middle elevations of the eastern Andean slopes of southern Peru and northern Bolivia.

SELECTED LOCALITIES (Map 488): **BOLIVIA:** La Paz, Cotapata (Salazar-Bravo et al. 2003), La Paz, Astillero (BM 1.6.7.57). **PERU:** Cusco, Amaybamba (MVZ 173100); Junín, Acobamba (BM 27.11.1.221), Cordillera Vilcabamba (USNM 582148); Puno, Inca Mines (type locality of *Dactylomys peruanus* J. A. Allen), San Juan (FMNH 71131).

SUBSPECIES: *Dactylomys peruanus* is monotypic.

NATURAL HISTORY: Little is known about the natural history of this rarely encountered species. The holotype was collected on the ground by a stream bank; the specimen from Amaybamba, Peru, was taken at night in a clump of bamboo about 2 m above ground; and the Bolivian specimens were taken in a bamboo thicket in wet mossy cloud forest at 2,000 m. Emmons found them to be common in the canopy of bamboo thickets at 2,000 m in wet cloud forest of the Vilcabamba region in Peru, where they vocalized with distinctive birdlike calls, unlike those known for any of its congeners. The species was also photo-documented in wet *Chusquea* bamboo forest at 2,600 m in the Machu Picchu Sanctuary, Peru (R. Williams, pers. comm. to L. H. Emmons), where *Dactylomys* sp. remains were found with a pre-Colombian Inca burial (Yale Peabody Mus. osteo. 3322, Ant. 196396).

Map 488 Selected localities for *Dactylomys peruanus* (●). Contour line = 2,000 m.

REMARKS: This species differs from both *D. dactylinus* and *D. boliviensis* in its softer and longer dorsal pelage and in its furred tail, the basis for Thomas's (1916e) assignment to the monotypic subgenus *Lachnomys*. Tate (1935) gave generic rank to *Lachnomys*, but Ellerman (1940:136) wrote "it scarcely seems even a valid subgenus." Upham et al. (2013) found *D. peruanus* basal to the sister-pair of *D. boliviensis* and *D. dactylinus* in DNA sequence analyses. The karyotype is unknown. Alberico et al. (2000) record the species in the Cundinamarca, Colombia, at an elevation of 1,700 m in the Andes Biogeographical Region, but without reference to a museum voucher. Given the documented distribution, this assignment seems likely in error, perhaps due to confusion with the externally somewhat similar *Olallamys*.

Genus *Kannabateomys* Jentink, 1891

Kannabateomys is a monotypic genus closely allied to, and strongly resembling, *Dactylomys* (Y. L. R. Leite and Patton 2002; Emmons 2005), but restricted in distribution to the Atlantic rainforest of Brazil, Uruguay, Argentina, and Paraguay (Emmons and Feer 1997). It is smaller than *Dactylomys* (head and body length 230–347 mm; mass up to 570 g) with a similarly long tail (tail length 300–420 mm; >120% of head and body length), moderately long hindfeet (45–57 mm), and relatively short ears (16–27 mm). The upper parts are uniform glossy olivaceous to fulvous, finely streaked with black, and the sides of the body and tail are sometimes fulvous. The fur is long and soft, the hairs blackish with buffy tips. The head is large with a square muzzle; vibrissae are long, dense, and coarse, with the mystacial vibrissae reaching the shoulder; the cheeks are grayish. The tail is much longer than the head and body, robust, furred to the tip, and tapering from thick body hair on the base to sparse hair distally, bicolored pale below, dark brown above at the base paling through dusky to white or buff near the tip. The tip sometimes has a tuft of dark brown hairs. The hands and feet have long, grasping toes; the hands have four long fingers, the center two of which are separated by a wide gap. Nails, not claws, are present on all digits. The under parts are orange with variable amounts of white on the throat and chest. The lips around the mouth are white.

The skull resembles that of other genera in the subfamily, except that the maxillary toothrows are nearly parallel and labial and lingual flexi of the cheek teeth remain separate, with the mesoflexus and hypoflexus not coalescing to divide the tooth into two Y- or V-shaped lochs.

SYNONYMS:

Dactylomys: Wagner, 1845a:146; part (description of *amblyonyx*); not *Dactylomys* I. Geoffroy St.-Hilaire.

Kannabateomys Jentink, 1891:109; type species *Dactylomys amblyonyx* Wagner, by original designation.

Cannabateomys Lydekker, 1896:91; incorrect subsequent spelling of *Kannabateomys* Jentink.

Kannabateomys amblyonyx (Wagner, 1845)

Atlantic Bamboo Rat

SYNONYMS:

Dactylomys amblyonyx Wagner, 1845a:146; type locality “Ypanema” (= Floresta Nacional de Ipanema, 20 km NW Sorocaba, São Paulo, Brazil, 23°26'7"S 47°37'41"W, 701 m; L. P. Costa et al. 2003).

Kannabateomys amblyonyx: Jentink, 1891:109; first use of current name combination.

Kannabateomys amblyonyx pallidior Thomas, 1903b:489; type locality “Sapucay,” Paraguarí, Paraguay.

Kannabateomys amblyonyx amblyonyx: Tate, 1935:435; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Kannabateomys amblyonyx* occurs along the Atlantic coast of Brazil south to Uruguay and inland to northeastern Argentina and eastern Paraguay (Emmons and Feer 1997).

SELECTED LOCALITIES (Map 489): ARGENTINA: Misiones, Parque Nacional Iguazú (Crespo 1982b). BRAZIL: Paraná, Usina Hidroelétrica Salta Caixas (Y. L. R. Leite and Patton 2002); Rio de Janeiro, Reserva Biológica de Poço das Antas (Y. L. R. Leite and Patton 2002); Rio Grande do Sul, Parque Estadual do Itapuã (R. B. Silva et al. 2008); Santa Catarina, Theresopolis (NMW 1691); São Paulo, Ipanema (type locality of *Dactylomys amblyonyx* Wagner). PARAGUAY: Paraguarí, Sapucay (type locality of *Kannabateomys amblyonyx pallidior* Thomas).

SUBSPECIES: Specimens from the southern part of the range in Argentina and Paraguay are notably dull, buff yellowish with the venter and tail almost white (Emmons and Feer 1997). Thomas (1903b) gave these southern populations the formal subspecies name *pallidior*, but an appropriate analysis of geographic variation and thus the validity of subspecies designations remains to be accomplished.

NATURAL HISTORY: This is an arboreal rat typically living singly or in pairs. The combination of paternal care of young, delayed juvenile dispersal, a reduced degree of sexual dimorphism, and exclusive home ranges for members of the same sex but with male and female ranges overlapping are attributes that suggest social monogamy as the basic mating system (R. B. Silva et al. 2008). Individuals feed on the young shoots and leaves of bamboo and other plants, and inhabit bamboo thickets, especially at watersides, and dense thickets without bamboo in swamps, in Atlantic coastal

Map 489 Selected localities for *Kannabateomys amblyonyx* (●). Contour line = 2,000 m.

forests, inland rainforest, wet gallery forest, and bamboo patches such as planted bamboo hedgerows between agricultural fields (Hensel 1872a; Kierulff et al. 1992; Olmos et al. 1993; Stallings et al. 1994). Paresque et al. (2004) described a karyotype with $2n=98$ and $FN=126$.

Genus *Olallamys* Emmons, 1988

This is a poorly known genus whose distribution is limited to the Andes of northern Colombia and northwestern Venezuela, at elevations generally above 2,000 m and in association with moist bamboo thickets. The smallest genus among the dactylomyines, with head and body varying between 150–225 mm, also with a long tail (>140% of head and body length). The tail is sparsely haired, faintly to strongly bicolored, and with the distal half paler than the proximal part. The fur is soft, without spines or bristles. Upper parts are a shade of reddish brown and the under parts are white to yellow. The genus is characterized by claws on all digits of forefeet and hindfeet, except d2 of the hindfoot that bears an oblique, asymmetrical nail. Two species are usually recognized, although the differences between them, beyond size, are slight, and it is possible that these represent a single, geographically differentiated species with subpopulations in the separate Andean cordilleras of northwestern South America.

SYNONYMS:

Thrinacodus Günther, 1879; type species *Thrinacodus albicauda* Günther, 1879:144, by original designation; pre-

occupied by *Thrinacodus* St. John and Worthen, 1875 (Chondrichthyes: Elasmobranchii).

Olallamys Emmons, 1988:241; replacement name for *Thrinacodus* Günther, with the same type species, *Thrinacodus albicauda* Günther.

KEY TO THE SPECIES OF *OLALLAMYS*:

1. Maximum zygomatic breadth <27 mm; maxillary tooththrow <15 mm. *Olallamys albicaudus*
- 1'. Maximum zygomatic breadth >28 mm; maxillary tooththrow >15 mm. *Olallamys edax*

Olallamys albicaudus (Günther, 1879)

White-tailed Olalla Rat

SYNONYMS:

Thrinacodus albicauda Günther, 1879:145; type locality “the vicinity of Medellín, Columbian Confederation,” Antioquia, Colombia.

Thrinacodus apolinari J. A. Allen, 1914c:387; type locality “Tomeque [= Fômeque], (altitude 6500 feet), Bogotá district,” Cundinamarca, Colombia.

Thrinacodus albicauda apolinari: Cabrera, 1961:545; name combination.

Olallamys albicauda: Woods, 1993:790; first use of current name combination, but incorrect gender of specific epithet.

DESCRIPTION: As for the genus; distinguishable from *O. edax* (below) primarily by tail color, for which proximal half is reddish-brown and terminal half white, with grayish tinge toward tip. Smaller than *O. edax*; head and body length 150 and 180 mm, respectively for holotypes of *albicaudus* Günther and *apolinari* J. A. Allen, respective tail lengths 255 and 260 mm.

DISTRIBUTION: Known only from the Andes of Colombia. Alberico et al. (2000) indicated that this species ranged in elevation from 2,000–3,200 m in the Andes Biogeographical Region in the departments of Antioquia, Cundinamarca, Nariño, and Quindío. These authors listed specimens from three Colombian collections (IAvH, ICN, and UV) without reference to the vouchers or specific localities.

SELECTED LOCALITIES (Map 490): COLOMBIA: Antioquia, Páramo de Belmira (Delgado and Zurc 2005), Reserva San Sebastián-La Castellana (Delgado and Zurc 2005); Cundinamarca, Reserve Biológica Carpanta (ICN 17047), San Cristobal (FMNH 71128); Nariño, Laguna de La Cocha (UV [RBM 4143]).

SUBSPECIES: Cabrera (1961) recognized two subspecies, the nominotypical form from the Cordillera Oriental near Medellín and *apolinari* J. A. Allen, from the Cordillera Central near Bogotá. No analysis of geographic variation in character traits has been done to validate this hypothesis.

Map 490 Selected localities for *Olallamys albicaudus* (●) and *Olallamys edax* (○). Contour line = 2,000 m.

NATURAL HISTORY: Little is known about the ecology of this species. Recent records (Delgado and Zurc 2005) are from disturbed primary forest containing homogeneous patches of dense bamboo at or near tree line.

REMARKS: Didier (1962) described and figured the baculum. J. A. Allen (1914c:387) defined *apolinari* as a species separate from Günther’s *albicauda* primarily on the basis of uniform pale brown color along the length of the tail as opposed to the terminal white present in the latter. Cabrera (1961) assigned *apolinari* J. A. Allen as a subspecies of *Thrinacodus* (= *Olallamys*) *albicauda* without comment.

Olallamys edax (Thomas, 1916)

Greedy Olalla Rat

SYNONYMS:

Thrinacodus edax Thomas, 1916e:299; type locality “Sierra de Mérida. Alt. 2800 m.,” Mérida, Venezuela.

Olallamys edax: Woods, 1993:791; first use of current name combination.

DESCRIPTION: Similar in color and other external characters to *O. albicaudus*, but tail completely white along its ventral surface and distal half white above. Larger than *O. albicaudus*, with head and body length of holotype 225 mm, tail length 345 mm, and skull length 57 mm.

DISTRIBUTION: Known only from the vicinity of the type locality in the Mérida Andes (O. J. Linares 1998).

SELECTED LOCALITIES (Map 490): VENEZUELA: Mérida, Sierra de Mérida (type locality of *Thrinacodus edax* Thomas).

SUBSPECIES: *Olallamys edax* is monotypic.

NATURAL HISTORY: This species is known from high-elevation bamboo thickets; its ecology and reproduction are undescribed.

REMARKS: *Olallamys edax* was separated from *O. albicauda* on the basis of tail color, skull size, and tooth size, characters that vary among specimens of the latter species from the Central Cordillera in Colombia. For example, the tail of the holotype of *apolinari* J. A. Allen is pale brown above and paler below (J. A. 1914c:388), and the terminal half of the tail of the holotype of *albicauda* Günther is white. Future studies may well show that *O. edax* is not a valid species, but too few specimens are currently available in museum collections for a proper analysis.

Subfamily Echimyinae Gray, 1825

Louise H. Emmons, Yuri L. R. Leite, and James L. Patton

All genera in this subfamily are arboreal rodents with a pelage that may be spiny, bristly, or soft, and a tail that is typically as long as or longer than the head and body length. The feet are short and broad, and possess raised, smooth plantar pads developed under the joints. Molars are brachydont, with four roots (except in *Callistomys*), but crowns are often high (hypselodont or coronal hypselodont). The occlusal plane is angled away from plane of the palate, achieved by tipping otherwise straight-sided teeth so that the labial gumline is higher than the lingual (except in *Callistomys*). The cheek teeth have deep reentrant flexi(id)s that may split teeth into separate, parallel laminae. One to three deep flexi are present on the labial side of the maxillary cheek teeth. The posterior tip of the lower incisor root terminates anterior to m3. Both the maxillary zygomatic process and the jugal are usually slender. Toothrows are long, over 25% of basilar length of the skull.

G. A. S. Carvalho and Salles (2004) assigned six genera to this subfamily, and Emmons (2005:299; Table 3) included eight. Five genera (*Callistomys*, *Diplomys*, *Echimyus*, *Makalata*, and *Phyllomys*) are in common between these two recent reviews, but Emmons (2005) described two as new (*Pattonomys* and *Santamartomys*). She placed three genera as *incertae sedis* within the subfamily because of their individually unique sets of attributes. One of these, *Isothrix*, has been consistently included within the subfamily by earlier authors (e.g., McKenna and Bell 1997; Woods and Kilpatrick 2005; G. A. S. Carvalho and Salles

2004)), and two, *Lonchothrix* and *Mesomys*, have usually been included within the Eumospinae (McKenna and Bell 1997; Woods and Kilpatrick 2005), despite sharing some characters with echimyine genera (see discussion in Patton and Reig 1990). Iack-Ximenes et al. (2005a) have recently added a ninth genus (*Toromys*).

Phylogenetic analyses of taxon-limited mitochondrial and nuclear DNA sequence data (Y. L. R. Leite and Patton 2002; Galewski et al. 2005; B. D. Patterson and Velazco 2008; Upham and Patterson 2012; P.-H. Fabre et al. 2012; Upham et al. 2013) consistently recover a well-supported clade consisting of (*Makalata* (*Echimyus*+*Phyllomys*)), (*Makalata*, (*Echimyus*+*Toromys*)), or (*Makalata*, *Echimyus* (*Phyllomys*+*Toromys*)), depending upon the genera included in the respective analyses. All molecular studies indicate that *Isothrix* groups at the base of this clade of three or four genera. Furthermore, the recent analysis by P.-H. Fabre et al. (2012) and Upham et al. (2013) supported Emmon's contention that *Lonchothrix* and *Mesomys*, long recognized as sister taxa, also group with these echimyine genera. In the expanded morphological analysis of G. A. S. Carvalho and Salles (2004), *Isothrix* is contained within a clade otherwise composed of (*Pattonomys* (*Echimyus* (*Isothrix*, *Makalata*, *Toromys*, (*Phyllomys*+*Diplomys*))))). *Callistomys* was placed outside this clade in their analysis, as were both *Lonchothrix* and *Mesomys*. The rarely collected *Callistomys*, *Diplomys*, *Pattonomys*, and *Santamartomys*, have not been included as yet in molecular phylogenetic studies.

SYNONYMS:

Echimyinae Gill, 1872:22; a subset of the genera contained within the Echimyina of Waterhouse (1848:286–359).
Echinomyinae Alston, 1876a:92; name attributed to Waterhouse (1848) on p. 72.
Loncherinae Thomas, 1897a:1024.

KEY TO THE GENERA OF ECHIMYINAE (SEE EMMONS 2005 FOR DESCRIPTIONS AND ILLUSTRATIONS OF CHARACTERS):

1. Occlusal surface of maxillary cheek teeth with one lingual and three labial flexi/fossettes 2
- 1'. Occlusal surface of maxillary cheek teeth with pattern other than one lingual and three labial flexi/fossettes. . . 4
2. Pelage of lower back soft. 3
- 2'. Pelage of lower back spiny *Echimyus*
3. Maxillary cheek teeth hypselodont with three roots; occlusal plane strongly angled labially *Callistomys*
- 3'. Maxillary cheek teeth brachydont with four roots; occlusal plane weakly angled labially *Isothrix*
4. Occlusal surface of maxillary cheek teeth with four separate and parallel laminae. 5
- 4'. Occlusal surface of maxillary cheek teeth with two labial and two lingual flexi (or fossettes) 6

5. Lower molars with three separate lophs; auditory meatus close to squamosal suture; guard hairs unbanded *Diplomys*
- 5'. Lower molars with anteroloph separate; auditory meatus well separated from squamosal suture; guard hairs banded *Phyllomys*
6. Anteroloph of lower premolar lacks fossetid; upper incisor root at level of or outside zygoma; maxillary and premaxillary portions of incisive foramina septum separate 7
- 6'. Anteroloph of lower premolar with central fossetid or with flexid opening lingually; upper incisor root within maxillary root of zygoma; maxillary and premaxillary portions of incisive foramina septum broadly fused 8
7. Dorsal pelage stiff; mesoloph of third upper molar approximate in size to protoloph; metalophid of lower premolar and anterolophid of lower molars separate; auditory tube directed forward; inferior jugal process inconspicuous *Santamartamys*
- 7'. Dorsal pelage spiny; mesoloph of third upper molar much smaller than protoloph; metalophid of lower premolar and anterolophid of lower molars not separate; auditory tube directed laterally; inferior jugal process elongate *Pattonomys*
8. Dorsal pelage spiny; plantar surface of hindfeet without tubercles; third upper molar with four or more well-developed lophs *Makalata*
- 8'. Dorsal pelage bristly; plantar surface of hindfeet with tubercles between pads; posteroloph of third upper molar reduced, or M3 with 3 lophs only *Toromys*

Genus *Callistomys* Emmons and Vucetich, 1998

Louise H. Emmons and Yuri L. R. Leite

Callistomys can be diagnosed by the following set of characters (taken from Emmons and Vucetich 1998:3; Emmons 2005): cheek teeth have three roots; both upper and lower cheek teeth are high crowned; PM4 and M1 are unilaterally hypsodont (lingual side of crown higher than labial side, crown curved outward); PM4–M3 are tetralophodont, with three labial flexi and one lingual flexus; hypoflexi and mesoflexi are deep, with PM4 completely divided by the joined hypoflexus-metaflexus into two U-shaped lophs with no mure; M1–3 have a narrow mure connecting protocone and hypocone. The hypoflexids of pm4–m3 are set at a strong oblique angle; the medial end of the flexid extends farther anterior than the labial end. Lower premolars are tetralophodont; the anteroconid and protoconid are united, enclosing the anteroexternal flexid as a slit-like fossetid; the anterior half

of the tooth approximates a triangle with its axis slightly tipped anterolabially; and the hypoflexids and metaflexids do not join (pm4 is not divided by a continuous flexid). The lower incisors are robust and strongly curved. Crani-ally, the jugals are expanded dorsoventrally; the lateral jugal fossa is wide and diffuse anteriorly, not coming to a sharp point, with the anterior edge of the fossa positioned above PM4, anterior to a line extended from the posterior border of the ascending maxillary process of the zygomatic arch. The superior zygomatic root of the maxillary is expanded posteriorly. The tympanic auditory bullae are inflated, with a large auditory meatus at the end of a strongly developed auditory tube. The angular process of the mandible is strongly projected ventrally with respect to the inferior projection of the symphysis such that an angle drawn between the ventral posterior tip of the angular process and the occlusal plane of the toothrow, with the apex at the anterior edge of the occlusal surface of pm4, is greater than 30°.

The single living species is a moderate-sized (head and body length 250–295 mm, tail length 273–325 mm, hind-foot length 43–47 mm, and ear length 16 mm) and arbore-ally adapted rat with a striking black (or brown) and white patterned pelage. The fur is long and dense, with hairs of uneven lengths; overhairs are slender and soft, lacking spines or bristles, and the underfur is dense, long, and wavy. Dorsal hairs are brown at their base with tips black or white such that color is entirely whitish except for the sharply defined glossy black saddle (fading to brown in old museum specimens) covering the dorsum from shoulders to tail, and across upper forelegs. A wide, black diamond-shaped patch extends over the nape and crown to between the eyes. The tail is black at its base, with the distal part silky white above, golden yellow below; it is thickly covered with short, dense, flat-lying hairs. Ear pinnae are small and inconspicuous. Vibrissae are slender; longest mystacial vibrissae reaches to shoulder when flattened back; super-ciliary vibrissae reach to ear tip. Lower legs and feet are stout and broad, toes are long. There are two pairs of lateral mammae.

SYNONYMS:

Nelomys: Pictet, 1843a:205; part (description of *pictus*).

Loncheres (Isothrix): Waterhouse, 1848:327; part (listing of *picta*); neither *Loncheres* Illiger nor *Isothrix* Wagner.

Echimyis: Tate, 1935:414; part (listing of *pictus*); not *Echimyis* F. Cuvier.

Callistomys Emmons and Vucetich, 1998:3; type species *Nelomys pictus* Pictet, by original designation.

REMARKS: This genus was erected to include two species from coastal Brazil. One of these is known only from a mandibular fragment collected by Lund at Lagoa Santa, Minas Gerais, and described by Winge (1887:71), who referred it to

"*Lasiuromys villosus* Dev. ? 1852)," a subjective synonym of *Isothrix bistrata*. This species is apparently without a name, and is listed by Emmons and Vucetich (1998:7) as *Callistomys* sp. The second species is *Callistomys pictus* (Pictet 1843a), which was originally placed in the genus *Nelomys* (= *Phyllomys*; see that account), an action continued by Emmons and Feer (1990 1997), but which has been varyingly assigned also to *Isothrix* (E.-L. Trouessart 1880; Ellerman 1940; Cabrera 1961; Patton and Emmons 1985; Eisenberg and Redford 1999) or *Echimys* (Tate 1935; Moojen 1952b; Woods 1993). These different assignments highlight the overall uniqueness of this taxon.

Indeed, several features distinguish *Callistomys* from other genera in the subfamily Echiomyinae and raise questions about whether it belongs in the subfamily: The possession of the eumysopine cheek tooth root pattern and hypselodonty, and the dorsoventrally expanded jugals and anterior zygomatic arch, likewise features common with the Eumysopinae (especially *Euryzygomatomys* and *Clyomys*) and not shared by any other living echimyine. The phylogenetic analysis of G. A. S. Carvalho and Salles (2004) place the genus as sister to a clade otherwise containing the dactylomyines and all other genera of echimyines. Leite's preliminary molecular sequence data suggest that *Callistomys* has no close relative among all living echimyid genera.

Callistomys pictus (Pictet, 1843)

Painted Tree Rat

SYNONYMS:

- Nelomys pictus* Pictet, 1841a:29; *nomen nudum*.
Nelomys pictus Pictet, 1843a:205; type locality "Bahia"; probably from Fazenda Almada in the region north of the city of Ilhéus, Bahia, Brazil (Moojen 1952b).
Loncheres (Isothrix) picta: Waterhouse, 1848:327; name combination.
Loncheres (Isothrix) pictus: E.-L. Trouessart, 1897:606; name combination.
[Isothrix] picta: Thomas, 1916e:295; name combination.
[Echimys] pictus: Tate, 1935:414; name combination.
Echimys pictus: Moojen, 1952b:133; name combination.
Isothrix picta: Cabrera, 1961:537; name combination.
Callistomys pictus: Emmons and Vucetich, 1998:3; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Callistomys pictus* is endemic to the Atlantic Forest with known localities limited to three adjacent municipalities near Ilhéus and Itabuna, in coastal Bahia, Brazil (Vaz 2002). Eisenberg and Redford (1999) list a specimen from the Rio de Birasa without documentation. Peter W. Lund collected subfossil remains from Lagoa Santa, Minas Gerais, but the species is unknown from the modern fauna of this region (Emmons and Vucetich 1998).

Map 491: Selected localities for *Callistomys pictus* (●).

SELECTED LOCALITIES (Map 491): BRAZIL: Bahia, Fazenda Almada (probable type locality of *Nelomys pictus* Pictet; Moojen 1952b), Reserva Particular do Patrimônio Natural Jequitibá (Vaz 2002), Rio do Braço (MNRJ 11207).

SUBSPECIES: *Callistomys pictus* is monotypic.

NATURAL HISTORY: An apparent inhabitant of evergreen lowland rainforest, but only 13 specimens are known. Recent fieldwork (Vaz 2002) found this species in cocoa plantations, but substantial habitat loss and modification has likely led to severe restriction in the number of extant populations. The species is locally hunted for food (Vaz 2002). Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

REMARKS: The first use of the name stems from Pictet (1841a:29), in a list of new species obtained by the Musée de Genève. Pictet (1843a:203) later provided the description of his new taxon. K. Ventura et al. (2008) described a karyotype with $2n = 42$, FN = 76.

Genus *Diplomys* Thomas, 1916

Louise H. Emmons and James L. Patton

These are moderate-sized arboreal rats without spines but with guard hairs flattened and slightly stiff, each with a

deep dorsal sulcus. The dorsal guard hairs are 1.8–2.0 cm long; underhairs are few, fine, and inconspicuous. The dorsal body fur extends from 1.5–5.0 cm onto base of the tail, and the distal part is fully but moderately clothed with stiff, bristle-like, brown hairs, and with scales visible beneath. The feet are without tiny tubercles between pads.

The skull is long and narrow, with the dorsal surface is curved throughout its length from nasals to occiput when viewed laterally. The jugal is narrow below the postorbital process, with an inconspicuous ventral process positioned well forward of the dorsal process. The tympanic bullae are not inflated, the auditory meatus is positioned close to the squamosal, and auditory tubes are well developed and directed strongly forward such that the middle ear bones are not visible in lateral view. The distance between the foramen ovale and the masticatory foramen of the alisphenoid is typically very short, and the ventral roof of the canal formed by these foramina is often nearly obsolete. The hamular process of the pterygoid has a prominent, anteriorly directed spur. A large, oval sphenopalatine vacuity is present anterior to the presphenoid-basisphenoid suture. The squamosotympanic fenestra is tube-like, opens forward, and is without a depression on squamosal below. The angle of the sigmoid notch, between angular and condyloid processes of the mandible, is shallow, and the mandibular foramen on the side of ramus is positioned well anterior to the condyloid ridge, not in a fossa. The maseteric crest is large.

Maxillary cheek teeth are large and the toothrow is relatively long. Morphology of the upper teeth resembles that of *Phyllomys* spp. (see below), with the occlusal surface divided by three flexi into four laminae. These laminae are parallel in M1–3, but in PM4 the labial ends of the two anterior lophes are bent forward. The flexi are of even depth, such that with wear, three straight fosses are centered on the molars. In the mandibular cheek teeth, all flexids may traverse all lophes in unworn teeth, but with wear the metaflexid divides m1–3 into a free posterolophid. The middle loph (entoconid + hypoconid) is usually connected to the anterolophid at near its midpoint by a short mure, forming a highly distinctive pattern of two crescent-shaped lophids connected by a central stem. The hypoflexids are positioned at an oblique angle. The lower premolar is split into three or four parts by two or three flexids; the anterior loph forms a rounded triangle enclosing a flattened oval transverse fossette, metalophid is a separate lamina, and the entoconid and posterolophid are either joined labially or divided into separate parts by the metaflexid. The lower incisors are strongly curved.

There are two pairs of lateral mammae. The phallus lacks deep lateral ridges, but the ventral surface has a long,

longitudinal slit distal to a short transverse fold. The dorsal tip possesses a long, slender, bacular papilla, and an inconspicuous urethral lappet is present.

Two species are now recognized within the genus, subsequent to Emmons's (2005) removal of *rufodorsalis* J. A. Allen to her new genus *Santamartamys*: *D. caniceps* (Günther) from Colombia and *D. labilis* (Bangs, 1901, with *darlingi* Goldman, 1912b, a synonym) from Panama south along the Pacific coast of Colombia to Ecuador. Hall (1981:874–875) provided a taxonomic summary for and mapped the distribution of *D. labilis* in Panama. Few specimens are available from either species, and given the lack of more than cursory comparisons in the literature, the number of species and their range(s) remain questions for the future to address. Largely by virtue of its relatively soft pelage and well-haired tail, *Diplomys* has often been associated with Amazonian and Guianan genus *Isothrix* (e.g., E.-L. Trouessart 1880; Goldman 1912b) or the Atlantic Forest *Phyllomys* (Goldman 1916). The phylogenetic analyses of G. A. S. Carvalho and Salles (2004) supported a sister relationship to the Atlantic Forest *Phyllomys*. Molecular data are as yet unavailable to test any phyletic hypothesis.

SYNONYMS:

Loncheres: Günther, 1876:745; part (description of *caniceps*); not *Loncheres* Illiger.

Loncheres (Isothrix): E.-L. Trouessart, 1880b:178; part (listing of *caniceps*); neither *Loncheres* Illiger nor *Isothrix* Wagner.

Echimyis (Isothrix): E.-L. Trouessart, 1904:504; part (listing of *caniceps*); neither *Echimyis* F. Cuvier nor *Isothrix* Wagner.

Phyllomys: Goldman, 1916a:126; part (listing of *caniceps*); not *Phyllomys* Lund.

Diplomys Thomas, 1916d:240; type species *Loncheres caniceps* Günther, by original designation.

KEY TO THE SPECIES OF *DIPLOMYS*:

1. Range restricted to Cauca Valley, Colombia; maxillary and mandibular molar tooththrows divergent, with ends curved outward such that a straight edge held against the first and last tooth shows a gap between them and the middle teeth *Diplomys caniceps*
- 1'. Range (in South America) restricted to western Colombia and northwestern Ecuador; both maxillary and mandibular tooththrows nearly straight *Diplomys labilis*

Diplomys caniceps (Günther, 1876)

Colombian Rufous Tree Rat

SYNONYMS:

Loncheres caniceps Günther, 1876:745; type locality "Medellin," Antioquia, Colombia.

Loncheres (Isothrix) caniceps: E.-L. Trouessart, 1880b:178; name combination.

Echimys (Isothrix) caniceps: E.-L. Trouessart, 1904:504; name combination.

Phyllomys caniceps: Goldman, 1916a:126; name combination.

Diplomys caniceps: Thomas, 1916d:240; first use of current name combination.

DESCRIPTION: Larger of two species; head and body length 212–320 mm, tail length 178–267 mm; hindfoot length 40–48 mm, ear length 12–20 mm, and mass 360–430 g. Upper parts dull or bright rusty red-brown faintly streaked with dark brown hairs, reddish brightest on rear half of body, and forequarters sometimes fulvous. Fur stiff and dense but lacks spines. Nose brown; head forward of the ears is gray streaked with black, face marked with small whitish spots over the eye and at base of vibrissae, and pale yellow spot present behind and below the ears. Ears short and generally do not protrude above crown. Vibrissae coarse and long, reaching to shoulder. Chin often white, throat whitish or orange, and remainder of the under parts range from pale to rich orange, often dark rust-orange along the midline of the abdomen and underside and sides of the tail base. Tail robust, subequal in length to body length (90–105%), and moderately but completely covered with dark brown hairs that stand outward to give bristly appearance; scales of tail just visible beneath the hair. Hindfeet broad, yellow-brown to gray or brown above.

Cranial and dental characters as for the genus.

DISTRIBUTION: *Diplomys caniceps* is apparently limited to the Caribe Biogeographical Region (Alberico et al. 2000) in northwestern Colombia, in the Cauca Valley in the vicinity of Medellín (Emmons and Feer 1997). Cuervo Díaz et al. (1986) extended the range to the Serranía de San Lucas in the state of Bolívar, but without documentation. Eisenberg (1989: map 13.73) reversed the ranges of *D. caniceps* and *D. rufodorsalis* (= *Santamartamys rufodorsalis*), incorrectly mapping the former to northeastern Colombia.

SELECTED LOCALITIES (Map 492): COLOMBIA: Antioquia, Finca Katiri (CTUA, C. Delgado-V., pers. comm.), vicinity of Medellín (type locality of *Loncheres caniceps* Günther); Bolívar, Corregimiento de Ventura (INDERENA 3856).

SUBSPECIES: *Diplomys caniceps* is monotypic.

NATURAL HISTORY: This species has not been studied in its natural habitat.

REMARKS: *Diplomys caniceps* is superficially similar to *D. labilis* (below) in external characters, but the two species seem to differ in cranial characters. The exact type locality is unknown. The collector, T. K. Salmon, shipped

Map 492 Selected localities for *Diplomys caniceps* (○) and *Diplomys labilis* (●). Range of *D. labilis* in Panama from Hall (1981). Contour line = 2,000 m.

specimens from Medellín to England, but worked in the Magdalena, Neche, Pocuné, Río Sucio, and Cauca valleys in all directions from that city (Sclater and Salvin 1879). It is unclear if *D. caniceps* is geographically isolated from coastal *D. labilis*. This species is represented only by specimens in the Natural History Museum in London, the Instituto de Investigación de Recursos Biológicos Alexander von Humboldt in Bogotá, Colombia (Alberico et al. 2000), and Colección Teriológica Universidad de Antioquia (CTUA), Medellín, Colombia (C. Delgado-V., pers. comm.).

Diplomys labilis (Bangs, 1901)

Central American Rufous Tree Rat

SYNONYMS:

Loncheres labilis Bangs, 1901:638; type locality “San Miguel Island, [Archipiélago de las Perlas], Panama.”

Isothrix darlingi Goldman, 1912b:12; type locality “Marangantí (near Real de Santa María), on the Rio Tuyra, eastern Panama.”

Echimys (Isothrix) labilis: E.-L. Trouessart, 1904:504; name combination.

Phyllomys labilis: Goldman, 1916:126; name combination.

Phyllomys darlingi: Goldman, 1916:126; name combination.

Diplomys labilis: Thomas, 1916d:240; first use of current name combination.

Diplomys darlingi: Thomas, 1916d:240; name combination.

D[iplomys]. l[abilis]. darlingi: Handley, 1966:787; name combination.

DESCRIPTION: Externally similar to *D. caniceps* but somewhat smaller (head and body length about 190 mm, tail length 267 mm, hindfoot 40 mm, and ear length 12 mm). Upper parts ochraceous buff to bright rusty, slightly darkened by admixture of black-tipped hairs, becoming grayish brown on middle of face and cheeks; nose, lips, and muzzle gray, with white vertical streak at base of vibrissae (see photograph in Tesh 1970a); wrists, ankles, and chin gray; feet silvery white above. A small pale spot present above eyes, contrasting with a black eye-ring; ears dark, with marginal fringe of longer hairs; narrow strip of white encircles the pinnae. Tail generally proportionally shorter than that of *D. caniceps*, 70–100% of the head and body length; unicolored brownish, tapering evenly to tip; thinly clothed with short hairs, which become somewhat longer although not denser or forming a distinct brush near tip. Dentition is similar to that of *D. caniceps*. Cranially, palate narrower and premaxillae sometimes extend posterior to nasals in *D. labilis* in comparison with conditions in *D. caniceps*. There is considerable variation of ventral color from dark to paler rufous, of the rostrum from broad to quite narrow, and of the premaxillary bones either even with, or extending posterior to nasals. Verification of current species boundaries, and therefore their geographic ranges, awaits analyses of existing specimens and further collecting.

DISTRIBUTION: *Diplomys labilis* occurs from central Panama, including Isla San Miguel in the Gulf of Panama, south along the Pacific coast of Colombia (Pacífico Biogeographic Region; Alberico et al. 2000) and extends into northwestern Ecuador. Specimens and localities from western Colombia were listed as “probably *D. labilis*” by Emmons and Feer (1997), and those in the collections of Museo de Historia Natural de la Universidad del Cauca and Universidad del Valle in Colombia from Cauca, Chocó, and Nariño departments were assigned to *D. labilis* by Alberico et al. (2000). Specific localities for these latter specimens, however, were not provided. We assign specimens in the Field Museum from western Colombia to *D. labilis*. Tirira (2007:223) mapped the range of this species as extending into northwestern Ecuador but records no specific localities. A subadult specimen collected in 1901 from “Bayone, N. Ecuador” exists in the collections of the Natural History Museum, London (BM). We have been unable to locate this locality, although it may be on the Río Borbón in Esmeraldas province as specimens of other species in the BM were collected there on the same date (Paynter 1993).

SELECTED LOCALITIES (Map 492; South America only): COLOMBIA: Antioquia, Turbo (FMNH 70101); Cauca, Río Saija, La Boca (FMNH 90109); Córdoba, Socorre, upper Río Sinu (FMNH 69119). ECUADOR: Esmeraldas, Bayone (BM 2.7.26.2).

SUBSPECIES: Two subspecies occur in Panama, the insular nominotypical form and *darlingi* Thomas on the mainland (Hall 1981). There has been no evaluation of variation in populations from Colombia or Ecuador.

NATURAL HISTORY (from Tesh 1970a, based on studies in Panama): This is a nocturnal, solitary, arboreal species that feeds on both fruits and leaves. Individuals nest in tree holes, usually in trees near the water, and can be seen sticking their heads out of the entrance if disturbed. They are agile climbers and aggressive when captured. Their habitat includes both mature and secondary rainforest and deciduous forest, including lowland and montane, mangroves, and plantations with trees. Litter size is one or two.

REMARKS: Both Thomas (1916d, e) and Goldman (1916) suggested that *labilis* Bangs and *darlingi* Goldman were allied, but retained each as separate species. Handley (1966:787) listed the mainland *darlingi* as a subspecies of the insular *labilis*, a conclusion followed by Hall (1981:874). Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

Genus *Echimys* F. Cuvier, 1809

Louise H. Emmons, Yuri L. R. Leite, and James L. Patton

Members of this genus are moderate-sized arboreal rats with the pelage including stout spines. The tail is longer than the head and body, completely covered with dense hair that forms a pencil at tip. Four pairs of mammae are present, three laterals and one inguinal. The phallus of *E. chrysurus* (Emmons 2005) is stout, strongly ridged on its sides, with a short, triangular bacular papilla at the dorsal tip; the ventral lip of urethral crater forms a short, U-shaped fold above a straight-line lip.

The skull has small to medium-sized auditory bullae with a small meatus on a short auditory tube directed laterally at nearly a right angle to the cranial axis; the meatus is positioned near (less than half its diameter) to the squamosal suture. The lateral process of the supraoccipital (erroneously termed mastoid process by Emmons et al. 2002 and Y. L. R. Leite 2003; see Verzi et al. 2013 for anatomical details) is short. The squamosotympanic fenestra is small and subcircular, with no raised ventral lip, and is entirely anterior to the auditory meatus. The premaxillary part of the septum of the incisive foramina is free posteriorly. The jugal is deep below the postorbital process, and the jugal

fossa is very broad, forming an angle of at least 40°. The postorbital process of the zygoma is formed only by the jugal. The mandibular foramen is anterior to the condyloid ridge, not in a fossa with base in ridge; the masseteric crest is weakly developed.

Maxillary toothrows are parallel, not converging anteriorly. The cheek teeth are rectangular, longer than wide, and with tall crowns. Only one lingual flexus is present (the hypoflexus), which usually joins with mesoflexus to completely divide tooth into two U-shaped lophs (that is, there is no mure connecting the protoloph and mesoloph); three labial flexi are present. The four lophs of PM4–M2 are subequal in length and width and nearly parallel. The paraflexus and metaflexus are long, about two-thirds or more of the width of the tooth, and parallel; the hypoflexus or its trace is short, about one quarter to one-third of the width of the tooth. Hypoflexids of the lower molars reach less than half way across tooth, open at a wide angle, and are scarcely, if at all angled forward, such that lophids adjoining the tip of the hypoflexid are about equal in width. The metaflexids of m1 and more prominently, m2, have an angled internal tip with two points (perhaps outlining a mesoconid) that bends slightly posteriorly; the mesoflexid has an internal tip that bends slightly anteriorly. The lower premolar is pentalophodont, completely divided by two flexids into three parts: a symmetrical triangular anterior loph, rounded at its anterior tip and enclosing a subcircular fossetid; a single, laminar, central metalophid bar; and posterolophid and entoconids of posterior third of tooth united labially into a single, V-shaped loph that opens lingually. The lower incisors are not strongly curved.

SYNONYMS:

- Myoxus*: Zimmermann, 1780:352; part (description of *chrysurus*); not *Myoxus* Zimmermann.
Hystrix: Schreiber, 1792: table 170B; part (description of *chrysuos*); not *Hystrix* Linnaeus.
Glis: Treviranus, 1803:182: part (listing of *chrysurus*); not *Glis* Brisson.
Echimys F. Cuvier, 1809:394; based on Allamand's (1778) "lérot a queue dorée" and Azara's (1801:73) "rat épineux"; type species *Echimys cristatus* Desmarest (= *Myoxus chrysurus* Zimmermann) by subsequent designation (Tate 1935:430).
Loncheres Illiger, 1811:90; type species *Myoxus chrysurus* Zimmermann, by original designation.
Echimys Desmarest, 1817b:54; type species *Echimys cristatus* Desmarest, by original designation (see Remarks).
Loncheris Olfers, 1818; incorrect subsequent spelling of *Loncheres* Illiger.
Nelomys Jourdan, 1837:522; type species *Echimys cristatus* Desmarest (see Remarks).

Echinomys Wagner, 1840:199; unjustified emendation of *Echimys* F. Cuvier (same unjustified emendation cited by I. Geoffroy St.-Hilaire 1840:1); see Remarks.

Echimys I. Geoffroy St.-Hilaire, 1840:30; not *Echimys* F. Cuvier (see Remarks).

Enchomys Gloger, 1841 (1842):100; replacement name for *Echimys* Desmarest, and thus an objective synonym (see Thomas 1895a:190).

Echmiys Miranda-Ribeiro, 1914:48; incorrect subsequent spelling of *Echimys* F. Cuvier.

REMARKS: J. A. Allen (1899c), Thomas (1916e), and Tate (1935) outlined the convoluted and intertwined taxonomic history of *Echimys* and *Loncheres*, two generic names that have been commonly applied to the arboreal spiny rats, including *Echimys* as we envision this genus herein. *Echimys* was first used by É. Geoffroy St.-Hilaire in a manuscript apparently written in either 1808 or 1809 but never published (I. Geoffroy St.-Hilaire 1838, 1840). F. Cuvier (1809) first published the name basing it on the "lérot à queue dorée" (from Allamand's [1778] supplements to Buffon's *Histoire Naturelle*, which was also the basis of *Myoxus chrysurus* by Zimmermann [1780]), and the "rat épineux" of Azara (1801). F. Cuvier (1812) described and figured the dentition of the only two species mentioned by him as belonging to this genus, namely the same "le lérot à queue dorée" (plate xv, Fig. 15) and "rat épineux" (plate xv, Fig. 14). Illiger (1811) described *Loncheres*, referring to it two species: *Loncheres paleacea*, a *nomen nudum* first made available by Olfers (1818:212; also see Hershkovitz 1959b) and *Myoxus chrysurus* Zimmermann. Because an undescribed species cannot be taken as the type of a genus, *Myoxus chrysurus* Zimmermann becomes the type of Illiger's *Loncheres*. The seven species of spiny rats that É. Geoffroy St.-Hilaire referred to the genus *Echimys* in his unpublished manuscript were then described by Desmarest (1817b), who specifically equated the "rat épineux de d'Azara" to *Echimys spinosus* (a *Euryzygomatomys*) and É. Geoffroy St.-Hilaire's "lérot à queue dorée" to *Echimys cristatus*, a renaming of *Myoxus* [= *Loncheres*] *chrysurus*. Desmarest wrote explicitly of *Echimys* "Le lérot à queue dorée d'Allamand et de Buffon en est le type" (1817b:54) and thus designated *Echimys cristatus*, which he equated with "lérot à queue dorée," as the type species of the genus *Echimys*. Tate (1935:418) considered this "clearly a designation of the type of *Echimys*," as do we. Many authors have overlooked Desmarest's designation, however, and since Cuvier's description and figures clearly indicated that his two species are not congeneric, J. A. Allen (1899c:262–263) argued that one of these needed to be selected as the type of his *Echimys* and further argued that the erection of *Loncheres* Illiger, with its type *M. chrysurus* (= *E. cristatus* Desmarest), automatically made *Echimys*

spinus Desmarest (or “*rat épineux de d’Azara*”) the type of *Echimys* F. Cuvier. Thomas (1916c:71) disagreed, pointing out that J. Fleming (1822:191) had much earlier selected “*Hystrix chrysurus* Lin Gmel” (= *Myoxus chrysurus* Zimmermann) as the type of *Echimys*. Finally, Tate (1935:430) stated that J. Fleming had merely listed the name *Hystrix chrysurus* without clearly and unambiguously selecting it as the type to F. Cuvier’s *Echimys*. He then (p. 430) designated “as the type species of *Echimys* F. Cuvier, 1809, the “*lérot à queue dorée*” (= *Myoxus chrysurus* Zimmermann, 1780, = *Echimys cristatus* Desmarest, 1817).” É. Geoffroy St.-Hilaire, followed by F. Cuvier and Desmarest, may have originally named the taxon because the Paris Museum had earlier acquired a specimen from French Guiana that is noted in É. Geoffroy St.-Hilaire’s 1803 catalogue as the basis for the description of the “*lérot à queue dorée*” (MHN A-7694 old no. 403), although Allamand stated that his (1778) description is of a Surinam specimen, which was sent to him by Klockner. It is not clear what became of the holotype from Surinam or if É. Geoffroy St.-Hilaire ever saw it. The lovely figure in Allamand (1778) was clearly drawn from the specimen he described in great detail, but subsequent figures in later editions of Buffon were progressively poorer copies. Zimmermann (1780) condensed his description of *Myoxus chrysurus* from Allamand’s more detailed one, and translated its name directly into Latin, without evidence that he ever saw a specimen.

In his 1899 paper, J. A. Allen also removed the terrestrial spiny rats from *Echimys* (and *Loncheres*) to his new genus *Proechimys* (p. 264), a broad concept in which he included species now grouped into four genera within the subfamily Eumysopinae (*Proechimys* proper, *Trinomys*, *Hoplomys*, and *Mesomys*). Many subsequent researchers have shared Allen’s narrowed view of the genera of arboreal spiny rats (Thomas 1928c, d; Tate 1935; Ellerman 1940; Cabrera 1961). Moojen (1952b), however, was the first to recognize further groups in the traditional *Echimys*, elevating the Atlantic Forest arboreal spiny rats to the genus *Phyllomys* Lund. Husson (1978) erected the genus *Makalata* to include *Nelomys armatus* I. Geoffroy St.-Hilaire, and more recently Emmons and Vucetich (1998) created *Callistomys* to include *Nelomys pictus* Pictet. Emmons, Leite et al. (2002; see also Y. L. R. Leite 2003) confirmed Moojen’s separation of *Phyllomys*. Most recently, Iack-Ximenes et al. (2005a) placed *Echimys grandis* Wagner in the new genus *Toromys*, and Emmons (2005) removed *Echimys semivillosus* I. Geoffroy St.-Hilaire to her new genus *Pattonomys*. What remains of *Echimys* F. Cuvier, therefore, is only a remnant of the large number of species once, and varying, included within the genus.

Echinomys has been commonly listed as a synonym of *Echimys* F. Cuvier, with the author given as either I. Geof-

froy St.-Hilaire, 1840 (e.g., Tate 1935) or Wagner, 1840 (Simpson 1945; Cabrera 1961; Woods 1993; McKenna and Bell 1997; Woods and Kilpatrick 2005). It is unclear which of these two publications has date priority. *Echinomys* is, however, an unjustified emendation of *Echimys* F. Cuvier (rationale for name modification given by Wagner [1840:199; 1843a:339]). Moreover, all species listed by Wagner (1843a:339) under his *Echinomys* belong not to *Echimys* but to other genera of echimyids, notably *Euryzgomatomys*, *Mesomys*, *Proechimys*, or *Trinomys* (see those accounts).

Cabrera (1961) included 19 valid species or subspecies in his concept of the genus *Echimys*. Most of these are now placed in other genera, three of which have been described subsequent to his work. Herein, we follow the recent revisionary analyses noted immediately above in the allocation of the names Cabrera listed within *Echimys* as follows: *Makalata* Husson (including *armatus* I. Geoffroy St.-Hilaire and *macrura* Wagner), *Pattonomys* Emmons (*carrikeri* J. A. Allen, *occasius* Thomas, *punctatus* Thomas, and *semivillosus* I. Geoffroy St.-Hilaire), *Phyllomys* Lund (*blainvillei* Jourdan, *braziliensis* Lund, *dasythrix* Hensel, *lamarum* Thomas, *medius* Thomas, *nigrispinus* Wagner, *thomasi* Ihering, and *unicolor* Wagner), and *Toromys* Iack-Ximenes, de Vivo, and Percequillo (*grandis* Wagner and *hipidurus* Thomas). With the removal of these names to other genera, *Echimys* as currently understood comprises three species, one of which was only recently described.

KEY TO THE SPECIES OF *ECHIMYS*:

1. Distributed in eastern Amazonia and Guianan region
..... 2
- 1'. Distributed in western Amazonia; head glossy black ..
..... *Echimys saturnus*
2. Wide to narrow white blaze from nose to crown, may be reduced to white tuft on top of head
..... *Echimys chrysurus*
- 2'. Top of head dark maroon. *Echimys vieirai*

Echimys chrysurus (Zimmermann, 1780)

White-faced Tree Rat

SYNONYMS:

Myoxus chrysurus Zimmermann, 1780:352; type locality “Surinam,” based on Allamand’s (1778) “*lérot à queue dorée*” with a nearly verbatim translation of Allamand’s description.

Hystrix chrysuos Schreiber, 1792:Table 170B; see also Schreiber, 1843:333; incorrect subsequent spelling of *chrysurus* Zimmermann.

M[yoxus]. chrysuos: H. F. Link, 1795:77; name combination.

Glis chrysurus: Treviranus, 1803:182; name combination.
Loncheres chrysurus: Illiger, 1811:90; name combination.
Loncheres paleacea Illiger, 1811:90; *nomen nudum*.

[*Loncheres*] *chrysurus*: Illiger, 1815:108, *lapsus* to be ignored.
Echimys cristatus Desmarest, 1817b:54; a renaming of Allamand's "lérot à queue dorée"; attributed the name to É. Geoffroy St.-Hilaire, not to Zimmermann.

Loncheres paleacea Olfers, 1818:212; type locality "Brazilien"; renaming of *Loncheres paleacea* Illiger, a *nomen nudum*; antedates Lichtenstein (1820) and Kuhl (1820), who both redescribed the same Berlin specimen seen by Olfers and Illiger.

Nelomys paleaceus: I. Geoffroy St.-Hilaire, 1838a:887; name combination.

Nelomys cristatus: I. Geoffroy St.-Hilaire, 1838a:887; name combination.

Loncheres cristata: Wagner, 1843a:332; name combination.

Echimys chrysurus: E.-L. Trouessart, 1904:503; first use of current name combination.

[*chimys*]. *paleaceus*: Thomas, 1916e:295; reference to Lichtenstein's name.

[*Echimys*] *paleacea*: Tate, 1935: 431; name combination and incorrect gender concordance.

Echimys paleacea: Ellerman, 1940:113; incorrect gender concordance, following Tate (1935).

DESCRIPTION: A relatively large species, mean head and body length 277.3 mm (range: 242–300 mm, N=11), tail length 336.8 mm (range: 305–370 mm), hindfoot length 50.8 mm (range: 42–54 mm), and ear length 19.5 mm (range: 19–20 mm). Upper parts colored dark to pale gray-brown, pelage of upper parts densely covered with wide, flat spines from neck to rump with remainder of pelage composed of stiff bristles. A pale-colored (whitish to yellowish) blaze occurs down center of head, from crown to nose, either completely covering face between the eyes or only as narrow stripe or small white tuft on crown; remainder of crown usually dark brown; cheeks and sides of neck sometimes reddish. Ears small, thinly haired, and brown. Eyes dark brown, with weak, dull red eyeshine. Tail longer than the head and body (mean 120%), fully haired, dusky basally with distal half to two-thirds white, yellow, or chestnut. Chin, throat, inguinal region, and a band across chest behind the elbows white; remainder of under parts gray-brown, not sharply differentiated from sides. Considerable individual variation present in color, particularly in extent of white on head, under parts, and tail. Feet large, broad, with strong claws on all toes; colored gray-brown above.

DISTRIBUTION: *Echimys chrysurus* is known from the eastern Amazon Basin and Guianan region of Brazil, Guyana, Surinam, and French Guiana, east of the Rio Negro north of the Rio Solimões and east of the Rio Xingu south of the Rio Solimões.

SELECTED LOCALITIES (Map 493): BRAZIL: Amapá, Serra do Navio (Iack-Ximenes et al. 2005b); Amazonas, Rio Pitinga (M. N. F. da Silva and Patton 1993); Maranhão, Vargem Grande (T. G. Oliveira and Mesquita 1998); Pará, 52 km SSW of Altamira, right bank Rio Xingu (Y. L. R. Leite and Patton 2002), Baião (Iack-Ximenes et al. 2005b), Peixe-Boi (Iack-Ximenes et al. 2005b), São Domingo do Capim (Iack-Ximenes et al. 2005b). FRENCH GUIANA: Cayenne (Iack-Ximenes et al. 2005b). GUYANA: East Berbice-Corentyne, Potaro Highlands (Iack-Ximenes et al. 2005b), Essequibo Islands–West Demerara, Supinaam River (Iack-Ximenes et al. 2005b); Upper Takutu–Upper Essequibo, Tamton (ROM 36840). SURINAM: Nickerie, Polder, near Nieuw Nickerie (Husson 1978), Paramaribo, near Paramaribo (Husson 1978).

SUBSPECIES: *Echimys chrysurus* is monotypic.

NATURAL HISTORY: Nocturnal, arboreal, and usually solitary, *E. chrysurus* occurs in mature lowland rainforest where it feeds on fruit and probably leaves. Individuals use the middle and upper levels of the forest, especially in viney areas, but are also present in open forest (Miles et al. 1981). They may run quickly through the branches but are more typically slow and methodical in their movements, making them difficult to spot. When disturbed they creep quietly into thick vegetation and sit motionless for many minutes, then sneak away silently (Emmons and Feer 1997). They make nests of leaves in tree holes. Known predators include the Spectacled Owl (Haverschmidt 1968).

REMARKS: Cuvier's (1809) *Echimys* included several species now classified in different genera, but Desmarest (1817b) clearly fixed the type species of *Echimys* by writing "Le lérot à queue dorée d'Allamand et de Buffon en est le type" (p. 54), which is *Myoxus chrysurus* Zimmermann. Iack-Ximenes et al. (2005b:57) followed Tate (1935:430) in considering *E. cristatus* Desmarest as a junior synonym of *Echimys chrysurus* Zimmermann. Lichtenstein (1820) has been generally regarded as the author of *Loncheres paleacea* (e.g., Thomas 1916e; Ellerman 1940; Cabrera 1961; Woods 1993; Woods and Kilpatrick 2005), with Illiger's (1811) first use of the name considered a *nomen nudum*. Iack-Ximenes et al. (2005b) suggested that *E. paleaceus* is a valid species, a conclusion that followed Moojen's (1952b) earlier opinion. Cabrera (1961:541) listed *paleaceus* as a valid subspecies of *E. chrysurus*, but cited Kuhl (1820) as the author of the name because his work apparently appeared earlier in 1820 than did Lichtenstein's description. However, both Iack-Ximenes et al. (2005b) and Cabrera (1961) overlooked Olfers' 1818 description of *Loncheris* [*sic*] *paleacea* (see Hershkovitz 1959b, for discussion), which was based on the same specimen in the Berlin Museum described later by both Kuhl and Lichtenstein. Thus, Kuhl and Lichtenstein only redescribed Olfers' *paleacea*.

Map 493 Selected localities for *Echimys chrysurus* (●) and *Echimys vieirai* (○).

Herskovitz (1959b) argued that Illiger's (1811:90) *L. paleacea* is actually valid, as it is contained within his diagnosis of the genus *Loncheres*. However, because Illiger (1811) listed two species under his new genus, one of which was a valid taxon at the time (*chrysurus*), the nonspecific description of the genus cannot be said to diagnose his new species (*paleacea*). Thus, *paleacea* Illiger remains as a *nomen nudum*, as thought by J. A. Allen (1899c). Lichtenstein (1820) redescribed the same Berlin specimen that formed the basis for Illiger's *paleacea* as like a porcupine with a white stripe on the head and a tail with a scaly base and tufted tip, features that clearly link *paleaceus* to *E. chrysurus*. Finally, Iack-Ximenes et al. (2005b:58) assigned a specimen from Peixe-Boi, Pará state, Brazil in the Natural History Museum of London (BM 14.6.10.1) to *E. chrysurus*, the same specimen which Thomas (1916e:295) remarked was "the closely allied but smaller Amazonian species *E. paleaceus*, Licht., [which] has been received from the Goeldi Museum, Para (locality, Peixe-Boi)." We have examined this specimen and agree that it represents *E. chrysurus*. Therefore, pending further field and museum work, we regard *paleaceus* as a synonym of *E. chrysurus* and accept Olfers as the valid author of the name.

Echimys saturnus Thomas, 1928

Dark Tree Rat

SYNONYM:

Echimys saturnus Thomas, 1928d:409, type locality "Rio Napo, Oriente of Ecuador. Alt. 3300'," probably Napo province.

DESCRIPTION: Also moderately large arboreal rat, head and body length 272–335 mm (N=2), tail length 295–383 mm, hindfoot length 50–51, ear length 17–18 mm. Upper parts generally glossy brown and head, mid-back, and tail base deep glossy black; sides chestnut or coppery in color. Dorsal pelage composed of stiff bristles and mid-back has wide, flat spines that do not extend onto rump; spines slaty with black tips. Ears short, buried in hair of head. Under parts white, white-spotted, or whitish with buff tinge; chin dark. Tail much longer than the head and body (140% in one individual); densely haired; black at base with variable length of white on or near tip. Hindfeet broad and strong, with strong claws on each toe. Some melanistic individuals known.

DISTRIBUTION: *Echimys saturnus* is known from the eastern Andean foothills and adjacent lowlands of Ecuador and northern Peru; all records are below 1,000 m.

SELECTED LOCALITIES (Map 494): ECUADOR: Napo, Cerro Galeras (AMNH 71903), Río Pucuno (MCZ 41569); Orellana, Río Cotapino (KU 68093), Tiputini Biodiversity Station (Blake et al. 2010). PERU: Amazonas,

Map 494 Selected localities for *Echimys saturnus* (●). Contour line = 2,000 m.

mouth of Río Santiago (AMNH 98262); Ucayali, Río Pisuqui (AMNH 98261).

SUBSPECIES: *Echimys saturnus* is monotypic.

NATURAL HISTORY: This species has not been studied in the field. Blake et al. (2010) obtained nine camera-trap photographs of this rare species on the ground at night beside a stream by a mineral lick. One photo included an apparent adult pair and one young traveling together in a tight group (color photo in Blake et al. 2010). Repeated presence at a lick suggests an herbivorous diet (Emmons and Stark 1979).

REMARKS: Virtually nothing is known about this very infrequently seen or collected species. Thomas (1928d:409) considered *E. saturnus* closely related to *E. chrysurus*, but “distinguishable by the absence of a white crown-patch, by its deep black head and centre area of the back, its copper-coloured sides, white middle line below, and nearly wholly black tail.” Iack-Ximenes et al. (2005b: table 1) provided comparative measurements for a single specimen of *E. saturnus* and a sample of similar aged (by tooth wear categories) *E. chrysurus*. The former species is slightly larger in all dimensions of the skull with the exception that it has smaller bullae. Emmons (2005:286, Fig. 14) provided dorsal, ventral, and lateral photographic views of the cranium and a lateral view of the left mandible of the holotype (BM 34.9.10.182).

Echimys vieirai Iack-Ximenes, de Vivo, and Percequillo, 2005

Vieira's Tree Rat

SYNONYM:

Echimys vieirai Iack-Ximenes, de Vivo, and Percequillo, 2005b:52; type locality “Barreirinha, right bank of the Tapajós River, near São Luis do Tapajós, Pará State, Brazil; geographic coordinates 04°25'S, 56°13'W.”

DESCRIPTION: Smallest species in genus, but only known from young individuals; head and body length of one specimen 245 mm, tail length 340 mm, hindfoot length 50 mm, and ear length 15 mm. Upper parts generally dark brown and head from muzzle to crown, mid-back, and tail base black; head with dark maroon medial stripe from rostrum to crown; sides dull brown only slightly distinct from back. Dorsal pelage composed of stiff bristles and mid-back has wide, flat spines that do not extend onto rump. Ears short, buried in hair of head. Under parts light brown. Tail long (139% of head and body length), densely haired, brown at base with terminal third white. Hindfeet broad and strong, with strong claws on each toe.

DISTRIBUTION: *Echimys vieirai* is known only from two localities south of the Rio Amazon in Amazonas and Pará states, Brazil (Iack-Ximenes et al. 2005b).

SELECTED LOCALITIES (Map 493): BRAZIL: Amazonas, Virgen Guajará (Iack-Ximenes et al. 2005b); Pará, Barreirinha (type locality of *Echimys vieirai* Iack-Ximenes, de Vivo, and Percequillo).

SUBSPECIES: *Echimys vieirai* is monotypic.

NATURAL HISTORY: This species has not been studied in the field.

REMARKS: Known from only two juvenile specimens, this species is distinguished from *E. chrysurus* primarily by the lack of the white blaze on the top of the head that is so characteristic of the latter throughout its broad range. In this respect, *E. vieirai* is similar to *E. saturnus* from the northwestern Amazon, but other features of the pelage and cranium, as well as the large hiatus between the known ranges, make it unlikely that they represent only geographic variants of the same taxon.

Genus *Isothrix* Wagner, 1845

Louise H. Emmons and James L. Patton

These are medium to relatively large arboreal rats with soft fur, and a tail covered with long, unbanded hair that curls outward like a bottlebrush but may not completely hide the underlying scales. The tail of both *I. pagurus* and *I. sinamariensis* has the tendency to coil at the tip into a tight downward spiral of loops (Patton and Emmons 1985; Vié et al. 1996).

The cranium is broad, with a short and broad rostrum; zygomatic arches are strongly bowed outward anterior to squamosal. The tympanic bullae are moderately inflated, and the auditory meatus is medium-sized, positioned near the squamosal, and with a short auditory tube strongly slanted forward. The squamosotympanic fenestra is a long, open slit that reaches posteriorly to the base of the lateral process of the supraoccipital. The postpalatal notch is deep, extending to the middle of M2; the incisive foramina are large and wide. In the pterygoid region, there is no shelf of bone behind the base of parapterygoid (hamular) processes on the wall of the buccinator foramen. Anterior to the presphenoid-basisphenoid suture is a round vacuity connected to a slit-like vacuity along the side of the presphenoid that is shaped like a written musical note. The base of the mandible has strongly developed masseteric and pterygoid crests; the mandibular foramen is anterior to the condyloid ridge and not in a fossa.

The maxillary tooththrows are short, $\leq 26.8\%$ of basilar length of Hensel. Maxillary cheek teeth are small and short, with a somewhat subcircular shape in occlusal view. The plane of the maxillary teeth is not strongly tipped laterally as in other echimyines; rather, the occlusal surface is nearly on a plane parallel to the palate (see Em-

mons 2005:258, Fig. 2). All hypoflexi(id)s of both upper and lower premolars and molars are oval to subcircular with a mure; the adjacent loph curve around the hypoflexi to nearly close at the rim of the tooth. Hypoflexids of the mandibular cheek teeth slant slightly backward, with the internal end of the flexid slightly posterior to the external end. The lower premolar is pentalophodont, hypoflexid is short, with a mure, and other flexids are close to parallel, and all are open lingually when unworn. This tooth quickly wears to a pointed oval, with three parallel lingual fossettes and a round labial fossette derived from the hypoflexid.

Mammae range in number from three to five lateral pairs with usually one inguinal pair. The phallus of *I. bistriata* is short and blunt, with deep longitudinal grooves on sides, the lappet above urethra is not salient from the crater (figured in Emmons 2005), and the baculum is long and narrow (Patton and Emmons 1985).

We recognize six species, which fall into two readily separable groups based on body size and pelage color and color pattern. The species within each group, however, lack easily observable morphological differences. The three species of the “*bistriata*” group (*I. bistriata*, *I. negrensis*, and *I. orinoci*) are all large, but separable from one another only by multivariate analyses of cranial mensural variables and, in the case of two of them, by molecular data (data for *I. orinoci* are lacking). The other three species (*I. barbarabrownae*, *I. pagurus*, and *I. simamariensis*) are all smaller; the latter two of this triad are largely distinguishable by karyotype as they share similar but reciprocally monophyletic mitochondrial sequences. Adult specimens documenting overall size and color pattern are unknown for the recently described *I. barbarabrownae*. Each of the six species has allopatric ranges, so species assignments of museum specimens can be confidently made by a combination of morphology coupled with distributional data.

SYNONYMS:

Isothrix Wagner, 1845a:145; type species *Isothrix bistriata* Wagner, by subsequent designation (Goldman, 1916:125.)

Loncheres (*Isothrix*): Waterhouse, 1848:327; part, as subgenus (listing of *bistriata* and *pagurus*).

Lasiuromys Deville, 1852:557; type species *Lasiuromys villosus* Deville, by monotypy.

Echimys (*Isothrix*): E.-L. Trouessart, 1904:504; part, as subgenus (listing of *bistriata*, *pagurus*, and *villosus*); not *Echimys* F. Cuvier.

REMARKS: Members of this genus, like *Callistomys* spp., have some characters shared with eumysopines and not with other echimyines. These include small and somewhat rounded cheek teeth with only the hypoflexi(id)s open (other flexi(id)s appearing as closed enamel folds), and an open squamosotympanic fenestra. Some molecular se-

quence analyses (Lara et al. 1996; Y. L. R. Leite and Patton 2002; Galewski et al. 2005; B. D. Patterson and Velazco 2008; Upham and Patterson 2012) failed to firmly support inclusion of *Isothrix* within the Echimyinae, although other studies did (P.-H. Fabre et al. 2012). Phylogenetic analyses of morphological characters (G. A. S. Carvalho and Salles 2004; B. D. Patterson and Velazco 2006) do place *Isothrix* within a group of echimyine genera. As mentioned previously, Emmons (2005) regarded the phylogenetic position to be sufficiently equivocal to list *Isothrix* as Echimyinae *incertae sedis*. The two most recent and comprehensive molecular analyses both place *Isothrix* as basal to other echimyine plus the dactylomyine genera (P.-H. Fabre et al. 2012; Upham et al. 2013).

The genus was reviewed by Patton and Emmons (1985), who included *Callistomys pictus*, following previous authors and without any character evaluation or other justification. Exclusive of *pictus*, these authors recognized two species: *Isothrix bistriata*, a wide-ranging western Amazonian taxon (in which they included the named forms *pachyura* Wagner, *villosa* Deville, *orinoci* Thomas, *negrensis* Thomas, *molliae* Thomas, and *boliviensis* Petter and Cuenca Aguirre) varyingly characterized by black or dark-brown supraorbital stripes extending onto the nape of the neck; and *Isothrix pagurus*, a smaller species with a reddish nose that lacks stripes on the head and that is limited to both sides of the lower Amazon River east of the Rio Negro-Madeira axis. Patton and Emmons (1985), however, documented that populations of *I. bistriata* from the Venezuelan Amazon (including the holotype of *orinoci* Thomas 1899) were separable from those of the western Amazon of Peru and Bolivia in multivariate morphometric characters as well as in color pattern. They lacked samples from the central Amazon of Brazil, except the holotype of *negrensis* Thomas, which by itself fell within a western Amazon morphometric group. Based on similar color and color patterns, Patton and Emmons (2005:12) treated *orinoci* Thomas as a valid subspecies of a polytypic *Isothrix bistriata*, and listed *negrensis* Thomas as a junior synonym of the nominotypical subspecies. Subsequently, based on newly collected materials and expanded analyses, Patton et al. (2000; see also M. N. F. da Silva and Patton 1993) showed that samples from the central Amazon of Brazil, including the geographic area from which the holotype of *negrensis* was obtained, were phylogenetically separable from those of western Amazonia in mtDNA sequences, and that these former samples were also different in a multivariate morphometric analysis from both western Amazonian samples and those from southern Venezuela. Bonvicino, Menezes, and Oliveira (2003) documented chromosomal differences between populations from the western and central Amazon and expanded on the molecular divergence

analysis of Patton et al. (2000). These authors concluded that *negrensis* Thomas was a valid species, diagnosable by morphometric, chromosomal, and molecular characters, a conclusion followed by Emmons (2005), Woods and Kilpatrick (2005), B. D. Patterson and Velazco (2006, 2008), and Lim et al. (2006). Emmons (2005) listed *orinoci* Thomas as a valid species but without comment, and B. D. Patterson and Velazco (2006) provided a thorough rationale for the species status of this taxon. Herein, we follow these recent trends and divide *Isothrix bistrata* (*sensu* Patton and Emmons 1985) into three species: *bistrata* Wagner, *negrensis* Thomas, and *orinoci* Thomas.

Additionally, two newly recognized species have been discovered in the past two decades. Vié et al. (1996) described *I. sinnamariensis* from French Guiana, closely related to *I. pagurus* but with a radically different chromosome complement. And, B. D. Patterson and Velazco (2006) described *I. barbarabrownae* from the eastern Andean slope in southern Peru.

Finally, *pachyura* Wagner, 1845 has been commonly referred to *Isothrix* as a valid species or subspecies (Palmer 1904; Tate 1935; Ellerman 1940; Cabrera 1961) or simply arranged as a junior synonym of *I. bistrata* (Patton and Emmons 1985). However, Wagner (1848) himself, while renaming *I. pachyura* as *I. crassicaudus*, stated that it was probably the same as Lund's *Nelomys antricola*, to which E.-L. Trouessart (1880b:179, as *Echimys* [*Thrichomys*] *antricola*) agreed. Thomas (1916e) also correctly allocated *pachyura* Wagner to *Cercomys* (= *Thrichomys*, see that account), and Moojen (1952b:172) regarded it as a valid subspecies of *C. cunicularis* (a composite taxon [see Remarks in the *Thrichomys* account] but as understood by Moojen would equal *Thrichomys apereoides* of today).

KEY TO THE SPECIES OF *ISOTHRIX*:

- 1. Size large (mean head and body length >235 mm; mean condyloincisive length of skull >49 mm); black stripes on top of head 2
- 1'. Size smaller (mean head and body length <225 mm; mean condyloincisive length of skull <44 mm); head uniformly colored without black stripes 4
- 2. Black head stripes remain separate behind ears; distribution in western Amazon *Isothrix bistrata*
- 2'. Black head stripes fuse behind ears into a black band on the neck 3
- 3. Distribution in central Amazonian Brazil *Isothrix negrensis*
- 3'. Distribution in upper Orinoco drainage of Venezuela. *Isothrix orinoci*
- 4. Tail color monochromatic; distribution in eastern Amazon and Guianan Shield 5

- 4'. Tail with terminal one-third white; distribution limited to eastern Andean slope of southern Peru. *Isothrix barbarabrownae*
- 5 Postauricular dark patch absent; 2n=22; distributed in east-central Amazonian Brazil *Isothrix pagurus*
- 5'. Postauricular dark patch present; 2n=28; distributed in Guianan region. *Isothrix sinnamariensis*

Isothrix barbarabrownae B. D. Patterson and Velazco, 2005

Barbara Brown's Brush-tailed Rat

SYNONYM:

Isothrix barbarabrownae B. D. Patterson and Velazco, 2006:179; type locality "Km 138.5 on the Carretera Paucartambo-Shintuya, near 'Suecia' (a roadside restaurant), 1900 m, Provincia de Paucartambo, Departamento de Cusco, Peru," in the Cultural Zone of the Manu Biosphere Reserve at 13°6.032'S, 71°34.124'W.

DESCRIPTION: Size small for genus (condyloincisive length of skull of subadult, 40.36 mm). Fur long and lax, hairs reach 20 mm on back, 15 mm on flanks, and 10 mm on belly. Head lacks conspicuous supraorbital stripes although blackish dorsal crest or mane is present. Tail uniformly haired and tricolored, with terminal 5 cm white, middle part black, and base brown. Skull compact, with long axis bowed; braincase not swollen, and temporal fossa not deep; infraorbital foramen narrow and triangular in shape; septum of incisive foramina with well-developed maxillary component; palate narrow; foramen magnum especially broad and with distinct dorsal median notch; auditory bullae small.

The holotype, and only known specimen, is a subadult without fully erupted cheek teeth. B. D. Patterson and Velasco (2006) provided craniodental measurements in comparison with other species in genus.

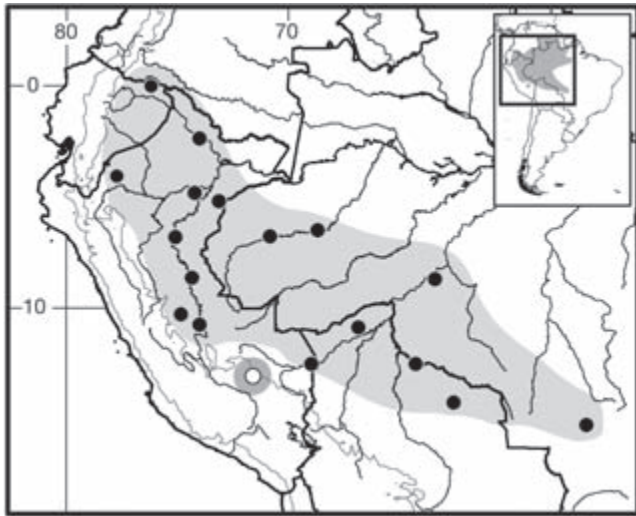

DISTRIBUTION: *Isothrix barbarabrownae* is known only from the type locality in southeastern Peru.

SELECTED LOCALITIES (Map 495): PERU: Cusco, near "Suecia" (type locality of *Isothrix barbarabrownae* B. D. Patterson and Velazco).

SUBSPECIES: *Isothrix barbarabrownae* is monotypic.

NATURAL HISTORY: This is the only species in the genus distributed in upper tropical forest rather than lowland rainforest. The holotype was collected on a steep, rocky slope covered by ferns, mosses, and bryophytes in elfin forest; a second individual was seen in similar circumstances but was not secured.

REMARKS: This species can be distinguished from all congeners by its long, lax, and reddish pelage. No other species have a dorsal crest or mane of blackish hairs. Cranially, *I. barbarabrownae* resembles *I. bistrata* but comparisons are limited because the holotype and only known specimen

Map 495 Selected localities for *Isothrix barbarabrownae* (○) and *Isothrix bistriata* (●). Contour line = 2,000 m.

is a subadult where PM4 has not yet erupted. Phylogenetic analysis of mitochondrial and nuclear DNA sequences (B. D. Patterson and Velazco 2008) placed *I. barbarabrownae* at the base of a clade comprising the remaining species in the genus (e.g., [*barbarabrownae* [[[*pagurus*, *sinnamariensis*]] [*negrensis*, *orinoci*] *bistriata*]]]).

Isothrix bistriata Wagner, 1845

Yellow-crowned Brush-tailed Rat

SYNONYMS:

Isothrix bistriata Wagner, 1845a:146; type locality “Río Guapore,” fixed herein to Isla Leomil, Río Guaporé, Beni, Bolivia (see Remarks).

Lasiuromys villosus Deville, 1852:560, plate 15, plate 16, Fig. 5, 5a; type locality “la Mission de Sarayacu (Pérou, Pampa del Sacramento, et le village de Saint-Paul, Haut-Amazone, partie brésilienne),” Río Ucayali, Loreto, Peru.

Loncheres (Isothrix) bistriatus: Thomas, 1899d:383; name combination.

Loncheres (Isothrix) villosus: E.-L. Trouessart, 1897:606; name combination.

Echimyus (Isothrix) villosus: E.-L. Trouessart, 1904:504; name combination.

[*Isothrix*] *villosa*: Thomas, 1916e:295; name combination.

Isothrix villosa molliae Thomas, 1924c:534; type locality “Tushemo, near Masisea, R. Ucayali. Alt. 1000’,” Loreto, Peru.

Isothrix villosa villosa: Thomas, 1928c:291; name combination.

[*Isothrix*] *bistriatus bistriatus*: Tate, 1935:414; name combination but incorrect gender concordance.

[*Isothrix*] *villosus villosus*: Tate, 1935:416; name combination but incorrect gender concordance.

Isothrix bistriata boliviensis Petter and Cuenca Aguirre, 1982:191; type locality “une région de forêt subtropicale humide (350 m d’altitude) au bord de la rivière Saint-Louis [= Río San Luis], sud-est du Béni (Bolivie)”;

subsequently stated to be (p. 199) “Barranca Colorada, Beni, Bolivie [= Bolivia].”

Isothrix bistriata bistriata: Patton and Emmons, 1985:12; name combination.

DESCRIPTION: One of larger species in genus, mean head and body length 249.2 mm (range: 214–275 mm; N=18), tail length 242.8 mm (range: 215–271 mm; N=18), hindfoot length 48.3 mm (range: 45–54 mm; N=18), ear length 18.5 mm (range: 15–20 mm; N=18), and mean condyloincisive length 50.7 mm (range: 44.5–55.0 mm; N=69). Dorsal color grizzled yellow-brown to olive mixed with black hairs, and well-defined black or dark-brown supraorbital stripes extending over forehead to nape and bordering a median pale creamy patch on crown. Brightness of crown patch and black supraorbital stripes varies, due to age, individual, or interpopulation variation. Unlike two similar species, *I. orinoci* and *I. negrensis*, black supraorbital stripes do not coalesce behind ears but remain separate onto neck. Venter pale yellow to buff. Tail fully haired, typically rust or golden colored over basal third to half with terminal portion usually black, but tail color varies considerably, with pale yellow to almost white tip in some animals but black in others. Tail about same length as body (mean tail: body ratio 97%, range: 87.6–108.9%). Baculum long and broad, more so than that of *I. orinoci* (comparison of Peru and Venezuela samples in Patton and Emmons 1985). Skull as for the genus.

DISTRIBUTION: *Isothrix bistriata* is known from the western Amazon Basin of Peru, Bolivia (S. Anderson 1997), and Brazil (Patton et al. 2000), and probably extends north to eastern Ecuador and possibly to southeastern Colombia. Tirira (1999:141) recorded a visual record from the Reserva de Producción Faunística Cuyabeno, Sucumbiós, and subsequently (Tirira 2007:225–226) he listed two localities from which photographic documentation was available and mapped a distribution in eastern Sucumbiós and Orellana provinces. L. H. Emmons (unpubl. obs.) likewise observed an *Isothrix* sp. in riverside forest on the Ecuador border near the mouth of the Río Napo, close to one of Tirira’s localities. We include the observational and photographic records in the map (Map 492), with the reservation that we cannot confirm identifications of either. However, there is certainly no obvious reason why *Isothrix bistriata* would not be part of the fauna of eastern Ecuador or even southern Colombia.

SELECTED LOCALITIES (Map 495): BOLIVIA: Beni, Barranca Colorada, Río San Luis (type locality of *Isothrix bistriata boliviensis* Petter and Cuenca Aguirre), Isla Leomil (type locality of *Isothrix bistriata* Wagner; see Remarks);

Pando, Ingavi (Patton et al. 2000). BRAZIL: Amazonas, Jaiú, left bank Rio Juruá (Patton et al. 2000), Sacado (Patton et al. 2000); Mato Grosso, Cuiabá (Moojen 1952b; Bonvicino, Menezes, and Oliveira 2003); Rondônia, Samuel (Bonvicino, Menezes, and Oliveira 2003). ECUADOR: Sucumbíos, Reserva de Producción Faunística Cuyabeno (Tirira 1999). PERU: Amazonas, La Poza (Patton et al. 2000); Loreto, Boca Río Cururay (Patton and Emmons 1985), Nuevo San Juan (AMNH 272808), Río Tigre, 1 km below Río Tigrillo (B. D. Patterson and Velazco 2006), Sarayacu (Patton and Emmons 1985); Madre de Dios, Reserva Cusco Amazonico (B. D. Patterson and Velazco 2006); Pasco, Nevati Mission (Patton and Emmons 1985); Ucayali, Lagarto (Patton and Emmons 1985), Tushemo (type locality of *Isothrix villosa molliæ* Thomas).

SUBSPECIES: As currently construed, *Isothrix bistrata* is monotypic. Thomas (1928c:291) placed his *molliæ* (Thomas 1924c) as a synonym of *villosa* Deville and suggested that the latter might prove to grade into *bistrata* from Brazil, of which *villosa* would then “form an Upper Amazonian subspecies.” Cabrera (1961) listed *negrensis* Thomas, *orinoci* Thomas, *pagurus* Wagner, and *pachyura* Wagner as valid subspecies in his concept of *I. bistrata*, the first three of which are herein elevated to species status and the latter referred to the genus *Thrichomys* (see above, and account of *Thrichomys*). Contrary to Thomas’s (1924c) suggestion, Cabrera (1961) maintained *villosa* Deville as a species separate from *I. bistrata*, and included *molliæ* Thomas as a valid subspecies. However, Patton and Emmons (1985) were unable to distinguish samples from Peru and Bolivia (including the holotype of *molliæ* Thomas and topotypes of *villosa* Deville) in a multivariate analysis of craniodental mensural characters, and listed both names as synonyms of *I. bistrata bistrata* Wagner. This is likewise the case with *I. b. boliviensis* (Petter and Cuenca Aguirre 1982), also from Beni, Bolivia. The type locality of *boliviensis* (Río San Luis, Barranca Colorada), although not precisely located, is <300 km from the type locality of *I. bistrata* (the maximum length of the Río San Luis).

NATURAL HISTORY: Nearly all specimens of *I. bistrata* have been collected in seasonally inundated or floodplain forest (*várzea*) along whitewater rivers. These are arboreal animals that nest in tree holes, and where male and female pairs have been observed on several occasions (Patton et al. 2000). Litter size averages two, based on embryo scar counts, and breeding may be continuous throughout the year (Patton et al. 2000).

REMARKS: Wagner (1845a:145) gave the type locality of *I. bistrata* as “Rio Guaporé,” which has been uniformly considered to be in Mato Grosso state, Brazil, by subsequent authors (Ellerman 1940; Cabrera 1961; Patton and Emmons 1985; Woods and Kilpatrick 2005). However, the

catalogue sheet for Wagner’s holotype in the Naturhistorisches Museum Wien, Vienna (NMW B914), reads “nahe Mündung des Rio Itonamas in den Guaporé ‘gegenüber Liomil am Guaporé’ (von Pelzeln 1883) Rondonia, Brasil oder Bolivia.” The Río Itonamas is in Bolivia, its mouth at 12.750°S, 64.633°W on the Río Guaporé. There is an Isla Leomil or Leamel in the Río Guaporé, Beni, Bolivia (64.1667°S, 12.50°W; Alexandria Digital Library). We thus fix the type locality of *I. bistrata* Wagner to Isla Leomil, Río Guaporé, Beni, Bolivia.

Patton et al. (2000) assigned Wagner’s *bistrata* to the western Amazon clade they defined on morphological and molecular grounds. Although they did not include specimens from the type locality in their analyses, one sample from Pando (“c,” p. 179; actually from Ingavi and not San Juan de Nuevo Mundo) is 350 km NW of the type locality. This sample clusters with those from Madre de Dios (Peru) and the upper Rio Juruá (Brazil) (Patton et al. 2000). If subsequent studies indicate that populations from southwestern Amazonia are separable, then this western Amazon clade would be appropriately named *I. villosa* Deville, with *I. bistrata* restricted in distribution to the area south of the Rio Juruá to southeastern Peru and Bolivia south and east to Cuiabá, Brazil. The karyotype (based on specimens from the Rio Jamarí, Rondônia, and the Rio Juruá, Acre and Amazonas, Brazil) consists of $2n=60$, FN=116, with a large acrocentric X chromosome and a very small, metacentric Y chromosome (Leal-Mesquita 1991, who illustrated both the nondifferentially stained and C-banded complement; Patton et al. 2000). Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

Isothrix negrensis Thomas, 1920

Rio Negro Brush-tailed Rat

SYNONYMS:

Isothrix bistrata negrensis Thomas, 1920f:277, type locality “Acajutuba, lower Rio Negro, near its mouth,” a little above Manaus on the Rio Negro, Amazonas, Brazil.

[*Isothrix*] *bistriatus negrensis*: Tate, 1935:416; name combination but incorrect gender concordance.

Isothrix bistrata negrensis: Patton and Emmons, 1985:12; name combination.

Isothrix negrensis: Bonvicino, Menezes, and Oliveira, 2003:206; first use of current name combination.

DESCRIPTION: Size large for genus, with mean head and body length 254.1 mm (range: 203–292 mm; N=3), tail length 226.5 mm (range: 182–271 mm; N=3), hind-foot length 49.3 mm (range: 43–45 mm; N=3), ear length 18.7 mm (range: 17–20 mm; N=18), and mean condyloincisive length 53.7 mm (range: 50.9–55.9 mm; N=3). Similar in color and color pattern to *I. orinoci*, and thus differ-

ing from *I. bistriata* by having marked, light postauricular patches and a shorter median light crown-patch, which ends opposite the middle of the ears instead of continuing down the nape so that the nape is completely blackish instead of divided down the center (Thomas 1920f); differs from *I. orinoci* in more ochraceous color, especially on rump, buffy rather than whitish ear patches, median crown patch distinct and buffy instead of whitish, and strongly ochraceous buffy venter. Tail proportionally longer than head and body length (mean 106.7%). Cranial vault deeper, in lateral view, and diastema shorter in this species than in either *I. bistriata* or *I. orinoci*; otherwise all three species are similar in cranial morphometric characters (Patton et al. 2000; B. D. Patterson and Velazco 2006).

DISTRIBUTION: *Isothrix negrensis* occurs in the central Amazon Basin of eastern Colombia and Brazil, from the lower Rio Juruá east to the Rio Madeira on the south side of the Rio Solimões, and on the north side throughout the Rio Negro drainage.

SELECTED LOCALITIES (Map 496): BRAZIL: Amazonas, Acajutuba (type locality of *Isothrix bistriata negrensis* Thomas), Colocação Três Barracas (Bonvicino, Menezes, and Oliveira 2003), Ilha das Onças (Patton et al. 2000), Lago Três Unidos (Patton et al. 2000), alto Rio Urucu (Patton et al. 2000). COLOMBIA: Vaupés, Yay Gojes (FMNH 88236).

Map 496 Selected localities for *Isothrix negrensis* (●) and *Isothrix orinoci* (○). Contour line = 2,000 m.

SUBSPECIES: *Isothrix negrensis* is monotypic.

NATURAL HISTORY: This species has been taken in seasonally inundated, lowland rainforest, along both whitewater and blackwater rivers.

REMARKS: *Isothrix negrensis* corresponds to the central Amazon clade of “*I. bistriata*” defined on mtDNA sequences by Patton et al. (2000:179, Fig. 117). Emmons (2005:278, Fig. 11) provided dorsal, ventral, and lateral photographs of the skull and lateral view of the mandible of the holotype (BM 20.7.1.20). Treated as a synonym of *I. bistriata bistriata* by Patton and Emmons (1985) but as a valid subspecies by Patton et al. (2000). Elevated to species status by Bonvicino, Menezes, and Oliveira (2003), who described a karyotype with $2n=60$, FN=112, and provided additional molecular sequence to support its separation from *I. bistriata*.

Isothrix orinoci (Thomas, 1899)

Orinoco Brush-tailed Rat

SYNONYMS:

Loncheres (Isothrix) bistriatus orinoci Thomas, 1899d: 382; type locality “Maipures, Upper Orinoco,” Vichada, Colombia.

Echimyus (Isothrix) bistriatus orinoci: E.-L. Trouessart, 1904: 504; name combination.

Isothrix bistriatus orinoci: Pittier and Tate, 1932:264; name combination but incorrect gender concordance.

[*Isothrix*] *bistriatus orinoci*: Tate, 1935:416; name combination but incorrect gender concordance.

Isothrix bistriata orinoci: Patton and Emmons, 1985:12; name combination.

Isothrix orinoci: Emmons, 2005:299; first use of current name combination.

DESCRIPTION: Similar in size, color, and color pattern to *I. bistriata* and *I. negrensis*. Mean head and body length 236.0 mm (range: 206–257 mm; N=19), tail length 242.9 mm (range: 168–278 mm; N=19), hindfoot length 48.4 mm (range: 45–50 mm; N=19), and mean condyloincisive length 49.9 mm (range: 47.0–52.2 mm; N=19), but with a bright yellow stripe over the head between the eyes and ears dulled to grizzled gray, passing on each side without sharp contrast into the dark supraorbital lines, which coalesce on the neck immediately behind the head to form a broad, black band; prominent whitish postauricular patch contrasting sharply with the blackish nuchal part of the coalesced supraorbital lines. The skull has a shorter rostrum but proportionately longer nasals than either *I. bistriata* or *I. negrensis* (Patton et al. 2000). The baculum is long and narrow, as in *I. bistriata*, but slightly smaller in all dimensions (Patton and Emmons 1985).

DISTRIBUTION: *Isothrix orinoci* is known from the Amazon Basin of the upper Río Orinoco in eastern Colombia and Venezuela as well as the Casiquiare of southern

Venezuela; it possibly extends into adjacent northern Brazil (Patton and Emmons 1985; B. D. Patterson and Velazco 2006).

SELECTED LOCALITIES (Map 496): COLOMBIA: Maipures, upper Orinoco (type locality of *Loncheres bistratus orinoci* Thomas). VENEZUELA: Amazonas, Boca Mavaca (Patton and Emmons 1985), Amazonas, Capibara (Handley 1976), Cerro Duida (Patton and Emmons 1985).

SUBSPECIES: *Isothrix orinoci* is monotypic.

NATURAL HISTORY: In Venezuela, *Isothrix orinoci* was found mostly in trees but rarely on the ground, always near streams, and always in lowland evergreen forest (Handley 1976).

REMARKS: In his original description, Thomas (1899d:383) remarked that he would have considered *orinoci* a species distinct from *bistriata* (from the Rio Madura [= Madeira]) “were it not that Natterer’s second specimen, from the Rio Negro, is, as I am kindly informed by Dr. Lorenz, more or less intermediate in character, as in locality, between the two.” These specimens of “*bistriata*” from the Rio Madeira and Natterer’s specimen from the Rio Negro, however, are actually *I. negrensis* as defined herein. It was treated as a valid subspecies of *I. bistrata* by Patton and Emmons (1985) and Patton et al. (2000), but elevated to species status by Emmons (2005) and B. D. Patterson and Velazco (2006). O. J. Linares (1998) suggested that the holotype, and thus the type locality, probably came from the right bank of the Río Orinoco at the Raudal de Maipures in Venezuela rather than on the left bank in Colombia, because the Colombian side is dominated by open savanna while that in Venezuela is evergreen forest, a more likely habitat for this arboreal rodent.

Isothrix pagurus Wagner, 1845

Plain Brush-tailed Rat

SYNONYMS:

Isothrix pagurus Wagner, 1845a:146, type locality “Borba,” Rio Madeira, Amazonas, Brazil.

[*Loncheres*] *pagurus*: Thomas, 1888a:326; name combination.

Loncheres (Isothrix) pagurus: E.-L. Trouessart, 1897:606; name combination.

Echimys (Isothrix) pagurus: E.-L. Trouessart, 1904:504; name combination.

DESCRIPTION: One of three smaller species in genus, with mean head and body length 221.8 mm (range: 170–234 mm; N=5), tail length 216.8 mm (range: 170–233 mm; N=5), hindfoot length 41.5 mm (range: 39–45 mm; N=6), and condyloincisive length 43.5 mm (range: 41.5–45.9 mm; N=6). Dorsal color from grizzled yellow or gray brown from forehead to midback, with flanks and rump distinctly russet; snout reddish, with that color circumscribing eyes;

no black supraorbital stripes over crown; tail grades uniformly from gray brown at base to yellow-brown toward tip; venter pale yellowish or buffy. Tail not only lacks black hairs characteristic of *bistriata*-complex species but typically exhibits opposite color pattern, being paler at the tip; it is subequal to the body length (mean ratio of tail: body 98%, range: 95.7–113.7%). It is smaller in each cranial dimension measured than any of the three *bistriata*-complex species (Patton and Emmons 1985). The baculum is similar in overall shape but substantially shorter in length in comparison to those of *I. bistrata* and *I. orinoci* (Patton and Emmons 1985).

DISTRIBUTION: *Isothrix pagurus* is known from the central Amazon Basin of Brazil, from the left (= east) bank of the lower Rio Negro east to the Rio Pitinga, north of the Rio Solimões, and from the lower Rio Madeira east to the lower Rio Tapajós, south of the Rio Solimões, in the states of Amazonas and Pará (Patton et al. 2000; B. D. Patterson and Velazco 2006).

SELECTED LOCALITIES (Map 497): BRAZIL: Amazonas, Borba (type locality of *Isothrix pagurus* Wagner), Lago Meduinim (Patton et al. 2000), 80 km N (by road) of Manaus (Patton and Emmons 1985); UHE Pitinga, Rio Pitinga (Patton et al. 2000); Pará, Boim (Thomas 1912d), Casa Nova (B. D. Patterson 1992b).

SUBSPECIES: *Isothrix pagurus* is monotypic.

NATURAL HISTORY: On the left (= east) bank of the lower Rio Negro in central Brazil, this species is found in seasonally inundated black water (*igapó*) forest while *I.*

Map 497 Selected localities for *Isothrix pagurus* (○) and *Isothrix sinnamariensis* (●).

bistriata occurs in *várzea*, or the floodplain forest of white-water rivers and streams. B. D. Patterson (1992b) noted that specimens have been taken in mature rainforest from tree holes in both living and dead trees.

REMARKS: Cabrera (1961) listed *I. pagurus* as a subspecies of *I. bistriata*, but Patton and Emmons (1985) and Patton et al. (2000) established its structural, karyotypic, and molecular distinctness. Patton and Emmons (1995) illustrated the karyotype ($2n=22$, FN=38), including both nondifferentially stained and C-band patterns.

Isothrix sinnamariensis Vié, Volobouev, Patton, and Granjon, 1996

Sinnamary Brush-tailed Rat

SYNONYM:

Isothrix sinnamariensis Vié, Volobouev, Patton, and Granjon, 1996:395; type locality “Sinnamary River right bank, 21 km upstream from the Petit Saut Dam, French Guiana (4°56.80'N–53°01.90'W—altitude below 20m).”

Isothrix sinamariensis Lim and Joemratie, 2011:144; incorrect subsequent spelling of *sinnamariensis* Vié, Volobouev, Patton, and Granjon.

DESCRIPTION: Small, with head and body length 212–215 mm, tail length 262 mm, hindfoot length 39–42 mm, and ear length 14–16 mm. Coloration generally dark brown, becoming reddish brown on hindparts and, less markedly, on nose; small but very distinct black spot apparent behind each eye, insertion point of a group of long genal vibrissae. Tail with short muff of dense fur at base, otherwise covered with curled hairs along entire length, terminating in tuft of long hairs (ca. 35 mm) coiled downward. Dorsal hairs bicolored, with gray base and reddish brown tip; ventral hairs shorter and also bicolored, with gray base and pale orange to reddish-brown tip. Zone of white hairs present in anogenital region. Hindfeet broad, with strong claws, and covered dorsally with short, pale hairs. Ears short and rounded, with small tufts of hairs on both inner and outer surfaces. Females have four pairs of lateral and one pair of inguinal mammae. Most similar to *I. pagurus* but tail longer (124% of head and body length) and less densely haired, and maxillary tooththrow shorter (mean length 9.81 mm versus 10.22 mm).

DISTRIBUTION: *Isothrix sinnamariensis* is restricted to the Guiana Shield, where it is known only from four localities, two in French Guiana and one each in Surinam and Guyana.

SELECTED LOCALITIES (Map 497): FRENCH GUIANA: Sinnamary River (type locality of *Isothrix sinnamariensis* Vié, Volobouev, Patton, and Granjon), Les Nouragues (B. D. Patterson and Velazco 2006). GUYANA: Upper Takutu–Upper Essequibo, Chodikar River (Lim et al.

2006). SURINAM: Sipaliwini, camp 1, Kutari River (Lim and Joemratie 2011).

SUBSPECIES: *Isothrix sinnamariensis* is monotypic.

NATURAL HISTORY: The two known specimens from French Guiana were both collected by hand during the daytime in trees, during flooding subsequent to dam construction, of undisturbed lowland rainforest within 100 m of the bank of the Sinnamary River (Vié et al. 1996). The single specimen from Guyana was caught in a live-trap placed on a vine about 15 cm above the ground in nonflooded, tall, evergreen, hill-land forest (Lim et al. 2006).

REMARKS: Vié et al. (1996) described and figured the chromosome complement ($2n=28$, FN=42), including G- and C-banding patterns, and document phylogenetic relationships to other species in the genus based on mtDNA sequences.

Genus *Makalata* Husson, 1978

Louise H. Emmons and James L. Patton

These are arboreal rats with short legs, long backs, and coarse pelage. The tail is about as long as the head and body, naked or sparsely clothed with stiff hair. Females typically have two pairs of functional lateral mammae, with a third, apparently obsolete, pair occasionally present. The phallus of *M. didelphoides* is slender, heavily ridged on the sides, with a long pointed dorsal bacular papilla positioned posterior to an extruded, large, and pointed urethral lappet (Emmons 2005:276, Fig. 10). The ventral lip of crater forms a deep V-shaped notch proximally abutting a straight, horizontal fold. The maxillary tooththrows are parallel or slightly divergent at either end; the cheek teeth are square to rectangular, longer than wide, with crowns of medium height, and usually two lingually opening flexi (hypoflexus, metaflexus) and two labially opening flexi (paraflexus and mesoflexus) such that M1 and M2 have two, U-shaped lophes opening in opposite directions. Several species, however, have one lingual and three labial flexi in some or all molars. The para-, meso-, and metaflexi extend two-thirds or more across PM4 as well as M1–M3, but hypoflexi are short, crossing about one quarter of the width of the tooth. Hypoflexids of the lower molars are positioned at an oblique angle such that the ectolophids at anterior tip of flexids are narrower than the lophid posterior to tip. The lower premolar is pentalophodont, with the anteroconid pointed; when unworn usually the flexid is not enclosed by lophids (no central fossette), but opens posteriorly such that anterior loph is an inverted V. The metaflexids of m1–m2 bend posteriorly at the internal tip, and mesoflexids are bent forward; the hypoflexid is often curved forward. The lower incisors are not strongly curved. The

auditory tympanic bullae are moderately inflated; the auditory meatus is medium sized to small; the auditory tube is short, outwardly or slightly forwardly directed; and the meatus is close to the squamosal suture. The squamoso-tympanic fenestra is slit-like but short, with its ventral lip raised in a ridge with a depression below. The maxillary septum of the incisive foramina is broadly fused to the pre-maxillary portion. The mandibular foramen is positioned in a fossa with its base on the condyloid ridge. The condyloid process of the mandible is short and dorsoventrally wide; the masseteric crest is strongly developed.

