Macrophages are part of the innate immune response to injury. As they are recruited to the site of injury, macrophages act by phagocytizing bacteria and damaged tissue. They also release cytokines and growth factors that initiate and promote healing. One study demonstrated that coculture of MSCs with specific macrophage subtypes enhanced osteogenic differentiation of MSCs. Antiinflammatory macrophages (M2) promoted osteogenic differentiation of MSCs better than proinflammatory macrophages (M1) or immature macrophages (M0) [128]. In another study, M1 macrophages increased osteogenic differentiation of MSCs more dramatically than M2 macrophages [129]. These two studies are seemingly contradictory, although in both studies, coculture of MSCs with M1 and M2 macrophages enhanced osteogenic differentiation, but the importance of macrophage polarity [130] and the molecular signaling pathways involved have yet to be clearly elucidated.

In practice, macrophages have been stimulated by the release of a macrophage-recruiting agent and platelet-rich plasma from a gelatin hydrogel scaffold to a defect site in the ulna bone in a rat model demonstrated enhanced bone healing [131]. Mechanistic studies that clarify the role of macrophages in bone healing are still limited.

T Cells

The adaptive immune response also has a role in bone regeneration in the form of activated T cells. T lymphocytes regulate callus formation in bone healing by secretion of pro-osteogenic cytokines (tumor necrosis factor-α and interleukins [IL]-6 and -1β). Coculture of activated T cells with MSCs enhances osteogenic differentiation owing to the osteogenic effect of soluble factors released by $CD4^+$ T lymphocytes [132]. Furthermore, there is a differential effect on osteoblast maturation from pro inflammatory and antiinflammatory $CD4^+$ T-cell subsets. $CD4^+$ T-helper 17—specific cytokines (IL-17A and IL-17F) increased ALP activity in MSCs, and IL-17A in particular works synergistically with BMP-2 to increase calcium deposition by MSCs.

Hair Cell Regeneration in the Inner Ear and Lateral Line

Matthew W. Kelley[1], *Jason R. Meyers*[2]

INTRODUCTION

The ability to detect sounds and motion is mediated through mechanosensory hair cells located in the inner ears of all vertebrates. The basic cellular structures of hair cells are similar across vertebrate classes, but mammals are unique in their inability to regenerate hair cells that have been lost as a result of aging or trauma. As a result, mammals are the only vertebrates that incur lasting deficits in hearing or balance. In this chapter, we will describe the process of hair cell regeneration that occurs in nonmammalian species, explore the factors that prevent regeneration in mammal inner ears, and discuss efforts to induce regeneration using transgenic mouse models and gene therapy.

STRUCTURE OF THE INNER EAR

The inner ear can be grossly divided into three structures: the membranous labyrinth, a series of epithelial-lined fluid filled chambers derived from the otocyst; the bony labyrinth, a dense bony structure that surrounds and protects the membranous labyrinth; and the eighth cranial nerve, also called the vestibulocochlear nerve, which provides afferent innervation to all sensory structures within the inner ear (Fig. 49.1). The membranous labyrinth can be further subdivided into a ventral auditory section that contains the cochlea and a dorsal vestibular section that contains the three semicircular canals that act to mediate balance, as well as two otolithic organs, the saccule and utricle, which have a role in perception of linear acceleration and gravitation forces. Each of these structures contains a sensory epithelium that is composed of mechanosensory hair cells and a population of surrounding epithelial cells referred to as supporting cells. Vestibular sensory epithelia appear as rounded or oblong patches containing thousands of mechanosensory hair cells. The overall structure of these sensory patches is grossly similar among all vertebrate classes. In contrast, auditory epithelia show a greater degree of diversity; some develop as narrower, elongated stripes of cells. The most extreme example of this is the mammalian auditory sensory epithelia, also called the organ of Corti, which features four or five rows of hair cells extending up to 70 mm [1], which are functionally and morphologically divided into one row of inner hair cells that detect auditory stimuli and three or four rows of outer hair cells that serve as a mechanical amplifier. Finally, aquatic vertebrates such as fishes and amphibians have an additional hair cell-based sensory system called the lateral line, which is composed of a series of canals and sensory patches arrayed along the outer surface of the head and body, and which enables the detection of flow and vibrations in the surrounding water.

Mechanosensory hair cells are so named because of the presence of a modified bundle of microvilli, referred to as stereocilia, that project from the lumenal surface of each cell [2,3]. The morphology of the bundle is characterized by an asymmetric staircase pattern in which the lengths of the individual stereocilia increase toward one end of the bundle. Deflection of the bundle in the direction of the longest stereocilia leads to opening of transduction channels, the influx of positively charged ions, and subsequent increases in the rate of neurotransmitter release. Each hair cell

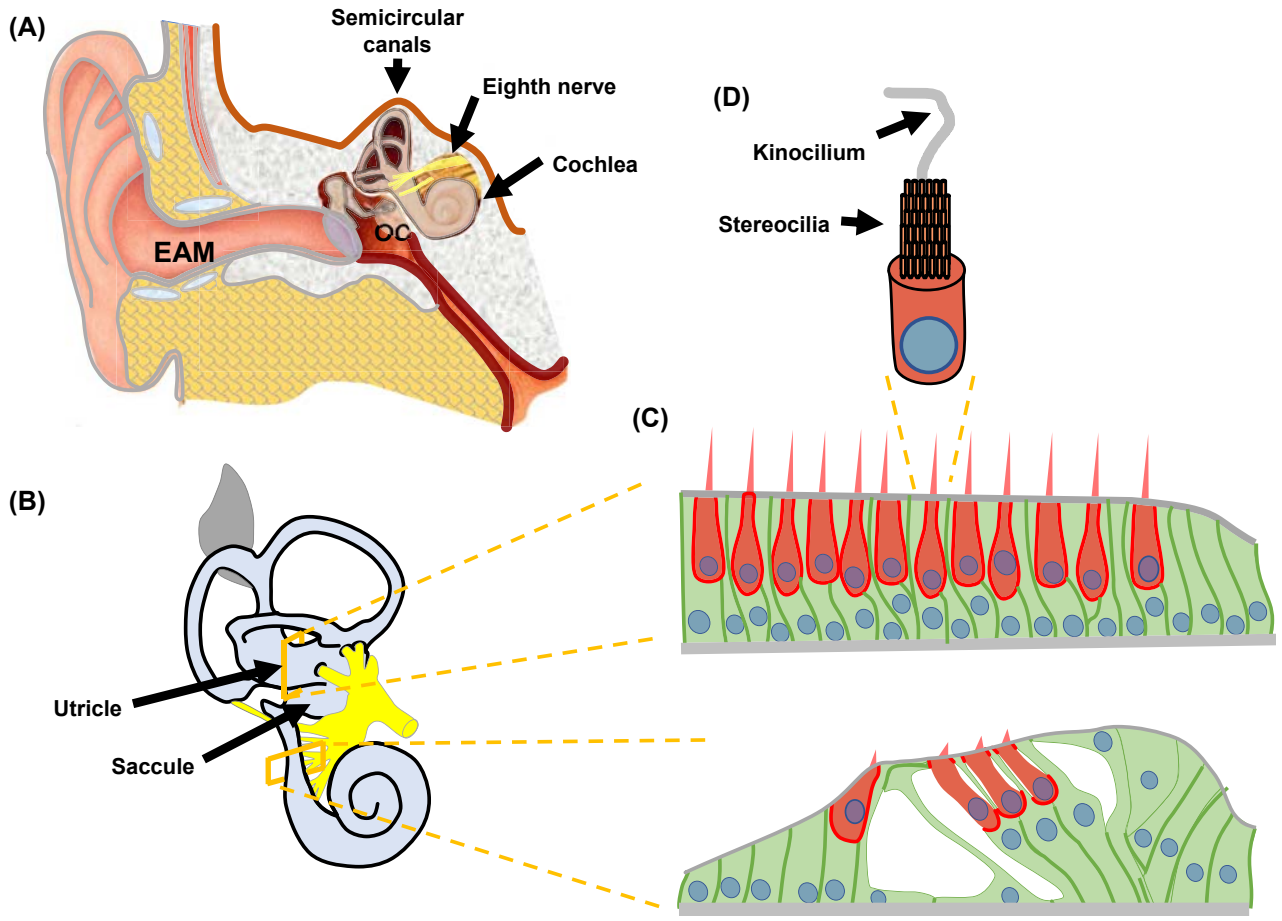

FIGURE 49.1 Overview of the inner ear. (A) Cut away view of the human ear. The pinna and external auditory meatus (EAM) transmit sound waves to the tympanic membrane located at the central end of the EAM. Vibration of the tympanic membrane is amplified through the middle ear ossicles (OC). The footplate of the stapes vibrates the footplate of the stapes, which creates a pressure wave that travels along the cochlear spiral. The three semicircular canals, along with the utricle and saccule, mediate sense of balance, acceleration, and gravity. Signals generated in the inner ear are carried to the central nervous system through separate branches of the eighth nerve. (B) View of the inner ear illustrating the three semicircular canals, cochlear spiral, and endolymphatic duct (*dark gray*). The branches of the eighth nerve are illustrated in *yellow*. (C) Schematic cross-sections of the sensory epithelia in the utricle (*upper image*) and cochlea (*lower image*). Hair cells are *red* and supporting cells are *green*. In the utricle, hair cells are arranged in a large patch whereas in the cochlea, hair cells are arranged in four or five rows that extend along the length of the cochlear spiral. (D) Schematic of a single utricular hair cell illustrating the staircase pattern of the stereocilia (*orange*) and the single kinocilium (*gray*).

forms synapses with peripheral axons from one or more afferent neurons that transmit changes in the rate of neurotransmitter release into brain stem nuclei and higher central nervous system structures, where these signals are interpreted as perceptions of sound, vibration, or movement.