SYNONYMS:

Echimys: Desmarest, 1817b:54; part (description of *didelphoides*); not *Echimys* F. Cuvier.

Nelomys: I. Geoffroy St.-Hilaire 1838:887; part (listing of *didelphoides* and *armatus*); not *Nelomys* Jourdan.

Loncheres: Wagner, 1840:196; part (description of *obscura*); not *Loncheres* Illiger.

Makalata Husson, 1978:445; type species *Nelomys armatus* I. Geoffroy St.-Hilaire, a junior synonym of *Echimys didelphoides* Desmarest (Emmons 1993), by original designation; name specifically noted to be treated as gender feminine.

REMARKS: Emmons (2005) divided the genus into two groups, the “*didelphoides* group” in which she placed seven taxa (*didelphoides* Desmarest, *guianae* Thomas, *macrura* Wagner, *castaneus* Allen and Chapman, *longirostris* Anthony, *handleyi* Goodwin, and *obscura* Wagner) and the “*grandis* group” with *grandis* Wagner and *rhipidurus* Thomas. That same year Jack-Ximenes et al. (2005a) erected the genus *Toromys* with Wagner’s *Loncheres grandis* as its type species. Herein we restrict the genus *Makalata* to encompass only those taxa in Emmons’s “*didelphoides* group.”

The number of species present in the concept of *Makalata* that we invoke here remains uncertain. The description and map given in Emmons and Feer (1997) encompass the ranges of both *M. macrura* and *M. didelphoides*, as herein recognized. However, these authors (p. 238) commented that large-bodied animals from the central Amazon with heavily black-streaked backs and entire gray-brown under parts might represent a species (*M. macrura*) distinct from *M. didelphoides* (see also Emmons 1993; and the following accounts). B. D. Patterson (1992b) had previously noted that specimens from western Amazonian Brazil contrasted with those to the east in both coloration and stiffness of the spines. Patton et al. (2000) documented strongly differentiated mtDNA clades that also segregated by these same morphological and distributional attributes, and recognized *M. didelphoides* and *M. macrura* as separate species. These authors, however, noted that each species included substantial geographic structure. Finally, Emmons (2005) listed all seven taxa in her “*didelphoides* group” as species but with-

out comment or documentation. Pending an adequate review of available museum materials, we recognize only three species. One of these (*obscura* Wagner) is a *nomen dubium* (see Emmons 1993), a second (*macrura* Wagner) is reasonably well defined morphologically and geographically, and a third (*didelphoides* Desmarest) is highly variable and most likely composite. As detailed below, the genus also contains several formally named taxa that have been varyingly applied at the species or subspecies levels. Several of these, as well as some other unnamed but distinctive forms, are likely to be recognized at the species level once new collections fill geographic gaps and both more expansive morphological and molecular analyses are accomplished.

KEY TO THE SPECIES OF MAKALATA (EXCLUDING *M. OBSCURA* WAGNER, WHICH CANNOT BE IDENTIFIED NOR BOUNDED WITH ANY CERTAINTY AT PRESENT):

1. Distribution in Guianan region, eastern Amazonia from Pará southeast to Ceará, and southwestern Amazonia; throat, inner thigh, and sometimes venter pale cream or buff; size smaller, mass generally <220 g *Makalata didelphoides*
- 1' Distribution west-central Amazonia; venter gray-brown not sharply differentiated from sides; size larger, mass often >300 g *Makalata macrura*

Makalata didelphoides (Desmarest, 1817)

Red-nosed Armored Tree Rat

SYNONYMS:

Echimys didelphoides Desmarest, 1817b:58; type locality “Amérique méridionale” without further restriction (see Remarks).

L[oncheres]. didelphoides: J. B. Fischer, 1829:307; name combination.

Mus hispidus Lichtenstein, 1830:plate 35, and unnumbered text; not *hispidus* Desmarest.

Nelomys armata I. Geoffroy St.-Hilaire, 1838a:887; type locality “Cayenne” (= French Guiana); a renaming of *Mus hispidus* Lichtenstein.

Nelomys armata: I. Geoffroy St.-Hilaire, 1840:plate 24; illustration of specimen upon which the manuscript name *didelphoides* of É. Geoffroy St.-Hilaire was formally described by Desmarest (1817b).

Loncheres armata: Wagner, 1840:335; name combination. *Loncheres guianae* Thomas, 1888a:326; type locality “British Guiana,” Guyana, possibly Demerara region.

Echimys castaneus J. A. Allen and Chapman, 1893:222; type locality “Princetown [= Princes Town], Trinidad,” Trinidad and Tobago.

Loncheres (Loncheres) armatus: E.-L. Trouessart, 1897:605; name combination.

Echimys macrourus Jentink, 1879b:97; type locality “Dieperinck, Surinam”; not *macrura* Wagner; the difference in spelling is acceptable (ICZN 1999:Art. 58), as noted by Tate (1939:181).

Loncheres (Loncheres) guianae: E.-L. Trouessart, 1897:605; name combination.

Loncheres (Loncheres) castaneus: E.-L. Trouessart, 1897:605; name combination.

N[elomys]. armatus: J. A. Allen, 1899c:261; name combination.

Echimys (Echimys) armatus: E.-L. Trouessart, 1904:503; name combination.

Echimys (Echimys) guianae: E.-L. Trouessart, 1904:503; name combination.

Echimys (Echimys) castaneus: E.-L. Trouessart, 1904:503; name combination.

Loncheres armatus: Thomas, 1912d:88; name combination.

Phyllomys armatus: Goldman, 1916:126; name combination, but in which the author placed *Mus hispidus* Lichtenstein, *Nelomys armatus* I. Geoffroy St.-Hilaire (as a new name for Lichtenstein’s *M. hispidus*), *Phyllomys brasiliensis* Lund, and *Loncheres armatus* Winge as synonyms. Note that only the first two names apply to *Makalata didelphoides* as we define this taxon here.

Echimys longirostris Anthony, 1921a:5; type locality “Kartabo, British Guiana [= Guyana].”

[Echimys]. longirostris: Thomas, 1928c:292; name combination.

Echimys guianae: Pittier and Tate, 1932:264; name combination.

Mesomys didelphoides: Tate, 1935:413; incorrect assignment of *didelphoides* Desmarest, 1817 to *Mesomys* Wagner (Emmons, 1993).

Echimys armatus: Tate, 1935:432; name combination.

[Echimys] guianae: Tate, 1935:432; name combination.

[Echimys] longirostris: Tate, 1935:432; name combination.

Echimys armatus armatus: Tate, 1939:181; name combination.

Echimys armatus macroura: Tate, 1939:181; considered *macroura* Jentink different from (and thus not a homonym of) *macrura* Wagner.

Echimys armatus castaneus: Hershkovitz, 1948a:127; name combination.

Echimys armatus handleyi Goodwin, 1962:1; type locality “Speyside, St. John Parish, eastern Tobago, the West Indies, at an altitude of 300 feet,” Trinidad and Tobago.

Makalata armata armata: Husson, 1978:445; name combination.

Makalata didelphoides: Emmons, 1993; first use of current name combination.

DESCRIPTION: This is a medium-sized arboreal rat, with mean head and body length 217.1 mm (range: 180–245 mm; N=21), tail length 207.1 mm (range: 180–234 mm; N=18), hind foot length 39.1 mm (range: 35–43 mm; N=22), ear length 15.8 mm (range: 14–17 mm), and mass 340–405 g. Dorsal color drab reddish brown to yellowish brown heavily streaked with black, becoming more rusty on the rump and tail base; midback and rump finely speckled by paler, reddish brown tips on blackish bristles. Dorsal fur mixture of thin bristles and flat, flexible, and sharp spines, sometimes with thin rusty hairs between them. Muzzle colored faint to bright rust-red, from top of nose to between eyes. Vibrissae coarse and long, reaching to shoulder, and brown in color. Ears small and thinly haired. Eyes dark brown and eyeshine is faint dull red. Tail usually shorter than head and body, thickly haired at base for 3–4 cm, with remainder nearly naked, scaly, and thinly haired with inconspicuous brown hairs that do not extend beyond tip as tiny tuft. Throat and inner thighs or entire venter pale cream or buff, sometimes with white areas; central part of abdomen may be gray-based or brownish; one specimen from Bolivia with entirely dark under parts. Rear of thighs and haired tail base below faint to bright rust. Hindfeet short and broad; dorsal color pale reddish or yellowish.

DISTRIBUTION: *Makalata didelphoides* occurs throughout the Guianan region, including the islands of Trinidad and Tobago, from northern Venezuela, Guyana, Surinam, French Guiana, to eastern Amazonia generally east of the Rio Negro and Rio Madeira, to Maranhão and Ceará, and southwest to northeastern Bolivia.

SELECTED LOCALITIES (Map 498): BOLIVIA: Beni, opposite Costa Marques (AMNH 210355); Santa Cruz, El Refugio (USNM 584590), Flor de Oro (Patton et al. 2000). BRAZIL: Amazonas, Itacoatiara (B. D. Patterson 1992b); Ceará, São Benedito (MNRJ 21490), Trairucu Aguiraz (MNRJ 21493); Maranhão, Miritiba (Thomas 1916e); Pará, Belem (AMNH 203047), Ilha de Marajo (FMNH 19502), Iroçanga (B. D. Patterson 1992b); Tocantins, Rio Santa Teresa (MVZ 197569). FRENCH GUIANA: Cayenne (type locality of *Nelomys armata* I. Geoffroy St.-Hilaire). GUYANA: Mazaruni-Potaro, Kartabo (type locality of *Echimys longirostris* Anthony). SURINAM: Saramacca, La Poule (FMNH 95696). TRINIDAD AND TOBAGO: Tobago, Speyside (type locality of *Echimys armatus handleyi* Goodwin); Trinidad, Princes Town (type locality of *Echimys castaneus* J. A. Allen and Chapman). VENEZUELA: Apuré, Nulita (Handley 1976); Bolivar, Río Supamo (Handley 1976); Monagas, Hato Mata de Bejuco (Handley 1976); Sucre, Cumanacoa (AMNH 69898).

SUBSPECIES: Some recent authors have recognized varying numbers of subspecies, but there is no consistency

among these treatments. For example, Ellerman listed *guianae* Thomas and *castaneus* Allen and Chapman as simple synonyms of the nominotypical subspecies that he contrasted with *armatus occasius* (now a species of *Pattonomys*). Goodwin (1962), in his description of *handleyi* from Tobago and citing a personal communication from C. O. Handley Jr. also stated that *castaneus* was indistinguishable from the nominotypical subspecies. However, Cabrera (1961) listed *castaneus* as a valid subspecies distinct from the nominotypical form, in which he placed *hispidus* Lichtenstein, *guianae* Thomas, and *longirostris* Anthony as synonyms. Given that there is clearly no consensus among authors and that there has never been even a cursory, much less reasonable, review of geographic variation, we hesitate to list subspecies except in the synonymy of this species.

NATURAL HISTORY: These are nocturnal, arboreal, and solitary rats that feed primarily on fruit, unripe seeds, and some leaves. Allen and Chapman (1893) noted that the collectors found this species (which they listed as *Loncheres guianae*) residing in mangroves at the mouth of the Río Caroní in Venezuela where it fed on the fruits of those trees. Individuals were commonly seen in the middle to late afternoon, suggesting a crepuscular activity period, but we have seen them active only at night. This species is generally restricted to riverine forests (see, for example, R. G. Rocha, Ferreira, Costa et al. 2011; R. G. Rocha, Ferreira, Leite et al. 2011), but has been trapped in gardens surrounding Amerindian houses (Catzeflis 2012).

REMARKS: The assignment of Desmarest's *didelphoides* to those populations of *Makalata* with a pale venter and distributed in the Guianas and eastern Amazonia, in place of the more commonly applied name *armatus* I. Geoffroy St.-Hilaire, is now well-established (Emmons 1993). However, given that this species is likely polytypic, based on the limited geographic sampling of molecularly quite distinct clades (Patton et al. 2000), further refinement of the very imprecise type locality of Desmarest's *didelphoides* would be welcome. Without further research, we hesitate to make such a refinement but note that the history of Desmarest's holotype mirrors that of the holotype of *Mesomys hispidus*, another taxon named by Desmarest (1817b) in his paper describing É. Geoffroy St.-Hilaire's manuscript names. For this latter taxon, Orlando et al. (2003) reviewed the available historical documents in the Museum National d'Histoire Naturelle in Paris and restricted the type locality of *M. hispidus* to the state of Amapá in eastern Amazonian Brazil. It is thus likely that this same region also represents that from which the holotype of *M. didelphoides* originally came.

Tate (1935:432) listed *guianae* Thomas and *longirostris* Anthony as valid species along with *armatus* I. Geoffroy St.-Hilaire in his "naked-tailed group" from Venezuela,

Colombia, Guiana, and Trinidad. Thomas (1916e:295) had earlier stated that his *guianae* "is unquestionably *E. armatus*, Geoff.," and later (Thomas, 1928c:292) doubted also that *longirostris* was distinct from *armatus*. Anthony (1921c) placed *castaneus* J. A. Allen and Chapman in synonymy with *armatus* I. Geoffroy St.-Hilaire. Cabrera (1961:539) listed both *guianae* Thomas and *longirostris* Anthony in the synonymy of the nominotypical subspecies *E. armatus armatus*. As above, whether or not any, or all, of these named populations warrant formal recognition as either species or subspecies must await adequate analyses of existing museum specimens. Patton et al. (2000) documented extensive mitochondrial sequence divergence between samples they assigned to this species from western Bolivia and eastern Amazonia, variation that likely signals separate species status. However, as molecular data are not as yet available from within the geographic boundaries of any of the available named taxa, it is premature both to further divide *didelphoides* much less to assign possible names to any subdivision.

This species is not known from Colombia, based on documented specimens, despite literature references to the contrary. Cuervo Díaz et al. (1986:500) verbalized the range of *Makalata armata* as a broad region across northern Colombia encompassing the western slope of the Cordillera Oriental, Pacific coast, lower Cauca region, Magdalena valley, and llanos piedmont. However, in the more recent synopsis of Colombian mammals, Alberico et al. (2000:67) limited the range of this species in Colombia to the Orinocan biogeographic region or upper llanos, citing the map in Emmons and Feer (1997) and the American Museum of Natural History as the "collection for reference." The American Museum contains no specimens of

Map 498 Selected localities for *Makalata didelphoides* (○) and *Makalata macrura* (●). Contour line = 2,000m.

this species from Colombia. The confusion with regard to the presence of this species in Colombia likely stems from a specimen of “*Echymys armatus*” cited by Hershkovitz (1948a:127). The specimen in question, however, is apparently USNM 282119, a *Mesomys* collected from the same locality in northern Colombia cited by Hershkovitz. The original label identified this specimen as “*Echymys armatus* near *occasius*.”

J. F. S. Lima et al. (1998) reported a karyotype with $2n=66$ and $FN=106$ for specimens from the Balbina hydroelectric dam on the Rio Uatumã, Amazonas, Brazil.

Makalata macrura (Wagner, 1842)

Long-tailed Armored Tree Rat

SYNONYMS:

Loncheres macrura Wagner, 1842c:360; type locality “Borba,” mouth of Rio Madeira, Amazonas, Brazil.

[*Echymys*] *macrura*: Tate, 1935:432; name combination.

Echymys macrurus: Cabrera, 1961:542; name combination.

E[chimys]. macrurus: Emmons, 1993:3; name combination.

Makalata macrura: Patton, da Silva, and Malcolm, 2000: 188; first use of current name combination.

DESCRIPTION: Similar to *M. didelphoides* in general external and cranial features, but larger in size, with mean head and body length 236.2 mm (range: 207–280 mm; $N=38$), tail length 203.2 mm (range: 170–242 mm), hind-foot length 41.8 mm (range: 38–46 mm), ear length 16.3 mm (range: 15–17 mm), and with dull gray-brown rather than pale cream or buff venter (B. D. Patterson 1992b; Patton et al. 2000). Both species with reddish muzzle and dorsal fur composed of a mixture of bristles, flexible spines, and fine hairs.

DISTRIBUTION: *Makalata macrura* occurs throughout the western Amazon Basin, including southern Colombia and Venezuela, eastern Ecuador, and north-central Peru east through western Brazil to the left bank of the lower Rio Negro and at least to the lower Rio Madeira. The geographic boundaries are poorly understood in the southern and eastern parts of its range, where it might contact or even overlap with *M. didelphoides*.

SELECTED LOCALITIES (Map 498): BRAZIL: Amazonas, Arquipélago da Anavilhanas (Patton et al. 2000), Borba (type locality of *Loncheres macrura* Wagner), Colocação Vira-Volta (Patton et al. 2000), Itacoatiara (B. D. Patterson 1992b), Nova Empresa (Patton et al. 2000), Redenção (B. D. Patterson 1992b), Tambor (Patton et al. 2000). COLOMBIA: Caquetá, Tres Troncos (FMNH 71123). ECUADOR: Sucumbios, Santa Cecilia (KU 114007). VENEZUELA: Amazonas, Boca Mavaca (Handley 1976), San Juan (Handley 1976), Tamatama (Handley 1976). PERU: Amazonas, Huampami, Río Cenepa (Patton et al. 2000); Loreto, Nazareth (= Amelia) (FMNH 19854); Ucayali, Yarinacocha (LSUMZ 14409).

SUBSPECIES: *Makalata macrura* is monotypic (but see Remarks).

NATURAL HISTORY: This species is typically found in lowland rainforest, in the seasonally inundated floodplain of whitewater (*várzea*) or blackwater (*igapó*) rivers (e.g., Hice and Velazco 2012). Nearly all specimens have been obtained in traps placed in trees or were shot from perches in the canopy. On the Rio Juruá in western Brazil, a pregnant female was taken in the dry season in September (Patton et al. 2000). In northeastern Peru, a lactating female was obtained in May, and a pregnant female, which gave birth to two young, was collected in June (Hice and Velazco 2012).

REMARKS: Some geographic variation in mtDNA cytochrome-*b* sequences is apparent with the limited samples available to date (Patton et al. 2000), indicating a deep phylogeographic history for this species and perhaps future recognition of further formal taxa. B. D. Patterson (1992b) allocated one specimen each from Itacoatiara, on the north bank of the Rio Amazonas below its confluence with the Rio Madeira, to his two morphological groups, which generally map to *M. didelphoides* and *M. macrura* as we construe these two species herein. If correct, this would represent the only known locality of overlap between them, and would further support their recognition as distinct species.

Makalata obscura (Wagner, 1840)

Dark Armored Tree Rat

SYNONYMS:

Loncheres obscura Wagner, 1840:196; type locality “Brasilien.”

[*Echymys*] *obscura*: Tate, 1935: 432; name combination.

M[akalata]. obscura: Emmons, 2005:299; first use of current name combination.

DESCRIPTION: Waterhouse (1848:323), based on the two specimens J. B. von Spix brought from Brazil, stated that this species has a robust body with the short feet and thick tail that characterizes other species of his *Loncheres*. The pelage color is brown, flecked with yellow, and the venter is yellowish. The tail is equal to head and body length, covered with very short, scattered hairs. The upper parts of the body, including the shoulders and thighs, are clothed in spines mixed with scattered coarse hairs, while elsewhere only coarse hairs are found. Hence, in all respects this species shares the major characteristics of other members of the genus and, with respect to the yellowish venter, is most similar to (and perhaps the same as) *M. didelphoides*.

DISTRIBUTION: Known only from the imprecise type locality, which cannot be placed geographically. J. A. Oliveira and Bonvicino (2006) provisionally gave the range as Pará and Maranhão states, in eastern Amazonian Brazil,

following the suggestion of Moojen (1952b). Bonvicino, Oliveira, and D'Andrea (2008) mapped this same range.

SUBSPECIES: *Makalata obscura* is monotypic.

NATURAL HISTORY: Nothing is known about this species.

REMARKS: The holotype of *Loncheres obscura* Wagner, 1840, collected by Spix in Brazil, has apparently been lost (Dr. Richard Kraft, pers. comm. to L. H. Emmons; see Emmons 2005). This taxon appears from the original description and figures to be a *Makalata* (Wagner 1840), but the name currently cannot be assigned to a specific population. Because of its yellowish ventral color (“*gastraeo flavicante*”), Emmons (2005:299) provisionally placed *obscura* Wagner within her *didelphoides*-group of *Makalata* and listed it as a species of questionable application (a *nomen dubium*) in her Table 3. We follow her decisions herein.

Genus *Pattonomys* Emmons, 2005

Louise H. Emmons and James L. Patton

Species in this genus are medium to large in body size and arboreally adapted rats. Their pelage color is generally gray on the head and sides, often with a yellowish cast; the back is tinged brown; and the tail is uniform reddish brown, lightly clothed throughout its length with fine hairs. The dorsal pelage includes strong spines, many of which on the rump are tipped whitish, imparting an overall speckled appearance. There are two pairs of lateral mammae. The phallus is long and slender, with a long and pointed bacular papilla, a small urethral lappet, and with the border of the ventral crater wall a straight line, without a V- or U-shaped ventral fold (phallus of *P. carrikeri* figured by Emmons [2005:276, Fig. 10]). The maxillary cheek teeth are square to rectangular and longer than wide. The posterior lophs are rounded. All cheek teeth have an uneven occlusal appearance due to unequal loph sizes. Two labial and two lingual flexi are always present on PM4–M3. The paraflexi and mesoflexi are short and usually reach only to midtooth; the hypoflexi are long and likewise reach mid-way across tooth, opening at a wide angle. PM4 and M1 always have a mure in the center of the tooth; a mure may or may not be present in M2–M3. The chief diagnostic features of the upper teeth include widely open flexi, some nearly as wide as the lophs themselves, and an anteroposteriorly expanded protocone and posteroloph (probably metaloph and posteroloph combined). These expanded lophs become accentuated with wear. The four lophs of PM4–M2 are markedly unequal in length and width. The anteroloph is broad and squared linguallly, tapering labially; and the posteroloph is pointed labially and strongly curved along the posterior margin of the tooth. The paraflexus and metaflexus of PM4–M2 slant in markedly opposite directions, with the metaflexi slanting posteriorly from the labial to medial edges of the tooth. The lower premolar is tetralophodont, with two labial and two lingual flexids. This tooth is usually divided by one central flexid into two V-shaped lophs, but it may have a central mure. The flexids of m1–m2 form nearly straight-sided Vs. The lower incisors are not strongly curved. The cranium is short and broad, with an expanded, winglike supraorbital shelf that curves upward from the frontals. The supraorbital region is broad, especially well developed in *P. carrikeri* but much narrower in *P. semivillosus*. The auditory bullae are moderately to considerably inflated; the auditory meatus is high, positioned near the squamosal, and directed outward; the auditory tubes short, their role taken by the formation of two overlapping bony rings, especially well developed in old individuals. The lateral process of the supraoccipital is short, usually positioned only to the middle of the auditory meatus and does not extend ventrally beyond the lower edge of the meatus. The angular process of the mandible is slender; the condyloid process is narrow; the mandibular foramen is usually placed in a fossa on the condyloid ridge; and the masseteric crest is strongly developed anteriorly. The teeth of members of this genus are so distinctive that any single tooth is diagnostic except m1–m3, and often these are as well.

Cabrera (1961) and subsequent authors synonymized most of the named forms we refer here to *Pattonomys* under the species *Echimys semivillosus* I. Geoffroy St.-Hilaire. Cabrera (1961) considered *carrikeri* J. A. Allen (with *flavidus* Hollister a synonym) and *punctatus* Thomas as valid subspecies of this species, as did O. J. Linares (1998), but who listed *flavidus* as valid subspecies. However, all but *P. flavidus* are cranially distinctive and readily diagnosable. Emmons (2005) considered them all to be valid species, but each merits further study. The species *P. flavidus* is cranially similar to coastal populations of *P. carrikeri* and may be synonymous, but as it also has distinctive features, such as an extremely deep mandible, we provisionally recognize it pending additional specimens and molecular genetic analysis (fide Emmons 2005). *Echimys occasius* Thomas was formerly placed in *Makalata* (Emmons and Feer 1997), which it resembles in pelage color, smaller size, and Amazonian geographic distribution. It does not possess, however, several of the more diagnostic characters *Makalata*, and groups in parsimony analysis with *Pattonomys* (Emmons 2005). We follow this placement, pending additional analyses, perhaps including molecular studies, which hopefully will better clarify its relationships. All five species replace one another geographically, with four serially positioned across northern Colombia and Venezuela and one in the western Amazon. To date, no species in

the genus *Pattonomys* has been included in any molecular phylogenetic analysis.

O. J. Linares's (1998:245) statement that *P. semivillosus* in Venezuela (which herein equals the three species: *P. carrikeri*, *P. flavidus*, and *P. punctatus*) is very common belies the few specimens known for all species of this genus in museum collections.

SYNONYM:

Nelomys: I. Geoffroy St.-Hilaire, 1838a:887; part (description of *semivillosus*); not *Nelomys* Jordan.

Loncheres: Wagner, 1843a:330; part (listing of *semivillosus*); not *Loncheres* Illiger.

Echimys: E.-L. Trouessart, 1904:503; part (listing of *punctatus*); not *Echimys* F. Cuvier.

Pattonomys Emmons, 2005:282; type species *Nelomys semivillosus* I. Geoffroy St.-Hilaire, 1838, by original designation.

KEY TO THE SPECIES OF *PATTONOMYS*:

1. Spines over mid-back and rump with rusty tips; muzzle reddish; greatest length of skull (in adults) <51 mm *Pattonomys occasius*
- 1'. Spines over mid-back and rump with white tips; muzzle not reddish; greatest length of skull (in adults) >51 mm. 2
2. Nonspinous dorsal hairs; color yellow-buff; range restricted to Isla Margarita, Venezuela. *Pattonomys flavidus*
- 2'. Dorsal hairs spiny, with spines white-tipped; color varying shades of gray; distributed on mainland of Colombia or Venezuela 3
3. Dorsal spines extend from shoulder to rump and down hind leg to heel. *Pattonomys semivillosus*
- 3'. Dorsal spines do not extend much forward of rump and onto hind leg 4
4. Throat in front of forelegs with dusky-based band, midabdomen dusky based; least interorbital constriction <14mm; range north of the Río Orinoco in llanos and Cordillera Central of Venezuela *Pattonomys carrikeri*
- 4'. Throat and chest, and usually abdomen, with hairs white to base; least interorbital constriction >14mm; distributed south of the Río Orinoco and its delta *Pattonomys punctatus*

Pattonomys carrikeri (J. A. Allen, 1911)

Carriker's Speckled Tree Rat

SYNONYMS:

Loncheres carrikeri J. A. Allen, 1911:251; type locality "San Esteban," Carabobo, Venezuela.

[*Echimys*] *carrikeri*: Thomas, 1916e:295; name combination.

[*Echimys*] *carrikeri*: Tate, 1935:432; name combination.

[*Echimys*]. *semivillosus carrikeri*: Tate, 1939:180; name combination.

Pattonomys carrikeri: Emmons, 2005:282; first use of current name combination.

DESCRIPTION: One of three relatively smaller *Pattonomys*, with mean head and body length 222.8 mm (range: 200–250 mm; N = 12), tail length 218.2 mm (138–242 mm), hindfoot length 36.3 mm (range: 35–40 mm), and ear length 11.9 mm (range: 11–18 mm). Similar in color to *P. punctatus*, with head and flanks overall grayish; mid-dorsal region grayish mixed with black and rufous; long stiff hairs and bristles black tipped; broad spines black with conspicuous white tips, most abundant on lower back; underfur finer, rufous in color on surface between bristles and spines. Venter white, with fairly distinct pectoral band of dusky-based hairs; center of abdomen usually same color as pectoral band. Outer surfaces of forefeet and hindfeet, limbs, and ventral surface at the base of the tail gray. Ears brownish black. Tail well covered with short stiff hairs, although scales remain visible along length. Skull robust, but rostral portion narrow and somewhat tapering, with anterior nares narrow and shallow, bullae swollen and spherical, and basioccipital short and narrow, all features that contrast with skull of *P. punctatus*.

DISTRIBUTION: *Pattonomys carrikeri* is known from the coastal cordillera and central llanos of Venezuela. O. J. Linares (1998) mapped localities from Caracas, Falcón, Lara, Yaracuy, Carabobo, Aragua, and Guárico states, without reference to museum vouchers or identification of specific localities.

SELECTED LOCALITIES (Map 499): VENEZUELA: Carabobo, San Esteban (type locality of *Loncheres carrikeri* J. A. Allen); Caracas, Caracas (AMNH 130815); Falcón, Coro (Aguilera et al. 1998), 19 km NW of Urama (Handley 1976); Guárico, Zaraza (AMNH 135442), Guárico, Río Orituco (ROM 107955); Lara, Caserio Boro (Handley 1976).

SUBSPECIES: *Pattonomys carrikeri* is monotypic.

NATURAL HISTORY: At the time the holotype was collected, the habitat in the vicinity of San Esteban was "heavy forest" (J. A. Allen 1911:239). Field notes of the collector (M. A. Carriker, in Allen 1911:252) state that the type specimen was shot from the lower branches of a large tree, "likely disturbed from the trunk where it ran out on a long limb." Carriker further remarked that local people had never seen such an animal before and that, therefore, the species was probably rare. Tate (1939:180) noted that this species lives in the hollow trunks of dwarfed trees in the arid or semiarid cactus belt of northern Venezuela, and thus are chiefly inhabitants of xerophytic vegetation or

Map 499 Selected localities for *Pattonomys semivillosus* (▲), *Pattonomys carrikeri* (○), *Pattonomys punctatus* (●), and *Pattonomys flavidus* (△). Contour line = 2,000 m.

savanna-like areas with sparse groves of trees and gallery forests. Of the large series (52) of *P. carrikeri* and the few *P. punctatus* collected by the Smithsonian Venezuelan Project (1965–1968) and grouped under the name *Echimyus semivillosus*, nearly all (98%) were taken in trees near streams or other moist places, usually in thorn forest but occasionally in scattered trees in the savanna and rarely in evergreen forest (Handley 1976).

REMARKS: Considered a valid subspecies of *P. semivillosus* by some authorities (Cabrera 1961; O. J. Linares 1998), but Hershkovitz (1948a:127) regarded *carrikeri* to be a synonym of *flavidus* Hollister without comment or documentation. Specimens assigned to *P. semivillosus* by Handley (1976:58) from Carabobo, Falcón, and Lara states are here assigned to *P. carrikeri*. Aguilera et al. (1998) described and figured a karyotype of $2n=94$, $FN=114$, from a single specimen of “*P. semivillosus*” from Coro, Falcón. Although we have not seen the voucher specimen, by geography it would fall at the western margins of the range of *P. carrikeri*, as we currently understand this species.

Pattonomys flavidus (Hollister, 1914)

Yellow Speckled Tree Rat

SYNONYMS:

Loncheres flavidus Hollister, 1914c:143, type locality “El Valle [= El Valle del Espíritu Santo], Margarita Island,” Nueva Esparta, Venezuela.

[*Echimyus*] *flavidus*: Tate, 1935:432; name combination.

Echimyus flavidus: Pittier and Tate, 1932:264; name combination.

E[*chimyus*]. *armatus castaneus*: Tate, 1939:180; considered *flavidus* Hollister a synonym of *castaneus* J. A. Allen and Chapman, 1893, a species of *Makalata* Husson.

Echimyus semivillosus flavidus: Hershkovitz, 1948a:127; name combination.

Pattonomys flavidus: Emmons, 2005:282; first use of current name combination.

DESCRIPTION: Slightly larger in external and cranial dimensions than either *P. carrikeri* or *P. punctatus*, with head and body length 252 mm, tail length 248 mm, hind foot length 40.8 mm (measurements of holotype). In comparison with *P. carrikeri* and *P. punctatus*, hairs between spines yellowish-buff or ochraceous rather than gray, and flanks more buffy, less streaked with darker colors. Under parts self-colored cream, without dusky pectoral or abdominal bands. Spines on lower back and rump strong and tipped white. Pelage long. Skull shares narrower rostrum, more spatulate nasals, and more inflated bullae of *P. carrikeri* from the adjacent mainland coastal mountains. It differs from all other taxa in having zygomatic arches, viewed dorsally, that taper anteriorly from jugal-squamosal suture, and strikingly deep mandible from below tooththrow to base of angular process.

DISTRIBUTION: *Pattonomys flavidus* is known only from two localities on Isla Margarita, off the north-central coast of Venezuela.

SELECTED LOCALITIES (Map 499): VENEZUELA: Nueva Esparta, El Valle, Isla Margarita (type locality of *Loncheres flavidus* Hollister), Nueva Esparta, Península Macanao, Isla Margarita (Aguilera et al. 1998).

SUBSPECIES: *Pattonomys flavidus* is monotypic.

NATURAL HISTORY: This species has not been studied in the field, and no data on habitat or life history traits are available. However, Isla Margarita is arid with chaparral and cactus dominated flora. It has some gallery forests along watercourses, but these are vanishing. If *P. flavidus* occupies such forests, it could be endangered.

REMARKS: Hollister (1914c), in his description of *flavidus*, considered it “an insular form of *Loncheres punctatus*.” Emmons (2005) stated that *P. flavidus* was cranially similar to coastal specimens of *P. carrikeri*, with which it may be synonymous, but that it possessed uniquely distinctive features, such as an extremely deep mandible. Aguilera et al. (1998) described a karyotype of $2n=94$, $FN=114$, for three specimens from the Península Macanao, the western portion of Isla Margarita. These authors assigned their specimens to *P. semivillosus*, but as construed herein, they should be identified as *P. flavidus*, the only species of *Pattonomys* known from that island.

Pattonomys occasius (Thomas, 1921)

Bare-tailed Tree Rat

SYNONYMS:

Echimyus occasius Thomas, 1921f:450, type locality “Guala, west of Pichincha. Alt. 4000’,” Pichincha, Ecuador; probably in error (see Emmons 2005, and Remarks).

E[chimys]. occasius: Thomas, 1928c:292.

[*Echimys*] *occasius*: Tate, 1935:432.

Echimys armatus occasius: Ellerman, 1940:112; name combination but incorrect assignment as subspecies of what is now known as *Makalata didelphoides*.

Makalata occasius: Emmons and Feer, 1997:237; name combination.

Pattonomys occasius: Emmons, 2005:282; first use of current name combination.

DESCRIPTION: Smallest species in genus, with head and body length 218 mm, tail length 225 mm, and hindfoot length 37 mm (measurements of holotype). Upper parts colored dull buff-brown streaked with dark brown. Body from shoulder to rump on both back and sides thickly covered with wide, flat, sharp, flexible spines that lie flat and may not be apparent from a distance; spines brown or black on back, many with pale rusty tips, especially on rump, and those flanks gray-brown; tips of spines blunt, not drawn out into hair-like processes. Fine, soft, and sparse orange hairs occur between spines over body. Head clothed with stiff, thin bristles. Ears short and naked. Tip of muzzle and cheeks reddish. Vibrissae fine, thin, but long, with mystacial vibrissae reaching shoulder. Tail robust and long, equal to or longer than the head and body. Body hair ends abruptly 1–2 cm from tail base; remainder of tail conspicuously naked and scaly. Under parts clear orange, often with white thoracic and inguinal regions. Undersurface of tail base and thighs dull brown. Hindfeet short and broad, brownish in color with whitish toes. Skull smaller than those of other species; auditory bullae not inflated, and supraorbital ridges only very weakly developed.

DISTRIBUTION: Except for the type locality (which may be in error; see Tate 1935:428; Emmons 2005), all referred specimens of *Pattonomys occasius* are known only from the western Amazon in Ecuador and Peru.

SELECTED LOCALITIES (Map 500): ECUADOR: Napo, Río Jatun Yacu (= Río Rutuno) (MCZ 37964); Orellana, Río Suno (AMNH 68177); Pichincha, Guala (type locality of *Echimys occasius* Thomas; probably an error; see Remarks). PERU: Loreto, boca Río Curaray (AMNH 71897), mouth of Río Santiago (AMNH 98262); Madre de Dios, Cocha Cashu Biological Station (B. D. Patterson et al. 2006), Río Colorado (FMNH 84259).

SUBSPECIES: *Pattonomys occasius* is monotypic.

NATURAL HISTORY: The habitat of the few known specimens is lowland rainforest, but the species may extend upward in elevation into more montane forests (Emmons and Feer 1997). There are no published reports of any aspect of the ecology, behavior, or reproductive biology of this species.

REMARKS: Thomas (1921f) did not give the etymology of his name *occasius*. Emmons (2005) surmised, from its

Map 500 Selected localities for *Pattonomys occasius* (●). Contour line = 2,000 m.

purported type locality west of the Andes, that Thomas derived the name from the Latin *occasus*, meaning western (to set as the sun), with the comparative superlative ending *-ius*, or westernmost. The suffix therefore does not change with the gender of the generic epithet. The type locality on the western slope of the Andes in northern Ecuador is certainly erroneous as is the accompanying natural history note that it was captured between rocks in a stream (Thomas 1921f) because all other known specimens are from the Amazonian lowlands on the eastern base of the Andes (see Tate 1935:428). Unfortunately, Thomas (1921f:450) in his description compared this species mostly with *E. armatus* (= *Makalata didelphoides*), although he did note that in coloration and white incisors “it shows an approach to the *E. punctatus* group.” Emmons and Feer (1997) placed *P. occasius* in the genus *Makalata*, comparing it to *M. didelphoides* and *M. rhipidurus* in external features.

Pattonomys punctatus (Thomas, 1899)

Orinocan Speckled Tree Rat

SYNONYMS:

Loncheres punctatus Thomas, 1899b:153; type locality “Caicara, Orinoco,” Bolívar, Venezuela.

Echimys (Echimys) punctatus: E.-L. Trouessart, 1904:503; name combination.

[*Echimys*] *punctatus*: Thomas, 1916e:295; name combination.

[*Echimys*] *punctatus*: Tate, 1935:432; name combination.
E[chimys]. semivillosus punctatus: Tate, 1939:180; name combination.

Pattonomys punctatus: Emmons, 2005:282; first use of current name combination.

DESCRIPTION: One of larger rats in genus, with head and body length 236 mm, tail length 233 mm, hindfoot length 34 mm, and ear length 20 mm (measurements of holotype). Fur spiny, with spines on back reaching 20 mm in length and 2.3 mm in width. Overall color pale gray with whitish speckles and rufous tint to back due to hairs with reddish tips and gray bases. Spines of rump grayish, white basally, and tipped white, most numerous posteriorly and sharply contrasting with general grayish color. Head above and laterally coarsely mixed black and white. Ears clothed with fine black hairs on edges, with small tuft of whitish hairs on antitragus and distinct whitish postauricular patch. Flanks coarsely mixed whitish gray. Venter white, sharply demarcated from sides. Inner surfaces of limbs white, outer surfaces gray. Upper surfaces of forefeet gray; hindfeet gray above, while along medial margin, with digits whitish. Tail of medium length, approximately equal to head and body, thinly haired with scales visible, and uniformly brown in color, only slightly paler below if at all. Skull with nasals equal in length to premaxillary processes, flattened frontal region, broadly expanded supraoccipital ridges, and narrow, not spatulate pterygoid processes. Few available specimens indicate that cranial dimensions are largest for genus.

DISTRIBUTION: *Pattonomys punctatus* is restricted to Venezuela south of the Río Orinoco and its delta and west of the Río Orinoco in Apure state. Tate (1939:180) stated that this species is known from the “Caura district” near the mouth of the Río Caura. O. J. Linares (1998) mapped two localities in the Orinoco delta (Delta Amacuro state) that presumably are of this species, but he did not provide locality details or refer to voucher specimens.

SELECTED LOCALITIES (Map 499): VENEZUELA: Apure, Río Cinaruco (Handley 1976); Bolívar, Caicara (type locality of *Loncheres punctatus* Thomas), Hato La Florida, 45 km SE of Caicara (Handley 1976).

SUBSPECIES: *Pattonomys punctatus* is monotypic.

NATURAL HISTORY: Nothing is known about the ecological range or life history of this species. The habitat at Hato La Florida, on the southern margins of the llanos, is tropical dry forest (Handley 1976).

REMARKS: Thomas (1899b) noted that *P. punctatus* was readily distinguished by the prominent white speckling on its lower back, which results from broad white tips of the spines in that region. This pattern, however, is also characteristic of both *P. semivillosus* and especially the geographically adjacent *P. carrikeri*, which was described

12 years later (J. A. Allen 1911). He considered it closely allied to *P. semivillosus*. He also (p. 154) provisionally referred a specimen “said to have come from Caracas” in the Natural History Museum, London, to this species, a locality that is well west of the Orinoco delta and thus probably a record of *P. semivillosus* itself, not *P. punctatus* as herein construed. Tate (1939), Cabrera (1961), and O. J. Linares (1998) regarded *P. punctatus* a subspecies of *P. semivillosus*.

Pattonomys semivillosus (l. Geoffroy St.-Hilaire, 1838a)
Colombian Speckled Tree Rat

SYNONYMS:

Nelomys semivillosus I. Geoffroy St.-Hilaire, 1838a:887; type locality “Carthagène, (Nouvelle-Grenade),” Cartagena, Bolívar, Colombia.

Loncheres semivillosa: Wagner, 1843a:330; name combination.

Loncheres (Loncheres) semivillosa: E.-L. Trouessart, 1880b:177; name combination.

Echimys (Echimys) semivillosus: E.-L. Trouessart, 1904:503; name combination.

[*Echimys*] *semivillosus*: Thomas, 1916e:295; name combination.

E[chimys]. semivillosus semivillosus: Tate, 1939:180; name combination.

Pattonomys semivillosus: Emmons, 2005:282; first use of current name combination.

DESCRIPTION: Moderately large species in genus, with head and body length ranging from 200–268 mm, tail length 210–261 mm, hindfoot length 36–43 mm, ear length 17–22 mm, and mass 194–407 mm. Distinctly white muzzle contrasts sharply with almost black crown of head; neck and shoulders often gray streaked with black; mid-back gray washed with fulvous; rump or mid-back, rump, and hind legs speckled with spines tipped white. Flanks either colored like back or are gray. Shoulder to rump heavily clothed with flat but flexible spines. Ears small, often with pale postauricular and subauricular patch. Vibrissae numerous, black, and long, extending to behind ear. Tail robust, 80–120% of the head and body in length, and appears naked and scaly, thinly covered with stiff, pale brown hairs. Hindfeet broad, gray or gray yellow above. Under parts white or pale orange, sometimes with gray across abdomen. Cranium more slender and lightly built than those of Venezuelan species, with relatively narrow supraorbital ledges, auditory bullae little inflated, and narrow incisive foramina. Incisors distinctly white. Emmons (2005:284) published photographs of skull and mandible.

DISTRIBUTION: *Pattonomys semivillosus* is known only from the lower Río Magdalena drainage in northeastern Colombia at elevations to at least 600 m. The species

may extend into northwestern Venezuela (O. J. Linares 1998).

SELECTED LOCALITIES (Map 499): COLOMBIA: Atlántico, lower Río Magdalena opposite Barranquilla (FMNH 69117); Bolívar, Cartagena (type locality of *Nelomys semivillosus* I. Geoffroy St.-Hilaire), Morales (ICN 513); Cesar, El Orinoco (Hershkovitz 1948a), Río Guaimaral (Hershkovitz 1948a).

SUBSPECIES: *Pattonomys semivillosus* is monotypic.

NATURAL HISTORY: These rats are presumably nocturnal and den in tree holes. The few available specimens were all collected from swampy lowland *cienagas* of the lower Magdalena Valley. This area appears more heavily forested and evergreen than the habitats of *P. carrikeri* and *P. punctatus*, a difference that may be associated with the small bullae of *P. semivillosus*.

REMARKS: The designation of Cartagena as the type locality may be in error, as this was the port from which the specimens that formed the basis of I. Geoffroy St.-Hilaire's description were shipped (Hershkovitz 1948a:127). However, recent specimens have been collected in swamps near to Cartagena. Thomas (1916e) considered *P. semivillosus*, *P. punctatus*, and *P. carrikeri* to be closely related, but noted that insufficient material was available for him to make a proper comparison among them. He did not comment on the fourth species, *P. flavidus*, which had been described two years earlier. O. J. Linares (1998) noted that *P. semivillosus* is not presently known from Venezuela, but suggested that it might occur in the Lago de Maracaibo region.

Genus *Phyllomys* Lund, 1839

Yuri L. R. Leite and Ana Carolina Loss

Y. L. R. Leite (2003) and Emmons (2005) provided detailed diagnoses of the genus, summarized as follows. These are medium-sized to large arboreal rats with the pelage spiny to soft fur, large eyes, small and rounded ears, and long vibrissae reaching the shoulders. The limbs are short, and the hindfeet are broad and short, with strong claws on all digits except the thumb, which bears a nail. Dorsal color varies from brown to reddish golden brown, ventral color from pure white to light gray-brown. Spines are conspicuous in most species, especially on the rump, where they can reach 1.5 mm in width. Mammary occur in four pairs, three lateral and one inguinal. A sternal gland is well developed in both sexes, but is larger in males. The tail is typically slightly shorter or longer than head and body; its base is covered with body-like hair for approximately 20 mm, with the remaining length varying from almost naked to thickly haired with a bushy tuft at the tip. The skull

is strong, with a relatively short rostrum, usually inflated bullae with the meatus low and directly slightly forward, and with a space as wide as the meatus between it and the squamosal, wide interorbital region with well-developed supraorbital ledges; the palate is narrow with nearly parallel tooththrows; and the incisive foramina vary from small to relatively large. The upper cheek teeth are rectangular and are composed of four transverse laminae separated by three labial flexi (para-, meso-, and metaflexus). In unworn teeth, the enamel of one lamina does not contact the others, but in older individuals two or more laminae coalesce at the labial and/or lingual side, forming a transverse U-shaped loph, similar to that in unworn teeth of *Echimy*s and *Makalata*. The pattern of coalescence varies (Winge 1887; Moojen 1952b), but usually the two posterior lophs unite labially with wear and the anterior lophs unite lingually (Emmons 2005). The hypoflexid is deep and angled forward in the lower teeth, connecting to the mesoflexid on M1. A slender mure is typically present on M2 and M3, separating the hypoflexid and mesoflexid, and forming the shape of the Arabic numeral 3. The lower premolar is pentalophodont, the first two lophs coalesce at an early age forming a triangle with a circular island of enamel inside. The lack of complete transverse laminae on unworn lower cheek teeth, but their presence on the uppers distinguishes *Phyllomys* from *Diplomys*.

SYNONYMS:

Phyllomys Lund, 1839a:226; type species *Phyllomys brasiliensis* Lund, by subsequent designation (Emmons, Leite et al. 2002:5).

Lonchophorus Lund, 1839b:206; proposed as a subgenus; type species *Lonchophorus fossilis* Lund (1839b:208), by monotypy (see also Lund 1840b:plate 1, Fig. 9; 1841c:plate 25, Fig. 9).

Nelomys: Jordan, 1837:522; part (description of *blainvillii*); see Remarks.

Loncheres: Wagner, 1840:203; part (listing of *blainvillei*); not *Loncheres* Illiger.

Mesomys: Ihering, 1897:171; part (description of *thomasi*); not *Mesomys* Wagner.

*Echimy*s: E.-L. Trouessart, 1904:503; part (listing of *blainvillei*, *armatus*, *dasythrix*, *nigrispina*, *unicolor*); not *Echimy*s F. Cuvier.

Euryzygomatomys: E.-L. Trouessart, 1904:506; part (listing of *thomasi*); not *Euryzygomatomys* Goeldi.

REMARKS: The taxonomy, systematics, and natural history of the Atlantic Forest tree rats have been recently reviewed and updated by Emmons, Leite et al. (2002) and Y. L. R. Leite (2003). The accounts that follow stem directly from these treatments, the first complete revisions of the genus and its member species. Until these publications appeared, the taxonomic and nomenclatural history

of the genus was complex and exceedingly confusing, and most recent authors either placed this group of species under the broadly encompassing genus *Echymys* F. Cuvier (Ellerman 1940; C. O. da C. Vieira 1955; Cabrera 1961; Woods 1993; McKenna and Bell 1997; Eisenberg and Redford 1999) or under *Nelomys* Jourdan (Emmons and Feer 1990, 1997). Although Moojen (1952b), in his compilation of Brazilian rodents, correctly allocated these species to *Phyllomys* Lund, it was not until the publication of Emmons, Leite et al. (2002) that the validity of this application was documented. Y. L. R. Leite (2003:2–3) succinctly documented the correct use of the name *Phyllomys* Lund for this group of rats, and the convoluted history of this and other names commonly applied to them, as follows.

“The name *Nelomys* Jourdan, 1837, although older than *Phyllomys* Lund, 1839, is a junior synonym of *Echymys* F. Cuvier, 1809, and, therefore, it is not available (Emmons, Leite et al. 2002). Most recent authors . . . erroneously attribute the name *Nelomys* to G. Cuvier. Cuvier’s report, based on a memoir written by Jourdan, was presented to the French Academy of Sciences on 2 January 1838. Although the paper came out in the 1837 volume of the *Annales des Sciences Naturelles*, the date on the paper itself takes precedence and the correct citation should therefore be G. Cuvier (1838, not 1837). As members of the Academy, G. Cuvier and Deméril were in charge of introducing Jourdan and presenting his research, since he was not a member. Part of Jourdan’s memoir, however, had already been published on 9 October 1837 in the *Comptes Rendus Hebdomadaires de Séances de L’Academie des Sciences* (vol. 15, date of publication printed on page 69), predating G. Cuvier’s report . . .

“Jourdan begins his description of *Nelomys* by stating: ‘Ce genre formé aux dépens du genre *Échymys* des auteurs, a pour type l’*Échymys cristatus* [sic]’ (Jourdan, 1837:522). This statement makes *Echymys cristatus* Desmarest, 1817 the type of his new genus *Nelomys*. However, *Echymys cristatus* is a junior synonym of *Myoxus chrysurus* Zimmermann, 1780, which is the genotype of *Echymys* F. Cuvier, 1809, and therefore *Nelomys* becomes a junior synonym of *Echymys* . . .

“The next available name for the Atlantic tree rats is *Phyllomys* Lund, first published in 1839 with a sentence describing the dentition in which the upper molars comprise four simple transverse laminae (Lund 1839a:226). This article in French is an extract based on three of Lund’s monumental memoirs, which were published a year later in Danish (Lund, 1840a; for the explanation as to why the date 1840 is correct, see Musser et al. 1998:330–331). *Phyllomys* was treated on page 243 and illustrated in plate 21, Figures 12 and 13. The figure captions reading ‘*Phyl-*

lostomus’ are obviously wrong as pointed out by Paula Couto (1950:559).”

Lund (1839b:206) coined the name *Lonchophorus* as a subgenus to include the fossil species *L. fossilis* (Lund 1839b:208) from “du bassin de Rio das Velhas” (Lagoa Santa, Minas Gerais, Brazil), and for which he subsequently illustrated the first and second lower right molars (Lund 1840b:plate 1 [1841c:294, plate 25, Fig. 9]). Emmons, Leite et al. (2002) regarded *L. fossilis* as a *nomen dubium* but perhaps a synonym of *P. brasiliensis* Lund.

Y. L. R. Leite (2003:45) incorrectly listed the type species of *Phyllomys* as *Nelomys blainvillii* Jourdan, the first species recognized that is now allocated to this genus. Emmons, Leite et al. (2002:5) had one year earlier clearly documented that the type species of this genus is *Phyllomys brasiliensis* Lund.

Oldfield Thomas (1916d,e) recognized that *Phyllomys* was generically distinct from *Echymys*, based on the laminar, transverse plates of the occlusal surface of the upper teeth, and from *Diplomys*, in which both upper and lower teeth have transverse plates. He erroneously believed, however, that *Phyllomys* was a junior synonym of *Nelomys*. Tate (1935), however, considered both *Nelomys* and *Phyllomys* as synonyms of “*Echymys*,” and most authors (as above) have followed the same path.

Lara et al. (1996), Y. L. R. Leite and Patton (2002), Galewski et al. (2005), and P.-H. Fabre et al. (2012) provided hypotheses of phylogenetic relationship among most extant genera of echimyids and documented a well-supported sister relationship between *Phyllomys* and *Echymys* based on DNA sequences. G. A. S. Carvalho and Salles (2004), Emmons (2005), and Candela and Rasia (2012), using a cladistic assessment of qualitative morphological characters, showed that member species of *Phyllomys* form a monophyletic assemblage, but with closer relationship to *Diplomys* (G. A. S. Carvalho and Salles 2004; Candela and Rasia 2012) or part of an unresolved polytomy (see comments above under the family). Y. L. R. Leite (2003) provided a phylogenetic hypothesis for 8 of the 13 species currently recognized, based on mtDNA sequence data. Y. L. R. Leite et al. (2007) added *P. unicolor* to the molecular assessment, and most recently Loss and Leite (2011) expanded the phylogenetic hypothesis of species relationships with both mitochondrial and nuclear gene sequences. In this latter study, Loss and Leite (2011) uncovered three monophyletic lineages, each with strong support, that identify apparently undescribed taxa. Loss and Leite (2011) obtained a different mtDNA sequence from the same specimen of *P. unicolor* originally examined by Y. L. R. Leite et al. (2007). This new sequence, when combined with additional nucDNA sequences, placed *P. unicolor* with *P. pattoni*. Therefore, the sequence of *P.*

unicolor reported by Y. L. R. Leite et al. (2007) should be considered erroneous.

Y. L. R. Leite (2003) reviewed species limits, defined species by a combination of a hypothesis of phyletic relationships based on molecular sequence data and qualitative characters, diagnosed each taxon morphologically (and chromosomally, where such data exist), reviewed all available specimens in museum collections in the United States and Brazil, and mapped their respective distributions. He summarized what few data are available on natural history, habitat range, and reproductive biology, and commented on conservation issues. These taxa, like others inhabiting the Atlantic Forest of coastal Brazil, have been severely and negatively impacted by habitat loss and modification in recent decades, and are thus of considerable conservation concern. A new species of *Phyllomys* has been more recently described (Y. L. R. Leite et al. 2008), bringing the total of extant species now known to 13. Four additional lineages remain to be described (Loss and Leite 2011; N. P. Araújo et al. 2014).

Lund (1839b) described a single fossil species, *Lonchophorus fossilis*, based on mandibular fragments from late Pleistocene cave deposits at Lapa dos Ossinhos, near Serra das Abelhas and Poções, Lagoa Santa, Minas Gerais, Brazil. Hadler et al. (2008) described abundant fossil material from Mid to Late Holocene (9,400–3,730 ybp) deposits in Rio Grande do Sul state, southern Brazil, but were unable to assign these to an extant species. Specimens allocated only to *Phyllomys* sp. have been reported from Quaternary deposits in São Paulo (M. C. Castro and Langer 2011) and Pernambuco (D. Ferreira et al. 2012) states, in southeastern and northern Brazil, respectively.

KEY TO THE SPECIES OF *PHYLLOMYS*:

1. Head and body length >280 mm; greatest skull length >56 mm. 2
- 1'. Head and body length <280 mm; greatest skull length <56 mm. 3
2. Fur long and spiny, aristiforms on rump >30 mm in length; incisive foramina teardrop in shape; rostral premaxillary foramen absent; endemic to Ilha São Sebastião, off the coast of São Paulo, Brazil *Phyllomys thomasi*
- 2'. Fur short and stiff, aristiforms on rump <25 mm in length; incisive foramina ovate; rostral premaxillary foramen present; known only from the vicinity of Helvécia, southern Bahia, Brazil *Phyllomys unicolor*
3. Aristiforms on rump with black tips 4
- 3'. Aristiforms on rump with orange tips 9
4. Spines conspicuous, aristiforms on rump >0.7 mm in width 5
- 4'. Spines inconspicuous, aristiforms on rump <0.7 mm in width 6
5. Maxillary tooththrow length >11.5 mm; rostral breadth <8 mm; interorbital constriction <11.5 mm *Phyllomys nigrispinus*
- 5'. Maxillary tooththrow length <11.5 mm; rostral breadth >8 mm; interorbital constriction >11.5 mm *Phyllomys kerri*
6. Aristiforms on rump >26 mm in length; body size larger, head and body length >215 mm; hindfoot length >40 mm. *Phyllomys medius*
- 6'. Aristiforms on rump <26 mm in length; body size smaller, head and body length <215 mm; hindfoot length <40 mm. 7
7. Pelage coarse, aristiforms on rump reach 0.6 mm in width *Phyllomys sulinus*
- 7'. Pelage soft, aristiforms on rump <0.2 mm in width 8
8. Tail slightly longer than head and body, without terminal tuft; coronoid process shorter than condyloid process *Phyllomys dasythrinx*
- 8'. Tail as long as head and body, with terminal tuft; coronoid process stands higher than condyloid process *Phyllomys mantiqueirensis*
9. Aristiforms on rump ending with a blunt tip; incisive foramina bullet-shaped. *Phyllomys pattoni*
- 9'. Aristiforms on rump ending with a whip-like tip; incisive foramina ovate. 10
10. Aristiforms on rump >25 mm in length; mesopterygoid fossa >4 mm in width; Interorbital constriction >12 mm *Phyllomys brasiliensis*
- 10'. Aristiforms on rump <25 mm in length; mesopterygoid fossa <4 mm in width; Interorbital constriction <12 mm 11
11. Tail thickly haired with terminal tuft; aristiforms on rump <0.9 mm in width *Phyllomys blainvillii*
- 11'. Tail nearly naked, with visible scales and no terminal tuft; aristiforms on rump >0.9 mm in width 12
12. Aristiforms on rump reach 1.3 mm in width; supraorbital ridges well developed; infraorbital foramen length <4.5 mm; ventral mandibular spine present. *Phyllomys lamarum*
- 12'. Aristiforms on rump <0.9 mm in width; supraorbital ridges weakly developed; infraorbital foramen length >4.5 mm; ventral mandibular spine absent *Phyllomys lundii*

Phyllomys blainvillii (Jourdan, 1837)

Golden Atlantic Tree Rat

SYNONYMS:

Nelomys blainvillii Jourdan, 1837:522; type locality “une petite île sur les côtes du Brésil, près du Bahia,” erroneously given by most subsequent authors as “Ilha de

Deos” based on I. Geoffroy St.-Hilaire’s (1840) listing as “Brazil, near Bahia; the small island Deos, off the coast of Brazil, likewise near Bahia” (translation in Emmons, Leite et al. 2002:15); restricted to “Seabra, Bahia, Brazil, ca. 12°25’S 41°46’W” based on itinerary of original collector (Emmons, Leite et al. 2002:15); lectotype chosen by Emmons, Leite et al. (2002).

Loncheres (Nelomys) blainvillei Wagner, 1840:203; part; name combination but subsequence incorrect spelling of *blainvillii* Jourdan.

[*Loncheres (Loncheres)*] *Blainvillii*: E.-L. Trouessart, 1880b: 177; part; name combination but subsequent incorrect spelling of *blainvillii* Jourdan.

[*Echimys (Echimys)*] *blainvillei*: E.-L. Trouessart, 1904:503; name combination but subsequent incorrect spelling of *blainvillii* Jourdan.

Nelomys blainvillei: Thomas, 1916d:240; name combination but subsequent incorrect spelling of *blainvillii* Jourdan.

Phyllomys lamarum: Moojen, 1952b:140, plate 20; not *Nelomys lamarum* Thomas.

Echimys blainvillei blainvillei: Cabrera, 1961:539; name combination but subsequent incorrect spelling of *blainvillii* Jourdan.

Echimys (Nelomys) blainvillei: Eisenberg and Redford, 1999: 487; name combination but subsequent incorrect spelling of *blainvillii* Jourdan.

Phyllomys blainvillii: Emmons, Leite, Kock, and Costa 2002: 9; first use of current name combination.

DESCRIPTION: Medium sized for genus, with head and body length 192–250 mm, tail length 155–220 mm, hindfoot length 33–40 mm, and ear length 14–20 mm. Dorsal surface spiny, ochraceous-brown streaked with black, paler on sides. Aristiforms average 24 mm long and 1 mm wide, are pale at base, darker in middle, and orange near thin, whip-like tip. Venter pale cream with hint of yellowish overwash. Tail robust, usually slightly longer than head and body, thickly covered with long blackish-brown or gold hair forming a 15 mm, slightly wavy tuft at tip; it darkens from base to tip, usually strongly contrasting with pale color of the body. Skull with well-developed supraorbital ridges; interorbital region with nearly straight edges that diverge posteriorly; zygomatic arch slender, with maximum height less than or equal to one-third of the length of jugal; postorbital process of zygoma usually spinose and formed mainly by jugal; lateral process of supraoccipital short, extending to horizontal midline of external auditory meatus; narrow, forming an angle of about 45°, mesopterygoid fossa reaches anterior lamina of M3; incisive foramina oval. Cheek teeth narrow, with palatine width greater than tooth width at M1; tooththrows slightly divergent at either end. Mandible with

ventral root of angular process deflected laterally. Upper incisors orthodont.

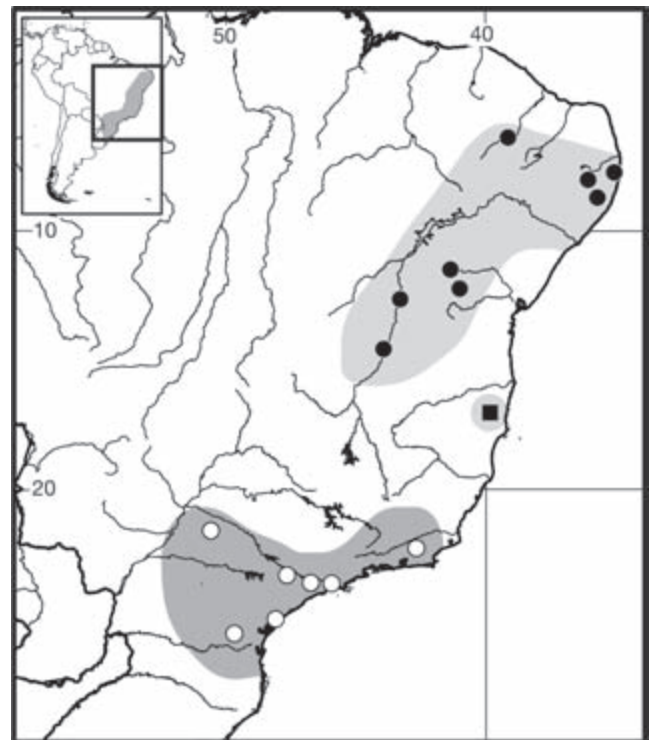

DISTRIBUTION: *Phyllomys blainvillii* occurs in the inland region of northeastern Brazil, from the southern portion of the state of Ceará (ca. 7° S) to the northernmost part of Minas Gerais (ca. 15° S), perhaps extending to the coast in Alagoas and Pernambuco states.

SELECTED LOCALITIES (Map 501; from Y. L. R. Leite 2003, except as noted): BRAZIL: Alagoas, Sítio Angelim; Bahia, Bom Jesus da Lapa, Fazenda Santa Rita, Seabra (type locality of *Nelomys blainvillii* Jourdan, as restricted by Emmons, Leite et al. 2002); Ceará, Chapada do Araripe; Minas Gerais, Mocambinho; Pernambuco, Igarassú (but see Remarks), Sítio Cavaquinho.

SUBSPECIES: *Phyllomys blainvillii* is monotypic.

NATURAL HISTORY: This species occupies fragmented habitat throughout a large area of northeastern Brazil, primarily in isolated areas of semideciduous forest, especially forest islands within the Caatinga termed *brejos* or *brejos de altitude*, and forest patches along the Rio São Francisco.

REMARKS: Identification of specimens from the coastal area of northeastern Brazil (Alagoas and Pernambuco states) should be reviewed, as these might represent an undescribed species. This is certainly the case for the specimen from Paraíba state reported by Campos and Per-

Map 501 Selected localities for *Phyllomys blainvillii* (●), *Phyllomys nigrispinus* (○), and *Phyllomys unicolor* (■).

cequillo (2007) as *P. blainvillii* (see Loss and Leite 2011). M. J. Souza (1981) and Y. L. R. Leite (2003) described a karyotype with $2n=50$, $FN=94-96$. This species has been often confused in the literature with *P. lamarum*. Moojen (1952b), for example, had them reversed; his plate 19 actually portrays an adult *P. lamarum*, identifiable by the speckled fur on the back and nearly naked tail, while plate 20 pictures a young *P. blainvillii* with a more uniform body color and a tufted tail.

Phyllomys brasiliensis Lund, 1840

Brazilian Atlantic Tree Rat

SYNONYMS:

- Phyllomys brasiliensis* Lund, 1839b:208; *nomen nudum*.
Phyllomys brasiliensis Lund, 1840b [1841c:294]; type locality fixed to "Lapa das Quatro Bocas," Lagoa Santa, Minas Gerais, Brazil, by selection of a lectotype (Emmons, Leite et al. 2002:7).
 [Loncheres] *brasiliensis* Waterhouse, 1848:330; name combination but subsequent incorrect spelling of *brasiliensis* Lund.
 [Loncheres (*Loncheres*) *armatus*] *brasiliensis*: E.-L. Trouessart, 1880b:177; name combination.
Loncheres armatus: Winge, 1887:71; name combination; not *armatus* I. Geoffroy St.-Hilaire.
Echimyus (*Echimyus*) *armatus*: E.-L. Trouessart, 1904:503; part; name combination; not *armatus* I. Geoffroy St.-Hilaire.
Phyllomys armatus: Goldman, 1916:126; part.
 [Nelomys] *brasiliensis*: Thomas, 1916d:240; name combination.
 [Echimyus] *brasiliensis*: Tate, 1935:431; name combination but subsequent incorrect spelling of *brasiliensis* Lund.
Echimyus (*Nelomys*) *brasiliensis*: Eisenberg and Redford, 1999:487; name combination.

DESCRIPTION: Medium sized for genus, head and body length 210mm, hindfoot length 36mm, and ear length 18mm (Reinhardt 1849). Dorsal pelage spiny, colored orange-brown sprinkled with black. Aristiforms tipped with orange and are relatively long (27mm), with whip-like tip, and wide (1.3mm) on rump. Venter cream-yellow with cream-white inguinal and axillary regions with white-based hair along midline. Tail about equal to the head and body length; covered with short brown hair such that scales remain visible except near tip, where longer hairs reach 20mm. Skull with well-developed and beaded supraorbital ridges; interorbital region slightly divergent posteriorly, with moderately developed postorbital processes; zygomatic arch slender to moderately robust, maximum height less than or equal to one-third the length of the jugal; spinose postorbital process of zygoma without squamosal contribution; lateral process of supraoccipital

long, extending below horizontal midline of external auditory meatus; mesopterygoid fossa sharply pointed anteriorly, wide posteriorly, forming angle $>60^\circ$, with anterior point reaching posterior lamina of M2. Incisive foramina oval. Cheek teeth narrow, palatine width equal to tooth width at M1; toothrows nearly parallel, diverging posteriorly in older individuals. Mandible with ventral root of angular process deflected laterally and ventral spine present posterior to junction of mandibular rami. Upper incisors are orthodont.

DISTRIBUTION: *Phyllomys brasiliensis* is known only from the Lagoa Santa region and Fazenda Santa Cruz, 150km to the northwest, all in Minas Gerais state, Brazil, in the valleys of the Paraopeba and das Velhas rivers.

SELECTED LOCALITIES (Map 502): BRAZIL: Minas Gerais, Fazenda Santa Cruz (Y. L. R. Leite 2003), Sumidouro (Emmons, Leite et al. 2002).

SUBSPECIES: *Phyllomys brasiliensis* is monotypic.

NATURAL HISTORY: *Phyllomys brasiliensis* inhabits the area between semideciduous forest and Cerrado, between 500 and 800 m.

REMARKS: *Phyllomys brasiliensis* has been frequently confused with the recently named *P. pattoni* (Emmons, Leite et al. 2002), but the description and measurements of *P. brasiliensis* given by Reinhardt (1849) and Winge (1887)

Map 502 Selected localities for *Phyllomys brasiliensis* (●), *Phyllomys pattoni* (○), and *Phyllomys thomasi* (■). Contour line = 1,000 m.

are rich in detail and provide unambiguous distinctions between these two species: “aristiforms grayish at the base, orange distally and grayish-brown at the tip, ending in a very fine, curved hairlike point” (Reinhardt 1849); “tail hairs get longer distally, forming a thick tuft at the tip” (Winge 1887). Known primarily from fragmentary skulls from owl pellets collected by Lund (1840a,b [1841b,c]) and described in more detail by Winge (1887), there is only one record of *P. brasiliensis* from the twentieth century.

Phyllomys dasythrix Hensel, 1872

Drab Atlantic Tree Rat

SYNONYMS:

Phyllomys dasythrix Hensel, 1872b:49, plate 1, Figs. 11 and 12; type locality “Rio Grande do Sul, Süd-Brasiliens”; restricted to “Porto Alegre, Rio Grande do Sul, Brazil, 30°04'S 51°07'W” (Emmons, Leite et al. 2002:21).

[*Loncheres* (*Loncheres*)] *dasythrix*: E.-L. Trouessart, 1880b:177; name combination.

[*Echimys* (*Echimys*)] *dasythrix*: E.-L. Trouessart, 1904:503; name combination.

[*Nelomys*] *dasythrix*: Thomas, 1916d:240; name combination.

Echimys dasythrix dasythrix: Cabrera, 1961:540; name combination.

Echimys (*Nelomys*) *dasythrix*: Eisenberg and Redford, 1999:487; name combination.

DESCRIPTION: Medium-sized for genus, head and body length 190–195 mm, tail length 205–225 mm, hind-foot length 32–39 mm, and ear length 13–19 mm (Y. L. R. Leite et al. 2008). Pelage soft, with very fine and long (0.2 × 26 mm) aristiforms on rump, paler at base and blackish distally, with thin whip-like tips. Tail moderately covered with brown hairs to tip, which lacks tuft. Skull with weakly developed supraorbital ridges; interorbital region slightly divergent posteriorly, sometimes with small post-orbital process present; zygomatic arches robust with maximum height approximately one-third length of jugal; lateral process of supraoccipital short, extending to horizontal midline of external auditory meatus; mesopterygoid fossa narrow, forming angle of 45–60°, reaching to last lamina of M2. Incisive foramina oval. Cheek teeth large with palatine width less than tooth width at M1, and tooththrows parallel. Mandible with ventral root of angular process not deflected laterally. Upper incisors orthodont.

DISTRIBUTION: The known range of *Phyllomys dasythrix* is along the south coast of Brazil; from the state of Paraná (ca. 26°S) to Rio Grande do Sul (ca. 30°S).

SELECTED LOCALITIES (Map 503; from Y. L. R. Leite 2003:67): BRAZIL: Paraná, Palmira (BM 0.6.29.20);

Map 503 Selected localities for *Phyllomys dasythrix* (●), *Phyllomys lundii* (○), and *Phyllomys mantiqueirensis* (■).

Rio Grande do Sul, Pinheiros (Y. L. R. Leite 2003), Porto Alegre (type locality of *Phyllomys dasythrix* Hensel, as restricted by Emmons, Leite et al. 2002), São Francisco de Paula (Y. L. R. Leite 2003).

SUBSPECIES: *Phyllomys dasythrix* is monotypic.

NATURAL HISTORY: The habitat range extends from semideciduous, and perhaps *Araucaria*, forests inland, usually below 800 m elevation.

REMARKS: While *P. dasythrix* has distinctly soft fur, Y. L. R. Leite (2003) recognized a second and sympatric animal with spiny fur but the same qualitative cranial characters, which he referred to as *P. aff. dasythrix*. Oldfield Thomas (1909) apparently mixed these two forms in his comparison of “*P. dasythrix*” with *P. medius*, which he described in that paper. Y. L. R. Leite et al. (2008) have now described this second taxon; see account for *P. sulinus*, below. Y. L. R. Leite (2003) gave the diploid number as 72, but details of the karyotype are unknown.

Phyllomys kerri (Moojen, 1950)

Kerr's Atlantic Tree Rat

SYNONYMS:

Echimys (*Phyllomys*) *kerri* Moojen, 1950:489, Figs. 1–5; type locality “Ubatuba, S[ã]o Paulo, Brasil,” restricted to “Estação Experimental de Ubatuba, Ubatuba, São Paulo, Brazil, 23°25'S 45°07'W” (Emmons, Leite et al. 2002:28).

Phyllomys kerri: Moojen, 1952b:142; first use of current name combination.

Echimyys kerri: C. O. da C. Vieira, 1955:437; name combination.

Nelomys kerrei Emmons and Feer, 1990:274; name combination, and incorrect subsequent spelling of *Echimyys* (*Phyllomys*) *kerri* Moojen.

DESCRIPTION: Medium-sized for genus, head and body length 212 mm, tail length 223 mm, and hindfoot length 38 mm, ear length 17 mm (measurements of holotype; Emmons, Leite et al. 2002). Dorsal pelage spiny, colored reddish brown streaked with black. Aristiforms hairs on rump black, averaging 27 mm in length and 1 mm in width, and terminated by thin, whip-like tips. Ventral color yellowish orange with hairs usually gray at base. Skull long and narrow; supraorbital ridges well developed; interorbital region diverges posteriorly, with inconspicuous postorbital process; zygomatic arch robust with maximum height approximately one-third the length of jugal; postorbital process of zygoma spinose and formed mainly by jugal; lateral process of supraoccipital short, reaching horizontal midline of external auditory meatus; palatine width equal to or greater than tooth width at M1; toothrows nearly parallel; mesopterygoid fossa wide, forming an angle of nearly 60°, reaching last laminae in M2; incisive foramina oval. Mandible with ventral root of angular process not deflected laterally. Upper incisors slightly opisthodont.

DISTRIBUTION: *Phyllomys kerri* is known only from the its type locality.

Map 504 Selected localities for *Phyllomys kerri* (○) and *Phyllomys lamarum* (●).

SELECTED LOCALITIES (Map 504): BRAZIL: São Paulo, Estação Experimental de Ubatuba (type locality of *Echimyys* [*Phyllomys*] *kerri* Moojen, 1950, as restricted by Emmons, Leite et al. 2002).

SUBSPECIES: *Phyllomys kerri* is monotypic.

NATURAL HISTORY: The type locality of *Phyllomys kerri* is within broadleaf evergreen rainforest close to sea level. No other information is known.

REMARKS: This species is known from only three specimens, all collected at the type locality. Y. L. R. Leite (2003:73) stated that the morphological differences between *P. kerri* and *P. nigrispinis* identified by Moojen (1950) in his description of the former fall within the natural range of variation of the latter species. Nevertheless, he provided additional diagnostic characters to separate these two taxa (shorter maxillary toothrow, broader rostrum, wider interorbital region, and reduced bullae) and thus provisionally maintained *P. kerri* as a valid species, at least until sufficient specimens of both taxa become available for adequate comparisons.

Phyllomys lamarum (Thomas, 1916)

Pallid Atlantic Tree Rat

SYNONYMS:

Nelomys lamarum Thomas, 1916e:297; type locality “Lamarão [sic], Bahia, about 70 miles N.W. of Bahia city [now Salvador]. Alt. 300 mm [sic],” amended to “Lamarão, about 70 miles NW Salvador, Bahia, Brazil, 11°47’S 38°53’W, elev. 300 m” (Emmons, Leite et al. 2002:26).

[*Echimyys*] *lamarum*: Tate, 1935:431; name combination.

Phyllomys blainvillii: Moojen, 1952b:139, plate 19; not *blainvillii* Jourdan.

Echimyys dasythrix lamarum: Cabrera, 1961:541; name combination.

Echimyys (*Nelomys*) *lamarum*: Eisenberg and Redford, 1999: 487; name combination.

Phyllomys lamarum: Emmons, Leite, Kock, and Costa, 2002: 26; first use of current name combination.

DESCRIPTION: Medium sized for genus, with head and body length 195–230 mm, tail length 210–233 mm, hindfoot length 32–35 mm, and ear length 13–16 mm (Emmons and Feer 1997). Dorsum yellow-brown with speckled pattern given by short (24 mm), broad (1.3 mm) aristiforms. Spines pale at base and darken toward tip where they become orange, ending in dark, thin, whip-like tips. Venter pale brown with white patches, varying to pure white; fulvous lateral line typically present. Tail relatively slender, slightly shorter than or equal to head and body length, and thinly covered with pale brown hairs such that scales remain visible to the eye along entire length. Skull with posteriorly diverging interorbital region, almost

straight-edged due to inconspicuous or absent postorbital processes, with well-developed supraorbital ledges; zygomatic arch relatively robust with maximum height less than or equal to one-third the length of jugal; postorbital process of zygoma spinose, usually without contribution from squamosal; lateral process of supraoccipital short, extending to midline of external auditory meatus; wide, forming an angle of more than 60°, mesopterygoid fossa reaches last lamina of M2; incisive foramina oval. Mandible with ventral root of angular process deflected laterally; ventral spine present near posterior junction of mandibular rami. Upper incisors orthodont.

DISTRIBUTION: *Phyllomys lamarum* extends along coastal Brazil from the state of Paraíba in the northeast (ca. 7°S) to Espírito Santo in the southeast (ca. 19°S), and inland to northern Minas Gerais. The three geographic sets of known localities are each about 700 km apart, and thus may represent truly disjunct populations.

SELECTED LOCALITIES (Map 504): BRAZIL: Bahia, Lamarão (type locality of *Nelomys lamarum* Thomas, as amended by Emmons, Leite et al. 2002), São Gonçalo (Y. L. R. Leite 2003); Espírito Santo, Pancas (Loss and Leite 2011); Minas Gerais, Estação Ecológica de Acauã (Y. L. R. Leite 2003), Fazenda Paiol (UMFG 1491); Paraíba, Mangauape (Y. L. R. Leite 2003).

SUBSPECIES: *Phyllomys lamarum* is monotypic.

NATURAL HISTORY: *Phyllomys lamarum* is found mainly in semideciduous forests but extends to the coastal forests in Paraíba state.

REMARKS: Identification of specimens assigned to this species from the coastal area of northeastern Brazil (states of Alagoas, Pernambuco, and Paraíba) should be reviewed; these likely represent an undescribed species of *Phyllomys* (see Loss and Leite 2011). As mentioned in the account of *P. blainvillii*, Moojen (1952b) had these two species reversed. Specimens of *P. lamarum* from the arid parts of the range, such as the type locality of Lamarão, are paler than specimens from moister areas, for example, in Minas Gerais (Y. L. R. Leite 2003).

N. P. Araújo et al. (2014) described the karyotype of a male with $2n=56$, FN=102 collected at Araçuaí, Minas Gerais (16.85°S, 42.07°W).

Phyllomys lundi Y. L. R. Leite, 2003

Lund's Atlantic Tree Rat

SYNONYM:

Phyllomys lundi Y. L. R. Leite, 2003:19; type locality "Fazenda do Bené, 4 km SE Passa Vinte, Minas Gerais, Brazil, 22°14'S 44°12'W 680 m."

DESCRIPTION: Among smallest species in genus, with head and body length 209 mm, tail length 204 mm, hindfoot length 36 mm, ear length 16 mm, and mass 145 g

(measurements of holotype; Y. L. R. Leite 2003). Dorsal pelage colored predominantly orange intermixed with black; neck and thighs markedly orange. Spines conspicuous from neck to tail. Ventral hairs cream with white base, providing overall washed aspect. Tail brown in color and hairy from base to tip. The forefeet are covered with brown-yellow hairs, except for gray-white fingers. Dorsal surfaces of hindfeet covered with golden-creamy hairs and toes with silver hair. Skull delicate with relatively narrow and long rostrum, and wide and convex interorbital region. M3 with only three transverse plates. Mandible with short coronoid process and shallow sigmoid notch.

DISTRIBUTION: *Phyllomys lundi* is known only from two localities separated by nearly 200 km, one each in the states of Minas Gerais (the type locality) and Rio de Janeiro, southeastern Brazil (Y. L. R. Leite 2003).

SELECTED LOCALITIES (Map 503): BRAZIL: Minas Gerais, Fazenda do Bené (type locality of *Phyllomys lundi* Y. L. R. Leite); Rio de Janeiro, Reserva Biológica de Poço das Antas (Y. L. R. Leite 2003).

SUBSPECIES: *Phyllomys lundi* is monotypic.

NATURAL HISTORY: *Phyllomys lundi* occurs in second growth, broadleaf evergreen rainforest with a dense understory, where most trees are at least 20 cm in diameter and crowns 20 m in height, and also in selectively logged mature forest on dry ridge-top soils, discontinuous overstory with emergents reaching 32 m, sparse understory, and lack of discernible boundaries between forest strata. Both specimens were taken in traps placed on tree limbs or lianas within 1–1.5 m above the ground.

REMARKS: The phylogenetic position of *P. lundi* remains uncertain. Analyses of mtDNA and nucDNA sequences suggest that this species is closely related to either a southern clade formed by *P. dasythrix*, *P. sulinus*, and *P. nigrispinus* or a northeastern clade comprised by *P. blainvillii*, *P. lamarum*, and *P. brasiliensis* (Loss and Leite 2011).

Phyllomys mantiqueirensis Y. L. R. Leite, 2003

Serra da Mantiqueira Atlantic Tree Rat

SYNONYM:

Phyllomys mantiqueirensis Y. L. R. Leite, 2003:25; type locality "Fazenda da Onça, 13 km SW Delfim Moreira, Minas Gerais, Brazil, 22°36'S 45°20'W 1850 m."

DESCRIPTION: Medium sized for genus, head and body length 217 mm, tail length 216 mm, hindfoot length 41 mm, ear length 18 mm, mass 207 g (measurements of holotype; Y. L. R. Leite 2003). Soft, densely furred arboreal rat with hairy tail tufted at tip. Dorsal body color brownish gray. Tail equal to head and body length and darker in color than body; covered with brown hairs that become denser and longer toward tip, forming a long (30 mm) terminal tuft. Skull with short and broad rostrum, narrow in-

terorbital region, well-developed lacrimal processes, small and oval incisive foramina. Mandible with slim and long coronoid process and deep sigmoid notch.

DISTRIBUTION: *Phyllomys mantiqueirensis* is known only from the type locality.

SELECTED LOCALITIES (Map 503): BRAZIL: Minas Gerais, Fazenda da Onça (type locality of *Phyllomys mantiqueirensis* Y. L. R. Leite).

SUBSPECIES: *Phyllomys mantiqueirensis* is monotypic.

NATURAL HISTORY: The type locality is in cool, wet montane forest with an open overstory composed of a 10-m canopy and emergent araucaria trees, on a steep slope with a moderately dense understory composed of shrubs, lianas, vines, abundant bamboos and lichens, and some ferns. The holotype, and only known specimen, was collected in a trap placed 2 m high on a liana connecting two trees.

REMARKS: This species is very distinctive, readily diagnosed by both morphological and molecular sequence characters. Phylogenetic analysis based on mtDNA and nucDNA sequences suggest a close relationship to *P. pattoni* and that, together, this pair of species may form the oldest lineage within the genus, one sister to all other extant forms (Loss and Leite 2011).

Phyllomys medius (Thomas, 1909)

Long-furred Atlantic Tree Rat

SYNONYMS:

Loncheres medius Thomas, 1909:239; type locality “Roça Nova Serro [*sic*] do Mar, Parana, S[outh]. Brazil. Alt. 1000m,” amended to “Roça Nova, Serra do Mar, Paraná, Brazil, 25°28’S 49°01’W, elevation 1000 m” (Emmons, Leite et al. 2002:24).

[*Nelomys*] *medius*: Thomas, 1916d:240; name combination.

[*Echimyis*] *medius*: Tate, 1935:432; name combination.

Phyllomys medius: Moojen, 1952b:138; name combination.

Echimys blainvillei medius: Cabrera, 1961:540; name combination.

Echimys blainvillei: Woods, 1993:791; part; not *blainvillii* Jourdan.

Phyllomys medius: Emmons, Leite, Kock, and Costa, 2002: 23; first use of current name combination.

DESCRIPTION: Medium sized for genus, head and body length 230 mm, tail length 240 mm, hindfoot length 40 mm, and ear length 17 mm (measurements of holotype; Emmons, Leite et al. 2002). Fur stiff but relatively soft. Dorsum dark brown sprinkled with black, darkest on mid-dorsum. Aristiforms on rump very long (36 mm), thin (0.4 mm), black distally, with thin whip-like tip. Ventral hairs distinctly gray-based, with fulvous tips. Skull robust

and long; supraorbital ledges well developed and interorbital region parallel sided or divergent posteriorly with inconspicuous, or absent, postorbital processes; zygomatic arch robust with its maximum height more than one-third the length of jugal; postorbital process of zygoma spinose and formed mainly by jugal; lateral process of supraoccipital short, extending to horizontal midline of external auditory meatus; incisive foramina are small and teardrop in shape; maxillary teeth narrow, with palatine width equal to tooth width at M1; tooththrows parallel; mesopterygoid fossa narrow, forming angle of about 45°, reaching last lamina of M2; tympanic bullae small. Mandible with ventral root of angular process not deflected laterally. Upper incisors opisthodont.

DISTRIBUTION: *Phyllomys medius* is known in southern Brazil from the states of Minas Gerais and Rio de Janeiro in the north to Rio Grande do Sul in the south.

SELECTED LOCALITIES (Map 505; from Y. L. R. Leite 2003, except as noted): BRAZIL: Minas Gerais, Alto da Consulta; Paraná, Rio Paracá, Roça Nova (type locality of *Loncheres medius* Thomas, as amended by Emmons, Leite et al. 2002); Rio Grande do Sul, Banhado do Pontal; Rio de Janeiro, Fazenda Comari; São Paulo, Barra do Ribeirão Onça Parda; Santa Catarina, Florianópolis.

SUBSPECIES: *Phyllomys medius* is monotypic.

NATURAL HISTORY: This species is found mainly along the coast in areas of broadleaf evergreen rainforest but extends into *Araucaria* forests in Paraná state (ca. 52°W). Northern records are from elevations as high

Map 505 Selected localities for *Phyllomys medius* (●).

as 1,000 m; those in the south are at lower elevations, suggesting a preference for cooler climates. Davis (1945a) provided detailed descriptions of the habitat of this species at Terezópolis, in Rio de Janeiro state.

REMARKS: Sbalqueiro et al. (1988) reported a diploid number of 96 for two specimens from Santa Catarina (as *Echimys dasythrix*, but one specimen identified by Y. L. R. Leite 2003:69 as *P. medius*).

Phyllomys nigrispinus (Wagner, 1842)

Black-spined Atlantic Tree Rat

SYNONYMS:

Loncheres nigrispina Wagner, 1842c:361; type locality “Ypanema,” amended to “Floresta Nacional de Ipanema, 20 km NW Sorocaba, São Paulo, Brazil, 23°26′S 47°37′ W, elev. 550–970 m” (Emmons, Leite et al. 2002:17).

[*Loncheres* (*Loncheres*) *Blainvillii*] *nigrispina*: E.-L. Trouessart, 1880b:177; name combination.

[*Loncheres* (*Loncheres*)] *nigrispina*: E.-L. Trouessart, 1897:604; name combination.

[*Echimys* (*Echimys*)] *nigrispina*: E.-L. Trouessart, 1904:503; name combination.

[*Nelomys*] *nigrispina*: Thomas, 1916e:297; name combination.

Echimys nigrispina: Tate, 1935:432; name combination.

Phyllomys nigrispina: Moojen, 1952b:141; name combination but incorrect gender concordance.

Echimys (*Nelomys*) *nigrispinus*: Eisenberg and Redford, 1999:488; name combination.

Phyllomys nigrispinus: Emmons, Leite, Kock, and Costa, 2002:17; first use of current name combination, and correct gender ending.

DESCRIPTION: Medium sized for genus, head and body length 215 mm, tail length 240 mm, hindfoot length 40 mm, and ear length 18 mm (Emmons and Feer 1997). Substantial variation within and among populations, but generally dorsum spiny with reddish brown hairs streaked with black, clothed with relatively narrow (1 mm), medium length (27 mm), and black aristiform hairs that terminate with thin, whip-like tips. Ventral color extremely variable, ranging from buffy-white to yellowish gray; hairs are usually white at base. Skull with supraorbital ridges well developed; interorbital region diverging posteriorly with absent or inconspicuous postorbital processes; zygomatic arch slender to moderately robust, maximum height between one-fourth and one-third length of jugal; postorbital process of zygoma rounded or spinose, formed mainly by jugal; lateral process of supraoccipital long, extending below horizontal midline of external auditory meatus; incisive foramina oval; palatine width equal to or broader than tooth width at M1; tooththrows parallel; wide mesoptery-

goid fossa, forming an angle of about 60° and reaching last laminae of M2 or first of M3. Mandible with ventral root of angular process not deflected laterally. Upper incisors slightly opisthodont.

DISTRIBUTION: *Phyllomys nigrispinus* occurs in southeastern Brazil from the state of Rio de Janeiro in the north (ca. 22°S) to Paraná in the south (ca. 26°S), mainly along the coastal zone although extending inland to western São Paulo state (ca. 50°W).

SELECTED LOCALITIES (Map 501; from Y. L. R. Leite 2003, except as noted): BRAZIL: Paraná, Guajuvira; Rio de Janeiro, Fazenda Alpina; São Paulo, Floresta Nacional de Ipanema (type locality of *Loncheres nigrispina* Wagner, as amended by Emmons, Leite et al. 2002), Ilha do Cardoso, Interlagos, Santos, Vanuire.

SUBSPECIES: *Phyllomys nigrispinus* is monotypic.

NATURAL HISTORY: *Phyllomys nigrispinus* occurs in both broadleaf evergreen rainforest and semideciduous forest.

REMARKS: Y. L. R. Leite (2003) noted that the extensive variation in morphological characters among the limited series of specimens available might signal multiple species within this taxon as he defined it. He reported a diploid number of 52 for specimens from Cachoeiras de Macacu, Rio de Janeiro state, but molecular data suggest these specimens represent an undescribed species (Loss and Leite 2011).

Phyllomys pattoni Emmons, Leite, Kock, and Costa, 2002

Patton's Atlantic Tree Rat

SYNONYMS:

Loncheres armatus: Burmeister, 1854:196; part; not *armatus* I. Geoffroy St.-Hilaire.

Nelomys brasiliensis: Thomas, 1916e:297; not *Phyllomys brasiliensis* Lund.

Phyllomys brasiliensis: Moojen, 1952b:141; not *Phyllomys brasiliensis* Lund.

Nelomys sp.: Emmons and Feer, 1990:220; under the common name “rusty-sided tree rat.”

Phyllomys pattoni Emmons, Leite, Kock, and Costa, 2002:30; type locality “Mangue do Caritoti, Caravelas, Bahia, Brazil, 17°43′30″S 39°15′35″W; at sea level.”

DESCRIPTION: Medium-sized for genus, head and body length 209–241 mm, tail length 190–223 mm, hindfoot length 40–42 mm, and ear length 16–18 mm. Most heavily spined species in genus; aristiforms on rump average 23 mm in length and 1.0 in width. Dorsal spines light gray at base, gradually darkening toward black medially, and terminate in blunt orange tip. Most aristiforms on rump lack characteristic whip-like tip present in all other

species (Emmons, Leite et al. 2002). Overall, dorsum dark brown, with speckled aspect given by rusty-tipped spines. Tail slightly shorter to slightly longer than head and body length and covered with fine hair to tip, although scales remain visible to eye. Skull robust and relatively broad; supraorbital ledges well developed and beaded; interorbital region divergent posteriorly and lacks postorbital process; zygomatic arch robust with maximum height approximately one-third the length of jugal; postorbital process of zygoma spinose, with contributions of both jugal and squamosal; lateral process of supraoccipital long, extending below horizontal midline of external auditory meatus; incisive foramina bullet shaped; maxillary toothrows relatively short and narrow, with palatine width equal to tooth width at M1. Mandible with ventral root of angular process deflected laterally. Upper incisors orthodont.

DISTRIBUTION: *Phyllomys pattoni* is a wide-ranging species of coastal Brazil, extending from the state of Paraíba (ca. 7°S) in the northeast to São Paulo (ca. 23°S) in the southeast.

SELECTED LOCALITIES (Map 502; see Emmons, Leite et al. 2002, except as noted): BRAZIL: Bahia, Fazenda Pirataquicê, Mangue do Caritoti (type locality of *Phyllomys pattoni* Emmons, Leite, Kock, and Costa, 2002), São Felipe; Espírito Santo, Fazenda Santa Terezinha, Parque Estadual da Fonte Grande; Minas Gerais, Além Paraíba, Fazenda Monte Claros, Mata Paraíso; Paraíba, João Pessoa; Pernambuco, Dois Irmãos; Rio de Janeiro, Fazenda União, Ilha Grande, Tijuca; São Paulo, Piquete.

SUBSPECIES: *Phyllomys pattoni* is monotypic.

NATURAL HISTORY: *Phyllomys pattoni* is found chiefly in broadleaf evergreen rainforest and associated habitats, such as mangroves, from sea level to 1,000 m.

REMARKS: Zanchin (1988) gave a diploid number of 80 for a specimen he identified as "*Echimyis* sp." and Severo described a karyotype of $2n=80$, FN=112, under the name "*Echimyis thomasi*." Both are reports of the same specimen from Espírito Santo state. Paresque et al. (2004) describe a karyotype of $2n=80$, FN=100, for *P. pattoni*, also a specimen from Espírito Santo. Whether the reported differences in the number of autosomal arms reflect real morphological distinctions or are methodological artifacts remains to be established. Specimens from Rio de Janeiro are $2n=72$, FN=114 (Y. L. R. Leite 2003). As documented by Emmons, Leite et al. (2002), this species was incorrectly associated with Lund's *P. brasiliensis* for more than a century (Burmeister 1854; Thomas 1916e; Moojen 1952b). Emmons and Feer (1990, 1997) referred to this species as the "Rusty-Sided Atlantic Tree Rat, *Nelomys* sp."

Phyllomys sulinus Y. L. R. Leite, Christoff, and Fagundes, 2008

Southern Atlantic Tree Rat

SYNONYM:

Phyllomys sulinus Y. L. R. Leite, Christoff, and Fagundes, 2008: 846; type locality "South bank of the Uruguay River, municipality of Aratiba, Rio Grande do Sul, Brazil, 27°23'39"S 52°18'01"W, 420 m elevation."

DESCRIPTION: Medium sized for genus for genus, head and body length 200–210 mm, tail length 160–248 mm, hindfoot length 35–40 mm, and ear length 11–18 mm (Y. L. R. Leite et al. 2008). Pelage coarse, with both aristiform and setiform hairs; aristiforms on rump medium in length (26 mm) and width (0.6 mm), wider and paler at base, thinning gradually into black and with thin whip-like tip; setiforms on rump (24 mm) slightly shorter than aristiforms, with basal portion gray, gradually turning to dark brown, with 4 mm orange band near tip. Overall dorsal color orange brown. Ventral region covered with short (10 mm), cream-colored hairs with gray bases; white patches of fur occur on chin, throat, axillary, and inguinal regions. Tail dark brown above and light brown below; hairy along entire length, usually with scales hidden; tail hairs longer toward the tip, forming conspicuous (20 mm) terminal tuft. Head dark brown, contrasting with lighter body; nose blunt and gray brown; cheeks pale cream. Mystacial vibrissae dark brown and long (65 mm); longest superciliary and genal vibrissae reach 45 mm. Ears dark brown and nearly naked, sparsely covered with long (15 mm) and very thin hairs, especially along edges. Tail long (about 120% of head and body length); hindfeet short and broad (with claws, about 21% of head and body length); ears round and small (about 8% of head and body length). Dorsal surfaces of forefeet and hindfeet silver gray; ungual tufts grayish white and long, extending slightly beyond claws. Ventral surface of forefoot with thenar, hypothenar, and three equidistant interdigital pads; ventral surface of hindfoot with thenar, hypothenar, and four equidistant interdigital pads. Glans penis elongate, with slight medial swelling; terminal portion cone shaped, ending in long pointed bacular papilla; urethral lappets present near proximal end intromittent sac.

Skull with well-developed supraorbital ridged; interorbital region slightly divergent posteriorly, sometimes with small postorbital process; zygomatic arch robust, with maximum approximately one-third the length of jugal; postorbital process of zygoma spinose, formed mainly by jugal; lateral process of supraoccipital short, extending to horizontal midline of the external auditory meatus; incisive foramina oval; mesopterygoid fossa narrow, forming an angle of 45–60°, and reach last lamina of M2. Cheek

teeth large; palatine width usually less than tooth width at M1; upper toothrows parallel. Mandible with ventral root of angular process not deflected laterally. Upper incisors orthodont.

DISTRIBUTION: *Phyllomys sulinus* occurs in the subtropical region of southern Brazil, from the states of São Paulo to Rio Grande do Sul. Y. L. R. Leite (2003) mentioned a possible occurrence in the state of Minas Gerais, just north of São Paulo, based on an unlabeled voucher (UFMG 3015) found in a freezer by E. L. Sábato and M. T. da Fonseca. Y. L. R. Leite's (2003) suggestion that *P. sulinus* is a highland species is incorrect because specimens have been collected below 500 meters at the type locality as well as on the island of Santa Catarina.

SELECTED LOCALITIES (Map 506; from Y. L. R. Leite et al. 2008, except as noted): BRAZIL: Paraná, Parque Barigüi; Rio Grande do Sul, Aratiba (type locality of *Phyllomys sulinus* Leite, Christoff, and Fagundes, 2008), Parque Nacional dos Aparados da Serra; Santa Catarina, Ilha de Santa Catarina; São Paulo, Teodoro Sampaio, Estação Biológica de Boracéia, Parque Estadual da Serra do Mar.

SUBSPECIES: *Phyllomys sulinus* is monotypic.

NATURAL HISTORY: Similar to the other species of *Phyllomys*, *P. sulinus* is a nocturnal, arboreal folivore, nesting above ground, usually in tree hollows (Y. L. R. Leite 2003; Y. L. R. Leite et al. 2008). Specimens of *P. sulinus* have been recorded in coastal Atlantic rainforest, as well as *Araucaria* and semideciduous forests inland. The Atlantic

Map 506 Selected localities for *Phyllomys sulinus* (●).

rainforest experiences warm and wet climate without a dry season, whereas a seasonal climate with a relatively severe dry season (generally from April to September) predominates in the Atlantic semideciduous and *Araucaria* forests (Morellato and Haddad 2000).

REMARKS: Y. L. R. Leite (2003) described and mapped this species as *P. aff. dasythrix*. Y. L. R. Leite et al. (2008) described and figured a karyotype with $2n=92$, FN=102 of a paratype from Rio Grande do Sul. Yonenaga (1975) reported a diploid number of 90 for a specimen from São Paulo state that likely is this species (see Y. L. R. Leite 2003:77 for discussion).

Phyllomys thomasi (Ihering, 1897)

Thomas's Atlantic Tree Rat

SYNONYMS:

Mesomys thomasi Ihering, 1897:171; type locality "Ilha de São Sebastião," amended to "Ilha da São Sebastião, São Paulo, Brazil, 23°46'S 45°21'W (Emmons, Leite et al. 2002: 23).

Loncheres nigrispina: Ihering, 1898:506; part; not *Loncheres nigrispina* Wagner.

[*Euryzygomatomys*] *thomasi*: E.-L. Trouessart, 1904:506; name combination.

L[oncheres]. thomasi: Thomas, 1909:239; name combination.

[*Nelomys*] *thomasi*: Thomas, 1916d:240; name combination.

[*Echimys*] *thomasi*: Tate, 1935:432; name combination.

Phyllomys thomasi: Moojen, 1952b:138; first use of current name combination.

Echimys blainvillei thomasi: Cabrera, 1961:540; name combination.

Echimys (Nelomys) thomasi: Eisenberg and Redford, 1999: 488; name combination.

DESCRIPTION: Largest species in genus: measurements of holotype include head and body length 287 mm, hindfoot length 47 mm (Emmons, Leite et al. 2002); unvouchered specimen with head and body length 270 mm, tail length 270 mm, mass 432 g (Olmos 1997). Dorsal pelage spiny; overall color reddish brown streaked with black, darker on mid-dorsum. Venter cream to light gray, grading gradually from sides. Aristiforms on rump long (33 mm), relatively narrow (0.7 mm), and gray-brown proximally and black distally with thin whip-like tip. Tail robust and covered with dark brown hair from base to tip. Skull with well-developed supraorbital ledges; interorbital region nearly parallel, with inconspicuous postorbital processes; zygomatic arch robust, reaching maximum height more than one-third the length of jugal; postorbital process of zygoma usually rounded and formed mainly by jugal; lateral process of supraoccipital

short, extending to midline of external auditory meatus; incisive foramina teardrop in shape; mesopterygoid fossa wide, forming an angle of about 60°, reaching posterior lamina of M2. Cheek teeth wide; palatine width equal to or greater than tooth width at M1; toothrows parallel to slightly divergent posteriorly. Mandible with ventral root of angular process not deflected laterally. Upper incisors slightly opisthodont.

DISTRIBUTION: *Phyllomys thomasi* is endemic to the island of São Sebastião, off the coast of São Paulo.

SELECTED LOCALITIES (Map 502): BRAZIL: São Paulo, Ilha da São Sebastião (type locality of *Mesomys thomasi* Ihering, 1897, as amended by Emmons, Leite et al. 2002).

SUBSPECIES: *Phyllomys thomasi* is monotypic.

NATURAL HISTORY: The habitat of this species is broadleaf evergreen rainforest over rugged topography, from sea level to 1,379 m. Olmos (1997) found a nest 13 m up in a fork of a tree, it was constructed of “interwoven dried and twisted leaves of *Terminalia* . . . forming a roughly oval dome with a base” and measured 380 × 300 × 200 mm. The female he caught in this nest and kept for three days ate fruit but not green fodder. Olmos (1997) noted that the rat was then (in 1994) uncommon. It is classified as Endangered (IUCN 2011) because of its small total range size endemic to a single island and declining population.

REMARKS: Ihering based his original description of *P. thomasi* on the fact that the only specimen he had examined had no tail (Ihering 1897). After he had inspected the remaining specimens collected in the original series, some with tails and others without, he concluded that it was conspecific with *P. nigrispinus* (Ihering 1898). *Phyllomys thomasi* is, however, distinguished from *P. nigrispinus* by its much larger size although it otherwise shares a similar general morphology. It is also very similar to *P. kerri* in cranial shape but is proportionally larger in all skull measurements (Y. L. R. Leite 2003:68). A photograph of a living specimen taken by F. Olmos (pers. comm. to L. H. Emmons) shows a handsome rat with a striking pitch black and thickly furred tail, blackish back, and warm brown sides. As all museum specimens are many decades to over a century old, possibly their original black colors have bleached to red-brown.

Phyllomys unicolor (Wagner, 1842)

Unicolored Atlantic Tree Rat

SYNONYMS:

Loncheres unicolor Wagner, 1842c:361; type locality “Brasília,” restricted to “Colônia Leopoldina [now Helvécia], 50 km SW Caravelas, Bahia, Brazil, 17°48’S 39°39’W, elev. 59 m” (Emmons, Leite et al. 2002:19).

[*Loncheres (Loncheres) Blainvillii*] *unicolor*: E.-L. Trouessart, 1880b:177; name combination, but incorrect subsequent spelling of *blainvillii* Jourdan.

[*Loncheres (Loncheres)*] *unicolor*: E.-L. Trouessart, 1897:604; name combination.

[*Echimys (Echimys)*] *unicolor*: E.-L. Trouessart, 1904:503; name combination.

Nelomys unicolor: Thomas, 1916e:297; name combination.

[*Echimys (Phyllomys)*] *unicolor*: Moojen, 1950:491; name combination.

Phyllomys unicolor: Moojen, 1952b:142; first use of current name combination.

DESCRIPTION: Second of two large species in genus, with estimated measurements of holotype including head and body length 280 mm, tail length 202 mm, hindfoot length 37–40.4 mm, and ear length 16.4 mm (Emmons, Leite et al. 2002). Pelage with short (<2.0 cm on dorsal mid-rump) and stiff narrow hairs of uniform color throughout length. Overall dorsal color uniformly pale rusty red-brown grading to buff on venter. Tail rust colored, completely covered with long hairs (ca. 5 mm) that hide scales and that become longer toward tip. Hindfeet broad but not long (average hindfoot length 40.5 mm), with stout claws and yellowish above. Ears nearly naked, short (average ear length 16.2 mm), with tuft on anterior rim. Skull massively built, dorsally flat in lateral profile, and with short and robust rostrum; jugals broad dorsoventrally; jugal fossa deeply concave and a strong, beaded ventral lip, with tip of fossa reaching anteriorly to ventral maxillojugal suture; postorbital process of zygoma rounded and formed mainly by jugal; lateral process of supraoccipital extends to lower edge of external auditory meatus; incisive foramina oval; mesopterygoid fossa wide, angle of fossa averaging 60°, reaching level of posterior edge of first lamina of M3; tympanic bullae conspicuously inflated. Cheek teeth especially large (maxillary tooththrow length averaging 13.85 mm); toothrows parallel. Mandible with ventral root of angular process deflected laterally. Upper incisors broad, orange, and orthodont.

DISTRIBUTION: *Phyllomys unicolor* is known only from its type locality in the southernmost part of Bahia state, Brazil (Emmons, Leite et al. 2002).

SELECTED LOCALITIES (Map 501): BRAZIL: Bahia, Colônia Leopoldina [now Helvécia] (type locality of *Loncheres unicolor* Wagner, as restricted by Emmons, Leite et al. 2002).

SUBSPECIES: *Phyllomys unicolor* is monotypic.

NATURAL HISTORY: The only known locality is within broadleaf evergreen rainforest close to the sea. This species appears rare and restricted to the region surrounding the type locality in southern Bahia, where it is sympatric with the more abundant and widespread *P. pattoni*.

REMARKS: The only known specimen is the holotype, collected before 1824, and redescribed fully by Emmons, Leite et al. (2002). Moojen (1952b:491) provided a brief description of a specimen he allocated to this species, and compared it to *P. kerri*, but this reference is likely a misidentification of some other species (Y. L. R. Leite 2003:66). After intensive field surveys at the type locality, Y. L. R. Leite et al. (2007) reported the rediscovery of *P. unicolor*. Their report was based on a young specimen identified as *P. unicolor* by a combination of morphological characters and a high level of mtDNA cytochrome-*b* sequence divergence from syntopic *P. pattoni*. However, Loss and Leite (2011) resequenced this same specimen and obtained a different cytochrome-*b* sequence. These new data, combined with additional nuclear sequences, unambiguously place the specimen within the *P. pattoni* clade. Thus, the original identification of the specimen obtained by Y. L. R. Leite et al. (2007) is erroneous, leaving *P. unicolor* still known solely by the holotype (Loss and Leite 2011).

Genus *Santamartamys* Emmons, 2005

Louise H. Emmons and James L. Patton

Santamartamys are medium-sized (head and body length 190 mm, tail length 267 mm, hind foot length 40 mm, and ear length 12 mm), bright rust-red arboreal rats, with sides and legs paling to yellowish orange and gray underfur (Emmons and Feer 1997:243). The throat and chest are pale orange, the tip of the chin is white, and the venter is washed with orange. The coat is not stiff or bristly but instead has long, lax overhairs, 2.0–3.8 cm in length on the dorsum. Overhairs are so slender that they are difficult to distinguish from other pelage. Dense woolly pelage covers the legs to the ankles and wrists. A crest of long hair, bright red in color like the back, is present on the crown between the ears. The muzzle and sides of the head are tawny yellow-gray streaked with black. The vibrissae are fine and relatively short, extending to behind the ears. The longest genal and mystacial vibrissae are 5 cm; vibrissae are present on the wrist. The ears are short, almost naked, with thin tufts of long brown hair sprouting from the inner rim. Two pairs of lateral mammae are present on the abdominal edge of lateral pelage, in the ventral pelage field. The tail is longer than the head and body, robust, thickly haired with rusty fur for 2 cm at the base but abruptly changing to fine brown or black hair that covers the scales for three-fifths the length but with a terminal two-fifths pure white. Forefeet and hindfeet are brown above, washed with silver; both palmar and plantar surfaces lack tiny tubercles between pads; and the pollux has a nail. The unusual and

spectacular color and color pattern of a living animal were published in a press release announcing the rediscovery of this species after a 113-year lapsus (Conservation International 2011).

Maxillary cheek teeth are rectangular in shape, longer than wide; the teeth and toothrow are relatively long and bowed inward. Each upper tooth (PM4–M3) is split by a deep flexus into two parts; the anterior lophs have flexi opening labially and posterior lophs have flexi opening lingually. Protocones are broad, conferring a wishbone shape to joined anteroloph/protoloph pairs, especially on PM4. Lower molars are split by mesoflexid and hypoflexid into two parts, a curved and laminar anterolophid and a somewhat wishbone-shaped entoconid/posterolophid. The lower premolar is split by two flexids into a small, closed triangular anterior loph apparently lacking a fossette; a laminar metalophid, and a wishbone-shaped posterior loph opens lingually. Hypoflexids are strongly oblique; protoconids large and squarish. The lower incisors are strongly curved. The cranium is conspicuously curved in dorsal profile; the rostrum short and broad. Auditory bullae are small and flattened, merging with the alisphenoid at a shallow angle. The auditory meatus is small and placed high near the squamosal; the auditory tube is short and strongly directed anteriorly; the lateral process of the supraoccipital is extremely short. A bony bridge present between the foramen ovale and the masticatory foramen is exceptionally long; there seems to be a small oval vacuity below the presphenoid-basisphenoid suture. The condyloid process of mandible is deep; the angle of the sigmoid notch between angular and condyloid processes of mandible are shallow; and the mandibular foramen is set in a fossa beside the condyloid ridge. The masseteric crest of lower edge of mandible is poorly developed and shallow; the pterygoid shelf is small.

SYNONYM:

Isothrix: J. A. Allen, 1899b:197; description of *rufodorsalis*; not *Isothrix* Wagner.

Echimys: E.-L. Trouessart, 1904:504; part (listing of *rufodorsalis*); not *Echimys* F. Cuvier.

Diplomys: Tate, 1935:415; part (listing of *rufodorsalis*); not *Diplomys* Thomas.

Santamartamys Emmons, 2005:282; type species *Isothrix rufodorsalis* J. A. Allen, by original designation.

REMARKS: *Santamartamys* seems closely allied to members of the genus *Diplomys*, where until recently it had been placed. It shares with *Diplomys* a number of probable apomorphies as well as close geographic affinity. Emmons (2005) segregated it as a genus primarily because of its distinctive cheek tooth occlusal morphology, which is different from all other living echimyids. This taxon likewise has unique pelage, mammae placement, bullar, and

alisphenoid configurations. Emmons based her description above largely on AMNH 34392, a young female with little-worn dentition. The teeth of the holotype, AMNH 14606, are extremely worn. The genus is monotypic.

Santamartamys rufodorsalis (J. A. Allen, 1899)

Red-Crested Tree Rat

SYNONYMS:

Isothrix rufodorsalis J. A. Allen, 1899b:197; type locality “Onaca, Santa Marta District,” Magdalena, Colombia.

Echimys (Isothrix) rufodorsalis: E.-L. Trouessart, 1904:504; name combination.

Diplomys rufodorsalis: Tate, 1935:415; name combination.

Santamartamys rufodorsalis: Emmons, 2005; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION (from Emmons and Feer 1997:243): *Santamartamys rufodorsalis* is known only from the Sierra Nevada de Santa Marta, between 700 and 2,000m. Eisenberg (1989: map 13.73) mapped a locality (incorrectly as *Diplomys caniceps*) in the Sierra de Parijá without documentation, and O. J. Linares (1998) suggested that the species might range to this mountain area in Venezuela.

SELECTED LOCALITIES (Map 507): COLOMBIA: Magdalena, El Dorado Nature Reserve, Sierra Nevada de

Santa Marta (Conservation International 2011); Onaca (type locality of *Isothrix rufodorsalis* J. A. Allen).

SUBSPECIES: *Santamartamys rufodorsalis* is monotypic.

NATURAL HISTORY: Presumably a montane forest inhabitant, *S. rufodorsalis* is among the most rare and poorly known species of South American mammals (Emmons and Feer 1997).

REMARKS: The single species is apparently known from only three specimens in the American Museum of Natural History in New York (AMNH 14605, 14606, and 34392) and an unrecorded number of specimens in the collection of the Instituto de Investigación Alexander von Humboldt in Colombia (Alberico et al. 2000). A living individual found at the El Dorado Nature Reserve Eco-lodge in the Sierra Nevada de Santa Marta was recently observed and photographed (Conservation International 2011). Rodríguez-Mahecha et al. (1995) incorrectly identified *O. Bangs* as the author of the name.

Genus *Toromys* lack-Ximenes, de Vivo, and Percequillo, 2005

Louise H. Emmons, Yuri L. R. Leite, and James L. Patton

This is a genus of large arboreal rats with an average head and body length ranging from 237 (*T. rhipidurus*) to 307 (*T. grandis*) mm, tail length averaging 80–90% of the body, and short, rounded ears. The genus is diagnosed primarily by its well-haired tail, either fully furred (*T. grandis*), or with sparser hairs that decrease in density from base to tip (*T. rhipidurus*). The body is covered with stiff setiform and arisiform hairs that terminate in hair-like processes instead of sharp points (termed “stiff bristles” as opposed to spines by Emmons 2005). Forefeet and hindfeet have small tubercular rugosities between the plantar and palmar pads. The skull shares the same basic morphological plan of *Echimyus*, *Phyllomys*, and *Makalata*, although the nasals are constricted medially, the squamosotympanic fenestra is a narrow horizontal slit, the supraorbital ridge is expanded into a shelf, and the protoloph and metaloph of PM4–M3 are often connected by a slender mure. The mean maxillary tooththrow length (13–15 mm) is longer than those of any *Makalata* (modified to include *T. rhipidurus* from lack-Ximenes et al. 2005).

SYNONYMS:

Loncheres: Wagner, 1845a:145; part (description of *grandis*); not *Loncheres* Illiger.

Echimys: E.-L. Trouessart, 1904:504; part (listing of *grandis*); not *Echimys* F. Cuvier.

Makalata: Emmons and Feer, 1997:236; part (listing of *grandis* and *rhipidurus*); not *Makalata* Husson.

Toromys lack-Ximenes, de Vivo, and Percequillo, 2005a:91; type species *Loncheres grandis* Wagner, by original designation.

Map 507 Selected localities for *Santamartamys rufodorsalis* (●). Contour line = 2,000m.

REMARKS: The genus was considered monotypic when described, but Emmons (2005) included *Echimys rhipidurus* Thomas within a “*grandis* group” in her concept of *Makalata*, in which she also placed *Loncheres grandis* Wagner, the type species of *Toromys*. Provisionally, therefore, we include these two species within the genus *Toromys*, pending a more thorough review. *Toromys* appears as the sister to a clade comprising *Phyllomys*+*Diplomys* in the phylogenetic analysis of G. A. S. Carvalho and Salles (2004), although in the same larger clade as *Echimys chrysurus* (the type species of *Echimys*), *Makalata* spp., and *Isothrix*. Molecular analyses place *Toromys* (as represented by *T. grandis*) in a clade with *Phyllomys*, *Echimys*, and *Makalata* (Upham and Patterson 2012; Upham et al. 2013).

KEY TO THE SPECIES OF *TOROMYS*:

1. Overall color golden and black; tail black and well furred; size larger, head and body length >270 mm, skull length >60 mm; distributed in lower Amazon of Brazil *Toromys grandis*
- 1' Overall color blackish to reddish brown; tail dark brown or grayish, lightly furred; size smaller, head and body length <260 mm, skull length <59 mm; distributed in upper Amazon of Peru *Toromys rhipidurus*

Toromys grandis (Wagner, 1845)

Black Toro

SYNONYMS:

Loncheres grandis Wagner, 1845a:146; type locality “vom Amazonenstrom,” but according to the catalogue “Manaqueri im Mündungsbereich des Rio Solimões” (Pelzeln 1883; now Manaquiri, lower Rio Solimões, Amazonas, Brazil [Moojen 1952b; Paynter and Traylor 1991]).

Loncheres (Loncheres) grandis: E.-L. Trouessart, 1897:604; name combination.

Echimys (Echimys) grandis: E.-L. Trouessart, 1904:503; name combination.

Echimys grandis: Thomas, 1916e:295; name combination.

E[chimys]. grandis: Thomas, 1928d:410; name combination.

[*Echimys*] *grandis*: Tate, 1935:431; name combination.

Makalata grandis: Emmons and Feer, 1997:236; name combination.

Toromys grandis: Iack-Ximenes, de Vivo, and Percequillo, 2005a:91; first use of current name combination.

DESCRIPTION: Larger species in genus, mean head and body length 303 mm (range: 275–354 mm), tail length 285.1 (range: 244–361 mm), hind foot 52.8 mm (range: 40–65 mm), and ear length 19.5 (range: 15–25 mm; Iack-Ximenes et al. 2005a). Pelage coarse, harsh, with stiff bristles. Upper parts mixture of golden and black, head black sprinkled with gold; tail completely furred, terminating in

Map 508 Selected localities for *Toromys grandis* (●).

very short pencil 2–3 mm long. Craniodental features as for genus, except anterior part of jugal greatly expanded dorsoventrally (Iack-Ximenes et al. 2005a:Fig. 8).

DISTRIBUTION: Iack-Ximenes et al. (2005a) mapped the 16 known localities along both sides of the lower Rio Amazonas, from near its confluence with the Rio Negro to Ilha Caviana at its mouth.

SELECTED LOCALITIES (Map 508; from Iack-Ximenes et al. 2005a, except as noted): BRAZIL: Amazonas, Lago do Batista, Manaquiri (type locality of *Loncheres grandis* Wagner), Urucurituba; Pará, Fazenda Paraíso, Fazenda Recreio, Fazenda São Pedro, Igarapé Açú, Lago Cuit-eua, Santarém.

SUBSPECIES: *Toromys grandis* is monotypic.

NATURAL HISTORY: These are nocturnal, arboreal rats that nest in tree holes, typically near water, and only in lowland rainforest. They are likely restricted to floodplain forest (Emmons and Feer 1997; Iack-Ximenes et al. 2005a).

Toromys rhipidurus (Thomas, 1928)

Peruvian Toro

SYNONYMS:

Echimys rhipidurus Thomas, 1928c:291; type locality “Pebas, 300’,” Loreto, Peru.

Echimys armatus rhipidurus: Sanborn, 1949b:286; name combination.

Makalata rhipidurus: Emmons and Feer, 1997:239; name combination.

M[akalata]. rhipidura: Emmons, 2005:299; name combination.

DESCRIPTION: Smaller species in genus, mean head and body length 229.8 mm (range: 210–260; N=16), tail length 196.6 mm (range: 180–215 mm; N=14), hindfoot length 38.3 (range: 31–49 mm; N=15), ear length 14.1 mm (range: 11–17 mm; N=16), and mass 315 g (N=1). Upper parts reddish to yellowish brown, finely to heavily streaked with black hairs. Head and forequarters more grayish or yellowish; rump and tail base more rusty or reddish. Pelage slightly glossy, a combination of stiff, narrow bristles and flexible spines with tips drawn out into hair-like processes; sharp and flat spines are lacking on forequarters or sides of body. Rump sometimes lightly sprinkled with few white speckles from white-tipped spines, but generally spines lack pale tips seen in *Makalata* and *Pattonomys* spp. Base of whiskers dull rust red, but this color does not extend onto muzzle or between the eyes (as it does in *Makalata* spp.). Vibrissae coarse, numerous, black in color, and long, reaching to shoulder. Ears small, almost naked. Tail robust, about 70–95% of head and body length, furred like the back over the initial 3.5 cm with remainder covered to tip with short, glossy dark brown or grayish bristly hairs that do not quite hide scales, and extending as very short, 2–3 mm tuft beyond tip. From a distance, however, tail appears naked. Base of tail and rear of thighs dull to bright rust-red. Hindfeet short and broad, reddish above; forefeet small and gray above. Hairiness of tail decreases in specimens from north to south.

Skull differs from that of *T. grandis* in that wedge of petrosal separating auditory meatus from squamosal approximately twice as deep (character illustrated by Iack-Ximenes et al. 2005a:Fig. 7). Otherwise, craniodental features as described for genus.

DISTRIBUTION: *Toromys rhipidurus* is known only from northern Peru in the western Amazon Basin. Tirira (2007:227) extended the range of this species throughout eastern Ecuador, citing a personal communication with L. H. Emmons regarding a specimen seen years earlier in a collection in Quito (presumably the Museo de Ciencias Naturales de la Escuela Politécnica Nacional), a specimen now apparently lost.

SELECTED LOCALITIES (Map 509): PERU: Loreto, Nazareth FMNH 19854), Pebas (type locality of *Echimyus rhipidurus* Thomas), Puerto Indiana (AMNH 73277), Río Yavarí (FMNH 19854); Ucayali, Suayo (AMNH 98667), Yarinacocha (Sanborn 1949b).

SUBSPECIES: *Toromys rhipidurus* is monotypic.

NATURAL HISTORY: This species occurs in lowland rainforest, with most specimens apparently coming from riverine forests. Other aspects of its biology are unknown.

REMARKS: Emmons (2005) placed *T. rhipidurus* in her “*grandis* species-group” of *Makalata*, which is herein considered equivalent to *Toromys* Iack-Ximenes, de Vivo, and Percequillo. A sister relationship between *T. rhipidu-*

Map 509 Selected localities for *Toromys rhipidurus* (●). Contour line = 2,000 m.

rus and *T. grandis*, however, has yet to be established unambiguously. Emmons (2005:281, Fig. 12) also provided photographs of the dorsal, ventral, and lateral views of the skull and both medial and lateral view of the left mandible of the holotype (BM 20.7.1.20).

Subfamily Eumysopinae Rusconi, 1935

James L. Patton and Louise H. Emmons

The nine genera we place in this subfamily include four that are generalized terrestrial rats (elongated limbs, narrow and long hindfeet, short recurved claws on forefeet and hindfeet, tail nearly as long as head and body length; *Hoplomys*, *Proechimys*, *Thrichomys*, and *Trinomys*), three that exhibit semifossorial adaptations (short limbs, well-developed claws on the forefeet, short tail; *Carterodon*, *Clyomys*, and *Euryzygomatomys*), and two that are adapted for climbing (short and broad hindfeet with enlarged plantar pads and well-developed digits, elongated tail as long as or longer than head and body length; *Lonchothrix* and *Mesomys*). Despite the range of body form resulting for

these differences in lifestyle, all nine genera share a common tooth structure, with both upper and lower cheek teeth rounded in occlusal outline, as opposed to square or rectangular, and with narrow folds (flexi, flexids) that become isolated as enamel islands in adults but for which the lophs never develop into transverse plates. Two to four, rarely five, flexi are present on the labial side of the maxillary cheek teeth. The maxillary zygomatic process and the jugal are typically robust. The toothrows are short, usually less than 20% of the basilar length of the skull.

The extant eumysopines have long been considered as a natural unit (Ellerman 1940) and thus comprise a formal group in all recent classifications (the Eumysopinae [Woods 1993; Woods and Kilpatrick 2005] or Heteropsomyinae [McKenna and Bell 1997]; see Patton and Reig 1990 for reasons to regard Eumysopinae Rusconi as the appropriate subfamily name). Vucetich and Verzi (1991), however, questioned the implicit monophyly of the included genera, a view supported by molecular sequence analyses (Lara et al. 1996; Y. L. R. Leite and Patton 2002; Galewski et al. 2006; P.-H. Fabre et al. 2012) and the cladistic analysis of morphological characters (G. A. S. Carvalho and Salles 2004). Most of these studies found the various eumysopine genera to form a basal polytomy with the dactylomyine and echimyine genera varying nested within. Within this basal group the generic pairs of *Hoplomys*+*Proechimys*, *Mesomys*+*Lonchothrix*, and *Clyomys*+*Euryzygomatomys* are consistently recovered as sisters, even if little other phylogenetic structure is apparent. The most recent molecular analysis (P.-H. Fabre et al. 2012), however, placed the *Mesomys*+*Lonchothrix* clade among the other echimyine genera. As noted in the introduction to the family, full resolution of clades, their generic membership, and thus subfamilial grouping within the Echimyidae remain vexing problems.

KEY TO THE GENERA OF EUMYSOPINAE
(CRANIODENTAL CHARACTERS LARGELY FROM
G. A. S. CARVALHO AND SALLES 2004:463,
TABLE 2):

1. Hindfeet short and broad (width at base of digits >30% of length); pelage consisting of dense, flat, broad, and very stiff spines; skull with short, wide rostrum; interorbital region with parallel, broadly overhanging supraoccipital ledges. 2
- 1'. Hindfeet narrow and elongated (width <25% of length); pelage varying in expression of aristiform spines; skull with either short and broad or long and narrow rostrum; interorbital region concave with varying developed supraorbital ledges. 3
2. Dorsal spines longer (>25 mm) and wider (>1.8 mm); spines tipped pale yellow; tail with long terminal tuft, up to 45 mm in length; skull with more parallel-sided nasals and narrower mesopterygoid fossa that reaches to the middle of M2 *Lonchothrix*
- 2'. Dorsal spines shorter (<25 mm) and narrower (<1.5 mm); spines tipped orange; tail with short terminal tuft, <30 mm in length; skull with convergent-sided nasals and wider mesopterygoid fossa that reaches to M3 *Mesomys*
3. Forefeet and hindfeet with elongated, straight, and strong claws (modified for digging); tail short (<50% of head and body length); dorsal pelage stiff but with nonspinous aristiform hairs; rostrum short (<32% of skull length) and broad; premaxilla projects anterior to tip of nasals; interorbital region broad (>80% of rostral length); partial contact between ectotympanic and squamosal resulting in cleft (see G. A. S. Carvalho and Salles 2004:462, Fig. 17); sphenopalatine vacuities greatly enlarged 4
- 3'. Forefeet and hindfeet with short, slightly recurved claws (not modified for digging); dorsal pelage varying from soft to heavily spinose; rostrum elongated (>39% of skull length) and narrow; premaxilla and nasals subequal in anterior length; interorbital region narrower (<60% rostral length); mastoid portion of bullae uninflated; ectotympanic and squamosal in contact along entire margin; sphenopalatine vacuities present or absent 6
4. Anterior face of upper incisors smooth; protoloph of dPM4 to M3 restricted to labial margin of tooth. 5
- 4'. Anterior face of upper incisors grooved; protoloph of dPM4 to M3 absent *Carterodon*
5. Dorsal color yellowish to reddish; inferior zygomatic root not exposed ventrally; incisive foramina narrow and elongate; mesopterygoid fossa wide, extending to M3; both mastoid and tympanic portions of bullae inflated *Clyomys*
- 5'. Dorsal color yellowish brown to dark brown; inferior zygomatic root exposed ventrally; incisive foramina short and oval; both mastoid and tympanic portions of bullae not inflated. *Euryzygomatomys*
6. Fur soft, without developed aristiform hairs modified into bristles or spines; tail well haired and completely covering scales; anterior projection of premaxilla well developed; sphenopalatine vacuities greatly enlarged *Thrichomys*
- 6'. Fur coarse, with aristiform hairs modified into bristles or spines; tail typically sparsely haired with scales visible; anterior projection of premaxilla very well developed with dorsal portion a well-marked anteromesial expansion in the region of the nasal openings; sphenopalatine vacuities small or absent 7
7. Cheek teeth typically simplified with no more than two folds, with the main fold almost completely separating

- the protocone and protoloph and between hypolophid and hypoconid; labial portion of neolophid absent; no contact between metalophid and ectolophid. *Trinomys*
- 7'. Cheek teeth more complex, typically with a minimum of three folds and sometimes with four or five, with main fold not deeply dividing protocone and protoloph and between hypolophid and hypoconid; labial portion of neolophid present or absent; contact between metalophid and ectolophid present 8
8. Dorsal pelage comprised predominantly of aristiform hairs modified into long, broad, flat, and stiff spines that extend onto the flanks; maxillary cheek teeth complex with four folds on each tooth; only lingual portion of neolophid present so that neolophid of mandibular teeth does not contact metalophid and thus does not form crest C (of G. A. S. Carvalho and Salles 2004) *Hoplomys*
- 8'. Dorsal pelage composed of both setiform and aristiform hairs, with the latter ranging in development as spines from weak bristles to stiff and broad, but when the latter, never extending onto the flanks; maxillary cheek teeth complex but varying greatly in number of folds, typically with three but occasionally four or only two; neolophid of mandibular cheek teeth uniformly in contact with metalophid forming crest C (see G. A. S. Carvalho and Salles 2004) *Proechimys*

Genus *Carterodon* Waterhouse, 1848

Alexandra M. R. Bezerra and Cibeles R. Bonvicino

The genus *Carterodon* contains the single species *C. sulcidens* (Lund, 1838), which occurs only in the tropical savanna and grassland habitats of the Cerrado biome in central Brazil, at elevations between 250 and 1,100m (Eisenberg and Redford 1999; Carmignotto 2005; Bezerra, Marinho-Filho, and Carmignotto 2011). This is a rare, medium-sized, semi-fossorial rodent (head and body length 135–250mm and mass 92–195g; Bezerra, Marinho-Filho, and Carmignotto 2011), with dense and soft hairs (setiforms) intermixed with soft spines (aristiforms), short limbs with long and powerful claws, short ears, and a short tail (less than half of head and body length) densely covered with short and unbanded hair partially covering the scales. The overall pelage color is predominantly brownish and grizzled, with black aristiforms on the dorsal surface, pale brown hairs on the gular and abdominal surfaces, and without a defined lateral line (Moojen 1952b; Bishop 1974).

The phallus of *Carterodon* has not been described.

The following craniodental descriptions are largely from G. A. S. Carvalho and Salles (2004). *Carterodon*

has conspicuous, grooved upper incisors (Bishop 1974), unique among the extant echimyids. The occlusal surface of the upper molariform teeth is nearly on a plane parallel to palate. Maxillary cheek teeth are unilateral hypsodont with three roots, one lingual root and two labial roots (G. A. S. Carvalho 1999). Both upper and lower premolar and molar surfaces are semicircular. On the upper toothrow, M2 is the largest tooth, M1 of intermediate size, and both dPM4 and M3 smallest and approximately equal in size. Molariform teeth have three transversal lophs, an anteroloph, a metaloph, and a posteroloph. A protoloph is lacking on all four maxillary teeth, and the metaloph is only partially inclined as a mure with the metaflexus more persistent with tooth wear. The hypoflexus is oriented anterolabially. Mandibular molars also have three distinctive transversal lophs, an anterolophid, hypolophid, and posterolophid. A fourth lophid continuous to lingual end of anterolophid may be visible on unworn lower teeth. The central portion of neolophid does not contact other crown structures in the dPM4. In the few available specimens, G. A. S. Carvalho (1999) observed that the hypolophid was not in contact with hypoconid. Two flexids, the mesoflexid and metaflexid, open lingually in the unworn condition.

The cranium is broad and the rostrum short and wide. An anterior projection of the premaxillary bone is well developed. The inferior zygomatic root is short and ventrally exposed in relation to the ventral surface of rostrum, and positioned at the same level as the palatal region. The auditory meatus is medium sized, with partial contact between the ectotympanic and squamosal, restricted to posterior portion of the dorsal margin of ectotympanic, and forming a cleft between these two bones. Incisive foramina are short and broadly oval in shape; palatine foramina are reduced in size or absent. Both the sphenopalatine foramen and sphenopalatine vacuities are well developed.

SYNONYMS:

Echimys: Lund, 1838:49; part (description of *sulcidens*); not *Echimys* F. Cuvier.

Nelomys: Lund, 1839a:227; part (listing of *sulcidens*); not *Nelomys* Jourdan.

Aulacodus: Lund, 1840c:315; part (*Aulacodus temminckii* Lund as a renaming of *Echimys sulcidens* Lund).

Carterodon Waterhouse, 1848:351; part; type species *Echimys sulcidens* Lund, by original designation and monotypy.

REMARKS: Several authors (Woods 1993; G. A. S. Carvalho and Salles 2004; Galewski et al. 2005) argued that the three genera *Carterodon*, *Clyomys*, and *Euryzygomatomys* formed a monophyletic group. However, Vucetich and Verzi (1991) suggested that *Carterodon* belonged to a different group, a hypothesis supported by unpublished molecular sequence data (C. R. Bonvicino, A. M. R. Bezerra and colleagues).

Carterodon sulcidens (Lund, 1838)

Groove-toothed Spiny Rat

SYNONYMS:

Echimys sulcidens Lund, 1838:49: type locality initially given as “bassin du Rio das Velhas” (Lund 1839a:231–234) and subsequently “Rio das Velhas Floddal” (Lund 1841a:133), Lagoa Santa, Minas Gerais, Brazil.

N[elomys]. sulcidens: Lund, 1839a:227; name combination.

Aulacodus Temminckii Lund, 1840:315; renaming of *sulcidens* Lund.

Carterodon sulcidens: Waterhouse, 1848:351; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Carterodon sulcidens* is known only for the Cerrado domain of central and western Brazil (Eisenberg and Redford 1999; Carmignotto 2005; Woods and Kilpatrick 2005).

SELECTED LOCALITIES (Map 510): BRAZIL: Distrito Federal, Brasília (G. A. S. Carvalho 1999); Goiás, UHE Serra da Mesa, Minaçu (G. A. S. Carvalho 1999), Parque Estadual da Serra de Caldas Novas, Caldas Novas (Bezerra, Marinho-Filho, and Carmignotto 2011); Mato Grosso, APH Manso, Chapada dos Guimarães (Bezerra, Marinho-Filho, and Carmignotto 2011), Caiê-Malu, Chapada do Parecis (Carmignotto 2005), Campos Novos, Serra do Norte, Chapada do Parecis (Miranda-Ribeiro 1914), Estação Ecológica Serra das Araras, Porto Estrela (Carmignotto 2005), Serra do Roncador, 264 km north of Xavantina, Ribeirão Cascalheira (Bishop 1974; municipality inferred from geographical coordinates in Bishop 1974); Mato Grosso do Sul, “Pedra am Rio Pardo,” Pedras Bataguassu (Bezerra, Marinho-Filho, and Carmignotto 2011; locality and municipality inferred from map and text in Krieg 1948); Minas Gerais, Fazenda Lapa Vermelha, Pedro Leopoldo (Carmignotto 2005), Rio das Velhas Floddal, Lagoa Santa (type locality of *Echimys sulcidens* Lund; see also Reinhardt 1851; Winge 1887; Lund 1950), Parque Nacional Grande Sertão Veredas (Carmignotto 2005).

SUBSPECIES: *Carterodon sulcidens* is monotypic.

NATURAL HISTORY: Few ecological, behavioral, or life history data are available for *Carterodon*. Lund’s original specimens were subfossil fragments obtained from cave deposits. The first recent specimens were collected by Reinhardt (1851) and came from “the open Pampas,” and all subsequent specimens have been collected in open areas of the Cerrado biome. This savanna environment encompasses a wide structural complexity of habitats (Eiten 1972). Bishop (1974) reported specimens captured in “campo” but did not specify the type. Moojen (1952b) reported that the German naturalist H. Burmeister found *Carterodon* specimens at Lagoa Santa in grass nests 30 cm deep within burrows. This species is preyed upon by the

Barn Owl (*Tyto alba*; Moojen 1952b; data on label of museum specimens). Based on surveys in southeastern Mato Grosso do Sul, Krieg (1948) reported *Carterodon* within Cerrado vegetation types such as grass, shrubs, and *ceradão* (a forest savanna dominated by trees above ca. 8 m in height), although he did not record actual localities where the species was taken. Bishop (1974) captured two pregnant females in the Serra do Roncador, one in August with a single fetus weighing 16 g and another in December with two embryos weighing 12 g each. Bishop (1974) also collected juveniles in both the dry (August and October) and wet seasons (November and December).

REMARKS: The publication date of Lund’s *Echimys sulcidens* is usually given as 1841 (e.g., Cabrera 1961, as p. 99; Woods and Kilpatrick 2005, as p. 49). However, while the name was discussed by Lund in several papers dealing with his Lagoa Santa collection, he described this species in 1838, on page 49, where he wrote “ved en Fure paa den forreste Flade af dens Skaeretaender, hvorfor jeg foreslaaer for den Navnet *Echimys sulcidens*” (approximate translation, “by a furrow on the anterior surface of the incisor, which is why I suggested the name *Echimys sulcidens*”) (see also Paula Couto 1950:123, 549). Lund’s description of the grooved incisors, unique among echimyid genera, clearly both diagnosed his new species and gave the foundation for Waterhouse’s (1848) later establishment of the genus-group name *Carterodon*, with *Echimys sulcidens* Lund as the type species. Subsequent to 1838, Lund (1841a) continued to regard *sulcidens* as a species of *Echimys* F. Cuvier, transferred it to *Nelomys* Jourdan (Lund

Map 510 Selected localities for *Carterodon sulcidens* (●).

1839a, 1841b), or renamed it *Aulacodus temminckii* (Lund 1840c, 1842).

This species has been encountered rarely, with only 32 completely intact specimens known in museum collections. One of these is in the FMNH; three are at the UNB; four are in the MZUSP; seven are in the MNRJ; five are at the ZMUC; and 12 in the BM. Salles et al. (1999) recorded additional subfossil remains from Quaternary deposits in the Igrejinha cavern in the Serra do Mesa region of Goiás state. The karyotype of *C. sulcidens* is unknown.

Genus *Clyomys* Thomas, 1916

Alexandra M. R. Bezerra and Cibele R. Bonvicino

The genus *Clyomys* contains a single species, *C. laticeps* (Thomas 1909), which occurs in tropical savanna and grassland habitat in Brazil and Paraguay, over an elevational range from about 100–1,100 m. This is a medium-sized, semifossorial rodent (head and body length 150–295 mm and mass 158–334 g; Bezerra 2002), with coarse and spinous fur, short limbs, long and powerful claws, and a short tail (less than the half of head-body size) sparsely covered with short and unbanded hair, partially covering scales, and short ears (Thomas 1909; Bishop 1974). General pelage color varies from grizzled rufous and black to grizzled yellow and black on the dorsal surface, and whitish or buffy, with or without the presence of grayish or pale rufous patches, on the gular and ventral surface; the sides are colored as the back (Thomas 1909; Moojen 1952a; Bishop 1974; Bezerra 2002).

Bezerra (2002) described the phallus of *Clyomys* as subcylindrical, elongated, and straight. Some specimens show a slight median constriction on the sides and/or an extension in the region of the intromittent sac. There are longitudinal grooves on sides of the glans, with simple, small spines uniformly covering the epidermis and extending into the intromittent sac. The dorsal side of the glans is longer than ventral side and distally is convergent on the apical mount, the lappet of which does extend only slightly from the crater. The baculum is simple, long, and narrow; in lateral view it is slightly concave at its proximal end.

G. A. S. Carvalho and Salles (2004) provided a thorough description of craniodental characters. *Clyomys* has robust incisors, unilateral hypsodont teeth with three roots, with the occlusal surface of the maxillary teeth nearly on a plane parallel to the palate, very similar to *Euryzygomatomys* (G. A. S. Carvalho 1999). Upper molariform teeth have one large lingual root and two almost inconspicuous labial roots. The surface of both upper and lower premolars and molars is semicircular in shape. M3 of the upper tooththrow is reduced in size, with dPM4 and M1 only slightly smaller

than M2; with enamel wear, M1 becomes the largest tooth in tooththrow. Maxillary cheek teeth have three transverse lophs, the anteroloph, metaloph, and posteroloph. Unworn teeth may exhibit a small protoloph restricted to the labial margin. The metaloph is oriented posterolabially from the mure, narrowing and enclosing the metaflexus. A mesoflexus becomes more persistent with tooth wear. The hypoflexus is anterolabially oriented. Worn dPM4–M2 teeth show two round labial fossettes derived from the metaflexus and mesoflexus and a round lingual fossette derived from the hypoflexus (see also Bezerra 2002). Mandibular molars have three distinctive transverse lophs, the anterolophid, hypolophid, and posterolophid. Unworn teeth may show another lophid continuous to the lingual end of the anterolophid. The hypolophid is always in contact with the hypoconid and ectolophid, and is directed posterolingually as is the hypoflexid. The mesoflexid and metaflexid open lingually when unworn. The lower m1 may show a round labial fossette derived from the hypoflexid with increasing wear.

The cranium is broad, the rostrum short and wide. The mesopterygoid fossa extends to the hypoflexus of M2 but not beyond (Bezerra 2002). The anterior projection of the premaxillary bone is short. Similarly, a short inferior zygomatic root is present at the same level in relation to the ventral surface of the rostrum and palatal region. Tympanic bullae are hypertrophied, being highly visible beyond the paraoccipital process when viewed from behind (Thomas 1916e). The auditory meatus is medium sized, with partial contact between the ectotympanic and squamosal restricted to the posterior portion of the dorsal margin of ectotympanic, forming a cleft between these two bones. The incisive foramina are narrow and elongate (Thomas 1909). Both the sphenopalatine foramen and sphenopalatine vacuities are well developed. A well-developed canal of the infraorbital nerve is present on the floor of the infraorbital foramen.

SYNONYMS:

Loncheres: Lund, 1839a:233; part (description of *laticeps* Lund, a *nomen nudum*); not *Loncheres* Illiger.

Mesomys: Winge, 1887:923; part (listing of *laticeps* Lund, a *nomen nudum*, as a synonym of *Mesomys spinosus* Desmarest).

Echimys: Thomas, 1909:240; part (description of *laticeps*); not *Echimys* F. Cuvier.

Clyomys Thomas, 1916e:300; type species *Echimys laticeps* (Thomas), by original designation.

REMARKS: The initial use of the name *laticeps* was by Lund (1839a), who simply included it in a list of species of *Loncheres* without a formal description. Winge (1887) wrongly placed Lund's *Loncheres laticeps* as a junior synonym of *Mesomys spinosus* Desmarest (= *Euryzygomatomys*

spinosus). Thomas (1909) recognized that Lund's *laticeps* was a *nomen nudum* and formally described *laticeps* under *Echimys*. Later, Thomas (1916e) described *Clyomys* with *Echimys laticeps* as the type species. Reig (1986:409, footnote *f*) regarded *Clyomys* to be inseparable from, and thus should be placed within, *Euryzygomatomys*. Morphological and molecular phylogenetic analyses indicate a very close sister relationship between these two taxa (Y. L. R. Leite and Patton, 2002; G. A. S. Carvalho and Salles 2004; Galewski et al. 2005; P.-H. Fabre et al. 2012). Fossils of the genus, assigned to the extinct species *C. riograndensis*, are known from Mid to Late Holocene (9,400–3,730 ybp) deposits in Rio Grande do Sul state, Brazil (Hadler et al. 2008).

Clyomys laticeps (Thomas, 1909)

Broad-headed Spiny Rat

Mesomys spinosus: Winge: 1887:92; name combination; not *spinosus* Desmarest.

Echimys laticeps Thomas, 1909:240; redescription of *Loncheres laticeps* Lund; type locality given initially on page 241 as "Lagoa Santa, Minas Geraes" and subsequently, on the same page, as "Lagoa Santa, on the Rio São Francisco, Minas Gerais," Brazil.

Clyomys laticeps: Thomas, 1916e:300; name combination.

Clyomys laticeps whartoni Moojen, 1952a:102; type locality "1 km north of Aca-Poi, long. 56°7'W., lat. 23°5'S., Department of San Pedro, Partido de Tacuatí, Paraguay; approximately 60 km east-northeast of Puerto Ybapobo and 10 km south of the Rio Ypané."

Clyomys bishopi Avila-Pires and Wutke, 1981:529; type locality "Itapetininga, São Paulo, Brasil."

DESCRIPTION: As for the genus.

DISTRIBUTION: *Clyomys laticeps* is known from the Cerrado domain of central Brazil, extending south to São Paulo state (Bishop 1974; Avila-Pires and Wutke 1981), and the Chaco of Paraguay (Moojen 1952a).

SELECTED LOCALITIES (Map 511): BRAZIL: Bahia, Fazenda Jatobá (Bezerra 2002); Distrito Federal, Parque Nacional de Brasília (Svartman 1989), Reserva Biológica de Águas Emendadas (Bezerra 2002); Goiás, Santa Rita do Araguaia, Assentamento Babilônia (Bezerra 2002); Mato Grosso, Ribeirão Cascalheira (Bishop 1974); Mato Grosso do Sul, Corumbá, Fazenda Alegria, Corumbá (Bezerra 2002), Bonito, Fazenda Bonito (Bezerra 2002); Minas Gerais, São Roque de Minas, Fazenda Chico Cera (Bezerra 2002), Lagoa Santa (type locality of *Echimys laticeps* Thomas), São Paulo, Campininha (Bezerra 2002); São Paulo, Itapetininga (type locality of *Clyomys bishopi* Avila-Pires and Wutke). PARAGUAY: San Pedro, 1 km N of Aca-Poi (type local-

ity of *Clyomys laticeps whartoni* Moojen); Canindeyú, Reserva Natural del Bosque Mbaracayú (Bezerra 2002); Concepción, 28 km S junction Rte 3 and Rte 5 on Rte 3 (MVZ 145318).

SUBSPECIES: We treat *Clyomys laticeps* as monotypic. Moojen (1952a) described *C. laticeps whartoni* based on two specimens collected in the Paraguayan Chaco, which he distinguished by the presence of grayish patches on the ventral surface, larger tympanic bullae, and a shorter palate. Bishop (1974) observed that only the shorter palate was a good character separating *whartoni* from the nominate subspecies. A multivariate analysis of craniodental measurements and qualitative data from both baculum and skull, however, did not corroborate the Paraguayan population as a different taxonomic unit (Bezerra, 2002; Bezerra and Oliveira 2010).

NATURAL HISTORY: All specimens have been collected in open areas of the Cerrado biome, a savanna environment that encompasses a wide structural complexity of habitats, including unflooded grassland and shrubby vegetation with ground cover of grasses, and areas of the Paraguayan Chaco, a somewhat drier western extension of the Cerrado (Moojen 1952a; Bishop 1974; Avila-Pires and Wutke 1981; Lacher and Alho 1989; M. V. Vieira 1989, 1997). Burrows can often be easily located due to semifossorial habits of this species (Lacher and Alho 1989; Amante 1975; C. T. Carvalho and Bueno 1975; A. M. R. Bezerra, unpubl. data). A. Bueno et al. (2004) verified the strong relationship between the burrows of armadillos and the presence of *Clyomys* in São Paulo state. Individuals are also dominant predators and dispersers of seeds of the palms *Attalea geraensis* and *Syagrus petraea* (L. B. de Almeida and Galetti 2007). Breeding may be seasonal. A pregnant female was captured at Itirapina, São Paulo state, at end of the dry period, and weaning and growth was completed during wet season (M. V. Vieira 1997). Bishop (1974) captured pregnant females in Mato Grosso state June, September (both dry season), and December (wet season), respectively, all with a single embryo. Juveniles were taken in December (two specimens) and April (one).

REMARKS: For the taxonomic history of this taxon, see Tate (1935:406) and the comments under Remarks for the genus. Bezerra (2002) revised the genus, placing *Clyomys bishopi* Avila-Pires and Wutke (1981) in the synonymy of *C. laticeps*, a decision supported by morphometric and qualitative analyses of cranial variables (Bezerra and Oliveira 2010). Woods and Kilpatrick (2005), however, maintained a concept of the genus *Clyomys* with two species, *C. laticeps* and *C. bishopi*. The comprehensive reviews of Cabrera (1961) and Woods and Kilpatrick (2005) continued Tate's (1935:406) incorrect listing of the type

locality as “Joinville, Santa Catherina, Brazil” while other authors (Bishop 1974; Avila-Pires and Wukte 1981) called attention to this mistake. Thomas (1909:241), in his original description of *Echimyys laticeps*, was unambiguous in listing the type locality as “Lagoa Santa, Minas Geraes.” We suspect that the recent literature confusion stemming from Tate (1935) arose because Thomas (1909) compared the holotype of *C. laticeps* with specimens of *Echimyys spinosus* (= *Euryzygomatomys spinosus*) from Paraguay and Joinville (Bezerra and Oliveira 2010).

The karyotype of *C. laticeps* is variable, with five separate chromosomal complements described to date. Yonenaga (1975) and M. J. Souza and Yonenaga-Yassuda (1984) described two karyotypes in specimens from São Paulo state: $2n=34$, FN=58 with 13 pairs of biarmed pairs and three pairs of acrocentric autosomes (Pagnozzi, Fagundes et al. 2000), and $2n=34$, FN=60, with 14 pairs of biarmed pairs and two pairs of acrocentric autosomes. Svartman (1989) recorded a karyotype of $2n=34$ and FN=62 with 14 metacentric/submetacentric pairs, one subtelocentric pair and one pair of acrocentric autosomes in specimens from the Distrito Federal. Specimens from Corumbá, Mato Grosso do Sul state, have a $2n=34$ and FN=58 karyotype with 13 biarmed pairs and three pairs of acrocentric autosomes (C. R. Bonvicino, unpubl. data). Finally, specimens from the Parque Nacional das Emas, Goiás state, had $2n=32$ and FN=54 with one submetacentric, 11 metacentric, and three acrocentric autosome pairs (Pagnozzi et al. 2000). It remains to be determined if

these karyological differences signal species boundaries or merely represent intraspecific polymorphism.

Genus *Euryzygomatomys* Goeldi, 1901

Cibele R. Bonvicino and Alexandra M. R. Bezerra

The genus *Euryzygomatomys* contains the single species *E. spinosus* (G. Fischer, 1814), occurring in forested habitats of southwestern Brazil, northeastern Argentina, and southern Paraguay. This is a medium sized, semifossorial rodent (head and body length 163–205 mm and mass 180–210 g), characterized by a short tail (less than half of head and body length) sparsely covered with short and unbanded hair, coarse and spinous fur, short limbs, long and powerful claws, and short ears. The dorsal pelage coloration varies from yellow-brown to dark brown, with black guard hairs; the sides are lighter in color; and the venter varies from white to slightly yellowish, except for a more ferruginous throat. The dorsal surfaces of both forefeet and hindfeet are dark brown, and the digits are paler. Manual claws are more developed than those of pes (Thomas 1909; 1916e; Moojen 1952b). Three pairs of mammae are present, one pectoral and two inguinal (J. A. Oliveira and Bonvicino 2006). The phallus of *Euryzygomatomys* has not been described.

Craniodental characters described here are taken from G. A. S. Carvalho and Salles (2004), unless otherwise indicated. *Euryzygomatomys* has large and heavy incisors (Thomas 1909), unilateral hypsodont teeth with three roots, with the occlusal surface of the maxillary teeth nearly on a plane parallel to that of the palate, very similar to the condition in *Clyomys* (G. A. S. Carvalho 1999). Upper cheek teeth have one large lingual root and two almost inconspicuous labial ones. All upper and lower cheek teeth are semi-circular in outline. In the upper toothrow, M3 is slightly reduced in size relative to the other teeth, with dPM4–M1 almost the same size and M2 only slightly smaller. With increasing wear M1 becomes the largest tooth in toothrow. All upper cheek teeth possess three transverse lophs, an anteroloph, metaloph, and posteroloph. A small protoloph restricted to the labial tooth margin may be present in unworn teeth. The metaloph is oriented posterolabially from the mure, narrowing and closing the metaflexus. The mesoflexus persists even with increasing tooth wear. The hypoflexus is oriented anterolabially. Worn dPM4–M2 typically have two round labial fossettes derived from metaflexus and mesoflexus and a round lingual fossette derived from the hypoflexus. The mandibular cheek teeth also have three distinctive transversal lophs, an anterolophid, hypolophid, and posterolophid. Unworn teeth may exhibit another lophid continuous with lingual end of anterolophid. The

Map 511: Selected localities for *Clyomys laticeps* (●).

hypolophid is always in contact with the hypoconid and ectolophid, and both it and the hypoflexid are posterolingually oriented. The mesoflexid and metaflexid are deep and open lingually in unworn teeth. The hypoflexid is always internally elongated in the lower m1 when worn.

The cranium is broad and the rostrum is short and wide. The mesopterygoid fossa extends to the hypoflexus of M2 (Thomas 1909, referred to as posterior palatal notch). The anterior projection of premaxillary bone is truncated. A short inferior zygomatic root is exposed ventrally in relation to ventral surface of rostrum, and at same level of palatal region. The auditory meatus is medium sized, with partial contact between the ectotympanic and squamosal restricted to the posterior portion of dorsal margin of the ectotympanic and thus forming a cleft between these two bones. The incisive foramina are short and oval (Thomas 1909). Sphenopalatine vacuities with well-developed openings are present as is a groove on the floor of the infraorbital foramen that houses the infraorbital nerve.

SYNONYMS:

Rattus: G. Fischer, 1814:105; part (description of *spinosus*, based on Azara's [1801:73] "*rat épineux*"); not *Rattus* Fischer.

Loncheres: Illiger, 1815:108; part (listing of *?brachyura*, a *nomen nudum*); not *Loncheres* Illiger.

Echimys: Desmarest, 1817b:57; part (description of *spinosus*, based on Azara's [1801:73] "*rat épineux*"); not *Echimys* F. Cuvier.

Loncheris: Olfers, 1818:212; part (description of *brachyura*, based on Azara's [1801:73] "*rat épineux*"); incorrect subsequent spelling of, but not *Loncheres* Illiger.

Ratton Brants, 1827:186; part (description of *espinoso*, based on Azara's [1802:76] "*el espinoso*"); suppressed for the purpose of Principle of Priority [but not Homonymy] by the International Commission [ICZN 1982:Opinion 1232]).

Hypudaeus: Brandt, 1835:432; part (description of *guiara*); not *Hypudaeus* Illiger.

Echinomys Wagner, 1840:199; part (listing of *spinosus*); unjustified emendation of *Echimys* F. Cuvier.

Mesomys: Burmeister, 1854:205; part (listing of *spinosus*); not *Mesomys* Wagner.

Euryzygomatomys Goeldi, 1901:179; type species *Echimys spinosus* Rengger (= *Rattus spinosus* G. Fischer), by original designation.

REMARKS: Tate (1935:402–405) thoroughly summarized the nomenclatural history of this genus, but he was wrong in stating that *spinosus* was based on Desmarest (1817b) rather than G. Fischer (1814). Both authors provided a name for Azara's (1801:73) "*rat épineux*," although because Fischer did so three years earlier his name has priority. Tate, however, failed to list *Ratton* Brants,

and *Ratton espinoso*, one of the species Brants included within his genus and which he based on "*el espinoso*" from the Spanish edition of Azara's book (1802:76), and the same animal as the "*rat épineux*" from the French version (Azara 1801). The International Commission (ICZN 1982:Opinion 1232) suppressed *Ratton* Brants for the purpose of the Principle of Priority, following petitions by Langguth (1966, 1978). Goeldi (1901) regarded *Echimys spinosus* Rengger as the type species of his new genus *Euryzygomatomys*. Likewise, however, Rengger's name is a junior synonym of *Rattus spinosus* G. Fischer. Reig (1986:409, footnote *f*) argued that *Clyomys* and *Euryzygomatomys* were inseparable and should be placed in the same genus. Morphologic and molecular phylogenetic studies based on nuclear and mitochondrial strongly support a sister relationship between *Euryzygomatomys* and *Clyomys* (Y. L. R. Leite and Patton 2002; G. A. S. Carvalho and Salles 2004; Galewski et al. 2005). Fossils of the genus (assigned to an extinct species, *E. mordax*) are known from Mid to Late Holocene deposits in Rio Grande do Sul state, Brazil (Hadler et al. 2008).

Euryzygomatomys spinosus (G. Fischer, 1814)

Guiara (Brazil), *Rata guira* or *Ratón espinoso* (Paraguay)

SYNONYMS:

Rattus spinosus G. Fischer, 1814:105; type locality "peuplade d'Atira, un peu plus de huit lieues (44 kilomètres), a l'Orient de l'Assomption," = Atyrá, 44 km E of Asunción, Cordillera, Paraguay; based on Azara's (1801:73) "*rat épineux*."

Loncheres ?brachyura Illiger, 1815:108; *nomen nudum* (Tate 1935:403).

Echimys spinosus Desmarest, 1817b:57; also based on Azara's "*rat épineux*."

L[oncheris]. (*sic*) *brachyura* Olfers, 1818:212; type locality "Paraguay"; also based on Azara's "*rat épineux*."

L[oncheres]. *rufa* Lichtenstein, 1820:192; also based on Azara's "*rat épineux*."

Ratton espinoso Brants, 1827:186: based on of Azara's (1802:76) "*el espinoso*"; ruled by the International Commission (ICZN 1982:Opinion 1232) to be a vernacular name and unavailable for use in zoological nomenclature.

Hypudaeus Guiara Brandt, 1835:432; type locality "Ypanema Provinciae St. Pauli Brasiliae" [= Floresta Nacional de Ipanema, 20 km NW Sorocaba, São Paulo, Brazil, 23°26'7"S 47°37'41"W, 701 m; L. P. Costa et al. 2003].

[*Echinomys*] *spinosus*: Wagner, 1840:199; name combination.

Echinomys brachyurus Wagner, 1843a:346; not *brachyura* Illiger nor *brachyura* Olfers; also based on Azara's [1802:76] "*el espinoso*."

Mesomys spinosus: Burmeister, 1854:205; part (listing of *spinus* Desmarest and *brachyurus* Wagner).

Euryzygomatomys spinosus: Thomas, 1916e:301; first use of current name combination.

Euryzygomatomys catellus Thomas, 1916e:301; type locality "Joinville, Santa Catarina, Brazil."

Euryzygomatomys guiara: Tate, 1935:405; name combination.

Euryzygomatomys spinosus spinosus: Ellerman, 1940:125; name combination.

Euryzygomatomys spinosus catellus: Ellerman, 1940:125; name combination.

Euryzygomatomys spinosus guiara: Cabrera, 1961:532; name combination.

SUBSPECIES: As currently construed, *Euryzygomatomys spinosus* is monotypic.

DISTRIBUTION: *Euryzygomatomys spinosus* occurs in southern Brazil, from the states of Espírito Santo, Rio de Janeiro, and Minas Gerais to Rio Grande do Sul, southern Paraguay, in La Cordillera and Guaira departments, and northeastern Argentina, in Misiones province. Cabrera (1961) also reported this species to northern Corrientes, Argentina, but without documentation. Santos-Filho, Friero-Costa et al. (2012) reported this species in an area within the Cerrado at the Serra das Araras Ecological Station, Porto Estrela, Mato Grosso state, Brazil (specimens misidentified as *Carterodon sulcidens*, with correction made by A. M. R. Bezerra from photos of an adult skull sent by M. Santos-Filho and confirmed by M. N. F. da Silva by examination of the skulls of vouchers at INPA).

SELECTED LOCALITIES (Map 512): **ARGENTINA:** Misiones, Posadas, Estancia Santa Inés (Massoia 1990; Pardiñas et al. 2005). **BRAZIL:** Espírito Santo, Viana, Coacac (I. S. Pinto, Loss et al. 2009); Minas Gerais, Caratinga (G. A. S. Carvalho 1999), Conceição do Mato Dentro (G. A. S. Carvalho 1999), Passos (G. A. S. Carvalho 1999); Rio Grande do Sul, Cambará do Sul (G. L. Gonçalves et al. 2007), Tapes (M. A. F. Andrade and Christoff 2001); Rio de Janeiro, Caxias (Moojen 1952b), Nova Friburgo (MNRJ [LBCE 5195]), Sumidouro (MNRJ [LBCE 73]); Santa Catarina, Itapiranga (Cherem, Simões-Lopes et al. 2004), Joinville (type locality of *Euryzygomatomys catellus* Thomas), Santo Amaro da Imperatriz (Cherem, Simões-Lopes et al. 2004); São Paulo, Casa Grande (Yonenaga 1975), Ipanema (type locality of *Hypudaeus guiara* Brandt). **PARAGUAY:** Guaira, Villarica (AMNH 66785); Cordillera, Atyrá (type locality of *Rattus spinosus* G. Fischer).

NATURAL HISTORY: *Euryzygomatomys spinosus* is a semifossorial species with features apparently related to burrowing habits, like short ears, short tail, and long foreclaws (Eisenberg and Redford 1999). This species is an herbivore that is active at night (Mares and Ojeda 1982), and

harmful to *Pinus* plantations (G. L. Gonçalves et al. 2007). Although primarily found under the riparian vegetation in dense forests, it is apparently a habitat generalist (Mares and Ojeda 1982). In Brazil, individuals occur in both altered and conserved vegetation communities (Bonvicino, Lindbergh, and Maroja 2002). Stallings (1988, 1989) found this species in wet meadows in Minas Gerais state. Pardiñas, Teta, and Heinonen Fortabat (2005) recorded the species in natural grasslands in Misiones, Argentina. Captured females contained one or two embryos (Davis 1947); a female had three embryos in November (Moojen 1952b). This rodent can be naturally infected by the tick *Amblyomma* (Barros-Battesti and Knysak 1999) and lice of the genera *Gliricola* and *Gyropus* (Cardosode Almeida et al. 2003; Valin and Linardi 2008), as well the Boraceia virus, a member of the *Anopheles* B arbovirus group (O. S. Lopes and Sacchetta 1974). M. Robles, Galliari, and Navone (2012) described nematode parasites from specimens collected in Misiones province, Argentina. Also in Argentina, this species is prey of the Barn Owl (*Tyto alba*; Massoia 1990).

REMARKS: Woods and Kilpatrick (2005:1582) suggested that, should G. Fischer (1814) become unavailable by future action of the International Commission on Zoological Nomenclature, *rufa* Lichtenstein (1820) would be the next available name for this species. However, these authors overlooked Desmarest's (1817b) *Echimyus spinosus* and Olfers's (1818) *Loncheris* [sic] *brachyura*, both of which are valid and predate Lichtenstein. Consequently, if G. Fischer's *Rattus spinosus* does become unavailable,

Map 512: Selected localities for *Euryzygomatomys spinosus* (●).

then the correct name would be *Echimyus spinosus* Desmarest, 1817. Tate (1935:405) provisionally listed *guiara* as a species of *Euryzygomatomys*, primarily based on Brandt's description of a short tail. However, Cabrera (1961:532) noted that the taxonomic position of *guiara* was dubious, but that if Tate's assignment were correct, *guiara* would only be a subspecies of *spinosus*.

The karyotype of *E. spinosus* is $2n=46$, $FN=82$, with 19 pairs of metacentric or submetacentric and three pairs of acrocentric autosomes (Yonenaga 1975, specimens from São Paulo state; D. I. Lima et al. 2006, a specimen from Santa Catarina state, without data on fundamental autosome number).

This species is considered critically endangered in Paraguay (Resolution No. 524/06 March 17 2006, Secretaria del Ambiente de Paraguay Lista Roja de Fauna y Flora de Paraguay); the IUCN (2011) lists *E. spinosus* in the Least Concern category.

Genus *Hoplomys* J. A. Allen, 1908

James L. Patton and Louise H. Emmons

Hoplomys is a terrestrial, large-bodied rat (mass up to 800 g; Adler et al. 1998) with a stout body, short and thick legs, relatively narrow and elongated hindfeet, a nearly naked and proportionately short tail (60–70% of head and body length), and short, rounded ears. Head and body length ranges from 212–300 mm, tail length from 114–240 mm, hind foot length from 47–61 mm, and ear length from 20–29 mm (Emmons and Feer 1997). The most characteristic external features are the broad, flat, and stiff spines that cover the dorsum from behind the shoulders to the flanks and rump. These range from 26–33 mm in length and 1.7–2.2 mm in width, and tend to obscure the soft underfur (Handley 1959). The spines are tipped black along the mid-dorsum but may have pale tips on the sides, which gives the lateral aspect of the skin a distinctive speckled pattern. As with other echimyids with well-developed spines (e.g., *Lonchothrix* and *Mesomys*), those of *Hoplomys* extend down the sides to the junction with the ventral fur. Coloration varies geographically, in South America ranging from reddish orange dorsally in the southern part of the range to more yellowish in the north (Handley 1959). Young are more typically colored dull brown dorsally. Individuals vary with regard to the presence or absence of black ocular and crown areas. The venter is predominantly white, although there may be a partial or complete dark brown collar across the throat, and buff lateral bands or a buff venter. Some extralimital individuals from Panama are melanistic, almost black, with dark brown venters variably spotted with white. Such coloration could occur in bordering areas of Colombia.

The skull is conformed as in most nonfossorial eumysopine genera, relatively narrow in shape with an elongate rostrum, concave interorbital region, and round cheek teeth with deeply oblique lateral folds that do not transect the crown and that become isolated as fossettes with wear. Prominent temporal ridges are present, the supraorbital shelf is beaded, the rostrum narrows toward the tip, the auditory bullae are very small, and the floor of the infraorbital foramen typically flat, although a slight groove that marks the passage of the infraorbital nerve is present in some individuals (Patton 1987). The size, flatness, and ridging of the skull of *Hoplomys* all increase with age (as judged by tooth eruption and wear), with growth apparently continuing well after all teeth are erupted and fully functional. As a consequence, skulls of "adult" individuals will exhibit a considerable range in overall size (Handley 1959), a characteristic of other eumysopine genera, most notably *Proechimys* (Patton and Rogers 1983; Lara et al. 1992) and *Trinomys* (Pessôa and Reis 1991b).

In his description of the genus, J. A. Allen (1908:650) diagnosed *Hoplomys* by the combination of the impressively broad and stiff dorsal spines and an enamel pattern with all maxillary and mandibular cheek teeth possessing four well developed and obliquely positioned folds, a character that he contrasted with the three folds typical of *Proechimys*. However, in nearly all characters, craniodental and well as pelage, *Hoplomys* is either indistinguishable from or only at the extreme end of a continuum represented by the diverse species of *Proechimys*. For example, the counterfold formula of *Hoplomys* does vary, particularly in the lower molars (from 4/4, 4/4, 4/4, 4/4 to, rarely, 4/4, 4/3, 4/3, 4/3), and some species of *Proechimys* also exhibit four counterfolds on most, or all cheek teeth (most notably *Proechimys semispinosus* Tomes and *Proechimys quadruplicatus* Hershkovitz; see Patton 1987, and below). Moreover, some species of *Proechimys* approach *Hoplomys* in aristiform spine development, such as *Proechimys hoplomyoides* Tate, which has been allocated to *Hoplomys* by some authors (Moojen 1948; Cabrera 1961) and *Proechimys echinothrix* Silva, which has aristiform spines nearly as long and broad (22 mm × 1.4 mm, on average; M. N. F. da Silva 1998). The range of spine depth, robustness, and particularly length of *Hoplomys* reported by Hoey et al. (2004) is well beyond that observed for the eight species of *Proechimys* these authors examined, but their complement of species did not include either *P. hoplomyoides* or *P. echinothrix*.

Both A. L. Gardner and Emmons (1984) and Patton and Reig (1990) questioned the generic distinction of *Hoplomys* relative to *Proechimys* based on morphological characters of the bulla and analysis of protein electrophoretic characters, which nested *Hoplomys* within a group of

10 species of spiny rats. MtDNA sequence data (Lara et al. 1996; Y. L. R. Leite and Patton 2002) also indicate a close phyletic relationship between *Hoplomys* and *Proechimys*, but too few species of the latter have been examined as yet to determine whether *H. gymnurus* is nested among the species of this large genus, as suggested by the allozyme analyses, or is sister to a clade otherwise comprising all species of *Proechimys*. Alternatively, G. A. S. Carvalho and Salles (2004) showed that *Hoplomys* has a uniquely complete neolophid in the mandibular molars among a phyletic triad of genera that includes *Proechimys* and *Trinomys*. All three of these genera are otherwise defined by a long and narrow rostrum relative to other echimyids and the presence of a very well-developed anterior projection of the premaxilla. Clearly, the generic status of *Hoplomys* remains an open question for future research to resolve.

Hoplomys is monotypic, with a single species *H. gymnurus* distributed from Honduras in Central America south to northwestern Ecuador along the Pacific coast of South America.

SYNONYMS:

Echimys: Thomas, 1897f:550; description of *gymnurus*; not *Echimys* F. Cuvier.

Hoplomys J. A. Allen, 1908:649; type species *Hoplomys truei* J. A. Allen, by original designation.

Hoplomys gymnurus (Thomas, 1897)

Armored Rat

SYNONYMS:

Echimys gymnurus Thomas, 1897f:550; type locality “Cachavi [= Cachabí], [Esmeraldas,] N. Ecuador, altitude 170 metres,” approximately 00°58'N 78°48'W (Paynter 1993).

[*Proechimys*] *gymnurus*: J. A. Allen, 1899c:264; name combination.

Hoplomys truei J. A. Allen, 1908:650; type locality “Lavata [= Savala], Matagalpa Province, Nicaragua.”

H[oplomys]. gymnurus: J. A. Allen, 1908:651; first use of current name combination.

Hoplomys goethalsi Goldman, 1912a:10; type locality “Rio Indio, near Gatun, Canal Zone, Panama.”

Hoplomys gymnurus goethalsi: Goldman, 1920:123; name combination.

Hoplomys gymnurus truei: Goldman, 1920:124; name combination.

Hoplomys gymnurus gymnurus: Ellerman, 1940:123; name combination.

Hoplomys gymnurus wetmorei Handley, 1959:9, type locality “Isla Escudo de Veraguas, Prov. Bocas del Toro, Panama.”

DESCRIPTION: As for the genus.

DISTRIBUTION: In Central America, from south-eastern Honduras (Pine and Carter 1970) south through Panama (Handley 1959; Hall 1981); in South America, from northwestern Colombia south along the Pacific coast and west of the Cordillera Occidental to northwestern Ecuador, from elevations ranging between 180–1,250 m in northwestern Colombia to sea level in southwestern Colombia and adjacent northwestern Ecuador.

SELECTED LOCALITIES (Map 513; South America only): COLOMBIA: Antioquia, Alto Bonito (Handley 1959), Villa Arteaga (FMNH 70102), Zaragoza (USNM 499753); Cauca, Río Saija (FMNH 90110); Chocó, Bagadó (Handley, 1959), Río Docampado (FMNH 90115); Nariño, Buenavista (Handley 1959); Valle del Cauca, 6 km N of Buenaventura (MVZ 162309), 1 km from San Isidro above Río Calima (ICN 8313). ECUADOR: Esmeraldas, Cachabí (type locality of *Echimys gymnurus* Thomas); Imbabura, 10 km E of Santa Rosa (T. E. Lee et al. 2010); Pichincha, Mindo, Río Blanco (Handley 1959).

SUBSPECIES: In his revision of the genus, Handley (1959) recognized a single species with four subspecies. Two of these have exclusively Central American distributions (*truei* J. A. Allen from mainland Nicaragua and Costa Rica and the Panamanian insular *wetmorei* Handley). One subspecies (*goethalsi* Goldman) was mapped from Panama to the central Pacific coast of Colombia in the provinces of Antioquia and Chocó, and the nominotypical subspecies was recorded from northwestern Ecuador to southwestern Colombia in the state of Nariño. However, given that many of the geographic gaps in the map illustrated by Handley (1959:3, Fig. 1) are now represented by specimens in museum collections, and that no adequate review of these has as yet taken place, we hesitate to recognize the subspecies boundaries depicted by Handley herein.

NATURAL HISTORY: Nocturnal and terrestrial, these rats feed primarily on fruit and seeds. They are the most numerous rodents in the pluvial rainforests of western Colombia, the wettest forest habitat in the New World. They frequent fallen logs, brush piles, rocks, and stream edges in evergreen rainforest, and in adjacent grassy clearings (see Adler et al. 1998; Goldman 1920; Handley 1959; Pine and Carter 1970). Tomblin and Adler (1998) described details of microhabitat structure and use by *Hoplomys* in Panama. Alberico and González (1993) recorded higher densities in primary as opposed to secondary forest, and measured seasonal shifts in population density, home range size, and movement distances. Alberico and González (1993) and Tesh (1970b) provided limited details on reproductive biology, including litter size and seasonality, for western Colombia and Panama, respectively. The species is sexually dimorphic, with males in Panama averaging 38% larger

than females (Adler et al. 1998). Tail autotomy is also common, a trait *Hoplomys* shares with other echimyids, especially terrestrial species (Adler et al. 1998). Aboriginal groups in Panama utilized *Hoplomys* as a protein food resource (O. F. Linares 1976). Brennan (1969), Brennan and Reed (1974b), Fain et al. (1982), Mendez (1969), and Tipton et al. (1967) described external parasites.

REMARKS: J. A. Allen (1908:650) suggested that *Echimyus semispinosus* Tomes (1860b) might be referable to his new genus *Hoplomys*, along with *Echimyus gymnurus* Thomas (1897f). On the same page, Allen referred also to *Echimyus subspinosus* Tomes, which is clearly an inadvertent misspelling of *semispinosus*. However, Tomes' *E. semispinosus* has been consistently placed within *Proechimyus* in all subsequent literature (Tate 1935; Ellerman 1940; Cabrera 1961; Patton 1987; Woods 1993; Woods and Kilpatrick 2005). Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

Honeycutt et al. (2003) reported mitochondrial and nuclear DNA sequences for a specimen of "*Hoplomys gymnurus*" from 52 km SSW of Altamira, Brazil (GenBank accession numbers AF520668 and AF520661). Either this specimen (Texas A&M University number AK 9671) has been misiden-

Map 513 Selected localities for *Hoplomys gymnurus* (●). See Hall (1981) for distributional records in Central America. Contour line = 2,000 m.

tified or the locality given is in error. There are no records of this genus from Brazil or from anywhere east of the Andes.

Genus *Lonchothrix* Thomas, 1920

James L. Patton

This monotypic genus is similar in all morphological and ecological features to the spiny tree rats, *Mesomys*, with which it also forms a close sister relationship (Lara et al. 1996; Y. L. R. Leite and Patton 2002). Head and body length varies from 155–220 mm, tail length from 150–230 mm, hind foot length from 30–37 mm, and ear length is 13 mm (Emmons and Feer 1997). As with *Mesomys*, this is a relatively small rat with the body covered with dense, wide (1.8–2.0 mm), long (26–28 mm), flat, and flexible spines mixed with fine hairs. The spines, in general, are wider and stiffer than those of *Mesomys*. The upper parts are gray-brown, the sides and rump speckled yellowish white, and the wide spines on the sides and rump have pale yellowish tips, in contrast with a more orange or buff tips on the spines in *Mesomys*. The ears are short, naked, brown in color, and buried among the spines of the head. The tail is robust, scaly, speckled with short, dark, evenly spaced but flat, scale-like hairs, and terminates in a tuft of long, coarse, red-brown hairs that may reach 45 mm in length. *Lonchothrix* departs from *Mesomys* primarily in these accentuated characteristics of the tail, although the recently described *Mesomys occultus* (Patton et al. 2000) has a terminal tail tuft averaging 30 mm in length. The under parts are white, grayish, or buff, often tending to buff along the midline. The chest is often pale gray-brown and the throat has white-tipped hairs. The feet are dirty white. The hindfeet are broad and short, with pink soles; the forefeet are small and also with a pink palmar surface. The skull and cheek teeth are generally as in *Mesomys*, although as Thomas (1920c) noted in his description, *Lonchothrix* differs slightly as follows: muzzle broader with nasals more parallel sided and less tapered posteriorly, the malar projects anteriorly, the incisive foramina are longer and more open, the mesopterygoid fossa is narrower (reaching the middle of M2), and the hamular processes of the pterygoids is narrower, not spatulate. Upper cheek teeth have one short lingual fold and have four labial folds, or flexi, that penetrate deep into the tooth and become isolated as fossettes with wear. All lower cheek teeth have a single, short labial fold but varying numbers of lingual folds: pm4 with four folds, m1 with three, with the most posterior quite small, and both m2 and m3 with just two.

SYNONYM:

Lonchothrix Thomas, 1920c:113; type species *Lonchothrix emiliae* Thomas, 1920, by original designation.

REMARKS: A strict phylogenetic definition could argue for the placement of *Lonchothrix* and *Mesomys* into a single genus in recognition of their strongly supported sister relationship (Lara et al. 1996; Y. L. R. Leite and Patton 2002). Indeed, as noted by Thomas (1920c:114), the skull of *Lonchothrix* is “so like that of *Mesomys hispidus* that it is difficult to find any character of more than specific value.” Despite this statement, however, Thomas was unsure of the closest relative, remarking that its short, climbing feet and strongly spiny pelage resembled that of *Echimyus*, although its brachydont and nearly rounded molars set it well apart from this genus or from either *Dactylomys* and *Kannabateomys*. He noted that the teeth resemble those of *Cercomys* (= *Thrichomys*). Although he compared his new genus to *Mesomys*, for some reason he made no special connection between these two genera as the close relatives they clearly are. However, I note here that the number of cheek tooth laminae differ between the genera, *Lonchothrix* with three reentrant folds and *Mesomys* spp. generally with four.

Lonchothrix emiliae Thomas 1920

Tuft-tailed Spiny Tree Rat

SYNONYM:

Lonchothrix emiliae Thomas 1920c:114; type locality “Villa Braga, on the left bank of the Rio Tapajós, just above the first rapids,” Pará, Brazil.

DESCRIPTION: As for the genus.

DISTRIBUTION: Known only from the lower reaches of the Rio Madeira, Rio Tapajós, and Rio Xingu; all south of the Amazon River in eastern Brazil.

SELECTED LOCALITIES (Map 514): BRAZIL: Amazonas, Igarapé Auara (AMNH 91868); Pará, Alter do Chão (Lara et al. 1996), Igarapé Amorim (AMMH 95549), Jacareacanga (Auricchio 2001), Tauari (AMNH 95776), Villa Braga (type locality of *Lonchothrix emiliae* Thomas).

SUBSPECIES: *Lonchothrix emiliae* is monotypic.

NATURAL HISTORY (from Auricchio 2001): This is a poorly known and rarely seen arboreal rat that has yet to be studied in the field. Collectors’ field notes suggest that it is nocturnal, lives in lowland mature and secondary (capoeira) rainforest, nests in tree holes, readily enters and uses the rafters of wooden structures, and is locally common despite its limited geographic range. Stomach contents of a few specimens included only the pulp of unidentified plant materials, most likely fruit of *Brysonima* sp., a common small tree in the family Malpighiaceae. A pregnant female with two embryos was taken in March.

REMARKS: Auricchio (2001) questioned the identification of the specimen from the Rio Madeira (AMNH 91868). The specimen in question lacks the terminal portion of its tail, but in its overall size, broader, stiffer, and

Map 514 Selected localities for *Lonchothrix emiliae* (●).

pale-tipped spines, and more naked appearing proximal portion of the tail, it matches *Lonchothrix* and not *Mesomys*. Barring additional character discovery, we regard AMNH 91868 as a *Lonchothrix emiliae*, and thus extend the known range of the species west to the lower Rio Madeira.

The report of the karyotype of *L. emiliae* by Aniskin (1993) based on specimens from Peru must be in error. His specimens most likely represent *Mesomys hispidus*, both because of the unlikely 3,000-km range extension and the fact that the karyotype reported is identical to that illustrated for this species by Patton et al. (2000:197, Fig. 129B) from multiple localities in western Amazonian Brazil.

Genus *Mesomys* Wagner, 1845

James L. Patton and Louise H. Emmons

These are also relatively small, heavily spined rats (head and body length averaging about 180 mm) with a tail as long or slightly longer than the body, thinly haired, and terminating in a tuft of hairs of varying length. Hindfeet are short and broad. The pelage possesses heavily developed and stiffened aristiform spines throughout the back, sides, and rump. The spines are shorter (24–25 mm) and somewhat more narrowed (1.5 mm) than those of the closely related *Lonchothrix*. Individuals are common in the canopy and lower strata of lowland rainforest throughout the Amazon Basin and the Guianan region, but extend to an elevation of 2,000 m in the lower montane forest along the

eastern slope of the Andes. They may be especially common in tree falls, in dense liana tangles, or in disturbed areas, as around villages where they can often be found on the rafters of thatched houses.

Within the family, *Mesomys* and its sister genus *Lonchothrix* are unique in their combination of a dorsal pelage composed of broad and stiff spines, a sparsely haired tail that terminates in a distinct brush or pencil, and small, rounded cheek teeth with flexi wearing to isolated oval fosses or pits rather than forming transverse laminae. These tooth characters are shared with other members of the subfamily Eumysopinae, while the foot structure and elongated tail are more characteristic of the Echimyinae, which are similarly arboreal in their habits. This combination of characters of taxa otherwise belonging to separate subfamilies was noted by Wagner (1845a) in his description of the genus and reemphasized by Thomas (1905a). As a consequence, the subfamilial placement of both *Mesomys* and *Lonchothrix* has been uncertain (see account above, and discussion in Patton and Reig 1990; Emmons 2005). These two genera do, however, form a well-supported sister pair in molecular sequence analyses (Lara et al. 1996; Y. L. R. Leite and Patton 2002; Galewski et al. 2005; P.-H. Fabre et al. 2012).

Thomas (1905a:591) provided an expanded description of *Mesomys* that we augment as follows: external form similar to that of *Proechimys*, but with an arboreal bauplan of long back, short legs, short and broad pink-soled feet, strong, curved claws, and long whiskers. The ears are shorter and the fifth hind toe is longer, reaching to the distal end of the first phalanx of the fourth toe. Aristiform hairs are in the form of stiff, broadened, prominent spines distributed over the mid-dorsum and rump. The tail is long, haired lightly to varying degrees, and sometimes terminated by a tuft or pencil. The cheek teeth are rounded, as in *Proechimys*, with four or five labial folds on each upper tooth, forming five or six lophs, which become isolated fosses with wear. The lower premolar has four oblique lingual folds, and each lower molar only three. The general conformation of the skull is as in genera of Echimyinae, with a short, parallel-sided rostrum and a broadened, square interorbital region. Along with *Lonchothrix*, these features contrast markedly with the elongated rostrum and generally concave interorbital region characteristic of other genera in the subfamily Eumysopinae. Tate (1935:413) noted that “*Mesomys* comprises small, densely spinous, buff-brown-bellied rats with short, rather broad feet, slightly tufted tails and *Proechimys*-like, rounded molars.” The tail is particularly susceptible to autotomy and is often truncated, as was that of one of the first individuals to be described, unfortunately, as *M. ecaudatus* (= tailless *Mesomys*, Wagner 1845a). Apart from *Lonchothrix*, the

sympatric taxon most easily confused with a *Mesomys* spp. is *Pattonomys occasius*, which has a conspicuously naked tail (Emmons and Feer 1997).

As emphasized by Voss et al. (2001:152), the genus *Mesomys* has never been revised, and recognition of its constituent species has been in flux essentially since Desmarest (1817b) described the first species (see Tate [1935] for a general review of the nomenclatural history of the genus). Tate (1939:179) considered *Mesomys* a monotypic genus “with possibly a few weakly differentiated races” because of the “obvious morphological stability throughout the known range.” Alternatively, Ellerman (1940), Moojen (1948), and Cabrera (1961) listed two or more species within the genus, although not the same ones in all cases. E.-L. Trouessart (1897) placed *ecaudatus* Wagner (= *hispidus* Desmarest) in the genus *Mesomys* (p. 608), but listed *hispidus* Desmarest and *ferrugineus* Günther (a synonym of *hispidus*) as species of *Echimyis* Desmarest (p. 610). Emmons (1993) reassigned two of the five species listed by Woods (1993) in *Mesomys* to the *Makalata* (*didelphoides* Desmarest and *obscurus* Wagner) and Patton et al. (2000) described an additional species (*occultus*). Voss et al. (2001) documented two morphological groups, a small-toothed form from the Guianan region and eastern Amazonia, and a large-toothed form from the western and central Amazon, and suggested that if these tooththrow groups represented species, then *M. hispidus* (with *stimulax* Thomas as a synonym) would apply to the small-toothed form and *M. ferrugineus* Günther to the large-toothed form. However, they also noted that tooththrow length was insufficient as a basis for taxonomic inference because that character was discordant with the molecular clade structure identified by Patton et al. (2000). They also suggested that Tate’s (1939) restriction of the type locality of Desmarest’s *M. hispidus* to Borba, Rio Madeira, in the central Amazon was likely in error. Orlando et al. (2003) expanded on the molecular analysis of Patton et al. (2000), and importantly included sequence data from the holotype of Desmarest’s *M. hispidus* housed in the Paris Museum. Their analyses confirmed the discordance between geographic clades and the tooththrow classes recognized by Voss et al. (2001). Desmarest’s holotype was molecularly nearly identical to samples from French Guiana, and, after a review of the most likely collection history of this specimen (see also discussion in Voss et al. 2001:153, footnote 22), Orlando et al. (2003:114) corrected the type locality from Tate’s Borba, Rio Madeira to Amapá state in eastern Brazil. The molecular data presented by Orlando et al. (2003) support the recognition of three species: a widely distributed and both morphologically and molecularly polytypic *M. hispidus*, a highly geographically localized *M. occultus* that is sympatric with

M. hispidus, and a southeastern Amazonian and small-toothed *M. stimulax*. The molecular data of both Patton et al. (2000) and Orlando et al. (2003), however, identify a number of divergent and geographically structured clades within *M. hispidus* that may warrant species status when additional sampling and analyses are forthcoming. Given this possibility, we comment on the application of available names to these clades in the account for *M. hispidus*, below. Finally, until *M. leniceps*, which is restricted to montane forests in northern Peru, is examined molecularly, we follow previous authors by treating it as a distinct species, pending further analyses.

SYNONYMS:

Echymys: Desmarest, 1817b:58; part (description of *hispidus* Desmarest); not *Echymys* F. Cuvier.
Loncheres: J. B. Fischer, 1829:307; part (listing of *hispidus* Desmarest); not *Loncheres* Illiger.
Nelomys: I. Geoffroy St.-Hilaire, 1838b:122; part (listing of *hispidus* Desmarest); not *Nelomys* Jourdan.
Echinomys: Wagner, 1843a:345; part (listing of *hispidus* Desmarest); unjustified emendation of *Echymys* F. Cuvier.
Mesomys Wagner, 1845a:145; type species, *Mesomys ecaudatus* Wagner, by original designation.
Proechimys: J. A. Allen, 1899c:262; part (listing of *hispidus* Desmarest); not *Proechimys* J. A. Allen.

KEY TO THE SPECIES OF *MESOMYS*:

1. Head, sides, mid-back, and rump covered with broad, long, and stiff spines with interspersed setiform hairs sparse and generally not visible externally 2
- 1'. Head covered with nonstiff hairs; sides, mid back, and rump covered with narrowed spines interspersed with long and softer hairs *Mesomys leniceps*
2. Body size small (head and body length averaging <170 mm; upper tooththrow averaging <6.3 mm); distributed south of the Amazon and east of the Rio Tapajós in Brazil *Mesomys stimulax*
- 2'. Body size usually larger (head and body length averaging >178 mm, upper tooththrow averaging >7.14 mm); distributed elsewhere throughout the Amazon Basin; or body size small (head and body length averaging 169 mm) and distributed in the Guianan region 3
3. Dorsal spines without orange mid-band; tail with short terminal tuft of hair (<25 mm) *Mesomys hispidus*
- 3'. Dorsal spines with orange mid-band; tail with long terminal tuft of hair (>30 mm) *Mesomys occultus*

Mesomys hispidus (Desmarest, 1817)

Ferreira's Spiny Tree Rat

SYNONYMS:

Echymys hispidus Desmarest, 1817b:58; type locality "Amérique meridionale"; restricted to "Borba, Rio Madeira,

Brazil" (Tate 1939:179) but more recently to the state of Amapá in eastern Brazil (Orlando et al. 2003:119), based on the known travel route of the original collector.

L[oncheres]. hispidus: J. B. Fischer, 1829:307; name combination.

E[chinomys]. hispidus: Wagner, 1843a:345; name combination.

Mesomys ecaudatus Wagner, 1845a:145; type locality "Borba in Brasilien," Borba, Rio Madeira, Amazonas, Brazil.

Echymys ferrugineus Günther, 1876:750; type locality "Chamicuros, Huallaga River"; upper Río Samiria [Stephens and Traylor 1983], Loreto, Peru.

Proechimys hispidus: J. A. Allen, 1899c:262; name combination.

Proechimys ferrugineus: J. A. Allen, 1899c:264; name combination.

M[esomys]. ferrugineus: Thomas, 1924c:535; name combination.

Mesomys ferrugineus spicatus Thomas, 1924c:535; type locality "Tushemo, near Masisea, R. Ucayali. Alt. 1000'," Ucayali, Peru.

Mesomys hispidus: Tate, 1935:413; first use of current name combination.

Mesomys hispidus ferrugineus: Cabrera, 1961:535; name combination.

Mesomys hispidus hispidus: Cabrera, 1961:535; name combination.

Mesomys hispidus spicatus: Cabrera, 1961:536; name combination.

DESCRIPTION: Orlando et al. (2003) defined this species as an assemblage of six monophyletic mtDNA clades distributed broadly across Amazonia from Peru to the Guianan region, exclusive of the partially sympatric *M. occultus* from west-central Brazil and *M. stimulax* from eastern Brazil south of the Amazon River. As acknowledged by these authors, *M. hispidus* thus encompasses a taxon that varies substantially in size, being smaller in the Guianan part of its range (mean head and body length 161 mm) and larger in western Amazonia (mean head and body length 178–186 mm, depending upon clade), but is otherwise characterized by well-developed, pale buffy to orangish-tipped spines covering the dorsum and a long, moderately hairy tail terminating with a short tuft of hairs. In most essential external and cranial characters, *M. hispidus* cannot be distinguished from sympatric *M. occultus*, except in its tendency to lack a median orange band on spines, have petiolate and black hairs among tail scales, and shorter tuft of tail tip. Cranially, these two species also are similar, but *M. hispidus* is larger with proportionately shorter rostrum and palate, longer and narrower incisive foramina that have absolutely longer premaxillary septum, and PM4–M3 with more strongly developed 4th fold.

The following external description is from Emmons and Feer (1997): Upper parts uniform pale to medium brown, with mid-back often heavily streaked with black. Pelage consists of conspicuous short, wide, flat, flexible spines from shoulder to rump, each spine brown with pale tip. Tail often broken short or completely missing. Spines on head and neck softer and narrower than those on back. Ears brown, short and rounded, thinly haired, and with small tuft of longer hairs at base. Eyes large, and eyeshine moderately bright yellow. Vibrissae fine and long, reaching shoulder. Tail robust, brown, and thinly covered with long, red-brown hairs that do not hide scales, and with short and sparse tuft at tip, 5–21 mm in length (Patton et al. 2000); six rows of tail scales per 5 mm (holotype of *M. ferrugineus*), with central, darkly pigmented hair of each scalar triad at base of tail sharp and spine-like. Under parts uniformly pinkish orange, which contrasts sharply with color of sides. Hind-foot short and broad, claws sharp and strongly curved, and soles pink and have large plantar pads.

DISTRIBUTION: *Mesomys hispidus* occurs in the Amazon Basin from northern and eastern Bolivia, north through eastern Peru, eastern Ecuador, southeastern Colombia, southern Venezuela, the Guianas, and all of Brazilian Amazon drainage except that part east of the Rio Tapajós and south of the Rio Amazon.

SELECTED LOCALITIES (Map 515): **BOLIVIA:** La Paz, 1 mi W Puerto Linares (TTU 34988), right bank Río Alto Madidi (Emmons 1993); Santa Cruz, El Refugio (USNM 584592). **BRAZIL:** Amapá, Amapá (Orlando et al. 2003); Amazonas, Cucui (USNM 255162), Tunui (AMNH 77034); Mato Grosso, left bank Rio Cristalino (Patton et al. 2000); Pará, Igarapé Amorin (Voss et al. 2001). **COLOMBIA:** Amazonas, Caserio “Kuiru” (Lemke et al. 1982); Putumayo, Río Mecaya (FMNH 71125); Vaupes, Río Apaporis, Iino Goje (FMNH 57242). **ECUADOR:** Orellana, Río Suno (AMNH 64015); Pastaza, Montalvo (FMNH 41461); Sucumbíos, Santa Cecilia (MSU 11780). **FRENCH GUIANA:** Cayenne, Paracou (Voss et al. 2001). **GUYANA:** Upper Takutu–Upper Essequibo, 5 km SE of Surama (Voss et al. 2001). **PERU:** Amazonas, headwaters Río Kagka (of Río Cenepa) (MVZ 155158); Cusco, Quince-mil (FMNH 75197), 2 km SW of Tangoshiari (Patton et al. 2000); Loreto, Yurimaguas (FMNH 19631); Pasco, Delfin, Pozuzo (MUSM 12135), Nevati Mission (AMNH 230928). **VENEZUELA:** Amazonas, Acanana (Handley 1976), Capi-bara (Handley 1976).

SUBSPECIES: Cabrera (1961) recognized five subspecies, including *ferrugineus* Günther (northern Peru), *leniceps* Thomas (Andes of northern Peru), *spicatus* Thomas (upper Amazon of Ecuador and northeastern Peru), and *stimulax* Thomas (lower Amazon of eastern Brazil). He

gave the range of the nominotypical form as the central Amazon of Brazil, including southern Venezuela, based on Tate’s (1939) restriction of the type locality to Borba, on the lower Rio Madeira. We treat both *stimulax* Thomas and *leniceps* Thomas as species, although the latter with reservation. The validity of the other taxa at the species or subspecies level must await adequate comparisons of museum samples available, coupled with increased molecular sampling.

NATURAL HISTORY: Of the series of specimens taken along the Rio Juruá in western Brazil by Patton et al. (2000), 97% were taken in canopy traps with the remainder on the ground. *Mesomys hispidus* was more common in upland, nonflooded forest than in the seasonally flooded várzea, but was found in a variety of forest types, including naturally and human-disturbed habitats as long as some trees remained. Pregnant females were found throughout the year, suggesting continuous breeding; litter sizes ranged from one to three, with the modal number of 1. In north-eastern Peru, 60% of captures were in canopy traps in mature forest, or the oldest disturbed forest (Hice and Velasco 2012). Litter size of a single pregnant female was two. In southern Venezuela 94% were taken in trees or houses, mostly near streams or other moist places, and all in lowland evergreen rainforest (Handley 1976). This species has also been captured in tropical semideciduous forest in Bolivia (L. H. Emmons, unpubl. data).

REMARKS: Thomas (1905a:591; and 1911b:607, in his description of *M. stimulax*) equated *Echimys ferrugineus* Günther with *M. ecaudatus* Wagner. Five years later Thomas (1916e:298) argued that the type skull of Desmarest’s *Echimys hispidus* “about which so much confusion has arisen from time to time, belongs to none of the genera to which it has been hitherto referred, but is a *Mesomys*, apparently quite similar to *M. ecaudatus* Wagner. As a result, the early and suitable name *hispidus* will happily replace the unfortunate term *ecaudatus*, given to a specimen which had lost its tail.” Goeldi (1897, 1901) discussed the history of *ecaudatus* but provided no resolution as to the validity of Wagner’s name. Consequently, most recent literature has listed both *ecaudatus* Wagner and *ferrugineus* Günther as synonyms of *hispidus* Desmarest. The type locality of Wagner’s *ecaudatus* (Borba, on the lower Rio Madeira, in central Amazonian Brazil) is within the known range of *M. hispidus* but also just east of the known range of *M. occultus*. Wagner’s holotype of *M. ecaudatus* is extant (NMW 915, examined by L. H. Emmons). Although the skin is in poor condition, characters of the skull place it near *M. hispidus* and do not conform to those of either *M. occultus* or *M. stimulax*; so we follow previous authors and maintain it in the synonymy of *M. hispidus*.

Thomas (1924c) described *spicatus* as a subspecies of *ferrugineus* Günther on the basis of browner, less ferruginous color, and the spines having a dark brown sub-terminal and pale buffy terminal band, imparting “a conspicuously speckled appearance to the animal.” The nominotypical subspecies was noted to range in the Hualaga drainage to the west of the central Ucayali, the vicinity of the type locality of *spicatus*. Thomas recognized *ferrugineus* Günther as a species separate from *hispidus* Desmarest primarily on the basis of a distinct, longer tail tuft (about “an inch long” [=24 mm]), while in typical *hispidus* these hairs do not exceed 10–11 mm. However, within the large sample of *hispidus* from the Rio Juruá in western Brazil (Patton et al. 2000:195), the terminal tuft was extremely variable among individual specimens, ranging from 5–21 mm. Thus, while there might be geographic variation in the length of the tail tuft, the specimens available to us do not segregate geographically into short- and long-tufted samples that might correspond with a lower Amazonian *M. hispidus* and an upper Amazonian *M. ferrugineus*. However, because there is extensive geographically ordered clade structure within what is now considered to be the single species *M. hispidus* (Patton et al. 2000; Orlando et al. 2003), additional analyses and inclusions of specimens from type localities may well delineate those clades as species, with one corresponding to Günther’s *ferrugineus*.

Voss et al. (2001) recognized a small-toothed form of *Mesomys* in the Guianan region and eastern Amazonia (maxillary tooththrow length ranging from 5.9–6.6 mm) and a large-toothed form from western Amazonia (with maxillary tooththrow length >7 mm; see Patton et al. 2000: tables 56, 58), and suggested that each represented a separate species. Because Desmarest’s type of *hispidus* is small toothed (maxillary tooththrow length = 6.4 mm), these authors suggested that this name would apply to the eastern, small-toothed form and argued that Tate’s (1939) restriction of the type locality to Borba on the Rio Madeira was incorrect. Orlando et al. (2003:114) provided an expanded history of Desmarest’s holotype and further restricted the type locality of *hispidus* to Amapá state, north of the Rio Amazon delta in eastern Brazil. As currently understood, *M. hispidus* is sympatric with *M. occultus* at both localities where *M. occultus* is known to occur (Patton et al. 2000) and maybe sympatric with *M. stimulax* at one locality on the lower Rio Tapajós (Voss et al. 2001).

Future studies may divide the morphologically variable *M. hispidus*, as we conceive it herein, into separate species coincident with those reciprocally monophyletic molecular clades defined by Orlando et al. (2003). If so, then *hispi-*

us Desmarest would apply at least to that part of clade F from the eastern Guianan region defined by Orlando et al. (2003), the source of Desmarest’s holotype. This would make Wagner’s (1845a) *M. ecaudatus* from Borba available for the large-toothed central Amazonian animals. We note that there seems no reason to doubt the provenance of Borba for Natterer’s specimen: his holotype of *I. pagurus* (Wagner 1845a), also from Borba, and also extant, is consistent with the geographic range of that species. However, Wagner’s *ecaudatus* could apply to either clade C from the central Amazon or to the southwestern portion of clade F, as its type locality lies between the mapped ranges of both. Because the type localities of both *ferrugineus* Günther and *spicatus* Thomas are probably contained within the range of clade A from the western Amazon of northern Bolivia, eastern Peru, and western Brazil, Günther’s name would apply to this clade because of priority. The remaining molecular clades, each currently delineated only by single localities in northeastern Bolivia, southern Venezuela, or Guyana, lack available names, at least on geographic grounds, should there be a desire to recognize each formally.