HAIR CELL LOSS

A number of factors have a role in the death of hair cells. Foremost among these is aging. According to the National Institute on Deafness and Other Communication Disorders, nearly 35% of all individuals will have a significant hearing loss by age 65 years, and this number will increase to over 50% by age 80 years. Similarly, virtually all individuals lose the ability to perceive frequencies above 17 kHz by age 25 years. The underlying cellular or genetic mechanisms that lead to this progressive hair cell loss remain largely unknown, although mutations in some genes, in particular *Cdh23*, have been shown to cause age-related hearing loss in mice [4]. Similar declines in hair cell numbers have also been reported in aged vestibular epithelia; however, a strict correlation between hair cell loss and loss of vestibular function has not been established [5].

Environmental factors can significantly accelerate the rate of hair cell loss. Exposure to loud noises, even in the short term, can lead to hair cell death from both mechanical damage and neurotoxicity from calcium, resulting in hearing loss. Toxins such as copper and *Gingko biloba* have also been shown to be harmful to hair cells [6,7]. In addition, several medicines, most notably aminoglycoside antibiotics and the anticancer drug cisplatin, have been shown to kill hair cells [8]. As is the case for age-related hearing loss, the cellular basis for hair cell death after exposure to any of these stressors is not particularly well-understood, but metabolic stress and generation of reactive oxygen species, may be important mediators [9]. This is particularly true for outer hair cells in the organ of Corti, which are highly sensitive to all environmental stressors. Outer hair cells are motile cells that generate cellular contractions in response to stimulation. Because these contractions typically occur at the optimal frequency for each cell, some cells may need to contract repeatedly at rates as high as 20 kHz. This high level of activity may produce a chronic metabolic stress that makes the outer hair cells particularly sensitive to additional external challenges.

HISTORY OF HAIR CELL REGENERATION

As discussed in the Introduction, in mammals, hair cells are primarily generated during the embryonic or early postnatal period, depending on the species. Therefore, in adults, hair cell loss is permanent. Before the 1980s, it was assumed that similar limitations existed in the inner ears of all other vertebrates. However, examinations of the inner ears of sharks and rays, which grow indeterminately, indicated an ongoing increase in the number of hair cells in the inner ear sensory patches of these animals. In several species of sharks, the increase in the number of hair cells is remarkable; more than 180,000 cells are added to just a single inner ear sensory patch, the macula neglecta, over the life of an individual animal [10]. Subsequent studies in amphibians used a mitotic tracer, tritiated-thymidine, to demonstrate that new hair cells in the inner ears of these animals were generated through cellular proliferation of surrounding cells [11]. These results motivated additional studies using chickens, homothermic vertebrates with determinant growth, and an elongated auditory structure, the basilar papilla (BP), which is functionally similar to the mammalian cochlea. After induction of hair cell damage using prolonged exposure to loud pure tones, initial experiments used scanning electron microscopy to image the BP [12]. Whereas BPs imaged immediately after noise exposure showed widespread hair cell loss and damage, analysis of similar BPs after a 2- to 4-week recovery period illustrated nearly complete recovery of the hair cell population. Moreover, recovery of auditory function tracked closely with morphological recovery, demonstrating that the new hair cells were functional and that the rest of the auditory system remained intact after exposure to noise. Finally, introduction of a mitotic tracer demonstrated that at least some of the regenerated hair cells arose from proliferation of the surrounding supporting cells [13,14]. To determine whether this regenerative ability is restricted to young birds, similar experiments were performed in aged quails [15]. Even quails that were near the end of their expected life span (3 years) were able to regenerate hair cells and recovery auditory function, which demonstrated that this ability is retained throughout the life of the animal.

Subsequent studies at the cellular level identified two different mechanism for the formation of regenerated hair cells (Fig. 49.2). As discussed previously, some new hair cells arise from the re-entry and subsequent division of supporting cells, but in other cases, supporting cells are able to convert into hair cells directly, a process referred to as transdifferentiation [16,17]. These results demonstrate that in birds, supporting cells can act as hair cell progenitors. This suggests that these cells retain some stem or progenitor capacity throughout the life of the animal. Whether every supporting cell can act as a stem or progenitor cell or whether this ability is limited to a subset of cells within the epithelium has not been determined. Interestingly, the response of supporting cells, in terms of whether they transdifferentiate or reenter the cell cycle, is spatially segregated; cells located on one edge of the BP are more likely to transdifferentiate whereas those on the other edge are more likely to re-enter the cell cycle [18]. The molecular and/or functional bases for these differences have not been determined.

A final consideration in the avian system is the unexpected observation that vestibular epithelia undergo constant turnover of hair cells; old cells are replaced with new ones such that the average life of a hair cell in a vestibular sensory epithelium is approximately 1 month [19]. This process may be a compromise of the ancestral trait of ongoing addition of hair cells, as seen in fish and amphibians, with the derived trait of determinant growth as occurs in birds and mammals. However, this also demonstrates that vestibular epithelia can efficiently maintain all of the neuronal connections required for normal function even as hair cells are being continually lost and regenerated.

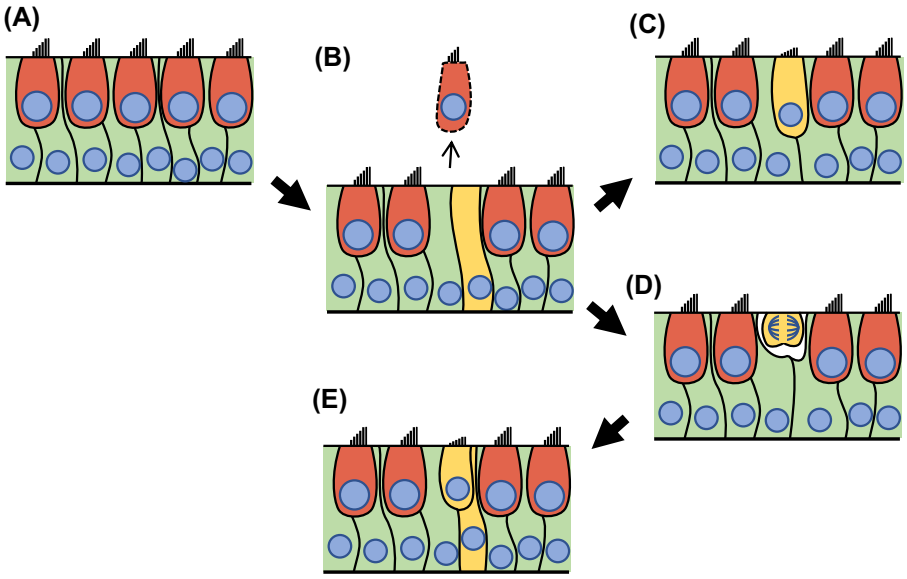

FIGURE 49.2 Modes of hair cell regeneration in the chick basilar papilla. (A) Cross-sectional view of an idealized basilar papilla. Hair cells (*red*) and supporting cells (*green*) are present in a pseudostratified epithelium. (B) In response to an insult, hair cells are ejected from the epithelium (*small arrow*), creating a gap in the mosaic of hair cells and supporting cells and eliciting a response from one or more of the remaining supporting cells (*yellow*). (C) Transdifferentiation. Under some circumstances one of the remaining supporting cells will directly transform into new hair cells (*yellow*). This results in a decrease in the number of supporting cells. (D) Proliferative regeneration. The second possible response is for a remaining supporting cell (*yellow*) to undergo mitotic proliferation to generate new progenitor cells. (E) These cells then go on to form new hair cells and supporting cells (*yellow*).

SPONTANEOUS HAIR CELL REGENERATION IN MAMMALIAN VESTIBULAR ORGANS

The discovery of spontaneous hair cell regeneration in birds sparked a re-examination of the regenerative potential within adult mammalian vestibular and auditory epithelia. As a first step, work from Warchol et al. [20] and Forge et al. [21] demonstrated limited proliferation of supporting cells in cultured utricles from Guinea pigs and humans, as well as the presence of hair cells with bundles that appeared immature in Guinea pigs. Although these results were compelling, the number of potential new cells was small and a preponderance of clinical data clearly suggests that meaningful vestibular hair cell regeneration does not occur in adult humans. In contrast to the findings in the utricle, similar studies in the adult mammalian auditory system confirmed the absence of hair cell regeneration in this epithelium [22]. Despite the importance of the findings in the utricle, further examination of potential hair cell regeneration in this structure was slowed by difficulty in reliably killing hair cells in the vestibular system in vivo.

In the auditory system, two different approaches have been developed to kill hair cells reliably and reproducibly: exposure to loud sounds and administration of aminoglycoside antibiotics such as neomycin or kanamycin, alone or combined with a loop-diuretic such as furosemide [23]. The effects of both of these treatments have been studied extensively and have led to precise protocols that yield consistent results. Moreover, because the auditory system is organized along a tonotopic gradient, damage can be mapped to particular regions of the auditory epithelium based on the results of tests for auditory sensitivity at different frequencies [24]. Because vestibular epithelia are not stimulated by auditory vibrations, exposure to loud sound does not cause hair cell loss, and whereas the sensitivity of vestibular hair cells to aminoglycosides is comparable to auditory hair cells in vitro, systemic treatments result in variable hair cell death. Moreover, many animals that exhibit significant vestibular loss of function after a chemical insult will show progressive and marked recovery over time as a result of functional compensation based on visual input [25]. As a result, between the late 1980s and the early 21st century, it was virtually impossible to assess the extent of hair cell regeneration accurately in vestibular epithelia in vivo because there was no way to kill the existing hair cells consistently. However, the situation changed with the development of several lines of transgenic mice beginning around 2010. First, lines were developed in which genes that are expressed specifically in supporting cells drive the expression of cre recombinase (cre). When one of these lines is combined with one of several reporter lines in which expression of cre leads to the permanent expression of a fluorescent molecule such as green fluorescent protein (GFP), it is possible to differentiate regenerated hair cells that will express GFP because they arise from supporting cells, from nonregenerated hair cells that are GFP-negative [26]. In addition, in 2013, Rubel and colleagues [27] developed a mouse model in which the promoter

for the hair cell–specific gene *Pou4f3* is used to drive expression of the human diphtheria toxin receptor (Dtr). Because the human Dtr is approximately 10,000 times more sensitive to diphtheria toxin [28] compared with the mouse Dtr, this line can be used to kill vestibular (and auditory) hair cells effectively and consistently by giving mice injections of diphtheria toxin.

In fact, injection of diphtheria toxin in this line consistently kills approximately 94% of hair cells in the utricle by 14 days after treatment [27]. Animals killed at specific recovery times between 15 and 180 days showed a modest recovery of hair cells, up to approximately 17% of the original number, and the loss of supporting cells and lack of incorporation of mitotic markers demonstrated that these cells arise from the conversion of surrounding supporting cells into hair cells. In addition, a small percentage of regenerated hair cells arose as a result of mitotic division; the number of mitotically generated cells decreased rapidly as animals aged past the very early postnatal period [27,29]. These results provide definitive evidence that a limited amount of spontaneous hair cell regeneration can occur in adult mammalian vestibular epithelia. However, whether the regenerated hair cells lead to recovery of function remains to be determined.

ROAD BLOCKS TO REGENERATION

An intriguing question which, if answered, might provide insights regarding the development of clinical strategies, is: Why do mammals have a greatly reduced capacity to regenerate hair cells, including a complete loss in the auditory system? At a systems level, one of the most appealing hypotheses is that the increased complexity of the organ of Corti relative to other auditory epithelia, and in particular the highly differentiated state of the supporting cells within the organ of Corti, has resulted in those cells losing the ability to de-differentiate, as might be required to change fate or re-enter the cell cycle. Although the basis for such a loss is not clear, one possibility would be alterations in the epigenetic landscape of the supporting cells, leading to an inability to reactivate important genes required for one or more aspects of regeneration [30]. There is ample evidence from other systems that is consistent with a negative correlation between cellular differentiation and plasticity, sometimes correlated with epigenetic changes, which supports this idea [31]. However, a noteworthy caveat is that this hypothesis does not explain why regenerative ability would also be greatly decreased in the vestibular system where supporting cells appear to be considerably less differentiated compared with similar cells in the organ of Corti and are comparable to those in nonmammalian vestibular organs. Still, it is possible that changes in the structural, transcriptional, or epigenetic state of auditory supporting cells might also lead to similar changes in other inner ear supporting cells.

The reduced capacity for mammalian supporting cells to regenerate hair cells seems to be tied to their own maturation. Generally, loss of cochlear or vestibular hair cells during embryonic or perinatal periods results in supporting cell proliferation and hair cell regeneration [29,32], although the capacity for regeneration decreased rapidly with postnatal age. Corwin and colleagues provided intriguing, albeit correlative, data suggesting that a structural component of supporting cells, dense actin belts located just beneath the lumenal surfaces of supporting cells, may act to inhibit the ability of those cells to undergo a regenerative response [33,34]. At early postnatal time points, lumenal cortical actin in supporting cells creates a thin circumferential belt located close to the lateral cell membrane. As discussed, supporting cells in the utricle generate a significant regenerative response, including cellular proliferation, during this same period. However, as an animal ages, the width of supporting cell lumenal actin belts increases while regenerative ability decreases. Examination of actin belts in non-mammalian vertebrates, including birds and fish, revealed thin belts similar to those observed in newborn mammals, regardless of the age of the animal. Unfortunately, it has not yet been possible to disrupt these belts to demonstrate whether they actually prevent supporting cells from initiating a regenerative response. The ability of postnatal supporting cells to respond to growth factors and extracellular matrix components in culture also decreases rapidly [35,36]. Thus, the lack of mammalian regeneration appears to be a trait acquired by the maturation of supporting cells.

INSIGHTS FROM DEVELOPMENTAL BIOLOGY

Because meaningful spontaneous regeneration does not occur in mammals, it seems likely that manipulation of the system, possibly through pharmacological and/or genetic approaches, will be necessary to induce a response. To develop an appropriate strategy, it will be necessary to identify the molecular and genetic pathways that regulate the key steps in a regenerative response. Based on the process that occurs during hair cell regeneration in non-mammalian vertebrates, hair cell regeneration can come from the nonmitotic conversion of supporting cells into

hair cells or the proliferation of supporting cells followed by differentiation of some of the progeny into hair cells. Because neither proliferation of supporting cells nor differentiation into hair cells occurs at a high rate in adult mammalian hair cell epithelia, one possible way to identify the factors that regulate each of these events is to examine them during development.

Significant progress has been made in understanding both proliferation and differentiation, but our understanding of the regulation of differentiation is more advanced and therefore will be discussed first. One of the initial findings was actually related to a genetic signal that inhibits rather than promotes hair cell formation (Fig. 49.3). The Notch signaling pathway is an ancient developmental process that regulates the number of cells that assume a particular cell fate through cell-cell based lateral inhibition [37]. Briefly, transmembrane Notch receptors are activated through binding similarly membrane-bound ligands called Deltas or Jaggeds. Because both ligands and receptors are membrane bound, cell−cell contact is required for receptor activation. After binding, Notch molecules are cleaved to generate a Notch intracellular domain (NICD) molecule that is then translocated to the nucleus of the cell, where it forms a transcriptional complex with other factors including Rbpj. The results of Notch activation vary, depending on the biological system, but a common effect is the inhibition of cellular differentiation through the induction of expression of a class of inhibitory transcription factors that includes Hes1, Hes5, and Hey2. In the developing cochlea, Notch1 is expressed broadly in the progenitor cells that will develop as both hair cells and supporting cells [38,39]. As cells begin to develop as hair cells, they upregulate expression of two Notch ligands, Jagged2 and Delta1. Binding of these ligands leads to the generation of NICDs and expression of Hes genes in surrounding cells [38,40,41]. Deletion of any component of this signaling pathway or prevention of Notch cleavage by pharmacological γ-secretase inhibitors results in an increase in the number of cells that develop as hair cells, which demonstrates that the Notch signaling pathway acts as an inhibitor of hair cell development [38,42]. Whether this pathway is still active in the adult auditory epithelium and could therefore have a role in inhibiting hair cell regeneration, is a matter of debate [43−45]. However, some initial results to be discussed subsequently suggest that this is possible.

The demonstration of a role for Notch signaling also provided clues regarding some of the genes that might have a positive role in inducing hair cell formation. As discussed, Notch is part of an ancient signaling pathway that includes Hes and Hey transcription factors. These transcription factors are part of a large family that share common structural motifs including a basic DNA binding domain (b) and a helix−loop−helix (HLH) dimerization domain. Other members of the basic HLH family include molecules that promote cellular differentiation [46]. Screening for basic HLHs expressed in developing hair cells indicated that Atoh1 might be a strong candidate. Results of both in situ hybridization and mouse reporter line studies demonstrated that Atoh1 turns on in a large number of cochlear progenitor cells before hair cell development, but by embryonic day (E)16 to E17 in the mouse, expression is restricted to the developing hair cells [47,48]. More important, genetic deletion of *Atoh1* leads to a complete absence of all inner ear hair cells whereas forced expression of Atoh1 in the embryonic inner ear can induce cells to adopt a hair cell fate [47,49,50]. Finally, lineage tracing experiments demonstrated that the number of cells that initially express *Atoh1* is greater than the number that ultimately develop as hair cells and that activation of Notch signaling has a critical role in determining which cells will maintain expression of Atoh1 [51]. Based on these results, Atoh1 has been established as a strong inducer of hair cell formation.

Following from these experiments, both expression of Atoh1 and modulation of Notch signaling have been examined as possible mechanisms to induce hair cell regeneration in the mature inner ear. Although promising in some respects, the results have unfortunately, been limited. To assess the ability of cells in different regions of the inner ear to develop as hair cells, transgenic mice in which broad expression of Atoh1 can be induced pharmacologically were generated by two laboratories. The results indicated that whereas forced expression of Atoh1 induces ectopic hair cell formation in embryonic or neonatal cochlea, this ability is completely lost in adult inner ear cells [52,53]. Furthermore, even in neonatal tissue, hair cells that were formed in response to forced expression of Atoh1 failed to mature completely. The reasons for both lack of hair cell maturation and loss of responsiveness to Atoh1 are unclear. The most likely explanation for the defects in hair cell maturation are that other factors (either co-factors for Atoh1 or possibly additional transcription factors) are required to drive hair cell maturation. This hypothesis was supported by a study showing that the efficacy and maturity of hair cells derived from embryonic stem cells could be significantly increased if the cells were forced to express three relatively inner ear−specific transcription factors: Atoh1, Gfi1, and Pou4f3 [54]. Gfi1 and Pou4f3 are expressed in hair cells soon after Atoh1, but both loss-of-function and gain-of-function experiments indicated that neither Gfi1 nor Pou4f3 is necessary or sufficient for initial hair cell formation [55,56]. Regardless, these results suggest that the combination of these three factors may have the ability to induce more mature hair cells in an adult inner ear epithelium, although this possibility has not yet been directly tested.