Leal-Mesquita (1991) and Patton et al. (2000) described and figured a chromosome complement of $2n=60$, $FN=116$. Aniskin (1993) reported the same karyotype from specimens he identified as *Lonchothrix emiliae* from northern Peru, several thousand kilometers west of the known range of this species (see *Lonchothrix* account). Aniskin’s specimens are mostly likely *M. hispidus* (Patton et al. 2000). Patton et al. (1994) documented two mitochondrial clades along the Rio Juruá and discussed the pattern of differentiation with reference to riverine barriers. Patton et al. (2000) showed that these two clades partially overlap in cranial multivariate morphometric analyses.

Map 515 Selected localities for *Mesomys hispidus* (●). Contour line = 2,000 m.

Mesomys leniceps Thomas, 1926

Long-haired Spiny Tree Rat

SYNONYMS:

Mesomys leniceps Thomas, 1926i:348; type locality “Yambrasbamba, Amazonas, 6500’,” Peru.

Mesomys hispidus leniceps: Cabrera, 1961:536; name combination.

DESCRIPTION: Size and general characters similar to those of the larger, western samples of *M. hispidus*, but fur much less strongly spinose throughout, and spines longer, thinner, and more liberally mixed with fur. Individual spines average about 20 mm in length (Thomas 1926i). Ventral fur also more hairy than spiny, as characteristic of other species in genus. Head distinctly hairier than back and rump, noted to be “scarcely hispid to the touch” (Thomas 1926i:348), with long hair of crown covering tops of ears. Both dorsal and ventral colors are similar to those of *M. hispidus*, in particular rich buffy ventral tones and large white patches on chin and in axillary and inguinal regions. Dorsal surfaces of both forefeet and hindfeet pale buffy; digits white. Tail long for a *Mesomys* (about 120% of head and body length), brown throughout, with body hair extending farther onto tail base than in other taxa (ca. 2.5 cm); tail hairs more appressed to body of tail than usual in genus; tail terminates in long, well-developed pencil. Tail scales smaller than those of other Peruvian *Mesomys*, with eight scale rows per 5 mm (data from the holotype). Skull resembles that of *M. hispidus* but is somewhat smaller, with more slender rostrum and nasals that do not extend behind premaxillary processes. Jugal and bones surrounding antorbital foramina slender such that vertical height of zygoma distinctly narrowed. Incisive foramina constricted posteriorly. Only type and one juvenile specimen known, so extent of variation in any feature of species completely unknown.

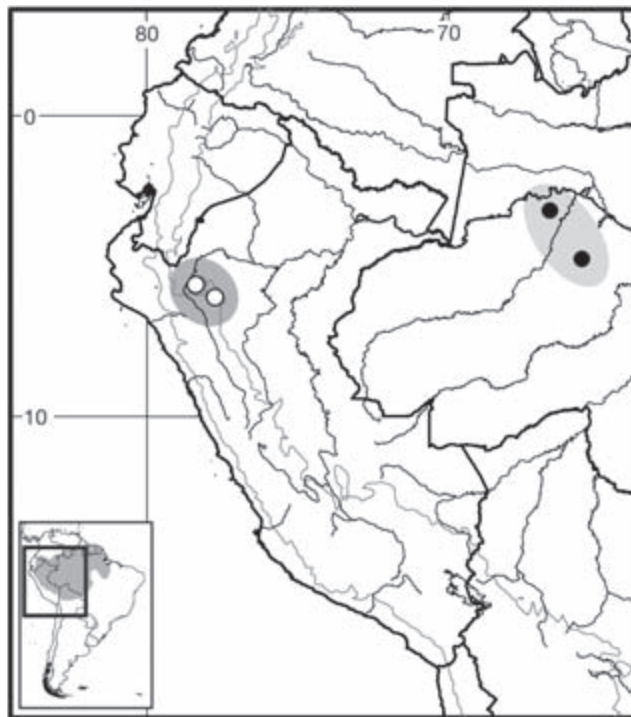

DISTRIBUTION: Known from only two localities in upper montane forest of northern Peru.

SELECTED LOCALITIES (Map 516): PERU: Amazonas, Yambrasbamba (type locality of *Mesomys leniceps* Thomas); San Martín, Puca Tambo (Thomas 1926i).

SUBSPECIES: *Mesomys leniceps* is monotypic.

NATURAL HISTORY: Nothing is known about the biology of this species, other than the comment in the original description that the holotype was “trapped under roots of tree in heavy forest, at same burrow as *Proechimys simonsi*” (Thomas 1926i:349).

REMARKS: Thomas (1926i:348) described *M. leniceps* as an “upland representative of the Amazonian *M. ferrugineus*,” gave the elevation as 5,100 feet, and characterized it mostly by its less spiny pelage, with a more liberal mix of hairs resulting in a comparatively long coat. These pelage features are consistent with a distributional occurrence at a

Map 516 Selected localities for *Mesomys leniceps* (○) and *Mesomys occultus* (●). Contour line = 2,000 m.

higher elevation (see, for example, the discussion by Patterson and Velazco [2006] in their description of a montane species of *Isothrix*). In his description, Thomas allocated a second specimen to *leniceps* from Puca Tambo, San Martín, that he had previously (1926g:162) referred to *ferrugineus* Günther. Most reviewers (e.g., Tate 1935; Ellerman 1940; Woods 1993; Woods and Kilpatrick 2005) since Thomas’s (1926i) original description have consistently listed *leniceps* as a distinct species. The sole exception is Cabrera (1961:536), who regarded *leniceps* as a subspecies of *M. hispidus*. No justification for these various decisions, however, has been provided by any set of authors subsequent to Thomas’s original description. As with so many cases for the Echimyidae, a thorough review of character variation among available museum specimens of *Mesomys* is badly needed to establish the status of *M. leniceps* at any level.

Mesomys occultus Patton, da Silva, and Malcolm, 2000
Hidden Spiny Tree Rat

SYNONYM:

Mesomys occultus Patton, da Silva, and Malcolm, 2000: 194; type locality “Coloção Vira-Volta, left bank Rio Juruá on Igarapé Arabidi, affluent of Paraná Breu, Amazonas, Brazil (3°17’S, 66°14’W).”

DESCRIPTION: Equivalent in size and similar in color, color pattern, and degree of aristiform spine development

to *M. hispidus* (see above). In contrast to sympatric *M. hispidus*, spines on neck and shoulders possess orange mid-band. Hairs along tail thin and colorless, and tuft at tip of tail contains longer hairs that average more than 30 mm in length. At base of tail, central pigmented hair of each scale elongated and not spinelike as in *M. hispidus*. Crani-ally, compared with sympatric *M. hispidus*, incisive foramina shorter and wider, with shorter premaxillary septum; grooves on anterior palate less conspicuous; and paroccipital processes flatter and broader. Four labial flexi present on P2, M1, and M2, with the fourth very small and usually lost with wear. M3 usually with only three labial flexi, or, if four, the two middle ones may coalesce into Y-branched structure.

DISTRIBUTION: *Mesomys occultus* is known only from two localities, one each on the lower Rio Juruá and on the Rio Urucu, to the south of the Rio Solimões in the central Amazon Basin of the state of Amazonas in Brazil.

SELECTED LOCALITIES (Map 516): BRAZIL: Amazonas, Colocação Vira-Volta, left bank Rio Juruá, Igarapé Arabidi (type locality of *Mesomys occultus* Patton, da Silva, and Malcolm), alto Rio Urucu (Patton et al. 2000).

SUBSPECIES: *Mesomys occultus* is monotypic.

NATURAL HISTORY: This species is known from only four specimens, all caught in upland, nonflooded (= *terra firme*) rainforest in traps placed at least 1.5 m above the ground. A pregnant female was captured in early June (Patton et al. 2000).

REMARKS: Externally, *M. occultus* is so similar to sympatric *M. hispidus* that it was not recognized as distinct until molecular sequence and chromosomal data were obtained. Patton et al. (2000) described and figured the karyotype as $2n=42$, FN=54, and compared it to the $2n=60$, FN=116, complement of *M. hispidus*.

Mesomys stimulax Thomas, 1911

Pará Spiny Tree Rat

SYNONYMS:

Mesomys stimulax Thomas, 1911b:607; type locality "Cametá, Lower Tocantins," Pará, Brazil.

Mesomys hispidus stimulax: Cabrera, 1961:536; name combination.

DESCRIPTION: Relatively small (head and body length averaging 169 mm, range: 154–196 mm; Voss et al. 2001:154, table 44), with a short tooththrow (mean 6.3 mm, range: 5.8–6.8 mm; Voss et al. 2001:154, table 44). Maxillary tooththrows slightly converge anteriorly, and M1 with three laminae rather than four, which is characteristic of *M. hispidus*. In size, *M. stimulax* similar to samples of *M. hispidus* from Guianan region (Voss et al. 2001; Orlando et al. 2003). Color above paler and buffier than in western samples of *M. hispidus* but difference minimal (Thomas 1911b). In contrast to uniformly buffy venter of *M. his-*

pidus, however, throat, axillae, chest, and inguinal region white, and belly more fawn-colored. Vibrissae and long hairs around ears black. Forefeet and hindfeet are whitish above and lack any buffy suffusion. Tail uniformly brown and terminates in thin tuft. Overall, skull smaller than western samples of *M. hispidus*, including among specimens that are apparently sympatric along lower Rio Tapajós (see Voss et al. 2001:153). Thomas (1911b:607) stated that difference in overall size is "almost entirely due to the considerable shortening of the muzzle." He noted that nasals are shorter than those of *ecaudatus* Wagner (which to him was equivalent to western samples of *M. hispidus*), parallel sided mesially, and narrowed in front rather than decidedly broader anteriorly than posteriorly. Tympanic bullae also smaller than in *M. hispidus*. The holotype (BM 11.4.28.29) has distinctive incisive foramina, with premaxillary portion converging anteriorly to narrow, straight-sided point (arrowhead shape); posterior portion with sides slightly pinching in to form shallow palatal grooves. Mesopterygoid fossa straight sided, rather than slightly bowed outward, and nasals not expanded anteriorly as in holotypes of *ferrugineus*, *hispidus*, *leniceps*, *occultus*, and *ecaudatus*.

DISTRIBUTION: *Mesomys stimulax* is known from the eastern Amazon Basin of Brazil, south of the Rio Amazonas from the Rio Tapajós east to at least the Rio Tocantins.

SELECTED LOCALITIES (Map 517): BRAZIL: Pará, 52 km SSW of Altamira, right bank Rio Xingu (Patton et al. 2000), Cametá (type locality of *Mesomys stimulax* Thomas), Igarapé Amorin (Voss et al. 2001), opposite Iroçanga (B. D. Patterson 1992b), Mata do Sequeirinho (CJ 7), Tauari (AMNH 94862), Vilarinho do Monte (AMNH 95971).

SUBSPECIES: *Mesomys stimulax* is monotypic.

NATURAL HISTORY: Along the Rio Xingu in eastern Amazonian Brazil, two individuals of this species were collected (by L. H. Emmons) at heights of 4 and 10 m, respectively, in vines on trees of tall evergreen forest.

REMARKS: Included in *M. hispidus* as a valid subspecies by Cabrera (1961). However, available samples from the southeastern Amazon of Brazil are strongly separated from *M. hispidus* by molecular sequence analyses (M. N. F. da Silva and Patton 1993; Patton et al. 1994, 2000; Orlando et al. 2003). Voss et al. (2001) examined the holotype and grouped it with the "small-toothed" forms from the Guianas, the basis for Husson's (1978) belief that *stimulax* was a species distinct from *M. hispidus*. However, Orlando et al. (2003) documented the molecular distinction between small-toothed populations from the Guianan region and the small-toothed *M. stimulax* from southeastern Amazonia (see the account of *M. hispidus*). On the lower Rio Tapajós, mixtures of the two tooththrow-size classes are present in

Map 517 Selected localities for *Mesomys stimulax* (●).

specimens in museum collections, and Voss et al. (2001:53) identified the small-toothed form as *M. stimulax*. However, the geography of the molecular clades hypothesized by Orlando et al. (2003) suggests that small-toothed animals from the Tapajós are more likely to represent true *M. hispidus* (Guyana clade) than *M. stimulax*, which may be restricted to east of the Rio Xingu. Both hypotheses can be tested by expanded collections, with appropriate molecular data, from the lower Rio Tapajós. The chromosomal complement is $2n=60$, $FN=116$, the same as that for *M. hispidus* (Patton et al. 2000).

Genus *Proechimys* J. A. Allen, 1899

James L. Patton and Rafael N. Leite

Proechimys is the most speciose and geographically most widely distributed genus of the family Echimyidae. All species are essentially limited to lowland rainforest habitats in Central America and both cis- and trans-Amazonian South America, although a few reach elevations of 2,000 m on the lower slopes of the eastern Andes or extend into dry forests in southeastern Bolivia and northern Paraguay and the Cerrado of central Brazil. These terrestrial spiny rats are often the most abundant nonvolant mammal of lowland Neotropical forests, and perhaps the most easily recognizable. Individuals can be easily heard scurrying through the leaf litter and are readily seen at night, by virtue of their bright red or yellow eyeshine, freezing when caught in a spotlight, or bounding off with a distinctive loping gait. They are important components of the terrestrial forest community, serving

as seed predators and dispersal agents and as reservoirs of zoonoses, such as leishmaniasis (Telford et al. 1972; Pajot et al. 1982; Dedet et al. 1984, 1989), encephalitis (Carrara et al. 2005), trypanosomiasis (Morales and Carreno 1976), and arboviruses (Travassos da Rosa et al. 1983).

In contrast to many other echimyids, all species of this diverse genus are terrestrial, with elongated heads and long rostra, large and erect ears, and narrow and long hindfeet. Body size ranges extensively among species, with the smallest (e.g., *P. kulinae* or *P. pattoni*) averaging about 180 mm in head and body length and the largest (e.g., *P. semispinosus*, *P. steerei*, and *P. quadruplicatus*) nearly 300 mm, and most are larger than sympatric sigmodontines rodents. The tail is always shorter than the head and body length (typically 65–70% of head and body length, but up to 85% in some species [e.g., *P. simonsi*]), and the dorsal pelage is a mixture of soft setiform hairs and expanded aristiform spines, varying in stiffness among species and/or populations (see M. N. F. da Silva 1998 and Hoey et al. 2004 for descriptions of aristiform development among species). The dorsal and lateral color is generally reddish brown to gray-brown, often streaked with black particularly along the midline, and the venter is white, although it can be tinged ochraceous or grayish, especially in the throat, thorax, and inner thighs. The narrow and elongate feet have slender toes and small plantar tubercles, the number of which may help define species (Patton and Gardner 1972). The color pattern on the dorsal surface of the foot is also often species specific (Patton and Gardner 1972; A. L. Gardner and Emmons 1984; Patton et al. 2000). The ears are distinctly larger than those of all similar-sized arboreal echimyid genera but are similar in length to those of the terrestrial spiny rats of the Atlantic Forest of Brazil, *Trinomys*.

The skull retains the same relatively narrow and elongated shape in all species currently recognized and despite substantial differences in overall size. A long rostrum, relatively narrow interorbital region with concave sides, and rounded cheek teeth with varying number of folds characterize the skull of all species. Characters such as the shape and structure of the incisive foramina, the degree of expression in temporal ridging, the degree of development of the groove on the floor of the infraorbital foramen produced by the passage of the maxillary nerve, the width and posterior palatal penetration of the mesopterygoid fossa, the size and construction of the postorbital process of the zygoma, the number and pattern of bullar septae, and the number of folds on both maxillary and mandibular cheek teeth (Patton and Gardner 1972; A. L. Gardner and Emmons 1984; Patton 1987; M. N. F. da Silva 1998; Patton et al. 2000) have proven useful in diagnosing species, as have bacular size and shape or the soft anatomy of the

male glans penis (Patton and Gardner 1972; Patton 1987; M. N. F. da Silva 1998; Patton et al. 2000).

Moojen (1948) revised those species of the genus distributed in Brazil, following earlier authors in distinguishing two subgenera: *Proechimys*, which contains those species from Central America south through greater Amazonia, and *Trinomys*, which contains those species limited to the coastal Atlantic Forest of Brazil. Cladistic analysis of morphological characters supports a sister relationship between *Proechimys* and *Trinomys*, along with *Hoplomys* (G. A. S. Carvalho and Salles 2004), but molecular sequence analyses do not support the sister status of *Proechimys* and *Trinomys* (Lara et al. 1996; Y. L. R. Leite and Patton 2002; Galewski et al. 2005). As a result, all recent literature has separated *Trinomys* from *Proechimys* (G. A. S. Carvalho and Salles 2004; Woods and Kilpatrick 2005) at the generic level. We agree with and follow these recent trends.

The extent of our knowledge of the systematics of this large and complex genus stand in stark contrast to their ubiquitous presence in all forest types, disturbed or pristine. The historically poor state of our understanding of the taxonomy of *Proechimys* is underscored by Oldfield Thomas's (1928b:262) famous statement: "The bewildering instability of the characters of these spiny rats makes it at present impossible to sort them according to locality into separate species, subspecies, or local races . . . I confess myself defeated in any attempt at present to distinguish the local races." A half-century later, Pine et al. (1981:267) echoed this sentiment, writing "among the rodents, *Proechimys* remains what may be the most problematical genus taxonomically in all mammal-dom."

Moojen (1948) recognized only five species within *Proechimys* (*sensu stricto*) while Woods and Kilpatrick (2005) listed 25. Three to five species might be present at a single locality (Patton et al. 2000); these may be truly syntopic, including sharing the same den sites on successive nights (Emmons 1982; Malcolm 1992), but they are often segregated by microhabitat (Patton et al. 2000; Voss et al. 2001). Although it is sometimes relatively easy to distinguish species when sympatric, identifying living animals to species takes a skilled eye, and defining species boundaries over larger segments of geography has proven very difficult. An extreme level of character variability, both within and among populations, hampered earlier studies attempting to diagnose species (Thomas 1928b; Moojen 1948; Hershkovitz 1948a). Even karyotypes, which have proven useful in differentiating sympatric taxa (Patton and Gardner 1972; M. N. F. da Silva 1998), may be quite variable geographically (Reig, Aguilera et al. 1980; A. L. Gardner and Emmons 1984; Patton et al. 2000; T. Machado et al. 2005). Patton and Rogers (1983) documented that individual spiny rats essentially grow continuously throughout

life, so mensural variables may increase substantially with advancing age. As a consequence, one must be exceedingly careful in morphometric comparisons between taxa and not be confused by age-related variation.

Despite these complexities and problems, considerable advances have been made in our understanding of species boundaries, definable geographic ranges, and morphological variation in the past two decades. Much of this progress has been fueled by the application of new methodologies (chromosomes and molecular genetic characters) and detailed examination of qualitative morphological characters. For example, Patton and Gardner (1972) sorted co-occurring species in eastern Peru using concordant karyotypic, soft anatomical, and phallic (including bacular) characters. Patton and Rogers (1983) documented that samples needed to age-grouped for effective morphometric comparisons of different species because of almost indeterminate growth. A. L. Gardner and Emmons (1984) used the septal patterns of the tympanic bullae to define species and group these into coherent units. Patton (1987) documented the utility of several qualitative cranial variables and bacular size and shape in allocating the 59 available names to one of nine species groups that he recognized. For each of these, he provided hypotheses of species units and remarked on the probable geographic range of each. M. N. F. da Silva (1998) described four new species from the western Amazon of Brazil and presented the initial mtDNA sequence data to help define these and other sympatric species. Subsequently, in the most thorough analysis of the genus to date Patton et al. (2000) defined, described, compared, and mapped the eight species that are now recognized in western Amazonia. These authors also made recommendations regarding species units elsewhere in Amazonia, based on patterns of morphological, karyotypic, and molecular phylogeographic variation. Reig, Aguilera et al. (1980) and Corti and Aguilera (1995) documented the distribution and limits of many species in Venezuela. Petter (1978), Steiner et al. (2000), and Voss et al. (2001) delineated sympatric species in French Guiana, describing morphological, molecular, and/or ecological differences. Weksler et al. (2001) revised one of the complexes of species occurring in eastern Amazonia and central Brazil. And, finally, Bonvicino, Otazu, and Vilela (2005) delineated karyotypic and molecular diversification among populations in the Rio Negro drainage of Amazonian Brazil, and suggested limited taxonomic changes.

J. A. Allen (1899c) proposed *Proechimys* to replace *Echimyis* I. Geoffroy St.-Hilaire (1840), which is not the same as *Echimyis* F. Cuvier (1809). Fortunately, Allen designated *Echimyis trinitatis* Allen and Chapman as the type species of his new genus, as *E. setosus*, the type of Geoffroy St.-Hilaire's *Echimyis* is a species in the genus

Trinomys Thomas. Voss and Abramson (1999) stated that the type species of the sigmodontine genus *Holochilus* Brandt at that time was *Mus leucogaster* Brandt, 1835, which was based on an example of the echimyid *Trinomys*, an oversight not previously recognized and which would have necessitated the application of *Holochilus* Brandt as the senior synonym of *Trinomys* Thomas. In Opinion 1894 the International Commission (ICZN 2001) asserted its plenary powers and fixed the type species of *Holochilus* Brandt as *H. sciureus* Wagner, thus keeping both *Proechimys* J. A. Allen and *Trinomys* Thomas on the Official List of Generic Names in Zoology.

SYNONYMS:

- Mus*: É. Geoffroy St.-Hilaire, 1803:194; part (description of *guyannensis*); not *Mus* Linnaeus.
Echimyis: Desmarest, 1817b:58; part (listing of *cayennensis* Desmarest); not *Echimyis* F. Cuvier.
Loncheres: Lichtenstein, 1830:plate 36, Fig. 2; figure of *longicaudatus*, not *myosurus* Lichtenstein (= *Trinomys setosus* [Desmarest]) as indicated.
Echinomys: Wagner, 1843a:341; part (listing of *cayennensis* Desmarest and *longicaudatus* Rengger); unjustified emendation of *Echimyis* F. Cuvier.
Thricomys: E.-L. Trouessart, 1897:607; part (listing of *brevicauda* Günther); incorrect subsequent spelling of, but not *Thrichomys* E.-L. Trouessart.
Proechimys J. A. Allen, 1899c:264; type species, *Echimyis trinitatis* J. A. Allen and Chapman, by original designation.
Tricomys: E.-L. Trouessart, 1904:504; part (listing of *brevicauda* Günther); incorrect subsequent spelling of, but not *Thrichomys* E.-L. Trouessart.
Proechinomys Elliott, 1904b:385; renaming of *Proechimys* J. A. Allen, based on the belief that it was misspelled.
Hoplomys: Moojen, 1948:315; listing of *hoplomyoides* Tate; not *Hoplomys* J. A. Allen.

We organize the species accounts of *Proechimys* around the species groups defined by Patton (1987), although these were established based simply on character similarity rather than on an explicit phylogenetic hypothesis. One group recognized includes species described subsequent to Patton's analysis (M. N. F. da Silva 1998), and other species that do not fit comfortably into these groups are treated separately. Phylogenetic data based on limited mtDNA sequences generally support the groups recognized (M. N. F. da Silva 1998; Patton et al. 2000; Weksler et al. 2001; Bonvicino, Lemos, and Weksler 2005; Bonvicino, Otazu, and Vilela 2005). However, while a reasonable understanding of species limits and distribution is now available for some geographic regions (e.g., western Amazonia, Guianan region, northern Venezuela), our understanding of the number of taxa for other large areas

(particularly trans-Amazonian Colombia and Ecuador) has progressed little since the initial taxon descriptions a century ago.

In the accounts that follow, 22 species of *Proechimys* are recognized. This list, however, clearly underestimates the actual number of species in the genus as even the limited molecular sequence data now available delineate deeply divergent phylogenetic clades within several of these taxa (Patton et al. 2000; Bonvicino, Otazu, and Vilela 2005) and substantial karyotypic differences characterize others (Reig, Aguilera et al. 1980; A. L. Gardner and Emmons 1984; Patton et al. 2000; Bonvicino, Otazu, and Vilela 2005; T. Machado et al. 2005; N. A. B. Ribeiro 2006). These common and easily trapped rats are ripe for both field and museum studies that must necessarily associate karyotypes and molecular sequences to defined morphological entities, especially with reference to holotypes and type series, so that available names can be properly assigned and truly new forms recognized and properly described.

REMARKS: G. A. S. Carvalho and Salles (2004) questioned the monophyly of all species that have been traditionally included within the genus *Proechimys* (Moojen 1948 [subgenus *Proechimys*]; Patton 1987; Woods and Kilpatrick 2005), suggesting that some are more closely related to *Hoplomys* while others are aligned to *Trinomys*. Because most of the characters that support their phylogenetic hypothesis are details of the cheek teeth, especially construction of folds and contact between loph(id)s, it is perhaps not surprising that highly varying fold number encountered among species of *Proechimys* partitions this genus into groups that align with the high fold count of *Hoplomys* and the low fold count of *Trinomys*. An expanded molecular analysis that includes the full range of taxa of all three genera is needed to resolve both generic limits and species assignments.

The holotype of Brandt's *Mus (Holochilus) langsdorffii* is now recognized to represent a species of *Proechimys* (Voss and Abramson 1999) rather than a sigmodontine rodent. This name, however, cannot be connected to any extant member of this large genus until adequate comparisons are made between the currently recognized species and the type specimen (a skin with skull, lacking mandibles, cataloged as ZINRAS 218). Once accomplished, *langsdorffii* will likely become a senior synonym of one of the species we recognize below.

KEY TO THE SPECIES GROUPS OF *PROECHIMYS*:

1. Head and body length short (<185 mm); pelage harsh to touch, aristiform spines with blunt tips but moderate to broad in width; distribution in western Amazonia.
 *gardneri* species group (*Proechimys gardneri*, *Proechimys kulinae*, and *Proechimys pattoni*)

- 1'. Head and body length larger (>200 mm); pelage varying from very harsh to soft, aristiform spines usually with whip-like tip, rarely blunt; distribution including full range of genus 2
2. Head and body length very large, up to 300 mm 3
- 2'. Head and body length moderate to large, usually <250 mm. 4
3. Dorsal color sandy fawn; pelage soft to touch, aristiform spines narrow; rostrum short and broad; floor of infraorbital foramen smooth; mesopterygoid fossa narrow and deep, reaching to M2; never four folds on upper cheek teeth, always two folds on lower m2 and m3.
. *decumanus* species group (*Proechimys decumanus*)
- 3'. Dorsal color reddish brown; pelage stiff, aristiform spines moderate in width; rostrum long and narrow; floor of infraorbital with groove; mesopterygoid fossa moderately wide, reaching only to M3; four folds commonly on upper cheek teeth, rarely two folds on m2 and m3.
. *goeldii* species group (*Proechimys goeldii*, *Proechimys quadruplicatus*, *Proechimys steerei*)
4. Distribution non-Amazonian (western Peru, Ecuador, Colombia; northern Colombia and Venezuela [except *Proechimys hoplomysoides*]) 5
- 4'. Distribution Amazonian, Guianan, or central Brazil . . . 7
5. Dorsal color grayish; pelage very soft, aristiform spines narrow with long whip-like tip; tail with very narrow scale annuli (13–16 per cm); rostrum short and broad; postorbital process of zygoma well developed; upper and lower molars always with two folds.
. *canicollis* species group (*Proechimys canicollis*)
- 5'. Dorsal color reddish yellow to reddish brown; pelage stiff, aristiform spines of moderate width or broad; tail with moderate to large scales (7–12 per cm); rostrum long and narrow; postorbital process of zygoma obsolete; always three (or more) folds on upper cheek teeth, usually three on lower cheek teeth 6
6. Dorsal color reddish yellow; tail indistinctly bicolored; incisive foramina oval in shape, anterior palate typically smooth; baculum long but stout.
. *trinitatis* species group (*Proechimys chrysaolus*, *Proechimys guairae*, *Proechimys hoplomysoides*, *Proechimys mincae*, *Proechimys trinitatis*)
- 6'. Dorsal color reddish brown; tail sharply bicolored; incisive foramina lyrate in shape, anterior palate with median ridge; baculum short and broad with well-developed apical wings *semispinosus* species group (*Proechimys semispinosus*, *Proechimys oconnelli*)
7. Body size moderate (head and body length <220 mm); pelage very stiff, aristiform spines very broad and blunt; floor of infraorbital foramen with groove and well-developed lateral flange *echinothrix* species group (*Proechimys echinothrix*)
- 7'. Body size moderate to large (head and body length >220 mm); pelage soft to moderately stiff, aristiform spines narrow to moderate in width, with whip-like tip; floor of infraorbital foramen smooth or with weakly developed groove 8
8. Tail proportionately short (60–70% head and body length) and indistinctly bicolored; tail scales moderate, with annuli 9–10 per cm; pelage stiff, aristiform spines moderately wide; incisive foramina strongly lyrate in shape, anterior palate with strongly developed grooves and median ridge; mesopterygoid fossa broad and shallow; baculum massive and broad, with apical wings or extensions.
. *longicaudatus* species group (*Proechimys brevicauda*, *Proechimys cuvieri*, *Proechimys longicaudatus*)
- 8'. Tail proportionately long (typically >80% head and body length) and sharply bicolored; tail scales small, with annuli 10–13 per cm; pelage may be stiff, with aristiforms moderately broad, or soft, with narrow aristiforms; incisive foramina oval in shape, anterior palate smooth or with only weak grooves and no median ridge; mesopterygoid fossa narrow and deep; baculum long and narrow, without apical extensions or wings. 9
9. Tail proportionately very long (>85% head and body length); plantar surface of hindfeet with five pads, lacking hypothenar; pelage soft to touch, aristiform spines narrow, terminated with whip-like tip; range in western Amazonia *simonsi* species group (*Proechimys simonsi*)
- 9'. Tail shorter (<85% head and body length); plantar surface of hindfeet with six pads, including hypothenar; pelage stiff to touch, aristiforms of moderate width, but with whip-like tip; range in Guianan region, eastern Amazonia, and central Brazil *guyannensis* species group (*Proechimys guyannensis*, *Proechimys roberti*).

Proechimys canicollis species group

According to Patton (1987), this group is monotypic, containing the single species *P. canicollis* (J. A. Allen).

Proechimys canicollis (J. A. Allen, 1899)

Colombian Spiny Rat

SYNONYMS:

Echimyus canicollis J. A. Allen, 1899b:200; type locality “Bonda, Santa Marta District,” on Río Manzanares, where joined by Quebrada Matogiro, 9 mi E of Santa Marta (Paynter 1997), Magdalena, Colombia.

[*Proechimys*] *canicollis*: J. A. Allen, 1899c:264; first use of current name combination.

Proechimys canicollis: J. A. Allen, 1904c:440; name combination.

DESCRIPTION: Moderate sized for genus, with largest individuals reaching head and body length approximately 225 mm, and with proportionately short tail (75% of head and body length). Pelage relatively soft, sparsely intermixed with weakly developed aristiform spines. Aristiform hairs long (22–25 mm) and quite narrow (0.02–0.03 mm), terminating in long whip-like tip. Dorsal color pale yellowish brown or pale golden brown sprinkled with black-tipped spines on back and paler and more gray on sides. Top of head and nape grayish, varied with black; sides of head and neck clear gray, extending onto sides of throat but becoming paler on cheeks. Ventral color white along midline from throat to inguinal region, but gray lateral bands encroach on midline, completely coalescing across belly in some specimens; sides and chin and jowls gray. Insides of limbs white; white of hind limbs may be continuous across ankles to meet whitish-gray dorsal surface of hindfeet. Ears broad but short, brown, and appear naked. Tail indistinctly bicolored, blackish above and dull-flesh colored below, and moderately haired, with hairs partially concealing narrow scale annuli (13–16 per cm at midpoint).

Skull moderate in size and, with exception of distinctively short and broad rostrum, conforms to general shape of other species in genus. Temporal ridges absent, or extend only weakly from supraorbital ledge onto anterior parietals. Incisive foramina broad and oval in shape, with weakly developed posterolateral flanges and thus an anterior palate that exhibits only faint grooves; premaxillary portion of septum broad and long, occupying at least half of opening; maxillary portion moderately to weakly developed, always in contact with premaxilla, and sometimes with a keel that extends limitedly onto anterior palate; vomerine portion of septum usually hidden from view. Floor of infraorbital foramen smooth; few specimens with barely perceptible groove. Mesopterygoid fossa relatively deep, extending to anterior half of M3s, and forming acute angle, averaging 54°. Postorbital process of zygoma moderately well developed, and formed by squamosal or of squamosal and jugal in equal frequency. Cheek teeth with fewest counterfolds of any species; counterfold formula uniform 3–2–2–2 for upper series and 2–2–2–2 for lower; only species of *Proechimys* with only two folds on 4th lower premolar.

Baculum relatively short (sample length 7.74–8.11 mm) and stout (mean distal width 2.64–22.80 mm; mean proximal width 2.55–2.78 mm) with rounded base, weakly concave sides, and rather flat distal tip with only weakly

developed apical wings (Patton 1987); general size and characters similar to members of *goeldii*-species group.

DISTRIBUTION: *Proechimys canicollis* inhabits the foothills and flatlands around the Sierra de Perijá and Sierra de Santa Marta in northeastern Colombia and northwestern Venezuela.

SELECTED LOCALITIES (Map 518): COLOMBIA: Atlántico, Ciénaga de Guájaro (Hershkovitz 1948a); Bolívar, San Juan de Nepumoceno (Patton 1987); Cesar, Río Guaimaral (= Río Garupal) (Patton 1987); Magdalena, Bonda (type locality of *Echimys canicollis* J. A. Allen), El Orinodo (Hershkovitz 1948a); La Guajira, Villanueva (USNM 280145). VENEZUELA: Zulia, Perijá (Patton 1987), Río Cachiri (Corti and Aguilera 1995).

SUBSPECIES: *Proechimys canicollis* is monotypic.

NATURAL HISTORY: This species occurs in dry tropical forest where it may be sympatric with both *P. mincae* and *P. chrysaolus*. Handley (1976) reported that all captures in northwestern Venezuela were on the ground and equally in moist evergreen and dry deciduous forest, cropland, or orchards.

REMARKS: A. L. Gardner and Emmons (1984) placed *P. canicollis* in their *brevicauda*-group based on bullar

Map 518 Selected localities for *Proechimys canicollis* (○) and *Proechimys decumanus* (●). Contour line = 2,000 m.

septal patterns, but Patton (1987) considered it the sole member of its own group, not closely related to any other species in the genus, and “one of the more readily recognizable in the entire genus” by virtue of its reduced counterfold pattern and distinctive, almost bicolored, dorsal color pattern with the gray head and yellow brown back and rump. The karyotype consists of a $2n=24$ and $FN=44$, with minor differences in the number of arms in an autosomal pair between samples from northwestern Venezuela (Aguilera et al. 1979) and topotypes from Bonda, north-eastern Colombia (A. L. Gardner and Emmons 1984). This species is positioned at the base of a group of nine other species of spiny rats in a tree based on allozyme electrophoretic characters (Patton and Reig 1990).

Proechimys decumanus species group

As currently understood, the *decumanus*-group is monotypic, and with no apparent close relatives among other spiny rats (Patton 1987).

Proechimys decumanus (Thomas, 1899)

Pacific Spiny Rat

SYNONYMS:

Echimys decumanus Thomas, 1899c:282; type locality “Chongon, Guayas Province, west of Guayaquil, Ecuador,” ca. 100 m, 25 km W of Guayaquil (Paynter 1993). [*Proechimys*] *decumanus*: J. A. Allen, 1899c:264; first use of current name combination.

Proechimys [(*Proechimys*)] *cayennensis decumanus*: Ellerman, 1940:120; name combination.

[*Proechimys semispinosus*] *decumanus*: Moojen, 1948:316; name combination.

DESCRIPTION: Large spiny rat, head and body length of adults 260–300 mm, but with proportionately short tail (about 65% of head and body length). Dorsal color coarsely grizzled sandy fawn with intermixed with darker hairs. Sides paler and grayer; face grizzled gray. Inner sides of forelimbs and hips pure white, with hairs white to base. Upper surfaces of forefeet and hindfeet white or slightly washed yellow, and white on inner thighs continuous across ankle onto foot. Aristiform spines long (length 25–27 mm) and thin (width 0.5 mm) and tipped with long, flexible filament; pelage thus inconspicuously spiny to eye and touch. Plantar pads of hindfoot large, particularly both thenar and hypothenar pads. Tail bicolored, dark above and pale below, and uniformly but thinly haired with scale annuli narrow (13 per cm at midpoint) and visible to eye.

Skull large and elongated, with short and broad rostrum. Temporal ridges moderately developed and either continuous or interrupted across parietals from posterior end of supraorbital flange. Incisive foramina oval to slightly lyrate

in shape and large, with weakly developed posterolateral flanges and weak grooves extending onto anterior palate; premaxillary portion of septum long, but tapers posteriorly and in direct contact with maxillary portion, which is varyingly developed as either thin, spiculate bone or broad shelf, often perforated by small foramen, and with either no or only limited keel that extends onto anterior palate; vomer not visible along septum. Floor of infraorbital foramen flat, rarely with limited evidence of lateral flange indicating passage of maxillary nerve. Mesopterygoid fossa moderately deep, reaching to anterior half of M3s, and rather narrow, with its angle averaging 53°. Postorbital process of zygoma obsolete. Cheek teeth simple, typically with three counterfolds on all upper teeth (although rarely only two on M3) and with three folds on pm4 and m1 but only two on m2 and m3; counterfold formula 3–3–3–(2)3/3–3–2–2.

Baculum long but stout, among longest of any *Proechimys*, mean length range: 9.2–11.8 mm, distal width 2.9–3.8 mm, proximal width 2.8–3.4 mm. In both size and shape, baculum most similar to those *trinitatis*-group members; sides nearly parallel, base rounded, and distal tip slightly expanded with weak median depression (Patton 1987).

DISTRIBUTION: *Proechimys decumanus* is known only from the tropical dry forests of southwestern Ecuador and adjacent northwestern Peru.

SELECTED LOCALITIES (Map 518): ECUADOR: El Oro, Santa Rosa (Patton 1987); Guayas, Chongón (type locality of *Echimys decumanus* Thomas); Los Rios, Hacienda Pijigal (Patton 1987); Manabí, Bahía de Caraques (Patton 1987); Santa Elena, Manglar Alto (UMMZ 80040). PERU: Piura, Quebrada Bandarrango (Patton 1987; not located); Tumbes, Matapalo (FMNH 81197).

SUBSPECIES: *Proechimys decumanus* is monotypic.

NATURAL HISTORY: An inhabitant of tropical semi-deciduous forest, this large spiny rat has not been studied for any aspect of its ecology, reproduction, or behavior. It may be sympatric, or nearly so, with *Proechimys semispinosus* in SW Ecuador, with the latter presumably inhabiting patches of more mesic, evergreen forest.

REMARKS: Thomas (1899c) considered this species closely allied to *P. semispinosus* (Thomas), and A. L. Gardner and Emmons (1984) placed it with in their broadly encompassing *brevicauda*-group. In bacular characters, *P. decumanus* appears most similar to members of the *trinitatis*-group, and not at all close to any species within the *semispinosus* or *longicaudatus* groups (Patton 1987). A. L. Gardner and Emmons (1984) described a chromosomal complement of $2n=30$ and $FN=54$ for topotypes, one indistinguishable from that of specimens of *P. semispinosus* from Costa Rica, but different from those of sympatric, or near-sympatric *P. semispinosus* from Ecuador.

Proechimys echinothrix species group

The single species within this group is the recently described *Proechimys echinothrix* Silva, which apparently has no close relatives within the genus (M. N. F. da Silva 1998). For the present, therefore, we list this as the sole member of another monotypic species group.

Proechimys echinothrix M. N. F. da Silva, 1998

Stiff-spined Spiny Rat

SYNONYM:

Proechimys echinothrix M. N. F. da Silva, 1998:441; type locality "Colocação Vira-volta, left bank Rio Juruá on Igarapé Arabidi, affluent of Paraná Breu, 66°14'W, 3°17'S, Amazonas, Brazil."

DESCRIPTION: Moderately large for genus, length of head and body 141–245 mm, with robust body, long ears (length 19–28 mm), moderately and proportionately long tail (length 106–209 mm, 77% of head and body length), and large hindfeet (length 41–54 mm). Dorsal color uniformly reddish-brown, coarsely streaked on back and sides with varying amounts of black; interspersed with heavy, dark brown guardhairs that make mid-dorsum darker, which grades evenly onto brighter and paler sides. Aristiform hairs long (length 19.3–24.1 mm) and much broader (width 1.2–1.6 mm) than other sympatric species, with strong and blunt tips conspicuous to eye and touch, especially in mid-dorsal region. Venter and inner surfaces of limbs pure white. Tail indistinctly bicolored, dark above and white below; well haired, with scales nearly completely obscured from view; scales small, 12 annuli per cm at midpoint. Hindfeet nearly unicolorous white on dorsal surfaces; all six pads present on plantar surfaces, but hypothenar weakly developed in relation to thenar pad.

Skull moderately large (condyloincisive length 39.8–49.0 mm), with long and narrow rostrum and well-developed supraorbital ledge extending over orbits but discontinuous across parietals as weakly developed temporal ridge. Zygoma usually lacks postorbital process or, if present, it is low and rounded with equal contributions by jugal and squamosal. Well-developed groove with lateral flange present on floor of infraorbital foramen. Incisive foramina ovate to lyrate in shape, with posterolateral margins mostly flat, or only weakly flanged with very shallow grooves extending onto anterior palate that lacks median ridge; premaxillary portion of septum long and narrow, extending between one-half and two-thirds of length of opening; maxillary portion typically attenuate, with weak to no contact with premaxillary portion; vomer visible in most specimens. Mesopterygoid fossa moderately deep, extending to front of M3s, but broad, with sides defining angle about 70°. Median number of folds on upper cheek

teeth three; m3 occasionally with two; counterfold formula 3–3–3–3/3–3–3– (2)3.

Baculum massive and relatively short (length 8.3–8.6 mm); shaft broad with thick and expanded base (proximal width 4.8–5.4 mm), distal end with pair of divergent apical extensions separated by shallow median depression (distal width 4.2–5.1 mm; M. N. F. da Silva 1998; Patton et al. 2000). M. N. F. da Silva (1998) described the soft anatomy of male phallus.

DISTRIBUTION: *Proechimys echinothrix* is known only from the western Amazon Basin of Brazil, west of the Rio Madeira and on both sides of the Rio Solimões (Patton et al. 2000:230, Fig. 145; Schetino 2008:12, Fig. 2), possibly extending into Colombia in the upper Rio Negro drainage.

SELECTED LOCALITIES (Map 519): BRAZIL: Amazonas, Barro Vermelho (M. N. F. da Silva 1998), Colocação Vira-Volta, left bank Rio Juruá (type locality of *Proechimys echinothrix* Silva), Comunidade Colina, Rio Tiquié (Patton et al. 2000), Lago Vai-Quem-Quer, right bank Rio Juruá (M. N. F. da Silva 1998), Macaco, Rio Jaú (Patton et al. 2000), alto Rio Urucu (M. N. F. da Silva 1998), Tambor, Rio Jaú (Patton et al. 2000), Comunidade Bela Vista (Schetino 2008).

SUBSPECIES: *Proechimys echinothrix* is monotypic.

NATURAL HISTORY (from Patton et al. 2000): This species typically inhabits upland, nonseasonally inundated (*terra firme*) forest, although it may be found along the margins of flooded *várzea* or *igapó* forest. Pregnant fe-

Map 519 Selected localities for *Proechimys echinothrix* (●). Contour line = 2,000 m.

males have been taken in both dry and wet seasons in western Brazil, where modal litter size was two (range: 1–3).

REMARKS: *Proechimys echinothrix* is one of the most readily recognizable among the sympatric assemblage of spiny rats of western Brazil, primarily due to the dense mid-dorsal cover of broad, stout, and blunt aristiform spines. Populations on opposite sides of the Rio Solimões are markedly distinct in mtDNA sequences (Patton et al. 2000), which might signal species-level differences. Both groups of populations, however, share the same karyotype and set of morphological attributes.

Proechimys gardneri species group

This complex includes three recently described species from the western Amazon of Brazil, Peru, and northern Bolivia (M. N. F. da Silva 1998). These are all of similar body size, with small ears, short hindfeet, and a similarly proportioned tail. Species in this group differ markedly in characters of the cranium, phallus (including baculum), and karyotype, yet appear to form a monophyletic clade based on mtDNA sequence data (M. N. F. da Silva 1998; Patton et al. 2000). The ranges of the three species are nonoverlapping, as all three replace one another along the length or on opposite banks of the Rio Juruá in western Amazonian Brazil.

KEY TO THE SPECIES OF THE *PROECHIMYS GARDNERI* SPECIES GROUP:

1. Aristiform spines on mid-dorsum thin so that pelage is relatively soft to the touch; tail not sharply bicolored; baculum stout and broad, with well-developed apical wings *Proechimys pattoni*
- 1'. Aristiform spines on mid-dorsum thick so that pelage is distinctly coarse to the touch; tail sharply bicolored; baculum without well-developed apical wings 2
2. Six tubercles on plantar surface of hindfeet; scales of tail annuli small (11 per cm); postorbital process of zygoma obsolete; mesopterygoid fossa long and narrow, reaching to M2s; baculum broad with weak apical wings *Proechimys gardneri*
- 2'. Five tubercles on plantar surface of hindfeet (missing hypothenar); scales of tail annuli large (nine per cm); postorbital process of zygoma well-developed and formed by squamosal; mesopterygoid fossa short but narrow, reaching only M3s; baculum short and narrow, without apical wings. *Proechimys kulinae*

Proechimys gardneri M. N. F. da Silva, 1998

Gardner's Spiny Rat

SYNONYM:

Proechimys gardneri M. N. F. da Silva, 1998:460; type locality "Altamira, right bank Rio Juruá, 68°54'W, 6°35'S, Amazonas, Brazil."

DESCRIPTION: One of three small species in western Amazonia, head and body length 154–209 mm, tail length 88–152 mm, hindfoot length 32–45 mm, and ear length 18–24 mm. Tail relatively short, about 70% of head and body length. Body color reddish brown or auburn, coarsely streaked with varying amounts of black both on dorsum and sides; midback appears darker, especially over rump, due to presence of heavy, dark brown aristiform spines. Aristiforms short (length 15.4–19.9 mm) and moderately wide (0.7–1.0 mm), with blunt tip, providing distinctly coarse or stiff texture to dorsal pelage. Venter and chin pure white; most specimens with white lips. Tail sharply bicolored, dark brown above and cream to white below; scales relatively small (11 annuli per cm at midpoint), but not completely hidden by hair. Inner surfaces of hindlimbs pure white, extending across ankle onto foot so that ankle lacks complete circular dark band. Dorsal surfaces of hindfoot yellowish white, not pure white, often with distal parts of toes brownish. Plantar surface of hindfoot with six tubercles.

Skull small (condyloincisive length 34.5–46.1 mm) and delicate, with relatively long and narrow rostrum, and beaded supraorbital ledges above orbits, which extend posteriorly as weakly developed ridges on anterior parietals. Postorbital process of zygoma obsolete. Floor of infraorbital foramen smooth, lacking ventral groove. Incisive foramina ovate to slightly lyrate in shape, with posterolateral margins lying flat or weakly flanged, and outlining shallow groove on anterior palate; maxillary portion of septum dorsoventrally compressed posteriorly and narrow anteriorly, visible over almost half length of foraminal opening, and fully connected to broad premaxillary portion about half foramina length; vomer not visible on ventral margin of septum. Palate smooth, without median ridge. Mesopterygoid fossa long, extending to middle of M2s, and narrow, with angle of indentation averaging 61°. Cheek teeth very small, maxillary toothrow 6.9–8.2 mm. Upper teeth typically with three folds, M3 occasionally with two; pm4 with four (occasionally three) folds, m1 and m2 with three, and m3 with either two or three; counterfold formula 3–3–3–(2)3/(3)4–3–3–2(3).

Baculum massive and relatively long (length 6.5–8.6 mm), especially relative to body size, with short, broad, and distolaterally directed apical extensions separated by shallow median depression; midshaft relatively broad and base thick and expanded (distal width 3.1–4.2 mm, proximal width 4.7–5.1 mm; M. N. F. da Silva 1998; Patton et al. 2000).

DISTRIBUTION: *Proechimys gardneri* is known only from only nine localities in western Amazonian Brazil and northern Bolivia, between the Rio Juruá and Rio Madeira (M. N. F. da Silva 1998; Schetino 2008).

SELECTED LOCALITIES (Map 520): BRAZIL: Amazonas, Altamira, right bank Rio Juruá (type locality of *Proechimys gardneri* M. N. F. da Silva), alto Rio Urucu

Map 520 Selected localities for *Proechimys gardneri* (○), *Proechimys kulinae* (▲), and *Proechimys pattoni* (●). Contour line = 2,000 m.

(M. N. F. da Silva 1998), Comunidade Bela Vista (Eler et al. 2012); Rondônia, Abunã, left bank Rio Madeira (Schettino 2008), Jirau, right bank Rio Madeira (Schettino 2008). BOLIVIA: Pando, San Juan de Nuevo Mundo (USNM 579615), Río Negro (USNM 579617).

SUBSPECIES: *Proechimys gardneri* is monotypic.

NATURAL HISTORY: This species has only been observed in upland, nonseasonally flooded (*terra firme*) forest. Pregnant females are known from the rainy season in western Brazil, although age structure suggests that breeding extends into the dry season. Modal litter size is two, with a range of one to three young (Patton et al. 2000). Subadults and juveniles were collected in Bolivia in July (L. H. Emmons, pers. comm.). Mendonça et al. (2011) reported this species in the stomach contents of the colubrid snake *Spilotes pullatus*.

REMARKS: This species is similar in most characters to *P. pattoni*, with which it is parapatric in distribution in western Brazil. On the Rio Juruá the two species share the same $2n=40$, $FN=56$, karyotype but differ in details of the baculum (M. N. F. da Silva 1998) and are strongly differentiated in mtDNA sequences (M. N. F. da Silva 1998; Patton et al. 2000). The karyotype of *P. gardneri* from the mid Rio Madeira is slightly different, with $2n=40$, $FN=54$ (Eler et al. 2012).

Proechimys kulinae M. N. F. da Silva, 1998

Kulina Spiny Rat

SYNONYM:

Proechimys kulinae M. N. F. da Silva, 1998:451; type locality "Seringal Condor, left bank Rio Juruá, 70°51'W, 6°45'S, Amazonas, Brazil."

DESCRIPTION: Another of smallest species in genus, head and body length 144–190 mm, tail length 95–140 mm, hindfoot length 38–44 mm, and ear length 17–23 mm. General appearance of slight build, small ears, short hindfeet, and short tail (about 70% of head and body length). Dorsal color uniform reddish brown, coarsely streaked with varying amounts of black on back and sides. Dorsal pelage interspersed with moderately short (16.4–20.0 mm) and thick (0.8–1.0 mm), dark brown aristiform hairs forming darker medial band contrasting with sides of body. Tip of each aristiform blunt. Venter, chin, and undersurfaces of forelimbs and hindlimbs pure white; upper lips dark, generally without patches of white hair; tarsal joint either ringed by dark and rusty-colored hair or interrupted by white hair confluent with that of undersurface of hindlimbs. Dorsal surfaces of hindfeet, including digits, white, tinged golden in some individuals. Plantar surfaces typically with five tubercles, lacking hypothenar pad in most specimens. Tail appears almost naked, distinctly bicolored with dark brown above and white below; scales larger than in other species of group (nine annuli per cm at midpoint).

Skull relatively small (condyloincisive length 33.9–40.8 mm), with short and narrow rostrum, and well-developed supraorbital ledge extending onto anterior portion of parietals. Postorbital process of zygoma well developed and formed mostly by squamosal. Floor of infraorbital foramen generally smooth, a demonstrable groove for maxillary nerve. Incisive foramina mostly square to oval in shape, with nearly flat posterolateral margins; anterior palate smooth, lacking both grooves extending posteriorly from the incisive foramina and median ridge; premaxillary portion of septum short, extending for less than half length of foramen; maxillary portion variable, attenuate to expanded anteriorly, and usually in contact with premaxillary part; vomer either completely enclosed or only barely visible. Mesopterygoid fossa narrow, with angle of indentation averaging 57°, moderately deep, usually extending well into M3s. Upper cheek teeth with three folds, M3 sometimes with two; four folds on pm4, three on m1 and m2, and two on m3; counterfold formula 3–3–3–(2)3/4–3–3–2.

Baculum elongate (length 5.4–8.2 mm) and relatively narrow (proximal width 1.6–2.1 mm, distal width 1.7–2.6 mm), with stout and short apical extensions (M. N. F. da Silva 1998; Patton et al. 2000).

DISTRIBUTION: *Proechimys kulinae* is known only from northeastern Peru, south of the Río Amazonas, and western Brazil along both sides of the central Rio Juruá.

SELECTED LOCALITIES (Map 520): BRAZIL: Amazonas, Barro Vermelho (M. N. F. da Silva 1998), Seringal Condor (type locality of *Proechimys kulinae* M. N. F. da Silva). PERU: Loreto, Jenaro Herrera (AMNH 276708), Nuevo San Juan (MUSM 13340), San Pedro (MVZ 198489).

SUBSPECIES: *Proechimys kulinae* is monotypic.

NATURAL HISTORY (from Patton et al. 2000): This species is only known from primary or second growth upland, seasonally noninundated (*terra firme*) forest. Pregnant females were taken only in the dry season in the Rio Juruá basin; the modal litter size was one young, maximum number two.

REMARKS: Substantial differences in mtDNA sequences are present between sampled localities, with samples from the central Rio Juruá in western Brazil and those from northeastern Peru strongly separable from those toward the mouth of the Rio Juruá. Despite these molecular differences, all known specimens share the same general morphology, including bacular type, and karyotype (Patton et al. 2000). The chromosomal complement is $2n=34$, FN=52 (M. N. F. da Silva 1998). Aniskin (1993) described the same karyotype for specimens identified as *Proechimys* sp. from northeastern Peru; as noted by M. N. F. da Silva (1998), these likely represent *P. kulinae* as she allocated specimens from nearby localities to this species.

Proechimys pattoni M. N. F. da Silva, 1998

Patton's Spiny Rat

SYNONYM:

Proechimys pattoni M. N. F. da Silva, 1998:454; type locality "Igarapé Porongaba, right bank Rio Juruá, 72°47'W, 8°40'S, Acre, Brazil."

DESCRIPTION: Third small species in western Amazonia, equal in size to *P. gardneri* and *P. kulinae* (head and body length 146–193 mm); individuals slender with short hindfeet (37–43 mm), short ears (20–22 mm), and proportionally medium length tail (106–141 mm; 70% of head and body length). General body color from reddish brown and auburn, coarsely streaked with varying amounts of black both on dorsum and sides. Interspersed dark brown aristiform spines give dorsum dark aspect, but contrast between color of back and sides not sharp. Dorsal pelage stiff to touch, with blunt tipped and shorter (13.2–15.9 mm), narrower (0.5–0.8 mm) aristiform spines compared with other species in group. Color of venter, chin, and upper lips pure white. Dark rings circumscribe tarsal joints, interrupting white of inner hind limbs and dorsal surfaces of hindfeet. Plantar surface of hindfeet with six pads. Dark brown dorsal surface of tail grades evenly, rather than sharply, with paler brown to cream color of its ventral surface. Tail scales small, 11 annuli per cm at midpoint.

Skull small (condyloincisive length 36.1–39.5 mm) and delicate, with overhanging supraorbital ledges but with only weakly developed beading extending onto temporal regions. Low but distinct postorbital process of zygoma present, usually formed solely by squamosal. Floor of infraorbital foramen smooth, lacking even hint of groove.

Incisive foramina ovate to nearly square, with flat posterolateral margins, an attenuate or dorsoventrally compressed maxillary portion of septum, and broad and short premaxillary portion usually not in contact with maxillary portion. Palate smooth, without median ridge. Mesopterygoid fossa long and narrow, angle of indentation acute (50° to 60°), and may penetrate to M2s. Cheek teeth markedly small, with entire toothrow <7.5 mm in length. Upper teeth with three lateral folds; lower cheek teeth with three folds, but pm4 sometimes with four and m3 occasionally with two; counterfold formula 3–3–3–3/3(4)–3–3–(2)3.

Baculum massive (length 7.4–9.1 mm, proximal width 4.2–5.1 mm, distal width 3.1–4.2 mm), especially in proportion to body size; shaft broad, base thick and expanded, divergent apical extensions long and separated by wide and deep median depression (Patton and Gardner 1972; M. N. F. da Silva 1998; Patton et al. 2000).

DISTRIBUTION: *Proechimys pattoni* is known only from two localities in the headwaters of the Rio Juruá in western Amazonian Brazil and adjacent parts of eastern and southern Peru (M. N. F. da Silva 1998).

SELECTED LOCALITIES (Map 520): BRAZIL: Acre, Sobral (M. N. F. da Silva 1998), Acre, Igarapé Porongaba (type locality of *Proechimys pattoni* M. N. F. da Silva). PERU: Madre de Dios, Pakitza (M. N. F. da Silva 1998); Puno, Putina Punco (M. N. F. da Silva 1998); Ucayali, Balta (Patton and Gardner 1972, as *P. guyannensis*).

SUBSPECIES: *Proechimys pattoni* is monotypic.

NATURAL HISTORY (from Patton et al. 2000): This species is known only from upland, nonseasonally flooded (*terra firme*) forest, where it might be found in undisturbed forest or in disturbed areas dominated by bamboo. Pregnant females were taken in the rainy season in western Brazil; modal litter size was two, with a range from one to two young.

REMARKS: This species was described and figured by Patton and Gardner (1972) based on specimens from eastern Peru, but under the name *P. guyannensis*. The karyotype is $2n=40$, FN=56 (Patton and Gardner, 1972), similar to that of *P. gardneri* (M. N. F. da Silva 1998).

Proechimys goeldii species group

Patton (1987) included 12 named taxa in this complex, but was unsure of how many of these might represent valid species. Considerable karyotypic and molecular data are now available to help define species limits and geographic ranges. Some of these data have been published (M. N. F. da Silva 1998; Patton et al. 2000), but much remains unpublished. Because of the relatively thorough geographic sampling, especially in regions that encompass most of the type localities of the names Patton (1987) placed in the group,

we recognize three species and assign with confidence the remainder of the available names as synonyms to one or the other of these three.

Members of this group are restricted to the lowland rainforest of the Amazon Basin where they most commonly inhabit the seasonally inundated *várzea* or *igapó* forests, in contrast to their sympatric congeners that live in nonseasonally flooded upland, or *terra firme*, forests (Patton et al. 2000). All three species have parapatric ranges, with rivers forming their common boundaries. These species are united by a uniformly large body size; by a common short, stout, but relatively narrow baculum (Patton 1987:316, Fig. 6); by skulls with weakly lyre-shaped or parallel-sided incisive foramina with a short premaxillary portion of the septum, typically attenuate maxillary portion sometimes not in contact with the premaxillary portion, and with the vomer only rarely exposed ventrally (Patton 1987:324, Fig. 15); a moderately narrow mesopterygoid fossa (angle 60° to 68°) that penetrates to the anterior part of M3s (Patton 1987:331, Table 4); and by upper cheek teeth typically characterized by four counterfolds (Patton 1987:332, Fig. 25; 334–335, Table 5).

KEY TO THE SPECIES OF THE *PROECHIMYS*
GOELDII SPECIES GROUP:

1. Distributed north of the Marañón-Solimões-Negro rivers in northern Peru, Ecuador, Colombia, north-central Brazil, and southern Venezuela; counterfold pattern of maxillary cheek teeth most commonly 4–4–4–4
. *Proechimys quadruplicatus*
- 1'. Distributed south or east of the Marañón-Solimões-Negro rivers in Peru, Bolivia, and Brazil; counterfold pattern of maxillary cheek teeth usually 3–3–3–3, but occasionally M3 and M4 with four folds 2
2. Distributed in western Amazonia, west of the Rio Madeira; M3 and M4 commonly with four folds; dpm4 always with four folds; m1, m2 with three folds
. *Proechimys steerei*
- 2'. Distributed in eastern Amazonia, east of the Rio Madeira and mostly south of the Rio Amazonas; M3 and M4 with three folds, only rarely with four; dpm4 often with three folds; m1, m2, and m3 sometimes with two folds *Proechimys goeldii*

Proechimys goeldii Thomas, 1905

Goeldi's Spiny Rat

SYNONYMS:

Proechimys goeldii Thomas, 1905a:587; type locality "Santarem [= Santarém], Lower Amazon," Rio Tapajós, Pará, Brazil (locality of holotype given as "Santarem, Barras de Tapajoz" in catalog of the Naturhistorisches Museum der Stadt Bern, Switzerland [Güntert et al. 1993]).

Proechimys [(*Proechimys*)] *cayennensis goeldii*: Ellerman, 1940:121; name combination.

Proechimys goeldii goeldii: Moojen, 1948:340; name combination.

Proechimys guyannensis hyleae Moojen, 1948:361; type locality "Tauarí, Rio Tapajós, Porto de Moz, Pará, Brazil; approximately 87 kilometers south of Santarem."

Proechimys guyannensis nesiototes Moojen, 1948:363; type locality "Ilha de Manapirí, Rio Tocantins, Pará, Brazil."

Proechimys guyannensis leioprinna Moojen, 1948:364; type locality "Cametá, left bank of Tocantins River, near its mouth, Cametá, Pará, Brazil."

DESCRIPTION: Size moderately large (head and body length 188–271 mm), hindfeet long (44–61 mm), and tail proportionately short (length 100–171 mm; about 65% of head and body length). Dorsal color dark reddish brown strongly mixed with black, especially over mid-back and rump, but specimens from more southern localities distinctly paler and more orangish-red in color. Venter clear white from chin to inguinal region; inner thighs white but separated from dorsal foot color by dark band. Dorsal surface of hindfeet bicolored, outer side dark, inner side pale, a pattern also characteristic of *P. quadruplicatus* and *P. steerei*. Six well-developed plantar pads, thenar and hypothenar large and subequal in size. Tail clothed with short, sparsely distributed hairs, so that it appears naked to eye; scales small, 12 annuli per cm at midpoint. Aristiform spines stout and stiff, length 18–20 mm, width about 1.1 mm in width, tip blunt.

Skull large (greatest skull length 49–68 mm), broad across zygomatic arches (zygomatic breadth 22.4–30.9 mm), with relatively long but broad rostrum (mean length 22.7 mm, mean width 8.3 mm). Older specimens exhibit weakly continuous temporal ridge extending from supraorbital ledge across parietals. Incisive foramina broadly open, weakly lyre-shaped or parallel sided, with posterior margins slightly flanged and extending onto anterior palate forming grooves; premaxillary portion of septum short, usually less than one-half length of opening; maxillary portion varies greatly, from weak and attenuate, perhaps not in contact with premaxillary portion, to spatulated and filling much of posterior opening; maxillary portion with slight keel that continues onto palate as median ridge; vomerine portion typically enclosed in premaxillary sheath and thus not visible. Floor of infraorbital foramen may be smooth, lacking any evidence of groove, or with groove defined by moderately developed. Mesopterygoid fossa moderately broad, defining angle of 65°, penetrating posterior palate to about midpoint of M3s. Postorbital process of zygoma moderately developed and comprised mostly by squamosal. Counterfold pattern of cheek teeth varies, with number of folds decreasing from west to east and from north to

south: Western samples with upper cheek teeth 3–(3)4–(3)4–3 and lower cheek teeth 4(rarely 3)–3–3–3 folds; eastern and southern samples with reduced fold number of 3–3–3–3 above and 3(rarely 4)–3–3–3 or 2 below.

Baculum same in general size and shape as those of other members of group (sample mean length 6.58–8.96 mm, proximal width 2.06–2.93 mm, distal width 1.88–2.75 mm); sides straight and parallel, base slightly expanded, and tip with faint development of apical wings and median depression (Patton 1987).

DISTRIBUTION: *Proechimys goeldii* occurs in eastern Amazonian Brazil along both banks of the Rio Amazonas largely east of the Rio Madeira, in the states of Amazonas and Pará, and south along the Tapajós, Xingu, and Tocantins-Araguaia rivers and their tributaries, reaching the Cerrado biome in Mato Grosso state.

SELECTED LOCALITIES (Map 521; from Patton 1987, except as noted): BRAZIL: Amazonas, Cachoeirinha (Schetino 2008), Itacoatiara; Mato Grosso, Reserva Ecológica Cristalino (MVZ 197575), Serra da Chapada, Utiariti; Pará, Baião, Cameté (type locality of *Proechimys guyannensis leioprimna* Moojen), Fazenda Paraíso (Moojen 1948), Itaituba, Óbidos (Moojen 1948), Project Pinkiati Research Station, Kayapo Indigenous Reserve (MVZ 199560), Vilarinho do Monte.

SUBSPECIES: Both Moojen (1948) and Cabrera (1961) listed *steerei* Goldman as a valid subspecies, along with the nominotypical form. We treat *steerei* as a separate species, following Patton et al. (2000). However, the several species-level names we list above as synonyms of *P. goeldii* may warrant formal recognition when appropriate analyses of geographic variation in morphological as well as molecular characters are undertaken.

NATURAL HISTORY: This species has not been studied in the field. Moojen (1948) stated that the holotype of his *leioprimna*, from the Rio Tocantins, was collected in seasonally flooded forest, which is consistent with the general habitat range of the two other species in the group. Moojen (1948) also recorded pregnant females in January for samples collected on the Rio Tapajós (*hyleae* Moojen) and Tocantins (*leioprimna* Moojen). *Proechimys goeldii* may be sympatric with two other species of spiny rats, commonly with *P. roberti* (of the *guyannensis*-group) and less commonly with *P. cuvieri* (of the *longicaudatus*-group).

REMARKS: Thomas (1920f:277) referred specimens from Manacaparu, west of Manaus, and Acajutuba, near Manaus, to *P. goeldii*. These are, however, most likely *P. steerei*, as both localities are within the known distribution of this species, which extends north of the Rio Solimões into the Imerí region between that river and the Rio Negro (see Patton et al. 2000, and the account for *P. steerei*). Moreover, the specimens to which Thomas referred (in

the British Museum and American Museum collections) have the four folds that characterize the cheek teeth of *P. steerei*. Moojen (1948:341–342) also listed specimens from Manaus as *P. goeldii*, but Patton et al. (2000) allocated all specimens from the left bank of the lower Rio Negro to *P. quadruplicatus* based on DNA sequence analyses.

Osgood (1944:199) suggested that *P. goeldii* was a synonym of *P. oris* (= *P. roberti* herein), which he also thought indistinguishable from *P. cayennensis* (= *P. guyannensis*). We agree that *P. oris* shares characters with *P. guyannensis*, and for that reason Patton (1987) placed it within his *guyannensis*-group. However, both *P. oris* (= *P. roberti* herein) and *P. goeldii* are broadly sympatric throughout eastern Amazonia, are readily separable by a number of external and craniodental traits (Patton 1987), and share no close phyletic relationship (R. N. Leite and J. L. Patton, unpubl. DNA sequence data).

Moojen (1948:340) considered *P. goeldii* and *P. steerei* “clearly related,” so much so that he included the latter as a subspecies of the former, an opinion followed by Cabrera (1961). While these two species are related, phylogenetic relationships based on mtDNA place *P. goeldii* as a basal node to the sister-species pair of *P. steerei* and *P. quadruplicatus* (Patton et al. 2000).

T. Machado et al. (2005) described and illustrated a karyotype with $2n=15$, FN=16, for a specimen from Juruena, Mato Grosso, Brazil (MZUSP 31924), which they identified as “*Proechimys* gr. *goeldii*.” From their description of craniodental morphology, this specimen clearly belongs to the *goeldii*-group and is most likely assignable

Map 521 Selected localities for *Proechimys goeldii* (●).

to *P. goeldii*, as currently understood, based on specimens that J. L. Patton examined from other localities in Mato Grosso. However, specimens from the Rio Xingu have a quite different karyotype of $2n=24$, $FN=44$ (L. H. Emmons, unpubl. data). Available data from mtDNA sequences (R. N. Leite and J. L. Patton, unpubl. data; R. do V. Vilela 2005; Schetino 2008) also suggest two well-defined clades within *P. goeldii*, one of which occurs through eastern Amazonia in an area encompassing the type localities of *goeldii* Thomas, *hyleae* Moojen, *nesiotes* Moojen, and *leioprimum* Moojen. The second clade is known from Mato Grosso state and two additional localities in the middle to upper Rio Madeira in Amazonas and Rondônia states. The likelihood, therefore, is that each clade maps to the different karyotypes described herein. Should these two clades be recognized as separate species based on future studies, there is no name currently available for the Mato Grosso clade.

Proechimys quadruplicatus Hershkovitz, 1948

Napo Spiny Rat

SYNONYMS:

Proechimys quadruplicatus Hershkovitz, 1948a:138; type locality "Llunchi, an island in the Río Napo, about 18 kilometers below the mouth of the Río Coca, [Orellano,] eastern Ecuador."

Proechimys semispinosus amphichoricus Moojen, 1948:344; type locality "Mount Duida, Esmeralda, Amazonas, Venezuela; altitude 325 m."

DESCRIPTION: So similar in external and cranial characters to *P. steerei* that, at least until adequate analyses of morphological characters are made, identification may rest solely on either chromosomes or molecules or on general geographic ranges (Patton 1987; Patton et al. 2000).

Size among largest in genus, with adult weights averaging 450–500 g, head and body length about 211–295 mm, hindfoot length 48–64 mm, ear length 20–28. Tail proportionately short (length 125–202 mm), approximately 70% of head and body length. Overall color ochraceous-orange, darkening along midline from head to rump. Venter may be pure white or lightly washed pale buff; pale thigh stripe extends across ankle onto hindfoot; dorsal surfaces of hindfeet characteristically bicolored, with outside dark longitudinal band encompassing digits IV and V contrasted with pale inner band encompassing at least digits I and II, and usually III. Tail weakly bicolored, appearing nearly naked as scales large and conspicuous, eight annuli per cm at midpoint. Dorsal pelage stiff to touch, with well-developed aristiform spines about 20 mm long and 1.0 mm wide, terminated by weakly developed whip-like tip; distal one-third black, which gives the overall darkened tone to midline of back and rump; spines most well developed on midback, less so on shoulder or over rump.

Skull large (greatest skull length 51.7–70.4 mm) and elongate with long rostrum and heavy supraorbital ridges that extend posteriorly onto parietals as distinct ridges, especially in older individuals. Incisive foramina vary from weakly lyre-shaped to oval, with lateral margins tapering slightly posteriorly or parallel sided; premaxillary portion of septum short, usually one-half or less length of foramen; maxillary portion varies greatly, typically weak and attenuate, often not in contact with premaxillary portion but sometimes broadly spatulated and filling much of opening; maxillary portion may be slightly ridged but never keeled; only rarely does ridge extend posteriorly to form moderately developed grooves on anterior palate. Posterolateral margins of foramen moderately flanged. Specimens for which Patton (1987:324, Fig. 15) illustrated incisive foramina and called *P. steerei* are actually *P. quadruplicatus* as now understood. Moderately developed groove present on floor of infraorbital foramen, although development varies among individuals. Mesopterygoid fossa narrower than either *P. goeldii* or *P. steerei*, with angle averaging 61°, and extends anteriorly to middle of M3s. Counterfold number varies slightly, but characteristic four folds upon which Hershkovitz based his name *quadruplicatus* is most common condition; pattern is 4(3)–4(3)–4(3)–4(3)/4–3(4)–3(4)–3 for samples from Colombia, Ecuador, and northern, but 3–3–3–3/3–3–3–3 in half of specimens examined from Venezuela and northern Brazil (including holotype of *amphichoricus* Moojen).

Baculum comparatively short and stout (sample mean length 7.11–8.28 mm, proximal width 2.45–2.87 mm, distal width 2.46–3.02 mm), with nearly straight sides and only slightly flared apical wings and expanded base, similar to those of *P. goeldii* and *P. steerei*. Of the nine specimens of the "goeldii-group" figured by Patton (1987), those of Figure 6a–d and f–g are *P. quadruplicatus* as this species is currently understood; others in figure either of *P. goeldii* or *P. steerei* (see those accounts). As with *P. steerei*, phallus remarkably small for body size, especially in comparison to those of other, smaller species (M. N. F. da Silva 1998).

DISTRIBUTION: *Proechimys quadruplicatus* occurs throughout the northwestern Amazon Basin essentially north of the Río Marañón–Rio Solimões axis, in northern Peru, eastern Ecuador, southern Colombia, southern Venezuela, and northern Brazil on the left (= north and east) bank of the Rio Negro to its mouth near Manaus. This species is replaced to the south by the morphologically and ecologically similar *P. steerei* (see account of that species).

SELECTED LOCALITIES (Map 522): BRAZIL: Amazonas, Arquipélago da Anavilhanas (Patton et al. 2000), Lago Meduinim (Patton et al. 2000), Manaus (Moojen 1948), Tahuapunta (= Tausa) (Patton 1987). COLOMBIA: Caquetá, Manganite (Patton 1987). ECUADOR: Napo,

Llunchi (type locality, Hershkovitz 1948a); Orellana, San José de Pay amino (MVZ 170291). PERU: Amazonas, La Poza (Patton et al. 2000); Loreto, El Chino (MVZ 198518), Peas (Patton 1987), Río Tigre (FMNH 123013). VENEZUELA: Amazonas, Boca del Río Orinoco (AMNH 78031), Neblina base camp (USNM 560667), 18 km SSE of Puerto Ayacucho (Patton 1987), San Carlos de Río Negro (Patton et al. 2000).

SUBSPECIES: We treat *Proechimys quadruplicatus* as monotypic, but adequate comparisons between western samples of the nominotypical form and *amphichoricus* Moojen have not as yet been made.

NATURAL HISTORY: As is true of *P. steerei*, *P. quadruplicatus* is most commonly found in seasonally flooded forest during the dry season, or along the margins of seasonally wet habitats during the flood season, in both black-water and whitewater river systems, although this species may also be locally common in *terra firme* forest. Hice and Velazco (2012) recorded pregnant or lactating females in most months from January through at least September, and suggested that breeding was year-round. Litter size averaged 2.5 (range: 1–4). In northern Peru and eastern Ecuador, it may be found sympatric with *P. brevicauda*, *P. cuvieri*, and *P. simonsi* (Hershkovitz 1948a; Patton et al. 1982; Hice and Velazco 2012).

REMARKS: The combination of large size, stiff pelage, bicolored hindfeet, and four folds on most cheek teeth

make this one of the most readily recognizable species of spiny rats in the northwestern Amazon Basin. In comparison to other species, *P. quadruplicatus* is remarkable for uniformity in, and with low levels of, molecular diversification across the known range (Patton et al. 2000; Matocq et al. 2000). Both *quadruplicatus* Hershkovitz and *amphichoricus* Moojen were published in the same year, but as noted by Patton et al. (2000), Hershkovitz's paper appeared earlier and thus has date of publication priority. Minor geographic variation in karyotype has been recorded, with $2n$ varying from 26 (southern Venezuela) to 28 (Ecuador, Peru, and Brazil) and FN ranging from 42–44 (Reig and Useche 1976; A. L. Gardner and Emmons 1984; Patton et al. 2000; Bonvicino, Otazu, and Vilela 2005).

Specimens in the Field Museum of Natural History from Gualaquiza, Río Santiago, Ecuador, referred to as *P. semispinosus* (Tomes) by Osgood (1944:200–201), are *P. quadruplicatus*. Osgood's misidentification probably stemmed from the confusion regarding the type locality of Tomes's rat (see A. L. Gardner 1983a), as both species share similarly complex occlusal patterns.

Proechimys steerei Goldman, 1911

Steere's Spiny Rat

SYNONYMS:

Proechimys steerei Goldman, 1911a:238; type locality "Río Purus, a southern tributary of the Amazon, in northwestern [Amazonas] Brazil," amended to "Hyutánahan [= Huitanaã], a small village of rubber gatherers, on the north side of the Río Purus, in the upper part of its course" (Goldman 1912d).

Proechimys kermi J. A. Allen, 1915b:629; type locality "Lower Río Solimões," amended to "Lower Río Solimões (up the Solimões 50 to 60 miles on the north bank of the river), Manacapará, Amazonas, Brazil" (Moojen 1948:345).

Proechimys pachita Thomas, 1923b:694; type locality "Puerto Leguia, 2000', Río Pachitea," Huánuco, Peru.

Proechimys hilda Thomas, 1924c:534; type locality "San Lorenzo. Alt. 500'. Marañon, just above the mouth of the Huallaga," Loreto, Peru.

Proechimys rattinus Thomas, 1926g:164; type locality "Ucayale, Tushemo, Masisea, 1000'," Ucayali, Peru.

Proechimys [(*Proechimys*)] *cayennensis pachita*: Ellerman, 1940:121; name combination.

Proechimys [(*Proechimys*)] *cayennensis hilda*: Ellerman, 1940:121; name combination.

[*Proechimys guyannensis*] *steerei*: Hershkovitz, 1948a:133; name combination.

[*Proechimys guyannensis*] *hilda*: Hershkovitz, 1948a:133; name combination.

Map 522 Selected localities for *Proechimys quadruplicatus* (○) and *Proechimys steerei* (●). Contour line = 2,000m.

[*Proechimys guyannensis*] *kermiti*: Hershkovitz, 1948a: 133; name combination.

[*Proechimys guyannensis*] *pachita*: Hershkovitz, 1948a: 138; name combination.

Proechimys goeldii steerei: Moojen, 1948:338; name combination.

[*Proechimys longicaudatus*] *pachita*: Moojen, 1948:316; name combination.

[*Proechimys longicaudatus*] *rattinus*: Moojen, 1948:316; name combination.

[*Proechimys semispinosus*] *hilda*: Moojen, 1948:316; name combination.

Proechimys semispinosus liminalis Moojen, 1948:343; type locality "Rio Quichito, affluent from the south of the Javari River, near Benjamin Constant, Benjamin Constant, Amazonas, Brazil."

Proechimys semispinosus kermiti: Moojen, 1948:345; name combination.

DESCRIPTION: Large, average mass 450g, with some individuals exceeding 800g. Head and body length 215–493 mm; hindfeet (length 49–63 mm) and ears large (length 20–26 mm); tail proportionately short (120–207 mm; 70% of head and body length). Dorsal color light reddish brown, only faintly streaked with darker hairs; most individuals lack dark midback characteristic of *P. quadruplicatus*. Venter pure white, and texture of ventral fur thicker and more velvety both to eye and touch than in other species. Aristiforms of dorsum distinctly long (about 15 mm), narrow (about 0.5 mm), delicate, soft to touch, with whip-like tip; pelage markedly softer than other sympatric species in the genus, including other *goeldii*-group members. Tail bicolored with dark above and pale below, and clothed in fine hairs but with scales conspicuous to eye; 7–8 scale annuli per cm. The color of dorsal surface of the hindfoot distinctly bicolored, with pale to dark brown outer band and whitish inner band along length, from tarsal joint to end of toes.

Skull large (condyloincisive length 41.0–55.4 mm), but smaller than other members of group; rostrum long and narrow (mean length 24.03 mm, mean width 8.73 mm); supraorbital ledge that extends onto parietals as weakly developed ridge well developed. Incisive foramina lyrate to oval in outline, with slightly to strongly flanged posterolateral margins that form grooves extending onto anterior palate; premaxillary portion of septum short, less than half length of opening, maxillary portion distinctly narrow, and both in contact in most specimens; vomer usually not visible. Groove present on floor of infraorbital foramen, but lateral flange is only weakly developed. Mesopterygoid fossa relatively broad (angle averaging 67°), but penetrates to midpoint of M3s. Counterfold number varies in upper teeth, but is constant in lowers; pattern 3(4)–3(4)–3(4)–4(3)/4–3–3–3.

Baculum comparatively short and moderately wide (sample mean length 7.11–8.67 mm, proximal width 2.45–2.93 mm, distal width 2.46–3.11 mm), with parallel or slightly concave sides, similar in size and shape to those of *P. quadruplicatus* and *P. goeldii*. Male phallus remarkably small, particularly in comparison to body size, with prepuce extended as narrow tube and terminated by characteristic tuft of hairs, rather than rounded and blunt as in most *Proechimys* phalli.

DISTRIBUTION: *Proechimys steerei* is known from eastern and southern Peru south of the Río Marañón–Río Amazonas, northwestern Bolivia, and western Brazil south of the Rio Solimões to at least the Rio Purus, but extending north of the Rio Solimões into the Imerí region south and west of the lower Rio Negro (Patton et al. 2000:250, Fig. 153). It is unclear if specimens from the lower Rio Madeira are of this species or represent *P. goeldii*.

SELECTED LOCALITIES (Map 522): **BOLIVIA:** Beni, Río Mamoré, 17 km NNW Nuevo Berlín (S. Anderson 1997, as *Proechimys hilda*); La Paz, Río Madidi, Moira camp (Patton et al. 2000). **BRAZIL:** Amazonas, Huitanaã (type locality of *Proechimys steerei* Goldman), Ilha Paxiuba (Patton et al. 2000), right bank Rio Jaú above mouth (Patton et al. 2000), Rio Quichito (type locality of *Proechimys semispinosus liminalis* Moojen), mouth of Rio Solimões, near Manacapará (type locality of *Proechimys kermiti* J. A. Allen), Tambor (Patton et al. 2000); Rondônia, Pista Nova (Patton 1987). **PERU:** Loreto, Orosa (Patton 1987), San Lorenzo (type locality *Proechimys hilda* Thomas), Loreto, Santa Elena (Patton 1987), Yurimaguas (Patton 1987); Madre de Dios, Albergue Cusco Amazónico (Patton et al. 2000), Itahuanía (Patton 1987); Ucayali, Cumaria (Patton 1987), Tushemo (type locality of *Proechimys rattinus* Thomas), Yarinacocha (Patton and Gardner 1972).

SUBSPECIES: By current understanding, *Proechimys steerei* is monotypic. The various synonyms listed above generally belie a rather fairly uniform character variation among populations of this species, although samples from that portion of the central Brazilian Amazon between the lower Rio Negro and Rio Solimões are sharply distinct from the remainder of the species range south of the Marañón–Solimões axis in western Brazil and northeastern Peru in mtDNA sequences (see Remarks).

NATURAL HISTORY: This species prefers the seasonally flooded white-water (*várzea*) or black-water (*igapó*) forests, where it is typically the only spiny rat present. It also occurs in secondary and disturbed *terra firme* forests where water or moist areas are nearby, active and abandoned gardens, and riverine or margins of flooded grasslands within the forest. Breeding apparently takes place throughout the year in western Brazil, females begin to

breed before they have molted into their adult pelage, and modal litter size is three, with a range from one to seven young (Patton et al. 2000). These reproductive characteristics suggest a more r-selected life history, one adapted for living in seasonally available habitats. Emmons (1982) examined the population ecology of *P. steerei* (she used the name *P. brevicauda* for this species, following Patton and Gardner 1972) and sympatric *P. simonsi* in southern Peru, including nightly movement pattern, seasonal home range, diet, and density. A notable finding was that both species feed on sporocarps of mycorrhizal fungi, potentially a pivotal ecological service (Emmons 1982; Janos et al. 1995).

Matocq et al. (2000) described molecular population genetic structure in relation to riverine barriers and habitat range in western Brazil, contrasting those patterns with the codistributed *P. simonsi*. And, E. P. Lessa et al. (2003) provided estimates of late and post-Pleistocene population expansion and stability based on coalescence analysis of molecular sequence data.

REMARKS: Thomas (1926g:164) considered *rattinus* close to *P. hendeei* (= *P. simonsi*) in both pelage and cranial characters. Osgood (1944:202) also thought that *rattinus* Thomas might be a “lowland race or phase of *hendeei*.” The holotype of *rattinus* Thomas is an adult, represented by a skull but not a skin; its cranial features are clearly those of *P. steerei*, not *P. simonsi* (= *P. hendeei*); see Patton (1987). Hershkovitz (1948a) noted that Thomas’s description of *rattinus* was based on the skull of an adult female (designated as the type, BM 24.2.22.16) and the skin of an immature female (BM 24.2.22.18). He argued that the skull was referable to *guyannensis*, which is clearly wrong, and that the skin “agrees closely with that of the type of *P. hendeei*” (= *P. simonsi*). However, the skin to which Hershkovitz referred has a gray throat patch, which is not typical of *simonsi*, although a note on the label reads: “the only skin of a dozen with belly other than wholly white.” One of us (JLP) has examined all specimens of spiny rats in the BM collection; each of those from the type locality of *rattinus* (including the holotype skull) are *P. steerei*.

Thomas (1927f) assigned specimens from Tingo Maria and Chinchavita, Huánuco, Peru to his *Proechimys pachita* (which we treat herein as a synonym of *P. steerei*); the entire series in the British Museum from both localities, however, are specimens of *P. brevicauda* Günther (see account of that species). Osgood (1944:202) also considered *pachita* Thomas a synonym of *P. simonsi*, noting that it differed primarily by “having a longer palatal foramina.” Thomas’s holotype, however, clearly displays the incisive foramina and other characters of *P. steerei* and not *P. simonsi*, as described and defined by Patton (1987).

Moojen’s *liminalis* can be assigned as a junior synonym to either *P. steerei* Goldman or *P. quadruplicatus* Hershkovitz based on Moojen’s (1948:343) description of the structure and shape of the incisive foramina, the vomerine sheath, as well as the four counterfolds on both M2 and M3. However, because these two species appear separated south and north, respectively, of the Marañón–Amazonas–Solimões axis, and the type locality of *liminalis* is on the south side, we assign the name to *P. steerei*. Should this prove incorrect, *liminalis* Moojen would become a junior synonym of *quadruplicatus* Hershkovitz, which has date of publication priority in 1948.

Proechimys steerei comprises two sharply divergent mtDNA clades (Patton et al. 2000), one limited to the Imerí region sandwiched between the Rio Solimões on the south and Rio Negro on the north and east, and the other south of the Rio Marañón–Rio Solimões axis in western Brazil, Peru, and Bolivia. Should these two clades be recognized in the future as separate taxa, then J. A. Allen’s *kermiti*, with its type locality near Manacapará on the north bank of the Rio Solimões, would be an available name for the clade in the Imerí region.

Karyotypic variation is minimal geographically, with multiple samples available to represent both mtDNA clades. All individuals for which voucher specimens have been examined by J. L. Patton as assignable to *P. steerei* have a karyotype with $2n=24$ and $FN=40-42$ (Patton and Gardner 1972; A. L. Gardner and Emmons 1984; Patton et al. 2000; M. N. F. da Silva and J. L. Patton, unpubl. data). N. A. B. Ribeiro (2006) also described a karyotype of $2n=24$, $FN=42$, from specimens from Pauini, Amazonas, Brazil, which he ascribed to *P. steerei*. We have not examined these. Patton et al. (2000) described a non-Robertsonian polymorphism in one pair of banded autosomes in samples from the Rio Juruá in western Brazil.

Proechimys guyannensis species group

We list two species in this complex, which is distributed mostly in eastern Amazonia, from east of the Rio Negro, including the Guianan region, and extending south into central Brazil. One species, *P. guyanensis*, occurs north of the Amazon, the other, *P. roberti*, occurs only to the south of this river. Both species, however, exhibit phylogeographic structure in mtDNA sequences (Weksler et al. 2001; Steiner et al. 2000; L. P. Costa, Y. L. R. Leite, and R. N. Leite, unpubl. data). Moreover, what we refer to here as *P. guyannensis* is also composed of multiple karyotypic forms (Reig and Useche 1976; Petter 1978; Weksler et al. 2001; Bonvicino, Otazu, and Vilela 2005; T. Machado et al. 2005). Both of these “species” thus may prove to be composite. Because there are multiple names already available but currently listed only as synonyms, the challenge

for future investigators will be to tie molecular clades and/or karyotypes directly to these names. Given that multiple species of spiny rats can co-occur at single sites, it is not sufficient to simply obtain “topotypes” for name application, as acknowledged by Hershkovitz (1948a) nearly 60 years ago; care must be taken to compare karyotyped or sequenced voucher specimens with holotypes.

KEY TO THE SPECIES OF THE *PROECHIMYS GUYANNENSIS* SPECIES GROUP:

1. Distributed north of the Rio Amazonas largely in the Guianan subregion; tail long, $\geq 77\%$ of head and body length; tail scales small with 11–14 annuli per cm; mid-dorsal aristiforms stout (0.9–1.0 mm in width); mesopterygoid fossa narrow (angle $< 58^\circ$), penetrating to the level of M2s *Proechimys guyannensis*
- 1'. Distributed south of the Rio Amazonas in eastern and central Brazil; tail short, $\leq 70\%$ of head and body length; tail scales large with 9–10 annuli per cm; mid-dorsal aristiforms narrow (0.6–0.8 mm); mesopterygoid fossa moderately wide (angle $> 64^\circ$), penetrating only to level of M3s *Proechimys roberti*

Proechimys guyannensis (É. Geoffroy St.-Hilaire, 1803)

Guyenne Spiny Rat

SYNONYMS:

- Mus guyannensis* É. Geoffroy St.-Hilaire, 1803:194; type locality “Cayenne,” French Guiana.
- Echymys cayennensis* Desmarest, 1817b:58; a redescription of *Mus guyannensis* É. Geoffroy St.-Hilaire.
- echymis cayennensis*: Desmarest 1822:292; inadvertent lapsus.
- E[chinomys]. cayennensis*: Wagner, 1843a:341; name combination.
- Proechimys cayennensis*: J. A. Allen, 1899c:264; name combination.
- Echymys cherriei* Thomas, 1899d:382; type locality “Munduapo [= Monduapo, Paynter 1982], Upper Orinoco,” on the right bank of the upper Río Orinoco at 4°45'N, 67°48'W, Amazonas, Venezuela.
- [*Proechimys*] *cherriei*: J. A. Allen, 1899c:264; name combination.
- Proechimys vacillator* Thomas, 1903b:490; type locality “Kanuku Mountains, British Guiana. Altitude 600 feet,” Upper Takutu–Upper Essequibo, Guyana.
- Proechimys warreni* Thomas, 1905b:312; type locality “Comackka, 80 miles up the Demerara River, British Guiana. Alt. 50 feet,” Upper Demerara-Berbice, Guyana.
- Proechimys* [(*Proechimys*)] *cayennensis cherriei*: Ellerman, 1940:121; name combination.
- Proechimys* [(*Proechimys*)] *cayennensis warreni*: Ellerman, 1940:121; name combination.

[*Proechimys guyannensis*] *cherriei*: Moojen, 1948:316; name combination.

[*Proechimys guyannensis*] *vacillator*: Moojen, 1948:316; name combination.

[*Proechimys guyannensis*] *warreni*: Moojen, 1948:316; name combination.

Proechimys guyannensis: Moojen, 1948:355; first use of current name combination.

Proechimys guyannensis riparum Moojen, 1948:367; type locality “Manaus, Manaus, Amazonas, Brazil.”

Proechimys guyannensis arabupu Moojen, 1948:369; type locality “Arabupu, Mount Roraima, Boa Vista, Territ. Rio Branco; about 1540 meters altitude,” Roraima, Brazil. [Moojen’s designation of the type locality in Brazil is in error; Arabupu [=Arabopó] is on the Río Arabopó, Bolívar, Venezuela; Paynter 1982.]

Proechimys canicollis vacillator: Cabrera, 1961:518; name combination.

DESCRIPTION: Moderate-sized spiny rat, with head and body length 180–230 mm (Moojen 1948; Catzeflis and Steiner 2000; Voss et al. 2001). Tail proportionately long (length 110–186 mm; 77–87% of head and body length (Catzeflis and Steiner 2000; Voss et al. 2001). Samples across northern Guianan region light reddish to yellowish brown lined with black along midback, distinctly paler on lower sides, but abruptly meeting pure white venter from chin to inguinal region. White inner thigh stripes typically continuous across ankle to dorsal surface of hindfoot, which is typically light colored with only slight brown patch on tarsus below digit I; all digits generally white. Plantar pads on hindfeet only moderately developed, but both thenar and hypothenar present and subequal in size. Tail sharply bicolored, light brown above and cream below; hairs on tail sparsely distributed and very short such that tail appears completely naked from distance; scales small and annuli consequently narrow (11–14 per cm at midpoint). Pelage stiff to touch, particular along midback, with aristiform spines rather short (length 16–19 mm) and stout (with 0.9–1.0 mm); tip either blunt or terminates with very short filament.

Skull like other species in general shape, but because of moderate body size, appears small (condyloincisive length 37.3–47.6 mm; Voss et al. 2001; Weksler et al. 2001) and rather delicate, lacking heavy ridging that may be present in skulls of larger species. Consequently, temporal ridges generally poorly developed, if at all, and maximally just a short and weak posterior extension from supraorbital ledges. Incisive foramina oval or teardrop in shape, with either no or only weakly developed posterolateral flanges so that anterior palate typically flat or only very slightly grooved; premaxillary portion of septum short, occupying less than half opening, and usually not in contact with

very attenuate maxillary portion; maxillary part short and unkeeled; anterior palate lacks medial ridging; vomerine portion to septum typically not visible in ventral view. Foraminal shape and structure similar to that of *P. roberti*, described below, and also similar to *P. simonsi*. Floor of infraorbital foramen either lack evidence of groove or have moderately developed lateral flange that forms groove for passage of the maxillary nerve. Width of mesopterygoid fossa ranges widely among geographic samples, but generally narrow with angle $<58^\circ$. Nevertheless, fossa penetrates to level of posterior half of M2s in nearly all specimens. Postorbital process of zygoma obsolete or only weakly developed, formed entirely by squamosal. Number of folds on upper cheek teeth relatively constant, with three characterizing PM4, M1, and M2, and either three or, more commonly, two present on M3; lower cheek teeth more variable, pm4 with three folds and m1–m3 typically only two, but occasionally three; counterfold pattern 3–3–3–(2)3/3–2(3)–2(3)–2(3). In comparison with sympatric *P. cuvieri*, the cheek teeth of *P. guyannensis* also notably small in size, with toothrow ≤ 8.0 mm in length (Voss et al. 2001).

Baculum relatively long and narrow (mean sample length 6.38–8.87 mm, proximal width 1.87–2.29 mm, distal width 1.99–2.38 mm); shaft straight with little dorsoventral curvature and only slightly tapered lateral indentations near midshaft, proximal end usually evenly rounded and paddle shaped, and distal tip with only slight development of apical wings and moderate median depression (Patton 1987).

DISTRIBUTION: *Proechimys guyannensis* is an Amazonian endemic largely confined in the Guiana subregion of eastern and southern Venezuela, Guyana, Surinam, French Guiana, and Brazil north and east of the Rio Negro and north of the Rio Amazonas (Patton 1987; Weksler et al. 2001; Voss et al. 2001:163).

SELECTED LOCALITIES (Map 523): BRAZIL: Amapá, Serra do Navio (Patton 1987); Amazonas, Faro (Patton 1987), Igarapé Araújo (Bonvicino, Otazu, and Vilela 2005, as “sp. A”), Manaus (type locality of *Proechimys guyannensis riparum* Moojen), São Gabriel da Cachoeira (INPA [JPB 0]). FRENCH GUIANA: Cayenne (type locality of *Mus guyannensis* É. Geoffroy St.-Hilaire). GUYANA: Demerara-Mahaica, Loo Creek (ROM 98216). SURINAM: Surinam, Santa Boma (Husson, 1978). VENEZUELA: Amazonas, Capibara (Patton 1987), Monduapo (type locality of *Echimyus cherriei* Thomas), Neblina base camp (USNM 560675), Pozon (ROM 107892); Bolívar, Arabupu [= Arabopó] (type locality of *Proechimys guyannensis arabupu* Moojen), 3 km E of Puerto Cabello del Caura (ROM 107944).

SUBSPECIES: We treat *P. guyannensis* as monotypic. The lack of an adequate review of any character set for

available specimens precludes the delineation of geographic units that might warrant recognition, despite the plethora of names listed in the synonymy. This is a highly variable species, however, and likely polytypic (see comments above and Remarks).

NATURAL HISTORY: At Paracou in French Guiana, Voss et al. (2001) caught this species mostly in well-drained forest but also occasionally in creekside forest, and significantly more commonly in primary forest than its sympatric congener *P. cuvieri*. All but two specimens were collected on the ground; those that were not came from traps placed 0.5–1.5 m above ground in liana tangles. Spiny rats are important seed predators and dispersers of tropical forest trees in French Guiana (Forget 1991, 1996), although field ecological studies have been hampered by the difficulty in distinguishing sympatric species (Malcolm 1992). Consequently, the several published studies in French Guiana, or elsewhere in the Guianan region and northeastern Amazonian Brazil, probably include data on *P. guyannensis*, but were unable to differentiate this species from sympatric *P. cuvieri*.

REMARKS: Woods (1993:795) used *cayennensis* Desmarest as the name for this species, following the argument of Wilson and Reeder (1993:831) that É. Geoffroy St.-Hilaire’s 1803 publication did not meet the requirements of the International Code of Zoological Nomenclature and thus that his names were unavailable. However, the International Commission (ICZN 2002:Opinion 2005) subsequently validated É. Geoffroy St.-Hilaire, 1803, an action that makes *cayennensis* Desmarest a junior synonym of *guyannensis* É. Geoffroy St.-Hilaire.

As noted by Voss et al. (2001), Husson (1978) used the name *P. warreni* to refer to this species in his book on Surinam mammals, and applied *P. guyannensis* incorrectly to the larger-bodied species that has been identified by subsequent authors as *P. cuvieri*.

Patton (1987) incorrectly mapped the type locality of *cherriei* Thomas in the lower, instead of upper, Orinoco basin (see Voss et al. 2001).

Proechimys guyannensis, as defined here, is most likely composite given the extensive karyotype diversity described in the literature and the limited DNA sequence data available (Weksler et al. 2001; Bonvicino, Otazu, and Vilela 2005). Reig, Tranier, and Barros (1980) described a karyotype of $2n=40$, FN=54, from the type locality (Cayenne, French Guiana). T. Machado et al. (2005) reported a karyotype of $2n=44$, FN=52, from a specimen from Manaus, in Amazonas state, Brazil, which probably represents *P. guyannensis*, as L. H. Emmons (unpubl. data) obtained the same karyotype from a specimen assignable to this species on morphological grounds and taken at 80 km N of Manaus (USNM 555638). Furthermore, Bonvicino, Otazu, and Vilela (2005) reported two

different karyotypes for specimens that belong to *P. guyannensis* (*sensu lato*), what they called “*Proechimys* sp. A,” with $2n=38$ and FN=52 (in the upper Rio Negro–Rio Aracá in Amazonas state, Brazil), and “*Proechimys* sp. B,” with $2n=46$, FN=50 (from the Rio Anauá, a tributary of the Rio Branco in Roraima state; the same karyotype obtained from the Rio Uatumã, in Amazonas state by C. E. F. Silva et al. 2012). They suggested that each karyotypic form represented a different species, and further suggested that *arabupu* Moojen was the correct name to apply to their “sp. B” because its type locality is close to the locality of their specimen. However, the holotype of *arabupu* (AMNH 75816) came from Arabopó in southeastern Venezuela at the base of Mt. Roraima (not in Brazil as Moojen 1948 stated), some 450 km to the north of the locality for “sp. B.” Moreover, there is a karyotype of $2n=40$, FN=50, for a specimen (MVZ 160094) collected near Icabarú, Bolívar, Venezuela, only 130 km west of the type locality of *arabupu* Moojen and with which it shares the same craniodental morphology. It is thus not possible to assign the name *arabupu* Moojen to the karyomorph Bonvicino, Otazu, and Vilela (2005) termed “sp. B” with any certainty. Eler et al. (2012) has also extended the distribution of the $2n=38$, FN=52, karyotype to the Rio Jari basin on the Amapá–Pará state boundary in eastern Amazonia, giving this chromosomal form an extensive range.

Map 523 Selected localities for *Proechimys guyannensis* (●) and *Proechimys roberti* (○). Contour line = 2,000m.

Clearly, care must be taken before applying an available name to a karyotypic form because different karyotypes do not always signal reproductive incompatibility within the genus (Aguilera, Reig, and Pérez-Zapata 1995; M. N. F. da Silva 1998). Moreover, an effort must be made to obtain karyotypes and molecular sequences from topotypes that have been compared directly to relevant holotypes or type series, as two or more species of spiny rats may co-occur at single sites throughout the range of the genus.

Van Vuuren et al. (2004) described molecular sequence variation among populations in French Guiana, noted low molecular diversity and the lack of haplotype structure within this limited geographic region, and suggested that the sampled region had undergone a recent population expansion.

Proechimys roberti Thomas, 1901

Robert's Spiny Rat

SYNONYMS:

Proechimys roberti Thomas, 1901g:531; type locality “Rio Jordão, S. W. Minas Geraes [*sic*], Alt. 960 meters,” Araguari, Minas Gerais, Brazil.

Proechimys oris Thomas, 1904e:195; type locality “Igarapé-Assu, near Pará. Alt. 50 m,” near Belém, Pará, Brazil (Moojen 1948:365).

Proechimys boimensis J. A. Allen, 1916c:523; type locality “Boim, Rio Tapajos,” Pará, Brazil.”

Proechimys [(*Proechimys*)] *cayennensis roberti*: Ellerman, 1940:121; name combination.

Proechimys [(*Proechimys*)] *cayennensis oris*: Ellerman, 1940:121; name combination.

Proechimys cayennensis arescens Osgood, 1944:198; type locality “Roca, near Fazenda Inhuma, below Santa Philomena [= Filomena], upper Rio Parnaíba [= Vitoria do Alto Parnaíba], Maranhão, Brazil” (Moojen 1948:366).

[*Proechimys guyannensis*] *boimensis*: Hershkovitz, 1948:128; name combination.

Proechimys longicaudatus boimensis: Moojen, 1948:350; name combination.

Proechimys longicaudatus roberti: Moojen, 1948:353; name combination.

Proechimys guyannensis oris: Moojen, 1948:365; name combination.

Proechimys guyannensis arescens: Moojen, 1948:366; name combination.

DESCRIPTION: Similar in size to *P. guyannensis*, with head and body length 200–230 mm, but tail distinctly shorter, both absolutely and proportionately (70% of head and body length). Dorsal color ranges from reddish brown in northern part of range in Amazonia proper to pale buff

in samples at southern terminus of range in dry and gallery forests of Cerrado, a difference in color that reinforced species status of *P. roberti* when Thomas (1904e) described *P. oris* a few years later. Venter white from chin to inguinal region, but white of inner thigh discontinuous, broken by dark ankle band, with pale surface of hindfeet; brownish patch extending from tarsus to the lateral toes in many specimens. Plantar pads of hindfoot moderately developed, both thenar and hypothenar present and subequal in size. As in *P. guyannensis*, tail very sparsely covered with short hairs so that it appears completely naked to the eye from a distance; scales large (9–10 annular rings per cm at midpoint). Pelage stiff to touch, but softer in southern samples; aristiform spines relatively short (length 20 mm) and narrow (width 0.6–0.8 mm), each terminating in long whip-like tip. Difference in softness of pelage between Amazonian and Cerrado specimens mostly in aristiform density, not to appreciable differences in width or other features.

Skull similar in all respects to that of *P. guyannensis*; medium-sized (mean condyloincisive length in five samples 40.8–43.6 mm; Weksler et al. 2001) but rather narrow and with narrowed, tapering rostrum. Slight temporal ridges extend posteriorly onto parietals from supraorbital ledge in older individuals, but most specimens lack ridges altogether. Incisive foramina cannot be distinguished from those of *P. guyannensis* in any feature; they are relatively wide, oval to teardrop in shape, with little or no posterolateral flange so that anterior palate is either flat or only weakly grooved; premaxillary portion of septum short, less than half opening, and either connected to very attenuate maxillary portion or separated entirely; maxillary portion unkeeled so that anterior palate lacks medial ridge; vomerine portion inconsistently visible ventrally. Floor of infraorbital foramen either flat or with only hint of groove formed by weakly developed lateral flange. Mesopterygoid fossa intermediate in width, with angle 64°–67°, and penetrating posterior palate to anterior half of M3s. Postorbital process of zygoma weakly to moderately developed, and formed completely by squamosal. Number of folds on upper cheek teeth three except M3, occasionally with two. Number of folds on lower teeth more variable, with three (or occasionally four) on pm4, and either two (usually) or three on each lower molar; counterfold count 3–3–3–(2)3/3(4)–2(3)–2(3)–2(3). As with other species of spiny rats whose populations span a range of forest types, southernmost samples of *P. roberti* in the drier Cerrado forests typically have simpler teeth, with higher proportion of individuals with only two folds on lower molars.

Baculum relatively short and narrow (sample mean length 5.43–6.08 mm, proximal width 1.74–2.27 mm, distal width 1.28–1.79 mm), with same general features as

P. guyannensis, except specimens from southern part of range tend to be smaller in length and width (Patton 1987).

DISTRIBUTION: *Proechimys roberti* occurs throughout the rainforest of Amazonian Brazil south of the Rio Amazonas and extends south to the Cerrado biome in east-central Brazil, in the states of Pará, Maranhão, Tocantins, Mato Grosso, Goiás, and Minas Gerais (Weksler et al. 2001).

SELECTED LOCALITIES (Map 523): BRAZIL: Goiás, Anápolis (Patton 1987), Fazenda Fiandeira (Weksler et al. 2001); Maranhão, Fazenda Lagoa Nova (Weksler et al. 2001); Mato Grosso, Gaúcho do Norte (T. Machado et al. 2005), Cláudia (T. Machado et al. 2005), Reserva Ecológica Cristalino (MVZ 197576); Minas Gerais, Rio Jordão (type locality of *Proechimys roberti* Thomas); Pará, 52 km SSW of Altamira, right bank Rio Xingu (Weksler et al. 2003), Belém (MVZ 196096), Boim, Rio Tapajós (type locality of *Proechimys boimensis* J. A. Allen), Curuá-Una (Weksler et al. 2001), Igarapé-Assú (type locality of *Proechimys oris* Thomas); Piauí, Estação Ecológica de Uruçuí-Una (T. Machado et al. 2005); Tocantins, Rio Santa Teresa (MVZ 197585).

SUBSPECIES: Populations in lowland Amazonian rainforest could be considered a subspecies (*P. r. oris*) separate from those in the semideciduous forests of the Cerrado (*P. r. roberti*), although the limited analyses available suggest clinal variation between these geographic and ecological extremes (Weksler et al. 2001).

NATURAL HISTORY: Neither the ecology nor life history of *P. roberti* has been studied extensively in the field, although Alho (1981) examined homing ability using radio telemetry in the Brazilian Cerrado. This species is sympatric with *P. goeldii* along the southern margins of the Rio Amazonas in eastern Brazil, and with *P. longicaudatus* in the dry forests of the Cerrado in central Brazil.

REMARKS: Thomas (1904e:196) suggested that his new species agreed “very closely with *P. oris* in its cranial characters, but differs by its paler and more uniformly buffy color, its fully haired under surface, and its much longer and softer fur, of which the spines form a less considerable proportion than usual.” The pelage characters, both color and spine development, are typical of populations of spiny rats that live in more open, drier forests in comparison with conspecific populations in denser, more humid forests. Weksler et al. (2001) reviewed geographic variation in both *P. roberti* and *P. oris* and concluded that the two belonged to the same taxon on morphological, karyotypic, and molecular grounds, a conclusion contrary to the more geographically limited morphometric study of Pessôa et al. (1990). Weksler et al. (2001) examined specimens that filled the large geographic hiatus between the ranges of the Amazonian lowland *P. oris* Thomas and the Cerrado isolate *P. roberti* Thomas, samples that documented clinal

rather than discordant variation in morphological characters across the north-to-south range encompassing both taxa, and thus reinforcing the conclusion of conspecificity. Molecular sequence data reported by Weksler et al. (2001) for specimens spanning this geographic range, from the mouth of the Amazon to south of Brasília, indicate only minor interpopulation differences (maximum sequence divergence 2.4%). However, specimens from Mato Grosso and Pará states, in the Tapajós-Xingu interfluvial region, not included in the Weksler et al. analyses, are somewhat different morphologically and twice as divergent in mtDNA sequence (R. do V. Vilela 2005; Schetino 2008; Y. L. R. Leite, L. P. Costa, and R. N. Leite, unpubl. data). Further analyses may warrant segregation of more than one species unit within what is considered as a single species (this account; Weksler et al. 2001).

A. L. Gardner and Emmons (1984), Leal-Mesquita (1991), Weksler et al. (2001), T. Machado et al. (2005), and N. A. B. Ribeiro (2006) described and figured the karyotype, as $2n=30$ and $FN=54-56$, noting limited regional differences in the number of small biarmed versus uniarmed autosomal pairs. Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

Proechimys longicaudatus species group

Patton (1987) included nine taxa within his concept of the *longicaudatus*-group, and suggested that at least two species were recognizable among them: *P. longicaudatus* Rengger, from the dry forests of southeastern Bolivia east across northern Paraguay to the Cerrado of central Brazil, and *P. brevicauda* Günther, from the lowland rainforest in northern Bolivia, eastern Peru, eastern Ecuador, southeastern Colombia, and western Amazonian Brazil. A. L. Gardner and Emmons (1984) had previously suggested that samples from northern Peru and eastern Ecuador might be separable from *P. brevicauda* as a third species, *P. gularis* Thomas, based on chromosomal differences. Although Patton (1987) did not include *P. cuvieri* Petter within his *longicaudatus*-group, available DNA sequence data suggest a relationship between this species and those members of the *longicaudatus*-group that he recognized (R. do V. Vilela 2005; Schetino 2008; R. N. Leite and J. L. Patton, unpubl. data). Because of this apparent phyletic coupling and the fact that each of these species shares a similar suite of craniodental features, we include *P. cuvieri* along with *P. longicaudatus* and *P. brevicauda* within the *longicaudatus*-group here. Common characters that uniquely unite this group of species include lyrate and strongly flanged incisive foramina, broad and long maxillary portion to the septum with the vomerine portion exposed, and deep grooves extending onto the anterior palate; a broad and relatively shallow mesopterygoid fossa;

a smooth floor to the infraorbital foramen; and a generally uniform three counterfolds on each cheektooth, with virtually never four folds on any upper tooth, but with two folds characterizing the lower posterior molars of a substantial portion of individual samples. All three share a wide baculum.

Two of these species (*P. brevicauda* and *P. cuvieri*) have been found in sympatry at several localities in the western Amazon (Patton et al. 2000), but the “test of sympatry” has not been established for *P. brevicauda* and *P. longicaudatus*. These two seem to grade from one to the other through the transition between the lowland rainforest of western Amazonia (*brevicauda*) to the dry forests of eastern Bolivia and central Brazil (*longicaudatus*). Whether these two are best treated as a single species that varies substantially over this transition area or as the two that we recognize herein must await further critical sampling. Regardless of the status of *brevicauda* and *longicaudatus*, however, the number of species in the group is likely much greater. The limited mtDNA sequence data synthesized in Patton et al. (2000) indicate well-defined geographic clades that differ by considerable levels of divergence within both *P. brevicauda* and *P. cuvieri*, and unpublished morphological and sequence data as well as published karyotypes (T. Machado et al. 2005; Eler et al. 2012) suggest the presence of an undescribed species in the middle and upper part of the Rio Madeira in western Brazil. Clearly, this is a group ripe for additional research.

KEY TO THE SPECIES OF THE *PROECHIMYS*

LONGICAUDATUS SPECIES GROUP:

1. Dorsal color dark, rich reddish brown; distributed in lowland rainforest of the Guianan region and Amazon Basin. 2
- 1'. Dorsal color pale, yellowish brown; distributed in the dry forests of eastern Bolivia, northern Paraguay, and central Brazil *Proechimys longicaudatus*
2. Ventral color always white; aristiform spines long, stout, and with a blunt tip; well-developed postorbital process of zygoma comprised mostly of squamosal; mesopterygoid fossa moderately wide (angle $<73^\circ$), penetrating to middle of M3s; baculum nearly as wide as long, with deep median depression and elongated apical extensions. *Proechimys cuvieri*
- 2'. Ventral color often brownish gray or reddish-buff; aristiform spines short and narrow with elongated tip; postorbital process of zygoma obsolete; mesopterygoid fossa broad (angle $>73^\circ$) and shallow, penetrating barely to posterior edge of M3s; baculum nearly twice as long as wide, with a shallow, or no, median depression and without apical extensions. *Proechimys brevicauda*

Proechimys breviceauda (Günther, 1876)

Short-tailed Spiny Rat

SYNONYMS:

Echimyus breviceauda Günther, 1876:748; type locality “Chamicuros, Huallaga river” (lectotype selected by Thomas, 1900f:301), Loreto, Peru.

Tricomys breviceauda: E.-L. Trouessart, 1904:504; name combination.

Proechimys bolivianus Thomas, 1901h:537; type locality “Mapiri, Upper Rio Beni, N.W. [La Paz,] Bolivia. Altitude 1000m.”

Proechimys securus Thomas, 1902b:140; type locality “Charuplaya, 1350–1400m,” Río Sécure, Cochabamba, Bolivia.

Proechimys gularis Thomas, 1911c:253; type locality “Canelos, Rio Bobonaza, Oriente of [= Pastaza] Ecuador. Alt. 2100’.”

Proechimys breviceauda: Ihering, 1904:422; first use of current name combination.

Proechimys breviceaudus securus: Osgood, 1916:209; name combination.

Proechimys [(*Proechimys*)] *cayennensis breviceauda*: Ellerman, 1940:120; name combination.

Proechimys [(*Proechimys*)] *cayennensis gularis*: Ellerman, 1940:120; name combination.

Proechimys [(*Proechimys*)] *cayennensis bolivianus*: Ellerman, 1940:121; name combination.

Proechimys [(*Proechimys*)] *cayennensis securus*: Ellerman, 1940:121; name combination.

Proechimys hendeei ellassopus Osgood, 1944:203; type locality “Santo Domingo, Rio Inambari, Puno, Peru. Altitude 6,000ft.”

Proechimys “*hendeei*” *ellassops* [sic]: Hershkovitz, 1948a:138; incorrect spelling of *ellassopus* Osgood.

P[*proechimys*]. *guyannensis gularis*: Hershkovitz, 1948a:138; name combination.

[*Proechimys guyannensis*] *breviceauda*: Hershkovitz, 1948a:138; name combination.

[*Proechimys guyannensis*] *bolivianus*: Moojen, 1948:316; name combination.

[*Proechimys longicaudatus*] *ellassopus*: Moojen, 1948:316; name combination.

Proechimys longicaudatus breviceauda: Moojen, 1948:349; name combination.

[*Proechimys longicaudatus*] *securus*: Moojen, 1948:316; name combination.

[*Proechimys semispinosus*] *gularis*: Moojen, 1948:316; name combination.

Proechimys guyannensis bolivianus: Cabrera, 1961:519; name combination.

Proechimys guyannensis gularis: Cabrera, 1961:520; name combination.

DESCRIPTION: Moderate sized, mean head and body length of samples from northern Peru and western Brazil 189–253 mm, tail length 137–167 mm, hind foot length 46–53 mm, and ear length 21–23 mm (Patton and Rogers 1983; Patton et al. 2000). Color of head, back, and rump reddish brown, but not as dark along the midline as in *P. cuvieri*, although overall tones lighten in samples in central Bolivia where range of *P. breviceauda* approaches that of *P. longicaudatus*. Fulvous lateral stripe characteristically separates darker dorsal pelage from paler venter; venter varying colored in different parts of geographic range, brownish or grayish in parts of eastern Ecuador (as in the named form *gularis* Thomas) or reddish-buff throughout most of northern and central Peru and western Brazil, and clear white in most individuals from southern Peru and Bolivia (Patton and Gardner 1972 [as *P. longicaudatus*]; Patton et al. 2000). Osgood (1914b:168) noted extensive variation in color and color pattern on venter in specimens from Yurimaguas in northern Peru, near type locality of Günther’s *breviceauda*, “which can scarcely be said to be exactly alike in any two individuals. Fulvous and white are distributed in varying proportions, in general occupying about equal areas of the under parts. The chin and throat with scarcely any exception are fulvous and likewise the sides of the belly. Sometimes the white is reduced to a small pectoral and an inguinal patch or it may cover practically the entire belly and run forward to the middle of the throat.” Fulvous lateral stripe continues across ankle to small paler patch at proximal base of metatarsal area on dorsal surface of hindfeet. Otherwise, upper surfaces of hindfeet, including all five toes, uniformly dark. Tail sparsely haired, much less so and with distinctly shorter hairs than that of *P. cuvieri*; scale annuli 9–10 per cm at midpoint. Dorsal pelage stiff to touch, but aristiform hairs less well developed than those of *P. cuvieri*; length 18–20 mm, width 0.6–0.8 mm; distinctly tapering tip present on all aristiforms.

Skull of *P. breviceauda* similar to other species in *longicaudatus*-group, moderate size (condyloincisive length 39.1–48.8 mm) with elongated but relatively broad rostrum. Temporal ridge moderately to weakly developed, often with anterior parietal portion separated from posterior lambdoidal portion. Incisive foramina typically strongly lyrate in shape, distally flanged so that anterior palate is deeply grooved with median ridge, and with complete and keeled septum. Postorbital process of zygoma nearly obsolete and fashioned predominantly by jugal. Mesopterygoid fossa shallow, generally only barely reaching posterior margins of M3s, and wide (angle 73°–80° among geographic samples). Floor of infraorbital foramen smooth, lacking groove indicative of infraorbital nerve. Counterfold

pattern of cheek teeth uniformly 3–3–3 above and 3(4)–(2)3–(2)3–(2)3 below. In rare individuals, upper M2 and M3 may have remnant fourth fold, and southern samples exhibit higher frequency of only two folds on m3.

Baculum massive, long and wide (sample mean length 7.79–11.67 mm, proximal width 3.72–5.11 mm, distal width 4.61–5.87 mm), with slight but broad apical wings and expanded base (Patton and Gardner 1972; Patton 1987; Patton et al. 2000). Massive size and length of baculum make phallus long and distinctly heavy or broad in appearance; palpating phallus in live males provides easy way to distinguish this species from sympatric congeners in the field.

DISTRIBUTION: *Proechimys brevicauda* occurs throughout the western Amazon Basin, from southern Colombia and eastern Ecuador south throughout eastern Peru, northwestern Bolivia, and east into Acre state in western Brazil.

SELECTED LOCALITIES (Map 524): **BOLIVIA:** Beni, Río Mamoré, 5 km NE of Río Grande mouth (Patton 1987), 10 km E of San Antonio de Lora (S. Anderson 1997); Cochabamba, Charuplaya (type locality of *Proechimys securus* Thomas), El Palmar (Patton 1987), Mission San Antonio (Patton 1987); La Paz, Mapiquí (type locality of *Proechimys bolivianus* Thomas). **BRAZIL:** Acre, Sobral, Rio Juruá (Patton et al. 2000). **COLOMBIA:** Caquetá, La Murelia (Patton 1987); Putumayo, Río Mecaya (Patton 1987). **ECUADOR:** Orellana, San José Abajo (Patton 1987); Pastaza, Canelos, Río Bobonaza (type locality of *Proechimys gularis* Thomas). **PERU:** Amazonas, Huampami (Patton et al. 2000); Huánuco, Chinchavito (Thomas 1927f); Loreto, Pebas (Thomas 1928c), San Fernando, Río Yavari (Patton 1987); Pasco, Montsinery (Patton 1987); Puno, Santo Domingo (type locality of *Proechimys hendeei elassopus* Osgood); Ucayali, Balta, Río Curanja (Patton and Gardner 1972, as *P. longicaudatus*).

SUBSPECIES: The number of taxa assigned to this species, as well as both variation in karyotype and the limited molecular sequence data (see Remarks), could signal valid geographic units, but the analyses needed to determine such have as yet to be done. For the present we regard *P. brevicauda* as monotypic.

NATURAL HISTORY: This species typically occupies upland, nonseasonally inundated (*terra firme*) lowland rainforest, both undisturbed and disturbed forest and second growth, where it is likely to be the most common spiny rat present. It is often found in garden plots (*chacras*), where individuals feed on yucca and plantains (Osgood 1914b). The few reproductive data, from northern Peru and western Brazil, suggest that breeding commences by the end of the dry season (Patton et al. 2000). Emmons (1982) recorded low densities, with males occupying larger

home ranges than females, and females with exclusive-use home ranges, suggesting a possible polygynous mating system (Adler 2011). *Proechimys brevicauda* may be sympatric with up to four other species of spiny rats throughout much of its range, typically with *P. simonsi*, *P. quadruplicatus*, and more rarely *P. cuvieri* in northern Peru, Ecuador, and Colombia; with *P. simonsi*, *P. steerei*, *P. cuvieri*, and *P. pattoni* in eastern Peru and western Brazil (Patton and Gardner 1972; Patton et al. 2000); and with *P. steerei* and occasionally *P. simonsi* in northern Bolivia (S. Anderson 1997, who listed *P. steerei* as *P. hilda*). Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

REMARKS: Günther (1876) based his description of *brevicauda* on two specimens, one from Chamicuros, Río Huallaga, and the other from a locality recorded only as “Upper Amazons.” Thomas (1900f:301) selected the specimen (a skin with a distinctly rufous throat and belly) from Chamicuros as the lectotype. Stephens and Traylor (1983) stated that Chamicuros is on the upper Río Samiria, about 35 miles east of Santa Cruz, which is on the Río Huallaga.

Specimens in the American Museum from Inca Mines, on the Río Inambari, Puno, Peru, and referred by J. A. Allen (1900a, 1901b) to *P. simonsi*, are *P. brevicauda*. Patton and Gardner (1972) applied the name *longicaudatus* Rengger to specimens from eastern Peru that A. L. Gardner and Emmons (1984) and Patton (1987) subsequently, and correctly, referred to *P. brevicauda* (Günther).

Thomas (1901h) regarded his *bolivianus* to be “most nearly allied to *P. simonsi*, but larger and different in cranial details.” The skull of the holotype, however, possesses all of the cranial attributes of *P. brevicauda* although the under parts of the skin are pure white, not with the varying degrees of fulvous in typical *brevicauda*, but characteristic of the white venter of all specimens we assign to this species from the southern part of its range in southern Peru and Bolivia. If this assignment of *bolivianus* Thomas to *brevicauda* Günther, following Patton (1987), is in error, the only other species we recognize to which this name could apply based on its characters is *P. steerei* Goldman. If this were true, then *bolivianus* Thomas would be senior to Goldman’s name.

Thomas (1911c) considered *P. brevicauda* to be the closest ally to his *gularis*, differing primarily by the dark-colored throat of the latter in comparison to the buffy venter of *brevicauda*. A. L. Gardner and Emmons (1984) suggested that *gularis* Thomas was a valid species, based on karyotypic and color differences. However, Osgood (1944:201) noted that variation in specimens of *Proechimys gularis* Thomas from the vicinity of the type locality “are practically identical with some of the variations of

typical *brevicauda*. It is, therefore, doubtful that the name should stand, even for a subspecies.”

Patton et al. (2000) noted the molecular uniqueness of *ellassopus* Osgood from southern Peru but nevertheless included it within their concept of *P. brevicauda*. A. L. Gardner and Emmons (1984) described the karyotype as $2n=28$, $FN=48$, based on specimens from nearby localities in southern Peru. This karyotype differs from that of *P. brevicauda* from northern Peru with the same $2n$ and FN in the number of different classes of banded autosomes (Patton et al. 2000). The type series of *ellassopus* Osgood has cranial features generally consistent with those of typical *longicaudatus*-group animals, yet differs in a more attenuate and weak maxillary portion to the septum of the incisive foramina with the vomer not visible and in a wide but much deeper anterior margin of the mesopterygoid fossa that penetrates the posterior palate to the level of M2s. In many respects, these are features also shared with *bolivianus* Thomas and *securus* Thomas, both from Bolivia and also from the lower Andean slopes. Future studies may well conclude that these three taxa deserve species status. If so, and if all three names belong to the same entity, then *bolivianus* Thomas would be the earliest name available.

The karyotype is geographically variable, ranging from $2n=30$, $FN=48$, in northern Peru and Ecuador (A. L. Gardner and Emmons 1984) to $2n=28$, $FN=48-50$, in central Peru and western Brazil (Patton and Gardner 1972; A. L. Gardner and Emmons 1984; M. N. F. da Silva 1998; Patton et al. 2000). Aniskin et al. (1991) described a similar karyotype, presumably of this species, from Peru south of the Río Marañón-Río Amazonas axis. The specimen referred to *P. longicaudatus* from Usina Hidroelétrica Samuel, in Rondônia state, Brazil, by T. Machado et al. (2005) is probably *P. brevicauda*. It has a karyotype with $2n=28$ and $FN=48$ and an acrocentric, not banded, Y chromosome typical of other samples of *P. brevicauda* from eastern Peru and western Brazil, and the locality is within lowland Amazonian rainforest rather than the tropical dry forest habitat characterizing *P. longicaudatus*. To whichever species these specimens can be assigned with confidence, it is apparently sympatric with an undescribed member of the *longicaudatus*-group that has a different karyotype ($2n=30$, $FN=52$), and that T. Machado et al. (2005) assign to the *longicaudatus*-group (MZUSP 27396). Specimens with this karyotype have both the enlarged baculum similar to other members of this group (R. E. Martin 1970; Patton 1987) and their mtDNA sequences are positioned with other group members. This undescribed entity is known from Amazonas, Rondônia, and Mato Grosso states, where it can be sympatric with *P. roberti* and *P. goeldii* in the middle to upper Rio Madeira and

Map 524 Selected localities for *Proechimys brevicauda* (●), *Proechimys longicaudatus* (○), and *Proechimys* sp. from the central Rio Madeira (□). Contour line = 2,000 m.

headwaters of the Rio Tapajós, but likely extends to near the mouth of these rivers as well (R. do V. Vilela 2005; Schetino 2008; Eler et al. 2012; M. N. F. da Silva, J. L. Patton, and R. N. Leite, unpubl. data). Additional sampling for DNA sequences and careful morphological comparisons of sequenced specimens to those already present in museum collections will be required to accurately map the ranges of *P. brevicauda*, *P. longicaudatus*, and this undescribed taxon in the southwestern Amazon Basin of Bolivia and Brazil.

Proechimys cuvieri Petter, 1978

Cuvier's Spiny Rat

SYNONYM:

Proechimys cuvieri Petter, 1978:263; type locality “Saül (S 21), Guyane française,” French Guiana.

DESCRIPTION: Moderate-sized species closely similar in external and craniodental characters to sympatric samples of *P. brevicauda* in western part of its range (Patton et al. 2000), but markedly distinct from sympatric *P. guyannensis* (Catzefflis and Steiner 2000; Voss et al. 2001) in Guianan region. Mean head and body length for western Brazilian and French Guiana samples 211 and 234 mm, respectively, tail length 144 and 168 mm, hindfoot length 48 and 51 mm, and ear length 22 and 24 mm. Tail proportionately short (approximately 70% of head and body length). Overall color is dark reddish orange, with midline of back darker than sides, which contrast sharply with white venter.

Specimens from western Brazil may have slight fulvous edge to ventral fur, but bright white contrasts sharply with typically buffy venter of sympatric *P. brevicauda*. Dorsal surfaces of hindfeet dark on toes and lateral margin, but short hairs above the metatarsals are silverish in color, or at least distinctly paler than toes, a pattern also contrasting with that of *P. brevicauda*, where dorsal surfaces dark and dull. Tail sharply bicolored and clothed in long, slightly curved and dark hairs, which convey distinctly “shaggy” appearance, rather remarkable for a *Proechimys* (Malcolm 1992; Voss et al. 2001). Nevertheless, tail scales visible to eye; annuli from 9–12 per cm at midpoint. Dorsal pelage stiff to touch, with well-developed aristiform spines averaging 0.9 mm in width and 20–21 mm in length. Some geographic variation in spine development apparent in samples J. L. Patton has examined, with narrower spines in those from Guianan region and tips with whip-like extension in those from south of Amazon in eastern Brazil; otherwise, samples characterized by rather blunt-tipped spines (Patton et al. 2000).

Skull relatively moderate-sized (mean condyloincisive length 39.7–47.1 mm), with long but relatively broad rostrum and well-developed supraorbital ridges, but temporal ridges weakly developed. Incisive foramina lyrate in shape with only moderate posterior constrictions; posterolateral margins flanged, but not as strongly so as in *P. brevicauda*, and extend onto palate forming only weak. Premaxillary portion of septum long and typically in contact with maxillary portion, which may be either keeled or smooth; vomer slightly to well exposed ventrally. Groove on floor of infraorbital foramen absent or only weakly developed, as is lateral flange of this groove. Postorbital process of zygoma well developed and formed completely by squamosal, or with only minimal jugal contribution. Mesopterygoid fossa relatively broad but penetrates posterior palate into M3s, with mean angle 66°–73° among on geographic samples. Cheek teeth large (mean length of maxillary toothrow 8.6–8.7. Three folds typically present on all four upper and lower cheek teeth, with limited variation among geographic samples). In particular, dpm4 may have either three or four folds, and m3 may likewise have either two or three folds; counterfold formula 3–3–3–3/3(4)–3–3–(2)3.

Baculum short and massive (sample mean width 6.13–8.61 mm, proximal width 5.30–6.70 mm, distal width 5.18–7.40 mm), with broad but short shaft, expanded base, and deep notch in distal portion resulting in distinct apical extensions (Patton 1987; M. N. F. da Silva 1998; Patton et al. 2000).

DISTRIBUTION: *Proechimys cuvieri* is widely distributed throughout the Amazon Basin, from eastern Ecuador and Peru to eastern Brazil, Venezuela, and the Guianas.

SELECTED LOCALITIES (Map 525): BRAZIL: Acre, Igarapé Porongaba (Patton et al. 2000); Amapá, 4 km N of Amapá (Patton 1987); Amazonas, Barro Vermelho (Patton et al. 2000), Comunidade Colina, Rio Tiquié (Patton et al. 2000), Lago Meduinim, left bank Rio Negro (Patton et al. 2000); Pará, Floresta Nacional Tapirapé-Aquiri (Patton et al. 2000), Ilha do Taiuno (Patton 1987). ECUADOR: Sucumbios, Laguna Grande, Río Cuyabeno (FMNH 125088). FRENCH GUIANA: vicinity of Cayenne (Catzefflis and Steiner 2000). GUYANA: Barima-Waini, Baramita (ROM 100890). PERU: Amazonas, La Poza (Patton et al. 2000); Loreto, Santa Luisa, Río Nanay (Patton 1967), Sarayacu, Río Ucayali (Patton 1987). SURINAM: Surinam, Lelydorpplan (Patton 1987). VENEZUELA: Bolívar, 69 km SE of Río Cuyuni (Patton et al. 2000).

SUBSPECIES: *Proechimys cuvieri* is monotypic.

NATURAL HISTORY: Habitat associations of *P. cuvieri* have been studied limitedly both in western (Patton et al. 2000) and central (Malcolm 1992) Amazonian Brazil, and French Guiana (Guillotin 1982, 1983; Voss et al. 2001; Adler et al. 2012). In all three areas, the species inhabits upland, or *terra firme* rainforest, but may be found equally in locally inundated forest or secondary upland forest and abandoned gardens. Malcolm (1992), for example, found *P. cuvieri* proportionally more abundant than sympatric *P. guyanensis* in early-successional and edge-dominated habitats. B. D. Patterson (1992b) also reported on specimens from the central Rio Juruá in western Brazil that were taken from dense virgin forest in hilly terrain, particularly within palm stands along an igarapé and on the margins of *igarapé* or *várzea* seasonally inundated forest. At Paracou in French Guiana, both Voss et al. (2001) and Adler et al. (2012) took most specimens in traps placed on the ground, but Voss et al. captured two individuals in liana tangles up to 1 m above the ground. The species was taken in well-drained primary forest, creek-side primary forest, and secondary vegetation beside logs, at the bases of trees, among stilt roots, on top of logs and under masses of fallen branches.

Proechimys cuvieri is broadly sympatric with *P. guyanensis* throughout the Guianan region (Voss et al. 2001) and northern Amazonian Brazil (Malcolm 1992), and may co-occur with up to four other species along the Rio Juruá in western Brazil, being absolutely syntopic with as many as three others on the same traplines (Patton et al. 2000).

In western Brazil pregnant females were only observed in the months of February and March, during the wet season, but data are too limited to define the actual length of the breeding season. Only adult females reproduce, and litter size was always composed of two young (Patton et al. 2000). In French Guiana, juveniles were taken in every month of the year, although at a substantially higher propor-

tion in March through May, suggesting that reproduction is continuous but with a peak in births also coinciding with the rainy season (Guillotin 1983). Males had larger home ranges than females, which were exclusive (Guillotin 1982), suggesting a polygynous mating system (Adler 2011).

Proechimys cuvieri has also been implicated as a vector for leishmania in French Guiana (Dedet et al. 1984).

REMARKS: Husson (1978) incorrectly identified specimens of this species from Surinam as *P. guyannensis guyannensis* (see Voss et al. 2001). Four strongly divergent geographic clades are defined by the limited mtDNA sequence data available (up to 10% divergence; Patton et al. 2000). One of these is distributed across the Guianan region and eastern Amazonian Brazil, east of the lower Rio Negro along both sides of the Rio Amazonas. A second is known from the Rio Juruá basin in western Brazil and northeastern Peru south of the Río Marañón. A third is known only from northern Peru, north of the Río Marañón. And a fourth is known only from the upper Rio Negro in Brazil, near the Colombian border. Each of these varied geographic clusters share the same basic set of morphological attributes, including the same bacular and glans characters and karyotype, with $2n=28$ and $FN=46-48$ (Reig, Tranier, and Barros 1980; Maia and Langguth 1993; M. N. F. da Silva 1998; Patton et al. 2000; N. A. B. Ribeiro 2006; Eler et al. 2012; C. E. F. Silva et al. 2012). However, as noted by Voss et al. (2001), differences in the relative proportions of the qualitative cranial features described by Patton (1987) are apparent in separate geographic regions such that more rigorous analyses of larger samples may well distinguish morphological groupings coincidental with the markedly distinct mtDNA clades. Should more than a single species be recognized for this group of geographic units, only that from the Guianan region, which contains the type locality of *P. cuvieri* Petter, would have a name to which it can be reliably referred. The remaining clades would lack a name. As with so many other “species” of *Proechimys*, here is another rich opportunity for further research to elucidate species boundaries and their geographic ranges. Steiner et al. (2000) and Van Vuuren et al. (2004) provided more detailed analyses of molecular genetic population structure for samples in the Guianan region, where there is higher sequence diversity and greater geographic structure than in the co-distributed populations of *P. guyannensis*.

Guillotin and Ponge (1984) doubted that *P. cuvieri* could be distinguished from sympatric *P. guyannensis* in French Guiana by standard craniodental measurements, but Catzeflis and Steiner (2000) countered this conclusion by a thorough morphometric analysis of appropriately aged samples. These latter authors also provided a detailed distribution map of known localities in French Guiana. Voss et al. (2001)

Map 525 Selected localities for *Proechimys cuvieri* (●). Contour line = 2,000m.

extended the Catzeflis and Steiner (2000) analysis and evaluated a number of qualitative characters that distinguish *P. cuvieri* from *P. guyannensis*. For example, the single, and easily measured, metric of maxillary tooththrow length is non-overlapping between their large series of both species (7.0–8.0mm in *guyannensis* and 8.2–9.3 in *cuvieri*; table 45, p. 157). Malcolm (1992) documented that these two species were also readily separable by tooththrow length as well as hindfoot length for populations in the central Brazilian Amazon near Manaus. In males, the difference in baculum width and shape is easily palpated in living specimens, even in juveniles (L. H. Emmons, pers. comm.). Lara et al. (1992) examined age and sex components of craniodental metrical dimensions in a large sample from Amapá state, eastern Brazil.

Proechimys longicaudatus (Rengger, 1830)

Long-tailed Spiny Rat

SYNONYMS:

Echimyus longicaudatus Rengger, 1830 236, type locality “Northern Paraguay.”

Loncheres myosurus: Lichtenstein, 1830:plate 36, Fig. 2, and unnumbered text; not *myosurus* Lichtenstein.

Echimyus myosurus: I. Geoffroy St.-Hilaire, 1840:15, 17; name combination; not *myosurus* Lichtenstein.

Echimyus cayennensis: Pictet, 1841b,145; name combination; not *Echimyus cayennensis* Desmarest.

E[chinomyus]. longicaudatus: Wagner, 1843a:341; name combination.

P[roechimys]. longicaudatus: Thomas, 1901g:532; first use of current name combination.

Proechimys [(Proechimys)] cayennensis longicaudatus: Ellerman, 1940:121; name combination.

Proechimys leucomystax Miranda-Ribeiro, 1914:42, type locality "Utiariti, Rio Papagaio," Mato Grosso, Brazil.

Proechimys longicaudatus: Moojen, 1948:346; name combination.

Proechimys longicaudatus longicaudatus: Moojen, 1948:351; name combination.

Proechimys longicaudatus leucomystax: Moojen, 1948:352; name combination.

Proechimys guyannensis villacauda Moojen, 1948:355; type locality "Tapirapoã, Rio Sepotuba, Cáceres, Mato Grosso, Brazil."

Proechimys guyannensis ribeiroi Moojen, 1948:361; type locality "Rio 12 de Outubro, affluent of the Camararé, Mato Grosso, Mato Grosso, Brazil; about 190 kilometers west of Utiariti; altitude 414 meters."

DESCRIPTION: Medium sized for genus, head and body length averaging about 220–250 mm, and with proportionately short tail, averaging about 60–63% of head and body length. Dorsal color distinctly pale reddish or yellowish brown, streaked with dark brown, contrasting sharply with dark reddish brown mixed with black of both *P. brevicauda* and *P. cuvieri*. Venter pure white, without hint of buffy overtones. Dorsal surfaces of hindfeet highly variable, from uniformly white, including toes (most specimens), to mostly dusky, or dusky on outside and white on inside. Dark ankle band may or may not separate white inner thigh from white foot. Tail bicolored, thinly haired with scales obvious; scale annuli 9–10 per cm at midpoint. Fur relatively soft to touch, with aristiforms narrow (0.6–0.7 mm), rather short (17–18 mm), and terminating with long whip-like tip.

Skull similar in nearly all features to other members of group, but the skull generally smaller than that of either *P. brevicauda* or *P. cuvieri*. Temporal ridge varies from weakly continuous across parietals or limited to simple posterior extension of supraorbital ledge. Incisive foramina lyrate in shape, as in *P. brevicauda* and *P. cuvieri*, with typically well-developed posterolateral flanges that extend onto anterior palate forming deep grooves, and an expanded and long premaxillary portion of septum with short, often thin, but typically keeled maxillary portion that continues as median ridge onto anterior palate; vomerine portion of septum short but exposed. Floor of infraorbital foramen smooth, without groove for infraorbital nerve. Postorbital process of zygoma well developed and comprised equally by both jugal and squamosal. Mesopterygoid fossa broad (angle averages 78°), but penetrates posterior palate to middle of M3s. All maxillary cheek teeth have three counterfolds; mandibular cheek teeth vary from three (rarely four) on pm4 to two or three folds on each molar. Counterfold formula 3–3–3–3/3(4)–2(3)–2(3)–2(3). Population samples of *P. longicaudatus* have higher

percentage of individuals with two folds on lower molars than do other two species. Pattern fits general trend of decreasing counterfold number in species, and/or their populations, along an environmental gradient from extremely wet forests (trans-Amazonian Cocó and western Amazon) to dry forests (eastern Amazonia and central Brazil; Patton 1987). Other examples of this trend are *P. quadruplicatus* in the western Amazon versus *P. goeldii* in east, or samples of *P. semispinosus* from Chocó in western Colombia versus those of isolated population of this species (*rosa* Thomas) in dry forests of southern Ecuador.

Baculum virtually identical to that of *P. brevicauda*; robust, long, and wide (sample mean width 10.17–11.08 mm, proximal width 3.20–5.02 mm, distal width 5.10–5.22 mm), with short, stout apical wings (Patton 1987).

DISTRIBUTION: *Proechimys longicaudatus* occurs in the dry tropical forests of eastern Bolivia, northern Paraguay, and central Brazil.

SELECTED LOCALITIES (Map 524): BOLIVIA: Santa Cruz, Buenavista (S. Anderson 1997), Santa Cruz, El Refugio (USNM 588195). BRAZIL: Goiás, Parque Nacional das Emas (T. Machado et al. 2005); Mato Grosso, Apiacás (T. Machado et al. 2005), Aripuanã (T. Machado et al. 2005), Fazenda São Luís (MVZ 197661); Mato Grosso do Sul, Urucum (Patton 1987). PARAGUAY: Alto Paraguay, 54 km E of Agua Dulce (Patton 1987).

SUBSPECIES: The number of taxa assigned to this species could signal valid geographic units, but the analyses needed to determine such have not as yet been done. Consequently, *P. longicaudatus* is treated as monotypic.

NATURAL HISTORY: Little has been published about the natural history of this species. S. Anderson (1997) recorded pregnant females in March and August in Bolivia. Emmons (2009) found that reproduction seems to begin after a hiatus about the first week in September, with appearance of lactating and late-gestation females, shortly after which young began to appear in the traps. This species was the most common rodent in some dry forests, where its populations remained stable over 10 years. The species also bred in mid-savanna grassland habitats shaded by trees and shrubs, where it denned in holes in termite mounds and in armadillo burrows (Emmons 2009, and pers. comm.) Three species of fleas have been reported, also from Bolivian specimens (Smit 1987). Valim and Linder (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

REMARKS: The exact locality from which the type specimen was collected has not been determined, although Thomas (1903c:240) wrote "Rengger's type was obtained on the 21st parallel of latitude, therefore not far south of Corumbá" (state of Mato Grosso do Sul, Brazil). He considered it "nearly allied to my *P. bolivianus*

[herein=*P. brevicauda* Günther], which differs from it by the cranial characteristics given in the description of the latter." Moojen (1948) assigned specimens from Utiariti on the Rio Papagaio in Mato Grosso, the type locality of Miranda-Ribeiro's *leucomystax*, to both *leucomystax* and *villacauda* Moojen, considering these to belong to separate species based on differences in counterfold counts of the lower pm4 and m1. Our view is that these are the same taxon with a varying expression of counterfold number, which is common in samples examined by one of us (JLP) from eastern Bolivia and western Brazil (Patton 1987:334–335, Table 5). However, as noted in the account of *P. brevicauda*, a clear understanding of both geographic and character range must wait additional sampling that explicitly focuses on the undescribed species we mention above. It is likely that northern localities in Brazil herein ascribed to *P. longicaudus* may actually represent this new taxon.

T. Machado et al. (2005) report karyotypic variation of $2n=28$ with the FN varying from 48–50 for samples from Mato Grosso and Goiás states in west-central Brazil. These karyotypes are the same as that described for *P. brevicauda* from Amazonian Brazil and Peru (Patton et al. 2000), except the Y chromosome is biarmed rather than uniarmed.

Proechimys semispinosus group

Patton (1987) included 13 named taxa in his concept of the *semispinosus*-group, most of which had been regarded in earlier literature as subspecies of *P. semispinosus* or as synonyms. He further suggested that only two valid species were contained within the group, *P. semispinosus* and *P. oconnelli*. Among South American taxa, the insular *P. gorgonae* Bangs and *P. rosa* Thomas from southern Ecuador had been recognized by some authors as a species, but listed as subspecies by others. Here, we follow A. L. Gardner and Emmons (1984) and Patton (1987) in recognizing two species, the widespread *P. semispinosus* and the limited range *P. oconnelli*.

KEY TO THE SPECIES OF THE *PROECHIMYS SEMISPINOSUS* SPECIES GROUP:

1. Distributed in Central American south from Honduras along the west coast of Colombia and Ecuador; temporal ridge well developed; cheek teeth complex, typically with four counterfolds commonly present on both upper and lower molar series and especially on lower pm4 *Proechimys semispinosus*
- 1'. Distributed east of the Cordillera Oriental in the north-western Amazon; temporal ridge nonexistent or only weakly developed; cheek teeth simplified, with three counterfolds on upper cheek teeth and lower pm4, and two to three counterfolds on lower molar series *Proechimys oconnelli*

Proechimys oconnelli J. A. Allen, 1913

O'Connell's Spiny Rat

SYNONYMS:

Proechimys o'connelli J. A. Allen, 1913a:479; type locality "Villavicencio (alt. 1600 ft.), Colombia," Meta.

Proechimys cayennensis o'connelli: Tate, 1939:178; name combination but incorrect use of an apostrophe (ICZN 1999:Art. 32.5.2.3).

[*Proechimys guyannensis*] *oconnelli*: Hershkovitz, 1948a: 133; name combination.

DESCRIPTION: Moderately large, head and body length up to 250 mm in adult individuals, and with a medium-length tail (about 70% of head and body length). Dorsal color orange rufous finely lined with black, paler on sides than mid-back and rump. Venter pure white, sharply defined against color of sides. Pale inner thigh stripes continuous across ankles onto dorsal surfaces of hindfeet, which are two-toned, pale cream on inner half and light brown on outer half, with dark color typically extending to digits IV and V; plantar pads moderate in size, with thenar and hypothenar pads subequal. Tail sharply bicolored, dark brown above and creamy-white below, and thinly clothed with short, fine hairs; visible scale annuli are relatively wide, averaging nine per cm at midpoint. Pelage neither distinctly nor heavily spinous, as aristiforms are weakly developed, long (18–21 mm) and thin (0.8–0.9 mm), and tipped with long whip-like filament.

Skull unremarkable, with elongated and tapering rostrum. Temporal ridge either weakly developed or nonexistent, extending posteriorly from supraorbital ledge onto parietals, contrasting sharply with condition in *P. semispinosus*. Incisive foramina angular or lyrate in shape, with moderately developed posterolateral flanges that extend onto anterior palate forming grooves on either side of midline, and despite only moderate development of maxillary keel and median palatal ridge. Premaxillary portion of septum well developed and elongated, encompassing more than half opening; premaxillary portion well developed and always in contact with premaxillary portion; vomer completely encased and not visible in ventral aspect. Floor of infraorbital foramen has obvious groove supporting passage of maxillary nerve, and formed by distinct lateral flange. Mesopterygoid fossa moderate in width, with angle averaging 63°, and penetrating to middle of M3s. Postorbital process of zygoma obsolete but formed completely by jugal. Cheek teeth both above and below simplified, with three counterfolds on each upper tooth and lower pm4 and two to three counterfolds on lower molars; counterfold pattern 3–3–3–3/3–(2)3–(2)3–2(3).

Baculum of medium length but broad (sample mean length 8.16–8.43 mm, proximal width 4.93–4.94 mm, distal width 4.63–5.26 mm), with blunt and thickened base and

Map 526 Selected localities for *Proechimys oconnelli* (○) and *Proechimys semispinosus* (●). Contour line = 2,000 m.

indented sides typical of *P. semispinosus*, but without distal apical extensions characteristic of that species (Patton 1987).

DISTRIBUTION: *Proechimys oconnelli* is known only from east central Colombia, east of the Cordillera Oriental in the headwaters of the Río Meta and Río Guaviare.

SELECTED LOCALITIES (Map 526): COLOMBIA: Cundinamarca, Mámbita (USNM 240036); Meta, Barrigona (Patton 1987), Meta, La Macarena Parque (FMNH 88051); Cundinamarca, La Aguadita (Patton 1987).

SUBSPECIES: *Proechimys oconnelli* is monotypic.

NATURAL HISTORY: There have been no published studies on the ecology or population biology of this species.

REMARKS: Both A. L. Gardner and Emmons (1984), using bullar septal patterns and karyotypes, and Patton (1987), using bacular and other craniodental characters, suggested that *P. oconnelli* was the only Amazon-drainage spiny rat to have a close affinity with the trans-Andean *P. semispinosus*. This hypothesis, however, has yet to be tested by a cladistic analysis of any character set, morphological or molecular. A. L. Gardner and Emmons (1984) described and illustrated a karyotype of $2n = 32$, $FN = 52$, from a topotype, which differs from that of *P. semispinosus* mainly in the presence of two medium acrocentrics instead of a single large submetacentric.

Proechimys semispinosus (Tomes, 1860)

Tomes's Spiny Rat

SYNONYMS:

Echinomys semispinosus Tomes, 1860b:265; type locality "Gualaquiza, southeastern Ecuador," amended to "Esmeraldas, Prov. Esmeraldas, on the Pacific coast of Ecuador" (A. L. Gardner 1983a).

Echinomys semispinosus: Thomas, 1882:101; name combination.

Echinomys semispinosus True, 1889:467; type locality "San Emilio, Lake Nicaragua, Nicaragua"; not *semispinosus* Tomes.

Echinomys centralis Thomas, 1896:312; renaming of *semispinosus* True.

[*Proechimys*] *semispinosus*: J. A. Allen, 1899c:264; first use of current name combination.

Proechimys rosa Thomas, 1900b:219; type locality "Santa Rosa, S. W. [= El Oro] Ecuador. Alt. 10 meters."

Proechimys centralis panamensis Thomas, 1900b:220; type locality "Savanna near Panama," Panama, Panama.

Proechimys centralis chiriquinus Thomas, 1900b:220; type locality "Bugava [=Bugaba], Chiriqui, N. W. Panama," Chiriqui, Panama.

Proechimys burrus Bangs, 1901:640; type locality "Isla San Miguel, Archipelago de las Perlas" Golfo de Panama, Panama.

Proechimys gorgonae Bangs, 1905:89; type locality "Gorgona Island," about 50 km W Punta las Reys, Cauca, Colombia.

Proechimys semispinosus calidior Thomas, 1911c:254; type locality "San Javier, Lower Cachavi R., N.W. [Esmeraldas] Ecuador. Alt. 60 feet."

Proechimys rubellus Hollister, 1914a:57; type locality "Anagostura Valley, Costa Rica," but holotype actually came from "Pacuare, Costa Rica" (True, 1889:467; A. L. Gardner, 1983a:136).

Proechimys centralis colombianus Thomas, 1914c:60; type locality "Condoto, Choco, W. Colombia. Alt. 300'."

Proechimys semispinosus panamensis: Goldman, 1920:120; name combination.

Proechimys semispinosus burrus: Goldman, 1920:122; name combination.

Proechimys semispinosus goldmani Bole, 1937:178; type locality "altos Cacao, Prov. Veraguas, Panama."

Proechimys semispinosus rosa: Moojen, 1948:316; name combination.

Proechimys guyannensis gorgonae: Cabrera, 1960:520; name combination.

DESCRIPTION: Moderately variable species geographically, larger in body size in Central America and northern Colombia than in southern part of range in Ecuador. Panamanian specimens may range to nearly 1 kg in mass (Adler 1996). Head and body length varies from about 290 mm in northern Colombia to 240 mm in northwestern Ecuador, with tail length varying proportionally from about 63% of head and body length in the north to 70% in the south; hindfoot length 45–60 mm; ear length 18–30 mm. Dorsal color in South American samples consistently dark reddish brown liberally speckled with black, with sides only slightly paler to contrast sharply with uniformly white venter. Pale inner thigh stripes do not continue across ankle onto uniformly dark dorsal surfaces of hindfeet. Plantar pads of hindfeet well developed; thenar and hypothenar pads enlarged and subequal in size. Tail sharply bicolored, dark brown above and pale below, particularly in northern samples, but less bicolored in southern samples from northwestern Ecuador. Hairiness of tail varies among individuals, with some moderately clothed in elongated hairs such that tail scales nearly hidden from view while others, from same population sample, with more sparsely haired tails; scales large, annuli obvious to eye, 7–8 per cm at midpoint. Dorsal pelage stiff to touch, but aristiform development varies from north to south. Spines consistently long (19–21 mm) in all populations, but vary in width, and hence stiffness (width 0.9–1.1 mm in northern samples and 0.6–0.8 in southern ones). Each aristiform terminates in elongated, filament-like, not blunt, tip.

Skull large (greatest skull length 51.2–67.0 mm) and broad across the zygomatic arches, but with an elongated and narrowed rostrum. Species uniquely characterized among spiny rats by its well-developed temporal ridges extending from supraorbital ledge across length of parietals, only rarely interrupted into anterior and posterior segments. Incisive foramina of specimens from Colombia and Ecuador narrow, with almost parallel sides, or weakly lyre-shaped; posterolateral margins usually strongly flanged, creating deep grooves extending onto anterior palate despite only moderate development of medial ridge; premaxillary portion of septum long, encompassing nearly entire length of opening; maxillary portion varies from well developed to attenuate, only weakly keeled at best, and nearly always in contact with premaxillary portion; vomer completely hidden from ventral view. Floor of infraorbital foramen with groove supporting maxillary nerve, formed by well-developed lateral flange. Mesopterygoid fossa of moderate width, but angle becomes broader from north to south (57°–62°). In contrast to *P. oconnelli*, postorbital process of zygoma moderately well developed and more commonly formed (especially in northern samples, less so in southern ones) by jugal. Counterfold count of cheek teeth similar to that of species of *goeldii*-group, with four folds commonly present on all upper teeth and on pm4, less commonly on lower m2 and even m3. However, fold number decreases in samples from northern Colombia to southern Ecuador (samples of *rosa* Thomas), where four folds are rare on all teeth and two folds may be found on M3 and all lower molars (Patton 1987:334–335, Table 5).

Baculum of massive, long, and broad (sample mean length 8.54–9.66 mm, proximal width 4.21–4.94 mm, distal width 5.11–6.19 mm), with deeply concave margins, broadly expanded and thickened base, and wide distal portion with well-developed apical wings separated by median depression (Patton 1987).

DISTRIBUTION (South America only): *Proechimys semispinosus* is found along the coastal lowlands of western Colombia and Ecuador, from the Panama border in the north to near the Peruvian border in the south.

SELECTED LOCALITIES (Map 526; from Patton 1987, except as noted): **COLOMBIA:** Cauca, Isla Gorgona (type locality of *Proechimys gorgonae* Bangs), Cauca, Río Saija; Nariño, Barbacoas (AMNH 34172); Chocó, Río Docompado, Unguía; Córdoba, Socorré; Valle de Cauda, Zabaletas (FMNH 86766). **ECUADOR:** Chimborazo, Puente de Chimbo; El Oro, Santa Rosa (type locality of *Proechimys rosa* Thomas); Esmeraldas, Esmeraldas (type locality of *Echimysemispinosus* Tomes); Guayas, Bucay; Manabí, Cuaque; Pichincha, Santo Domingo.

SUBSPECIES: Hall (1981) recognized six subspecies in Central America (*burrus* Bangs, *centralis* Thomas,

goldmani Bole, *ignotus* Kellogg, *panamensis* Thomas [with *chiriquinus* Thomas as a synonym], and *rubellus* Hollister. The number and range of subspecies in the South American part of the distribution has not been assessed. The insular *gorgonae* Bangs averages smaller than samples from the Colombian mainland, and is unique in its very dark brown, almost black, dorsal color, and gray-brown infusion across the chin, throat, upper chest, and encroachment along the sides to the inguinal region. This taxon might justify status as a subspecies on the basis of its unique coloration alone.

NATURAL HISTORY: Extensive ecological and life history studies of this species have been published for populations in Panama, including microhabitat use and spacing patterns (Adler et al. 1997; Tomblin and Adler 1998; T. D. Lambert and Adler 2000; Endries and Adler 2005); density, home range overlap, and mating system (Adler et al. 1997; Seamon and Adler 1999; Endries and Adler 2005); seed predation and food habits (Bonaccorso et al. 1980; Adler 1995; Hoch and Adler 1997; Adler and Kestell 1998; Mangan and Adler 1999; Adler 2000); growth and reproduction (Tesh 1970b; Gliwicz 1984; Adler and Beatty 1997); life span (Oaks et al. 2008); and comparative life history (T. H. Fleming 1971). Adler et al. (2003) described infestation by bot flies, Durette-Desset (1970a) described nematode parasites, and McKee and Adler (2002) documented tail autotomy. Little apparent ecological or life history data are available for populations in South America. Bangs (1905) did note, however, that spiny rats on Isla Gorgona were so common that not all specimens trapped could be preserved before the crabs ate them. Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

REMARKS: Thomas (1900b:219), in describing *P. rosa*, considered it “most nearly allied to *P. chrysaolus*” and not belonging to *P. semispinosus* Tomes, although he also thought *P. rosawas* “allied to the Central American species *P. centralis*,” which now is considered a synonym (and valid subspecies) of *P. semispinosus* (Hall 1981).

Bangs (1905), in his description of *P. gorgonae* from Isla Gorgona off the Pacific coast of southwestern Colombia, stated that this “species” was marked only by its unique color, as its skull was indistinguishable from mainland samples of *P. centralis* (= *P. semispinosus*).

Specimens in the Field Museum from Lagunas, near the junction of the Marañón and Ucayali rivers, in northern Peru that Osgood (1944:200–2001) referred to *P. semispinosus* are *P. steerei* (see that account).

Patton and Gardner (1972) described and figured a karyotype of $2n=30$, FN=54, from Costa Rica, and A. L. Gardner and Emmons (1984) reported intraspecific variation in the morphology of two pairs of small autosomes,

with $2n=30$ but FN=50–54, in samples from Panama, Colombia, and Ecuador, including near-topotypes of *rosa* Thomas. Gómez-Laverde et al. (1990) described and figured the karyotype of *gorgonae* Bangs as $2n=30$, FN=56, and M. L. Bueno and Gómez-Laverde (1993) recorded two karyotypes for the Pacific lowlands of Colombia, both $2n=30$, FN=56, that differ in the amount and pattern of constitutive heterochromatin. Based on similarities in C-banding patterns, M. L. Bueno and Gómez-Laverde (1993) suggested a close relationship between *gorgonae* Bangs and mainland populations of *P. semispinosus* in southern Colombia and western Ecuador.

Proechimys simonsi species group

This group is defined on the basis of its relatively large size; long and slim body form with elongated and narrow head and skull; absolutely and proportionately long tail, bright white venter and white hindfeet; distinctive, rather oval shaped incisive foramina with a noticeably weak maxillary part to the septum often not in contact with the premaxillary portion; flat and smooth anterior palate without a median ridge; narrow and deeply penetrating mesopterygoid fossa; and long and narrow baculum (Patton 1987). Only a single species is currently recognized, but deeply divergent and geographically structured DNA sequence clades may underlie greater levels of species diversity than presently understood (Patton et al. 2000; R. N. Leite and J. L. Patton, unpubl. data).

Proechimys simonsi Thomas, 1900

Simons's Spiny Rat

SYNONYMS:

Proechimys simonsi Thomas, 1900f:300; type locality “Perené River, Junin Province, Peru. Altitude 800 m.”

Proechimys hendeei Thomas, 1926g:162; type locality “Puca Tambo, 5100’,” 1,480 m, on trail from Chachapoyas to Moyobamba, Río Huallaga drainage (Stephens and Traylor 1983), San Martín, Peru.

Proechimys [(*Proechimys*)] *cayennensis simonsi*: Ellerman, 1940:121; name combination.

Proechimys hendeei nigrofulvus Osgood, 1944:199; type locality “Montalvo, Río Bobonaza, southeast of Sarayacu,” Pastaza, Ecuador.

[*Proechimys longicaudatus*] *hendeei*: Moojen, 1948:316; name combination.

[*Proechimys longicaudatus*] *nigrofulvus*: Moojen, 1948:316; name combination.

[*Proechimys longicaudatus*] *simonsi*: Moojen, 1948:316; name combination.

Proechimys rattinus: Cabrera, 1961:524; referral of paratype (BM 24.2.22.18), but not holotype, to *P. hendeei* (= *P. simonsi* Thomas).

DESCRIPTION: One of largest species in genus, equaled or exceeded in body size only by *P. semispinosus*, *P. quadruplicatus*, and *P. steerei* (head and body length 165–275 mm). Body of living individuals distinctly elongated, face long and narrow, ears long (length 21–28 mm), tail absolutely (length 118–231 mm) and proportionately long (mean 85% of head and body length), hindfeet long (length 45–57 mm). Tail sharply bicolored, dark above and white below; covered by sparse, fine hair, although small scales remain conspicuous to eye (9–13 annuli per cm at mid-point). Mid-dorsal color darker than sides, reddish brown, coarsely streaked with black hairs and interspersed by dark brown aristiforms. Aristiform hairs long (22–24 mm) and thin (0.2–0.4 mm) with distinctly whip-like tip. Venter, chin, sides of upper lips, undersurfaces of forelimbs, and hind limbs pure white. White of inner legs extends across tarsal joint onto white dorsal surfaces of hindfeet. As noted by Patton and Gardner (1972), *P. simonsi* apparently unique among all species of genus in lacking hypothenar pad on plantar surface of hindfeet.

Skull large (greatest skull length 44.1–63.7 mm), rostrum distinctly long and narrow (mean length 21.9 mm, mean width 8.2 mm). Supraorbital ridges well developed, but do not extend onto parietals as temporal ridge. Incisive foramina diagnostically ovoid in shape, sometimes slightly elongated but never with strongly constricted posterior margins, flat posterolateral margins lacking grooves extending onto anterior palate, short and rounded premaxillary portion of septum usually no more than half length of opening, and attenuate maxillary portion usually not in contact with premaxillary part. Floor of infraorbital foramen usually grooved, with moderately developed lateral flange. Anterior border of mesopterygoid fossa acutely angled (49°–53°), penetratingly deeply into palate, reaching anterior half of M3s or middle of M2s. PM4 and M1 typically with three folds while M2–M3 have three or four; number of folds, particularly on lower pm4, varies from north to south from four to three. Counterfold formula 3–3–3(4)–3(4)/(3)4–3–3–(2)3.

Baculum is long and narrow (sample mean length 8.42–10.09 mm, proximal width 1.93–2.50 mm, distal width 1.51–1.89 mm), with rounded and slightly broadened base (Patton and Gardner 1972 [as *P. hendeei*]; see Patton 1987).

DISTRIBUTION: *Proechimys simonsi* occurs in the western Amazon Basin, including the eastern Andean slopes, from southern Colombia through eastern Ecuador, eastern Peru, northern Bolivia, and into western Brazil.

SELECTED LOCALITIES (Map 527): **BOLIVIA:** Beni, Río Mamoré (S. Anderson 1997); La Paz, Alto Río Madidi, Moira Camp (USNM 579259); Pando, 18 km N of San Juan de Nuevo Mundo (USNM 579616). **BRAZIL:** Amazonas, Altamira, Rio Juruá (Patton et al. 2000), Colo-

cação Vira-Volta, Rio Juruá (Patton et al. 2000), alto Rio Urucu (Patton et al. 2000). **COLOMBIA:** Caquetá, La Morelia (Patton 1987); Putumayo, Río Mecaya (Patton 1987). **ECUADOR:** Morona-Santiago, Gualaquiza (Patton 1987); Napo, San Francisco (UMMZ 80046); Orellana, San José Abajo (Patton 1987); Pastaza, Río Pindo Yacu (Patton 1987). **PERU:** Amazonas, Yambrasbamba (Patton 1987); Cajamarca, Huarandosa (Patton 1987); Cusco, Consuelo, 15.9 km SW of Pilcopata (Solari et al. 2006), 2 km SW of Tangoshiari (USNM 588058); Huánuco, Tingo Maria (FMNH 24800); Loreto, Boca Río Curaray (Patton 1987), Orosa (Patton 1987); Madre de Dios, Río Tavara, Fila Boca Guacamayo (USNM 579696); Pasco, San Pablo (Patton 1987); San Martín, Puca Tambo (type locality of *Proechimys hendeei* Thomas).

SUBSPECIES: As currently understood, *P. simonsi* is monotypic (but see Remarks).

NATURAL HISTORY: This species primarily inhabits upland, nonseasonally flooded or *terra firme* forests, including undisturbed rainforest and secondary or disturbed forests and garden plots in the western Amazon Basin. However, it extends upward to above 2,000 m in montane forest on the eastern slope of the Andes, and thus has the broadest elevational range of any species of *Proechimys*. In western Brazil, reproductive females (those pregnant or lactating) were taken in all seasons, suggesting that breeding may take place throughout the year. The modal litter size was two, with the range in embryo number from one to three. Both males and females apparently do not reach reproductive maturity until they are fully grown and have molted into their adult pelage (Patton et al. 2000).

Emmons (1982) examined the population ecology, including habitat association, home range size, nightly movement patterns, and density in sympatric populations of *P. simonsi*, *P. steerei*, and *P. brevicauda* in southeastern Peru (for which she used the names *hendeei*, *brevicauda*, and *longicaudatus*, respectively, following Patton and Gardner 1972). Females appear to be territorial, which is likely the reason they reproduce only as adults (they may be unable to acquire territories on which to breed as subadults; Emmons 1982, and pers. comm.).

REMARKS: In his description of *P. simonsi*, Thomas (1900f) considered it externally similar to *P. chrysaeolus* and *P. rosa* (= *P. semispinosus* herein), with the skull “scarcely distinguishable from that of the outwardly very different *P. brevicauda*” (p. 300–301). Osgood (1944:202) referred specimens from the Río Perené at an elevation of 800 ft in central Peru to *P. simonsi*, stating that the species is “probably allied to *brevicauda*, from which it differs at least in immaculate white under parts.” It is, however, difficult to reconcile either of these comparisons, as *P. simonsi* is perhaps the most easily recognizable spiny rat, readily

separable from all others externally by virtue of its elongated body, pure white venter, elongated and sharply bi-colored tail, and five hindfoot pads; and cranially by its uniquely shaped and constructed incisive foramina and narrow, deeply penetrating mesopterygoid fossa (Patton 1987; Patton et al. 2000). Neither of these conditions even approach those of the other species to which both Thomas and Osgood referred.

Cabrera (1961:524) referred the paratype of *Proechimys rattinus* used by Thomas (1926g) in his description of this species to *P. hendeei* (= *P. simonsi* herein). This specimen (BM 24.2.22.18) is a skin only of a young animal, with juvenile pelage still on the lower back and rump. It is dark colored with a white venter and gray throat patch but a proportionately long tail (79% of head and body length). Without a skull, identification is difficult, but Cabrera's allocation appears to be correct.

Two markedly divergent geographic clades are apparent in the limited mtDNA sequence data available (Patton et al. 2000). One of these is in northern Peru, north of the Río Marañón–Río Amazonas axis, and the second covers the remainder of the range in eastern and southern Peru, western Brazil, and northern Bolivia. If subsequent studies document that these clades correspond to diagnosable taxa, then *nigrofulvus* Osgood would be an available name for the northern clade. The karyotype varies only mini-

mally throughout the sampled range, from eastern Ecuador to southern Peru and western Brazil, with $2n=32$ and $FN=56-58$ (Patton and Gardner 1972; A. L. Gardner and Emmons 1984; Patton et al. 2000; N. A. B. Ribeiro 2006). Reig and Useche (1976) described an identical karyotype for specimens from southern Colombia, but we have not examined the vouchers and thus cannot unequivocally allocate them to *P. simonsi*. Similarly, Aniskin et al. (1991) described a $2n=32$, $FN=58$, karyotype from northern Peru but without a morphological description to assign those specimens to *P. simonsi* with confidence.

Matocq et al. (2000) described molecular population genetic structure in relation to riverine barriers and habitat range in western Brazil, contrasting those patterns with the codistributed *P. steerei*. E. P. Lessa et al. (2003) provided estimates of late and post-Pleistocene population growth and stability based on coalescence analysis of these same molecular sequence data. Milishnikov (2006) contrasted patterns of variation in allozyme loci between *P. simonsi* and other co-occurring species of spiny rats in northern Peru.

Proechimys trinitatis species group

Patton (1987) assigned nine nominal taxa to this group, but made no recommendations as to the actual number of species. Curiously, most members of this group have been better studied with a broader range of methods and characters than any other group of spiny rats, yet species boundaries remain uncertain and phylogenetic relationships among species are unclear. Karyotypic variation is extensive (reviewed by Reig and Useche 1976; Reig et al. 1979; Reig, Aguilera et al. 1980; Reig 1981), and both karyotypic and electromorphic data (Benado et al. 1979; Reig, Aguilera et al. 1980) differentiate a *guairae* superspecies (including *guairae* Thomas and *poliopus* Osgood) and a *trinitatis* superspecies (composed of *trinitatis* Allen and Chapman and *urichi* Allen). The *guairae* superspecies exhibits a sequence of karyotypic diversity from $2n=42-62$, $FN=72-76$, that form a ring of ill-defined species or subspecies around the eastern-most branch of the northern Andes (Benado et al. 1979; Reig, Aguilera et al. 1980; Corti et al. 2001). Although we acknowledge the extensive karyotypic diversity, for the present we consider these forms to represent a single species, *P. guairae*. Karyotypic intermediates are known from points of geographic contact between some of these chromosomal forms (Aguilera, Reig, and Pérez-Zapata 1995), all karyotypic forms are very closely related, based on protein allozyme comparisons (Benado et al. 1979; Pérez-Zapata et al. 1992), and all share a similar craniometric morphology (Aguilera and Corti 1994; Corti and Aguilera 1995; Corti et al. 2001). Following the arguments of Reig, Aguilera et al. (1980)

Map 527 Selected localities for *Proechimys simonsi* (●). Contour line = 2,000 m.

in their delineation of the *trinitatis* superspecies, we place both *trinitatis* J. A. Allen and Chapman and *urichi* J. A. Allen into the single species *P. trinitatis*. O. J. Linares (1998), however, included all members of both the *P. guairae* and *P. trinitatis* superspecies (*sensu* Reig, Aguilera et al. 1980) in the single species *P. trinitatis*, recognizing three subspecies (*P. t. trinitatis* from the Cordillera Oriental and Orinoco delta; *P. t. guairae* from the Cordillera Central, Llanos, and flanks of the Mérida Andes; and *P. t. ochraceus* from the Maracaibo Basin). We retain the usual consideration of *P. mincae* as a valid species, although A. L. Gardner and Emmons (1984) suggested that it is also a member of the *guairae* superspecies. Finally, we recognize that *P. chrysaеolus* Thomas (including *magdalenae* Hershkovitz) and *P. hoplomyoides* Tate, although they are members of Patton's (1987) *trinitatis* group, are outside of either the *P. guairae* or *P. trinitatis* superspecies. We thus retain each as a separate species, at least until additional data can verify both the phylogenetic cohesion of this group of taxa as well as help resolve species boundaries within them.

The *trinitatis*-group of *Proechimys* is defined by a moderate to large body, relatively soft fur with narrow and elongated aristiform spines (except in *P. chrysaеolus* or *P. hoplomyoides*), a long but stout baculum in males, weakly developed or nonexistent temporal ridges, large and open incisive foramina with an attenuated maxillary portion to the septum that is seldom connected to the premaxillary portion, a groove present on the floor of the infraorbital foramen, a narrow and deeply penetrating mesopterygoid fossa, and simplified cheek teeth, with many individuals expressing only two folds on the lower molars.

KEY TO THE SPECIES OF THE *PROECHIMYS TRINITATIS* SPECIES GROUP:

1. Body size large (average head and body length >260 mm); pelage relatively soft to the touch, as aristiform spines are thin (0.4–0.5 mm in width) and terminate with a long whip-like tip *Proechimys trinitatis*
- 1'. Body size moderate (average head and body length <240 mm); pelage stiff to touch, with aristiforms moderate (0.6–0.8 mm) to wide (0.9–1.1) and often with blunt tip 2
2. Tail proportionately long (85–90% of head and body length); aristiform spines of moderate width; lower molars with only two counterfolds 3
- 2'. Tail proportionately short (70–75% of head and body length); aristiform spines well developed and wide; all lower molars usually with three counterfolds 4
3. Floor of infraorbital foramen with groove and lateral flange to accommodate maxillary nerve; range limited to lower Magdalena Valley in northern Colombia *Proechimys mincae*

- 3'. Floor of infraorbital foramen smooth, or with only weakly developed groove; range in Colombia east of Sierra de Perijá and Cordillera Oriental, otherwise range in Venezuela *Proechimys guairae*
4. Narrowed mesopterygoid fossa, penetrating to M2s; baculum long and narrow; range Guianan and Amazonian Venezuela *Proechimys hoplomyoides*
- 4'. Mesopterygoid fossa wide, penetrated only to M3s; baculum long but broad; range restricted to northern Colombia *Proechimys chrysaеolus*

Proechimys chrysaеolus (Thomas, 1898)

Boyacá Spiny Rat

SYNONYMS:

Echimyus chrysaеolus Thomas, 1898b:244; type locality "Muzo, N. of Bogota," Cundinamarca, Colombia (but see Hershkovitz 1948a, who questioned the designation of Muzo as the type locality).

Proechimys chrysaеolus: J. A. Allen, 1899c:264; first use of current name combination.

P[roechimys]. xanthaeolus Thomas, 1914c:61; incorrect subsequent spelling of *chrysaеolus* Thomas.

Proechimys [(*Proechimys*)] *cayennensis chrysaеolus*: Ellerman, 1940:120; name combination.

Proechimys guyannensis chrysaеolus: Hershkovitz, 1948a:136; name combination.

Proechimys guyannensis magdalenae Hershkovitz, 1948a:136; type locality "Río San Pedro, a small stream in the northern foothills of the Cordillera Central, above the village of Norosí altitude 178 meters, department of Bolívar, Colombia."

[*Proechimys*] *magdalenae*: A. L. Gardner and Emmons, 1984:14; name combination.

DESCRIPTION: Moderate-sized spiny rat, head and body length averaging 210–220 mm, with medium length tail averaging 70–75% of head and body length. Overall dorsal color dark yellowish to reddish brown speckled with black, with sides only marginally paler than mid-back and abruptly contrasting with white venter from chin to inguinal region. White inner thigh stripe discontinuous with few white hairs on dorsal surface of hindfoot by broad, dark ankle band. Hindfoot varies in color above, but typically dark or may have silvery hairs sprinkled across metatarsals; toes always dark brown. Plantar pads well developed, with thenar and hypotheneal subequal in size. Tail dark brown above and pale below, sparsely haired, appears naked to eye, with scale annuli forming distinct rings, more so than in most other species (10–13 per cm at midpoint). Pelage stiff and bristly to touch, with well-developed aristiform hairs (length 20–22 mm, width 0.9–1.1 mm); tip either blunt or terminating in very short whip.

Skull robust but long and narrow, with particularly elongated rostrum. Temporal ridge absent or only weakly developed, extending onto anterior parietals from supra-orbital ledge if present. Incisive foramina oval to teardrop in shape, tapering slightly with weak posterolateral flanges extending onto anterior palate forming shallow groove. Premaxillary portion of septum well developed, broad, and extends at least half length of opening; maxillary portion may be broad or narrow, but always contacts premaxillary portion so that vomerine portion not visible; maxillary part of septum unkeeled, so palate lacks median ridge. Floor of infraorbital foramen may be entirely smooth or with only moderately developed groove resulting from slight lateral flange. Mesopterygoid fossa moderately wide, with an angle averaging 59° , and penetrating to middle of M3s. Counterfold pattern of all maxillary cheek teeth uniformly 3-3-3-3; that of lower cheek teeth varies slightly, pm4 typically with three folds but rarely four, m1 always with three folds, and m2 and m3 with either two or three folds, and in about equal frequencies. Counterfold formula 3-3-3-3/3(4)-3-2(3)-2(3).

Baculum long but relatively broad (sample mean length 9.01-10.97 mm, proximal width 2.74-3.11 mm, distal width 2.34-2.62 mm), base bulbous with median depression, and apical wings slightly developed with median notch at distal end; similar in size and shape to other members of *trinitatis*-group, and to baculum of *P. decumanus* (Patton 1987).

DISTRIBUTION: *Proechimys chrysaеolus* occurs in northern Colombia from the Caribbean coast into the lower Cauca and Magdalena valleys west of the Cordillera Oriental.

SELECTED LOCALITIES (Map 528): COLOMBIA: Antioquia, Pure (Patton 1987); Bolívar, above Norosí (type locality of *Proechimys guyannensis magdalenae* Hershkovitz), San Juan Nepomuceno (Patton 1987); Boyacá, Muzo (type locality of *Echimyс chrysaеolus* Thomas), Puerto Boyacá (M. L. Bueno et al. 1989); Córdoba, Datival (Patton 1987), Socorré (Patton 1987); Norte de Santander, Guamalito (Hershkovitz 1948a); Santander, Finca San Miguel (MVZ 196095); Sucre, Las Campanas (Patton 1987).

SUBSPECIES: *Proechimys chrysaеolus* is monotypic, although the relationships between typical *P. chrysaеolus* and *magdalenae* Hershkovitz are unresolved and may signal racial, or even species-level, differences.

NATURAL HISTORY: This species has not been studied in the field. *Proechimys chrysaеolus* may be found in sympatry with *P. canicollis*. It is apparently an important zoonotic vector of equine encephalitis in Colombia, where a laboratory colony has been established in the Instituto Nacional de Salud in Bogotá (M. L. Bueno et al. 1989).

REMARKS: In his original description (Thomas 1898b:244) stated that *P. chrysaеolus* was similar in pelage and cranial characters to *P. trinitatis*. Hershkovitz (1948a:136) suggested that the holotype must have come from farther down the Magdalena Valley and not from Muzo, which he argued was at an elevation (1,240 m) too high for this species. We provisionally include *magdalenae* Hershkovitz in our concept of *P. chrysaеolus*, although Hershkovitz (1948a:136-137) specifically compared his *magdalenae* to the geographically adjacent *P. chrysaеolus*, both of which he assigned as valid subspecies of *P. guyannensis* É. Geoffroy St.-Hilaire. Hershkovitz believed that *magdalenae* was more similar to what he termed the "western" forms of the races of *P. guyannensis* (in which he included *decumanus* Thomas, *panamensis* Thomas, and *calidior* Thomas; the former now a species unto itself and the latter two are synonyms of *P. semispinosus*) than to the geographically adjacent *mincae* J. A. Allen or *chrysaеolus* Thomas by virtue of a consistent three folds on each lower molar. However, *P. decumanus* has only two folds on each lower molar, samples of *P. semispinosus* from western Colombia and Ecuador may have either two or four folds, in addition to the more typical three, and most individuals of *P. chrysaеolus* have three folds on their lower molars (Patton 1987:335, Table 5). Consequently, *magdalenae*

Map 528 Selected localities for *Proechimys chrysaеolus* (●) and *Proechimys mincae* (○). Contour line = 2,000 m.

Herskovitz falls within the range of counterfold number found in *P. chrysaolus*. A. L. Gardner and Emmons (1984) placed *magdalenae* Herskovitz in their *brevicauda*-group, not in their *guairae*-group, on the basis of bullar septal pattern. These authors did not examine specimens of *P. chrysaolus*. Because one of us (JLP) has seen specimens from the INS laboratory colony in Bogotá which he regards as *P. chrysaolus*, we believe specimens from the same colony for which M. L. Bueno et al. (1989) described and figured a karyotype of $2n=32$, $FN=54$, are this species.

Proechimys guairae Thomas, 1901

La Guaira Spiny Rat

SYNONYMS:

Proechimys guairae Thomas, 1901a:27; type locality "La Guaira," Vargas, Venezuela.

Proechimys ochraceus Osgood, 1912:56; type locality "El Panorama, Rio Aurare, Zulia, Venezuela."

Proechimys poliopus Osgood, 1914a:141; type locality "San Juan de Colon, State of Tachira, Venezuela. Altitude, 2500 ft."

Proechimys [(*Proechimys*)] *cayennensis guairae*: Ellerman, 1940:121; name combination.

[*Proechimys guyannensis*] *ochraceus*: Herskovitz, 1948a:133; name combination.

Proechimys guyannensis poliopus: Herskovitz, 1948a:133; name combination.

[*Proechimys guyannensis*] *guairae*: Moojen, 1948:316; name combination.

DESCRIPTION: Moderate to large, with head and body length of adults 210–240 mm. Tail absolutely and proportionately long, averaging nearly 85% of head and body length. Dorsal coloration light reddish brown lined with black, along southern slopes of Merida Andes, but distinctly paler and more yellowish brown in drier forests around Lake Maracaibo. Ventral color white from chin to inguinal region, including white inner thighs where stripe may be continuous across ankles onto dorsal surface of hindfeet. Hindfeet pale above, but often with outer light brown stripe extending from ankle to cover digits IV and V. Plantar pads of hindfeet well developed, with thenar and hypothenar pads large and subequal in size. Tail bicolored, light brown above and pale below, lightly haired so that large scales obvious to eye; scale annuli 7–8 per cm at midpoint. Pelage coarse but relatively soft to touch, with long (length 20–22 mm) and narrow (width 0.5–0.7 mm) aristiform spines tipped with whip-like extension.

Skull unremarkable, sharing conformational shape of most spiny rats. Temporal ridges undeveloped, or present only as weak and short posterior extension from supraorbital ledge. Incisive foramina broad and long, oval to slightly teardrop in shape, and with weakly developed

posterolateral flanges that extend onto the anterior palate forming slight moderate grooves. Premaxillary portion to septum narrow, extends at least to midpoint of septal opening, but may be only weakly connected to maxillary portion or not at all; maxillary portion of septum thin and attenuated, slightly keeled such that medial ridge may be present on anterior palate; vomer visible between premaxillary and maxillary septal elements in ventral view. Floor of infraorbital foramen may be either smooth or with slight groove developed by short lateral flange. Mesopterygoid fossa varies from narrow to moderate in width, with angle 47°–55°, penetrating palate to at least posterior margins of M2s and commonly even deeper. Postorbital process of zygoma moderately developed and composed of jugal alone or by equal contributions of jugal and squamosal. Three counterfolds uniformly present on PM4, M1, and M2, with M3 having either two or three folds in about equal proportions within samples. Lower cheek teeth uniform with three folds on pm4 and two folds on molar series. Counterfold formula 3–3–3–(2–3)/3–2–2–2.

Baculum with same shape and general size as other species in *trinitatis*-group (sample mean length 8.62–10.01 mm, proximal width 2.93–3.57 mm, distal width 2.78–3.34 mm), with bulbous base notched at midline and weakly developed apical wings (Patton 1987).

DISTRIBUTION: *Proechimys guairae* occurs in northern and western Venezuela in the foothills of both sides of the Andes and upper Llanos north of the upper Río Orinoco, including around Lake Maracaibo and the eastern slopes of the Sierra de Perijá, and into adjacent northeastern Colombia.

SELECTED LOCALITIES (Map 529): COLOMBIA: Arauca, Fatima (FMNH 92608), Río Arauca (FMNH 92576); Norte de Santander, San Calixto (USNM 280182), Tarrá (Reig, Aguilera et al. 1980). VENEZUELA: Anzoátequi, Cueva de Agua (Corti and Aguilera 1995); Apure, Guasualito (Reig, Aguilera et al. 1980); Aragua, Ocumare de la Costa (Aguilera, Reig, Pérez-Zapata 1995); Barinas, Buena Vista (Reig, Aguilera et al. 1980); Cojedes, El Baul (Reig, Aguilera et al. 1980); Falcón, Carrizalito (Aguilera, Reig, Pérez-Zapata 1995), Sanare (Reig, Aguilera et al. 1980); Monagas, San Juan (Pérez-Zapata et al. 1992); Guárico, Dos Caminos (Reig, Aguilera et al. 1980); Táchira, San Juan de Colón (Reig, Aguilera et al. 1980); Vargas, La Guaira (type locality of *Proechimys guairae* Thomas); Zulia, El Panorama (type locality of *Proechimys ochraceus* Osgood), Los Angeles del Tucuco (Corti and Aguilera 1995).

SUBSPECIES: Reig, Aguilera et al. (1980) delineated the extensive karyotypic variation they described in *P. guairae* and regarded each chromosomal "segment" in the circular distribution of forms as either species (*poliopus*

Osgood plus the unnamed “Barinas” species) or subspecies (*guairae* Thomas and *ochraceus* Osgood, plus two to four unnamed races). Counterclockwise around the ring, beginning in Apure and Barinas states in southwestern Venezuela, these included: “Barinas” ($2n=62$, FN=72; Reig and Useche 1976; Reig, Aguilera et al. 1980), “ssp.” ($2n=48-50$, FN=72; Reig and Useche 1976; Reig, Aguilera et al. 1980), *guairae guairae* ($2n=46$, FN=72; Reig and Useche 1976), *guairae ochraceus* ($2n=44$, FN=76; Reig, Aguilera et al. 1980), and, finally, *guairae poliopus* ($2n=42$, FN=76; Reig and Useche 1976; Reig, Aguilera et al. 1980). A geographically disjunct $2n=52$, FN=74, karyomorph is also known from Anzoátegui and Monagas states. Samples of each of these races can be delineated by both standard multivariate morphometrics (Aguilera and Corti 1994; Corti and Aguilera 1995) and geometric morphometrics (Corti et al. 2001), but a formal taxonomy defining and diagnosing each subspecies has yet to be produced.

NATURAL HISTORY: Aguilera (1999) examined the population ecology of *P. guairae* at a single site in coastal Venezuela, including home range size, density, reproductive schedule, and spatial organization of the sexes, and estimated the census effective population size. Males had larger home ranges than females, but those of females were exclusive, which suggested a polygynous or promiscuous mating system to Adler (2011). Handley (1976) included both *P. guairae* and *P. quadruplicatus* within a taxon he recognized as “*P. semispinosus*” from Venezuela. Although

Map 529 Selected localities for *Proechimys guairae* (●), *Proechimys hoplomyoides* (■), and *Proechimys trinitatis* (○). Contour line = 2,000m.

it is possible to allocate the specimens in his list of localities (p. 57) to either of these two species, it is unfortunately not possible to parse the habitat and trap data he provides in the same manner. Osgood (1912) collected specimens from the roots of the wild pineapple in the arid parts of the northeastern slope of Lake Maracaibo, where he found spiny rats to be common. Valim and Linardi (2008) described the host association of ectoparasitic lice in the genus *Gyropus*.

REMARKS: Thomas (1901a:28), in his description of *P. guairae*, recognized that it was “evidently closely allied to *P. trinitatis* and its continental representatives of *P. urichi* and *P. mincae*” but differed from them primarily by a much paler color. Osgood (1912) believed that *P. ochraceus* was most similar to *P. guairae* but smaller and paler. Two years later when he described *P. poliopus*, Osgood (1914a:141) regarded this new species as being most similar to *ochraceus*. He also made comparisons to *P. guairae* as well as with *P. mincae* and *P. canicollis*, stating that *poliopus* was “doubtless related” to *P. guairae*, which is distinguishable by its larger size and white feet.

Proechimys hoplomyoides Tate, 1939

Guianan Spiny Rat

SYNONYMS:

Proechimys cayennensis hoplomyoides Tate, 1939:179; type locality “Rondon Camp, Mt. Roraima, 6800 feet,” Bolívar, Venezuela.

Hoplomys hoplomyoides: Moojen, 1948:315; name combination.

Hoplomys gymnurus hoplomyoides: Cabrera, 1961:532; name combination.

Proechimys hoplomyoides: Handley, 1976:57; first use of current name combination.

Proechimys guyannensis hoplomyoides: O. J. Linares, 1998: 238; name combination.

DESCRIPTION: Moderate-sized spiny rat (head and body length of holotype 213mm) with moderately long tail (72% of head and body length). Tate diagnosed species by its blackish-brown and heavily spined dorsal pelage and slightly larger cheek teeth in comparison to other spiny rats nearby (which would have been samples of *P. guyannensis*). Broad and very stiff aristiform spines so reminiscent of those of *Hoplomys* that Moojen (1948) and subsequently Cabrera (1961) placed *P. hoplomyoides* in that genus. (No data are available on aristiform dimensions, characters of tail scales and scale annuli, or number and size of plantar tubercles; indeed, with only six specimens known, an adequate understanding of character variation is not possible at present.) As detailed by Patton (1987), skull relatively long and narrow, with elongated rostrum characteristic of all spiny rats. Temporal ridges extend pos-

teriorly from supraorbital ledges absent; floor of infraorbital foramen smooth, without groove indicative of passage of maxillary nerve; incisive foramina somewhat lyre shaped with weakly flanged posterolateral margins that define grooves extending on anterior palate; premaxillary portion of septum of foramen enlarged, extending at least one-half length of opening, but maxillary portion attenuate and not in contact with premaxilla. Mesopterygoid fossa narrow and deeply penetrating, to at least level of posterior half of M2s. Counterfold pattern simple, with three folds on each upper and lower tooth; counterfold formula 3-3-3-3/3-3-3-3.

Baculum long and rather narrow (length of single specimen 11.64 mm, proximal width 2.47 mm, distal width 1.79 mm), more so than any other species of spiny rat, including other members of *trinitatis*-group (Patton 1987).

DISTRIBUTION: The known range of *Proechimys hoplomyoides* is limited to the tepui area of southeastern and southern Venezuela. This the only species in the *trinitatis*-group with a distribution south of the Río Orinoco and within Amazonia and the Guianan region.

SELECTED LOCALITIES (Map 529): VENEZUELA: Amazonas, Tamatama (Handley 1976); Bolívar, km 125, 85 km SSE of El Dorado (Handley 1976), Rondon Camp (type locality of *Proechimys cayennensis hoplomyoides* Tate).

SUBSPECIES: *Proechimys hoplomyoides* is monotypic.

NATURAL HISTORY: *Proechimys hoplomyoides* is known from evergreen rainforest and gardens, near streams or other moist areas (Handley 1976). The holotype was taken at the highest elevation (6,800 ft, or 2,000 m) recorded for any spiny rat in the Guianan region (Tate 1939).

REMARKS: Moojen (1948) placed *P. hoplomyoides* in the genus *Hoplomys* because of the heavy and dense spines, an action followed by Cabrera (1961). The bullar septal pattern, however, is close to other species in the *trinitatis*-group (A. L. Gardner and Emmons 1984) although the long and narrow baculum is more similar to that of *P. simonsi* than to those of other species in the *trinitatis*-group (Patton 1987:Fig. 12, p. 321). O. J. Linares (1998) assigned the species as a valid subspecies of *Proechimys guyannensis*, likely following Tate (1939) in his original description, but without comment. The species is known from only six specimens, including the holotype, and four localities in southern Venezuela.

Proechimys mincae (J. A. Allen, 1899)

Minca Spiny Rat

SYNONYMS:

Echimyus mincae J. A. Allen, 1899b:198; type locality "Minca, Santa Marta District," Magdalena, Colombia.

[*Proechimys*] *mincae*: J. A. Allen, 1899c:264; first use of current name combination.

Proechimys [(*Proechimys*)] *cayennensis mincae*: Ellerman, 1940:120; name combination.

Proechimys guyannensis mincae: Hershkovitz, 1948a:134; name combination.

DESCRIPTION: Moderately large spiny rat (head and body length 220–230 mm) with a proportionately long tail (90% of head and body length). Coloration across dorsum reddish brown speckled with black, becoming slightly paler on sides, and with white venter from chin to inguinal region but varyingly bordered by light buff margins. White inner thigh stripe passes weakly across ankle to be confluent with basically dirty white dorsal surface of hindfoot, with toes only slightly darker. Plantar pads of hindfeet enlarged and well developed, with thenar and hypothenar large and subequal in size. Tail bicolored, brownish gray above and pale cream below. Tail thinly haired with scales large, irregular in shape, and readily visible to eye; scale annuli average 8–9 per cm at midpoint. Aristiform spines long (length 20–22 mm) and thin (width 0.6–0.8 mm) but stiff, giving pelage raspy texture when brushed. Tip of each aristiform may terminate in short, whip-like extension or be blunt.

Skull similar to that of most species of *Proechimys*, elongated, relatively narrow, and with tapering rostrum. Temporal region of braincase smooth, lacking virtually any evidence of ridges extending posterior to supraorbital ledge). Incisive foramina wide and with somewhat rounded sides conferring oval shape to opening; posterolateral flanges either nonexistent or so weakly developed that anterior palate lacks grooves. Premaxillary portion of septum well developed and long, filling more than half distance of opening, but either does not or only rarely contacts greatly attenuated maxillary portion; midpalate may have small medial ridge, but small maxillary portion of septum lacks any hint of keel; vomer can often be seen in ventral view. Floor of infraorbital foramen typically grooved, resulting from moderate development of lateral flange. Mesopterygoid fossa moderately broad, opening at angle averaging 57°, and penetrating posterior palate to level of M2s. All cheek teeth relatively simple, with never more than three folds in upper series, but often only two folds on M2 and especially M3; lower cheek teeth typically with three folds on pm4 but only two on each molar. Counterfold formula 3-3-2(3)-2(3)/3-2-2-2.

Baculum of *P. mincae* long and stout, similar in size and shape to that of other species in *trinitatis*-group, except that of *P. hoplomyoides* (mean length 7.29–9.98 mm, proximal width 2.04–2.17 mm, distal width 2.42–2.94 mm; Patton 1987).

DISTRIBUTION: *Proechimys mincae* is known only from the lower Magdalena valley in northern Colombia to the west and south of the Sierra Nevada de Santa Marta.

SELECTED LOCALITIES (Map 528): COLOMBIA: Cesar, Colonia Agrícola de Caracolicito (USNM 280198); Magdalena, Bonda (Patton 1987), Don Dago (Patton 1987), Minca (type locality of *Echimys mincae* J. A. Allen).

SUBSPECIES: *Proechimys mincae* is monotypic.

NATURAL HISTORY: *Proechimys mincae* has not been studied in the field. It is sympatric with *P. canicollis* at Bonda, the type locality of the latter species (J. A. Allen 1899b).

REMARKS: A. L. Gardner and Emmons (1984) described and figured the karyotype of *P. mincae* as $2n=48$ and $FN=68$, similar to that of some karyotypes of *P. guairae*. In his description of this species, J. A. Allen (1899b:199) noted that it belonged to the same group as *P. trinitatis*, with the "same white belly, the same general proportions, and practically the same dentition." He considered it separate from *P. trinitatis* by virtue of smaller size and golden brown rather than dark chestnut brown dorsal color. However, the skull of *P. mincae* is more different in geometric shape than any members of Reig, Aguilera et al.'s (1980) *P. guairae* or *P. trinitatis* superspecies groups, and even the unrelated *P. canicollis* (Corti et al. 2001).

Proechimys trinitatis (J. A. Allen and Chapman, 1893)

Trinidad Spiny Rat

SYNONYMS:

Echimys trinitatis J. A. Allen and Chapman, 1893:223; type locality "Princetown [= Princes Town], Trinidad, " Trinidad and Tobago.

E[chinomys]. trinitatis: Thomas, 1896:313; name combination.

Echimys urichi J. A. Allen, 1899b:199; type locality "Quebrada Secca," Villarroel, Sucre, Venezuela.

[*Proechimys*] *trinitatis*: J. A. Allen, 1899c:264; first use of current name combination.

[*Proechimys*] *urichi*: J. A. Allen, 1899c:264; name combination.

Proechimys urichi: Pittier and Tate, 1932:264; name combination.

Proechimys [(*Proechimys*)] *cayennensis urichi*: Ellerman, 1940:121; name combination.

Proechimys [(*Proechimys*)] *cayennensis trinitatis*: Ellerman, 1940:121; name combination.

[*Proechimys guyannensis*] *trinitatis*: Moojen, 1948:316; name combination.

[*Proechimys guyannensis*] *urichi*: Moojen, 1948:316; name combination.

Proechimys guyannensis urichi: Cabrera, 1961:523; name combination.

DESCRIPTION: Moderately large (head and body length 265–270 mm in mature adult individuals), with a proportionately long tail (75–80% of head and body length). Dorsal color brownish orange heavily mixed with

black lines, only slightly paler on sides, and contrasting with pure white venter. White inner thigh stripe may continue across ankle to inner side of hindfoot surface, which is otherwise brownish in color. Plantar pads of hindfeet well developed with both thenar and hypothenar pads enlarged and subequal in size. Tail covered very sparsely with short hairs such that it appears quite naked to eye; scales large, almost oval in shape, with 6–7 annuli per cm at midpoint. Pelage relatively soft to touch, with aristiform spines long (length 20–22 mm), thin (width 0.3–0.5 mm), and terminating in extended whip-like tip.

Overall shape as in other species of spiny rats, relatively narrow and elongated, with long and tapering rostrum. Weak temporal ridges extend back to midparietal from supraorbital ledges present in older individuals less obvious in younger specimens. Incisive foramina wide and oval, with only weakly posterolateral flanges, if at all, so that anterior palate either flat or weakly grooved. Premaxillary portion of septum variable in size laterally and may extend virtually entire length of opening or only to midpoint; maxillary portion narrow and weakly developed, barely in contact with premaxilla, and only weakly keeled, typically without extending onto anterior palate as continuing medial ridge; vomerine portion of septum usually not visible ventral view. Floor of infraorbital foramen grooved, bordered laterally by typically moderately developed flange. Mesopterygoid fossa relatively narrow, forming angle of about 53°, and deeply penetrating to anterior edges of M3s or posterior edges of M2s. Paroccipital processes distinctly broad, flattened, and tightly appressed to each bulla, more so than in any other species of *Proechimys*. Postorbital process of zygoma weakly to moderately developed, and composed entirely of squamosal. Upper cheek teeth uniform with three folds on each, except that M3 occasionally has only two. Lower cheek teeth all have three folds, with each molar often with only two. Counterfold formula 3–3–3–(2)3/3–(2)3–(2)3–(2)3.

Baculum elongated but moderately wide (sample mean length 9.97–10.46, proximal width 3.10–3.15, distal width 3.14–3.32), with slightly expanded base with median notch, straight sides, and slight apical wings, similar to that of other species within the *trinitatis*-group (Patton 1987).

DISTRIBUTION: *Proechimys trinitatis* occurs on the island of Trinidad and the adjacent coastal lowlands of northern Venezuela (see maps in Pérez-Zapata et al. 1992; Corti and Aguilera 1995).

SELECTED LOCALITIES (Map 529): TRINIDAD AND TOBAGO: Trinidad, Chaguaramas (MVZ 168949), Oropuche Heights (FMNH 20960), Princes Town (type locality of *Echimys trinitatis* J. A. Allen and Chapman). VENEZUELA: Monagas, 6.5 km of NE Cachipo (Pérez-Zapata et al. 1992), Guanaguana (Aguilera, Reig, Pérez-Zapata

1995); Sucre, El Argarobo (Aguilera, Reig, Pérez-Zapata 1995), Guaraunos (Aguilera, Reig, Pérez-Zapata 1995), Quebrada Seca (type locality of *Echymys urichi* J. A. Allen).

SUBSPECIES: Spiny rats from the Venezuelan mainland are somewhat smaller than those on the island of Trinidad. Ellerman (1940), Moojen (1948), and Cabrera (1961) regarded these mainland populations as a distinct subspecies, but listed it as *P. guyannensis urichi* (J. A. Allen).