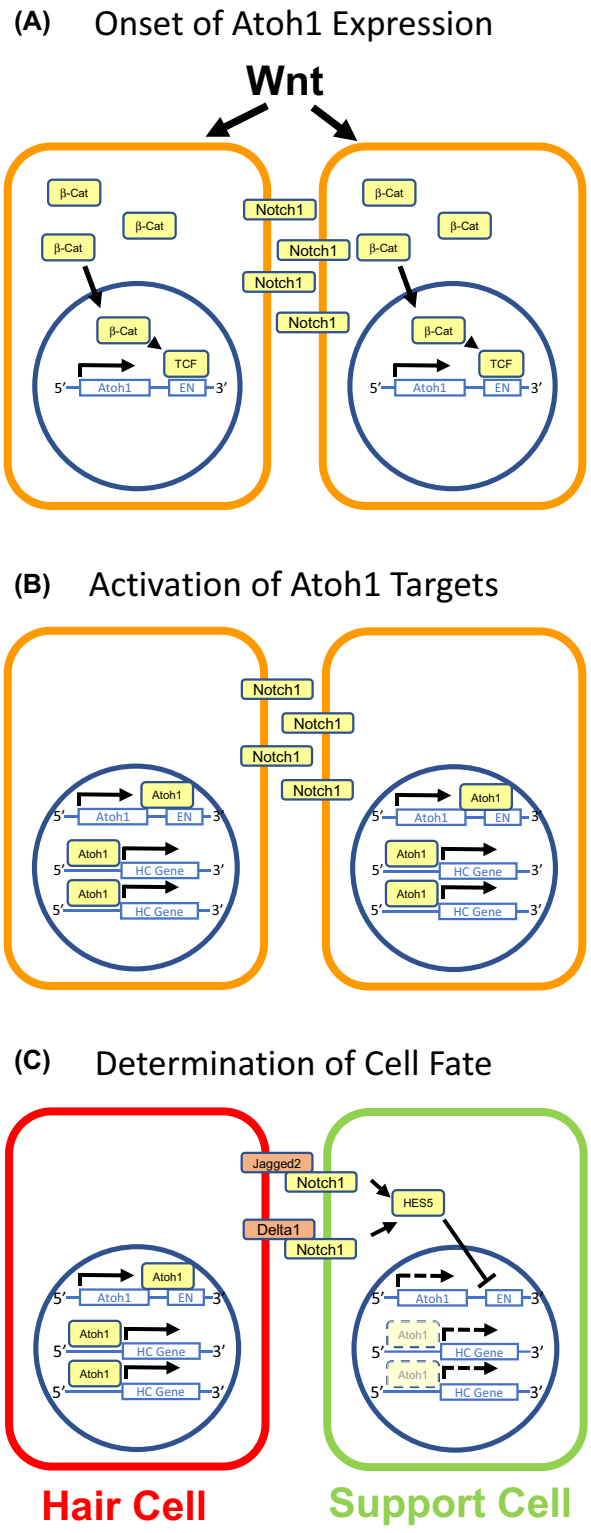

FIGURE 49.3 Regulation of cell fates during inner ear development. Three stages of molecular signaling interactions are illustrated. (A) An initial period of Wnt signaling leads to stabilization and subsequent nuclear-translocation of β-catenin (β-cat). In the nucleus, β-catenin induces expression of TCF/Lef transcription factors that bind directly to an *Atoh1*-3′ enhancer leading to the initial expression of *Atoh1*. (B) Atoh1 protein binds to multiple DNA recognition sites, including one in the Atoh1-3′ enhancer and others in uncharacterized hair cell (HC) genes. (C) In some cells, expression of two Notch ligands, Delta1 and Jagged2, is initiated. Delta1 and Jagged2 bind to Notch1 receptors on neighboring cells, causing the upregulation of inhibitory transcription factors such as HES5. HES5 inhibits the expression of Atoh1, resulting in a downregulation of Atoh1 target genes, including *Atoh1*. Cells that maintain expression of Atoh1 go on to develop as hair cells whereas cells in which Atoh1 is down-regulated develop as supporting cells.

Regarding the loss of ability of Atoh1 to induce hair cells in more mature inner ear cells, the most likely explanation for this change is progressive epigenetic changes that prevent Atoh1 from binding to and activating essential downstream target genes. Although this type of epigenetic modulation has been reported in other cell types, no definitive studies have been performed in the inner ear. Other possibilities include downregulation of essential co-factors or required post-translational modifications that do not occur in more mature cells.

The results described earlier focused on the cochlear epithelium; however, an experiment demonstrated consistent, although not entirely similar, results for the vestibular epithelia. As is true for the cochlea, forced expression of Atoh1 induced hair cell formation in utricular epithelia at early postnatal ages and the efficacy of this effect decreased over time with 75% fewer hair cells formed in response to Atoh1 expression at postnatal day 21 (P21) versus the same level of induction at P0 [57]. However, the formation of new hair cells in the utricle at P21 contrasted with results from the cochlea in which no new hair cells were formed at that age. Unfortunately, the ability of Atoh1 to induce new hair cells in the utricle was not tested at ages older than P21, so it is not clear whether the level of induction observed at P21 represents a plateau or whether further loss of efficiency would occur at older ages. Similar experiments in which Atoh1 expression was induced using viral vectors in more mature animals reported the formation of a limited number of hair cell–like cells in different regions of the inner ear, which is consistent with the possibility that some adult inner ear cells located outside the cochlear duct retain the ability to develop as hair cells [58]. In fact, recovery of some degree of vestibular function was reported in animals in which hair cells were killed using systemic applications of aminoglycosides and loop diuretics [23]. However, as discussed previously, it was difficult to determine the relative contributions of hair cell regeneration and functional compensation in those experiments.

During development, activation of the Notch pathway serves to inhibit hair cell formation. This observation raised the question of whether continued activation of this pathway, in particular in response to injury, might have a role in inhibiting hair cell regeneration. Consistent with this idea, examination of the expression of Notch pathway genes in the chicken basilar papilla indicated that both Notch and its receptors are re-expressed during a regenerative response, although these factors were subsequently downregulated once the epithelium completed the regenerative process [59]. Neither Notch1 nor the ligands Delta1 and Jagged2 were observed in the mature intact organ of Corti. However, examination of epithelia after noise trauma yielded contrasting results; one laboratory reported an increase in the expression of Notch pathway genes, whereas a second observed the opposite result [43]. More intriguing are the results of a study in which partial recovery of hearing sensitivity was demonstrated after noise trauma in animals treated with a systemic γ-secretase inhibitor [45]. γ-Secretase is required for the cleavage of Notch [60]. Although the recovery was modest, the results suggested a potential role for Notch signaling in inhibiting hair cell regeneration.

Finally, the Wnt signaling pathway has been shown to have diverse roles in hair cell development. Wnts are secreted glycoproteins that have been implicated in myriad biological processes including cell fate, cellular polarity, and the regulation of cancer [61]. Studies in which a highly conserved target of the canonical Wnt signaling pathway, β-catenin (β-cat), was modulated both in vitro and in vivo demonstrated important roles for β-cat, and presumably Wnt signaling, in cochlear proliferation and subsequent hair cell formation [62,63]. In particular, inhibition or deletion of β-cat causes a significant disruption in hair cell development whereas increased activation of β-cat leads to increased proliferation of cochlear prosensory cells and subsequent formation of extra hair cells. Unfortunately, it has been difficult to identify the specific Wnts and Wnt receptors that may mediate these effects. A study used a combination of microarray analysis and in situ hybridization to identify and profile the expression of Wnts and Wnt receptors in the developing cochlea, but because of redundant expression and function, it is not yet possible to determine which factors might act to activate Wnt signaling within the cochlea.

As discussed earlier, under some circumstances, cellular proliferation may be required to facilitate hair cell regeneration. For instance, the loss of structural differentiation that typically occurs before cellular mitosis may increase the ability of an individual cell to undergo a phenotypic switch. In some epithelia, such as the organ of Cori, the limited number and high degree of specialization of supporting cells may necessitate the generation of new cells to maintain a functional epithelium after the conversion of some supporting cells into new hair cells. Cellular proliferation is minimal to non-existent in adult mammalian inner ear sensory epithelia [64]; however, before hair cell differentiation, the progenitor cells that will develop as hair cells are highly proliferative. Understanding how cellular proliferation is promoted or inhibited in these cells could provide valuable insights regarding possible approaches to inducing mature supporting cells to reenter the cell cycle. Extensive previous studies have identified a large number of factors that modulate cell cycle progress and exit. The first of these to be examined in the developing cochlea was the cell cycle inhibitor Cdkn1b (formerly $p27^{kip1}$). Cdkn1b is specifically expressed in all cochlear prosensory cells before terminal mitosis; expression is maintained in supporting cells through

adulthood [65,66]. Deletion of *Cdkn1b* results in approximately one additional round of mitosis within the prosensory population, leading to the generation of supernumerary hair cells and supporting cells and to auditory dysfunction. Subsequent experiments demonstrated important roles for a number of other cell cycle regulators including cyclin D1, N-myc, retinoblastoma, p130, p19, and p21 [67]. Deletion of factors that promote proliferation such as N-myc leads to reduced cells within the inner ear and significant defects in cellular patterning, whereas deletions of cell cycle inhibitors leads to supernumerary cells and some level of cell cycle reentry in adults, although in most cases those cells undergo subsequent cell death.