NATURAL HISTORY: Everard and Tikasingh (1973a) examined the population ecology of *P. trinitatis* on Trinidad, including recapture rates, home range, and movement patterns, longevity, reproduction, sex ratio, and parasites. Here, the species is common in secondary rainforest, reaching monthly densities from 3.7–5.3 individuals per acre, with mean distances moved by individuals between successive captures up to 300 ft, average home range size of 0.425 acres, and extensive overlap of male and female home ranges. Individuals lived at least 20 months under natural conditions in the field, and a maximum of 41 months in captivity. Captive breeding indicated a gestation period of 62–64 days, a mean litter size of 2.4, mean birth weight of 24.7 g, and reproductive maturity about five months following birth. Individuals were docile in captivity, but were aggressive when kept together, often inflicting wounds on each other. Everard and Tikasingh (1973a) and Valim and Linardi (2008) described the host association of ectoparasitic lice, ticks, and fleas. One of 285 individuals examined had *Cuterebra* larvae in the skin (Everard and Tikasingh 1973a). Everard et al. (1974) examined filarial nematodes, and Stunkard (1953) described cestodes.

REMARKS: Reig and colleagues (Reig et al. 1979; Reig, Aguilera et al. 1980; Pérez-Zapata et al. 1992) report a karyotype of $2n=62$, $FN=80$, for both Trinidad and Venezuelan populations of *P. trinitatis*. Benado et al. (1979) examined allozyme relationships and show that *P. trinitatis* is the sister to a group of four karyomorphs of the *P. guairae* superspecies. However, Patton and Reig (1990) showed that *urichi* Allen (= *P. trinitatis*) is nested phylogenetically within three karyomorphs of *P. guairae*, including two examined by Benado et al. (1979; $2n=46$ and 62 forms) plus $2n=42$ *poliopus* Osgood. If more sophisticated molecular analyses support the phylogenetic position of *P. trinitatis* within the *P. guairae* superspecies, then O. J. Linares's (1998) conspecific hypothesis should be reevaluated.

Genus *Thrichomys* E.-L. Trouessart, 1880

Leila M. Pessôa, William C. Tavares, Antonio C. A. Neves, and André L. G. da Silva

Species of *Thrichomys* comprise a morphologically and ecologically distinct group within the family Echimyidae. The

genus is distributed widely across different biomes from Caatinga, Cerrado, and Pantanal in Brazil to the Chaco of Bolivia and Paraguay. In Brazil, this distribution is closely associated with the diagonal belt of open vegetation that stretches in a northeast to southwest direction sandwiched between the coastal Atlantic Forest and Amazon Basin (Alho 1982; Mares and Ojeda 1982). In Bolivia, *Thrichomys* inhabits the northern edge of the Chaco, which is characterized by scattered shrubs without large rock outcrops (S. Anderson 1997), but it is also associated with rocky outcrops of the Brazilian Shield in Chiquitania dry forest and Cerrado (Emmons et al. 2006, and unpubl. data). Species are terrestrial but may climb into the lower strata of trees and shrubs.

The oldest fossil unambiguously assignable to *Thrichomys* dates from Pleistocene deposits at Lagoa Santa, Minas Gerais (Lund 1839, 1840a, 1841b; Paula Couto 1950). McKenna and Bell (1997) suggested that the oldest record of the genus was from the late Miocene, but Reig (1989) argued that the identity of this material was uncertain because the specimen is very fragmented (Verzi et al. 1995). Olivares et al. (2012) phylogenetically linked the late Miocene *Pampamys emmonsae* (Huayquerian South American Land Mammal Age, from central Argentina) to *Thrichomys*, which both supports 6 mya as a minimum age for the genus and relates the simplified-molar echimyids to expansion of open environments during the late Miocene. Nascimento et al. (2013), based on mtDNA and nucDNA sequences, estimated the basal divergence of living member of the genus at 8.46 mya, and posited an ancestral origin in the central Caatinga and/or northern Cerrado of Brazil.

The generic name *Thrichomys* is etymologically associated with the presence of soft fur and a thickly haired tail, characteristics not shared with any other terrestrial echimyid (Ellerman 1940). The tail is moderate in length, approximately 86% of the head and body length. It is bicolored, uniformly covered by blackish hairs dorsally and whitish or grayish hairs ventrally. The dorsum of the body is generally ash gray in color in all species; setiform hairs are gray basally, black near the tip, and have a yellowish subapical zone. The venter is whitish, contrasts with dorsal coloration, but is not sharply demarcated from the lateral coloration. A grayish stripe is typically present in the gular region. The eye is outlined by contrasting white lines above and below. Long vibrissae extend posteriorly to the shoulder. A spot of white hairs is present at the base of each ear. White, sparse hairs cover the ears (Ellerman 1940; Moojen 1952b). Females have four abdominal mammae. In adult specimens, the head and body length varies from 170–310 mm and tail length from 175–226 mm (Moojen 1952b; data from museum specimens MNRJ 22066,

MNRJ 67899). Mass varies from 150–700 g (MNRJ 67760, MNRJ 64460).

As in other terrestrial echimyids, the feet are elongated and narrow, ranging from 39–42 mm in adults. The hindfeet bear six well-developed plantar pads. The thenar and hypothenar pads are very elongated, extending toward the heel. The hallux is very short and does not reach the base of the second toe. The second toe is long, almost reaching the tip of the third and fourth toes, which are the longest and subequal in length. The fifth toe reaches the level of the proximal third of the fourth toe. Each toe bears a claw covered by long white unguis hairs that do not extend more than 1 mm beyond the claws. The short forefeet bear five plantar pads, three interdigitals, hypothenar, and thenar. Only the pollex does not possess a claw. This tiny digit bears a thin nail not covered by hairs. The second and fifth digits are short, subequal in length, and extend to the proximal third of the third and fourth digits. Dense, short hairs that are either white or gray at the base and white at the tip cover the dorsal surfaces of both forefeet and hindfeet. All plantar pads are surrounded by smaller tubercles that are most evident in fresh specimens. The surface between pads is rough.

Neither the external morphology of the phallus nor baculum of *Thrichomys* has been described previously. The following description is based on MNRJ 64623 from Barão de Melgaço in Mato Grosso. The glans is an elongated and cylindrical structure with a slight constriction apparent on the lateral and dorsal general outlines of the body wall. The main body is uniformly covered with spinous epidermis and lacks evidence of any groove along the length of its ventral or dorsal surfaces. A dorsal constriction that delimits the intromittent sac is present midway along the length of the shaft. The apical tip shows three lobes, a median one that extends beyond the lateral two. This glans measured 17 mm in total length (from the base of the prepuce to the tip) with a greatest diameter of 4.3 mm.

The baculum of adult males is elongate and narrow with a straight shaft with a slight dorsoventral curvature and broadened proximal end. Both the proximal and distal ends vary in shape. The proximal end is typically paddle-shaped but the distal end can be straight or possess a median depression with slightly developed apical wings. This description is based on one individual from Matozinhos (MNRJ 68158) and three from Santana do Riacho (MNRJ 68602–68604), all from in Minas Gerais; eight individuals from four localities from Chapada Diamantina (MNRJ 67504, MNRJ 67571, MNRJ 67597, MNRJ 67626, MNRJ 67698, MNRJ 67771, MNRJ 67772, MNRJ 67783) in Bahia; and four individuals from Barão de Melgaço (MNRJ 64029, MNRJ 64460, MNRJ 64478,

MNRJ 64623) in the northern part of the Pantanal in Mato Grosso.

The adult skull is broad and robust with conspicuous supraorbital ridges, extending almost in parallel along the anterior half of the frontals and diverging toward the squamosoparietal suture. The rostrum is short and wide. The nasal bones do not extend forward of the posterior limit of the premaxillae. An anterior projection of the premaxilla is well developed. The inferior zygomatic root is short and, in lateral view, located almost at the same level of the ventral surface of the rostrum and the palate. The intermaxillary foramen is very marked. The incisive foramina are wide and oval or lyre shaped; the septum is discontinuous, with the premaxillary portion robust and either and elongated or barely reaching the level of the premaxillo-maxillary suture; the maxillary part is short. The vomer is visible in ventral view. Palatal grooves are well developed and house a pair of palatine foramina placed anterior to or at the same level as PM4; more posterior foramina, when present, vary in number, position, and size. A groove with a well-developed lateral flange is present on the floor of the infraorbital foramen. The mesopterygoid fossa is V- or U-shaped, and its extension into the posterior palate varies with age. Among most adults, it typically extends to the middle of M3. The sphenopalatine foramen and vacuities are well developed. The masticatory foramen and foramen ovale accessorius are separated either by a narrow strut or a broader plate. The bullae vary in size from large to small and thus is well or only slightly inflated. The lateral tube of the auditory meatus either extends at right angles to the long axis of the skull or is slanted slightly forward. The contact between the ectotympanic and squamosal is often restricted to the central portion of the dorsal margin of the ectotympanic; this condition is associated with the formation of anterior and posterior clefts between these bones. The jugal may be broad or narrow but always contains a deep fossa. The inferior jugal process is moderately developed, often pointed; it is projected as far as the level of postorbital process of zygoma, which is pointed and formed only by squamosal or by squamosal and jugal. The mandibular foramen is positioned between the posterior limit of the toothrow and the tip of condylar process. The angular process of the dentary extends to or beyond the posterior edge of the condylar process. The coronoid process of the dentary is lower than condylar process.

The dental formula is I 1/1, C 0/0, PM 1/1, M 3/3, total 20. Three roots are present in each maxillary tooth, one lingual and two labial. The occlusal surfaces of the cheek teeth are rounded in the upper toothrow but more prismatic in the lower, where dpm4 is elongated. The first and second molars are larger than the premolar and third molar, with the difference more pronounced in the upper

toothrow. The molar series are parallel or converge slightly anteriorly.

The homology of dental structures remains debatable among living and fossil echimyid genera; here we follow the nomenclature of G. A. S. Carvalho and Salles (2004). Occlusal surfaces of unworn upper teeth have three or four major lophs, including an anteroloph, protoloph, metaloph, and posteroloph. Two or three moderately short and shallow transverse flexi open at the labial surface and extend half way across the tooth width; these become closed islands with wear. Continuous connections are present between the protoloph and protocone and between posteroloph and hypocone; rarely in young individuals both connections may be interrupted by a shallow sulcus. The hypoflexus is short, extends only to the middle of each tooth, and opens primarily to lingual surface; it is the last flexus to close as a dentine island with wear.

The lower dpm4 has four major lophids, including the anterolophid, metalophid, hypolophid, and posterolophid. The metalophid-protoconid and hypolophid-hypoconid pairs are each connected by an ectolophid without interruption by a sulcus. Continuous connections are present between the hypolophid and hypoconid and the anterolophid and protoconid; rarely both connections may be interrupted by a shallow sulcus in young individuals. Three shallow flexids (anteroflexid, mesoflexid, and metaflexid) open from the labial surface, but each becomes fully closed, forming dentine islands, by the time all teeth are fully erupted. A hypoflexid opens primarily from the labial surface but quickly becomes isolated with wear.

Three major lophids are present on m1 to m3, including the anterolophid, hypolophid, and posterolophid. The ectolophid is orientated anteroposteriorly in unworn teeth. The ectolophid of m3 in subadults is sometimes interrupted by a connection between the metaflexid and hypoflexid. There is a continuous connection between the hypolophid and hypoconid and another between the anterolophid and protoconid; rarely both connections are interrupted by a shallow sulcus in young individuals. Two short flexids open primarily from the lingual surface but become closed with wear; these extend about halfway across the occlusal surface. The hypoflexid is short, extending toward the lingual surface maximally to midwidth of the tooth; it opens primarily from the labial surface but also becomes isolated with wear.

Five nominal taxa are identified in the taxonomic literature of *Thrichomys*, including *Echimyus apereoides* Lund, *Echimyus inermis* Pictet, *Isotrix pachyura* Wagner, *Thrichomys fosteri* Thomas, and *Thrichomys laurentius* Thomas. For much of the twentieth century, these names were placed either in *Cercomys* F. Cuvier (*apereoides*, *inermis*, *fosteri*, and *laurentius*) or *Isotrix* (*pachyura*; see Tate

1935). Moreover, until recently most authorities recognized only a single species, *Thrichomys apereoides*, with all other taxa treated as subspecies of as synonyms (Cabrera 1961; Woods 1993; S. F. Reis and Pessôa 2004).

An initial set of morphometric analyses of *Thrichomys* attempted to determine the degree and pattern of geographic structure in the genus, including studies that examined patterns of age and sex variation within specific localities (Moojen et al. 1988; Monteiro et al. 1999), and those that utilized standard (Bandouk and dos Reis 1995; Bandouk et al. 1996) and geometric morphometrics (L. C. Duarte et al. 2000; S. F. Reis et al. 2002a,b; Monteiro et al. 2003). These analyses restricted their geographic scope to samples from central and northeastern Brazil. The resulting geographic patterns were complex, with single population samples often sharply segregated from all others (Bandouk and Reis 1995; L. C. Duarte et al. 2000) or with geometric shape descriptors of the skull and mandible significantly associated with a latitudinal environmental gradient (Monteiro et al. 2003). Nevertheless, these analyses recovered two geographic groupings that differentiated samples from central and northeastern Brazil. Interlocality distances within both the central and northeastern groups exhibited isolation by distance, suggestive of recurrent gene flow, but no such pattern was observed in the among-group comparisons (S. F. Reis et al. 2002b). This pattern was hypothesized as evidence that each group comprised an independent evolutionary unit, without taxonomic implications on the monotypy of the genus (S. F. Reis et al. 2002b). Subsequently, Pessôa et al. (2004) employed standard morphometrics and karyological data to samples from southeastern Brazil (including the material collected by Lund used to describe *apereoides* and more recently collected topotypes) and southwestern Brazil. This study recognized marked divergences between the two geographic samples and referred the latter to *pachyurus* Wagner. Additional analyses in unpublished graduate theses (A. L. G. da Silva 2005; Teixeira 2005; Neves 2008) recognized subtle qualitative discontinuities among some Brazilian populations and have helped to clarify the limits among the described nominal taxa, including different ontogenetic growth patterns among samples from northeastern, central, and southeastern Brazil (Neves 2008; Neves and Pessôa 2011).

Especially for samples from northeastern and central Brazil, results from morphometric studies contrast with published cytogenetic data. The latter have found a wide range of karyological variation, with diploid numbers from 26–34. At least five karyotypes have been described, each with a relatively defined geographic range within Brazil (M. J. Souza and Yonenaga-Yassuda 1982; Svartman 1989; Leal-Mesquita 1991; Leal-Mesquita et al. 1993; J. F. S. Lima 2000; Bonvicino, Otazu, and D'Andrea

2002; Pessôa et al. 2004; Bonvicino, Lemos, and Weksler 2005; A. H. Carvalho and Fagundes 2005; A. L. G. da Silva 2005; L. G. Pereira and Giese 2007; A. H. Carvalho et al. 2008). These samples include one topotype (*T. apereoides* Lund) and three samples collected close to type localities of three other nominal taxa (*T. pachyurus* Wagner, *T. inermis* Pictet, and *T. laurentius* Thomas). One karyotype, however, including samples from central Brazil and northern Tocantins, does not correspond to any available name (A. H. Carvalho and Fagundes 2005; A. H. Carvalho et al. 2008).

Molecular analyses of the mtDNA cytochrome-*b* gene that included most of the known karyomorphs of *Thrichomys* have helped to elucidate intrageneric diversity. These data documented a general correspondence between clade structure and karyotypic units. Braggio and Bonvicino (2004) found high levels of molecular divergence among samples and the recognition of four monophyletic lineages that they named *T. inermis*, *T. pachyurus*, an undescribed species from Tocantins state, and a clade formed by *T. a. apereoides* and *T. a. laurentius*, this last clade composed of two distinct karyomorphs. Most subsequent workers have treated *Thrichomys* as polytypic, with three valid species (Woods and Kilpatrick 2005; J. A. Oliveira and Bonvicino 2006). However, tests of postzygotic reproductive isolation based on crossbreeding experiments indicated that *T. apereoides*, *T. laurentius*, and *T. pachyurus* are best considered as separate biological species (Borodin et al. 2006). In each set of crosses, F1 males were sterile.

Despite the complexity in establishing species boundaries within the genus, including some incongruence among morphometric, cytogenetic, and molecular analyses, recent advances in each have independently documented that at least five species can be recognized, some yet to be described (S. Anderson 1997; Bonvicino, Otazu, and D'Andrea 2002; S. F. Reis et al. 2002a,b; Braggio and Bonvicino 2004; Pessôa et al. 2004; A. L. G. da Silva 2005; Bonvicino, Oliveira, and D'Andrea 2008). After examining type specimens of all nominal forms associated with the genus *Thrichomys* and all available sources of information, especially new data from ontogenetic series (Neves 2008; Neves and Pessôa 2011), we here recognize four named species: *T. apereoides*, *T. inermis*, *T. pachyurus*, and *T. laurentius*. We regard *fosteri* Thomas as a synonym of *T. pachyurus* based on our examination of the qualitative morphology of type material and other specimens from Sapucay and Concepción, Paraguay. We base the morphological characterization of each species on specimens from localities as near as possible of their type localities. However, we recognize that the number of valid species will likely increase in the near future.

We limit our accounts to the four taxa for which available names can be applied with some confidence, but also map the known range of the karyotypic morph that may represent an undescribed species without providing additional details. Further studies that combine data sets and more expansive geographic sampling are required to fully delineate species boundaries and their geographic ranges.

SYNONYMS:

Echimys: Lund, 1839c:98; part (description of *apereoides*); not *Echimys* F. Cuvier.

Nelomys: Lund, 1841:242; part (listing of *antricola* as replacement name for *apereoides*); not *Nelomys* Jourdan.

Isotrrix: Wagner, 1845a:146; part (description of *pachyura*); not *Isotrrix* Wagner.

Thrichomys E.-L. Trouessart, 1880b:179; no type species designated; type species *Echimys apereoides* Lund, by subsequent designation (S. F. Reis and Pessôa 2004).

Loncheres: Pelzeln, 1883:61; part (listing of *pachyura* in synonymy, accorded to Waterhouse 1848); not *Loncheres* Illiger.

Thricomys E.-L. Trouessart, 1897:606; incorrect subsequent spelling of *Thrichomys* E.-L. Trouessart.

Tricomys E.-L. Trouessart, 1904:504; incorrect subsequent spelling of *Thrichomys* E.-L. Trouessart.

Trichomys Miranda-Ribeiro, 1914:42; incorrect subsequent spelling of *Thrichomys* E.-L. Trouessart.

Cercomys: Thomas, 1912e:116; part (listing of *fosteri* and *laurentius*); incorrect generic usage, see Remarks.

REMARKS: In 1880, E.-L. Trouessart proposed the generic name *Thrichomys* to include the names *antricola* Lund (= *Echimys apereoides* Lund), *inermis* Pictet, and *brevicauda* Günther (now a *Proechimys*) but did not designate a type species. By 1912, however, F. Cuvier's much earlier name *Cercomys* became associated with E.-L. Trouessart's *Thrichomys*. Goldman (1912c:94) examined the plates of the skull and dentition of *Cercomys cunicularis* in F. Cuvier (1829b) and concluded that the skull was similar to that of a *Proechimys* J. A. Allen. Thomas (1912e:115–116) analyzed the same plates and agreed that the skull and dentition were similar to *Proechimys*, but argued that adult specimens of *Proechimys* always had spiny pelage, a feature clearly not evident in the specimen figured in Cuvier's plate. To solve this problem, Thomas used a specimen identified as *Cercomys* that he borrowed from Paris Museum, and concluded that this skull was the same as *Thrichomys*, not *Proechimys*, an action that for the next 60 years relegated E.-L. Trouessart's name as a synonym of *Cercomys*. However, the tail figured in Cuvier's plate of *Cercomys cunicularis* was naked, not fully furred as in *Thrichomys*. The incorrect assignment of *Thrichomys* to *Cercomys* was retained in the literature (Ellerman 1940; Moojen 1952b; Cabrera 1961) until Petter (1973) exam-

ined the holotype of *Cercomys cunicularius* F. Cuvier in the Paris Museum and concluded that it was a composite consisting of a skin referable to *Nectomys squamipes* (Brants), a skull referable to *Proechimys* J. A. Allen, and a mandible referable to *Echimys* F. Cuvier. Consequently, since no elements of F. Cuvier's type of *C. cunicularis* represented any taxon connected to E.-L. Trouessart's *Thrichomys*, *Cercomys* F. Cuvier must be removed from its association with that genus. Thus, *Thrichomys* is restored as the correct name applied to the soft-haired, furry-tailed rodents from northeastern Brazil southwest to Paraguay and Bolivia that Thomas (1912e), Tate (1935), and others had placed within *Cercomys*. S. F. Reis and Pessôa (2004) designated *Echimys apereoides* Lund, 1839 as the type species of E.-L. Trouessart's *Thrichomys* (but see Remarks under this species).

KEY TO THE SPECIES OF *THRICHOMYS*:

1. Incisive foramina wide, with a slight constriction due ossification in premaxillomaxillary suture; distal end of hamular processes of pterygoid bone broadening to the tip and often rectangular 2
- 1'. Incisive foramina elongated without constriction between premaxillomaxillary suture; distal end of hamular processes of pterygoid bone becoming thinner and pointed to the tip 3
2. Skull robust; bullae large and well inflated (bullar length 12–15 mm); jugal wide dorsoventrally; paroccipital process not appressed to each bulla; wide plate (ca. 2 mm) between oval and masticatory foramina
. *Thrichomys pachyurus*
- 2'. Skull slender; bullae small and uninflated (bullar length 10–13 mm); jugal narrow dorsoventrally; paroccipital process appressed to each bulla; narrow strut (ca. 0.7 mm) between ovale and masticatory foramina
. *Thrichomys inermis*
3. Lateral flange present on posterior margins of incisive foramina; mesopterygoid fossa U-shaped; palate keeled with well-developed and deep palatal grooves
. *Thrichomys apereoides*
- 3'. Lateral flange on posterior margins of incisive foramina absent; mesopterygoid fossa V-shaped; palate almost flat, with shallow palatal grooves
. *Thrichomys laurentius*

Thrichomys apereoides (Lund, 1839)

Lagoa Santa Punaré

SYNONYMS:

N[elomys]. antricola Lund, 1839a:227, 233; *nomen nudum*.
E[chimys]. apereoides Lund, 1839c [1841a:98]; type locality "Rio das Velhas Floddal" (see Lund 1841a:133–134), Lagoa Santa, Minas Gerais, Brazil.

E[chimys]. antricola Lund, 1840a [1841b:242, footnote; plates 22 and 23]; renaming of *E[chimys]. apereoides* Lund.

Nelomys antricola Lund, 1841:242; name combination.

[Thrichomys] antricola: E.-L. Trouessart, 1880b:179; name combination.

[Thrichomys] apereoides: E.-L. Trouessart, 1880b:179; first use of current name combination.

[Thrichomys] antricola: E.-L. Trouessart, 1897:606; name combination.

[Tricomys] apereoides: E.-L. Trouessart, 1904:504; name combination.

Trichomys apereoides: Miranda-Ribeiro, 1914:42; name combination.

[Cercomys] apereoides: Tate, 1935:409; name combination.

Cercomys cunicularius apereoides: Moojen, 1952b: 173; name combination.

Nelomys apereoides: Petter, 1973:422; incorrect name combination justified as a synonym of *antricola* Lund.

Nelomys apereoides Woods, 1993:798; incorrect subsequent designation of type species and incorrect subsequent spelling of *apereoides* Lund.

T[richomys]. a[pereoides]. apereoides: S. F. Reis and Pessôa, 2004:1; name combination.

DESCRIPTION: Larger in body size than *T. laurentius* and *T. inermis*. Dorsal coloration brownish gray, ventral hairs completely white or with light gray base and contrast with dorsal coloration. Dorsal tail hairs often dark brown, whereas ventral tail hairs whitish gray. The greatest skull length in adults averages 55.61 ± 3.18 mm (N=9). Skull broad with supraorbital ridges extending almost in parallel to middle of frontal bones, and then diverging toward squamosoparietal suture; rostrum short and wide; nasals relatively short, not extending to posterior limit of premaxillae. Anterior projection of premaxilla well developed. Inferior zygomatic root short and, in lateral view, located almost at same level as ventral surface of rostrum and palatal. Interpremaxillary foramen elongated and incisive foramina slender and elongated, lyre shaped, and with lateral flange. Septum of incisive foramina incomplete, its premaxillary portion elongated and extending posterior to premaxillomaxillary contact; maxillary part reduced to small process, and portion of vomer visible in ventral view. Palatal grooves well developed and contain pair of palatal foramina placed at same level as anterior portion PM4. More than two pairs of palatal foramina present, one in median region of palate and other located near level of third molar. Infraorbital foramen large, and floor houses canal with well-developed lateral flanges. Mesopterygoid fossa U-shaped and among most adults extends to middle of M3s. Hamular processes of pterygoid pointed. Sphenopalatine foramen and vacuities well developed. Narrow

strut separates masticatory foramen and foramen ovale accessorius. Bullae large but barely inflated. Lateral tube of auditory meatus perpendicular to longitudinal axis of skull. Jugal moderately wide; jugal fossa very deep. Inferior jugal process conspicuous, often pointed, and projecting at least to level of postorbital process of zygoma. Postorbital process of zygoma pointed and formed only by squamosal or by squamosal and jugal. Mandibular foramen midway between posterior limit of toothrow and tip of condylar process. Angular process of dentary extends as far as condylar process or exceeds its posterior limit; coronoid process lower than condylar process.

DISTRIBUTION: *Thrichomys apereoides* is known from the type locality and a few other localities in Minas Gerais state, Brazil.

SELECTED LOCALITIES (Map 530): BRAZIL: Minas Gerais, Fazenda Canoas, Juramento (Bonvicino, Otazu, and D'Andrea 2002), Lagoa Santa (type locality of *E[chimys]. apereoides* Lund).

SUBSPECIES: *Thrichomys apereoides* is monotypic.

NATURAL HISTORY: Lund (1839c, 1841a) reported that *T. apereoides* often inhabited caves and could be found in human dwellings, stating that the species was an important agricultural pest. He also noted a large number of insect remains at the entrance of burrows and believed that arthropods were important dietary items. The recent dietary study by L. G. Lessa and Costa (2009) confirmed Lund's observation of the importance of insects in the diet, especially during the dry season when fruit availability is low. These authors further documented that seeds comprise the most frequent component of the diet, after arthropods, with large seeds severely damaged after chewing while small seeds of pioneer plants retained a high capacity for germination after passage through the gut. Their data suggested that *T. apereoides* is an important potential disperser of small seed (<1 mm) plants. Arends and McNab (2001) provided physiological attributes for what they referred to as *T. apereoides*, but we cannot confirm the taxon because these authors did not provide data on their voucher specimens.

REMARKS: *Thrichomys apereoides* was one of several species of hystricognath rodents that P. W. Lund described during his work at Lagoa Santa, Minas Gerais, Brazil. He initially (Lund 1839c) described *Echimys apereoides* based on fossil and living material found in and near the caves at Lagoa Santa. Nevertheless, he did not specifically designate a holotype. Later, Lund (1840a, preprint of Lund 1841b:243) divided *Echimys* into four different genera based on the occlusal structure of their cheek teeth. Within one of these, *Nelomys* Jourdan, Lund placed *N. sulcidens* (now *Carterodon sulcidens*) and *N. antricola*, both larger species with short ears and densely haired tails. Lund

(1840a, 1841b:241–242, footnote) coined *antricola* as a replacement name of his earlier name *apereoides*, an allusion to this rodent's habit of living in holes. He (1840a:plate 19; 1841b:plate 22) illustrated the skull and mandibles of his *Nelomys antricola*, drawings that correspond to specimen L. 117 of the Zoologisk Museum, Copenhagen (UZM), and listed there as the "syntypus of *Echimys apereoides* Lund, also syntypus of *Nelomys antricola* Lund." As this is apparently the only specimen of *apereoides* or *antricola* in the Lund collection at UZM (http://www.zmuc.dk/VerWeb/lund/lund_mammals.html), this specimen can be considered the holotype of both *Echimys apereoides* Lund and *Nelomys antricola* Lund.

In 1880, E.-L. Trouessart proposed the name *Thrichomys* as a substitute for *Nelomys* Lund, which was preoccupied by *Nelomys* Jourdan. E.-L. Trouessart did not give priority to *apereoides*, the earliest name used by Lund (1839c), but instead listed *Thrichomys antricola*. Only in 1904 did E.-L. Trouessart allocate *apereoides* to *Tricomys* [sic], when he again misspelled the generic name.

Thrichomys apereoides is known from Pleistocene deposits at Lagoa Santa (Paula Couto 1950).

The chromosomal complement from specimens from Lagoa Santa today is $2n=28$ and $FN=50$ (Pessôa et al. 2004). Bonvicino, Otazu, and D'Andrea (2002) described additional fundamental numbers of 50 and 52 from Juramento, Minas Gerais, and Jaborandi, Bahia, respectively,

Map 530 Selected localities for *Thrichomys apereoides* (○), *Thrichomys inermis* (■), and *Thrichomys pachyurus* (●). Contour line = 2,000 m.

referring both to *T. apereoides*. Herein, we associate specimens with the $2n=28$, $FN=50$, karyotype with Lund's *T. apereoides*, because this karyotype is present in individuals from the type locality. It is unclear at present whether the $2n=28$, $FN=52$, karyotype belongs to the same species or might represent one that is separate and as yet undescribed. Laboratory crosses imply reproductive isolation of topotypical *T. apereoides* from both *T. laurentius* and *T. pachyurus* due to postzygotic barriers (Borodin et al. 2006).

Thrichomys inermis (Pictet, 1843)

Jacobina Punaré, Rabudo

SYNONYMS:

Echimyus inermis Pictet, 1843a:207; type locality "la Jacobine (dans les montagnes de las Almas, province de Bahia," Jacobina, Bahia, Brazil.

[*Thrichomys*] *inermis*: E.-L. Trouessart, 1880b:179; first use of current name combination.

[*Thricomys*] *inermis*: E.-L. Trouessart, 1897:607; name combination.

[*Tricomys*] *inermis*: E.-L. Trouessart, 1904:504; name combination.

Echimyus inermis: Miranda-Ribeiro, 1914:48; name combination.

[*Cercomys*] *inermis*: Tate, 1935:409; name combination.

Cercomys cunicularius inermis: Moojen, 1952b:173; name combination.

T[richomys]. apereoides inermis: Braggio and Bonvicino, 2004:316; name combination.

DESCRIPTION: Smallest species of punaré. Dorsal color ash gray, but slightly more yellow than that of *T. pachyurus* and less yellowish than other two species. Ventral hairs usually completely white, rarely with light-gray base; dorsal tail hairs darker, blackish brown, contrasting sharply with mid-dorsal body color. Ventral tail hairs whitish gray. Skull small and less robust, with greatest length in nonsenile adults averaging 50.58 ± 2.3 mm ($N=16$). Supraorbital ridges extend only to contact between frontal and squamosal bones. Inferior zygomatic root short and, in lateral view, displaced slightly below level of rostrum and palate. Interpremaxillary foramen broad and elongated. Incisive foramina broad, ovate, and sometimes slightly elongated, constricted in region of premaxillomaxillary suture, but not to degree as found in *T. pachyurus*. Septum of incisive foramina discontinuous; its premaxillary portion robust, extending posterior to premaxillomaxillary suture. Vomerine sheath visible in ventral view, at level of premaxillary portion of septum. Maxillary part reduced to small process continuous with well-developed palatal crest, more prominent than in *T. laurentius*. Groove with well-developed lateral flange for passage of infraorbital nerve

present on floor of infraorbital foramen. Mesopterygoid fossa V-shaped and extends anteriorly the middle of M3s in adults. Hamular processes of pterygoid almost always rectangular at tip. Bullae small to medium; lateral tube of auditory meatus directed perpendicular to long axis of skull. Jugal thinner than in other species, but jugal fossa remains very deep. Postorbital process of zygoma pointed and often formed mainly by squamosal in adults. Thin strut separates masticatory foramen, and foramen ovale accessorius separated. Mandibular foramen with middle position between posterior limit of toothrow and tip of condylar process. Angular process of dentary slender and extends to posterior limit of coronoid process; coronoid process of dentary spiny and lower than condylar process.

DISTRIBUTION: *Thrichomys inermis* is known from the type locality and few other localities in the central region of Bahia state north to central Tocantins state in central Brazil.

SELECTED LOCALITIES (Map 530): BRAZIL: Bahia, Barreiras (L. C. Duarte et al. 2000), Chapada Diamantina (L. G. Pereira and Geise 2007), Jacobina (type locality of *Echimyus inermis* Pictet), Lençóis (J. A. Oliveira and Pessôa 2005), Mucujê (Leal-Mesquita et al. 1993), Santo Inácio (Leal-Mesquita et al. 1993), Sento Sé (Bonvicino, Otazu, and D'Andrea 2002), Vacaria (Leal-Mesquita et al. 1993); Tocantins, Jalapão (A. H. Carvalho and Fagundes 2005), Rio Sono (A. H. Carvalho et al. 2008).

SUBSPECIES: *Thrichomys inermis* is monotypic.

NATURAL HISTORY: The Caatinga, the semiarid biome where both *T. inermis* and *T. laurentius* occur, is characterized by an unpredictable rainfall regime (Streilein 1982a). Compared to areas where species of echimyid rodents occur, the Caatinga also records the highest insolation, lowest degree of cloudiness, highest mean temperature, and lowest relative humidity (Nimer 1979). Some physiological and behavioral characteristics of species of *Thrichomys* may have evolved as a response to this extreme environment (Streilein 1982a, 1982b, 1982c; Roberts et al. 1988; Meyerson-McCormick et al. 1990; Mendes et al. 2004). Individuals frequent granite or sandstone formations, locally called *lajeiros* or *lajedos*, which provide crevices for temporary refuges and secure shelter (Streilein 1982d). The nests constructed of cotton, straw, or dry leaves are built in rocky crevices or in hollow trees (Moojen 1943a). For a small mammal that lives in this extreme biome, the heat-retaining and insulating properties of rock help in thermoregulation, providing a cool refuge during warm hours and a warm home during the cold night (Nutt 2007).

In common with Lund's (1839c, 1841a) observations on *T. apereoides*, we captured individuals of *T. inermis* inside the entrance of the Lapa de Brejões, a large cave in the northern Chapada Diamantina, Bahia. Moojen (1943a)

also reported that northeastern *rabudos* might live in tree cavities or more rarely among stems of the spiny macambira bromeliad (*Bromelia lacinosa*), likely a characteristic of both *T. inermis* and *T. laurentius*. Although *T. inermis* appears primarily terrestrial, we captured it at a height of 2 m on a tree branch at Morro do Chapéu, thus indicating at least a limited climbing ability.

Few data are available on reproductive biology of *T. inermis*. Moojen (1952b) recorded females with two, three, or four embryos or young at two localities in February and March in Bahia state.

Mendes et al. (2004) reported on physiological responses to stressful environmental conditions in a comparative study on populations from Curaçá and Ibiraba, Bahia state. Although these authors treated both populations they studies as *T. apereoides*, we believe the sample from Curaçá is more appropriately referred to *T. inermis* and the population from Ibiraba to *T. laurentius* based on karyological data of individuals from Ibiraba (Leal-Mesquita et al. 1993) and on the small mass of the specimens from Curaçá (Mendes et al. 2004). These authors argued that some feeding parameters were partially driven by precipitation conditions. Individuals from Ibiraba, where mean annual precipitation is 700 mm, decrease their relative food intake and relative urine volume while increasing the urine osmolality when exposed to water scarcity. On the other hand, individuals from Curaçá, where annual precipitation is 50% less, maintained stability in these parameters under the same stimulus.

Although *T. laurentius* has been given as the type host of the lice *Gyropus cercomydis* and *G. scalaris*, the type locality of these two parasites is Xique-Xique, Rio São Francisco, Bahia, Brazil. Only *T. inermis*, not *T. laurentius*, is present at this locality (Valim and Linardi, 2008).

REMARKS: Woods and Kilpatrick (2005:1589) erred in giving the publication date for Pictet's *Echimyis inermis* as 1841 rather than 1843. The chromosomal complement is $2n=26$, $FN=48$ (Pessôa et al. 2004). The species status of *T. inermis* is supported by both chromosomal data (Bonvicino, Otazu, and D'Andrea 2002) and molecular phylogenetics (Braggio and Bonvicino 2004).

Thrichomys laurentius Thomas, 1904

São Lourenço Punaré

SYNONYMS:

Thrichomys laurentius Thomas, 1904c:254; type locality "São Lourenço [=São Lourenço da Mata], near Pernambuco, Alt. 50 m," Pernambuco, Brazil.

C[ercomys]. laurentius: Thomas, 1912e:116; name combination.

Cercomys cunicularius laurentius: Ellerman, 1940:124; name combination.

T[richomys]. apereoides laurentius: Braggio and Bonvicino, 2004:316; name combination.

[*Thrichomys apereoides*] *laurentius* Woods and Kilpatrick, 2005:1589; incorrect subsequent spelling of *laurentius* Thomas.

DESCRIPTION: Medium-sized punaré when compared with other species. Dorsum generally yellowish gray and ventral hairs completely white or with gray base, contrasting with dorsal coloration. Dorsal tail hairs yellowish gray and markedly longer on dorsal surface; ventral tail hairs whitish. Cranium of *T. laurentius* small, but larger than that of *T. inermis*. Average length of adult skulls 53.75 ± 3.28 mm ($N=15$). Supraorbital ridges extend posteriorly to squamosoparietal suture. Rostrum short and wide; nasal bones do not reach posterior limit of premaxillary bones. Anterior projection of premaxilla well developed. Inferior zygomatic root short and, in lateral view, placed slightly below level of rostrum and palate. Interpremaxillary foramen narrow with constrictions on both ends. Incisive foramina wide and oval shaped; septum of incisive foramina occupies more than half foraminal opening. Palatal grooves little developed and contain single pair of foramina placed near front of PM4. Palate almost flat. Floor of infraorbital foramen with groove for passage of infraorbital nerve, with well-developed lateral flange. Mesopterygoid fossa V-shaped, extending in adults to middle of M3s. Hamular processes of pterygoid bones pointed at tip. Sphenopalatine foramen and vacuities well developed. Narrow strut separates masticatory foramen and foramen ovale accessorius. Bullae medium in size and only slightly inflated; lateral tube of auditory meatus short. Jugal narrow but contains very deep fossa. Inferior jugal process pointed, projecting to level of postorbital process of zygoma, which is pointed and formed mainly by squamosal. Mandibular foramen located closer to tip of condylar process when compared with other species. Angular process of dentary exceeds posterior edge of condylar process; coronoid process of dentary is lower than condylar process.

DISTRIBUTION: *Thrichomys laurentius* occurs in northeastern Brazil.

SELECTED LOCALITIES (Map 531): BRAZIL: Alagoas, Delmiro Gouveia (Braggio and Bonvicino 2004), Palmeira dos Índios (L. C. Duarte et al. 2000); Bahia, Caetitê (Bonvicino, Otazu, and D'Andrea 2002), Queimada (Leal-Mesquita et al. 1993); Ceará, Chapada Ibiapaba (Bonvicino, Otazu, and D'Andrea 2002), Itapagé (Bandouk and Reis 1995), Jaguaruana (Bonvicino, Otazu, and D'Andrea 2002); Pernambuco, São Lourenço da Mata (type locality of *Thrichomys laurentius* Thomas); Piauí, Fazenda Felicidade (Bonvicino, Otazu, and D'Andrea 2002), João Costa (Braggio and Bonvicino 2004).

SUBSPECIES: *Thrichomys laurentius* is monotypic.

NATURAL HISTORY: Moojen (1952b) reported that in dry season *T. laurentius* ate *emacambira* buds (*Bromelia lacinosa*), leaves of the cactus locally named *mandacaru* (*Cereus jamacaru*), and the *catolé* coconut (*Attalea* sp.). In Caatinga habitat, *T. laurentius* also forages on the pads of the cactus *Opuntia palmadora*, using them as a source of water (Streilein 1982a). At Exu in Pernambuco state, this species has an activity peak at dusk but may also be active during short periods of both day and night (Streilein 1982a). In the same population, female home ranges rarely overlapped, but those of males overlapped with multiple females but were relatively exclusive to other males. Streilein (1982e) showed that reproductive activity occurred in every month of the year, with a peak from September to December. Adult females produced two or three litters per year, with an interbirth interval of four to six months. Litter size averaged 3.1 but varied from one to six (Streilein 1982c). Pregnant females in Ceará state were captured in July with one to four embryos, with two most common (Moojen 1952b). Roberts et al. (1988) found litter size in captive individuals to vary from one to seven, with an average of 3.2 (1.42 s.d.), a positive correlation between the mother's age and litter size, and a gestation period of 95 to 98 days. The milk of captive females has high fat content, a possible adaptation to minimize water loss in an arid environment (Meyerson-McCormick et al. 1990). Neonates are precocial, born at an average weight of 2.1 g, with sufficient motor coordination to eat solid food a few hours after birth, with eyes and ears open, a fully furred body, and upper and lower incisors erupted (Roberts et al. 1988).

Records of predators of *T. laurentius* are rare, but include the Barn Owl (*Tyto alba*; Roda 2006), and the Maned wolf (*Chrysocyon brachyurus*; F. H. G. Rodrigues et al. 2007). In northeastern Brazil, punaré may be included in diet of local human populations (C. T. Carvalho 1979).

Thrichomys laurentius is the type host of the louse *Gyropus lenti lenti*, whose type locality is Ceará, Brazil. The same louse also parasitizes *T. apereoides* and *T. inermis* from localities in the states of Bahia, Ceará, Goiás, Minas Gerais, and Pernambuco (Valim and Linardi 2008). While *T. inermis* is given as the type host of another louse, *G. freitasi*, with type locality Serra do Pacoti, Ceará, only *T. laurentius* occupies this area (Valim and Linardi 2008).

REMARKS: M. J. Souza and Yonenaga-Yassuda (1982) recorded a karyotype of $2n=30$ and $FN=54$ from several localities in Pernambuco state. Later, Bonvicino, Otazu, and D'Andrea (2002) found this karyotype in other localities from northeastern Brazil, which they allocated to *T. laurentius*, although the karyotype of specimens from the type locality is unknown. Other specimens collected in central Brazil (Brasília, Distrito Federal; Fazenda Osara, Tocantins state; and Cavalcante, Mimoso de Goiás,

Map 531 Selected localities for *Thrichomys laurentius* (●) and *Thrichomys* sp. [$2n=30$, $FN=56$ karyomorph] (○).

and Teresina de Goiás, Goiás state) have the same diploid number but a different fundamental number ($FN=56$; Svartman 1988; J. F. S. Lima 2000; Bonvicino, Otazu, and D'Andrea 2002). These specimens cannot currently be assigned to any described taxon, but Bonvicino, Otazu, and D'Andrea (2002), Braggio and Bonvicino (2004), and Bonvicino, Oliveira, and D'Andrea (2008) argued they represented an undescribed species. We map these localities separately from the range of *T. laurentius* in Map 531.

Specimens collected at Jaíba, in the northern part of Minas Gerais, were also $2n=30$, but their fundamental number was undetermined (Pessôa et al. 2004), and thus their allocation to karyomorph, and perhaps to species, cannot be determined as yet. It is of note that Moojen (1952b), based on morphological data, recognized two taxa from Minas Gerais state, one from Lagoa Santa and another from further to the north.

Thrichomys pachyurus Wagner, 1845

Paraguayan Punaré; Rato-boiadeiro

SYNONYMS:

Isothrix pachyura Wagner, 1845a:146; type locality "Cuyaba [= Cuiabá]," Mato Grosso, Brazil, by subsequent designation (Pelzeln 1883:61).

Isothrix pachyurus: Wagner, 1848:291; name combination, but incorrect gender concordance.

Isothrix crassicaudus Wagner, 1848:291; replacement name for *Isothrix pachyurus* Wagner; incorrect gender concordance.

Loncheres (Isothrix) pachyura: Pelzeln, 1883:61; name combination.

Thrichomys pachyurus: E.-L. Trouessart, 1880b:179; first use of current name combination.

[*Tricomys*] *pachyurus*: E.-L. Trouessart, 1897:607; name combination.

Thrichomys Fosteri Thomas, 1903a:227; type locality "Sapucay," Paraguari, Paraguay.

[*Tricomys*] *fosteri*: E.-L. Trouessart, 1904:504; name combination.

[*Tricomys*] *pachyurus*: E.-L. Trouessart, 1904:504; name combination.

C[*ercomys*]. *fosteri*: Thomas, 1912e:116; name combination.

Cercomys cunicularius fosteri: Ellerman, 1940: 124; name combination.

Cercomys cunicularius pachyurus: Moojen, 1952b:172; name combination.

Isothrix bistrata pachyura: Cabrera, 1961:537; name combination.

Thrichomys apereoides fosteri: S. Anderson, 1997:512; name combination.

[*Thrichomys*]. *apereoides pachyurus*: Braggio and Bonvicino, 2004:316; name combination.

DESCRIPTION: Largest species in genus. Dorsum generally ash gray, and ventral hairs either completely white or a light gray base, thus contrasting with dorsal coloration. Dorsal tail hairs blackish brown and contrast strongly with color of mid-dorsum; underside of tail whitish gray. Skull broadest and most robust of any species in genus; greatest skull length averages 55.43 ± 2.06 mm (N=10). Supra-orbital ridges extend at least to frontosquamosal suture. Rostrum short and wide, and nasal bones do not extend posterior to premaxillae. Anterior projection of premaxilla well developed. Inferior zygomatic root short and, at lateral view, placed at slightly lower level than rostrum and palate. Interpremaxillary foramen rounded and intermediate in size when compared with other species. Incisive foramina oval, and widest of all congeners, with indentation caused by ossification of premaxillomaxillary suture; septum of incisive foramina incomplete, its premaxillary portion elongated in younger individuals but shorter in adults; its posterior margin does not extend to premaxillomaxillary suture; maxillary part of septum reduced to small process, and significant portion of vomer visible ventrally. Palatal grooves and median ridges more strongly developed than in other species; palatal foramina of varying number and size found within these grooves, although first is always placed at front of palate, often inside groove formed

by incisive foramina. Groove for passage of infraorbital nerve present on floor of infraorbital foramen; it possesses well-developed lateral flange. Mesopterygoid fossa U-shaped, its extension varying ontogenetically but among adults often reaching to middle of M3s. Hamular process of pterygoid rectangular in shape and broad at tip. Sphenopalatine foramen and vacuities well developed. Wide and complex plate separates masticatory foramen and foramen ovale accessorius. Bullae largest and most inflated among all species, and lateral tube of auditory meatus not directed outward as in other species but curves up in both juveniles and adults. Jugal robust and the major contributor to zygomatic arch, which possesses very deep fossa. Inferior jugal process often pointed, projecting as far as level of postorbital process of zygoma. Postorbital process of zygoma pointed and formed mainly by squamosal. Mandibular foramen positioned half way between posterior limit of toothrow and tip of condylar process. Angular process of dentary slender and extends to posterior limit of coronoid process, which is spiny and lower than condylar process.

DISTRIBUTION: *Thrichomys pachyurus* has the westernmost range of the genus, occurring from western Brazil, in states of Mato Grosso and Mato Grosso do Sul, through Paraguay and Bolivia.

SELECTED LOCALITIES (Map 530): BOLIVIA: Santa Cruz, Roboré (S. Anderson 1997). BRAZIL: Mato Grosso, Cuiabá (type locality of *Isothrix pachyura* Wagner), Reserva Particular do Patrimônio Natural do Serviço Social do Comércio (Pessôa et al. 2004), Tucum (MNRJ 1947), Usina Hidroelétrica Manso (Lacher and Alho 2001); Mato Grosso do Sul, Corumbá, Fazenda Alegria, Corumbá (Bonvicino, Otazu, and D'Andrea 2002); Fazenda Princesinha (Cáceres et al. 2007). PARAGUAY: Alto Paraguay, Fortín Madrejon (UMMZ 125552); Amambay, Pedro Juan Caballero (UMMZ 125301); Concepción, 8 km E of Concepción (MVZ 145320); Paraguari, Sapucay (type locality of *Thrichomys fosteri* Thomas).

SUBSPECIES: *Thrichomys pachyurus* is monotypic.

NATURAL HISTORY: Pelzeln (1883) reported that individuals from Cuiabá were collected inside human dwellings. Moojen (1952b) reported a lactating female in July taken near Cuiabá. During our own fieldwork at Barão de Melgaço (from 1999–2004) in the northern Pantanal region, this species was collected in traps set in trees about 1.5 m above the ground during the rainy season in February. We also observed a female with two young in a nest constructed inside an abandoned house.

In contrast to the Caatinga, the Pantanal is a very humid area with predictable rainfall characterized by distinct dry and rainy seasons. In this area, rocky outcrops do not occur, and *T. pachyurus* are commonly found among aggregations of the *acuri* palm, *Attalea phalerata* (Z. Cam-

pos and Mourão 1988; Camilo-Alves and Mourão 2010). These authors also reported that animals took palm fruits to their borrows or nearby, where they ate both mesocarp flesh and seed. *Thrichomys pachyurus* is primarily terrestrial but may climb trees. Püttker et al. (2012; see also Püttker, Prado et al. 2013) and Oliveira-Santos et al. (2013) estimated home range by telemetry and distances between successive captures.

Thrichomys pachyurus and *T. laurentius* are natural hosts of *Trypanosoma cruzi*, the vector agent of Chagas disease (Rodrigues Roque et al. 2005; Xavier et al. 2007). As a consequence, breeding colonies of both species have been established to serve as experimental models in various parasitological studies. Both taxa exhibit attributes that make them excellent laboratory models: they can be easily maintained in standard laboratory conditions, breed throughout the year, do not have any special dietary demands, and can be sustained on food pellets designed for laboratory mice. In captivity, *T. pachyurus* produces precocial offspring that have both eyes and ears open, teeth erupted, fur well developed, and that are capable of eating solid food in the first week of life. *Thrichomys pachyurus* has smaller litter sizes with larger masses at birth in comparison to *T. laurentius*. Teixeira et al. (2005) compared reproductive traits of *T. pachyurus* and *T. laurentius*, noting that females of the former became reproductively active later and at a larger mass than those of the latter.

Thrichomys pachyurus is the type host of the louse *Gyropus lenti distinctus*, with type locality of Salobra, Mato Grosso do Sul, Brazil (Valim and Linardi 2008). Gentili et al. (2012) recorded 12 species of helminths in specimens from two localities in the Pantanal of Brazil. Species richness of worms was higher during the wet season, with only a few very common species present in the dry season. These authors related this seasonal pattern with increased habitat availability and host population increases during the dry season.

REMARKS: Cabrera (1961) followed Wagner (1845a) and allocated *pachyura* (including *crassicaudus* Wagner) to the genus *Isothrix* as a valid subspecies of *I. bistriata*. Patton and Emmons (1985) maintained this error in their review of the species of *Isothrix*. Our comparisons of the type specimens of *pachyura* Wagner and *bistriata* Wagner in the Natural History Museum in Vienna, Austria, confirmed the hypothesis posed by Pessôa et al. (2004) that Wagner's *pachyura* is indeed a *Thrichomys* and not an *Isothrix*, as E.-L. Trouessart established in 1880. Tate (1935:414) incorrectly dated *crassicaudus* Wagner to 1850 instead of 1848 (see Sherborn 1925b).

S. F. Reis and Pessôa (2004) followed S. Anderson (1997) and regarded *fosteri* Thomas as a subspecies of *T. apereoides* (*sensu lato*). Qualitative characters used by Thomas

in the original description of *fosteri* were applied in comparisons to the type specimen of *pachyurus* Wagner, and no differences were found. Thus, we regard *fosteri* as a junior synonym of *pachyurus*. Future analyses of geographic variation in morphology, karyotype, and molecular sequences that include samples from Paraguay and the Pantanal from Mato Grosso are needed to confirm this hypothesis.

Salles et al. (2005) recovered subfossil remains of *Thrichomys* from cave deposits in the Serra da Bodoquena, Mato Grosso do Sul. These presumably represent *T. pachyurus* because this species is present in the area today (Cáceres et al. 2007).

The chromosomal complement in *T. pachyurus* is $2n=34$, FN=54 (Pessôa et al. 2004).

Genus *Trinomys* Thomas, 1921

Leila M. Pessôa, William C. Tavares, João A. de Oliveira, and James L. Patton.

Species within *Trinomys* are terrestrial, cursorial rats that share a similar gross craniodental and body morphology to those of *Proechimys*. Primarily as a result of these shared similarities, species of both taxa, popularly called spiny rats, were united within a single genus (*Proechimys*) for most of the past century, divisible only at the subgeneric level. However, the combination of biogeographic data, details of dental morphology, and molecular phylogenetic analyses have progressively characterized *Trinomys* as a singular entity in the echimyid radiation, one that does not share a sister relationship with *Proechimys*. Today, *Trinomys* is treated as a genus that comprises one of the most diversified and complex hystricognathous groups in eastern Brazil, with 10 described species currently recognized. Species in the genus are distributed over a wide area in the Atlantic Forest and Caatinga of eastern and southern Brazil, within a myriad of local environments ranging from very humid pluvial forests to semiarid sand dunes (Moojen 1948; Pessôa and Reis 1992a; P. L. B. Rocha 1996; Lara and Patton 2000; Attias et al. 2009; Tavares and Pessôa 2010).

The oldest fossil unambiguously assignable to *Trinomys* dates from the Pleistocene deposits at Lagoa Santa, Minas Gerais (Lund 1839c, 1841a; Paula Couto 1950; McKenna and Bell 1997). However, molecular clock studies suggest that genus began diversification by the Late Miocene (Y. L. R. Leite and Patton 2002; Galewski et al. 2005; Upham and Patterson 2012).

These are moderately large rats with the head and body length of adults varying from 152 mm in *T. albispinus* to 246 mm in *T. paratus* (with respective tail length 148–246 mm), and mass from 120–350 g (Pessôa and Reis 2002). As in other cursorial echimyids, the tail is moderate

in length (ranging from 80–120% of head and body length) and the hindfeet are elongated and narrow (ranging from 39 mm in *T. albispinus* to 55 mm in *T. eliasi*; Pessôa and Reis 2002; Tavares and Pessôa 2010). The tail is markedly bicolored in all species, although there are rare localized exceptions. Hairs along tail are sparse and very short, but the distal tip of the tail may or may not present a hairy bush, which is variable in color and size. General dorsal coloration ranges from light cinnamon to dark brownish, gradually becoming lighter on sides. The venter is always uniformly white, contrasting sharply with the darker dorso-lateral coloration. Dorsal aristiforms extend from head to the base of tail. There is a broad range of variation in the general appearance of aristiform spines, with their mean width varying greatly among species. The vibrissae are elongated and extend posteriorly as far as the shoulder. Females have two abdominal mammae.

The adult skull is slender with a moderately long rostrum and supraorbital ridges that diverge posteriorly along the frontals toward the frontoparietal suture. The nasal bones extend forward of the posterior limit of the premaxillae. An anterior projection of the premaxilla is well developed. The inferior zygomatic root is short and, in lateral view, located almost at the same level of the ventral surface of the rostrum and the palate. The interpremaxillary foramen is absent or dot-like. Incisive foramina are moderately wide and oval or lyre shaped; the septum may be either continuous or discontinuous; and the vomer is either visible or not in ventral view. Palatal grooves are not well developed and house a variable number of palatine pits. The floor of the infraorbital foramen lacks a groove for the passage of the infraorbital nerve. The mesopterygoid fossa is V- or U-shaped, and its extension into the posterior palate varies with age. The sphenopalatine foramina and vacuities are moderately developed. The bullae vary in size from large to small, ranging from well to slightly inflated. The contact between the ectotympanic and squamosal is often restricted to the central portion of the dorsal margin of the ectotympanic; this condition is associated with the formation of anterior and posterior clefts between these bones. The jugal may be broad or narrow and may present a moderately deep fossa. The inferior jugal process is moderately developed, often pointed. The postorbital process of the zygoma is pointed or rounded and formed by squamosal or by the jugal alone, or by both elements. The mandibular foramen is positioned between the posterior limit of the toothrow and the tip of condylar process. The angular process of the dentary extends to or beyond the posterior edge of the condylar process. The coronoid process of the dentary is lower than condylar process.

The first and second molars are larger than the premolar and third molar, with the difference more pronounced

in the upper toothrow. The molar series are parallel or converge slightly anteriorly. Homology of dental structures among living and fossil echimyid genera remains debatable (G. A. S. Carvalho and Salles 2004; Candela and Rasia 2012). Occlusal surfaces of unworn upper teeth have three to five major lophs, including an anteroloph, protoloph, metaloph, and posteroloph. Herein, we follow Moojen's (1948) nomenclature of mainfolds and counterfolds in the diagnosis of species.

The baculum of adult males in *Trinomys* species is elongate and narrow, with a shaft that is straight or with a slight dorsoventral curvature and a broadened proximal end. Both the proximal and distal ends vary in shape. The proximal end is typically paddle shaped, but the distal end can be straight or possess a median depression with slightly or developed distal wings (Pessôa and Reis 1992a; P. L. B. Rocha 1996; Pessôa et al. 1996; Lara et al. 2002; Tavares and Pessôa 2010).

Moojen subsumed 14 nominal taxa then known into five species, three polytypic and one included in *Trinomys* only as *incertae sedis*. Subsequent researchers have invested considerable effort to understand the variation of taxa allocated to the genus *Trinomys*. These have resulted in the reordering of existing taxa as well as the description of new ones, at both the species (Pessôa et al. 1992; P. L. B. Rocha 1996; Lara et al. 2002) and subspecies levels (Pessôa and Reis 1993a; S. F. Reis and Pessôa 1995). Each of these studies used morphological markers (as, for example, unique qualitative aspects of the bacular morphology) to define limits of variation at the species level (Pessôa and Reis 1992a, 1994; P. L. B. Rocha 1996; Pessôa et al. 1996; Lara et al. 2002; Iack-Ximenes 2005). Lara and Patton (2000) also developed the initial hypothesis of specific and infraspecific structure within the genus based on mtDNA cytochrome-*b* sequences. Their analyses recovered three clades, each of which had some morphological cohesion (Lara and Patton 2000), including general concordance between the ordination of taxa based on cranial shape, using geometric morphometrics, and the molecular phylogeny (Nicola et al. 2003). Two nominal taxa (*panema* Moojen, 1948 and *moojeni* Pessôa, Oliveira, and Reis, 1992) have yet to be included in any molecular phylogenetic analysis. Karyotypic data are now available for nine of the nominal taxa in the genus (Yonenaga-Yassuda et al. 1985; Leal-Mesquita et al. 1992; Corrêa et al. 2005; Pessôa et al. 2005; A. L. G. Souza et al. 2006), with A. L. G. Souza et al. (2006) documenting congruence between cytogenetic and molecular data. Thus, despite the complexity in establishing morphological boundaries that map to species units within the genus, further integration of diverse data sets offers the hope that more clearly defined limits will be forthcoming in the near future.

Of the 19 nominal taxa now allocated to the genus (e.g., Woods and Kilpatrick 2005), we limit our accounts to 10 species for which available names can be applied with some security. As noted above, further studies that combine data sets and more expansive geographic sampling are required to delineate fully species boundaries and their geographic ranges. The species we regard as unequivocally valid include: *Trinomys albispinus* (I. Geoffroy St.-Hilaire), *Trinomys dimidiatus* (Günther), *Trinomys eliasi* (Pessôa and Reis), *Trinomys graciosus* (Moojen), *Trinomys iheringi* (Thomas), *Trinomys mirapitanga* Lara, Patton, and Hingst-Zaher, *Trinomys moojeni* (Pessôa, Oliveira, and Reis), *Trinomys paratus* (Moojen), *Trinomys setosus* (Desmarest), and *Trinomys yonenagae* (Rocha). We comment on hypothesized relationships, based on molecular or other character traits, in the accounts that follow.

SYNONYMS:

Echimys: Desmarest, 1817b:59; part (description of *setosus*); not *Echimys* F. Cuvier.

Loncheres: Lichtenstein, 1820:192; part (description of *myosurus*); not *Loncheres* Illiger.

Mus: Brants, 1827:150; part (description of *leptosoma*); not *Mus* Linnaeus.

Echinomys: Wagner, 1843a:339; part (listing of *albispinus*); unjustified emendation of *Echimys* F. Cuvier.

Proechimys: J. A. Allen, 1899c:264; part (listing of *albispinus*, *dimidiatus*, and *setosus*); not *Proechimys* J. A. Allen.

Trinomys Thomas, 1921h:140; part; proposed as a subgenus of *Proechimys* J. A. Allen, 1899; type species *Proechimys albispinus* I. Geoffroy St.-Hilaire, by original designation.

Prochimys: Cerqueira, Gentile, Fernandez, and D'Andrea, 1994:512, Fig. 2; listing of *iheringi*; *lapsus calami*.

Trinomys: Lara and Patton, 2000:661; first regarded as full genus.

REMARKS: Historically, the generic name *Trinomys* was etymologically based on of the number of counterfolds in the molariform teeth. Thomas (1921h) recognized two subgenera in the genus *Proechimys* (*Proechimys* and *Trinomys*), defining *Proechimys* as those terrestrial spiny rats with four counterfolds and *Trinomys* as those with three. According to this definition, the subgenus *Proechimys* encompassed all species occurring in Central America, the Amazon Basin, and central Brazil plus one species, *P. iheringi*, from the Atlantic Forest in southeastern Brazil. Moojen (1948:312) observed, however, that the main fold in molariform teeth was short in all forms allocated by Thomas to the subgenus *Proechimys*, except *P. iheringi*, while in all Atlantic Forest taxa, including *P. iheringi*, this fold extended entirely across the occlusal surface. Moojen (1948) then used this character difference to diagnose the two subgenera, rather than the number of counterfolds,

which he documented as highly variable at the subspecific level. The subgeneric division between *Trinomys* and *Proechimys* espoused by both Thomas and Moojen assumed a close, sister relationship between the two taxon groups, a hypothesis supported by cladistic analysis of craniodental traits (G. A. S. Carvalho and Salles 2004) and dental characters alone (Candela and Rasia 2012) but refuted by all molecular phylogenetic studies using either, or both, mitochondrial and nuclear gene sequences (Lara et al. 1996; Y. L. R. Leite and Patton 2002; Galewski et al. 2005; Upham and Patterson 2012). All molecular studies document a strongly supported relationship between *Trinomys* species and *Clyomys*+*Euryzygomatomys* to the exclusion of *Proechimys* species, which in turn are sisters successively to *Hoplomys* and then *Thrichomys* within the Eumysopinae.

Voss and Abramson (1999) pointed out that *Mus leucogaster* Brandt, then regarded as the type species of the sigmodontine rodent *Holochilus*, was in fact based on a specimen of *Trinomys*. If allowed to stand, *Holochilus* Brandt would become the senior synonym for the spiny rats grouped by Thomas into *Trinomys* 90 years ago, an action that would contravene name associations that have stood in the literature for more than a century. Hence, Voss and Abramson (1999) petitioned the International Commission on Zoological Nomenclature to conserve *Holochilus* Brandt for the myomorphous marsh rats and both *Proechimys* and *Trinomys* for the hystricomorphous spiny rats, to which the International Commission (ICZN 2001:Opinion 1984) agreed, using its plenary power to designate *Holochilus sciureus* Wagner as the type species of *Holochilus* and preserve *Trinomys* Thomas for the southern Brazilian spiny rats. Because the holotype of Brandt's *leucogaster* is a specimen of *Trinomys*, this name is appropriately connected to the genus. Comparisons of the holotype (a skin with skull and mandibles, cataloged as ZINRAS 219; see Voss and Abramson 1999:257) are needed to link Brandt's name to one of the species we recognize herein, and once done, *leucogaster* may well become a senior synonym of one of them.

KEY TO THE SPECIES OF *TRINOMYS*:

1. Tail shorter than head and body length (about 87–96%), without a conspicuous brush of elongated hairs in the tip. 2
- 1'. Tail length similar or longer than head and body length (from 100–130%), with conspicuous brush of elongated hairs in the tip. 7
2. White aristiforms on back sides, rump and at base of tail; septum of incisive foramen often incomplete, with premaxillary portion at a level lower than maxillary portion; molars with only one counterfold; baculum longer than 11 mm in adult specimens, with large distal wings *Trinomys albispinus*

- 2'. Without marked white aristiforms on back sides, rump and at base of tail; septum of incisive foramina variable; molariform teeth with more than one counterfold; baculum less than 10 mm in length in adult specimens, without conspicuous large distal wings. 3
3. Incisive foramina medium sized to large (3.3–5.9 mm), premaxillary portion of septum broad and maxillary portion very constricted, septum often incomplete; baculum with a broad basal paddle-shaped expansion, lateral indentation near distal end. 4
- 3'. Incisive foramina small to medium sized (2.8–4.8 mm); septum always complete; baculum often with basal expansion rounded, with lateral indentation near mid-shaft. 5
4. Incisive foramina long and constricted posteriorly; $2n=56$; $NA=108$ *Trinomys graciosus*
- 4'. Incisive foramina large and wide posteriorly; $2n=56$; $NA=106$ *Trinomys moojeni*
5. General mid-dorsal coloration very dark tending to blackish; mid-dorsal aristiform hairs very wide (mean width 1.49 mm) and *Trinomys mirapitanga*
- 5'. General mid-dorsal coloration dark tending to brownish; very narrow mid-dorsal aristiforms (mean width 0.6 mm) 6
6. Differentiated light-colored pelage on outer thighs; incisive foramen constricted on posterior end; postorbital process of zygoma contributed by jugal and squamosal; presence of dot-like supernumerary chromosomes, $2n=61-65$, $NA=116$ *Trinomys iheringi*
- 6'. No differentiated light-colored pelage on outer thighs; incisive foramen wide posteriorly; postorbital process of zygoma contributed primarily by the squamosal; absence of dot-like supernumerary chromosomes, $2n=60$; $NA=116$ *Trinomys dimidiatus*
7. Molariform teeth with only one counter-fold; very inflated auditory bullae (mean bullar length 11.70 mm); skull small to medium sized (mean basilar length 32.79 mm) and slender; dorsal pelage pale brownish; very elongated hindfeet (about 27% the head and body length in adults); tail length about 130% of head and body length; terminal tail brush highly developed. *Trinomys yonenagae*
- 7'. Molariform teeth almost always with two or more counterfolds; auditory bullae small to moderately inflated; skull usually large and stout; dorsal pelage variable from dark brownish to cinnamon 8
8. Incisive foramina oval and long, with posterolateral margins of maxillary flat or slightly flanged; septum of incisive foramina complete and columnar; vomer not visible under ventral view; mid-dorsal aristiforms very wide (mean width 1.58 mm) and dark. . . . *Trinomys paratus*
- 8'. Incisive foramen often lyre shaped and long, with posterolateral margins of maxillary markedly flanged; septum of incisive foramina comprised mainly by premaxillary portion, often becoming gradually narrower toward maxillary portion, and may be complete or incomplete; mid-dorsal aristiforms width variable. 9
9. Conspicuously spiniform and long postorbital process of zygoma formed primarily by jugal; auditory bullae small and least inflated (mean 10.08 mm); $2n=56$, $NA=104$, uniarmed X and Y chromosomes *Trinomys setosus*
- 9'. Moderately spiniform and short postorbital process of zygoma formed primarily by jugal, but sometimes with important contribution of squamosal; auditory bullae moderately to well inflated (mean bullar length 10.67 mm); $2n=58$, $NA=112$, biarmed X and Y chromosomes. *Trinomys eliasi*

Trinomys albispinus (l. Geoffroy St.-Hilaire, 1838a)

White-spined Spiny Rat

SYNONYMS: See under Subspecies.

DESCRIPTION: Small spiny rat with wide and stiff guard hairs, distinguishable from other species smaller body and skull size, by presence of lanceolate and clavate guard hairs, and by whitish aristiforms on back, sides, rump, and base of tail (Moojen 1948; Pessôa and Strauss 1999; Pessôa and Reis 2002). Mean external measurements of each subspecies (Pessôa and Reis 2002): *P. a. albispinus* from Jaguaquara, Bahia (N=10): head and body length 177 mm (153–190 mm), tail length 166 mm (148–175 mm), hindfoot length 40 mm (37–42 mm), ear length 26 mm (22–30 mm), and mass 173 g (120–230 g); *T. a. minor* from Morro do Chapéu, Bahia: (N=6) head and body length 163 mm (152–165 mm); tail length 141 mm (126–160 mm); hindfoot length 36 mm (34–38 mm); ear length 25 mm (23–26); and mass 134 g (N=1).

Dorsal pelage ochraceous-tawny gradually changing to ochraceous-buff on sides. Differentiated light-colored guard hairs occur on back, sides, rump, and at base of tail. Aristiform guard hairs in mid-dorsal region with whitish base that gradually blackens toward tip, interrupted by ochraceous-tawny subdistal zone. Lanceolate guard hairs also with whitish base that gradually blackens toward tip, but lack visible subdistal zone; total length 25–28 mm, maximum width 1.2 mm. Guard hairs on outer thighs show two color patterns, one with whitish base that gradually blackens toward tip and another that also gradually blackens distally but with distal fifth, including tip, colored ochraceous-tawny. Ventral pelage of body and inner sides of legs totally white, and well delimited from the sides. Forefeet and hindfeet are whitish on dorsal parts, with some specimens darker outer margins of hindfeet. Tail blackish

above, white below, without hairy pencil at tip (Moojen 1948; Pessôa and Reis 1995; Pessôa and Strauss 1999).

Skull short and smooth in comparison with other species, average cranial measurements of each subspecies (Pessôa and Reis 1991b; Pessôa and Reis 2002; Pessôa and Strauss 1999) are: *T. a. albispinus* (N=18; Moojen 1948): skull length 45.0 mm (37.6–48.9 mm), condyloincisive length 40.1 mm (38.3–41.4 mm), zygomatic breadth 23.9 mm (22.8–24.5 mm), nasal length 15.9 mm (13.5–16.8 mm), interorbital constriction width 10.8 mm (9.7–11.6 mm), palatal length 15.9 mm (15.2–16.4 mm), toothrow length 7.7 mm (7.3–8.3 mm); *T. a. minor* (N=4): skull length 40.8 mm (39.0–42.5 mm), condyloincisive length 34.7 mm (32.2–36.9 mm), zygomatic breadth 22.6 mm (21.5–23.2 mm), nasal length 13.9 mm (13.4–14.8 mm), interorbital constriction 9.5 mm (9.1–9.8 mm), palatal length 14.1 mm (13.5–14.7 mm), toothrow length 7.0 mm (6.9–7.1 mm). Sexual dimorphism in cranial measurements negligible (Pessôa and Reis 1991b). Incisive foramina oval and short, about 33% of diastema length; septum often incomplete, with premaxillary portion at level lower than maxillary portion, maxillary part small, and vomer not visible ventrally. Posterior palatine foramina at plane of first molars; postorbital process of zygoma well developed and involves both jugal and squamosal. Auditory bullae small, smooth, elongated, and least inflated. Molar teeth with only one counterfold; PM4 rarely with two counterfolds in *T. a. albispinus* (Moojen 1948; Pessôa and Strauss 1999).

Baculum larger than those of other species (mean length 11.4 mm, N=10 adults); shaft with dorsoventral curvature and slightly tapered lateral indentation near midshaft; proximal end paddle shaped, and distal end with well-developed distal wings with pronounced median depression (Pessôa and Reis 1992a; Pessôa et al. 1996).

DISTRIBUTION: *Trinomys albispinus* is known from Sergipe, Bahia, and Minas Gerais states in coastal Brazil.

SELECTED LOCALITIES (Map 532): *T. albispinus albispinus*—BRAZIL: Bahia, Cachoeira do Ferro Doido (MNRJ 67903), Feira de Santana (MNRJ 14019), Ibiraba (MZUSP 26772), Jequié (MNRJ 13820), Lamarão (Thomas 1921h), Seabra (MNRJ 13790), Senhor do Bonfim (MNRJ 6454), Vitória da Conquista (MNRJ 13778); Minas Gerais, Bocaiúva (MNRJ 73436), Irapé (MNRJ 73429); Sergipe, Canindé de São Francisco (Iack-Ximenes 2005)], Cristinápolis (MNRJ 30537). *T. albispinus minor*—BRAZIL: Bahia, Caetité (MNRJ 63343), Catolés de Cima, Abaíra (MNRJ 67814), Fazenda Juramento, Morro do Chapéu (S. F. Reis and Pessôa 1995).

SUBSPECIES: We recognize two subspecies of *T. albispinus*.

T. a. albispinus (I. Geoffroy St.-Hilaire, 1838a)

SYNONYMS:

- Echimyus albispinus* I. Geoffroy St.-Hilaire, 1838a:886; type locality “Ile Deos, sur la cotê du Brésil,” emended by Moojen (1948) to Itaparica, near Salvador, Bahia, Brazil.
E[chinomys]. albispinus: Wagner, 1843a:344; name combination.
Loncheres albispinis Schinz, 1845:111; incorrect subsequent spelling of *albispinus* I. Geoffroy St.-Hilaire.
Echimyus albispinosus Waterhouse, 1848:341; incorrect subsequent spelling of *albispinus* I. Geoffroy St.-Hilaire.
[Echinomys (Echinomys) cayennensis] albispinus: E.-L. Trouesart, 1880b:180; name combination.
[Proechimys] albispinus: J. A. Allen, 1899c:264; name combination.
[Proechimys (Trinomys)] albispinus albispinus: Thomas 1921h:141; name combination.
Proechimys (Trinomys) albispinus sertonius Thomas, 1921h:142; type locality “Lamarão, Bahia, about 70 miles north of Bahia City. Alt. 300 m,” Brazil.
[Proechimys] serotinus Woods, 1993:795; incorrect subsequent spelling of *sertonius* Thomas.
Trinomys albispinus: Lara, Patton, and da Silva, 1996; name combination.
[Trinomys albispinus] serotinus: Woods and Kilpatrick, 2005:1590; name combination and incorrect spelling of *sertonius* (Thomas).

The nominotypical subspecies occurs in coastal and interior parts of Bahia, Minas Gerais, and Sergipe states, Brazil (combined distributions of *albispinus* and *sertonius* in Pessôa and Strauss 1999; Pessôa and Reis 2002).

T. a. minor (S. F. Reis and Pessôa, 1995)

SYNONYMS:

- Proechimys albispinus minor* S. F. Reis and Pessôa, 1995:239; type locality “Morro do Chapéu, 800 m above sea level, state of Bahia, Brazil.”
Trinomys albispinus minor: Manaf, Morato, and Oliveira, 2003:129; first use of current name combination.
Trinomys minor: J. A. Oliveira and Bonvicino, 2006:398; name combination.

This subspecies is known from upland areas in the interior of Bahia state in southeastern Brazil (Pessôa and Strauss 1999; Pessôa and Reis 2002).

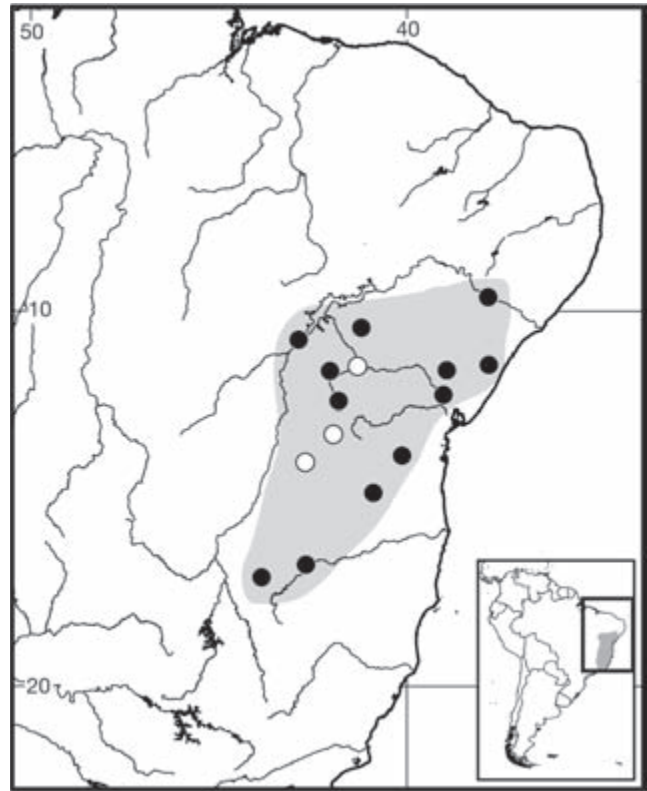

NATURAL HISTORY: *Trinomys albispinus* is one of the most specialized forms in the genus for drier habitats (Moojen 1948). This habitat is part of the Caatinga biome, which is characterized by unpredictable rainfall and semiarid conditions, with vegetation including plants of the families Cactaceae and Bromeliaceae (Ab'Saber 1974). The subspecies *T. a. minor* occurs in northern edge of the

Espinhaço range in the state of Bahia, an area characterized by rock formations produced by a geosyncline of pre-Cambrian age, which is 800–2,000 m. From 800–1,000 m, the vegetation is characteristically savanna, grading into grassland between 1,000 and 1,100 m (S. F. Reis and Pessôa 1995; Pessôa and Strauss 1999). Museum labels indicate that females are pregnant between January and June, with numbers of embryos varying from two to four.

REMARKS: Thomas (1921h) described *Proechimys albispinus sertoniui* from Lamarão, Bahia, an inland form that he distinguished from *P. a. albispinus*, which he believed to be a coastal form. S. F. Reis and Pessôa (1995) described *P. a. minor*, a smaller form from Morrão, Morro do Chapéu, Bahia. Pessôa and Strauss (1999) subsequently showed that craniometric discriminant scores of *P. a. albispinus* and *P. a. sertoniui* overlapped widely, although samples of the two taxa differed in average greatest skull length, with these two together well differentiated from *P. a. minor*, which presented smaller skulls and body size. Jack-Ximenes (2005) regarded *minor* as a distinct species, and documented cranial qualitative and quantitative variation along geographic transects in *T. albispinus*, although he did not regard this variation worthy of subspecific distinction. He also examined the type specimens of *T. a. albispinus* and *T. a. sertoniui* and considered them indistinguishable.

A. L. G. Souza et al. (2006) and A. L. G. Souza (2011) examined population samples identified as *T. a. sertoniui* and *T. a. minor* from two localities near Morro do Chapéu, Bahia, and showed that they have the same diploid and fundamental numbers and shared mtDNA cytochrome-*b* haplotypes. These samples also have cytochrome-*b* haplotypes similar to a specimen from Sergipe identified as *T. a. sertoniui*, differing from it by only 2.2%. Two other mtDNA sequences belonging to specimens from Abaíra and Caetité, Bahia, both identified as *T. a. minor*, formed a sister clade with respect to the Morro do Chapéu–Sergipe clade. The authors argued that the region near Morro do Chapéu was a contact zone between *T. a. minor* and *T. a. sertoniui* (= *T. a. albispinus*). A. L. G. Souza (2011) also postulated that the two subspecies had diverged recently or were in a process of divergence, a condition that would justify their taxonomic distinction at subspecific level.

We reexamined the specimens deposited in the Museu Nacional in Rio de Janeiro, including the extensive series obtained by the Serviço Nacional de Peste, the type and toptotypical series of *T. a. minor* from Morro do Chapéu, as well as more recently collected samples, including a series from northern Minas Gerais and the Chapada Diamantina, in Bahia, in the light of recent unpublished analyses of Jack-Ximenes (2005) and A. L. G. Souza (2011). We here regard specimens from Morrão and Fazenda Jaboticaba

Map 532 Selected localities for *Trinomys a. albispinus* (●) and *Trinomys a. minor* (○).

(Morro do Chapéu), and from Catolés de Cima (Abaíra) and Caetité, as the museum representatives of *T. a. minor*. We also examined specimens from north of Minas Gerais that had previously been allocated to *T. a. minor*, which we reidentified as *T. a. albispinus*.

The karyotype is $2n=60$ and $NF=116$, with 29 pairs of biarmed autosomes, 17 of which are metacentric, 7 submetacentric, and 5 subtelocentric. The X chromosome is a large submetacentric intermediate in size between autosomal pairs 1 and 2. The Y chromosome is a small acrocentric. Two NORs, based on Ag-NOR staining, are located in the interstitial region of the long arm of chromosome pair 10 (A. L. G. Souza et al. 2006).

Trinomys dimidiatus (Günther, 1876)

Rio de Janeiro Spiny Rat

SYNONYMS:

Echimyus dimidiatus Günther, 1876:747; type locality unknown; regarded as “probably southwestern Rio de Janeiro, Brazil,” by Moojen (1948:371); herein fixed to “Parque Nacional da Tijuca, Rio de Janeiro, Estado do Rio de Janeiro, Brasil” (see Remarks).

[*Proechimys*] *dimidiatus*: J. A. Allen, 1899c:264; name combination.

P[roechimys]. [*Proechimys*] *dimidiatus*: Thomas, 1921h: 141; name combination.

[*Proechimys* (*Proechimys*)] *dimidiatus*: Ellerman, 1940: 122; name combination.

Proechimys [(*Trinomys*)] *dimidiatus*: Moojen, 1948:371; name combination.

Trinomys dimidiatus: Lara, Patton, and da Silva, 1996:405; first use of current name combination.

DESCRIPTION: Large species, with head and body length 203 mm (170–244 mm; s.d. 14.5; N=1 32), tail length 185 mm (150–220 mm; s.d. 14.0; N=90), hindfoot length 48 mm (40–55 mm; s.d. 2.7; N=137), ear length 25 mm (19–30 mm; s.d. 2.0; N=136), and mass 204 g (100–290 g; s.d. 33.5; Iack-Ximenes 2005). General color of upper parts ochraceous-buff, finely lined with blackish brown, gradually becoming lighter on sides, and contrasting with white ventral coloration (Moojen 1948). Tail bicolor, brownish above and white below, averaging 90% of head and body length, without conspicuous hairy pencil at tip. Aristiforms narrow and soft, length from 16–19 mm and average maximum width 0.5 mm, imparting nonspiny appearance to pelage (Pessôa and Reis 1993b). Setiforms on mid-dorsal region whitish basally, gradually blackening toward tip but interrupted by ochraceous-buff subdistal zone; setiforms on outer thighs whitish on their basal half then gradually become grayish at middle and finally light ochraceous-buff on distal third, or have blackish tip and ochraceous-buff subdistal zone (Moojen 1948).

Skull elongated and slender, with no conspicuous ridges, with average length of 51.7 mm (s.d. 1.9; N=217), basilar length 36.2 mm (s.d. 1.7, N=227), and zygomatic width 25.6 mm (s.d. 0.9; N=237) (data from Moojen 1948; Pessôa and Reis 1993b; Iack-Ximenes 2005). Incisive foramina oval, short (averaging about 32% of diastema length) and wide posteriorly; septum complete and columnar with thick and wide maxillary part, and vomer not visible ventrally. Posterior palatine foramina situated at plane of first molars or slightly anterior to them. Postorbital process of zygoma rounded and involves only squamosal. Auditory bullae small, smooth, elongated, and uninflated.

Baculum of medium size, with average length 7.64 mm (s.d. 0.57; N=7; elongate, with straight shaft without dorsoventral curvature but with lateral indentation near mid-shaft; proximal and distal ends evenly rounded, without median depressions or wings (Pessôa and Reis 1992a, 1993b).

DISTRIBUTION: *Trinomys dimidiatus* is known from Rio de Janeiro state and along the northern coastal border of São Paulo state (Moojen 1948; Pessôa and Reis 1993b; Pessôa et al. 2005; Attias et al. 2009).

SELECTED LOCALITIES (Map 533): BRAZIL: Rio de Janeiro, Barro Branco, Duque de Caxias (Iack-Ximenes 2005), Fazenda Carlos Guinle, Estrada Rio-Teresópolis

(MNRJ 33725), Fazenda Nova Freiburg (Lara and Patton 2000), Fazenda do Tenente, São João de Marcos (MNRJ 4019), Gávea (MNRJ 10358), Mambucaba, Angra dos Reis (Lara and Patton 2000), Mata da Rifa, Parque Estadual do Desengano (Lara and Patton 2000), Rio Bonito (Pessôa et al. 2005); São Paulo, Piciguaba, Ubatuba (Pessôa et al. 2005).

SUBSPECIES: *Trinomys dimidiatus* is monotypic.

NATURAL HISTORY: *Trinomys dimidiatus* is regularly found in climax forests, especially in moist places near windfalls (Davis 1945a). The typical habitat is the relatively open interior of these forests, characterized by sparse vegetation near the ground and a marked middle layer of vegetation under large trees, up to 30 m in height and belonging predominantly to families Lauraceae and Melinaceae, plus smaller trees of the families Anonaceae, Melastomataceae, Myrsinaceae, and Rubiaceae. Lianas and epiphytes are also common (Davis 1947). The best shelter and nesting ground is usually under boulders, commonly not farther than 10 m from water sources; nesting places were also located at the base of trees and near fallen logs, where litter accumulates. No more than two adult animals (male and female) were captured in the same shelter, but occasionally young were captured in the same place with adults. At Teresópolis, the species was found breeding from March to May and from September to November. The number of juveniles varied from one to five but was commonly two. Specimens in captivity survived more than two years, and one specimen, already adult when captured, lived an additional 1,139 days (Moojen 1948, 1952).

REMARKS: Günther (1876) described *Trinomys dimidiatus* on the basis of a juvenile specimen of unknown provenance. Miranda-Ribeiro (1905), commenting on a specimen from Mont-Serrat, Itatiaia, identified by O. Thomas as *P. dimidiatus*, suggested Itatiaia as the *patria* of the species. Thomas (1921h:141) assigned two specimens from Itatiaia (BM 14.2.23.19 and BM 14.2.23.19) to *P. dimidiatus*, prompting Moojen (1948:373) to suggest “southwestern Rio de Janeiro” as the probable type locality for the species. Recent samples of spiny rats from Itatiaia, however, were allocated to *T. gratiosus* (Geise, Pereira et al. 2004). Iack-Ximenes (2005) examined museum specimens from Itatiaia, including those analyzed by Thomas, and assigned them to either *T. gratiosus* or *T. panema*. Furthermore, there are no known localities documenting the occurrence of *T. dimidiatus* from the Itatiaia region (Attias et al. 2009). Therefore, Moojen’s (1948) suggestion that southwestern Rio de Janeiro is the probable type locality for this species is untenable. Here, we fix the type locality of *T. dimidiatus* to “Parque Nacional da Tijuca, Rio de Janeiro, Estado do Rio de Janeiro, Brasil.” This locality, a national park within the city limits of Rio de Janeiro, is in the central portion of the known distribution of this species and

from which *T. dimidiatus* is both known and the only species of *Trinomys* present. As documented by Attias et al. (2009), other regions of the state of Rio de Janeiro where *T. dimidiatus* is known may also house other species.

Analysis of 393 bp of the mtDNA cytochrome-*b* (Lara and Patton 2000) revealed relatively high levels of DNA sequence divergence (4.0–4.8%) between sequences from populations that are 150–200 km apart (Parque Nacional do Desengano and Serra dos Órgãos), but high levels of similarity between populations separated by 180 km (Serra dos Órgãos and Mambucaba, 0.81%). Despite this variability, all samples of *T. dimidiatus* formed a monophyletic assemblage, consistent with its current species status. *Trinomys dimidiatus* is a member mtDNA Clade 1 along with *T. iheringi* as its sister species, with these two species differing by 15.6–17.1% (Lara and Patton 2000). Moojen (1948:321) had previously called attention to the morphological similarity between *dimidiatus* and *iheringi*. Lara et al. (2002:240) observed extreme morphological bacular variation in population samples of *T. dimidiatus* when compared with other species such as *T. albispinus*. This fact prompted these authors to suggest that this variation may not reflect solely ontogenetic differences.

Cytogenetic analyses of one female and one male collected in Rio Bonito (about 100 km east of Rio de Janeiro city) and two females and one male collected at Ubatuba (São Paulo state, near the western limit of Rio de Janeiro state and 300 km west of Rio de Janeiro city) revealed a diploid number of $2n=60$ and $FN=116$ (Pessôa et al. 2005). This karyotype comprises 29 pairs of metacentric and submetacentric autosomes, of which pair 10 has a secondary constriction on

Map 533 Selected localities for *Trinomys dimidiatus* (●).

the long arm, probably coincident with a nucleolar organizer regions. The X chromosome is a large submetacentric (corresponding to the second pair of the complement), and the Y is a metacentric intermediary to pairs 20 and 21.

Trinomys eliasi (Pessôa and Reis, 1993)

Elias's Spiny Rat

SYNONYMS:

Proechimys iheringi eliasi Pessôa and Reis, 1993a:182; type locality "Restinga da Barra de Maricá, Maricá, Rio de Janeiro."

[*Proechimys* (*T[rinomys]*.) *iheringi*] *eliasi*: Pessôa, Reis, and Pessôa, 1996:130; name combination.

Trinomys eliasi: Lara, Patton, and da Silva, 1996:405; first use of current name combination.

Trinomys iheringi eliasi: Lara and Patton, 2000:666; name combination.

[*roechimys*]. *eliasi*: Lara and Patton, 2000:681; name combination.

DESCRIPTION: Large member of genus, with mean head and body length 197 mm (range: 186–215 mm; s.d. 7.8; N=15), tail length 206 mm (181–231 mm; s.d. 13.1; N=11), hindfoot length 52 mm (47–55 mm; s.d. 2.2; N=15), ear length 28 mm (25–31 mm; s.d. 2.4; N=15), and mass 221 g (124–262 g; s.d. 43.8; N=13; Iack-Ximenes 2005). General color of upper parts varies from olivaceous-brown to cinnamon-brown, becoming paler on sides, and contrasting with white ventral coloration. Tail long, averaging 110% of head and body length, markedly bicolored (dark above, white below) in samples from some localities (e.g., Maricá and Morro do Itaoca), but in central part of geographic distribution bicolor pattern not very marked (e.g., in sample from Silva Jardim), and terminating in conspicuous hairy pencil. Aristiforms stiffest and longest for genus, similar to those of *T. paratus* and *T. mirapitanga*. Mid-dorsal aristiforms very long and wide, averaging 22.6 mm by 1.5 mm, colored white to pale buff basally, gradually becoming sepia in apical region and black at tip; on rump aristiforms white basally transitioning to ochraceous-tawny toward tip but sometimes interrupted by subapical zone pale brownish-olive band. Setiforms in mid-dorsal region whitish or pale-buff basally, becoming sepia toward tip but interrupted by cinnamon-brown subapical zone; on rump, setiforms white basally becoming sepia toward tip, but interrupted by cinnamon or pale pinkish-cinnamon subapical zone (Pessôa and Reis 1993a; Tavares 2007).

Skull elongated and stout, with marked ridges in most specimens, an average length of 51.5 mm (s.d. 2.0, N=16), basilar length of 35.2 mm (s.d. 1.7; N=16), and zygomatic width of 25.8 mm (s.d. 0.8). Incisive foramina lyre shaped, of medium size (mean length 4.8 mm; occupying about 45%

of diastema length), and broader at premaxillomaxillary suture level but becoming narrower and constricted toward posterior end; septum almost always complete in samples from type locality, in which it tends to become narrower toward posterior end, but often incomplete at other localities; premaxillary portion always more developed than maxillary portion, comprising about 70% of septum length; the vomer often visible in ventral view as tiny structure in septum. Two pairs of palatine foramina often present, first at level of PM4, and second at level of M1. Postorbital processes of zygoma well developed and often slightly pointed, often formed from both jugal and squamosal (Pessôa and Reis 1993a; Tavares and Pessôa 2010). Auditory bullae large, smooth, and well inflated (mean bullar length 10.7; s.d. 0.2). PM4–M2 typically with single major fold, often two counterfolds in samples from type locality, rarely one or three counterfolds in other samples.

Bacular shaft of medium length and thin, without marked lateral indentation, with slight dorsoventral curvature proximally; proximal end paddle shaped, large and wide, corresponding to about 20% of total length of bone, with marked edges in specimens from Barra de Maricá, while those from Silva Jardim general form more oval and smooth; distal end with slight median depression (Pessôa and Reis 1993a; Tavares and Pessôa 2010).

DISTRIBUTION: *Trinomys eliasi* occurs in the coastal sandy plains and contiguous forested lowland habitats of eastern and northeastern Rio de Janeiro state, Brazil.

SELECTED LOCALITIES (Map 534; from Tavares and Pessôa 2010, except as noted): BRAZIL: Rio de Janeiro, Cabiúnas, Macaé (MNJR [PRG 1649]), Mata do Carvão, São Francisco do Itabapoana, Morro do Itaoca, Campos dos Goytacazes, Quissamã, Reserva Biológica Poço das Antas, Silva Jardim, Reserva Biológica União, Rio das Ostras, Restinga da Barra e Maricá, Maricá (type locality of *Proechimys iheringi eliasi* Pessôa and Reis).

SUBSPECIES: *Trinomys eliasi* is monotypic.

NATURAL HISTORY: *Trinomys eliasi* preferentially inhabits forested formations, both semideciduous and evergreen moist forests (Tavares and Pessôa 2010). Even in coastal sandy lowland ecosystems (*restingas*), where open vegetation predominates, this spiny rat occurs exclusively in forest patches (F. A. S. Fernandez 1989; Cerqueira et al. 1990; Gentile and Cerqueira, 1995; Bergallo et al. 2004).

Trinomys eliasi was the third most frequently captured terrestrial small mammal in a long-term study at the type locality, with an average population density of 1.6 individuals per hectare (F. A. S. Fernandez 1989). However, recent field surveys indicated that this species is relatively rare in other areas (Bergallo et al. 2004; our unpubl. field data). Population size remained relatively constant throughout the year at the type locality, with limited dispersal, and an

average residence time by individuals of 9.7 months per year (Cerqueira et al. 1994; Gentile and Cerqueira 1995). Longevity varied from 6.1 to 20.6 months, with an average of 11.5 months (s.d. = 7.3; F. A. S. Fernandez 1989), and sex ratio did not differ significantly from 1:1. Reproductive activity was found throughout the year, except in April, with the largest proportion of sexually active individuals in January (F. A. S. Fernandez 1989). At Campos dos Goytacazes a female and a juvenile male were captured together in the same trap, indicating that pups may follow their mother during foraging (our unpubl. data).

Trinomys eliasi is cursorial and has ricocheteal-like movements when liberated from live-traps (Cerqueira et al. 1990). Temporal capture pattern indicates a crepuscular peak of activity (Gentile and Cerqueira 1995).

Until recently, only specimens from the type locality were known (Tavares and Pessôa 2010). *Trinomys eliasi* has been classified as Endangered in a list of endangered species of Rio de Janeiro state because of endemism and human population pressure in the area immediately around its small range (Bergallo et al. 2000; see also D. Brito 2004). D. Brito and Figueiredo (2003) estimated that the Maricá population was not viable in the medium to longer time frame based on a population viability analysis. The IUCN (2011) red list classifies *T. eliasi* as Endangered (category B1ab.iii).

REMARKS: *Trinomys eliasi* was described as a subspecies of *Proechimys (Trinomys) iheringi* but later recognized as a species based on phylogenetic analyses of mtDNA cytochrome-*b* sequence data (Lara and Patton 2000), which indicated the polyphyly of *Proechimys iheringi* (*sensu* Moojen, 1948). *Trinomys eliasi* was placed in clade 2 (*sensu* Lara and Patton 2000) as sister to *T. paratus* with a relatively low (for the genus) molecular distance of about 7%.

Tavares and Pessôa (2010) identified remarkable morphological qualitative and quantitative variation along the geographic range of *T. eliasi*, including both bacular and craniodental traits usually recognized as good species-specific markers. Specimens collected at the type locality were statistically distinct from those from more eastern localities within the range, and pointed out that such a degree of intraspecific variation had not been recorded in other congeners. Tavares and Pessôa (2010) hypothesized that environmental heterogeneity along the present geographic distribution or possible regional environmental rearrangements in the Quaternary might be associated with the origin of the remarkable morphological variation recorded in the species.

In contrast to morphological variation, the karyotype is apparently conservative in this species, with $2n=38$, $FN=112$, for specimens from the type locality (Pessôa et al. 2005) and also from Silva Jardim (Tavares 2007) as well as four other localities in the eastern part of the species range (our unpubl. data).

Map 534 Selected localities for *Trinomys eliasi* (●).

Following Galewski et al. (2005), the divergence between *T. eliasi* and *T. paratus* occurred after the Middle Pliocene, a relatively recent split considering that major speciation events in the genus *Trinomys* were apparently centered in the Miocene (see also Upham and Patterson 2012).

Trinomys graciosus (Moojen, 1948)

Gracile Atlantic Spiny Rat

SYNONYMS: See under Subspecies.

DESCRIPTION: Medium to large member of genus, with head and body length 200 mm (163–232 mm; s.d.=14.5; N=93), tail length 178 mm (150–220 mm; s.d.=12.7; N=82), hindfoot length 47 mm (41–57 mm; s.d.=2.8 N=82), ear length 25 mm (21–36 mm; s.d.=2.1; N=92), and mass 209 g (162–270 g; s.d.=26.6; N=68; Iack-Ximenes 2005). General color of upper parts ochraceous-buff contrasting with white venter (Moojen 1948). Tail bicolored, brownish above and white below, averaging 90% of head and body length, lacking conspicuous hairy pencil at tip. Aristiform hairs darker along mid-dorsal region, forming back that contrasts with paler setiform hairs on sides of body. Aristiform hairs long, varying from 21–27 mm in length, and relatively narrow, maximally 0.6 mm wide, but become shorter and more narrowed laterally (18–21 mm and 0.5 mm, respectively); gray at base, blackening toward tip. Setiforms on mid-dorsal region gray basally, blackening toward tip, but interrupted by ochraceous-buff subdistal zone; on outer thighs setiforms gray basally, gradually becoming black toward middle and entirely ochraceous-buff distally, occasionally with blackish tip. Hairs on both forefeet and hindfeet dorsally white (Moojen 1948).

Skull slender, with no conspicuous ridges, with mean greatest length 50.6 mm (s.d. 1.7; N=92), basilar length 35.6 mm (s.d. 1.4; N= 79), and zygomatic width 25.9 mm (s.d. 0.97; N=81) (Moojen 1948; Iack-Ximenes 2005). Incisive foramina lyre shaped, relatively long (mean length 4.8 mm; averaging about 46% of diastema length), and constricted posteriorly; septum always incomplete, with maxillary part lacking or, if present, slender; premaxillary portion extends well over half foramina length; vomer does not contribute to ventral aspect of septum. Posterior palatine foramina positioned at plane of first molars or slightly anterior to them. Postorbital process of zygoma rounded and involves only squamosal. Auditory bullae small, smooth, elongated, and inflated. Upper molariform teeth with two primary folds (Moojen 1948).

Baculum with accentuated dorsoventral curvature over proximal third and lateral indentation near distal end; it broadens near proximal end and tapers at tip; distal end with weak medial depression and without distal wings (Pessôa and Reis 1992a; Pessôa et al. 1996).

DISTRIBUTION: This species is known from several localities along the Serra do Mar and Serra da Mantiqueira mountains of Espírito Santo, Minas Gerais, and Rio de Janeiro states, Brazil (Moojen 1948; Iack-Ximenes 2005).

SELECTED LOCALITIES (Map 535): *T. graciosus bonafidei*—BRAZIL: Rio de Janeiro, Fazenda Boa Fé, Teresópolis (type locality of *Proechimys iheringi bonafidei* Moojen), Fazenda São José da Serra Bonsucesso, Sumidouro (Iack-Ximenes 2005) Fazenda Santo Antônio da Aliança, Valença (Attias et al. 2009). *T. graciosus graciosus*—BRAZIL: Espírito Santo, Campinho, Colatina (type locality of *Proechimys iheringi panema* Moojen), Castelinho, Cachoeiro do Itapemirim, Parque Nacional do Caparaó (Lara and Patton 2000), Hidroelétrica São Pedro, Domingos Martins (Iack-Ximenes 2005), Floresta da Caixa d'Água, Santa Teresa (type locality of *Proechimys iheringi graciosus* Moojen); Minas Gerais, Estação Biológica Mata do Sossego, Simonésia (UFMG [YL 42]), Fazenda do Bené, 4 km SE of Passa Vinte (Lara and Patton 2000), Parque Estadual da Serra do Brigadeiro (J. C. Moreira et al. 2009); Rio de Janeiro: Parque Nacional do Itatiaia, Itatiaia (Geise, Pereira et al. 2004).