Overall, studies on the development of the inner ear sensory epithelia have provided valuable insights regarding the genes and signaling pathways that regulate processes relevant to hair cell regeneration. In particular, identification of the transcription factor Atoh1 as a strong inducer of a hair cell fate and the demonstration that the Notch signaling pathway has a critical role in inhibiting cells from differentiating as hair cells suggest two possible approaches to enhancing hair cell regeneration in an adult epithelium. Similarly, the discovery that the Wnt signaling pathway and cell cycle regulators act to modulate proliferation of inner ear progenitor cells may provide insights regarding methods to induce cell cycle reentry in an adult inner ear. Results described in the next section will discuss initial attempts to induce regeneration by modulating these pathways.

INDUCTION OF HAIR CELL REGENERATION USING TRANSGENIC MICE

The development of inducible transgenic mouse lines in which specific genes can be activated or inactivated in specific cell types at specific time points has revolutionized the ability to study inner ear regeneration. Based on the results of the developmental studies described earlier, four genes (Cdkn1b, Atoh1, Notch1, and β-cat) have been targeted. In most cases, two general concepts were addressed individually or together. The first of these is that forced activation of Atoh1 alone or combined with the deletion of Notch1 can enhance hair cell differentiation by expressing a hair cell inducer (Atoh1) and removing a hair cell inhibitor (Notch1). The second is that removal of the cell cycle inhibitor Cdkn1b might allow supporting cells to reenter the cell cycle. Finally, activation of the Wnt pathway has been implicated in both proliferation and differentiation, and so it might be able to mediate both events. For the bulk of these projects, the basic experimental design has been to use supporting cell-specific inducible cre lines combined with floxed deletion or activator lines to modulate one or more of these factors after injury [68,69]. These approaches have yielded encouraging results after induced hair cell loss in neonatal cochleae; unfortunately, similar results have not been obtained in adult inner ears. Because newborn mouse pups do not begin to hear until approximately 14 days postpartum, it seems possible that the results obtained in neonates may be a remnant of the embryonic developmental program or immaturity of the supporting cells. Whether the inability of these factors to induce new hair cells in adult cochleae is a result of changes in post-transcriptional or post-translational processing, loss of obligate co-receptors, epigenetic changes, or a progressive loss of stem cells within the epithelium remains to be determined.

The results of two studies shed some light but also provide some confusion regarding the mechanism that might act to prevent hair cell regeneration in the cochlea. As discussed, activation of Notch1 requires a γ-secretase–dependent cleavage of the Notch1 protein leading to the formation of NICD, which is then translocated to the nucleus to initiate signaling. Several pharmacological inhibitors of γ-secretase have been shown to block Notch1 activation effectively in vitro. Mizutari and colleagues induced hair cell damage in adult mice using noise or driving caspase expression in hair cells to promote apoptosis and then injected LY411575, a new, highly potent γ-secretase inhibitor into the inner ears of these animals for several days [45]. The mice in these studies also carried a lineage marker that allowed the authors to mark all of the supporting cells in the cochlea permanently. After 3 months of recovery, the LY411575-treated animals showed some improvement in auditory function and evidence of replacement hair cells in the cochlea. Moreover, the new hair cells expressed the lineage marker, which suggested that they had developed from existing supporting cells, although it is not clear whether they were exclusively from nonmitotic conversion or whether any proliferative regeneration was induced. This result was particularly exciting in that the use of a pharmacological agent is well-suited for development as a clinical application. From a biological standpoint, this result suggested that the Notch pathway remains active or is re-activated after injury in adult tissue. In fact, both this study and work from a separate laboratory indicated re-expression of some components of the Notch pathway in response to injury [44].

However, a subsequent study by a different group of researchers observed a different result. In that case, explant cultures of neonatal cochleae were established, treated with γ-secretase inhibitors and then assayed for the development of new hair cells. The results indicated a marked decrease in the number of new hair

cells that developed even in cochleae as young as P3. In addition, polymerase chain reaction analysis of the expression of Notch pathway genes after noise damage in adult animals indicated no reactivation of the Notch pathway [43]. Thus, these two studies would seem to present two highly disparate results for which the bases for the differences cannot easily be determined. One possibility is that the mechanisms of hair cell damage were different, as were the time scales. Another possibility is that although Notch genes are a main target of γ-secretase, they are not the only target, which raises the possibility that the regeneration observed in vivo is mediated through a different pathway. Therefore, although the results are intriguing, additional studies are clearly required.

STUDIES OF HAIR CELL REGENERATION USING THE LATERAL LINE

As discussed, in mammals and other terrestrial vertebrates, hair cell sensory epithelia are confined to the inner ear. In contrast, aquatic vertebrates, such as fishes and amphibians, possess an additional hair cell sensory structure, the lateral line system (Fig. 49.4). This sensory system is composed of a series of organs, termed neuromasts, arrayed along the surface of the skin or in bony dermal canals that connect to the skin surface (Fig. 49.4A). The amphibian lateral line is indeed the first place that hair cell regeneration was observed. After amputation and subsequent

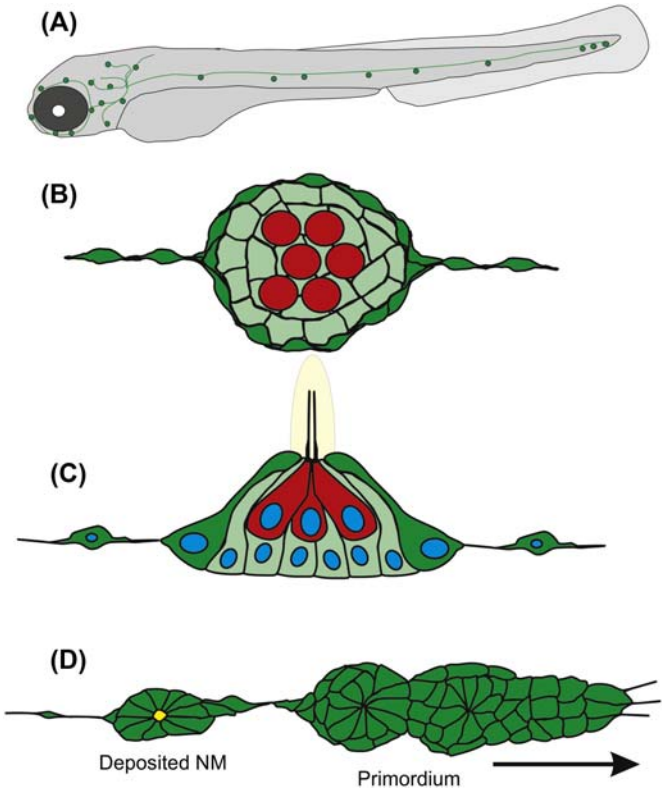

FIGURE 49.4 Overview of the lateral line. (A) Schematic diagram of the lateral line in a 4-day-old zebrafish embryo. The *green circles* represent the position of neuromasts (NM) and the *green lines* represent the underlying nerve. The neuromasts in the head make up the anterior lateral line, whereas those along the body make up the posterior lateral line. (B) Schematic of a surface view of an individual neuromast in a 3- to 4-day-old zebrafish. The mantle cells make up the outer edge of the neuromast and the interneuromast cells are a line of cells connecting adjacent neuromasts (*dark green*). The supporting cells (*light green*) surround the sensory hair cells (*red*). (C) Cross-section of a neuromast in a 3- to 4-day-old zebrafish. The apical side of the neuromast is constricted and the hair cells (*red*) extend their hair bundles into an overlying gelatinous cupula (*yellow*). Mantle cells and interneuromast cells (*dark green*) lie at the edge of the neuromast, with supporting cells (*light green*) extending the width of the epithelium and interdigitating between the hair cells. (D) Schematic of the development of the posterior lateral line. The leading edge of the primordium (*arrow*) has migratory mesenchymal cells that crawl forward, driving the primordium along the horizontal myoseptum of the fish from head to tail. Cells in more posterior positions within the primordium begin to organize into rosettes, which are deposited as the primordium continues to migrate. In the deposited neuromast, centrally positioned cells become the Atoh1-expressing hair cell precursor (*yellow*) and organize the neuromast.

regrowth of larval salamander tails, Stone reported in the 1930s that replacement neuromasts, which contain new sensory hair cells, were produced from cells located in the most distal remaining neuromast [70,71]. As a result, the amphibian lateral line was used as a model for both sensory organ regeneration and hair cell regeneration for many years. The development of zebrafish as a genetically manipulatable model system has allowed more extensive investigation of the molecular control of these regenerative phenomena.

The mechanosensory lateral line is used to detect the flow of water and water pressure differences across the fish's or amphibian's body and has important roles in schooling behavior, predator and prey detection, rheotaxis, obstacle avoidance, and, potentially, communication between individuals [72–74]. Each neuromast is composed of a number of sensory hair cells and supporting cells and, at the outermost edge, a layer of mantle cells (Fig. 49.4B,C). The lateral line sensory hair cells are morphologically and physiologically similar to those in the inner ear, and although there are fewer markers or identifying features, the supporting cells also appear to be similar to those in the inner ear [75–77]. During development, the lateral line system is established by several different primordia that migrate from the region of the otic placode along the head and trunk, progressively depositing clusters of cells that organize into neuromasts (Fig. 49.4D). Whereas the migrating primordia establish an initial series of neuromasts, additional, new neuromasts arise from latent, multipotent interneuromast cells that are also deposited by the initial primordia as well as from budding of new neuromasts from existing ones, ultimately to form stitches, or linear arrays of neuromasts, along the body [70,71,78–80]. Once a neuromast begins to develop, the initial formation of hair cells is coordinated by *atoh1* and Notch signaling, similar to the development of hair cells in the vertebrate inner ear (see earlier discussion). Cells in the center of each new neuromast acquire *atoh1* expression, becoming hair cell precursors, and those cells use Notch and fibroblast growth factor (FGF) signaling to suppress hair cell precursor fate in neighboring cells [80–82]. The hair cell precursors then divide using planar polarity cues oriented during the migration of the primordium, such as *vangl2*, to produce pairs of hair cells oriented in the opposite direction; the hair bundles and kinocilia are oriented 180 degrees away from each other, with the kinocilia of both located closest to the center of the plane of division [83,84]. The similarity of the genes, signals, and patterns used to develop sensory hair cells within the lateral line and the vertebrate inner ear has suggested that studying the robust regeneration that occurs in the lateral line will provide valuable insights into the mechanisms that control (and limit) hair cell regeneration in all systems.

FORMATION OF NEW NEUROMASTS FROM MULTIPOTENT PROGENITORS

As mentioned previously, the first evidence that hair cells could be regenerated from supporting cells came from early experiments in salamander tail regeneration, in which it was noted that replacement neuromasts were derived from the outermost (mantle) cells on the posterior edge of the distal-most remaining neuromast after tail amputation [70,71]. Experimentation revealed that the anterior mantle cells also had the capacity to regenerate lost neuromasts if they were rotated to be proximal to the amputation site, and that these mantle cells were responsible for the budding of new neuromasts during stitch formation. These results suggested that the mantle cells retained an intrinsic latent multipotency that could be stimulated to proliferate, forming new or replacement neuromasts [70,71,78,85–87]. It has also been suggested that macrophages responding to the injury may have an important role in initiating regeneration [87], and that the regenerative primordium may reexpress markers used in the developmental primordia [88], but little is known about the signals that initiate either neuromast budding or regeneration from the mantle cells (Fig. 49.5).

In addition to the mantle cells, it has been suggested that interneuromast cells, which are deposited by the developmental primordia between primary neuromasts, may also serve as a pool of multipotent progenitors capable of forming new or replacement neuromasts. In fact, several studies suggested that the glia ensheathing the lateral line nerve, which runs beneath the lateral line, suppress the interneuromast cells from forming new neuromasts, and that interstitial growth may therefore come from de-repressed interneuromast cells that escape glial inhibition [89–92]. In addition, in response to localized destruction of an entire neuromast, interneuromast cells are capable of replacing the missing neuromast, and this regeneration is enhanced by blocking the development of lateral line nerve glia [93]. Thus, there appear to be at least two populations of latent multipotent progenitors capable of producing new sense organs in the lateral line: the mantle cells and the interneuromast cells, with both populations held in check until injury or growth requirements stimulate them (Fig. 49.5A). Notably, although full molecular characterization of mantle and interneuromast cells is incomplete [94], many common markers are expressed in both populations, which raises the possibility that these are highly similar cells, even though the mantle cells are epithelial whereas interneuromast cells appear to be more mesenchymal.

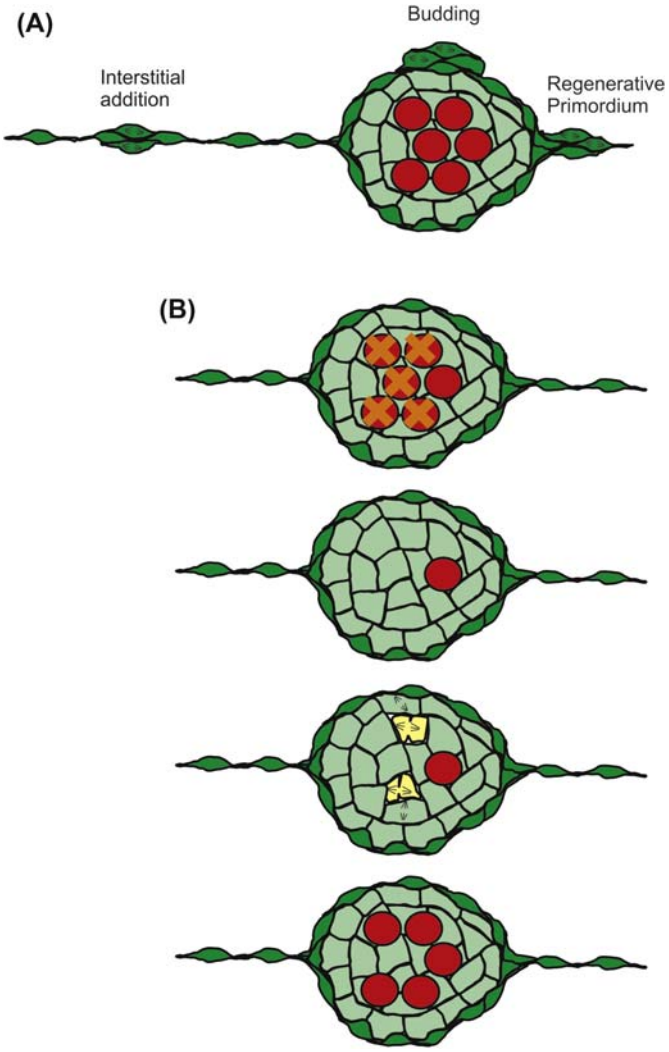

FIGURE 49.5 Models of progenitor cells in the lateral line. (A) Schematic diagram of a neuromast showing the areas where multipotent progenitors (interneuromast cells and mantle cells) can develop into new neuromasts. Interneuromast cells can divide and form a new neuromast between two existing neuromasts. Mantle cells can proliferate on the dorsoventral sides of the neuromast to bud off additional neuromasts during stitch formation. In response to amputation of the tail, the posterior neuromasts divide to become a migratory regenerative primordium that forms and deposits replacement neuromasts as it migrates into the regenerating tail. (B) Model of hair cell regeneration in the lateral line. When hair cells are ablated (Xs), they are rapidly extruded from the epithelium. Adjacent supporting cells divide symmetrically to develop into two replacement hair cells, and more peripheral supporting cells divide to give rise to replacement supporting cells.

HAIR CELL REGENERATION IN THE LATERAL LINE

The ability to regenerate entire sensory organs within the lateral line demonstrates a robust regenerative capacity; moreover, the ability also to regenerate just damaged or missing hair cells within the sensory organs makes this an important system for working out the mechanisms underlying hair cell regeneration. Like inner ear hair cells, lateral line hair cells are susceptible to damage from aminoglycoside antibiotics and chemotherapeutics such as cisplatin [95–97], and the presence of sensory structures on the surface of the fish means that hair cells can be killed simply by placing a fish in water containing ototoxins for 15–60 min. The result is rapid hair cell death and extrusion from the neuromast. The ease of applying such compounds to the lateral line hair cells, particularly in zebrafish larvae, has been leveraged to develop several screens for the discovery both of new potential ototoxins, such as copper ions and other clinically relevant compounds [98,99], as well as compounds that serve protective functions [100–103]. In addition, the surface location of the cells allows for the direct ablation of individual cells, such as by laser irradiation, and tracking of the regenerative response [104,105].

Notably, even without the addition of ototoxic compounds or other insults, there is a significant and ongoing turnover of hair cells in lateral line neuromasts [106,107], similar to that seen in avian vestibular organs [108–110]. The correlation between levels of cell death and levels of proliferative regeneration both at baseline and after the induction of damage suggests that each neuromast uses a feedback mechanism to maintain the number of hair cells within a certain range [106]. After an acute insult, loss and regeneration of hair cells occur rapidly; hair cell loss and extrusion occur within 3 h and the first regenerated hair cells appear within 12 h. Baseline numbers of hair cells are typically restored within 72 h [96,111].

Similar to results from nonaquatic vertebrates, studies in both amphibian and zebrafish lateral line have clearly identified the supporting cells as the source of regenerated hair cells [83,96,97,104–106,111,112]. Most studies suggest that regenerated hair cells are formed as a pair after the single division of a supporting cell [83,111–113]; indeed, treatment with mitotic inhibitors inhibits hair cell regeneration [97,112,114]. However, there are reports that a few regenerated hair cells may be derived via nonmitotic conversion of a supporting cell into a hair cell [105,111,115]. Because there is constant turnover within neuromasts, this nonproliferative conversion may reflect the presence of some recently produced, undifferentiated progeny at the time of lesion, or it may be tied to the specific type and level of damage induced. However, this type of regeneration is composed of only a minor percentage of new hair cells; the vast majority originate from the proliferation of nearby supporting cells. The ability of the supporting cells to regenerate hair cells extends from larval stages through to adulthood with little loss in capacity and only slight changes in the kinetics, and there is little evidence that the population of progenitors can be exhausted, because repeated rounds of neomycin still lead to robust regeneration [107,116].

Because regenerated hair cells appear to be produced as a pair from the division of one supporting cell [83], repeated rounds of regeneration would lead to a depletion of supporting cells (and loss of regenerative capacity) without proliferative replacement of the supporting cell population. However, the fates of supporting cell divisions appear to be compartmentalized based on their position within the neuromast. More central supporting cells divide to produce hair cells, whereas more peripheral supporting cells divide to renew the supporting cell population. Differences have been observed among mantle cells, with more anterior supporting cells representing a slower dividing or quiescent pool [107,117]. Mantle cells rarely appear to contribute to regeneration after limited damage, but they can contribute to the production of new supporting cells after more extensive damage such as the forced depletion of the supporting cell pool [118]. Thus, although mantle cells may be a multipotent progenitor for new sensory organ formation, they may not have regular roles in maintaining and regenerating hair cells and supporting cells, although the relationship between mantle cells and peripheral support cells, such as whether they have niche-like interactions, needs to be clarified.