SUBSPECIES: We recognize two subspecies of *T. graciosus*.

T. g. graciosus (Moojen, 1948)

SYNONYMS:

Proechimys iheringi graciosus Moojen, 1948:379; type locality “Floresta da Caixa D'água, Santa Teresa, Espírito Santo, Brazil; altitude 750 meters.”

Proechimys iheringi panema Moojen, 1948:380; type locality “Campinho, Colatina, Espírito Santo, Brazil; altitude 500 meters.”

[*Proechimys (Trinomys) iheringi*] *gratiosus*: Pessôa, Reis, and Pessôa, 1996:131; name combination.

[*Proechimys (Trinomys) iheringi*] *panema*: Pessôa, Reis, and Pessôa, 1996:131; name combination;

Trinomys iheringi gratiosus: Lara and Patton, 2000:665; name combination.

T[rinomys]. i[heringi]. panema: Lara and Patton, 2000:681; name combination.

Trinomys gratiosus: Lara and Patton, 2000:682; name combination.

Trinomys g[ratiosus]. gratiosus: Lara and Patton, 2000:683; first use of current name combination.

Trinomys panema: J. A. Oliveira and Bonvicino, 2006:397; name combination.

The nominotypical subspecies is known from coastal forests in Espírito Santo and northeastern Rio de Janeiro, inland to southern Minas Gerais and the Parque Nacional do Itatiaia in northwestern Rio de Janeiro, Brazil.

T. g. bonafidei (Moojen, 1948)

SYNONYMS:

Proechimys iheringi bonafidei Moojen, 1948:378; type locality “Fazenda Boa Fé, Teresópolis, Rio de Janeiro, Brazil; alt. 850 meters.”

[*Proechimys (Trinomys) iheringi*] *bonafidei*: Pessôa, Reis, and Pessôa, 1996:130; name combination.

Trinomys iheringi bonafidei: Lara and Patton, 2000:665; name combination.

Trinomys gratiosus bonafidei: Lara and Patton, 2000:682; first use of current name combination.

Trinomys bonafidei: G. A. S. Carvalho and Salles, 2004:452; name combination.

This subspecies occurs in forested habitats in the coastal ranges of Rio de Janeiro state, Brazil.

NATURAL HISTORY: The holotype of *T. g. gratiosus* and four paratypes were collected in climax forest in Floresta da Caixa D’água, altitude 750m. Females of *T. g. bonafidei* were captured with one or two embryos in April and September, with juveniles most common in April. Paratypes were collected in secondary forest with elevated humidity (Moojen 1952). A specimen assigned to *T. gratiosus panema* was recorded at Fazenda do Bené, Minas Gerais, in a forest patch running along the Rio Preto at an elevation of 680m, in a habitat described as old second-growth rainforest with a dense overstory, where most trees are 20cm in diameter with crowns 20m in height. The terrain here was moderately steep (30°–60°), with rocky outcrops and relatively few fallen logs on the ground, and sparse understory usually reaching 1.5m height, few lianas and vines, some arboreal bromeliads, abundant arboreal lichens, and many palm and fruit trees (Y. L. R. Leite 2003).

Map 535 Selected localities for *Trinomys g. gratiosus* (●) and *T. g. bonafidei* (○).

REMARKS: Moojen (1948:380) distinguished *P. i. gratiosus* from *P. i. panema* by the presence of only one counterfold in lower molariform teeth in a small percentage of specimens and by an ochraceous-buff rather than cinnamon subdistal zone of aristiforms. Lara and Patton (2000:181) did not consider *P. i. panema* to be morphologically distinct from *Trinomys gratiosus* (= *P. i. gratiosus* in Moojen’s sense) and included *P. i. bonafidei* Moojen as a subspecies of *T. gratiosus*, based on the results of mtDNA analysis. Here, we follow Lara and Patton (2000) in considering *bonafidei* as subspecies of *T. gratiosus gratiosus*, and *panema* as a junior synonym of *T. gratiosus*.

Cytogenetic analyses specimens of *T. gratiosus gratiosus* collected in Monte Verde, Espírito Santo, revealed a diploid number of $2n=56$ and $FN=108$. This karyotype consists of 26 pairs of metacentric and submetacentric autosomes (Zankin 1988). The karyotype of *T. g. bonafidei* from type locality showed the same diploid and fundamental number; the X chromosome was a large submetacentric and Y chromosome a small metacentric (Pessôa et al. 2005). See Remarks for *T. paratus* for further comments.

Trinomys iheringi (Thomas, 1911)

São Paulo Spiny Rat

SYNONYMS:

Proechimys iheringi Thomas, 1911c:252; type locality “Island of São Sebastião, off São Paulo, Brazil.”

P[roechimys]. [Proechimys] iheringi: Thomas, 1921h:141; name combination.

Proechimys [(*Proechimys*)] *iberingi*: Ellerman, 1940:122; name combination.

Proechimys [(*Trinomys*)] *iberingi iberingi*: Moojen, 1948: 378; name combination.

Trinomys iberingi: Lara, Patton, and da Silva, 1996:405; first use of current name combination.

Trinomys iberingi iberingi: Lara and Patton, 2000:666; name combination.

DESCRIPTION: Medium-sized member of genus the tail shorter than head and body; average head and body length 191 mm (s.d. 16.1; N=82), tail length 171 mm (s.d. 12.4; N=68), hindfoot length 44 mm (s.d. 2.5; N=81), ear length 25 mm (s.d. 2.26; N=79), and mass 209 g (s.d. 33.5; Iack-Ximenes 2005). General color of upper parts cinnamon-buff, gradually becoming lighter on sides, and contrasting with white venter (Moojen 1948). Tail bicolored, brownish above and white below, averaging 87% of head and body length, and lacking conspicuous hairy pencil at tip (Pessôa and Reis 1996). Aristiforms hairs narrow and soft, 18–23 mm in length and with maximum width 0.6 mm (Pessôa and Reis 1996). Setiforms on mid-dorsal region whitish basally, gradually blackening toward tip but interrupted by cinnamon-buff subdistal zone; setiforms on outer thighs whitish on basal half but gradually turning to grayish at midshaft and finally pale cinnamon-buff along distal third. Hairs on both forefeet and hindfeet white dorsally (Moojen 1948).

Skull elongated and slender, with conspicuous ridges, average length 51.0 mm (s.d. 2.2; N=119), basilar length 35.6 (s.d. 1.7, N=125), and zygomatic width 25.6 mm (s.d. 0.8; N=125) (Moojen 1948; Iack-Ximenes 2005). Incisive foramina oval, short (length 3.7 mm, averaging about 48% of diastema), and constricted posteriorly; septum always complete and columnar, with maxillary part short and vomer not visible ventrally. Posterior palatine foramina positioned at plane of premolars. Postorbital process of zygoma rounded and formed by both jugal and squamosal. Auditory bullae small, smooth, and uninflated (Moojen 1948; Pessôa and Reis 1996). Upper molariform teeth with three primary folds, with rudimentary fourth fold on posterior of M3; lower teeth also with three folds, first smaller than others (Moojen 1948; Pessôa and Reis 1996).

Baculum shorter than those of most other species (length 6.7 mm); dorsoventral curvature and lateral indentations lacking (Pessôa and Reis 1992a, 1996; Pessôa et al. 1996); distal end evenly rounded, lacking distal wings or median depression; proximal end with overall rounded shape.

DISTRIBUTION: This species is known from several localities along the littoral and plateau of São Paulo state and from Ilha Grande on the southern coast of Rio de Janeiro state, Brazil (Moojen 1948, Pessôa and Reis 1996; Iack-Ximenes 2005).

SELECTED LOCALITIES (Map 536): BRAZIL: Rio de Janeiro: Ilha Grande, Abraão (MNRJ 62285); São Paulo, Alto da Serra (Iack-Ximenes 2005), Barra do Icapara (MZUSP 23857), Caraguatatuba (MZUSP 26646), Cotia (MZUSP 10212), Fazenda Intervalles, Capão Bonito (MZUSP 23397), Ilha de São Sebastião (type locality of *Proechimys iberingi* Thomas), Ilha do Cardoso (MZUSP 27756), Iporanga (Yonenaga-Yassuda et al. 1985), Juréia (Iack-Ximenes 2005), Ubatuba (Lara and Patton 2000), Varjão do Guaratuba, Bertioiga (MZUSP 25904).

SUBSPECIES: *Trinomys iberingi* is monotypic.

NATURAL HISTORY: Bergallo (1994) examined reproductive seasonality and population ecology at Ilha do Cardoso, São Paulo state over a two-year period. Both reproduction and survival rate in females was directly related to food availability and rainfall. Individuals reproduced throughout the year, but with peaks during the rainy season (Bergallo and Margnussón 1999). Home range size was larger than those of other rodent species of comparable body size inhabiting rainforests (Manaf, Morato, and Oliveira 2003). Bergallo (1995) also reported on home range size, with males using greater area than females and female home ranges exclusive, both elements suggesting a polygynous mating system (see also Adler 2011).

REMARKS: *Trinomys iberingi* was reviewed by Pessôa and Reis (1991a, 1992b, 1993a, 1996) and S. F. Reis et al. (1992), who recognized the six subspecies listed by Moojen (1948)—*bonafidei*, *denigratus*, *gratiosus*, *iberingi*, *panema*, *paratus*—and described a seventh, *eliasi*. These authors concluded that *bonafidei*, *denigratus*, *eliasi*, *gratiosus*, and *panema* might be specifically distinct from *iberingi*. Lara and Patton (2000) based on molecular analysis concluded that *T. iberingi* was a monotypic taxon, to the exclusion of the remaining forms listed as subspecies by Moojen (1948) and Pessôa and Reis (1996). *Trinomys iberingi* is a member of the mtDNA clade formed by *T. dimidiatus*, *T. mirapitanga*, *T. g. gratiosus*, and *T. g. bonafidei* (Lara and Patton 2000; Lara et al. 2002).

The karyotype of *T. iberingi* has a variable diploid number ($2n=60-65$) due to the presence of B chromosomes; excluding these elements, the FN=116 (Yonenaga-Yassuda et al. 1985; Fagundes et al. 2004). The basic autosomal complement consists of 25 biarmed and four uniarmed pairs; the X chromosome is a large submetacentric, and the Y a minute metacentric. Because all populations of *T. iberingi* sampled do date show variable numbers (from 1–5) of supernumerary chromosomes (Yonenaga-Yassuda et al. 1985), both the morphology of the Y chromosome and the presence of supernumerary chromosomes are useful markers to differentially diagnose *T. iberingi* from *T. dimidiatus*. Typically these chromosomes are heteroge-

Map 536 Selected localities for *Trinomys iheringi* (●).

neous relative to size, morphology, banding patterns, presence/absence of NORs, and presence/absence of interstitial telomeric signals after fluorescence in situ hybridization (Pessôa et al. 2005).

Trinomys mirapitanga Lara, Patton, and Hingst-Zaher, 2002

Pau Brasil Spiny Rat

SYNONYM:

Trinomys mirapitanga Lara, Patton, and Hingst, 2002:237; type locality “Estação Ecológica do Pau Brasil, 16 km W Porto Seguro, Bahia, Brazil, 40 m alt.”

DESCRIPTION: Medium sized in comparison to congeners (Iack-Ximenes 2005), with average head and body length 216 mm (s.d. 15.3; N=9), tail length 201 mm (s.d. 13.3; N=7), hindfoot length 50 mm (s.d. 2.8; N=8), ear length 28 mm (s.d. 1.9; N=9), and mass 259 g (s.d. 33.8). Overall coloration much darker along mid-dorsal region than in other species, forming dark cape on middle of back that contrasts with paler setiform hairs and much paler sides of body. Aristiforms in midback smoky-gray at their base with ochraceous-buff midsection and dark brown tip. Lateral setiform hairs typically with four color bands, drab-gray basally followed by smoky-gray, ochraceous-buff, and a black tip. Tail less than head and body in length (ca. 80%) and covered with short hairs. Aristiforms very long (mean 24.9 mm) and wide (1.5 mm) at mid-dorsum, but shorter and more narrowed laterally (mean 19.5 mm and 1.3 mm, respectively). Hairs on both forefeet and hindfeet white dorsally.

Skull large, with average length 52.4 mm (s.d. 1.5; N=4), basilar length 36.8 (s.d. 1.2, N=4), zygomatic

width 25.8 mm (s.d. 1.0; N=4) (Lara et al. 2002; Iack-Ximenes 2005). Incisive foramina oval, short (averaging about 32% of diastema length), and constrict posteriorly; septum complete and columnar; vomer does not contribute to ventral aspect of septum. Posterior palatine foramina located at plane of first molars. Postorbital process of zygoma rounded and comprising both squamosal and jugal; it never forms sharp spine. Auditory bullae smooth and of moderate size (11.3 mm, on average). Upper molariform teeth with three primary folds, with rudimentary fourth fold on posterior end of M3; lower teeth also have three folds, first smaller than rest.

Baculum shorter than most other species (length 7.9 mm in only known male), with weakly developed distal wings and broad basal expansion that is strongly flexed ventrally. Median trough evident along dorsal surface of basal portion.

DISTRIBUTION: This species is known from only two localities along the southern coast of Bahia state, Brazil (Lara et al. 2002). Iack-Ximenes (2005) recorded specimens he identified as *T. mirapitanga* from Estação Ecológica Nova Esperança-Wenceslau Guimarães (UFMG 2155) and Fazenda São João (UFMG 2157) on the central coast of Bahia; however, these specimens are *T. setosus*.

SELECTED LOCALITIES (Map 537): BRAZIL: Bahia, Cumuruxatiba Prado (MNRJ 48012), Estação Ecológica do Pau Brasil (type locality of *Trinomys mirapitanga* Lara, Patton, and Hingst).

SUBSPECIES: *Trinomys mirapitanga* is monotypic.

NATURAL HISTORY: The type specimen and two paratypes were collected at the Estação Ecológica do Pau Brasil, a biological reserve established to protect one of the largest remaining stands of *Caesalpinia echinata* (Fabaceae). No data are otherwise available on ecology, behavior, or any other aspect of the population biology of *T. mirapitanga*.

REMARKS: *Trinomys mirapitanga* is a member of mtDNA Clade 1 (*sensu* Lara and Patton 2000; see also Lara et al. 2002), sister to the *T. dimidiatus* and *T. iheringi* species pair. It differs from *T. eliasi*, *T. paratus*, *T. setosus*, and *T. yonenagae* in having a tail less than the head and body length and no brush of elongated hairs at its tip, a round rather than speculate postorbital process of the zygoma, oval incisive foramina, and a baculum with both distal and basal expansions. In comparison to *T. dimidiatus*, *T. iheringi*, and *T. gratosus*, *T. mirapitanga* differs by having a well-developed maxillary portion of the septum of the incisive foramina, a postorbital process of the zygoma formed by both squamosal and jugal elements, a more well-developed basal expansion of the baculum relative to the distal, strong ventral flexion to the bacular base, and a median trough on its dorsal surface.

Map 537 Selected localities for *Trinomys mirapitanga* (●).

Trinomys moojeni (Pessôa, Oliveira, and Reis, 1992)

Moojen's Spiny Rat

SYNONYMS:

Proechimys moojeni Pessôa, Oliveira, and Reis, 1992:40; type locality "Mata do Dr. Daniel, Conceição do Mato Dentro, Minas Gerais, Brazil."

T[rinomys]. moojeni: Lara, Patton, and Hingst, 2002: 235; first use of current name combination.

DESCRIPTION: Medium-sized species in comparison to congeners, average head and body length 187 mm (s.d. 18.2; N=7), tail length 179 mm (s.d. 15.7; N=6), hindfoot length 44 mm (s.d. 2.6; N=7), and ear length 24 mm (s.d. 1.5; N=7) (Pessôa et al. 1992; Iack-Ximenes 2005). Dorsal and lateral color orange-brown, with orangish areas over neck and shoulders due to predominance of orange-banded setiform hairs. Dorsal pelage not particularly stiff, with relatively long (mean 20.4 mm) and narrow (mean 0.6 mm) blackish tipped aristiform hairs that become less common, smaller (mean 15.9 mm), and narrower (mean 0.5 mm) on sides and lateral thighs, where some aristiform hairs have distal half ochraceous rather than gradually darkening toward tip. Ventral pelage completely white, well defined from sides and dorsum. Tail bicolored on its anterior two-thirds, brownish dorsally and whitish below, with distal third whitish. Tail covered by short hairs along most of

length, colored as skin to which they are attached. Hairs of tail tip much longer but do not form notable pencil. Hairs on both forefeet and hindfeet dorsally white, with whitish unguis tufts barely covering claws feet (Pessôa et al. 1992).

Skull slender, of moderate size, and slightly convex with average length 50.2 mm (s.d. 2.1; N=7), basilar length 35.5 mm (s.d. 1.9, N=7), and zygomatic width 25.5 mm (s.d. 0.7; N=7) (Pessôa et al. 1992; Iack-Ximenes 2005). Incisive foramina oval in shape, long (averaging about 40% of diastema length), and wide posteriorly; septum incomplete and formed almost exclusively by premaxillae; maxillary part short. Posterior palatine foramina present at plane of first molars. Postorbital process of zygoma well developed and formed by both jugal and squamosal bones. Auditory bullae small and smooth. Two counterfolds on both upper and lower molariform teeth; upper incisors orthodont (Pessôa et al. 1992).

Baculum short (6.6 mm in length the only specimen examined), with slight dorsoventral curvature and tapered lateral indentation near midshaft; proximal end straight and paddle shaped, and distal end has weakly developed distal wings (Pessôa et al. 1992, 1996).

DISTRIBUTION: *Trinomys moojeni* is apparently restricted to the southern Espinhaço massif in east-central Minas Gerais state, Brazil. The original series composed of seven individuals was obtained in August 1954 by Cory T. Carvalho and João Moojen at two sites about 1,200 m elevation along the road that connects the cities of Lagoa Santa and Conceição do Mato Dentro, at the section in which it crosses the upper parts of Serra do Cipó, Espinhaço Massif (Avila-Pires 1960b). More recently, *T. moojeni* was reported from Parque Nacional da Serra do Cipó (A. M. O. Paschoal et al. 2004) and Serra do Caraça Private Reserve (Cordeiro and Talamoni 2006).

SELECTED LOCALITIES (Map 538): BRAZIL: Minas Gerais, Mata do Dr. Daniel, Conceição do Mato Dentro (type locality of *Proechimys moojeni* Pessôa, Oliveira, and Reis), Serra do Caraça Private Reserve, Tanque Grande (MNRJ 73489).

SUBSPECIES: *Trinomys moojeni* is monotypic.

NATURAL HISTORY: Data recorded on specimen labels of the type series suggest that *T. moojeni* is restricted to the upper forest formations. A total of 29 specimens of *T. moojeni* were captured, marked, and recaptured 49 times in the Serra do Caraça between January 2001 and January 2002 (Cordeiro and Talamoni 2006). The sex ratio of adults was skewed in favor of females (1:2.3), with males predominantly captured in the dry season and females in equal numbers in both dry and rainy seasons. Mean dispersal distance of males (174.4 ± 40.0 m, N=5) was greater than that of females (88.5 ± 24.1 m, N=6).

Sexual dimorphism in body measurements was not significant, and reproductive animals were observed throughout the year. Likewise, young animals as well as pregnant and lactating females were captured during both dry and rainy seasons, indicating that there is no seasonal pattern to the reproduction in this species; recruitment probably occurs shortly after weaning.

Trinomys moojeni is classified as Endangered (B1ab.iii) by the IUCN (2011).

REMARKS: The phylogenetic relationship of *T. moojeni* and other species in the genus has been uncertain. Lara and Patton (2000; see also Lara et al. 2002) hypothesized a link between this species and the molecular clade including *T. setosus*, *T. paratus*, *T. eliasi*, and *T. yonenagae* based on morphological similarity. However, Lara and Patton (2000) also called attention to the fact that *T. moojeni* was the only taxon in the genus, apart from *T. graciosus* and *T. g. panema*, with an incomplete vomerine septum of the incisive foramina. Our close inspection of other usually relevant taxonomic characters also suggested a closer morphological affinity between *T. graciosus* and *T. moojeni*, including a tail of similar length as the head and body and without a pencil, a postorbital process of the zygoma well developed and formed by jugal and squamosal bones, upper and lower molariform teeth with two counterfolds, and a short baculum with weakly developed distal wings. Karyotypes ($2n=56$, FN=106; autosomal complement with 26 pairs of biarmed and one pair of uniarmed elements, with the X a large submetacentric and the Y a medium-sized metacentric; Corrêa et al. 2005) from Morro do Pilar, Minas Gerais, near the type locality of *T. moojeni*,

Map 538 Selected localities for *Trinomys moojeni* (●).

are also similar to those of *T. graciosus* from Monte Verde, Espírito Santo ($2n=56$; FN=108). Finally, our unpublished mtDNA cytochrome-*b* sequence analyses support a sister relationship between *T. moojeni* and *T. graciosus*, with the divergence level between the two species is about 10%.

Trinomys paratus (Moojen, 1948)

Rigid-spined Atlantic Spiny Rat

SYNONYMS:

Proechimys [(*Trinomys*)] *iberingi paratus* Moojen, 1948:382: type locality “Floresta da Capela de São Braz, Santa Teresa, Espírito Santo, Brasil; altitude 630 meters.”

Trinomys paratus: Lara, Patton, and da Silva, 1996:405; first use of current name combination.

Trinomys iberingi paratus: Lara and Patton, 2000:670; name combination.

DESCRIPTION: Large for genus, with mean head and body length 211 mm (187–246 mm; s.d. 14.1; N=23), tail length 212 mm (171–235 mm; s.d. 15.2; N=21), hindfoot length 498 mm (25–54 mm; s.d. 5.8; N=28), ear length 28 mm (18–33 mm; s.d. 3.4; N=27), and mass 259 g (195–350 g; s.d. 40.2; N=21). General color of upper parts varies from cinnamon to blackish-brown, becoming paler on sides, and contrasting with white venter. Tail approximately same length as head and body, and markedly bicolored (dark above, white below), with conspicuous hairy pencil at tip. Aristiform spines most rigid and large in genus; very long and wide at mid-dorsum, with average length 24.2 mm and mean width 1.6 mm. Aristiform color at mid-dorsum whitish or pale buff basally, becoming gradually sepia toward apical region and black at tip; on rump aristiforms white basally becoming ochraceous toward to tip but sometimes interrupted by subapical zone light brownish-olive color. Setiforms on mid-dorsal region white or pale buff basally, becoming sepia toward tip but interrupted by tawny or orange-cinnamon subapical zone; setiforms on rump white basally, becoming sepia toward tip but also interrupted by cinnamon or pale pinkish-cinnamon subapical zone (Moojen 1948; Tavares 2007).

Skull large, elongated, and stout, with well-marked ridges in most specimens; average length of 52.4 mm (s.d. 1.4; N=10), basilar length 37.0 mm (s.d. 1.3 mm; N=10), and zygomatic width 25.9 mm (s.d. 0.7; N=10). Incisive foramina fusiform or oval in shape, and medium sized (mean length 4.4 mm, occupying about 40% of diastema length); septum complete and columnar, its premaxillary portion long, constituting about 75% of septum length; vomer not visible in ventral view and maxillary portion small and wide. Posterior palatine foramina present at plane of premolars. Postorbital processes of zygoma well developed and often slightly pointed, often composed of both jugal

and squamosal. Auditory bullae large, smooth, and slightly inflated (mean bullar length 10.3; s.d. 0.5; N=10; Tavares 2007). PM4–M1 in specimens from type locality with one major fold and often two counterfolds.

Baculum elongated and moderate to thin (average length 9.8 mm), with slight dorsoventral curvature and without expansions or apical wings; proximal end slightly broader than shaft, elongated and almost rectangular; distal end concave (Lara and Patton 2000; Lara et al. 2002; Lack-Ximenes 2005; see Remarks).

DISTRIBUTION: *Trinomys paratus* is known from few localities in the southern half of Espírito Santo and east-central Minas Gerais states (Lack-Ximenes 2005).

SELECTED LOCALITIES (Map 539): BRAZIL: Espírito Santo, Aracruz Florestal, Aracruz (Lara and Patton 2000), Barra do Jucu, Vila Velha (MNRJ 33776), Cariacica (Tavares and Pessôa 2010), Floresta da Capela de São Bráz, Santa Teresa (type locality of *Proechimys* [(*Trinomys*)] *iheringi paratus* Moojen), Lagoa de Sete Pontas, Itapemirim (Tavares and Pessôa, 2010); Minas Gerais, Estação Biológica de Caratinga, Caratinga (Tavares and Pessôa 2010).

SUBSPECIES: *Trinomys paratus* is monotypic.

NATURAL HISTORY: Information about natural history of *Trinomys paratus* is very limited. The geographic range extends along Atlantic Forest formations in relatively low elevations (below 400 m). According to label data, specimens of the type series were captured in *mata virgem* (undisturbed original forest). The type locality is in a submontane region of moist dense forest, but the species also inhabits lowland dense moist forests (as at Viana, Espírito Santo), coastal sand vegetation *restinga* close to the littoral (Lagoa de Sete Pontas, Itapemirim), and inland semideciduous forests (as in Caratinga). Compared to other terrestrial small mammals, *Trinomys paratus* was very abundant in a parasitological survey carried out in Reserva Biológica Duas Bocas (I. S. Pinto, Botelho et al. 2009; I. S. Pinto, Loss et al. 2009; I. S. Pinto, Santos et al. 2009; T. M. Pereira et al. 2010), with a relatively high prevalence of siphonaptera infestation (I. S. Pinto, Botelho et al. 2009). At Viana, Espírito Santo, individuals of *T. paratus* collected in a secondary forest were infected with *Leishmania forattini*, with the parasite isolated from skin lesions (Falqueto et al. 1985, 1998).

REMARKS: Lara and Patton (2000) obtained partial mtDNA cytochrome-*b* sequences from specimens collected at Caratinga, Minas Gerais state, and Aracruz, Espírito Santo state, which showed to be very similar (0.5% of divergence), despite the geographic distance of about 250 km between these localities. In their analyses, *T. paratus* formed a clade with *T. eliasi*, the two lineages having

probably diverged in a relatively recent cladogenic event (see Remarks under *T. eliasi*).

Based on cranial qualitative and quantitative data, Tavares and Pessôa (2010) delineated a notable cohesion along all known samples of *T. paratus*, confirming Lack-Ximenes (2005) assertion that samples from Minas Gerais and Espírito Santo are indistinguishable based in cranial and external morphology. Contrasting to this uniformity, different bacular morphologies have been described for *T. paratus* from Santa Teresa, Espírito Santo (Pessôa et al. 1996) and those from Caratinga, Minas Gerais (Lara and Patton 2000; Lara et al. 2002). Whereas the proximal end of the baculum from Caratinga is rectangular, in the specimen from Santa Teresa it is pointed. We reanalyzed the baculum described by Pessôa et al. (1996) and noted that it is damaged at the proximal end. If this broken piece is replaced to its original position, the general morphology will have the same general appearance of the baculum described from Caratinga. More specimens from Espírito Santo state should be analyzed to allow a more reliable assessment of bacular variation in the species.

The karyotype *T. paratus* is unknown. Paresque et al. (2004) published a karyotype attributed to *Trinomys iheringi* from Espírito Santo, with specimens collected from Estação Biológica de Santa Lúcia, Santa Teresa (where *T. graciosus graciosus* is known to occur), and in Reserva Biológica Duas Bocas, Cariacica (a locality of *T. paratus*). Unfortunately, the authors did not specify the provenance of the published karyotype, which had the same $2n$ and FN described and attributed to *T. graciosus* by Zanchin (1988).

Map 539 Selected localities for *Trinomys paratus* (●).

Trinomys setosus (Desmarest, 1817)

Elegant-spined Atlantic Spiny rat

SYNONYMS: See under Subspecies.

DESCRIPTION: Medium to large spiny rat, with mean head and body length 204 mm (range: 180–226 mm, s.d. 13.9; N=28), tail length 209 mm (168–230 mm, s.d. 16.1; N=27), hindfoot length 49 mm (43–53 mm, s.d. 2.7; N=31), ear length 27 (20–33 mm, s.d. 2.0; N=31), and mass 203.6 g (s.d. 33.5; N=22) (Jack-Ximenes 2005). General color of upper parts varies from brownish-olive to cinnamon, gradually changing to olive or pale cinnamon on sides and outer thighs, contrasting with white venter; marked cinnamon color at nape present in most individuals. Tail bicolored, brownish above and white below, with conspicuous whitish or cinnamon hairy pencil at tip (Moojen 1952), and slightly longer than head and body (about 103%). In northernmost part of geographic range, specimens tend to have very spiny appearance, whereas those from southernmost part have softer pelage. Aristiforms of mid-dorsal region long (ranging from 17–22 mm), wide in *T. s. setosus* (mean 1.1 mm; N=10) but narrow in *T. s. elegans* (mean 0.7 mm; N=10). Setiforms on mid-dorsal region gray basally, gradually blackening toward tip but interrupted by cinnamon subdistal zone. Setiforms on outer thighs gray on basal half then gradually become cinnamon at tip (Moojen 1948).

Skull large, without conspicuous ridges, and with length averaging 51.3 mm (s.d. 2.4; N=42), basilar length 36.7 mm (s.d. 1.8, N=47), and zygomatic width 25.2 mm (s.d. 1.0; N=53) (Jack-Ximenes 2005). Incisive foramina lyre shaped, long, and narrow (4.7 × 2.2 mm, averaging about 44% of diastema length), usually without conspicuous constriction at posterior end; foramina slightly shorter in specimens from Sergipe state; septum complete, with premaxillary portion elongated and vomer visible, extending along most of length of septum with its posterior part touching maxillary part, which is reduced to a small process. Posterior palatine foramina obsolete but located at level of M1. Postorbital process of zygoma well developed and markedly spiniform, slender, and involves only jugal. Auditory bullae large and inflated. Upper premolars with two counterfolds; upper molars have one to three counterfolds.

Bacular morphology varies both among and within subspecies (Pessôa and Reis 1992a; Pessôa et al. 1996; Lara et al. 2002; Jack-Ximenes 2005). Two bacular types present in specimens of *T. s. setosus*. Specimens from Itabuna, Bahia, with dorsoventrally curved shaft on proximal third and lateral indentation near middle, broadened near proximal end, and round at tip; distal end concave and without median depressions or distal wings. In contrast, specimens from Conceição do Mato Dentro, Minas Gerais, shaft narrow and lacks dorsoventral curvature and lateral indenta-

tions; proximal end round and distal end thin and concave. In *T. s. elegans*, bacular shaft straight without dorsoventral curvature or lateral indentations; distal end lacks both median depression and distal wings; and proximal end straight, without lateral expansions.

DISTRIBUTION: *Trinomys setosus* has the broadest geographic range of any species in the genus, occurring throughout the states of Sergipe, Bahia, Minas Gerais, Espírito Santo, and Rio de Janeiro, Brazil.

SELECTED LOCALITIES (Map 540): *T. setosus setosus*—BRAZIL: Bahia, Fazenda Aldeia, 7 km NNW of Valença (Lara and Patton 2000), Itambé (MNRJ 8323), Mata do Nono, São Felipe (Jack-Ximenes 2005), Mata do Ribeirão da Fortuna, 40 km W of Ilhéus, Itabuna (*Proechimys* [(*Trinomys*)] *iberingi denigratus* Moojen); Espírito Santo, Linhares (Pessôa et al. 1996), São Mateus (Jack-Ximenes 2005); Minas Gerais, Almenara (MNRJ 73409), Mata da Praúna, 5 km N (by road) of Conceição do Mato Dentro (Lara and Patton 2000); Sergipe, Fazenda Cedro, near Estância, outside Crasto (MNRJ 29370), Fazenda Cruzeiro, 13 km SSE of Cristinápolis (Lara and Patton 2000). *T. setosus elegans*—BRAZIL: Minas Gerais, Fazenda Cauaia, Matozinhos (Jack-Ximenes 2005), Fazenda Esmeralda, 30 km E and 4 km N (by road) of Rio Casca (Lara and Patton 2000), Juiz de Fora (MNRJ 34127), Santa Bárbara (Jack-Ximenes 2005); Rio de Janeiro, Cambuci (Attias et al. 2009).

SUBSPECIES: We recognize two subspecies, following Moojen (1948) and Lara and Patton (2000).

T. s. setosus (Desmarest, 1817)

SYNONYMS:

Echimyus setosus Desmarest, 1817b:59; type locality “Amérique”; Moojen (1948) suggested that the type came from “(southern?) Bahia,” Brazil.

L[oncheres]. myosurus Lichtenstein, 1820:192, Fig. 2; type locality “Provinz Bahia,” Brazil.

- Trinomys setosus elegans*: Lara and Patton, 2000:665; first use of current name combination.

This subspecies occurs in the southwestern part of the species range, in interior Minas Gerais and northern Rio de Janeiro, Brazil.

NATURAL HISTORY: A single female captured at Itabuna, Bahia, on 9 January 1944 gave birth to two young on 26 January 1945 (Moojen 1948). Each measured 177 mm in total length and weighed 27.8 g shortly after birth. Moojen (1948) gave external and craniodental measurements at the age of two months, by which time head and body length had increased to 120 mm and skull length to 35–36 mm, for example. Young specimens were captured from January to May. Despite the high levels of rainfall in the area of the Itabuna, Moojen (1948) mentioned that the type series of *T. denigratus* came from a forest with deciduous trees, and that all animals were trapped near water. On the basis of observations reported by Lund (1841b), Moojen (1952) reported that *elegans* is found near water bodies, being a good swimmer and building nests on the grass at the margin of lakes.

G. A. B. Fonseca and Kierulff (1988) found that *T. setosus* was the most abundant rodent in a 17-month study in semideciduous forest in Minas Gerais state. Individuals were captured in all months of the study, but with a peak in the late dry season. Pregnant and lactating females were present year-round, although breeding individuals were more frequent in mid-dry and midrainy seasons. They classified *T. setosus* as entirely terrestrial, lacking any scansorial ability. Analysis of stomach contents indicated that this spiny rat is primarily frugivorous, but also opportunistically feeds on insects and seeds.

Individuals from Três Braços, Bahia state, served as a natural reservoir of *Leishmania forattini* (Barretto et al. 1985; Yoshida et al. 1993; reported as *Proechimys iberingi denigratus*).

REMARKS: The precise type locality of *Echimys setosus* Desmarest is unknown. Thomas (1921h) reviewed the type specimens of *setosus* and *elegans* and treated them as synonyms. Moojen (1948) identified specimens collected by Wied-Neuwied as *setosus*, and only examined one speci-

men of *elegans*, recognizing two subspecies, *P. setosus setosus* and *P. s. elegans*. Moojen (1948) also described *P. iheringi denigratus* based on a series from Itabuna, southern Bahia.

In their mtDNA cytochrome-*b* phylogenetic study, Lara and Patton (2000) analyzed specimens from Cristinápolis (Sergipe) and Valença (Bahia), regarding them as *T. s. setosus*, a sample from Rio Casca (Minas Gerais), which they identified as *T. s. elegans*, and specimens from Conceição do Mato Dentro (Minas Gerais), which they referred to as *T. i. denigratus*. These samples were grouped in a monophyletic lineage belonging to their “Clade 2,” leading these authors to reallocate the three subspecies to *T. setosus*. Iack-Ximenes (2005) examined holotypes of these three taxa and, based on a lack of definable morphological differences between *setosus* and *denigratus*, proposed that the latter be regarded as a junior synonym of *T. setosus*. He also suggested that *elegans* be elevated to species category, recognizing both *T. setosus* and *T. elegans* in his “*setosus* group.” The topology of Clade 2 (Lara and Patton, 2000), however, does not corroborate the monophyly of *T. setosus sensu* Iack-Ximenes (2005) because a haplotype of an individual identified by him as *T. elegans* emerges as a lineage inside *T. setosus* in the Lara and Patton (2000) analysis. Despite the absence of monophyly, a relatively high divergence in mtDNA sequences (7.88%) was found between samples from Sergipe and Minas Gerais (Lara and Patton 2000), indicating some degree of differentiation between the *setosus* from Sergipe and *elegans* from Minas Gerais.

We analyzed recently collected samples from central and northern Minas Gerais state, and observed that combinations of characters usually considered diagnostic between the two forms in the extremes of the distribution (e.g., constricted incisive foramina characteristic of *elegans* and the basally expanded baculum of *setosus*) could be found in a same individual. Likewise, aristiform width and coloration, which are quite distinct at the extremes of the distribution, showed intermediate conditions in this part of the geographic range. Therefore, the molecular and morphological data currently available do not support a clear distinction between *setosus* and *elegans* and suggest a contact zone between these two forms. We thus recognize *denigratus* and *setosus* as synonyms, following Iack-Ximenes (2005), but regard *Trinomys setosus* as a single taxon with two subspecies: *T. s. setosus* (occurring in the northernmost part of range) and *T. s. elegans* (in the southernmost part of range).

The karyotype of *T. s. setosus* from Almenara, Minas Gerais state, is $2n=56$ and FN=108 (unpublished data). *Trinomys setosus elegans* from Santa Bárbara, Minas Gerais has $2n=56$ and FN=104. This karyotype consists

Map 540 Selected localities for *Trinomys s. setosus* (●) and *Trinomys s. elegans* (○).

of 25 pairs of metacentric, submetacentric, and subtelocentric autosomes and two pairs of acrocentric autosomes (pairs 26 and 27). The X chromosome is a large acrocentric corresponding in size to the third autosomal pair; the Y chromosome is acrocentric and one of the smallest chromosomes in the set (Corrêa et al. 2005).

Trinomys yonenagae (P. L. B. Rocha, 1996)

Torch-tail Spiny Rat, Yonenaga's Spiny Rat

SYNONYMS:

Proechimys yonenagae P. L. B. Rocha 1996:540; type locality “Ibiraba, Bahia, Brazil (10°48'S, 42°50'W).”

Trinomys yonenagae: Lara and Patton, 2000:665; first use of current name combination.

Trinomys yonenga: Lara and Patton, 2000:668; *lapsus calami* in the spelling of *yonenagae* (Rocha).

DESCRIPTION: Small to medium-sized member of genus, with mean head and body length 164 mm (141–195 mm; s.d. 14.2; N=23), tail length 191 mm (169–225 mm; s.d. 10.1; N=23); hindfoot length 44 mm (41–51 mm; s.d. 2.3; N=23), and ear length 24 (20–27 mm; s.d. 1.7; N=23) (Iack-Ximenes 2005). General color of upper parts paler than any other congeneric species, generally pale cinnamon mixed with darker hairs on mid-dorsum, gradually becoming lighter on sides, and only slightly contrasting with white ventral coloration. Pelage relatively soft for genus; aristiforms on mid-dorsum of medium length and soft, with average total length 16–19 mm and maximum width about 0.6 mm. Tail markedly bicolored (brownish above

and white below) and long, averaging about 120% of head and body length, with very long hairy pencil at tip (hairs extend more than 30 mm beyond tail tip). Hindfeet especially long for genus (P. L. B. Rocha 1996).

Skull medium in length and relatively narrow, being more robust in parietal and occipital region, and with marked ridges, but becoming progressively more slender and delicate toward rostrum. Average skull length 44.7 mm (s.d. 4.4; N=31), basilar length 30.8 mm (s.d. 3.5; N=31), and zygomatic width 21.9 mm (s.d. 1.8; N=31). Incisive foramina often oval and elongated (mean length \times length, 4.3 \times 2.4 mm), occupying about 45% of diastema; septum complete, with long premaxillary portion, occupying about 75% of septum, short maxillary portion, and vomer not visible in ventral view. Postorbital process of zygoma well developed and typically formed only by jugal; unique among other species in having laminar inflection of jugal. Auditory bullae large, smooth, and distinctively very inflated (mean bullar length 10.3 mm; s.d. 0.5). PM4–M1 with one major fold and one counterfold.

Baculum elongated (mean length 8.1 mm; s.d. 0.7; N=7) and slender, with slight dorsoventral curvature; distal end median depression or apical wings; shaft with slight lateral indentations near distal end and broadening toward proximal end, but interrupted by terminal constriction at about its fifth part; proximal end pointed (P. L. B. Rocha 1996).

DISTRIBUTION: *Trinomys yonenagae* is known from sandy dunes on the left bank of middle Rio São Francisco, in northwestern Bahia state, Brazil.

SELECTED LOCALITIES (Map 541): BRAZIL: Bahia, Ibiraba (type locality of *Proechimys yonenagae* Rocha), Queimadas (P. L. B. Rocha 1996).

SUBSPECIES: *Trinomys yonenagae* is monotypic.

NATURAL HISTORY: This species is restricted to a small area in a semiarid sandy dune habitat characterized by a sparse vegetative covering and subject to the macroclimatic conditions of Caatinga biome (P. L. B. Rocha 1996). Local herbaceous vegetation is composed mainly of spiny bromeliads and cacti, but with the genus *Eugenia* (Myrtaceae) comprising 35% of shrub and tree species (J. W. Santos and Lacey 2011). Some ecological, behavioral, and morphological traits of this species are very distinctive relative to its forest-dwelling congeners and apparently represent generalized convergent traits of desert rodents broadly recognized as adaptations to semiarid conditions. Among these traits are the medium to small sized body, very inflated tympanic bullae, long hindfeet and tail, strongly penciled tail, asymmetrical pattern of limb coordination, colonial behavior, and burrow-dwelling habits (P. L. B. Rocha 1996; P. L. B. Rocha et al. 2007; J. N. S. Freitas et al. 2008, 2010; J. W. Santos and Lacey 2011).

Trinomys yonenagae is the only small mammal found on the sand dunes near Ibiraba, and should be the prey of multiple predators (P. L. B. Rocha 1996; J. W. Santos and Lacey 2011). Most food and water consumed by this spiny rat is obtained from seeds of *Eugenia* (Myrtaceae). Individuals live in self-dug burrow systems, the majority of which are located in valleys among sand dunes, where vegetation is sparse, resulting in high soil temperature (60°C) during daylight hours (J. W. Santos and Lacey 2011). Mean density of occupied burrow systems is 9.9 ± 1.6 per hectare, with each system having 1 to 13 entrances (mean 5.4 ± 4.2) per burrow system. Field data suggested that adults of both sexes share burrow systems and, in some cases, nest sites (J. W. Santos and Lacey 2011). *Trinomys yonenagae* meets the spatial criteria used to diagnose sociality in fossorial rodents (J. W. Santos and Lacey 2011). In accordance with sociality indices found in the field, captive experiments showed that the intensity of affiliative behavior in *T. yonenagae* is high, both in intersexual and intrasexual encounters (J. N. S. Freitas et al. 2003, 2008, 2010). This species was thus markedly more affiliative than other *Trinomys* or *Thrichomys* species, lacking the types of anxiety signals often associated with social interactions (J. N. S. Freitas et al. 2008). Affiliation was mediated by acoustic communication by for males and females, and does not differ between animals from the same social group or from different social groups. However, females tended to spend more time near familiar males than unfamiliar males, a pattern interpreted as an evidence of social monogamy (Manaf and Oliveira 2009). Alternatively, J. W. Santos and Lacey (2011) provided data on extensive overlap in home ranges of males and females and suggested a promiscuous mating system. *Trinomys yonenagae* may use secretions from an anal scent gland as communication signals in social interaction (Manaf, Brito-Gitirana, and Oliveira 2003).

In captive experiments, *T. yonenagae* employed stop-and-go search (in accordance with field data; P. L. B. Rocha 1991), a pattern of locomotion characterized by a notable component of vigilance (Manaf, Brito-Gitirana, and Oliveira 2003). Individuals use saltatorial locomotion and leave burrows at night (P. L. B. Rocha 1991); captive studies indicated a regular pattern of circadian activity restricted to nocturnal hours (Marcomini and Oliveira 2003).

Trinomys yonenagae is classified as Endangered (B1ab, iii) by the IUCN (2011).

REMARKS: P. L. B. Rocha (1996) hypothesized that *T. yonenagae* shared a closer relationship with *T. albispinus*, forming a natural clade in the genus, based in tooth morphology and geography. Alternatively, Pessôa et al. (1998) suggested a close affinity with a polytypic *Trinomys iheringi* (which then included *eliasi* and *paratus* as valid

Map 541 Selected localities for *Trinomys yonenagae* (●).

species and *bonafidei*, *denigratus*, *gratiosus*, and *panema* as subspecies of *iheringi*) based on bacular structure and quantitative cranial variation. Finally, in their mtDNA phylogenetic analysis, Lara and Patton (2000) placed *T. yonenagae* within a clade comprising *T. paratus*, *T. setosus*, and *T. eliasi*, and to the exclusion of both *T. albispinus* and *T. iheringi*. Although this analysis supported *T. yonenagae* as a very distinct taxon, its relationship to the remaining species in its clade remains unclear.

The karyotype of *T. yonenagae* is $2n = 54$ and $FN = 104$, including an autosomal complement of 26 pairs of metacentrics or submetacentric chromosomes; the X chromosome is a large-sized acrocentric; the Y is a small metacentric (Leal-Mesquita et al. 1992).

Subfamily Myocastorinae Ameghino 1902

James L. Patton

These are large-bodied, robust, and heavy rodents adapted for an aquatic lifestyle. Head and body length ranges to 600 mm, tail length to 450 mm, hindfoot length to 120 mm, and mass averages more than 1 kg. The ears are small (maximally 35 mm in height), nearly hidden in the thick fur; the mouth is closable behind the incisors; the tail is long, round, thick, scaly, and sparsely haired; the limbs are short; the hindfeet have four toes, each with a long claw, and webbed between; the pollex is reduced in size and the fifth toe of the forefoot is unwebbed; and the pelage is soft and thick with dense underfur and long guard hairs. Sebaceous glands are located near the corner of the mouth

and near the anus. There are four or five pairs of mammae, each lateral in position and located high on the side.

As with other echimyids, the fourth upper and lower premolars are not replaced and are thus generally considered deciduous. All cheek teeth, above and below, are flat-crowned and extremely hypsodont but not hypselodont. The upper toothrows converge anteriorly, but not to the degree as in *Dactylomys*, and are inclined outward. Upper cheek teeth have two labial flexi and three lingual flexi; lower cheek teeth have one labial and three lingual flexids, although pm4 has an additional anterior lake. The reentrant folds of both upper and lower cheek teeth become lakes with wear. The incisors are broad and deep, with the enamel strongly pigmented orange. The skull is long and broad, flat in lateral profile, and with a broad, deep, and elongated rostrum. A sagittal crest is well developed. The zygomatic arch is broad and flaring, the jugal is thick but does not approach the lacrimal, and the jugal fossa is reduced. The infraorbital foramen is large without a distinct groove on the ventral surface for nerve passage. The angular process of the mandible is strongly deflected and the coronoid process is vestigial. Stems of the internal carotid artery and stapedial artery are both missing (description from Woods 1984). The subfamily contains the single, monotypic extant genus *Myocastor*, but the fossil record is rich, with nine genera recognized in deposits from the Early Miocene to Late Pliocene (McKenna and Bell 1997).

As noted earlier, myocastorines have been frequently treated as a subfamily of the Capromyidae (Hall 1981; Simpson 1945). However, Woods and Howland (1979) documented numerous important morphological differences between these two groups that supported their phyletic distinctness. Landry (1957) placed the myocastorines as a separate family in his superfamily Octodontoidea. B. Patterson and Pascual (1968a), B. Patterson and Wood (1982), and McKenna and Bell (1997) placed *Myocastor* as a subfamily of the Echimyidae. Woods (1984:445) considered it “slightly more closely related to echimyids than to capromyids or octodontids” and treated it as a separate family in the same superfamily as the echimyids and octodontids. He concluded, however, that the myocastorids had their origin from echimyids of the subfamily Adelphomyinae in the Oligocene, which would make the Echimyidae paraphyletic to his Myocastoridae. Both molecular sequence analyses (Y. L. R. Leite and Patton 2002; Galewski et al. 2005; Upham and Patterson 2012) as well as a cladistic analysis of morphological traits (G. A. S. Carvalho and Salles 2004) solidly place *Myocastor* as nested within the Echimyidae. These studies form the basis for the inclusion of myocastorines as a subfamily of the Echimyidae herein.

Genus *Myocastor* Kerr, 1792

SYNONYMS:

Mus: G. I. Molina, 1782:287; part (listing of *huidobrius*, a *nomen dubium*, and description of *coypus*); not *Mus* Linnaeus.

Myocastor Kerr, 1792:225; type species *Mus coypus* G. I. Molina by subsequent designation (Palmer 1904:438).

Hydromys É. Geoffroy St.-Hilaire, 1804:253; partly based on *Mus coypus* G. I. Molina; not *Hydromys* É. Geoffroy St.-Hilaire in current usage (Muridae; see Tate 1936:642; Ellerman 1941:298; Musser and Carleton 2005:1333).

Myopotamus É. Geoffroy St.-Hilaire, 1805:82; based on manuscript name of the French naturalist Philibert Commerson (see Palmer 1904:440).

Hydromis É. Geoffroy St.-Hilaire, 1805:86; part (description of *coypou*); incorrect subsequent spelling of *Hydromys* É. Geoffroy St.-Hilaire.

potamys F. Cuvier, 1823b:184; name given under *Myopotamus* but stated as different from Commerson's animal ("qui est plus régulièrement formé que celui de Commerson"); see also Desmarest (1826:491).

Potamys Larranhaga, 1823:83; based on the "*quouiya*" of Azara (1801:5), which equals *Mus coypus* G. I. Molina.

Castor J. B. Fischer, 1829:286; part (listing of *huidobrius* and *coypus*); not *Castor* Linnaeus.

Mastonotus Wesmael, 1841:61; type species *Mastonotus popelairi* Wesmael (= *Mus coypus* G. I. Molina).

Guillinomys Lesson, 1842:126; type species *Guillinomys chilensis* Lesson, which was based on *Castor Huidobrius* G. I. Molina.

Tramyocastor Rusconi, 1936:1; based on two fossil species, *T. andiai* Rusconi and *T. majus* Rusconi.

REMARKS: J. A. Allen (1895a), Thomas (1920h), Tate (1935), and Osgood (1941, 1943b) have discussed the taxonomic history of *Myocastor* Kerr and other names associated with it. G. I. Molina (1776), under the vernacular names *guillin* (or *guillino*) and *coipu*, was the first to write about the Coypu. He subsequently (G. I. Molina 1782) described *Castor Huidobrius* (p. 285) for the *guillino* and *Mus coypus* (p. 287) for the *coipu*, the former "with the dimensions and habits of an otter, and the dentition of a rodent" (Osgood 1941:408–409). Thus, both Thomas (1920h:225) and Osgood (1941:408–409, 1943b:132) argued that Molina's *huidobrius* and subsequent names derived from it (such as *Guillinomys chilensis* Lesson 1842) should be regarded as composite and unidentifiable. This leaves Molina's second species, *Mus coypus*, which Molina thoroughly described, as the type for *Myocastor*.

Étienne Geoffroy St.-Hilaire's name *Myopotamus* was universally used for the coypu throughout the nineteenth

century (e.g., Waterhouse 1848; E.-L. Trouessart 1880) until J. A. Allen (1895a:182–183) pointed out that *Myocastor* Kerr was a valid, earlier name. Kerr's *Myocastor* was based on both *Mus coypus* G. I. Molina and *Castor zibethicus* Linnaeus [= *Ondatra zibethicus*, the muskrat], and Allen selected the coypu as the type species by elimination. This action was solidified in Opinion 55 of the ICZN (1913), which fixed *zibethicus* Linnaeus as the type of *Ondatra* Link, leaving *Mus coypus* G. I. Molina as the sole member of Kerr's *Myocastor*. Other nineteenth century names (e.g., *Potamys* Larranhaga or *Mastonotus* Wesmael) were either based directly or indirectly, through Azara's (1801) "*quouiya*," on Molina's *Mus coypus*, and *Guillinomys* Lesson was based on Molina's indeterminable *Castor Huidobrius*. Cabrera (1961:568) and Woods and Kilpatrick (2005:1593) gave Desmarest, 1825 as the author and date for *Potamys*, but both F. Cuvier (1823b) and Larranhaga (1823) had proposed the name two years earlier. Furthermore, Desmarest's paper appeared in 1826, not 1825.

B. Patterson and Pascual (1968a:7) regarded *Tramyocastor* Rusconi, proposed for two fragmentary fossil species, as indistinguishable from *Myocastor*, and Verzi, Deschamps, and Vucetich (2002) reviewed the status of *Paramyocastor* and other generic names assigned to it from the Late Miocene to Late Pliocene. Earliest records of *Myocastor* are from the Late Miocene Mesopotamian deposits in Argentina (Candela and Noriega 2003; Candela 2004).

Myocastor coypus (G. I. Molina, 1782)

Coypu*, *Nutria

SYNONYMS:

Castor Huidobrius G. I. Molina, 1782:287; Latinized name for the 'guillino' of G. I. Molina (1776); see also Alsop's English translation of Molina (1808:240); regarded as a *nomen dubium* by Thomas (1920g:225) and Osgood (1941:408–409).

Mus coypus G. I. Molina, 1782:287; type locality "Chili"; given as "Rio Maipo, Santiago Province, Chile" by Woods et al. (1992:1).

Myocastor coypus: Kerr, 1792; first use of current name combination.

Ondatra coypus: H. F. Link, 1795:76; name combination.

Hydromys coipou É. Geoffroy St.-Hilaire, 1804:254; name combination and incorrect subsequent spelling of *coypus* G. I. Molina.

Myopotamus Bonariensis É. Geoffroy St.-Hilaire, 1805:82; type locality given as "Rio Parana, Paraguay" by Woods et al. (1992).

Hydromis coypou É. Geoffroy St.-Hilaire, 1805:86; name combination and incorrect subsequent spelling of *coypus* G. I. Molina.

Mus castorides Burrow, 1815:168; type locality "the Brazils."

Castor ? huidobrius: Illiger, 1815:108; name combination.
Hydromys coypus: Illiger, 1815:108; name combination.
Castor Chilensis Oken, 1816:886; unavailable name (ICZN 1956).
Potamys coypou: Desmarest, 1826:491; name combination and incorrect subsequent spelling of *coypus* G. I. Molina.
Myopotamus canariensis Gray, 1827:223; probably a spelling lapsus for *bonariensis* É. Geoffroy St.-Hilaire (Cabrera 1961:568).
Myopotamus coypus: I. Geoffroy St.-Hilaire, 1827:374; name combination.
Castor coypus: J. B. Fischer, 1829:288; name combination.
Myopotamus antiquus Lund, 1840b [1841c:289, plate 21, Figs. 1–5]; type locality “Rio das Velhas’s Floddal” (Lund 1841c:292, 294), Lagoa Santa, Minas Gerais, Brazil; described from fossil remains.
Mastomys Popelairi Wesmæl, 1841:61; type locality “Ces animaux, qui habitent les bords des eaux douces du Chile, ont les plus grands rapports avec les Couia [*Myopotamus* Comm.], etc,” given as “Bobica, Bolivia” (S. Anderson 1997) but type specimen stated as coming from Chile, not Bolivia (Woods et al. 1992).
Guillinomys Chilensis Lesson 1842:126; renaming of *Castor huidobrius* (Osgood 1943b: 90).
Myopotamus Coypu rufus Fitzinger, 1867b:134, type locality “Am. Paraguay”; based on J. B. Fischer’s (1829:288) *C[astor]*. *Coypus* β.
Myopotamus Coypu dorsalis Fitzinger, 1867b:134, type locality “Am. Paraguay”; based on J. B. Fischer’s (1829:288) *C[astor]*. *Coypus* γ.
Myopotamus Coypu albomaculatus Fitzinger, 1867b:134, type locality “Am. Chili”; based on J. B. Fischer’s (1829:288) *C[astor]*. *Coypus* δ.
Myopotamus coypu Thomas, 1881b:6; incorrect subsequent spelling of *coypus* G. I. Molina.
Myocastor coypus santacruzae Hollister, 1914a:57; type locality “north bank Rio Salado, near Los Palmares, Santa Cruz [corrected to Santa Fe, see Poole and Schantz 1942:490], Argentina.”
Myocastor coypus coypus: Hollister, 1914a:57; name combination.
[*Myocastor coypus*] *bonariensis*: Hollister, 1914a:58; name combination.
Myocastor coypus brasiliensis Marelli, 1931:45; *nomen nudum*; contained in a list of synonyms.
Myocastor coypus melanops Osgood, 1943b:132; type locality “Quellon, Chiloe Island,” Los Lagos, Chile.
Myocastor coypus popelairi: Osgood, 1943b:132; name combination.
Myocastor coypus castoroides: Paula Couto, 1950:291, footnote 323; name combination.

[*Myocastor coypus*] *santacruzae*: Woods and Kilpatrick, 2005:1593; incorrect subsequent spelling of *santacruzae* Hollister.

DESCRIPTION: As for the subfamily.

DISTRIBUTION: *Myocastor coypus* is native to Chile and Argentina, northward to Bolivia, Paraguay, Uruguay, and southern Brazil, in wetland habitats within a broad range of biomes, including humid and dry Chaco, Patagonian steppe, pampas grassland, and coastal margins. The native range in Brazil is limited to the southern states of Rio Grande do Sul and Santa Catarina; feral populations are now established in São Paulo state following introduction by commercial breeders (Bonvicino, Oliveira, and D’Andrea 2008). Lund (1840a, 1841b:266, plate 21, Figs. 1–5) recorded this species in the fossil record from the caves near Lagoa Santa, Minas Gerais (as *Myopotamus antiquus*, which was equated to the extant *M. coypus* by Paula Couto 1959:291, footnote 323). The species is now introduced widely into northern South America, North America, Europe, central Asia, and east Africa (Woods et al. 1992; J. Carter and Leonard 2002; Bertolino et al. 2012).

SELECTED LOCALITIES (Map 542; native range only): ARGENTINA: Buenos Aires, Delta del Paraná (FMNH 21694), Partido Balcarce (MSU 20469); Jujuy, Aguas Negras (Heinonen and Bosso 1994); La Pampa, Laguna Guatrache (TTU 66631); Neuquén, 11 km NNE of Nahuel Huapi (MVZ 179309); Santa Fe, Los Palmares (type locality of *Myocastor coypus santacruzae* Hollister); Tucumán, Los Sarmientos (AMNH 41543). BOLIVIA: Beni, Piedras Blancas (S. Anderson 1997); Cochabamba, Todos Santos (S. Anderson 1997); Santa Cruz, Buena Vista (S. Anderson 1997). BRAZIL: Rio Grande do Sul, Itaqui (MZUSP 3190), São Lourenço do Sul (AMNH 134145); Santa Catarina, Paulo Lopes (Cherem et al. 2004); São Paulo, Pedreira (Bonvicino, Lindbergh, and Maroja 2002), Guarapiranga Reservoir, Interlagos (MZUSP 25808). CHILE: Araucanía, Temuco (MSU 9652); Biobío, Concepción (Wolffsohn 1923); Los Lagos, Chiloé Island, Quellon (type locality of *Myocastor coypus melanops* Osgood); O’Higgins, Cachapoal (Wolffsohn 1923). PARAGUAY: Alto Paraguay, Estancia Tres Marias (UMMZ 79836); Neembucú, Estancia Yacaré (UMMZ 80583); Paraguari, Ybycui (UMMZ 124717), Presidente Hayes, Estancia Juan de Zalazar, 2 km S of headquarters (UMMZ 57389). URUGUAY: Río Negro, 15 km S of Paysandu (AMNH 206455); Soriano, 15 km SW of Dolores (Sanborn 1929); Treinta y Tres, 16 km SSW mouth of of Río Tacuari (AMNH 206459).

SUBSPECIES: Hollister (1914a) recognized three races within the native range: *coypus* G. I. Molina from Chile (with *popelairi* Wesmæl a synonym), *bonariensis* É. Geoffroy St.-Hilaire from northern Argentina and Paraguay,

and *santacruzae* Hollister from southern Argentina. Osgood (1943b) described *melanops*, from Chiloé Island in southern Chile, and recognized four other subspecies: the nominotypical form from central Chile, *bonariensis* from northeastern Argentina and Uruguay, *sanctacruzae* from southwestern Argentina, and *popelairi* from southeastern Bolivia. Cabrera (1961) extended the range of *bonariensis* to include the subtropical pampas of northeastern Argentina, Uruguay, Paraguay, and southwestern Brazil. No modern analysis of geographic variation in any character set, morphological or molecular, has been undertaken to test the validity of these geographic units.

NATURAL HISTORY: Willner et al. (1979), Willner (1982), Woods et al. (1992), and Bounds et al. (2003) reviewed the life history, ecology, reproductive biology, and behavior of *Myocastor coypus*. Most research on natural populations has centered on those introduced into the United States or Europe. However, there has been substantial recent fieldwork on populations within the native range in southern South America, particularly in northern and eastern Argentina, covering nearly all aspects of the population biology, in part because of the importance of nutria in the fur market trade. Bó et al. (2006a,b) summarized their “Proyecto Nutria” program to evaluate population density and other parameters, habitat suitability, and hunting pressure, among those aspects necessary for the sustainable management of this species within Argentinean wetlands. Individually, there have been recent studies covering a wide range of natural history topics, from diet (Borgnia et al. 2000; Colares et al. 2010), habitat use (D’Adamo et al. 2000; Corriale et al. 2006), population structure, social behavior, and group formation (Guichón, Borgnia et al. 2003; Guichón, Doncastor, and Cassini 2003), foraging behavior (Guichón, Benítez et al. 2003), and genetic variability and relatedness with respect to social organization (Túnez et al. 2005, 2009). In Chile, the predators of nutria include the puma, *Puma concolor* (Rau et al. 2002), and in Brazil Geoffroy’s cat, *Leopardus geoffroyi* (K. S. Sousa and Bager 2008). A variety of cestode, trematode, and nematode internal parasites of coypus have been detailed by F. A. Martínez (1988), Paulsen and Brum (1999), Paulsen et al. 1999), Flores et al. (2007), Gayo et al. (2011), and P. E. Martino et al. (2012).

Coypus are aquatic, inhabiting slow-moving streams, lakes, freshwater marshes, and brackish water. Their density in the Argentinean Pampas was positively associated with the width of the alluvial plain of watercourses and agricultural land uses, negatively with urbanization and semiurban landscapes (Leggieri et al. 2011). They feed on grains and the roots, rhizomes, stems, and leaves of a wide range of aquatic plants, as well as mussels and snails, using logs or other floating debris as feeding stations. They are

excellent swimmers, can remain submerged for up to five minutes, and nest in self-dug burrows in banks. Burrows are usually short with no branches and a single nest chamber, although more complex burrows have been described in parts of their native range. The gestation period is long, up to 132 days, and litter size varies from three to five, on average. Coypus are capable of breeding throughout the year in all areas of their range, both native and introduced. Sexual maturity may be reached within six months, but more typically between 12 and 15 months of age. Their chief predators are crocodilians, fish, large snakes, turtles, raptors, and canids. Where they have been introduced, coypus have become a major agricultural pest. The fur can be a major income source in some areas.

REMARKS: Both *Castor chilensis* Oken and *Guillimys chilensis* Lesson are renamings of *Castor huidobrius* G. I. Molina, an indeterminate name based on characters of both an otter and coypu (Thomas 1920g; Osgood 1941, 1943b). Furthermore, all names Oken proposed in his *Lehrbuch* (Vol. 3) are unavailable (ICZN 1956). Woods et al. (1992) stated that the type specimen of *popelairi* Wesmæl, 1841 came from Chile, not Bobica, Bolivia. These authors considered the single distinguishing character of this taxon (the nipples located high on the back) to be an individual anomaly. As a result, they concluded that *popelairi* Wesmæl was a junior synonym of the nominotypical subspecies, *M. c. coypus*. Tsigalidou et al. (1966), W. George and Weir (1974), and S. González and Brum-Zorrilla (1995) described a karyotype of $2n=42$, FN=76.

Map 542 Selected localities for *Myocastor coypus* (●). Contour line = 2,000 m.

Family Octodontidae Waterhouse, 1839

Diego H. Verzi, M. Mónica Díaz, and Rubén M. Barquez

The family Octodontidae comprises an assemblage of medium- to small-sized caviomorph rodents endemic of southern South America. Previous to Tate (1935), *Ctenomys* and the extinct allied genera were usually included among octodontids without a category to separate them from the other genera (Ameghino 1889; Rovereto 1914; G. S. Miller and Gidley 1918; Rusconi 1931a; Kraglievich 1934). Indeed, Bennett (1841) showed that his genus *Octodon* was intermediate in molar occlusal structure between F. Cuvier's *Poephogomys* (= *Spalacopus*) and *Ctenomys*. Tate (1935) and later Reig (1958; see justification in Pascual et al. 1965) segregated *Ctenomys* and related extinct genera from the other octodontids. This proposal is currently adopted in the literature but without agreement in relation to the taxonomic rank assigned to both lineages (as families Octodontidae and Ctenomyidae [Simpson 1945; Wood 1955; Cabrera 1961; Woods 1993; M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003], as subfamilies of Octodontidae [Pascual et al. 1965; Reig 1989], or as tribes of Octodontinae [McKenna and Bell 1997]). Here we follow the strictest definition of the Octodontidae (after Honeycutt et al. 2003), which excludes the Ctenomyidae. According to this criterion, Octodontidae comprises 16 extant species grouped in six living genera with surface-dwelling (*Octomys*), fossorial (*Octodontomys*, *Octodon*, *Tympanoctomys* [including *Pipanaoctomys* and *Salinocotomys*], semisubterranean (*Aconaemys*), and completely subterranean (*Spalacopus*) habits (Reig 1986, 1989; R. A. Ojeda et al. 1996; M. H. Gallardo et al. 2007; E. P. Lessa, Vassallo et al. 2008).

Although the Octodontidae probably originated in the Late Oligocene (23.4–25.5 mya; Voloch et al. 2013; Verzi et al. 2013), most analyses of molecular evidence (Köhler et al. 2000; M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005) suggest that the six extant genera diversified into two major clades in the Late Miocene, a time period consistent with the fossil record indicating a major radiation of octodontids in response to climatic change (Vucetich et al. 1999; Verzi et al. 2013). The combined mtDNA/nucDNA gene analyses by Voloch et al. (2013) provided an older, Early Miocene age for this divergence. The two clades comprise the genera (*Octomys* + *Tympanoctomys*), estimated to have diverged at 4.28 ± 1.08 mya, and (*Octodontomys* (*Octodon* (*Aconaemys*, *Spalacopus*))), with a basal divergence date of 6.07 ± 1.34 mya (Opazo 2005). Protein electrophoresis (Köhler et al. 2000), DNA/DNA hybridization (M. H. Gallardo and Kirsch 2001), and both mitochondrial and nuclear DNA sequences (Honeycutt et al. 2003; Opazo 2005) have each

recovered the same basic topology. The position of *Octodontomys* is somewhat ambiguous, however, as Upham and Patterson (2012) place this genus as sister to *Octomys* + *Tympanoctomys* in their Bayesian analysis while this genus is grouped with (*Octodon* + (*Aconaemys*, *Spalacopus*)) in a chronogram using fossil calibrations. Most studies also have not recovered the monophyly of *Aconaemys* species (but see Gallardo et al. 2007), with *A. porteri* forming a sister-relationship with *Spalacopus* and not to *A. fuscus* + *A. sagei*. The association of these taxa is, however, weak, and their correct phyletic relationships remain to be resolved (Upham and Patterson 2012). Diversification of the extant species within each genus apparently stems from the late Pliocene or mid-Pleistocene, with dates ranging from 2.57 ± 0.76 mya for three species of *Octodon* to 1.74 ± 0.59 mya for two species of *Tympanoctomys* (Opazo 2005).

The only living Octodontidae genus recognized in the fossil record is *Tympanoctomys* (Verzi, Tonni et al. 2002; but see Reig 1986). Modern (i.e., hypsodont) members of the family are known in the fossil record of Argentina since the Late Miocene, but their phylogenetic relationships to living species remain unknown (Reig and Quintana 1991; Verzi 2001; Deschamps et al. 2012).

Species of octodontids are distributed in mesic to arid open land biomes, in the Andean region or adjacent lowlands, between 16°S latitude in southwestern Bolivia, to 43°S latitude in southern Argentina and Chile (L. C. Contreras et al. 1987; Woods 1993; Hutterer 1994; Mares et al. 2000; M. H. Gallardo and Kirsch 2001; Verzi, 2001; M. H. Gallardo et al. 2007, 2009). These modern representatives originated in the Patagonian region (including the Monte desert and southern Andes), the northern portion of the Monte desert being the most probable ancestral area (Upham and Patterson 2012; A. A. Ojeda et al. 2013). The genera *Octomys* and especially *Tympanoctomys* are the South American rodents most highly adapted to desert environments (Mares 1975, 1993, 1997; Bozinovic and Contreras 1990; R. A. Ojeda et al. 1996, 1999; M. M. Díaz and Ojeda 1999; Ojeda and Tabeni 2009). *Spalacopus* (and *Aconaemys* to a lesser degree) is one of the more highly specialized subterranean rodents in the South American fauna, with independent development of a number of highly derived morphological attributes also found in the tuco-tucos (*Ctenomys*; see Reig 1970; E. P. Lessa, Vassallo et al. 2008; Morgan and Verzi 2011; Morgan and Alvarez 2013).

Octodontids are medium-size species, ranging in head and body length from 150 to almost 400 mm and body mass from 100 to nearly 300 g. The pelage is usually long, dense, and soft. The hind feet have a comb of stiff hairs extending beyond the middle digits. Most species are grayish or drab in dorsal color with white or cream venters, except *Spalacopus*, which is uniformly darkish brown to black. In

general, apart from the semisubterranean and subterranean genera, most species have a long tail with a terminal tuft. The feet are short, with four well-developed digits ending in sharp and curved claws, whereas the first digit (especially the pollex) is strongly reduced and usually bears only a small nail. As in other South American hystricognath rodents, the glans penis has an intromittent sac below the urethra that is everted during sexual activity. Spines, highly variable in number and morphology, are present in the floor of the sac (Spotorno 1979; L. C. Contreras et al. 1993).

Cranial morphology is diverse, corresponding to different types of mastication, from oblique to propalinal, and terrestrial to subterranean habits (Olivares et al. 2004; E. P. Lessa, Vassallo et al. 2008). Endocranial volume (a proxy of the brain size) of octodontids is relatively larger than those expected for a caviomorph, except for the fossorial and subterranean *Aconaemys* and *Spalacopus* (Vassallo and Echeverría 2009). The tympanic bullae are hypertrophied in desert-adapted genera *Octodontomys*, *Octomys*, and especially *Tympanoctomys* (Ojeda et al. 1999), but general characteristics of the middle ear are shared between subterranean specialists (e.g., *Spalacopus*) and nonsubterranean taxa (e.g., *Octodon*). Argyle and Mason (2008) presented evidence that low-frequency hearing, usually considered a specialization of subterranean taxa, is plesiomorphic in the Octodontoidea. The paroccipital process is short, ventrolaterally oriented, and completely joined to the bulla (Verzi 2001). The mandible is strongly hystricognathous, with markedly expanded masseteric crests, in the fossorial to subterranean *Aconaemys* and *Spalacopus*. The origin of the masseteric crest, posterior to the notch for the tendon of the medial masseter muscle, is ventrally deflected (Verzi et al. 2013).

The dental formula is I 1/1, C 0/0, PM 1/1, M 3/3 = 20. Incisors are long and deeply implanted in the skull and mandible, especially in the subterranean *Spalacopus*. Molariform teeth are euhypsodont, with a typical to modified figure-8 occlusal design; the first molariform teeth are the deciduous fourth premolars (DP4/dp4), which are retained throughout life. Adult DP4/dp4-M3/m3 lack some folds (flexi): paraflexus, metaflexus(id), and posteroflexus, or the corresponding fossettes(id)s. The alveolar sheaths of the molars protrude into the orbital region. The humerus of the fossorial to subterranean *Aconaemys* and *Spalacopus* is robust, with wide epicondyles (Lessa et al. 2008; Morgan and Alvarez 2013), the hand of these genera showing relatively short carpal bones, robust metacarpals, and incipient mesaxony (metacarpal III > metacarpal IV > metacarpal II); the metacarpal V is remarkably broad and shortened in *Spalacopus* (Morgan and Verzi 2011).

Octodontids are mainly herbivorous (M. H. Gallardo et al. 2007). The gestation period is long, and young are precocial at birth, typically well haired and, in some species,

with eyes and ears open. Although the deserticolous *Octomys* and *Tympanoctomys* are solitary, sociality is common in the clade of mesic-adapted *Octomys-Aconaemys-Spalacopus* (Lacey and Ebensperger 2007; Ebensperger et al. 2008), and an evolutionary trend from solitary to social habits has been proposed for the family (Ebensperger et al. 2008).

Octodontids show extensive chromosomal repatterning. Members of this family exhibit one of the largest ranges in chromosomal number of any mammal, with diploid numbers from $2n=38$ in *Octodontomys* to $2n=102$ in *Tympanoctomys* (L. C. Contreras et al. 1990; M. H. Gallardo 1992, 1997; M. H. Gallardo et al. 2007). M. H. Gallardo et al. (1999; see also M. H. Gallardo, Garrido et al. 2004; M. H. Gallardo, Kausel et al. 2004; M. H. Gallardo et al. 2006) proposed by both *T. barrerae* and *T. aureus* are the only known cases of mammalian polyploidy (but see Svartman et al. 2005), their putative tetraploid condition acquired via hybridization (M. H. Gallardo et al. 2007; Suárez-Villota et al. 2012).

KEY TO THE GENERA OF OCTODONTIDAE:

1. Tail short, up to 50% of head and body length, and without terminal tuft of hairs 2
- 1'. Tail long, more than 70% of head and body length, and with a terminal tuft of hairs 3
2. Pelage uniformly darkish brown to black; upper incisors highly procumbent, with the incisor alveolus extended up to M1–2; molariforms with lingual and labial folds not connected at the middle *Spalacopus*
- 2'. Pelage dark drab; upper incisors orthodont and normally implanted; molariforms with lingual and labial folds connected at the middle *Aconaemys*
3. Upper and lower molariforms with figure-8 occlusal pattern; dorsal wall of the epitympanic recess of the bulla forming a large bony "island" on the braincase roof. 4
- 3'. Upper and lower molariforms with asymmetrical occlusal pattern; the upper ones with the posterior lobe not labially extended; dorsal wall of the epitympanic recess as a small dorsal ossification on the braincase roof or absent. 5
4. Auditory bullae large but not hypertrophied; length of the braincase less than 3.5 times the maxillary toothrow length *Octomys*
- 4'. Auditory bullae hypertrophied; length of the braincase nearly four times the maxillary toothrow length. *Tympanoctomys*
5. Upper and lower molariforms with folds (flexi/flexids) shallow or absent; the upper ones without a penetrating lingual fold (hypoflexus) *Octodontomys*
- 5'. Upper and lower molariforms with folds (flexi/flexids) well developed; the upper ones with a deep lingual fold (hypoflexus) *Octodon*

Genus *Aconaemys* Ameghino, 1891

Diego H. Verzi, M. Mónica Díaz, and Rubén M. Barquez

Aconaemys is a semisubterranean octodontid that inhabits open areas and forests, on both eastern and western slopes of the Andes (Cabrera 1961; Pine et al. 1979; Pearson 1984; M. H. Gallardo and Mondaca 2002), where it builds complex systems of burrows (Greer 1965; Pearson 1983; Nowak 1999). Species in this genus are presumed to be social (Lacey and Ebersperger 2007). Three species are currently included within the genus: *A. fuscus*, *A. porteri*, and *A. sagei*.

Aconaemys is a medium-sized octodontid (mass of males averages 118.9g; length of head and body length ranges from 135–190mm, tail length from 57–100mm, and ear length from 15–21mm; Greer 1965; Pearson 1984; M. H. Gallardo and Reise 1992; specimens in the MLP). As in the other subterranean octodontid *Spalacopus*, the body is short and robust, and the tail is short, representing up to 50% of the head and body length, and has no terminal tuft. The forefeet have long claws, except for the first digit, which is reduced. The pelage is dark drab, but varies regionally and locally related to soil variation. Specimens from more xeric areas have a paler coloration than those from humid regions, revealing a north-to-south gradient (M. H. Gallardo and Reise 1992). More northern specimens have a brown dorsum that changes gradually to the ventral region, while the specimens from the south have a more cinnamon venter. The coloration of the tail is highly variable. The dorsal surface of the feet is washed with white or cream (Pine et al. 1979).

Brain size is smaller than expected in comparison to those of caviomorph rodents (Vassallo and Echeverría 2009). The glans penis has two spines on each side within the intromittent sac, although some specimens of both *A. fuscus* and *A. sagei* exhibit individual variation, with patterns of 2–3 and/or 3–3 (Spotorno 1979; L. C. Contreras et al. 1993). The bacula of both *A. fuscus* and *A. sagei* have a slightly expanded base that gradually tapers to the tip; that of *A. fuscus* is longer (average length 7.6mm), wider (average width 1.7mm), and thus more massive (index of robustness=0.23) than that of *A. sagei* (comparable values are length 5.8mm, width 0.9, and robustness 0.14; L. C. Contreras et al. 1993).

The skull has a flattened interorbital region with divergent edges. As in *Spalacopus*, but unlike the remaining genera, the sphenopalatine foramen in the orbital region is small, vertical, and extends in front of the alveolar sheath of the M1. The zygomatic arches are parallel. As in *Spalacopus*, they are expanded toward outside, and the ventral zygomatic root (area for the origin of the masseter lateralis muscle) is wide and thin. The lateral flange of the canal for

the infraorbital nerve is joined to the alveolar sheath of the incisor. The auditory bullae are small and oval as in *Octodon*, unlike the much larger condition in desert-adapted octodontids. The epitympanic recess is only slightly developed, as in *Octodon* and *Spalacopus*. The incus and malleus are unfused, also as in *Spalacopus* and *Octodon degus* (Wood and Patterson 1959:292–293).

The mandible is strongly built and deep. The angle is expanded laterally, and the coronoid and condyloid processes are vertical as in *Spalacopus*. In rodents, this morphology is related to subterranean habits (Laville et al. 1989; Olivares et al. 2004). Vassallo and Mora (2007), in examining the scaling and ontogenetic growth of the skull and mandible of ctenomyid and octodontid genera, documented an intensification of the lateral expansion of the mandibular angle and masseteric crest in *Aconaemys* (as well as in *Spalacopus* and ctenomyids; E. P. Lessa, Vassallo et al. 2008), features indicative of the evolution of convergent morphologies in these subterranean or partially subterranean genera.

The upper incisors are broad, orthodont, and with orange enamel face. Molariform teeth are similar to those of *Octomys*, with their occlusal surfaces shaped as a figure-8, with the labial and lingual extremes of each lobe more acute than in *Octomys*. The two lobes are separated by lingual and labial folds (mesoflexus/flexid, and hypoflexus/flexid) that are transverse and meet in the middle; each fold is occupied by cement. The first lobe of the lower molariform teeth is triangular in shape in occlusal view. The last molars (M3/m3) are moderately reduced, and especially the lower is highly variable in morphology. Chewing is propalinal (Koenigswald et al. 1994; Olivares et al. 2004). Microstructure of the molar enamel has been studied in *A. fuscus*; two layers of radial enamel enclose a layer of multiseriate Hunter-Schreger bands (Koenigswald et al. 1994).

Ameghino (1891) reported on mandibular remains and isolated teeth of *Aconaemys* for the “Pampeano inferior” of Córdoba (Pleistocene). Unfortunately, we have been unable to locate these specimens in the MACN collections. Simonetti (1989) and Saavedra and Simonetti (2003) recorded *A. fuscus* in Holocene archaeological sites in Andean areas close to Santiago through coastal sectors of the Río Maule, up to 120 km north of its present distribution.

Molecular data suggest that *Aconaemys* is very closely related to *Spalacopus* (M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005). Most trees constructed from either DNA/DNA hybridization data (M. H. Gallardo and Kirsch 2001) or both mitochondrial and nuclear gene sequences (Honeycutt et al. 2003; Opazo 2005) support a sister relationship between *A. porteri* and *Spalacopus* with respect to the sister-pair of *A. fuscus* and *A. sagei*. This paraphyletic condition of *Aconaemys*, however, weak, and their correct phylogenetic relationships

remain to be resolved (see Upham and Patterson 2012). The estimated date of divergence between these two pairs of species is 2.77 ± 0.75 mya, in the late Pliocene; divergence between *A. fuscus* and *A. sagei* is estimated at 7 kya (Opazo 2005). Paleontological data suggest, alternatively, the early Pliocene (nearly 5.0 mya) as a minimum age for the divergence between the lineages of *Spalacopus* and *Aconaemys* (Reig 1986; Verzi et al. 2013).

The number of species within *Aconaemys* has been uncertain (Pearson 1984; L. C. Contreras et al. 1987; M. H. Gallardo and Reise 1992; M. H. Gallardo and Mondaca 2002). Several authors have recognized only two species, *A. fuscus* and *A. sagei*, with *A. porteri* included as a subspecies of *A. fuscus* (Osgood 1943b; Cabrera 1961; Mann 1978; Pine et al. 1979; Pearson 1984). M. H. Gallardo (1992), M. H. Gallardo and Reise (1992), and M. H. Gallardo and Mondaca (2002) described different karyotypes for each of the nominal taxa, and M. H. Gallardo and Reise (1992) documented concordant morphometric and color differences between them. These authors have also reassigned specimens from localities in Chile previously referred to *A. fuscus* to *A. sagei* based on karyotype, and thus expanded greatly the known range of this recently described species. Thus, the three species we recognize herein (*A. fuscus*, *A. porteri*, and *A. sagei*) are based the analyses and conclusions of M. H. Gallardo and his colleagues, an action also accepted by other authors, such as Pearson (1995) and Woods and Kilpatrick (2005). M. H. Gallardo and Mondaca (2002) map contiguously allopatric ranges from that of *A. fuscus* in the north, *A. sagei* in the middle, and *A. porteri* in the south. In general, *A. porteri* may be more easily distinguished from the other two species by the pelage coloration and cranial morphology (Pearson 1984; M. H. Gallardo and Reise 1992). We caution, however, that morphological variation among populations is extensive along with both clinal or mosaic distribution patterns (M. H. Gallardo and Mondaca 2002), and that there are large collecting gaps within the known ranges of each species such that their distributional limits remain poorly known.

SYNONYMS:

Schizodon Waterhouse, 1842:91; type species *Schizodon fuscus* Waterhouse, by original designation; preoccupied by *Schizodon* Agassiz, in Spix and Agassiz (1829; Characiformes: Anostomidae).

Aconaemys Ameghino, 1891:245; replacement name for *Schizodon* Waterhouse, with the same type species, *Schizodon fuscus* Waterhouse.

REMARKS: Tate (1935) reviewed the rather uncomplicated taxonomic history of the genus *Aconaemys*. Waterhouse (1842) erected the genus *Schizodon*, with *S. fuscus* as the type species. But Ameghino (1891) showed that *Schizodon* Waterhouse was preoccupied by *Schizodon*

Agassiz, and proposed *Aconaemys* as a replacement name. Reig (1986:408) regarded *Aconaemys* as inseparable at the generic level from the Pliocene genus *Pithanotomys* Ameghino, 1887, a position accepted by McKenna and Bell (1997). Although the sister-group relationship between *Pithanotomys* and *Aconaemys* suggested by Verzi et al. (2013) is consistent with this proposal, the generic status of *Aconaemys* remains to be tested; if Reig's statement is correct, *Pithanotomys* Ameghino would have priority over *Aconaemys* Ameghino.

KEY TO THE SPECIES OF ACONAEMYS:

1. Dorsal color rich brown, venter bright rufous; inferior jugal process of zygoma more posterior than paraorbital process; lobes of the molariform teeth lateromedially elongated; last molars (M3/m3) with deep flexi/flexids. *Aconaemys porteri*
- 1'. Dorsal color between Mummy Brown and Proust's Brown, venter tawny; inferior jugal process of zygoma more anterior or level with paraorbital process; lobes of the molariform teeth not lateromedially elongated; last molars (M3/m3) with reduced flexi/flexids 2
2. $2n = 56$, FN = 108 *Aconaemys fuscus*
- 2'. $2n = 54$, FN = 104 *Aconaemys sagei*

Aconaemys fuscus (Waterhouse, 1842)

Chilean Rock Rat

SYNONYMS:

Schizodon fuscus Waterhouse, 1842:91; type locality "from Chile," = "the Valle de las Cuevas, on the eastern side of the Andes, about six leagues from the Volcano of Peteroa" (Waterhouse 1848:265; Thomas 1917b:282; Pearson 1984:228); lectotype chosen by Thomas (1927b:553).

Aconaemys fuscus: Ameghino, 1891:245; first use of current name combination.

Aconaemys fuscus fuscus: Osgood, 1943b:112; name combination.

DESCRIPTION: Somewhat intermediate in size between small *A. sagei* and larger *A. porteri*. Two samples assignable species by karyotype (Siete Tazas and Chillán; M. H. Gallardo and Reise 1992: table 1) range in average head and body length from 156.1–156.9 mm, tail length 65.1–74.3 mm, hindfoot length 29.2–29.4 mm, and ear length 18.1–19.1 mm. Dorsal color paler brown than that of other species, with slightly tawny venter, presumably as adaptation to more xeric environments; tail uniformly bicolored (M. H. Gallardo and Reise 1992). Skull illustrated in Osgood (1943b:Fig. 14) shows interorbital region diverging gradually from anterior part of orbit, contrasting with pattern particularly of *A. sagei* (see Pearson 1984). Length of upper toothrow equivalent to that of *A. porteri* (9.6–9.9 mm) and much larger than that of *A. sagei* (8.6 mm

in type series; Pearson 1984). Breadth of incisors at their tip also intermediate between other two species with mean of 4.2–4.3 mm (versus 3.9 for *A. sagei*; Pearson 1984). Only 17% of specimens examined in Siete Tazas sample of *A. fuscus* had persistent fontanelle at frontoparietal juncture in fully grown specimens (M. H. Gallardo and Reise 1992).

DISTRIBUTION: *Aconaemys fuscus* is found in Andean areas of central-west Argentina and in central Chile from Curicó province to Ñuble province (M. H. Gallardo and Reise 1992; M. H. Gallardo and Mondaca 2002).

SELECTED LOCALITIES (Map 543): ARGENTINA: Mendoza, Valle de Las Cuevas (type locality of *Schizodon fuscus* Waterhouse). CHILE: Biobío, Las Quilas, Termas de Chillán (Pine et al. 1979); Maule, Lircay (M. H. Gallardo and Mondaca 2002), Radal (M. H. Gallardo and Mondaca 2002), Valle de Río Teño (M. H. Gallardo and Reise 1992).

SUBSPECIES: *Aconaemys fuscus* is currently considered monotypic.

NATURAL HISTORY: This species inhabits highland forests of *Araucaria araucana* (Araucariaceae) as well as flat and sandy areas covered with xerophytic vegetation and dunes (Muñoz-Pedreros 2000). It feeds on pinenuts (*A. araucana*) and roots as well as subterranean bulbs of Amaryllidaceae and Alstromeriaceae (Muñoz-Pedreros 2000). This species forms colonies up to seven individuals, with its burrows forming mounds 0.5 m high and as much as 2 m in diameter. They build nests within the tunnel system where vestiges of vegetable and insect (primarily beetles) are found (Muñoz-Pedreros 2000). Newly born young and pregnant females of *A. fuscus* have been recorded in the spring, between October and November (Nowak 1999; Muñoz-Pedreros 2000).

Aconaemys fuscus is host to a rich ectoparasitic fauna that includes several species of fleas (Lewis 1976; Beaucournu and Torres-Mura 1986; Hastriter 2001), ticks (Keirans et al. 1976), and lice (Moreno Salas et al. 2005).

Aconaemys fuscus has suffered significant reduction in population distribution at its northern limits within the Holocene (Saavedra and Simonetti 2003). The cause of this historical retraction is unknown, but it may result from the complex changes in vegetative cover due both to long-term climate shifts and more recent human-induced landscape disturbances. At the local level, extinction risk exists because of the habitat alteration for livestock grazing and the conversion of native vegetation communities to plantations of *Pinus radiata* (Muñoz-Pedreros 2000).

REMARKS: Earlier descriptions purported of this species (e.g., Osgood 1943b) are compromised because they were based on composite samples that included what are now regarded as multiple species. Pearson (1984) summarized the taxonomic history of *A. fuscus*. Waterhouse (1842) described *A. fuscus* based on two specimens col-

lected by Thomas Bridges but failed to designate a type or provide a more precise locality than “from Chile.” Waterhouse (1848:265) subsequently stated, based on communication with Bridges, that the specimens came from “the Valle de las Cuevas, on the eastern side of the Andes, about six leagues from the Volcano of Peteroa (S. lat. about 75° [clearly an error, should be 35°]), at an elevation from five to seven thousand feet.” Volcán Peteroa is in Mendoza Province, Argentina. Thomas (1927b) designated BM 55.12.24.195 as the lectotype, the second of two specimens from the same locality originally listed by Waterhouse. The publication year for Waterhouse’s *Schizodon fuscus* has been given as either 1841 (Thomas 1927b; Tate 1935; Osgood 1943b) or 1842 (Cabrera 1960; Woods and Kilpatrick 2005). Waterhouse presented his description to the Zoological Society of London on November 9, 1841, but the *Proceedings* for that year were not published until March 1842 (Sherborn 1930).

The karyotype of *A. fuscus* is $2n=56$, FN=108 (M. H. Gallardo and Reise 1992; M. H. Gallardo and Mondaca 2002), although Venegas (1976) reported FN=112 for animals with the same diploid number. Specimens from Tolhuaca and Nahuelbuta (Malleco Province, Chile) that were previously assigned to this species (Venegas 1976;

Map 543 Selected localities for *Aconaemys fuscus* (■), *Aconaemys sagei* (○), and *Aconaemys porteri* (●). Contour line = 2,000 m.

L. C. Contreras et al. 1987; M. H. Gallardo and Reise 1992) belong to *A. sagei* based on their karyotypes (M. H. Gallardo and Mondaca 2002).

Aconaemys porteri Thomas, 1917

Porter's Rock Rat

SYNONYMS:

Aconaemys porteri Thomas, 1917b:281; type locality "Osorno, S. Chile," slopes of Volcán Osorno, Los Lagos Region.

Aconaemys fuscus porteri: Osgood, 1943b:114; name combination.

DESCRIPTION: Large for *Aconaemys*, 40% larger in all body and cranial measurements than, and nonoverlapping with, *A. sagei* (Pearson 1984). Average head and body length 176.4 mm (148–192 mm), tail length 77.8 mm (68–85 mm), hindfoot length 34.7 mm (30–37 mm), ear length 21.0 mm (20–22 mm), and mass 131.5 g (105–160 g; N=10, specimens in MVZ, see also Pearson 1984:228–229). Mean measurements slightly smaller for sample from Chile reported by M. H. Gallardo and Reise (1992: table 1, Huerquehue sample). As with *A. fuscus*, dorsal hairs long (averaging 13.5 mm), with dark, rich brown dorsal color and bright rufous venter, and strikingly bicolored tail (Pearson 1984; M. H. Gallardo and Reise 1992). Molariform teeth with lobes more lateromedially elongated, and last molars (M3/m3) with deeper flexi/flexids; 33% of sample from Huerquehue reported by M. H. Gallardo and Reise (1992; presumptively as *A. porteri*), with conspicuous fontanelle at frontoparietal junction.

DISTRIBUTION: *Aconaemys porteri* extends from Volcán Villarica to Puyehue in Chile, and from both Parque Nacional Lanín and Parque Nacional Nahuel Huapi in Argentina (Pearson 1984, 1995; M. H. Gallardo and Reise 1992; M. H. Gallardo and Mondaca 2002).

SELECTED LOCALITIES (Map 543): ARGENTINA: Neuquén, Lago Curruhué, Parque Nacional Lanín (Verzi 2001), Ruca Malén, Parque Nacional Nahuel Huapi (Pearson 1984). CHILE: Araucanía, Quetropillán, Parque Nacional Villarrica (M. H. Gallardo and Mondaca 2002); Los Lagos, Volcán Osorno (type locality of *Aconaemys* M. H. Gallardo Thomas), Puyehue, Parque Nacional Puyehue (M. H. Gallardo and Mondaca 2002).

SUBSPECIES: *Aconaemys porteri* is monotypic.

NATURAL HISTORY: This species inhabits dense bamboo and southern beech forests (*Nothofagus dombeyi*; Pearson 1983, 1984; M. H. Gallardo and Reise 1992) where it lives in small groups in communal burrow systems, which are large and conspicuous. Some burrows contained small piles of thin bamboo stems and large aggregations of fecal pellets. In captivity, individuals displayed a high tolerance for conspecifics. They make a high-pitched

squeak that is audible only to humans with good hearing. Both diurnal and nocturnal activity has been recorded. They feed on leaves, sprouts, little branches of bamboo, and probably other type of vegetation. One female caught at the end of October had three embryos. The sexes are monomorphic (Pearson 1983).

REMARKS: Several authors considered *A. porteri* as a subspecies of *A. fuscus* (Osgood 1943b; Cabrera 1961; Mann 1978; Pine et al. 1979; Pearson 1983, 1984), but others have supported Thomas's (1917b) original proposal as a valid species (M. H. Gallardo and Reise 1992; Pearson 1995; M. H. Gallardo and Mondaca, 2002). This species is clearly distinguishable from the other two by its morphology, and molecular sequence analyses indicate that *A. porteri* is phylogenetically basal to the sister pair of *A. fuscus* and *A. sagei* (Honeycutt et al. 2003; Opazo 2005). *Aconaemys porteri* also has a unique karyotype of $2n=58$, $FN=112$, which represents an ancestral condition for the genus and one shared with other octodontids (M. H. Gallardo and Reise 1992; M. H. Gallardo and Mondaca 2002). Specimens of *Aconaemys* sp. reported by Verzi and Alcover (1990) from Parque Nacional Lanín should be assigned to *A. porteri* based on morphology.

Aconaemys sagei Pearson, 1984

Sage's Rock Rat

SYNONYM:

Aconaemys sagei Pearson, 1984:229; type locality "Pampa de Hui Hui, 4 km west and 2 km south of Cerro Quillén, 1050 m, Province of Neuquén, Argentina."

DESCRIPTION: Smallest species in genus *Aconaemys*; head and body length of type series averaging 150.5 mm (140–159 mm), tail length 61.3 mm (58–68 mm), hindfoot length 28.3 mm (26–29 mm), ear length 18.3 (17–19 mm), and mass 95.7 g (range: 83–110 g; N=6, MVZ). Specimens from Chilean populations somewhat larger in most dimensions (M. H. Gallardo and Reise 1992: table 1, Nahuelbuta and Tolhuaca samples). All dimensions of skin and skull at least 40% smaller relative to samples of *A. porteri* from nearby localities in Argentina (Pearson 1984). Pearson (1984) characterized species by slightly darker dorsal coloration ranging between mummy brown and Proust's brown and grading indistinctly to slightly more tawny venter. Tail lightly furred and slightly bicolored, but much thinner than series of *A. porteri* from nearby in Argentina. Also in comparison to *A. porteri*, dorsal fur flatter and shorter in length, averaging only 9 mm; claws distinctly smaller than those of *A. porteri*. Skull smaller in all dimensions, anterior border of mesopterygoid fossa is more pointed, and interorbital region flat with straight edges that diverge to side of cranium at their posterior edge rather than continually diverging from their anterior border. Upper inci-

sors especially narrow at tips, width averaging 3.9 mm, and maxillary toothrow short, averaging 8.6 mm in length. All individuals in type series (Pearson 1984) and 90% of those from Chilean localities assigned to *A. sagei* based on karyotype (M. H. Gallardo and Reise 1992; M. H. Gallardo and Mondaca 2002), with conspicuous frontoparietal fontanelle.

DISTRIBUTION: *Aconaemys sagei* is known from Lago Quillén and Lago Hui Hui in Neuquén Province in Argentina and Malleco and Cautín provinces in Chile (Pearson 1984, 1995; M. H. Gallardo and Mondaca 2002).

SELECTED LOCALITIES (Map 543): ARGENTINA: Neuquén, Pampa de Hui Hui (type locality of *Aconaemys sagei* Pearson). CHILE: Araucanía, 27 km WNW of Angol (Greer 1965), Parque Nacional Nahuelbuta (M. H. Gallardo and Mondaca 2002), Parque Nacional Tolhuaca (M. H. Gallardo and Mondaca 2002), Pedregosa (M. H. Gallardo and Mondaca 2002), Reigolil Pass (M. H. Gallardo and Mondaca 2002); Los Lagos, vicinity of Valdivia (MVZ 142176).

SUBSPECIES: *Aconaemys sagei* is monotypic.

NATURAL HISTORY: This is a diurnal herbivore that Pearson (1984) found to be especially abundant in ungrazed bunchgrass but that he also encountered in second growth *Nothofagus* forest with a bamboo understory. Stomachs of individuals contained only green vegetable matter, and the caecum was enormous, indicative of herbivory. Areas occupied by individuals had numerous open burrows with small piles of excavated earth in from; these were frequently trampled to form runways, a characteristic described by Osgood (1943b) and Greer (1965) for Chilean populations likely assignable to all three species. Pearson (1984) argued that *A. sagei* in particular, and *Aconaemys* in general, is moderately specialized for a subterranean lifestyle but suggested that runway construction indicated that individuals spent considerable time above ground, with behavioral characteristics more like those of Holarctic microtine rodents or ground squirrels than highly specialized subterranean genera such as the closely related *Ctenomys*.

REMARKS: This species is apparently the sister to *A. fuscus*, based on molecular phylogenetic analyses (M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005). The karyotype is $2n=54$, $FN=104$ (M. H. Gallardo and Mondaca 2002). M. H. Gallardo and Mondaca (2002) assigned specimens from localities in Malleco (Tolhuaca National Park, Río Colorado, Pedregoso, and Nahuelbuta National Park) and Cautín (Reigolil) provinces to *A. sagei* based on karyotype. Specimens from these localities had been previously allocated to *A. fuscus* (Osgood 1943b:113; Greer 1965:133; Pine et al. 1979:365). M. H. Gallardo and Mondaca (2002) also recorded specimens

from Huerquehue National Park as *A. sagei* in their Table 1 (p. 107) but included this locality within the mapped range of *A. porteri* in Fig. 1 (p. 106). M. H. Gallardo and Reise (1992) had earlier stated that specimens from this locality had both the karyotype of *A. porteri* ($2n=58$) and the morphological features (large size, long and dense fur) of this species. Because of this apparent confusion in the identity of these specimens, we do not include this locality in the list for either *A. porteri* or *A. sagei*.