PATHWAYS COORDINATING HAIR CELL REGENERATION IN THE LATERAL LINE

The ability to use both forward and reverse genetics techniques in zebrafish, the strength of various gene expression assays, as well as the ease of adding pharmacological compounds to the water has allowed extensive investigation of the pathways and genes coordinating the regeneration of hair cells after damage and comparison of those with both the developmental pathways and regeneration in other vertebrates. Transcriptomic analysis of supporting cells and mantle cells has begun to characterize genes that are active during different windows of regeneration [94,118]. Shortly after hair cell loss, Wnt, Notch, and FGF signaling pathways are each inhibited; Wnt and Notch become active in later stages of regeneration [118]. In particular, Wnt10a and the Frizzled 7b and 8a receptors are regulated during the first 5 h after hair cell ablation [118]. Consistent with these results, several studies found that the inhibition of Wnt signaling, either genetically or pharmacologically, blocks supporting cell proliferation and hair cell regeneration, whereas the activation of Wnt signaling promotes supporting cell proliferation [117,119–121]. Similarly, the inhibition of Notch signaling promotes increased numbers of supporting cells returning to the cell cycle and biases the progeny to differentiate into hair cells, whereas the activation of Notch blocks supporting cell proliferation and hair cell regeneration [111,112,117]. These pathways appear to be hierarchically arranged, because Notch inhibition activates Wnt signaling in supporting cells, likely via the loss of Notch-mediated expression of the Wnt-inhibitor *dkk2* [117,120]. This relationship is similar to that reported for Wnt/Notch control of the proliferation of supporting cells in the mouse utricle [122]. Although FGF signaling is modulated after hair cell death and is known to be important in the initial development of hair cells within neuromasts [81,82,118], the specific role of FGF signaling in hair cell regeneration is less clear. During regeneration, hair cell progenitors appear to have active FGF [123], similar to the progenitors during development, and inhibition of FGF signaling or ablation of FGF *receptor 1*-expressing support cells reduces hair cell regeneration [124]. Retinoic acid

(RA) signaling also seems to be an important inducer of supporting cell proliferation by altering $p27^{kip}$, and although RA and FGF signaling often interact, they seem to be independent during hair cell regeneration in the lateral line [123].

In addition to studies finding signals required for hair cell regeneration, negative regulators have been found. An insertional mutagenesis screen identified N-glycosylation by *mgat5a* as an important negative regulator of hair cell regeneration, because mutations in this gene had increased regeneration [125]. Although the specific pathway(s) modulated by *mgat5a* is not known, transforming growth factor-β (TGFβ) has been suggested as a candidate. Consistent with this idea, inhibition of Stat3, which is typically downstream of TGFβ signaling, enhances hair cell regeneration [126], although the early upregulation of Stat3 suggests that it may also have a role in initiating the regenerative response [118,126]. Studies have also begun to examine how epigenetic control of these signaling pathways may mediate regeneration, in particular focusing on histone methylation and its control of Wnt and FGF signaling [127,128].

Many of the most heavily studied pathways seem to mediate proliferation and/or differentiation of the hair cell progenitors, but it remains unclear what signals initiate the regenerative response, because none of the pathways that have been studied appear to be sufficient to stimulate supporting cell proliferation. Transcriptomic studies have identified other cell−cell signaling pathways including insulin, mitogen-activated protein kinase, tumor necrosis factor-α, nitric oxide, reactive oxygen species, Fat, and integrins, that are activated during regeneration, but specific analysis of the roles of these pathways during hair cell regeneration are still required [94,118]. Several of these candidate pathways, such as nitric oxide and reactive oxygen species, could be tied to pathways active in and released by dying hair cells. It has also been proposed that hair cell death may stimulate regeneration via recruitment of immune cells that secrete cytokines, because macrophages migrate to the sites of hair cell damage before the initiation of proliferation [104,105] and ablation of recruited macrophages delays hair cell regeneration [129]. Although there have been similar proposals for macrophage involvement in initiating hair cell regeneration in the avian inner ear [130−133], ablation of macrophages does not appear to limit hair cell regeneration in that system [134].

In contrast to the extensive study of hair cell regeneration in the fish and amphibian lateral line, less is known about the pathways underlying regeneration within the inner ears of fish and amphibians. Hair cells lost from the saccule, utricle, and cristae after aminoglycosides, laser ablation, or acoustic overstimulation are regenerated within 1−7 days from *sox2*-expressing supporting cells [123,126,135−137]. RA and FGF signaling appear to regulate inner ear and lateral line regeneration similarly, [123]. Interestingly, although proliferative regeneration was found in cristae and saccule [123,135], rapid recovery of hair cells in the utricle after laser ablation occurred without proliferation of the supporting cells [136], which suggests a potential capacity for direct phenotypic conversion.

OPEN QUESTIONS ABOUT LATERAL LINE REGENERATION

The lateral line system provides a unique opportunity to study hair cell regeneration at multiple levels. As described earlier, it has provided valuable insights regarding the regeneration process. One of the central questions still to be answered is whether there are unique populations of supporting cells responsible for regenerating hair cells, or whether all supporting cells have this capacity and instead environmental factors regulate which cells respond to injury. In either case, the specific gene interactions that distinguish the subset of supporting cells responsible for hair cell regeneration (in contrast to quiescent or self-renewing supporting cells) remain to be clarified. Similarly, whether there are distinctions between subpopulations of mantle or interneuromast cells in the lateral line is unclear. The ability of mantle cells and supporting cells to generate hair cells, directly in the case of supporting cells and secondarily in the case of mantle cells, suggests some common stem cell−like properties, but also important differences in their control. The separation of hair cell production and self-renewal of supporting cells into separate populations of symmetrically dividing cells is different from the mixture of symmetric and asymmetric (i.e., producing both hair cells and supporting cells) divisions reported in hair cell regeneration in the chick [18]. Whether this represents a unique adaptation of the neuromast or is a general property of hair cell regeneration in fish will require more careful examination of regenerative proliferation in the fish inner ear. Similarly, open questions still surround the potential role of nonproliferative regeneration among the lateral line, the utricle, and the saccule: in particular, whether the differences are more tied to the levels of damage that is induced, relate to different temporal effects, or reflect differences among these sensory organs.

CONCLUSIONS

All vertebrates use sensory structures containing mechanosensory hair cells to perceive sound, motion, and gravity. Although the overall structure of both the hair cells and their surrounding sensory epithelia appear to be largely comparable among orders, only mammals have lost almost all ability to regenerate hair cells. As a result, humans and all other mammals have the potential to develop permanent deficits in auditory and/or vestibular function. The biological basis for the loss of regenerative ability in mammals remains unclear.

In an effort to understand the molecular bases for hair cell formation and regeneration, two general strategies have been developed: an examination of the development of hair cells in mammals and studies of regeneration in other vertebrates, in particular zebrafish. Results from both of these studies have identified general concepts that appear to apply to hair cell formation and regeneration in all vertebrates. Hair cells typically arise from surrounding supporting cells that become activated in response to injury. The nature of that response can vary based on the extent of the injury and the cells that respond. In some cases, supporting cells directly convert into hair cells, whereas in more severe situations, different classes of supporting cells may reenter the cell cycle to generate new progenitor cells before differentiation. In both developing and regenerating epithelia, the number of cells that develop as hair cells is mediated through the Notch signaling pathway, with developing hair cells expressing ligands that bind to and activate Notch in neighboring cells preventing those cells from developing as hair cells. Similarly, the transcription factor Atoh1, which is inhibited by the Notch pathway, acts as a positive regulator of hair cell fate for all vertebrate hair cells. Based on these results, efforts have been made to manipulate both Atoh1 expression and/or the Notch pathway to induce hair cell regeneration in a mature mammal auditory organ. The results of those experiments are equivocal. Some studies suggest possible regeneration in animal models whereas others have concluded the opposite. Although subsequent work will be required to determine whether these or other factors or pathways hold the key to inducing hair cell regeneration in a mature mammalian epithelium, progress that has been achieved has been remarkable and suggests that a clinical therapy for hearing loss may be developed in the not too distant future.

CLINICAL TRIAL

Based on the results of some of these experiments, a multicenter Phase I clinical trial to examine the safety of introducing Atoh1 into the inner ears of patients was initiated in October, 2014 (NCT02132130) by Novartis. The general concept of the trial was to use an adenoviral vector to drive expression of Atoh1 in the ears of patients with profound hearing loss. As a Phase I trial, the primary end points of this study were concern regarding patient safety and the ability to tolerate the adenoviral injections. However, some patients may have been examined for possible recovery of auditory function. Although the results of this trial will not be available for some time, its approval marks the first step toward the application of gene therapy to the inner ear. As discussed, the ability of Atoh1 to induce hair cell formation in cells of an adult ear is probably limited, but if the results indicate that gene therapy can be applied safely to the inner ear, these results have the potential to usher in a series of clinical trials based on manipulations of the signaling pathways discussed in this chapter. Which of these pathways, if any, have the potential to induce a meaningful recovery of function remains to be determined. Nevertheless, that a trial of this nature has been initiated is a remarkable event in and of itself.

INTRODUCTION

The craniofacial region is composed of several tissue types and a number of niche environments. As such, the need to regenerate injured or diseased tissues requires strategies for engineering both hard and soft tissue, taking into account their surroundings. Tissue engineers have made great strides developing techniques that support and encourage new tissue growth. However, it is imperative that one first appreciates the unique characteristics associated with the defect. With this knowledge, health care providers can select specific approaches that optimize aspects of tissue engineering technology. Additive manufacturing (AM) techniques have become more popular in the clinical setting, and attention has turned to how patient-specific models can be used to plan and execute surgical care whereas patient specific implants can be leveraged to enhance tissue regeneration further within the craniofacial region. This chapter will discuss the craniofacial environment, review current clinical reconstructive practices, and highlight bone tissue engineering strategies with applications in craniofacial reconstruction.