Genus *Octodon* Bennett, 1832

M. Mónica Díaz, Rubén M. Barquez, and Diego H. Verzi

This is the most speciose octodontid genus, comprising the four species *O. bridgesii*, *O. degus*, *O. lunatus*, and *O. pacificus*. Three of these are endemic to Chile, occurring between approximately 28°S and 38°S latitude, and the fourth is distributed primarily in Chile but extends to Neuquén Province, Argentina. *Octodon* has also been recorded from Peru (Tschudi 1845; Yepes 1930; Cabrera and Yepes 1960), but this highly disjunct record is believed to correspond to an escaped pet (Woods and Boraker 1975). The genus spans an elevational range from sea level to 1,800 m. All species are primarily herbivorous (A. L. G. da Silva 2005), may be either diurnal or nocturnal in activity pattern, and are typically social (or presumably so; Lacey and Ebensperger 2007), with several individuals of both sexes occupying what may be an extensive, common burrow system.

Octodon is a medium-sized octodontid, with the total length ranging from 200–390 mm and tail length from 81–170 mm. The ears are large (23–30 mm), except in *O. pacificus* (20 mm); the hindfeet are adapted for jumping; the tail is as long as 70–80% of the head and body length, and it terminates in a small tuft developed to different degrees depending upon the species. Forefeet have four well-developed digits, with sharp claws on each; the fifth toe is poorly developed and bears a nail. Hindfeet have granular plantar pads. The dorsal coloration is grayish or drab with orange shades, and the venter is yellowish cream; tail color is similar to that of the dorsum, with the tuft black.

The glans penis is characterized by a variable number of medium sized spikes on each side of the intromittent sac (about five on each side, but more frequently a pattern of two on each side; Spotorno 1979; L. C. Contreras et al. 1993).

The skull has a slender rostrum, narrower than the interorbital region. The zygomatic arches are parallel sided. The jugal fossa for the origin of the masseter posterior muscle is nearly horizontal and continuous with the area for the origin of the anterior part of the masseter lateralis

muscle on the zygomatic root. The lateral flange separating the canal for the infraorbital nerve is large. In the orbital region, the dorsal portion of the alveolar sheath of M1 is hidden inside of an elongated fissure-like sphenopalatine foramen. The auditory bullae are piriform and medium to small sized. Morphological details of the middle ear are shared with subterranean octodontoids (e.g., *Ctenomys* and *Spalacopus*; Argyle and Mason 2008).

The incisors may be orthodont to slightly opisthodont in different species, but the enameled face is uniformly pale orange. Molariform cheek teeth have a peculiar and asymmetrical morphological pattern. The upper molariform teeth (dPM4 through M3) have the posterior lobe not extended labially, similar to those of Ctenomyidae, but with a moderate to deep lingual fold (hypoflexus) filled with cement. The three anterior lower molariform teeth (dpm4 through m2) have an oblique figure-8 occlusal design, with two oblique lobes separated by a labial (hypoflexid) and a lingual (mesoflexid) fold filled with cement. The last lower molariform (m3) almost lacks a labial fold (hypoflexid). Chewing is oblique (Verzi 2001; Olivares et al. 2004). Microstructure of the molar enamel in *O. bridgesii* is three-layered, as in *Aconaemys*, with two layers of radial enamel enclosing one of Hunter-Schreger bands (Koenigswald et al. 1994).

Octodon is the sister genus to a clade comprising *Aconaemys* and *Spalacopus* (M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005), with an estimated time of divergence of 3.69 ± 0.93 mya, in the Pliocene (Opazo 2005). Of the living species, both *O. bridgesii* and *O. lunatus* form a sister-species pair relative to *O. degus*, with the basal radiation of these lineages estimated at 2.57 ± 0.76 mya, also in the Pliocene (Opazo 2005). The phylogenetic position of the insular *O. pacificus* is not known. The genus has no fossil record, although specimens assignable to the extant species have been recorded from archaeological sites (Massoia 1979a; Massoia et al. 1980; Massoia and Silveira 1996; Pearson 1987, for Neuquén Province, Argentina; Saavedra and Simonetti 2003, for central Chile). Saavedra and Simonetti (2003) reported coexistence of the three continental *Octodon* species at the Holocene archaeological site of Quivolgo, Chile.

SYNONYMS:

Sciurus: G. I. Molina, 1782:303; part (description of *degus*); not *Sciurus* Linnaeus.

Myoxus: Bechstein, 1800:179, part (listing of *degus*); not *Myoxus* Zimmermann.

Octodon Bennett, 1832b:46; type species *Octodon Cumingii* Bennett (= *Sciurus degus* G. I. Molina), by monotypy.

Dendroleius Meyen, 1833: table xlv; type species *Dendroleius degus* G. I. Molina (= *Sciurus degus* G. I. Molina), by monotypy.

Dendrobis Meyen, 1833:601; incorrect subsequent spelling of *Dendroleius* Meyen.

REMARKS: The taxonomic history of the genus *Octodon* has been relatively uncomplicated (Tate 1935:378–379). G. I. Molina (1782) described *Sciurus degus* and Bennett (1832b) erected *Octodon* with the single species, *O. cumingii*. Meyen (1833) wrote of *Dendroleius*, with *Dendrobis (sic) degus* as its single species. Waterhouse (1839) detailed *Octodon*, stating that *cumingii* Bennett was the same as the “degu” of Molina, and thus fixed *degus* G. I. Molina as the senior synonym of *cumingii* Bennett. Bennett (1841) provided additional details of his *cumingii*, compared his genus *Octodon* to *Poepthagomys* F. Cuvier (= *Spalacopus*) and *Ctenomys*, and illustrated the skull, mandibles, and colored plate of a living animal. Bridges (1844) also equated *cumingii* Bennett with both *Sciurus degus* G. I. Molina and *Dendrobis degus* Meyen.

KEY TO THE SPECIES OF OCTODON:

1. Size small (total length maximally to 300 mm); tail terminates in well-developed tuft; anterior molariform teeth with shallow lingual fold (hypoflexus) filled with little cement *Octodon degus*
- 1'. Size medium to large (average total length >300 mm); tail terminates in short or inconspicuous tuft; anterior molariform teeth deep lingual fold nearly touching labial enamel and filled with abundant cement 2
2. Size medium (average total length 350 mm); tail terminated with moderate tuft; M3 without lingual fold. *Octodon lunatus*
- 2'. Size medium to large; tail with inconspicuous terminal tuft; M3 with moderate to deep hypoflexus 3
3. Size medium (total length <370 mm); dorsal color blackish brown; lower molariform teeth with moderately transverse lobes *Octodon bridgesii*
- 3'. Size large (total length >385 mm); dorsal color orange drab; lower molariform teeth with strongly transverse lobes. *Octodon pacificus*

Octodon bridgesii Waterhouse, 1845

Bridges's Degu

SYNONYMS:

Octodon Bridgesii Waterhouse, 1845:155; type locality “Chile,” restricted to “Río Teno, Colchagua,” O'Higgins, Chile (Thomas 1927b:553).

Octodon bridgesii Tate, 1935:378; incorrect subsequent spelling of *bridgesii* Waterhouse.

DESCRIPTION: Medium-sized species, smaller than *O. lunatus* but larger than *O. degus* (total length 250–370 mm, tail length 102–167 mm). Tail straight and shorter than head and body, with terminal tuft only slightly developed. Eyes larger, ears smaller, and pelage softer and more

grayish in color in comparison to *O. degus*. Ventral color uniformly ochraceous coffee, with white axillary and inguinal spots. Molariform teeth similar to those of *O. lunatus*, but M3 possesses moderate fold on lingual side (Huttrer 1994:Fig. 6).

DISTRIBUTION: In Chile, *Octodon bridgesii* occurs in the mountains of the coast of Cauquenes (Maule Region), Tomé (Biobío Region) and Nahuelbuta (Araucanía Region) west of the Central Valley, and through the Andes from Baños de Cauquenes (O'Higgins Region) to Baños del Río Blanco (Araucanía Region). In Argentina, it is found in the Parque Nacional Lanín in Neuquén Province (Verzi and Alcover 1990; Pearson 1995; Podestá et al. 2000). Elevational range is from sea level up to 1,200 m (Muñoz-Pedreros 2000).

SELECTED LOCALITIES (Map 544): ARGENTINA: Neuquén, Estancia La Querencia (Podestá et al. 2000), Refugio (MVZ 184958), 0.8 km E and 3.3 km N junction Rte 234 and Río Pichi Trafal (MVZ 199699). **CHILE:** Araucanía, 4 km W of Baños Río Blanco (Greer 1965), Nahuelbuta, Parque Nacional Nahuelbuta (Muñoz-Pedreros 2000); Biobío, Quirihue, Los Remates (Verzi 2001), Tomé (Muñoz-Pedreros 2000); Maule, Constitución (Muñoz-Pedreros et al. 1988), Parque Inglés-Siete Tazas (Reise and Venegas 1987); O'Higgins, Baños de Cauquenes (Osgood 1943b).

SUBSPECIES: *Octodon bridgesii* is monotypic.

NATURAL HISTORY: This species inhabits rocky areas with dense shrubs (primarily *Aristotelia* [Elaeocarpaceae], *Lithraea* [Anacardiaceae], *Peumus* [Monimiaceae], and *Ugni* [Myrtaceae], among others), prefers a low density of trees, bare ground, and dead branches (Muñoz-Pedreros 2000). It is a skilled climber and builds nests within vegetation; some nests have been found among bamboo (*Chusquea*; Redford and Eisenberg 1992; Muñoz-Pedreros 2000). Verzi and Alcover (1990) found individuals in burrows in Argentina, and Pearson (1995) collected specimens in both semiopen forests and jumbled lava blocks at the upper edge of the forest, also in Argentina.

Muñoz-Pedreros (2000) recorded reproductive activity in the months of April and December, with a litter size of two to three offspring. *Octodon bridgesii* is primarily nocturnal and rarely seen, but its presence can be detected because of the noisy alarm screams produced when it perceives the presence of strangers (Mann 1978). It feeds on herbaceous plants (A. L. G. da Silva 2005), of which the most important item may be the introduced *Pinus radiata* (Muñoz-Pedreros 2000). Major predators include the Barn Owl (*Tyto alba*), the Black-chested Eagle Buzzard (*Geranoaetus melanoleucus*), and the Culpeo (*Lycalopex culpeus*; Muñoz-Pedreros 2000; Podestá et al. 2000). Maintenance of water balance is more difficult in *O. bridgesii* than *O.*

degus, a fact likely restricting the distribution of the species to more mesic habitats (L. C. Contreras et al. 1987). Massoia (1979a) recovered skulls that may belong to this species (see Pearson 1995) from owl pellets at an estancia in west-central Neuquén Province, Argentina. Muñoz-Pedreros et al. (1988) also collected skulls of *O. bridgesii* from pellets of Barn Owls in Chile.

The local extinction of this species in the Andes and in the coastal range close to Santiago (Chile) in the Holocene has resulted mainly from human activities modifying natural habitats (Simonetti 1989; Simonetti and Saavedra 1998). *Octodon bridgesii* is a dense vegetation specialist, and the development of agriculture and intense woodcutting triggered the local extinction of the species (Simonetti and Saavedra 1998). This species is considered vulnerable in Chile as its distribution range has

Map 544 Selected localities for *Octodon bridgesii* (●) and *Octodon lunatus* (○). Contour line = 2,000 m.

diminished in recent years and currently only in three discrete populations are known. Habitat fragmentation is a major influence of local population persistence (Saavedra and Simmonetti 2005). However, *O. bridgesii* is also considered a plague species because it can severely damage plantations of *Pinus radiata* (Redford and Eisenberg 1992; Muñoz-Pedreros 2000; Mella et al. 2002). In Argentina, the species is also considered vulnerable (G. B. Diaz and Ojeda 2000).

REMARKS: Thomas (1927b:553) selected one of the two co-types collected by Bridges and used by Waterhouse (1845) in his description of *Octodon bridgesii*. This specimen (BM 55.12.24.196) is from the Río Teno, Colchagua province; he thus emended the type locality to this site. The Argentinean populations are provisionally regarded as *O. bridgesii*, but the affinities of these specimens are in need of careful review (Pearson 1995). The year of publication of Waterhouse's *Octodon bridgesii* is varyingly given as 1844 (Thomas 1927b; Tate 1935; Osgood 1943b; Cabrera 1960) or 1845 (Woods and Kilpatrick 2005). Waterhouse read his paper before the Zoological Society of London on October 8, 1844, but that issue of the *Proceedings* was not published until February 1845 (Sherborn 1924a; Duncan 1937).

The karyotype is $2n=58$, FN=116 (Venegas 1976).

Octodon degus (G. I. Molina, 1782)

Common Degu

SYNONYMS:

Sciurus Degus G. I. Molina, 1782:303; type locality "St. Jago," Santiago, Chile (see Osgood 1943b:108).

Myoxus degus: Bechstein, 1800:479; name combination.

Myoxus ? degus: Illiger, 1815:107; *nomen nudum*; in a list of South American species.

Myoxus getulinus Poeppig, in Froriep, 1829:278; type locality "Santiago, Chile."

Octodon Cumingii Bennett, 1832b:47; type locality "in the neighbourhood of Valparaiso, . . . in the high-road between that place and St. Jago," Chile.

Dendroleius degus: Meyen, 1833:601; name combination.

Dendrobis degus: Meyen, 1833:610; inadvertent subsequent spelling of *Dendroleius* Meyen.

Octodon kummingii Schinz, 1845:101; incorrect subsequent spelling of *cumingii* Bennett.

Octodon pallidus Wagner, 1845b:33; type locality "Chili."

O[ctodon]. cumingii Tschudi, 1845:171; incorrect subsequent spelling of *cumingii* Bennett.

Octodon cumingii var. *peruana* Tschudi, 1845:172; type locality "Quebrada von San Mateo, in der Nähe des dorfes San Juan de Matucana, etwa 9000' ü. m.," Lima, Peru" (probably based on escaped pet; Thomas, 1927c:557).

Octodon degus: Waterhouse, 1848:253; first use of current name combination.

[*Octodon Cumingii*] var. *albus* Fitzinger, 1867b:131; *nomen nudum* (see Osgood 1943b:108).

Octodon degus clivorum Thomas, 1927c:556; type locality "Puente Alto, E. of Santiago. Altitude 800m," Santiago, Chile.

DESCRIPTION: Smallest species in genus, with total length 200–307 mm, tail length 81–138 mm, and mass 200–300 g, Ears and eyes large, and tail dorsally curved and terminates in well-developed tuft; individuals can autotomize tail as mechanism to escape predators, but without regenerative capability. Pelage soft, yellowish brown dorsally, and yellowish cream ventrally; albino specimens occasionally observed. First three upper molariform teeth (dPM4–M2) have short fold (hypoflexus) on lingual margin but lack lingual fold on M3 (Hutterer 1994:Fig. 6; Verzi 2001).

DISTRIBUTION: *Octodon degus* is endemic to Chile (Mella et al. 2002), where it occurs between 28°S and 35°S latitude and from sea level to 1,800 m (Woods and Boraker 1975; Muñoz-Pedreros 2000). As noted by Woods and Boraker (1975), Waterhouse's (1848) report of this species from Peru is in error (see also Thomas 1927c).

SELECTED LOCALITIES (Map 545): CHILE: Atacama, Vallenar (Osgood 1943b), 40 km E of Vallenar (TTU 28636); Coquimbo, 10.5 km E of Illapel (USNM 541813), Parque Nacional Fray Jorge (Verzi 2001), 10 km N of Pte. Los Molles (FMNH 119658), Romero (Osgood 1943b); Maule, Curicó (Woods and Boraker 1975; Muñoz-Pedreros 2000); O'Higgins, Rapel (Muñoz-Pedreros 2000); Santiago, Las Condes (USNM 391827); Santiago, Puente Alto (type locality of *Octodon degus clivorum* Thomas), Rinconada de Maipú (Osgood 1943); Valparaíso, La Calera (Osgood 1943b).

SUBSPECIES: *Octodon degus* is currently viewed as monotypic (Osgood 1943b; Cabrera 1961; Woods and Boraker 1975; Woods and Kilpatrick 2005), although Ellerman (1940) listed five subspecies, while Thomas (1927c) and Yepes (1930) distinguished lowland (*O. d. degus*) and highland (*O. d. clivorum*) races.

NATURAL HISTORY: *Octodon degus* is one of the most well-known small mammals of central Chile (see L. C. Contreras et al. 1987 and literature therein). It has also been studied extensively in the laboratory, including determinants of circadian rhythm (Ocampo-Garcés 2005; Vivanco et al. 2007), reproductive features such as placentalation (Bosco et al. 2007), behavior, including vocalizations (Long 2007), communal versus solitary breeding (Ebensperger et al. 2007), and mother-offspring relationships (Jesseau et al. 2008). In captivity, degus reproduce and live between five and seven years and show hallmarks of neurodegenerative diseases (including Alzheimer's disease), diabetes, and cancer (Ardiles et al. 2012, 2013; see

also husbandry and breeding guidelines in Palacios and Lee 2013).

This species inhabits semiarid environments on the western slopes of the Andes, in open areas near rocks, stone-walls, and groves, associated with steppes dominated by *Acacia caven* (Mann 1978; L. C. Contreras et al. 1987; Kenagy et al. 2002b). It digs tunnels among rocks and brushes; dens have several tunnels and openings where a few individuals or even large groups may live (Mann 1978; Muñoz-Pedreros 2000). In general, the social group includes a male, two or three females with young, and four or six juvenile females (Redford and Eisenberg 1992; Muñoz-Pedreros 2000); these groups occupy communal burrow systems (Ebensperger and Bozinovic 2000a; Ebensperger, Chech et al. 2011) and engage in collective detection of predators (Ebensperger, Hurdado, and Ramos-Jiliberto 2006). These communally nesting groups are composed of female kin (Ebensperger et al. 2004) and a breeding female does not discriminate between her own offspring and those of other females during lactation (Ebensperger, Hurtado, and Valdivia 2006). Per capita fitness decreases as a function of group size (Ebensperger, Ramírez-Estrada et al. 2011). Degus spend significantly less time being vigilant as group size increases (“group size effect”; Vásquez 1997). Dust bathing behavior plays an important role in social communication among unfamiliar, same-sex conspecifics (Ebensperger 2000; Ebensperger and Ciozzi 2002). Ebensperger and Bozinovic (2000b) examined the energetic costs of burrowing. Burrowing costs and predation risk are interpreted as drivers of total group size and group composition (Ebensperger et al. 2012), while social competition explains juvenile dispersal (Quirici et al. 2011). Also, ecologically based explanations of sociality in degus are controversial, but it could represent a case of phylogenetic inertia given that group living is common within hystricognath families basal to Octodontidae (Ebensperger et al. 2012).

In a study of fluctuating asymmetry, Saavedra (2003) demonstrated that males of *O. degus* preferred asymmetric females during nonreproductive periods but symmetric females during the reproductive season. Both *O. degus* and *O. bridgesii* showed preferences based on visual cues, despite their contrasting diurnal and nocturnal lifestyles (Saavedra 2003).

The four to six offspring are born mainly in the spring and summer (September–October and December–January); they are precocial at birth with open eyes, fur, and the capability to eat vegetation within a few days (Woods and Boraker 1975; Muñoz-Pedreros 2000).

This species is primarily diurnal although its activity is greatest at twilight, with activity peaks both in the morning and in the last hours of the night (Mann 1978; Redford and Eisenberg 1992; Muñoz-Pedreros 2000; Bacigalupe

et al. 2003; Kenagy et al. 2004). In laboratory conditions, an individual’s temporal feeding strategy seems mainly arrhythmic, whereas its wheel-running pattern is driven by a strongly circadian bimodal rhythm (García-Allegue et al. 2006). In the wild, individuals feed outside and can be observed climbing in brushes while searching for seeds and sheaths (Woods and Boraker 1975; Mann 1978; Muñoz-Pedreros 2000). The species is thus primarily herbivorous-folivorous, feeding on grasses, seeds, fruits, roots, and bark of a variety of plants, such as *Stipa plumosa*, *Cestrum palqui*, *Mimosa cavenia*, *Erodium cicutarium*, *Che-nopodium petiolare*, *Proustia cuneifolia*, *Atriplex repunda*, and *Acacia caven* (Redford and Eisenberg 1992; Muñoz-Pedreros 2000). Mass-independent basal metabolic rate is strongly influenced by habitat productivity, with populations from more productive habitats having “faster” metabolic rates (Bozinovic et al. 2009). In the field, degus are constrained to specific foraging areas, mainly by their limited thermal tolerance and by environmental food quality, with food availability strongly influencing home range sizes (Quirici et al. 2010). Individuals thus balance their diet selection by maximizing nutrients relative to digestible energy intake, but food selection is compromised by seasonal and spatial changes in food quality and environmental temperatures, coupled with feeding time and digestive and thermoregulatory constraints (Torres-Contreras and Bozinovic 1997). Naya et al. (2008) examined the complex interplay among energy acquisition, storage, and expenditure during lactation. Veloso and Bozinovic (2000) examined the effect of food quality on ingestion, digestion, and metabolic rate during pregnancy and lactation. Sabat and Veloso (2003) analyzed ontogenetic development of intestinal disaccharides. Vega-Zuniga et al. (2013) compared vision characteristics between two species (*O. degus* and *O. lunatus*), relating the degree of frontal binocular overlap to differences in diel activity pattern.

The limited capacity for thermoregulation also likely prevents individuals from leaving their tunnels in unfavorable periods of the year (Bozinovic and Vásquez 1999; Kenagy et al. 2002a). Thermal limitation is also a factor determining space use, with individuals restricted above ground to covered as opposed to open areas (Lagos et al. 1995). However, animals do not drink and lose little water through respiration (Muñoz-Pedreros 2000). They also have a high capacity of renal concentration, which implies a strong physiological specialization to relatively xeric conditions (Woods and Boraker 1975; Mann 1978; Muñoz-Pedreros 2000).

Primary predators include mammals such as foxes and the grison (*Pseudalopex*, *Galictis*), and both diurnal and nocturnal birds of prey (*Buteo*, *Parabuteo*, *Athene*, and *Tyto*; Woods and Boraker 1975; Jaksic 1986; Meserve et al. 1993; Torres-Contreras et al. 1994).

Among ectoparasites, fleas of the genus *Ectinorus* have been recorded (also present in other rodents) as well as the lice *Abrocomphaga hellenthalii*, *Ferrisella chilensis*, and *F. disgrega* (the latter also present in *Octodontomys gliroides*; Torres-Mura and Contreras 1998; Muñoz-Pedrerros 2000; D. Castro and Verzi 2002). *Octodon degus* is also parasitized by a number of endoparasites, including a pinworm (*Octodontoxys gigantea*), a whipworm (*Trichuris bradleyi*), the cestodes (*Aprostotandrya octodonensis* and *Echinococcus granulosus*), and several nematodes (Woods and Boraker 1975; Muñoz-Pedrerros 2000), and serves as a host for the protozoan *Trypanosoma cruzi* (Rozas et al. 2005), which causes Chagas disease.

Muñoz-Pedrerros (2000) suggested that this species is of conservation concern, but Mella et al. (2002) regarded it to be excessively abundant. *Octodon degus* was used as

food by the Araucanian Indians as well as by European colonists. Currently, it may infrequently cause damage in vineyards as a result of local population irruption (Mann 1978). Unlike *O. bridgesii* and *O. lunatus*, this species prefers habitats with limited vegetation cover, typical of human-modified habitats. Based on this, *O. degus* may have been favored by human-induced changes in habitat cover (Mann 1978; Simonetti 1989). However, these same human-modified areas have been invaded by European rabbits, which have resulted in a reduced food supply and probably have had a negative impact on native species such as *O. degus* (Simonetti 1983).

REMARKS: Bridges (1844) equated *Octodon cumingii* Bennett with *Sciurus degus* G. I. Molina and *Dendrobius degus* Meyen. The highly disjunct Peruvian record of *O. degus*, the basis for Tschudi's *peruana* and which he stated was from San Juan de Matucana, east of Lima, is likely an error. Thomas (1927c:556–557) examined the holotype of Tschudi's *peruana* and stated “the specimen proves in every detail of size and colour to be so exactly like ordinary Valparaiso specimens of *O. degus* that I must frankly express my disbelief that it ever lived in Peru, unless as a pet.” Furthermore, Thomas noted that the presumptive type locality is quite close to areas where both Perry O. Simons and Russell Hendee made substantial collections, yet failed to secure any belonging to *Octodon*. No member of the family Octodontidae is known from Peru. The karyotype of *O. degus* is $2n=58$, FN=116 (R. Fernández 1968).

Octodon lunatus Osgood, 1943

Coastal Degu

SYNONYM:

Octodon lunatus Osgood, 1943b:110; type locality “Olmue, Province of Valparaiso, Chile.”

DESCRIPTION: Similar in size to *O. bridgesii*, with total length 328–382 mm, tail length 152–161 mm, and mass averaging 233 g. Tail straight as in *O. bridgesii*. Pelage denser than in *O. degus* but similar in coloration to *O. bridgesii*, only slightly more chestnut, and tail ventrally blackish for least half of its length. Also like *O. bridgesii*, *O. lunatus* with white axillary and inguinal spots. Skull similar to *O. bridgesii* with interorbital region slightly wider (Osgood 1943b). Molariform teeth with deep folds, as in *O. bridgesii*, but last upper molar (M3) lacks fold on lingual side (Hutterer 1994:Fig. 6).

DISTRIBUTION: *Octodon lunatus* is restricted to the coastal hills on the west side of the central valley of Chile (Osgood 1943b; L. C. Contreras et al. 1987; Redford and Eisenberg 1992).

SELECTED LOCALITIES (see Fig. 544): CHILE: Coquimbo, Parque Nacional Fray Jorge (Verzi 2001); Santi-

Map 545 Selected localities for *Octodon degus* (●) and *Octodon pacificus* (○). Contour line = 2,000 m.

ago, Fundo Santa Laura (MVZ 150088); Valparaíso, Los Molles (MVZ 150087), Olmué (type locality of *Octodon lunatus* Osgood), Papudo (Osgood 1943b).

SUBSPECIES: *Octodon lunatus* is a monotypic species.

NATURAL HISTORY: This species lives along the coast, in rocky areas with dense heaths and groves, from sea level to 1,200 m. Unlike *O. degus*, this species has been little studied in its natural environment. Apparently individuals have a variable activity rhythm, with authors reporting diurnal, crepuscular, or nocturnal activity patterns (Muñoz-Pedreros 2000). Cortés, Rosenmann, and Bozinovic (2000a) reported low respiratory water loss, indicating an excellent ability to conserve water. Lice are a known ectoparasite of *O. lunatus*, including one species shared with *O. degus* (D. Castro and Cicchino 2002). Only the Burrowing (*Athene cunicularia*) and Barn Owls (*Tyto alba*) are known as predators (Muñoz-Pedreros 2000). Like *O. bridgesii*, this species prefers areas with dense vegetation and has suffered a reduction in its range during the Holocene, based on the zooarchaeological record, likely due to human-induced habitat modifications (Saavedra and Simonetti 2003). Currently, this species is considered vulnerable (Muñoz-Pedreros 2000; Mella et al. 2002). Vásquez and Simonetti (1999) assessed life history traits in relation to vulnerability to habitat change, concluding that *O. lunatus* was among a group of birds and mammals that exhibited a high sensitivity index to change, primarily due to the combination of low reproductive effort and narrow habitat requirements.

REMARKS: Some authors have suggested that *O. lunatus* is conspecific with, and thus a synonym of, *O. bridgesii*, because the two are very similar and hard to distinguish (Tamayo and Frassinetti 1980; L. C. Contreras et al. 1987). However, *O. lunatus* has a distinct karyotype of $2n=78$, FN=128 (Spotorno et al. 1995).

Octodon pacificus Hutterer, 1994

Mocha Degu

SYNONYM:

Octodon pacificus Hutterer, 1994:28; type locality "Isla Mocha (38°22' S, 73°55' W), Arauca Province," Biobío, Chile.

DESCRIPTION: Larger and heavier than other species in the genus (two available specimens have total length of 389 and 390 mm, tail length of 165 and 170 mm, and a mass of 290 g, respectively). Pelage soft and long; ears relatively short; and tail long, 74–77% of head and body length. Tail ends in inconspicuous tuft. Dorsal coloration orange drab, venter paler. Skull long, especially diastema. Zygomatic arch diagnostic, with insertion higher than in other species, leaving considerable space between inferior jugal process of zygoma and upper toothrow. Mandible

larger and heavier than in other species. Incisors opisthodont with deep notch at tips. Both upper and lower molariform teeth wider than in other species, with deeper folds that filled with abundant cement, especially third molars (Hutterer 1994:Fig. 6).

DISTRIBUTION: *Octodon pacificus* is known only from the type locality.

SELECTED LOCALITIES (Map 545): Chile, Biobío, Isla Mocha (type locality of *Octodon pacificus* Hutterer).

SUBSPECIES: *Octodon pacificus* is monotypic.

NATURAL HISTORY: The only known locality of *Octodon pacificus*, Isla Mocha, is near the edge of the Valdivian rainforest zone (Hutterer 1994). There is little information available for this species. The only known specimens were collected in 1959 during an expedition made by Dr. Francisco Behn, who was primarily interested in birds. The mammals collected were held in a private collection for more than 30 years (Hutterer 1994). Reproductive activity apparently begins in September, and offspring are born in December (Hutterer 1994). Saavedra et al. (2003) recorded this species from the Holocene zooarchaeological record of Isla Mocha.

REMARKS: The karyotype is unknown. Hutterer (1994:39), in his commentary about insular species, including *O. pacificus*, stated that "what seems certain is that the natural range of the species covers only a few square kilometers and for this reason alone it must be regarded as vulnerable." Muñoz-Pedreros (2000) also considered this species as vulnerable, but Mella et al. (2002) regarded the conservation status as undefined. E. P. Lessa, Ojeda, and Bidau (2008a) considered *O. pacificus* as Critically Endangered, with deforestation the major threat. The lowlands of Isla Mocha are now dominated by grasslands, and the original Valdivian forest is restricted to the highest elevations on the island.

Genus *Octodontomys* Palmer, 1903

Diego H. Verzi, M. Mónica Díaz, and Rubén M. Barquez

This genus includes only the single species *Octodontomys gliroides*. It is a mainly a fossorial octodontid that inhabits the Andean and sub-Andean zones of southwestern Bolivia, northern Chile, and northwestern Argentina (Cabrera 1961; Pine et al. 1979; L. C. Contreras et al. 1987; S. Anderson 1997).

Octodontomys is a medium to large-sized octodontid, with a body mass ranging from 100–200 g, total length from 200–380 mm, and tail length from 100–190 mm. The pelage is relatively long and silky; dorsal coloration is grayish drab; and the venter has white hairs with gray bases, except on the chin and throat where they are pure white,

and contrasts strongly with the dorsum. The ears are large, finely covered by short grayish hairs, with a white tuft on their anterior end (Ipinza et al. 1971). The tail is nearly 80% of the head and body length; it is bicolored, with an elongated, brown or ochraceous brush extending from the tip. Plantar surfaces have fine granulations (L. C. Contreras et al. 1987). Juveniles are darker with grayer venters, and have an essentially unicolored tail that terminates in a short and black or dark drab brush.

The glans penis of *Octodontomys* has two long spines on each side of the intromittent sac, although some specimens show a two–three pattern (Spotorno 1979; L. C. Contreras et al. 1993). These spines are the longest among octodontids (average length 5.6 mm; L. C. Contreras et al. 1993). As in other genera of the family, the baculum gradually tapers from its base to the tip.

The skull is roughly similar to that of *Octomys*. The rostrum is relatively long and narrow. Incisive foramina are large and with their posteriormost ends behind the premaxillary-maxillary suture. Unlike other genera, the intra-alveolar portion of the first molariform tooth (dP4) is slightly inclined forwardly, medial to the incisor. Consequently, an anterior extension of the maxillaries into the posterior margins of the incisive foramina, where the dP4 are housed, is scarcely developed to nearly absent. The lateral flange of the canal for the infraorbital nerve is well developed and has the dorsal end free, not joined to the maxillary. The zygomatic arches are little expanded, and with a low and slightly deep jugal fossa for the masseter posterior muscle. The paroccipital processes are completely joined to the bullae, with each root is medially oriented by the development of the mastoid bullae. As is characteristic for the other desert-adapted octodontids, the bullae are large. The mandible is slender, low, and moderately hystricognathous.

The incisors are orthodont, narrow, and short. Upper molariform teeth are roughly similar to those of primitive, extinct members of the Ctenomyidae. They lack folds (flexi) and have the posterior lobe not extended labially. Lower molariform teeth have a nearly figure-8 shaped occlusal morphology, with slightly oblique and rounded lobes and shallow traces of folds (mesoflexids and hypoflexids). The last upper and lower molars (M3/m3) are reduced in size. Chewing is oblique (Olivares et al. 2004). T. Martin (1992) and Vieytes et al. (2007) described incisor enamel microstructure.

Historically *Octodontomys* was a genus with uncertain affinities (W. George and Weir 1972; Rossi et al. 1990; M. H. Gallardo 1992, 1997; Verzi 2001). Although most molecular data (M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005; Rowe et al. 2010) support a sister relationship to a clade comprising (*Octodon* [*Acon-*

aemys + *Spalacopus*]), Upham and Patterson (2012) place it basal to the desert-adapted *Octomys* + *Tympanoctomys*. Although no fossil record is known, *Octodontomys* exhibits similarities with some species from the Mio-Pliocene of Argentina (Verzi and Iglesias 1999; Verzi et al. 1999; Verzi et al. 2013), suggesting that it may belong to an early octodontid offshoot. Opazo (2005) estimated the divergence of *Octodontomys* from its sister clade to be 6.07 ± 1.34 mya, near the end of the Miocene, a value in agreement with M. H. Gallardo and Kirsch's (2001) estimate based on DNA hybridization but older than the date estimated by Honeycutt et al. (2003).

SYNONYMS:

Octodon: P. Gervais and d'Orbigny, 1844:22; part (description of *gliroides*); not *Octodon* Bennett.

Neoctodon Thomas, 1902g:114; type species *Neoctodon simonsi* Thomas (= *Octodon gliroides* P. Gervais and d'Orbigny) by original designation; preoccupied by *Neoctodon* Bedel, 1892 (Insecta: Coleoptera).

Octodontomys Palmer, 1903:873; replacement name for *Neoctodon* Thomas.

REMARKS: Originally regarded as a species of *Octodon*, this monotypic taxon was raised to generic status by Thomas (1902g) under the name *Neoctodon*. Palmer (1903), however, pointed out that *Neoctodon* Thomas was preoccupied by *Neoctodon* Bedel, 1892, a genus of beetle, and provided *Octodontomys* as a replacement name. The taxonomy of this species has been stable since Palmer's action.

Octodontomys gliroides (P. Gervais and d'Orbigny, 1844)

Mountain Degu, Chozchori

SYNONYMS:

Octodon gliroides P. Gervais and d'Orbigny, 1844:22; type locality "des Andes boliviennes, à Lapaz"; La Paz, Bolivia.

Neoctodon simonsi Thomas, 1902g:115; type locality "Mountainous region south and south-east of the Titicaca-Poopo basin. Potosí, 4400 metres," Bolivia.

Octodontomys gliroides: Thomas, 1913a:143; first use of current name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Octodontomys gliroides* has a disjunct distribution in the Andean and sub-Andean areas of southwestern Bolivia (from La Paz to Potosí departments), northern Chile (Tarapacá Province), and northwestern Argentina (from Jujuy to La Rioja provinces; Cabrera 1961; Mann 1978; Pine et al. 1979; L. C. Contreras et al. 1987). This species has a wide elevational range, from 200–300 m at Saladillo in Jujuy, Argentina to 4,400 m in Potosí, Bolivia.

SELECTED LOCALITIES (Map 546): ARGENTINA: Jujuy, Saladillo (G. B. Diaz and Ojeda 1999), 8.2 km S of Sey (OMNH 34965), Sierra de Zenta (M. M. Díaz and Barquez 2007); La Rioja, Villa Unión (Yepes 1936); Salta, 16 km S and 1.8 km W of Barrancas (OMNH 34964), 17 km NW of Cachi (ARG 6396); BOLIVIA: La Paz, Andes de Bolivia, vicinity of La Paz (type locality of *Octodon gliroides* P. Gervais and d'Orbigny); Oruro, Oruro (S. Anderson 1997); Potosí, Lipez (S. Anderson 1997), Potosí, Livichuco (S. Anderson 1997), Potosí (type locality of *Neoctodon simonsi* Thomas), Yuruma (S. Anderson 1997); Tarija, 2 km SE of Cieneguillas (FMNH 162891). CHILE: Arica y Parinacota, Cuesta Zapahuira (USNM 541823); Tarapacá, Miñita (Mann 1978).

SUBSPECIES: *Octodontomys gliroides* is monotypic.

NATURAL HISTORY: This species occupies dry Andean and sub-Andean zones (L. C. Contreras et al. 1987) and is the only octodontid present in the high areas of the Puna (Reig 1986). It inhabits rocky areas with vegetation dominated by columniform cacti (*Browningia*, *Cereus*, *Polycererus*, and *Opuntia*), shrubs, and herbaceous vegetation (Mann 1978). It possesses a tail with well-developed terminal brush, which is capable of autotomy similar to that of *Octodon degus*. When climbing, the tail is used for substrate support (Muñoz-Pedreros 2000). Although *O. gliroides* has no obvious morphological adaptations of the skull or limbs for a fossorial lifestyle (E. P. Lessa, Vassallo et al. 2008), it digs short burrows at the base of cacti and acacias and inhabits rocky caves, including Indian tombs (Mann 1978; L. C. Contreras et al. 1987; Nowak 1997). In northwestern Argentina, it can be seen during the day and in the first hours at night (M. M. Díaz 1999). Individuals feed on acacia sheaths in winter and cactus fruits during summer, and eat leaves and bark of resinous shrubs (Mann 1978). Similar to *Octodon*, it can use cactus tissues to satisfy water requirements (Mann 1978). Eisenberg (1974) identified the menace vocalizations of *Octodontomys* as a gurgle or twitter similar to those produced by some birds. *Octodontomys gliroides* and *Octodon degus* emit not only low and middle frequency calls, but also several high frequency or ultrasonic vocalizations (Eisenberg 1974), which is in contrast with the predominant low-frequency range of vocalizations of subterranean rodents (Schleich et al. 2007). Arends and McNab (2001) reported physiological parameters of basal metabolic rate, conductance, and body temperature. G. B. Diaz and Ojeda (1999) suggested poor physiological adaptation to desert conditions and thus survival on a water-rich diet of cacti because the kidney has a small renal papilla, low renal indices, and low urine concentration.

Pine et al. (1979) reported a lactating female and a juvenile in November, in the spring in Chile. In Argentina,

in Jujuy Province, M. M. Díaz (1999) recorded juveniles of different ages in the same month, and S. Anderson (1997) found both pregnant females and juveniles in January and May. Weir (1974b) reported a gestation period of 100–109 days, with a litter of one to three offspring. The young are precocial, born completely furred and with open eyes.

Individuals of *O. gliroides* are hosts for *Trypanosoma cruzi*, the hemoflagellate responsible for Chagas disease, and the species may have been involved with the domestic cycle of transmission with humans from prehistoric times (Schweigmann et al. 1992). Other ectoparasites include fleas of the genus *Ectinorus* (Hastriter and Sage 2009), and lice of the genera *Ferrisella* (D. Castro, Gonzalez, and Cicchino 1998; D. Castro and Verzi 2002), *Amblycera*, and *Anoplura* (Moreno Salas et al. 2005).

The species is known from archaeological sites in Jujuy Province, Argentina, from 2,000 years BP (Teta and Ortiz 2002). It has no apparent conservation problems (G. B. Diaz and Ojeda 2000; Muñoz-Pedreros 2000), and the IUCN (2011) considers *O. gliroides* a species of Least Concern.

Map 546 Selected localities for *Octodontomys gliroides* (●). Contour line = 2,000 m.

REMARKS: D'Orbigny and Gervais (1847:plate 16) illustrated the living animal and line drawings of the skull and teeth, presumably of the type specimen. The chromosome complement is $2n=38$, $FN=64$ (W. George and Weir 1972; M. H. Gallardo 1992; L. C. Contreras et al. 1994). This diploid number is interpreted to result from a reduction from the family modal $2n=56-58$ (M. H. Gallardo 1992, 1997, 2007).

Genus *Octomys* Thomas, 1920

Diego H. Verzi, M. Mónica Díaz, and Rubén M. Barquez

This genus includes the single species *Octomys mimax*, which is primarily a surface-dwelling, desert-adapted octodontid limited to the sub-Andean areas of the Monte biome in northwestern Argentina (Cabrera 1961; L. C. Contreras et al. 1987; R. A. Ojeda and Tabeni 2009).

Octomys is a medium-sized octodontid, with recorded mean body mass 95.8–31 g, mean total length 279.3–314.3 mm, and mean tail length 145.4–162.5 mm (Redford and Eisenberg 1992; Sobrero et al. 2010). The dorsal coloration is pale tan, with the venter and feet whitish. The tail is longer than the head and body, bicolored, well haired, and has a well-developed tuft at the tip. The ears are large, appearing hairless but covered with fine white hairs and elongated guard hairs in front of the meatus (Thomas 1920d; Redford and Eisenberg 1992; Sobrero et al. 2010). Berman (2003) described the superficial facial musculature and oral cavity morphology. The dorsal oral cavity of *Octomys* has dense concentrations of vibrissae, caudal to the incisors on either side of a palatal median cleft, similar to those in *Tympanoctomys*. These vibrissae have follicles less robust than those of *Tympanoctomys*, operated by the intermaxillaris muscle as in the latter genus (Berman 2003).

The glans penis has one spine on each side of the intromittent sac. This pattern is regarded as ancestral for the family (Spotorno 1979; L. C. Contreras, Torres-Mura et al. 1993).

The skull has a slender rostrum and weak zygomatic arches, similar to that of *Octodontomys*. The supraorbital borders of the frontals are straight and divergent; the distance between the frontal bone and the zygomatic arch is shorter than in *Octodon*, *Aconaemys*, *Spalacopus*, and *Octodontomys*, but similar to that in *Tympanoctomys*. The lateral flange of the canal for the infraorbital nerve is well developed, and its dorsal border is free, not attached to the maxillary. As in *Tympanoctomys*, only the squamosal bone forms the postorbital process of the zygomatic arch, as is visible in lateral view. The roots of the paroccipital processes in the occiput are medially oriented by the devel-

opment of the mastoid bullae, similar to the condition in *Octodontomys*. The bullae are large but smaller than those of *Tympanoctomys* (Ojeda et al. 1999); the dorsal wall of the epitympanic recess forms a large bony “island” on the roof of the braincase, also as in *Tympanoctomys*.

Upper incisors are orthodont to opisthodont, short, and narrow. Molariform teeth have a figure-8 occlusal design, with two transverse lobes separated by folds (mesoflexus/flexid and hypoflexus/flexid) on both the labial and lingual faces. There is little cement in the folds. The last upper and lower molars (M3/m3) are reduced in size. Chewing is proplinal (Verzi 2001; Olivares et al. 2004).

The general external aspect of *Octomys* is similar to that of *Octodontomys* and *Tympanoctomys*, but with a shorter tail and a less developed terminal tuft. The skull is long and slender, and with large bullae, although these are less developed than in *Tympanoctomys*.

Thomas (1920d:118) pointed out that his new genus *Octomys* was related to *Spalacopus* and *Aconaemys*. However, cladistic analyses of morphological traits (Verzi 2001) as well as all molecular data (Köhler et al. 2000; M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005; Upham and Patterson 2012) strongly support a sister relationship between *Octomys* and *Tympanoctomys*. The time of divergence between these generic lineages has been estimated at 6.5 mya (based on DNA hybridization data; M. H. Gallardo and Kirsch 2001), 4.28 ± 1.08 mya (DNA sequences; Opazo 2005), or 3.57 mya (95% confidence interval 2.77–4.37 mya; DNA sequences; M. H. Gallardo et al. 2013). The genus is monotypic and has no fossil record. Two hypothetical *Octomys* lineages and the living species *Octomys mimax* have been proposed as ancestors of tetraploid *Tympanoctomys aureus* and *Tympanoctomys barrerae*, the implied evolutionary processes involving production of unreduced gametes and introgressive hybridization (M. H. Gallardo et al. 2004, 2007).

SYNONYM:

Octomys Thomas, 1920d:117; type species *Octomys mimax* Thomas, by original designation.

Octomys mimax Thomas, 1920

Viscacha Rat

SYNONYMS:

Octomys mimax Thomas, 1920d:118; type locality “La Puntilla, near Tinogasta . . . a few miles out from Tinogasta towards Copacabana, at an altitude of about 1000 metres” (Thomas 1920d:116), Catamarca, Argentina.

Octomys joannius Thomas, 1921i:217; type locality “Pedernal, about 60 km. S.W. of San Juan, and 30 W. of Cañada Honda. Altitude, 1200 m.” (Thomas 1921i:214), San Juan, Argentina.

Octomys mimax mimax: Ellerman, 1940:157; name combination.

Octomys mimax joannius: Ellerman, 1940:157; name combination.

DESCRIPTION: As for the genus.

DISTRIBUTION: An endemic species of Argentina (Redford and Eisenberg 1992; R. A. Ojeda et al. 2002), *Octomys mimax* is found only in La Rioja, Catamarca, Mendoza, San Juan, and San Luis provinces in northwestern Argentina.

SELECTED LOCALITIES (Map 547): ARGENTINA: Catamarca, La Puntilla (type locality of *Octomys mimax* Thomas); La Rioja, Cañón de la Reserva, Talampaya (IADIZA 03785), Chilecito (Yepes 1930); San Juan, Parque Provincial Ischigualasto, Valle Fértil (IADIZA 03067), Pedernal (type locality of *Octomys joannius* Thomas); San Luis, 6 km W of Hualtaran, Parque Provincial Sierra de las Quijadas (ARG 3262).

SUBSPECIES: Currently *O. mimax* is considered monotypic (Cabrera 1961; Woods and Kilpatrick 2005). However, Yepes (1930, 1942) regarded *Octomys joannius* Thomas as a valid species while Ellerman (1940) and Lawrence (1941a) listed it as a subspecies of *O. mimax*.

NATURAL HISTORY: Sobrero et al. (2010) summarized available information on ecology, including habitat range, space use, behavior, food habits, and other population attributes. Ebensperger et al. (2008) reported general behavior, including diel activity pattern, nesting, resting patterns, habitat use, and home range derived from radio telemetry. Individuals live among rocks in the Monte biome of northwestern Argentina, at elevations ≤ 800 m. In San Luis province, *O. mimax* occurs in a transitional area between the Monte and a semiarid partition of the Chaco biome (Sobrero et al. 2010). Individuals use rock crevices for refuges, and there is no evidence that they modify daytime resting sites through digging (Ebensperger et al. 2008). Rocky habitat provides a thermally stable environment, and nocturnal activity could allow *O. mimax* to avoid the high temperatures and low relative humidity of the day (Sobrero et al. 2010). This nocturnal activity is in accord with the relatively good thermoregulatory capabilities of these rodents (Bozinovic and Contreras 1990). However, although *O. mimax* has specialized oral vibrissae like those used by *T. barrerae* to strip salt-laden epidermis from leaves of halophytes, this species does not eat halophytes. At Ischigualasto (San Juan province), its diet is mainly leaves and fruits of *Prosopis*, (Fabaceae), but also includes *Larrea* (Zygophyllaceae), cacti, seeds, and arthropods (Oyarce et al. 2003). Water conservation capability of the kidney of *O. mimax* is less developed than in *Tympanoctomys*, and more like that of *Octodontomys* in aspects of the renal papilla, re-

Map 547 Selected localities for *Octomys mimax* (●). Contour line = 2,000 m.

nal indices, and low urine concentration (G. B. Díaz and Ojeda 1999).

At Valle de la Luna (also San Juan province), one of us (RMB) captured young individuals in the same trap in November, suggesting that breeding occurs in the late winter or early spring. Another individual was also observed during the day at this same locality. *Octomys mimax* is solitary, a social system shared with its sister genus *Tympanoctomys*, and different from most octodontid genera, which are group living (Lacey and Ebensperger 2007).

Both fleas of the genus *Ectinorhis* (Beaucournu et al. 2004) and lice of the genus *Ferrisella* (D. Castro, Gonzales, and Cicchino 1998) are part of the ectoparasitic fauna of *O. mimax*. G. B. Díaz and Ojeda (2000) regarded *O. mimax* as vulnerable; E. P. Lessa, Ojeda, and Bidau (2008b) and the IUCN (2011) placed this species in the Least Concern category while stating that if current agricultural trends persist it may qualify for “Near Threatened” status in the future.

REMARKS: The chromosome complement is $2n=56$, $FN=108$ (M. H. Gallardo 1992; L. C. Contreras et al. 1994).

Genus *Spalacopus* Wagler, 1832

Diego H. Verzi, Mónica G. Díaz, and Rubén M. Barquez

The genus *Spalacopus* has only one species, *S. cyanus*, distributed in central Chile from the coast to 3,400 m in the

Andes, and from Copiapó to Ñuble province (Pine et al. 1979; Nowak 1999; Muñoz-Pedreros 2000). The genus has no fossil record deeper than the Holocene. L. C. Contreras et al. (1987) suggested that *Spalacopus* became specialized in situ during the Pleistocene. Biogeographic (Reig 1970), molecular (M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005), and morphological evidence (Verzi 2001), however, support an older origin, dating at least to the Pliocene. Opazo (2005) date the split of *Spalacopus* and its sister genus *Aconaemys* at 2.77 ± 0.75 mya. *Spalacopus cyanus* has not modified its distribution during the Holocene, although it became sympatric with the other subterranean octodontid *Aconaemys fuscus* in central Chile during this time period (Saavedra and Simonetti 2003).

Spalacopus is a medium to small-sized octodontid, with mass ranging from 80–120 g, total length 140–225 mm, and tail length 28–57 mm (Torres-Mura and Contreras 1998). Specimens from lower elevations are smaller and have more striking sexual dimorphism than those from the Andes (J. R. Contreras 1986). Like other subterranean rodents, the body is short and robust, the eyes are small and dorsally located, and the ears are short (8–12 mm). The eyes, however, are not especially small, in contrast to those of many other subterranean rodents (Stein 2000). The forefeet are strong and with long claws, except for the first digit which is reduced, and its claw does not extend beyond the digital pad (Nowak 1999; Torres-Mura and Contreras 1998). The tail is shorter than those of other octodontid genera, approximately 25% of the total length; it is cylindrical, scaly, lacks a terminal tuft, and has hairs longer than those of either *Aconaemys* or *Octodon*. The pelage is soft, lustrous, and short. Color overall the entire body is uniformly darkish brown or black, but some specimens have pectoral and pelvic spots colored white or coffee brown. Complete or partial albinism has also been recorded (Nowak 1999; Torres-Mura and Contreras 1998; Muñoz-Pedreros 2000).

As in the sister genus *Aconaemys*, *Spalacopus* has smaller brain size compared with those expected for a caviomorph rodent (Vassallo and Echeverría 2009). Eyes show lower rod density than that of nocturnal surface-dwelling rodents, suggesting adaptation to visual demands of diurnal surface activity (Peichel et al. 2005). Ear morphology includes an enlarged eardrum and mobile-type ossicles that are believed to improve hearing sensitivity at lower frequencies (Begall and Burda 2006). The glans penis is characterized by a variable number of spines on each side of the intromittent sac (up to five on each side, but more frequently in a 3–3 or 2–2 pattern; Spotorno 1979; L. C. Contreras 1993). The spikes are smaller than those of other octodontids. Females have two pairs of abdominal

and one pair of inguinal mammae (Torres-Mura and Contreras 1998).

The skull is robust, short, broad, and flat. A vertical sphenopalatine foramen, similar to that of *Aconaemys*, is present in the orbitotemporal region in front of the alveolar sheath of M1, partially covered by the alveolar sheath of the incisor. The zygomatic arches are expanded, with the jugal fossa lower, shallow, and placed more posteriorly than in other octodontids. The lateral flange of the canal for the infraorbital nerve is reduced or absent. The bullae are piriform, smaller than in other octodontids, and nearly filled with small, bony septae. The incus and malleus are not fused as in *Aconaemys* and *Octodon*. The mandible is moderately hystricognathous, with the condyloid and coronoid processes nearly vertical. The angular (lunar) notch is shallow.

The upper incisors are long, narrow, and with the enameled face white or pale yellow. They are strongly procumbent (Thomas's angle about 117° [Thomas 1919h; E. P. Lessa and Thaele 1989; Reig and Quintana 1992]), contrasting sharply with the orthodont or opisthodont condition of all other octodontids. The incisor alveolar sheath is extended posteriorly through the orbital region and ends at the level of the two first upper molars (E. P. Lessa, Vassallo et al. 2008). The base of the lower incisor extends to the level of the mandibular condyle. The first to third upper and lower molariform teeth (DP4/dp4-M2/m2) have a figure-8 occlusal shape with two transverse lobes separated by dual-faced folds (mesoflexus/flexid and hypoflexus/flexid). Neither pair of folds contact in the middle of the tooth, unlike *Aconaemys*, and little cement is present. The last molars (M3/m3) are slightly reduced in size. Chewing is propalinal with a slight oblique component (Koenigswald et al. 1994; Olivares et al. 2004). Microstructure of the molar enamel is one layered and consists entirely of multiseriate Hunter-Schreger bands, except for the trailing edge of the lower molars, which also has an inner layer of radial enamel (Koenigswald et al. 1994).

The clavicle is wide distally and both shallow and slender proximally. The deltoid crest of the humerus is well developed. The femur has the third trochanter enlarged, as in *Octodon degus*. The tibia and fibula are fused proximally (Torres-Mura and Contreras 1998).

SYNONYMS:

Mus: G. I. Molina, 1782:300; part (description of *cyanus*); not *Mus* Linnaeus.

Bathyergus Froriep, 1829:279; not *Bathyergus* Illiger, 1811; *nomen nudum*; based on *Bathyergus maritimus* Poepig, a manuscript name quoted from a letter written by E. Poeppig to L. F. Froriep.

Spalacopus Wagler, 1832:1219; type species *Spalacopus poepigii* Wagler (= *Mus cyanus* G. I. Molina), by monotypy.

Poephagomys F. Cuvier, 1834:323; type species *Poephagomys ater* F. Cuvier, by original designation.

Psammomys Poepig, 1835a:166; type species *Psammomys noctivagus* Poepig, by original designation; preoccupied by *Psammomys* Cretzschmar, 1828 (Rodentia: Gerbillinae).

Psammoryctes Poepig, 1835b:252; replacement name for *Psammomys* Poepig, with the same type species, *Psammomys noctivagus* Poepig.

REMARKS: The taxonomic history of the genus *Spalacopus* has been relatively uncomplicated (Tate 1935:381–382). Wagler (1832) erected the genus *Spalacopus* with the single species *S. poeppigii*, which he based on a description by R. F. Froriep contained in a letter received by him from E. L. Poepig. Cuvier (1834) described *Peophagomys ater* and Poepig (1935a) described *Psammomys noctivagus*. Poepig (1835b) subsequently erected *Psammoryctes* as a replacement for his earlier *Psammomys*, which he realized was preoccupied by *Psammomys* Cretzschmar, 1828, a gerbilline rodent from North Africa and the Middle East. Wagner (1843a) recognized *noctivagus* with *poeppigii* and *ater* in its synonymy, but under the Poepig's *Psammoryctes*. Bridges (1844) then argued that *Poephagomys ater* F. Cuvier was the same as *Mus cyanus* G. I. Molina. E.-L. Trouessart (1880b:174–175) placed both *ater* and *noctivagus* in the synonymy of *poeppigii*, with *cyanus* listed as a questionable subspecies. Thomas (1925e) finalized the current species-level taxonomy by arguing that *Mus cyanus* G. I. Molina was the same species as that represented by Wagler's *poeppigii*, Cuvier's *ater*, and Poepig's *noctivagus*.

Spalacopus cyanus (G. I. Molina, 1782)

Cururo, Coruro, Guanque

SYNONYMS: See under Subspecies.

DESCRIPTION: As for the genus.

DISTRIBUTION: *Spalacopus cyanus* is endemic to central Chile, between 27°S to 36°S latitude, where it ranges from the coast to about 3,400 m in the Andes (Reig et al. 1972; L. C. Contreras et al. 1987; Nowak 1999; Torres-Mura and Contreras 1998; Muñoz-Pedreras 2000).

SELECTED LOCALITIES (Map 548): CHILE: Atacama, Quebrada de Pajonales, 22 km N of Caldera (L. C. Contreras et al. 1987); Biobío, Quirihue (type locality of *Spalacopus cyanus maulinus* Osgood); Coquimbo, Huetauquén (Opazo et al. 2008), La Serena (Opazo et al. 2008), Parque Nacional Fray Jorge (Urrejola et al. 2005); O'Higgins, Los Cipreses, Rancagua (L. C. Contreras et al. 1987; Torres-Mura and Contreras 1998; Bacigalupe et al. 2002); Santiago, Alicahue (Torres-Mura and Contreras 1998), Lagunillas (Opazo et al. 2008), Santuario de la naturaleza Yerba Loca (Urrejola et al. 2005), Santiago, Villa

Alhué (USNM 541832); Valparaíso, 3 km N of Los Molles (Mares et al. 2000), 1 km N of Pte. Los Molles (FMNH 119604), Quilpué (MSU 8720).

SUBSPECIES: Osgood (1943b) and Woods and Kilpatrick (2005) recognized two subspecies that correspond to coastal and Andean populations. L. C. Contreras et al. (1987) and Torres-Mura and Contreras (1998) recognized three subspecies, a view that we follow here.

Spalacopus cyanus cyanus (G. I. Molina, 1782)

SYNONYMS:

Mus Cyanus G. I. Molina, 1782:300; no type locality identified, but restricted by Osgood (1943b:114) to "Chile; Province of Valparaiso."

Hypudaeus ? cyanus: Illiger, 1815:108; name combination; in a list of South American species.

Mus cyaneus Lesson, 1827:271; incorrect subsequent spelling of *Mus cyanus* G. I. Molina.

Bathyergus maritimus Poepig, in Froriep, 1829:279; *nomen nudum*.

Poephagomys ater F. Cuvier, 1834:323; type locality "Coquimbo, Chile."

Psammomys noctivagus Poepig, 1835a:166; type locality "sand dunes in the coastal region of northern Chile."

Psammoryctes noctivagus Poepig, 1835b:252; renaming of *Psammomys noctivagus* Poepig.

Peophagomys cyanus: Bridges, 1844:55; name combination, equated *ater* F. Cuvier with *cyanus* G. I. Molina.

Psammoryctes ater: Schinz, 1845:103; name combination.

Spalacopus cyaneus Wolffsohn and Porter, 1908:80; incorrect subsequent spelling of *cyanus* G. I. Molina.

Spalacopus cyaneus: Cabrera, 1917:52; incorrect subsequent spelling of *cyanus* G. I. Molina.

Spalacopus cyanus cyanus: Osgood, 1943b:114; first use of current name combination.

This subspecies occurs in central Chile from Caldera (Copiapó province, Atacama Region) to Curicó (Curicó province, Maule Region) from sea level to 1,000 m (Torres-Mura and Contreras 1998).

Spalacopus cyanus maulinus Osgood, 1943

SYNONYM:

Spalacopus cyanus maulinus Osgood, 1943b:115; type locality "Quirihue, Province of Maule," now Ñuble Province, Biobío, Chile.

This subspecies is found in the coastal area of Ñuble province, Biobío Region, south of the range of *S. c. cyanus*.

Similar in size to *S. c. cyanus* (mass 64–130 g, total length 140–195 mm, tail length 30–43 mm; Torres-Mura and Contreras 1998), but Osgood (1943b:116) noted cranial and dental differences with *S. c. cyanus*. L. C. Contreras et al. (1987) retained this subspecies but questioned

its validity. *Spalacopus c. maulinus* is considered at risk (Muñoz-Pedreros 2000).

Spalacopus cyanus poeppigii Wagler, 1832

SYNONYMS:

Spalacopus Poeppigii Wagler, 1832:1219; type locality “vom Fuss der Anden Chile’s.”

Spalacopus tabanus Thomas, 1925c:585; type locality “South Chili”; exact type locality unknown (Osgood 1943b:116).

Spalacopus cyanus tabanus: Osgood, 1943b:116; name combination.

S[palacopus]. c[yanus]. poeppigii: L. C. Contreras et al. 1987: 405; first use of current name combination (see also Reig et al. 1972).

This subspecies is found on the western slope of the Andes, from Cordillera (Santiago Region) south to Curicó (Maule Region) provinces and at an elevational range from 1,500 to 3,400 m (Torres-Mura and Contreras 1998). It averages larger than *S. c. cyanus*, with total length 162–225 mm, tail length 39–57 mm, and mass 68–151 g (Torres-Mura and Contreras 1998). Both Osgood (1943b) and Mann (1978) regarded *poeppigii* Wagler as a synonym of *S. c. cyanus*, and Mann (1978) also considered *tabanus* Thomas to be a junior synonym of the nominotypical form. However, Reig et al. (1972) pointed out that Andean populations of *Spalacopus*, assignable to *S. c. poeppigii* (including *S. tabanus* Thomas), are phenotypically distinct from the coastal ones, a separation verified by Yáñez and Zülch (1981) through morphometric analyses. L. C. Contreras et al. (1987) concluded that *S. c. poeppigii* Wagler was a valid subspecies distinct from the nominotypical form.

NATURAL HISTORY: Torres-Mura and Contreras (1998) reviewed the literature covering aspects of the ecology, reproduction, physiology, and behavior of *S. cyanus*. This species is social, an unusual attribute for a strictly subterranean animal. Populations occur in discrete patches (M. H. Gallardo et al. 1992) from alpine grasslands in the Andes to sand dunes on the coast (L. C. Contreras et al. 1987; Torres-Mura and Contreras 1998). Local populations comprise many small colonies, each with a relatively stable home range (L. C. Contreras and Gutierrez 1991 vs. Reig 1970) of about 16 (up to 26) animals (Begall et al. 1999; Begall and Gallardo 2000). Burrow systems consist of a complex network of interconnected tunnels (Begall and Gallardo 2000; E. P. Lessa, Vassallo et al. 2008). A burrow system excavated at El Alamo (Ñuble province) was estimated to be 600 m long (Begall and Gallardo 2000). Incisors are used in digging, and individuals inhabiting harder soils in the Andes have longer incisors, in relation to a more frequent use with respect to those of the populations of the coastal dunes (Bacigalupe et al. 2002).

Cururos exhibit a lower basal metabolic rate relative to similar-sized above-ground species, a physiological feature in common with other subterranean rodents, but there is no difference in either basal or digging metabolic rates among populations inhabiting contrasting climatic and soil conditions (Bozinovic et al. 2005). They have lower ventilation in normoxia than expected for their body mass and a blunted hyperventilatory response, characteristic of fossorial mammals, when exposed to hypercapnia (Tomasco et al. 2010). The suggestion that ambient temperature limits above-ground activity (Rezende et al. 2003) may be an artifact of captivity because field studies document diurnality with substantial time spent on the surface (Urrejola et al. 2005).

Activity in free-living populations in both the coast and Andes is largely diurnal, and significant time is spent on the ground surface away from the burrow (Urrejola et al. 2005), a pattern contrasting sharply with the pattern observed in captive populations (Begall et al. 2002). Diurnal, above-ground activity is in accord with eyes of typical size for a nonspecialized surface-dwelling rodent and dichromatic color vision (Peichel et al. 2005). Cururos are also highly vocal, with a complex acoustic repertoire composed of a number of different true vocalizations and at least one mechanical sound (Veitl et al. 2000). The most distinctive and unique vocalization is a long musical trill that may last up to two minutes. Vocalizations in the wild are largely restricted to daylight hours, in accord with the diurnal activity pattern (Urrejola et al. 2005). The middle and inner ear morphology is typical of the pattern generally seen in subterranean rodents, which are generally characterized by specializations for low frequency and low-sensitivity hearing (Begall and Burda 2006). Nevertheless, cururos have a broader hearing range (covering frequencies at least between 0.25 and 20 kHz) coupled with an unusually high sensitivity, both atypical features in audiograms of subterranean rodents (Begall et al. 2004). Odor receptors are well developed, and cururos can discriminate among individuals within their colony or adjacent ones (Hagemeyer and Begall 2006).

Cururos are strictly herbivorous, foraging on tubers (*Libertia* [Iridaceae], *Leucocoryne* [Amaryllidaceae]) and bulbs (*Rodophiala*, [Amaryllidaceae], *Dioscorea* [Dioscoreaceae]) (Ipinza et al. 1971; Reig 1970; Torres-Mura and Contreras 1998; Begall and Gallardo 2000). At Los Maitenes, individuals were found foraging on the ground on leaves of *Convolvulus* (Convolvulaceae) (Begall and Gallardo 2000). *Spalacopus* damage cultivated crops both by their construction of tunnel systems and because they forage on food plants, but at the same time they can increase the biomass of herbaceous plants in tunnel areas (L. C. Contreras and Gutiérrez 1991) and on above-ground establishment through soil disturbance (Torres-Díaz et al. 2012).

Reproductive activity has been recorded for the months of March through January (Begall et al. 1999). The sex ratio of reproductive adults is skewed in favor of females (about 2:1), the gestation period is 77 days, and the mean litter size 3.5 (range: 2–5). Young are born altricial, but the eyes open at two to eight days, pups are weaned after two months, and adult body weight is attained by six to seven months of age.

This species is able to swim short distances. Interestingly, northern populations regard water as a novel element, but more southern ones will enter water without hesitation (Hickman 1988; Reise and Gallardo 1989).

REMARKS: *Spalacopus* shares the same karyotype with *Octodon degus*, *Octodon bridgesii*, and *Aconaemys porteri* (Reig et al. 1972; M. H. Gallardo 1992), supporting the close phyletic relationship among these three genera derived from molecular analyses (Opazo 2005). Zülch

et al. (1982) compared G- and C-bands of montane and coastal samples of *Spalacopus* and of *Octodon*.

Population genetic attributes have been examined by both allozyme (M. H. Gallardo et al. 1992) and mtDNA sequence methodologies (Opazo et al. 2008). Both independent data sets indicate that diversity is medium to low, mostly contained within populations, and with little genetic contact among regions. Phylogeography of mtDNA documented asymmetrical migration from the Andes to the coast, and suggested a montane origin of the species (Opazo et al. 2008). Both Bacigalupe et al. (2000) and Bozinovic et al. (2002) had previously proposed this biogeographic scenario.

Genus *Tympanoctomys* Yepes, 1942

M. Mónica Díaz, Rubén M. Barquez, and Diego H. Verzi

Four living and one extinct species comprise the genus *Tympanoctomys*. One extant species was recently described from Patagonia (Teta et al. 2014) and two were originally placed in different genera, *Salinoctomys* and *Pipanoctomys* (Mares et al. 2000). Barquez et al. (2002) subsequently treated both as *Tympanoctomys* based on morphological characters. Alternatively, Woods and Kilpatrick (2005) and M. H. Gallardo et al. (2007) have continued to recognize all three as valid genera. We concur with the arguments of Barquez et al. (2002) and recognize four species herein.

Species of *Tympanoctomys* are endemic to the arid regions of central and western Argentina, within the Monte, Chaco, and Patagonian desert biomes. Within these habitats they are known from salt basins (*salares*), sand dunes, and open scrubland habitats in Catamarca, Chubut, La Rioja, Mendoza, San Juan, La Pampa, and Neuquén provinces (Justo et al. 1985; R. A. Ojeda et al. 1996; Mares et al. 2000; A. A. Ojeda et al. 2007; Udrizar Sauthier, Teta et al. 2011, 2014). We regard this patchy distribution as relictual, and the particular habitats occupied as probable interglacial refuges. Verzi, Tonni et al. (2002) recorded the extinct *Tympanoctomys cordubensis* in the Early-Middle Pleistocene of central Argentina, in sediments representing a glacial event.

Tympanoctomys is a small-sized octodontid, with mean mass ranging from 67–104 g, mean head and body length from 130–170 mm, and mean length of tail from 114–135 mm (Mares et al. 2000; Teta et al. 2014). Overall coloration is different in each species, but ranges from dark brown to golden yellow. The tail is longer than or subequal to head and body length and terminates in a distinct tuft. Both the length and color of this tuft vary with age, as in *Octodontomys*, but in general young individuals have a short and black tuft while in adults it is longer and reddish. Claws are not well developed on the forefeet.

Map 548 Selected localities for *Spalacopus cyanus* (●). Contour line = 2,000 m.

Tympanoctomys is unique because it possesses a pair of bundles of stiffened hairs located on either side of the palate, just posterior to the upper incisors, and two oral glands not seen in other rodents (Mares, Ojeda, Borghi et al. 1997; Berman 2003). The bristle bundles vibrate against the lower incisors and remove the hypersaline epidermis from their major food plants (Berman 2003).

The glans penis of *T. barrerae* has one spike on each side of the intromittent sac, a condition similar to that in *Octomys* and likely the ancestral pattern for the family (Spotorno 1979; L. C. Contreras et al. 1993).

The skull has short nasals. The frontal width increases markedly posteriorly and the borders are straight and divergent. Consequently, the distance between the frontal bone and the zygomatic arch is shorter than in other octodontids, except *Octomys*. The zygomatic arches are short, anteriorly deep, and with their ventral border descending posteriorly. The jugal fossa (for the origin of the masseter posterior muscle) is deep, level with the paraorbital apophysis, and is directed posteriorly. The paraorbital process, in lateral view, is formed only by the squamosal, as in *Octomys*. The lateral flange of the canal for the infraorbital nerve is small or absent. In the orbital region, between the alveolus for the incisor and the sphenopalatine foramen, the nasolacrimal canal is exposed through a hole larger than in other genera. The auditory bullae are the largest for any taxon in the family, with the mastoid portion extending posteriorly well past the plane of the occiput, and the dorsal wall of the epitympanic recess forms a large bony "island" on the roof of the braincase. The root of the paroccipital process is strongly medial and close to the occipital condyle, due to enlargement of the mastoid. The mandible is short and wide, with the angular process thin and not flattened because the pterygoid shelf is very narrow. The angular (lunar) notch is deep and the postcondyloid process is laterally oriented.

The incisors are orthodont to opisthodont, and deeply implanted. The base of the lower incisor is posterodorsal to the last molar (m3). The occlusal pattern of the molariform teeth is figure-8 shaped as in *Octomys*, *Aconaemys*, and *Spalacopus*, but with lobes compressed anteroposteriorly. The mesoflexus/flexid and hypoflexus/flexid are in contact at the midline; each is wide and with abundant cement. The first lower molariform, dpm4, usually has a secondary lingual fold in the anterior lobe. The last lower molar, m3, is very reduced, variable in morphology, and usually has only an oblique labial fold (hypoflexid). The lower m3 of the newly described *T. kirchnerorum* is uniquely figure-8 shaped, similar in morphology to m2 (Teta et al. 2014). Chewing is propalinal (Verzi 2001; Olivares et al. 2004).

Ameghino (1889) was the first to describe species of *Tympanoctomys*, an extinct species that he included it in

the genus *Pithanotomys* as *P. cordubensis*. Thus, a fossil of *Tympanoctomys* was known for more than 50 years before the genus was described as part of the living fauna. Yepes (1942) named *Tympanoctomys* based on the extant species, *Octomys barrerae* Lawrence, and recognized the supraspecific level of differences between Lawrence's *O. barrerae* and *O. mimax*, the type species of *Octomys* Thomas. Subsequent analyses of morphology (De Santis et al. 1991; Verzi 2001), chromosomes (L. C. Contreras et al. 1990; M. H. Gallardo 1992), and molecular data (M. H. Gallardo and Kirsch 2001; Honeycutt et al. 2003; Opazo 2005) have confirmed Yepes's decision. Although cladistic analyses of both craniodental characters (Verzi 2001; Verzi et al. 2013) and molecular data based on DNA hybridization (M. H. Gallardo and Kirsch 2001) and sequences (Honeycutt et al. 2003; Opazo 2005) support a close phylogenetic relationship with *Octomys*, the extinct Pliocene genus *Abalosia* is the apparent sister to *Tympanoctomys* (Verzi 2001). Verzi (2001) suggested that this triad of genera was part of a clade of desert specialists that differentiated east of the Andes during the Late Pliocene, a time of expansion of arid environments. The living representatives are thus likely remnants of an earlier much wider radiation. Opazo (2005) estimated the mean divergence between *Tympanoctomys* and *Octomys* at 4.28 mya, in the Pliocene, and between two living species *T. barrerae* and *T. aureus* at 1.74 mya, at the Plio-Pleistocene boundary. M. H. Gallardo et al. (2013) estimated that *T. kirchnerorum* diverged from *T. barrerae* during the Daniglacial phase of the Middle Pleistocene, at approximately 1.47 mya, a period following the Great Patagonian Glaciation.

Milton Gallardo and colleagues (M. H. Gallardo 1997; M. H. Gallardo et al. 1999, 2006; M. H. Gallardo, Garrido et al. 2004; M. H. Gallardo, Kausel et al. 2004; Teta et al. 2014) presented evidence that three species of this genus (the karyotype of *T. loschalchalersorum* is unknown) are the first known tetraploid mammals, although Svartman et al. (2005) argued against this conclusion.

SYNONYMS:

Pithanotomys: Ameghino, 1889:165; part; not *Pithanotomys* Ameghino, 1887.

Tympanoctomys Yepes, in de la Barrera, 1940:569; *nomen nudum*.

Octomys: Lawrence, 1941a:43; part (description of *barrerae*); not *Octomys* Thomas.

Tympanoctomys Yepes, 1942:75; type species *Octomys barrerae* Lawrence, by original designation.

Pipanacoctomys Mares, Braun, Barquez, and Díaz, 2000:3; type species *Pipanacoctomys aureus* Mares, Braun, Barquez, and Díaz, by original designation.

Salinoctomys Mares, Braun, Barquez, and Díaz, 2000:6; type species *Salinoctomys loschalchalersorum* Mares, Braun, Barquez, and Díaz, by original designation.

REMARKS: Woods and Kilpatrick (2005:1573) incorrectly cited “Yepes, 1941. Rev. Inst. Bact., 9, 1940 [1941]:569” as the basis for the genus *Tympanoctomys*. This citation, however, is a *nomen nudum* since the taxon was neither formally described nor was a holotype designated in that paper. Rather, *Tympanoctomys* as a valid name stems from Yepes (1942:75).

KEY TO THE SPECIES OF *TYMPANOCTOMYS*:

1. Lateral flange of the canal for the infraorbital nerve reduced to absent; bristle bundle with stiff hairs well developed; dorsal color pale brown to tan washed with black. 2
- 1'. Lateral flange of the canal for the infraorbital nerve present; bristle bundle absent or not well developed 3
2. Tail proportionally longer (>80% head and body length); lower m3 distinctly unilobed, “comma”-shaped.
. *Tympanoctomys barrerae*
- 2'. Tail proportionally shorter (50% or less of head and body length); lower m3 distinctly bilobed, figure-8 shaped
. *Tympanoctomys kirchnerorum*
3. Posterolateral border of incisive foramina raised; posterior lobe of M3 anteroposteriorly not shortened, longer than the anterior lobe; dorsal color golden blond.
. *Tympanoctomys aureus*
- 3'. Posterolateral border of incisive foramina not raised; posterior lobe of M3 anteroposteriorly shortened as the anterior one; dorsal color brownish-black
. *Tympanoctomys loschalchalerosorum*

Tympanoctomys aureus (Mares, Braun, Barquez, and Díaz, 2000)

Golden Viscacha Rat

SYNONYM:

Pipanaoctomys aureus Mares, Braun, Barquez, and Díaz, 2000:3; type locality “28 km S, 9.3 km W Andalgala, Departamento Pomán, Catamarca Province, Argentina, 27°50'03”S 66°15'59”W; elevation 680 m,” Salar de Pipanaco, Saujil department.

Tympanoctomys aureus: Barquez, Díaz, and Ojeda, 2002:38; first use of current name combination.

DESCRIPTION: Largest species in genus, with mean head and body length 170 mm (166–178 mm). Tail long, averaging 135 mm (127–145), 76–85% of head and body length. Ears short and rounded, averaging 20 mm in length; hindfeet long for genus, averaging 37 mm. Dorsal coloration uniquely golden blond and venter white to pale cream. Tail with well-developed rufous terminal tuft in adults. Juveniles gray with black, short-tufted tail, color pattern contrasting sharply with that of adult specimens. Bristle bundles present, but not as well developed as in *T. barrerae*. Diagnostic characters of cranium include distinct

groove and flange for infraorbital nerve, postorbital process or protuberance located on frontal, long palate that extends beyond posterior borders of M2s, wide and flat paroccipital processes completely appressed to bullae, raised posterolateral border of incisive foramina that appears as protuberance anterior to DPM4 in lateral view, sharply acute angle formed by jugal and zygomatic process of maxilla, small interpremaxillary foramen, large and inflated auditory bullae, fused masticatory and buccinator foramina, light orange upper incisors with narrow white lateral edge, long upper and lower toothrows, and well-developed metacone and hypocone forming triangular-shaped posterior loph on M3.

DISTRIBUTION: *Tympanoctomys aureus* is known only from the type locality in the Salar de Pipanaco, within the Monte Phytoecographic Province, of Catamarca Province, Argentina.

SELECTED LOCALITIES (Map 549): ARGENTINA: Catamarca, 28 km S and 9.3 km W of Andalgala (type locality of *Pipanaoctomys aureus* Mares, Braun, Barquez, and Díaz).

SUBSPECIES: *Tympanoctomys aureus* is monotypic.

NATURAL HISTORY (data from Mares et al. 2000, and M. M. Díaz and R. M. Barquez, pers. obs.): This species lives on the sandy substrate of the narrow strip of halophytic vegetation between the central, bare salt flat (“salar”) and the more typical surrounding Monte Desert vegetation composed of *Prosopis*, (Fabaceae), *Larrea* (Zygophyllaceae) and other perennial trees and shrubs. Nocturnal, individuals feed exclusively on chenopodiaceous shrubs of the Amaranthaceae genera *Heterostachys*, *Atriplex*, and *Suaeda* that dominate the perisaline shrubland. They construct burrows in the earthen mounds that accumulate at the base of these same shrubs, with apparently more than one individual inhabiting a single mound, different from *T. barrerae*. Burrows are shallow and have several openings; in the active burrows, food and feces eliminated by individuals cleaning the burrows can be observed at the entrances. A birth was observed in October; the newborn was well haired, and the eyes and ears were open within a few hours after birth. Ectoparasites are unknown.

This species is at risk of extinction because the single known locality is experiencing expansion of olive tree cultivation that causes the loss of habitat, reducing both food and living space. Strong conservation measures are needed to avoid the extinction of this recently described species.

REMARKS: The karyotype of $2n=92$ is characterized by 44–45 pairs of biarmed chromosomes that mostly group into quartets, and a biarmed X chromosome and uniarmed Y chromosome. M. H. Gallardo, Kausel et al.

Map 549 Selected localities for *Tympanoctomys aureus* (○), *Tympanoctomys barrerae* (●), *Tympanoctomys kirchnerorum* (□), and *Tympanoctomys loschalchalersorum* (■). Contour line = 2,000 m.

(2004) argued that the karyotype of *T. aureus* is a tetraploid derivative, like that of *T. barrerae*. According to the model proposed by M. H. Gallardo (2007), *T. aureus* originated through a reticulated speciation event.

Tympanoctomys barrerae (Lawrence, 1941)

Red Viscacha Rat

SYNONYMS:

Tympanoctomys barrerae Yepes, in de la Barrera, 1940:69; *nomen nudum*.

Octomys barrerae Lawrence, 1941a:43; type locality "La Paz, Mendoza Province, Argentina."

Tympanoctomys barrerae: Yepes, 1942:69; name combination and incorrect gender concordance.

Tympanoctomys barrerae: Cabrera, 1961:516; first use of current name combination.

Tympanoctomys barrerae: M. M. Díaz and Verzi, 2006:235; name combination and incorrect gender concordance.

DESCRIPTION: Middle sized of three species in genus, only slightly larger than *T. loschalchalersorum* but considerably smaller than *T. aureus*. Mean head and body length 145 mm (125–160 mm), tail length 118 mm (93–147 mm), hindfoot 34 mm (30–36 mm), and ear length 16.3 mm (13–19 mm; Mares et al. 2000). Dorsal color-

ation tan washed with black; venter white. Tail proportionally longer (82% of head and body length) than in other species, and terminates in black brush. Forefeet and hindfeet small with claws covered by white hairs. Oral bristle bundles well developed and composed of stiff hairs, absent or not well developed in other species. Skull with flange for infraorbital nerve absent; small flange in other two species.

DISTRIBUTION: *Tympanoctomys barrerae* is endemic to the arid regions of central and western Argentina, within the Monte and Patagonian desert biomes. The geographic range is restricted and the preferred habitat is patchy (G. B. Diaz et al. 2000). The species is known only from scattered localities of salt flats, sand dunes, and open scrubland habitats in the provinces of Neuquén, La Pampa, Mendoza, and San Juan (Justo et al. 1985; R. A. Ojeda et al. 1989, 1996; G. B. Diaz et al. 2000; A. A. Ojeda et al. 2007). Populations range in elevation from 300–1,400 m.

SELECTED LOCALITIES (Map 549): ARGENTINA: La Pampa, Gran Salitral (A. A. Ojeda et al. 2007), Lihuel Calel (De Santis et al. 1991); Mendoza, 27 km N of Desaguadero (Mares et al. 2000), La Batra, SW of Laguna Llanquanelo (Torres-Mura et al. 2003), La Paz (type locality of *Octomys barrerae* Lawrence), Las Catitas (G. B. Diaz et al. 2000), Malargüe (G. B. Diaz et al. 2000), Nihuil Dam (Mares, Braun, and Channell 1997); Neuquén, Salar de Añelo (A. A. Ojeda et al. 2007); San Juan, Ischigualasto (A. A. Ojeda et al. 2007).

SUBSPECIES: *Tympanoctomys barrerae* is monotypic.

NATURAL HISTORY: G. B. Diaz et al. (2000) summarized the literature on the ecology, behavior, reproductive biology, and physiology of *T. barrerae* prior to 2000. This species inhabits salt basins and sand dunes in lowland habitats. Individuals are nocturnal and solitary (Mares, Braun, and Channell 1997), living in complex burrow systems built in soft soil mounds (R. A. Ojeda et al. 1996; Mares, Braun, and Channell 1997; G. B. Diaz 2003; Torres et al. 2003). Litters have been born in captivity from pregnant females captured in the wild (from Nihuil, Mendoza Province) in February. Neonates were altricial, with eyes closed and only 4 g in weight at birth. This species is strictly herbivorous, specializing on halophytic vegetation of the Amaranthaceae shrub genera such as *Atriplex*, *Allenrolfea*, *Heterostachys*, and *Suaeda* (Torres-Mura et al. 1989; R. A. Ojeda et al. 1996). They scrape off the surface of *Atriplex* leaves with their lower incisors and bristle brushes of stiff hairs before consumption, greatly reducing their electrolyte intake (Mares, Ojeda, Borghi et al. 1997; G. B. Diaz et al. 2000; Giannoni et al. 2000; Berman 2003). They are able to concentrate urine, to a maximum of 7,080 mosm/l, similar to other desert rodents that forage on halophytes (such as the North Amer-

ican kangaroo rat, *Dipodomys microps* [Heteromyidae] and the African and Middle Eastern sand rat, *Psammomys obesus* [Gerbillinae]; Bozinovic and Contreras 1990; G. B. Diaz and Ojeda 1999; R. A. Ojeda et al. 1999; G. B. Diaz 2003; G. B. Diaz et al. 2006).

Justo et al. (1985) recovered skulls of *T. barrerae* from pellets of the Barn Owl (*Tyto alba*). De la Barrera (1940) recorded ectoparasites, such as fleas of the genera *Hectopsylla* and *Parapsyllus*, on both individuals and in nests. Two species of *Parapsyllus* (De la Barrera 1940) and one of the louse genus *Ferrisella* (D. Castro and Verzi 2002) are exclusive parasites of *T. barrerae*. The Red Viscacha Rat is considered a Near Threatened species (E. P. Lessa, Ojeda, and Bidau 2008c), although it was considered as “vulnerable” under prior criteria (Reca et al. 1996; R. A. Ojeda and Díaz 1997).

REMARKS: Lawrence (1941a:43) described *Octomys barrerae*, naming her new taxon for Sr. J. M. de la Barrera “through whose kind offices the specimen was obtained.” Although Sr. Barrera was a male, Lawrence was correct to use the Latinized feminine genitive ending (ICZN 1999:Art. 31.1.1) rather than the masculine genitive ending *barrerai* employed by Yepes (1940, 1942) and M. M. Díaz and Verzi (2006).

A. A. Ojeda (2010) described molecular phylogeographic structure based on mtDNA sequences that uncovered two geographically overlapping clades with a modest level of differentiation, low levels of gene flow, and evidence for post-Pleistocene expansion in the central part of the current species range.

The completely biarmed karyotype of *T. barrerae* is among the largest in both diploid and fundamental number ($2n=102$, $FN=200$) for any mammal, and includes 36 pairs of metacentric to submetacentric chromosomes, 14 pairs of subtelocentric autosomes, and an XY sex-chromosome system (L. C. Contreras et al. 1990; M. H. Gallardo 1992). All chromosomes have discrete blocks of centromeric heterochromatin (M. H. Gallardo 1992). The cellular DNA content is also larger than that of any other mammal, with an average $2C$ -value of 16.8 pg per nucleus (M. H. Gallardo et al. 1999, 2003). This species was proposed as the first tetraploid mammal known (M. H. Gallardo et al. 1999, 2006; M. H. Gallardo, Garrido et al. 2004), and Bacquet et al. (2008) suggest that both genetic and epigenetic mechanisms were important in the functional diploidization of a tetraploid genome. Svartman et al. (2005), however, presented evidence that the genome of *T. barrerae*, while large, is diploid rather than polyploid. Finally, Suárez-Villota et al. (2012) provided detailed analyses of repetitive DNA sequence composition and suggested that the unique karyotype of *T. barrerae* originated by hybridization.

The macrocephalic and distinctive paddle-like sperm head of *T. barrerae* is the largest reported for rodents, differing from the common oval-shaped ones found in other Octodontidae (M. H. Gallardo et al. 2002).

Tympanoctomys kirchnerorum Teta, Pardiñas, Udrizar Sauthier, and Gallardo, 2014

Kirchners' Viscacha Rat

SYNONYM:

Tympanoctomys kirchnerorum Teta, Pardiñas, Udrizar Sauthier, and Gallardo, 2014:62; type locality “Argentina, Province of Chubut, Department of Gastre, 18 km NNE by road of Los Adobes, conjunction between Ruta Provincial 58 and Zanjón El Colorado (43°13'51.6”, 68°38'49.1”, 517m).”

DESCRIPTION: Slightly smaller than *T. barrerae*; mean head and body length 129.4 mm (range: 111–136 mm), tail length 114 mm (111–114 mm), hindfoot 31.7 mm (29–35 mm), and ear length 14.5 mm (14–15 mm). Dorsal coloration pale brown; venter whitish or pure white; forefeet and hindlegs whitish. Tail bicolored, sparsely haired, proportionally short (ca. 43–50% of head and body length), with medium terminal pencil. Forelegs and hindlegs whitish. Oral bristle bundles well developed, composed mostly of thick white hairs. Skull more bowed than that of *T. barrerae* in dorsal profile, with posteriorly cuneate nasals; supraoccipital without lateral wings; dpm4 with very shallow lingual secondary fold and conspicuous labial secondary fold; m3 distinctly figure-8 shaped, similar to morphology of m2.

DISTRIBUTION: Known range of extant populations are limited to the type locality and vicinity; fossil remains (Late Holocene) are known from the middle and lower parts of the Río Chubut well to the east of the type locality (see Udrizar Sauthier et al. 2009; Pardiñas, Udrizar Sauthier, and Teta 2012).

SELECTED LOCALITIES (Map 549): ARGENTINA: Chubut, 18 km NNE by road of Los Adobes (type locality of *Tympanoctomys kirchnerorum* Teta, Pardiñas, Udrizar Sauthier, and Gallardo), 3 km W of Los Adobes (Teta et al. 2014).

SUBSPECIES: *Tympanoctomys kirchnerorum* is monotypic.

NATURAL HISTORY: *Tympanoctomys kirchnerorum* inhabits sandy terrain within a general badlands landscape (M. H. Gallardo et al. 2009), with the type locality located within the *Chuquiraga avellanadae* (Asteraceae) steppe of the Central District of the Patagonian Phytogeographic Region (León et al. 1998). Here, plant cover is sparse, consisting mostly of low shrubs in the families Amaranthaceae, Anacardiaceae, Asteraceae, and Fabaceae, such as *Atriplex*, *Chuquiraga*, *Prosopis*, *Prosopidastrum*,

and *Schinus*. Burrows are readily recognized by their typical semicircular entrances about 10 cm high, well curved dorsally and flat below, and usually placed under *Atriplex* bushes. Other small mammals found together with *T. kirchnerorum* in owl pellets include the didelphid marsupial *Lestodelphys halli*, cricetid rodents *Akodon iniscatus*, *Eligmodontia* sp, *Euneomys chinchilloides*, *Graomys griseoflavus*, and *Reithrodon auritus*, and the caviomorph rodents *Microcavia australis* and *Ctenomys* sp. (Teta et al. 2014).

REMARKS: M. H. Gallardo et al. (2009:158) recorded the type locality as “Estancia La Porfía (43°13'51.6", 68°38'49.1", 517 masl . . .) approximately 20 km NE of Los Adobes, on provincial route 58.” Phylogenetic analyses of mtDNA indicate that *T. kirchnerorum* is sister to the two clades identified within *T. barrerae* among members of the genus (A. A. Ojeda 2010; M. H. Gallardo et al. 2013). However, phylogenetic analyses including larger data sets of all species in the genus remain necessary. The karyotype is similar to that of *T. barrerae* with $2n=102$, with approximately 32 pairs of metacentric and submetacentric chromosomes and 18 pairs of subtelocentric elements (Teta et al. 2014). M. H. Gallardo et al. (2009) described sperm morphology as smaller in size but similar in shape to that of *T. barrerae*.

Tympanoctomys loschalchalerosorum (Mares, Braun, Barquez, and Díaz, 2000)

Chalchalero Viscacha Rat

SYNONYM:

Salinoctomys loschalchalerosorum Mares, Braun, Barquez, and Díaz, 2000:6; type locality “26 km SW Quimilo, Departamento Chamental, La Rioja Province, Argentina (30°02'43.4"S 65°31'13.4"W; elevation 581 m.”

Tympanoctomys loschalchalerosorum: Barquez, Díaz, and Ojeda, 2002:38; first use of current name combination.

DESCRIPTION: Medium-sized species, with total length 255–275 mm. Tail long (111–119 mm), >75% of head and body length (144–156 mm); ears short and rounded (16–17 mm); hindfeet short (28–30 mm). Dor-

sal color brown-black dorsally and white ventrally; hairs with pale gray basal band. Proximal one-third to half of tail bicolored; terminal tuft black. Bristle bundles present but not well developed, and composed of soft hairs. Crani-ally, characterized by distinct groove and small flange for infraorbital nerve, large interpremaxillary foramen, supra-occipital with distinct medial crest, short palate that extends only to middle of M2s, wide and flattened paroccipital processes completely appressed to bulla, sharply acute angle of suture between jugal and zygomatic process of maxilla, distinct “knob” posterior to suture between jugal and zygomatic process of maxilla, large and inflated auditory bullae, posterior opening of alisphenoid canal and foramen ovale present with latter displaced toward bulla, foramen magnum directed distinctly downward, light orange upper incisors with narrow white edge, and M3 with well-developed metacone and hypocone.

DISTRIBUTION: *Tympanoctomys loschalchalerosorum* is only known from its type locality, in the Chaco Phytogeographic Province of La Rioja province, Argentina.

SELECTED LOCALITIES (Map 549): ARGENTINA: La Rioja, 26 km SW of Quimilo (type locality of *Salinoctomys loschalchalerosorum* Mares, Braun, Barquez, and Díaz).

SUBSPECIES: *Tympanoctomys loschalchalerosorum* is monotypic.

NATURAL HISTORY: *Tympanoctomys loschalchalerosorum* inhabits perisaline shrublands in a salt basin associated with the Salinas Grandes. The area is in to the Chaco Phytogeographic Province, in a thorn scrub island dominated by cactus, shrubs, and grasses (Amaranthaceae, Scrophulariaceae, Gramineae, Asteraceae, Solanaceae, Fabaceae, Leguminosae) that arise within a salt flat. Like the other species of *Tympanoctomys*, it is associated with halophytic plants. The mounds of this species are not as obvious as are those of the other two, but large nests with accumulated grasses occur in the center of a burrow system. A pregnant female with two embryos was collected in July (Mares et al. 2000). Ectoparasites are unknown.

REMARKS: The karyotype is unknown. No information on conservation status is available.

Gazetteer of Localities

THIS VOLUME follows the same protocol used by A. L. Gardner for volume 1 of this series on South American mammals, namely, localities are arranged alphabetically by country and by major political unit (state, district, province, region, or department) within each country, except for French Guiana and Trinidad and Tobago. Place names are arranged alphabetically according to the name of the reported site of capture or to the nearest place name. Different sites of capture referenced to the same place name are arranged from north to south and from west to east. Variants of place names, including errors and alternative spellings used by the authors cited, are placed in their appropriate alphabetical sequence. Note that new high-level administrative units (departments, provinces, regions, or states) have been added to some countries so that the same locality may be placed in a different unit in volume 1 than here. For example, Peru recently changed its highest level administrative divisions from Departamento to Región plus the Provincia de Lima.

The first volume in this series provided coordinates in degrees and minutes, but we have adopted decimal degree designations, in part because the latter are easier to map using various Global Information Systems software or Google Earth. The coordinates themselves come from a variety of sources, including handheld GPS units now in near-universal use by field investigators. The museum collections participating in the Mammal Networked Information Systems project (MaNIS, <http://manisnet.org/>; which has now been transitioned to VertNet, <http://vertnet.org/>) have retrospectively georeferenced locali-

ties based on guidelines developed for that project (see <http://manisnet.org/GeorefGuide.html>). These collection databases thus served as the source for many of the coordinates listed herein. Other coordinate sets are those given in the gazetteer of volume 1 but converted to decimal degrees. These are largely based on the U.S. Board on Geographic Names or on information contained in the Ornithological Gazetteers of the Neotropics series available through the Bird Department of the Museum of Comparative Zoology at Harvard University (expanded and corrected for Brazil by Vanzolini 1992). This series of gazetteers is particularly useful for older place names that may no longer be in use. Finally, coordinates were also obtained from a number of different website databases, such as the U.S. Board on Geographic Names (<http://geonames.usgs.gov>), the Alexander Digital Library (<http://middleware.alexandria.ucsb.edu/>), Glosk (<http://www.glosk.com/>), Google Earth (<http://earth.google.com/>), and especially Geonames (<http://www.geonames.org>), or from the gazetteers of many publications or papers citing particular localities. The datum for each coordinate pair is not given, as it is unknown for the majority of coordinates cited. This important piece of information is available for localities georeferenced by the MaNIS protocol. English or metric measures of distances and elevations are given as provided in the original citation or locality designation. The political division wherein a specific locality is placed has been updated to reflect current usage if such has changed since the original citation (specimen label or publication).

- Genus *Scapteromys*
S. aquaticus Argentinean Swamp Rat
S. tumidus Uruguay Swamp Rat
- Genus *Thalpomys*
T. cerradensis Cerrado Akodont
T. lasiotis Hairy-eared Akodont
- Genus *Thaptomys*
T. nigrita Ebony Akodont
- Tribe Ichthyomyini
- Genus *Anotomys*
A. leander Earless Water Mouse
- Genus *Chibchanomys*
C. orcesi Orces's Andean Water Mouse
C. trichotis Northern Andean Water Mouse
- Genus *Ichthyomys*
I. hydrobates Silver-bellied Ichthyomyine
I. pitieri Pittier's Ichthyomyine
I. stolzmanni Stolzmann's Ichthyomyine
I. tweedii Tweedy's Ichthyomyine
- Genus *Neusticomys*
N. ferreirai Ferreira's Ichthyomyine
N. monticolus Montane Ichthyomyine
N. mussoi Musso's Ichthyomyine
N. oyapocki Guianan Ichthyomyine
N. peruviensis Peruvian Ichthyomyine
N. venezuelae Venezuelan Ichthyomyine
- Tribe Oryzomyini
- Genus *Aegialomys*
A. galapagoensis Galapagos Aegialomys
A. xantheolus Yellowish Aegialomys
- Genus *Amphinectomys*
A. savamis Ucayali Water Rat
- Genus *Cerradomys*
C. goytaca Goytacá Cerradomys
C. langguthi Langguth's Cerradomys
C. maracajuensis Maracaju Cerradomys
C. marinhus Marinho's Cerradomys
C. scotti Lindbergh's Cerradomys
C. subflavus Flavescent Cerradomys
C. vivoi Vivo's Cerradomys
- Genus *Drymoreomys*
D. albimaculatus
. White-throated Montane Forest Rat
- Genus *Eremoryzomys*
E. polius Gray Eremoryzomys
- Genus *Euryoryzomys*
E. emmonsae Emmons's Euryoryzomys
E. lamia Buffy-sided Euryoryzomys
E. legatus Tarija Euryoryzomys
E. macconnelli Macconnell's Euryoryzomys
E. nitidus Elegant Euryoryzomys
E. russatus Russet Euryoryzomys
- Genus *Handleyomys*
H. fuscatus
. Colombian Western Andes
. Cloud Forest Mouse
H. intectus
. Colombian Central Andes
. Cloud Forest Mouse
- Genus "Handleyomys"
"H." *alfaroi* Alfaro's Rice Rat
- Genus *Holochilus*
H. brasiliensis Brazilian Marsh Rat
H. chacarius Chacoan Marsh Rat
H. sciureus Amazonian Marsh Rat
H. venezuelae Venezuelan Marsh Rat

H. vulpinus Crafty Marsh Rat
 Genus *Hylaeamys*
H. acritus Bolivian Hylaeamys
H. laticeps Atlantic Forest Hylaeamys
H. megacephalus
 Azara's Broad-headed Hylaeamys
H. oniscus
 Northern Atlantic Forest Hylaeamys
H. perenensis Western Amazonian Hylaeamys
H. tatei Tate's Hylaeamys
H. yunganus Amazonian Hylaeamys
 Genus *Lundomys*
L. molitor Lund's Water Rat
 Genus *Melanomys*
M. caliginosus Dusky Rice Rat
M. columbianus Colombian Dusky Rice Rat
M. robustulus Robust Dark Rice Rat
M. zunigae Zuniga's Dark Rice Rat
 Genus *Microakodontomys*
M. transitorius Transitional Colilargo
 Genus *Microroryzomys*
M. altissimus Páramo Colilargo
M. minutus Montane Colilargo
 Genus *Mindomys*
M. hammondi Hammond's Mindomys
 Genus *Neacomys*
N. dubosti Dubost's Spiny Mouse
N. guianae Guianan Spiny Mouse
N. minutus Minute Spiny Mouse
N. musseri Musser's Spiny Mouse
N. paracou Paracou Spiny Mouse
N. spinosus Common Spiny Mouse
N. tenuipes Slender Foot Spiny Mouse
 Genus *Nectomys*
N. apicalis Western Amazonian Water Rat
N. grandis Magdalena Water Rat
N. palmipes Trinidad Water Rat
N. rattus Common Water Rat
N. squamipes Atlantic Water Rat
 Genus *Nephelomys*
N. albigularis White-throated Nephelomys
N. auriventer Golden-bellied Nephelomys
N. caracolus Costal Cordilleran Nephelomys
N. childi Child's Nephelomys