UNDERSTANDING THE CRANIOFACIAL REGENERATIVE ENVIRONMENT

Several types of craniofacial defects are associated with different environments; the characteristics of each must be considered if predictable regenerative medicine results are expected. Although comprehensive descriptions of each environment are incomplete, some of the most important features have been identified through a detailed study of the normal development of tissue types and regenerative technologies based on a reproduction of embryological and remodeling biology. Using bone engineering as an example, defect characteristics exist such as [1]:

1. the resident population of pluripotent or multipotent stem cells available for differentiation;
2. vascularity of the defect and the ability of the newly formed tissue to undergo neovascularization;
3. the activity of critical genes, growth factors, and signal transduction agents that mediate tissue formation and remodeling;
4. physical features of the defect that promote tissue formation, including available space and naturally occurring scaffolds;
5. mechanical influences on the defect, including types and magnitude of loads; and
6. interactions between epithelial and mesenchymal elements.

In addition to these features, the ability of different craniofacial defects to undergo successful reconstruction is affected by the cause and the presence of infection. We will examine several common defects with different

[a] These authors contributed equally.

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00050-3

environmental characteristics to illustrate the need for customized regenerative strategies and why techniques for regeneration work for some defects but not for others.

One of the smallest and most challenging defects to regenerate is the periodontal apparatus that surrounds an erupted tooth and is responsible for its support. The periodontium is composed of an epithelial gingival cuff supported by mesenchymal connective tissue covering the alveolar bone, which forms the tooth socket encasing the root(s). The connective tissue fibers that attach the cementum lining of the tooth root to the socket walls are known as the periodontal ligament; within these fibers lies a network of vascular channels and neural elements with associated cells in various stages of differentiation. Loss of the periodontium typically follows chronic inflammation caused by the accumulation of bacteria- or virus-laden biofilms on the surface of a tooth and root (Fig. 50.1) [2].

The resulting infection results in osteolysis creating a pocket between the alveolar bone and overlying gingival soft tissue and in loss of the periodontal ligament attachments between the bone and root surface cementum (Fig. 50.1). This defect can have single or multiple bony walls. Defects with multiple bony walls constitute more protected environments and regenerative technologies are more successful in these circumstances. Complete restoration of the composite structures within periodontal defects remains elusive, but certain treatment strategies are required to achieve any measure of regenerative success. An appreciation of these factors provides general guidelines for the successful reconstruction of craniofacial defects that can be applied broadly.

To begin with, physical removal of the biofilm covering all surfaces of the defect is necessary. Systemic and local delivery of broad-spectrum antibiotics against periodontal pathogens are also beneficial [3,4]. The effect of infection and inflammation on bone formation is a complex topic that acknowledges the important role of proinflammatory mediators in initiating the coordinated processes responsible for bone regeneration. Some important mediators of early inflammation include interleukin (IL)-1, IL-6, tumor necrosis factor-α, and eicosanoids such as prostaglandin (PGE) (e.g., PGE_2). Evidence of the role of these mediators is provided by knockout animal studies or the observed effects of anti-PGE_2 medications such as nonsteroidal antiinflammatory drugs, which result in compromised bone formation. After these initial events, the activity of proinflammatory mediators abates and a rise in local levels of antiinflammatory mediators such as resolvins, protectins, and lipoxins (autacoids) is responsible for countering inflammation and coincides with the start of the reparative process. Both eicosanoids and autacoids are derivatives of arachidonic acid, and the mechanism for a change in synthesis from inflammatory to antiinflammatory mediators has been characterized as "class switching" and occurs by activating enzymes such as 15-lipooxygenase. If inflammation in a defect site persists as a result of chronic infection, osseous regeneration is diminished. An excellent review of the topic of inflammation and bone regeneration may be found in an article by Thomas and Puleo [5].

Once regeneration begins, the kinetics of the different reparative tissues becomes important. More specialized components of the periodontium, such as the bony walls, ligament, and bone-cementum attachments, take longer

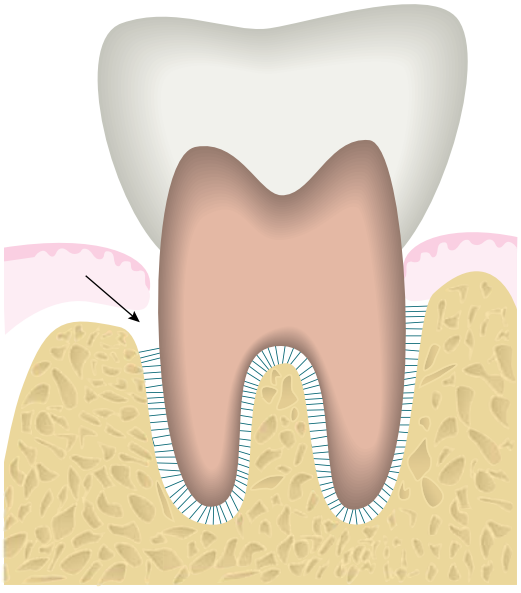

FIGURE 50.1 Periodontal pocket (marked by *arrow*) produced by loss of alveolar bone under the gingival cuff.

to form than do epithelium or connective tissue. Unless a physical void is preserved by preventing the ingrowth of epithelium and connective tissue (a technique known as *osteopromotion* by barrier techniques), periodontal regeneration is compromised. Scaffolds in combination with barrier membrane technology have been shown to be effective in restoring bone volume, and the addition of exogenous growth factors and gene therapy for the local production of growth factors are additional approaches that have been studied in preclinical studies [6].

Larger defects of the craniofacial skeleton extending beyond the periodontal defect differ from each other in a number of physical and biological ways. Defects can be intrabony and surrounded with multiple bony walls (Fig. 50.2A). In this case, the rigidity of the walls facilitates bone regeneration by protecting biological scaffolds such as blood clots, healing tissue, and neovasculature. In addition, periosteum lining the bone surfaces and the underlying endosteal surfaces are an excellent source of cells capable of differentiation under the influence of the proper growth factors. When a bony defect is segmental (Fig. 50.2B), only two bony walls remain, leading to greater instability of the skeletal structure, reduced apposition of osteogenic cell beds, and the potential for adjacent soft tissue to prolapse into the defect, later reducing bone formation. Immobilization of the bone ends (with bone plates) is important to protect early reparative activities such as the secretion of extracellular matrix and neovascularization from mechanical disruption by external loads. Filling such defects with rigid graft material (autologous, allogeneic, or alloplastic) also enhances regeneration by providing a source of living cells or tissue with inductive or osteogenic

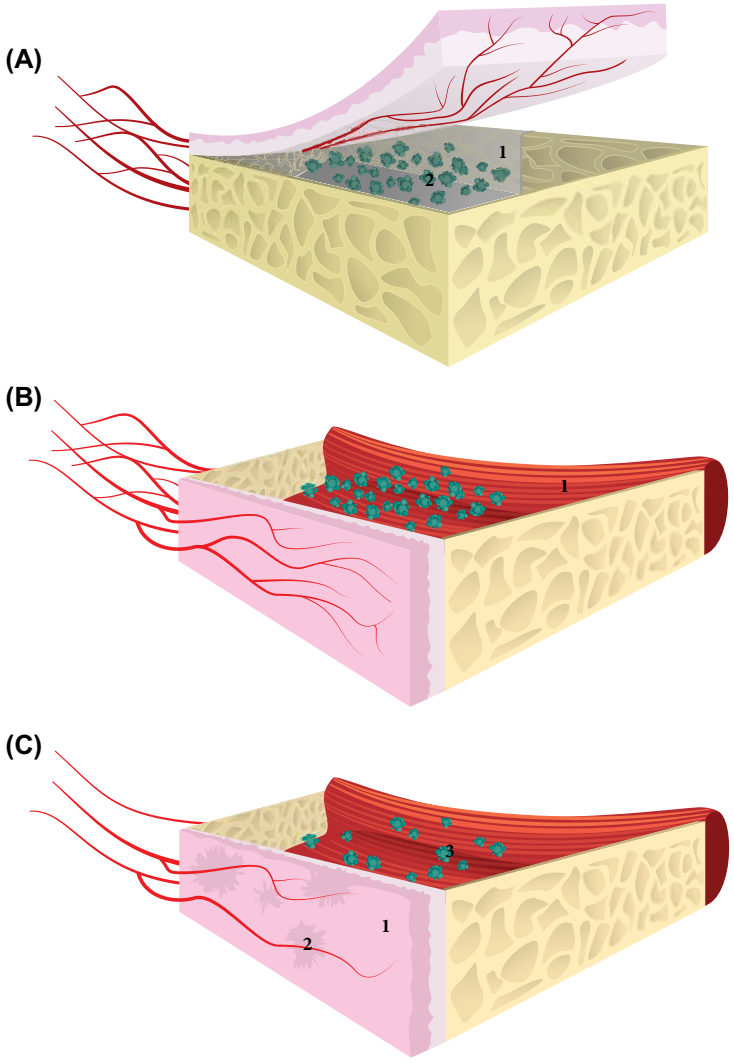

FIGURE 50.2 (A) A five-wall bone defect covered with periosteum (1) provides a protected space that contains a reparative scaffold and cells (2). (B) Segmental defects typically have a reduced number of bony walls with soft tissue (e.g., muscle [1]) adjacent to the defect. (C) Segmental defects with compromised vasculature typically have fewer vessels (1) in the soft tissue envelope, areas of fibrosis (2), and a reduced number of reparative cells (3).

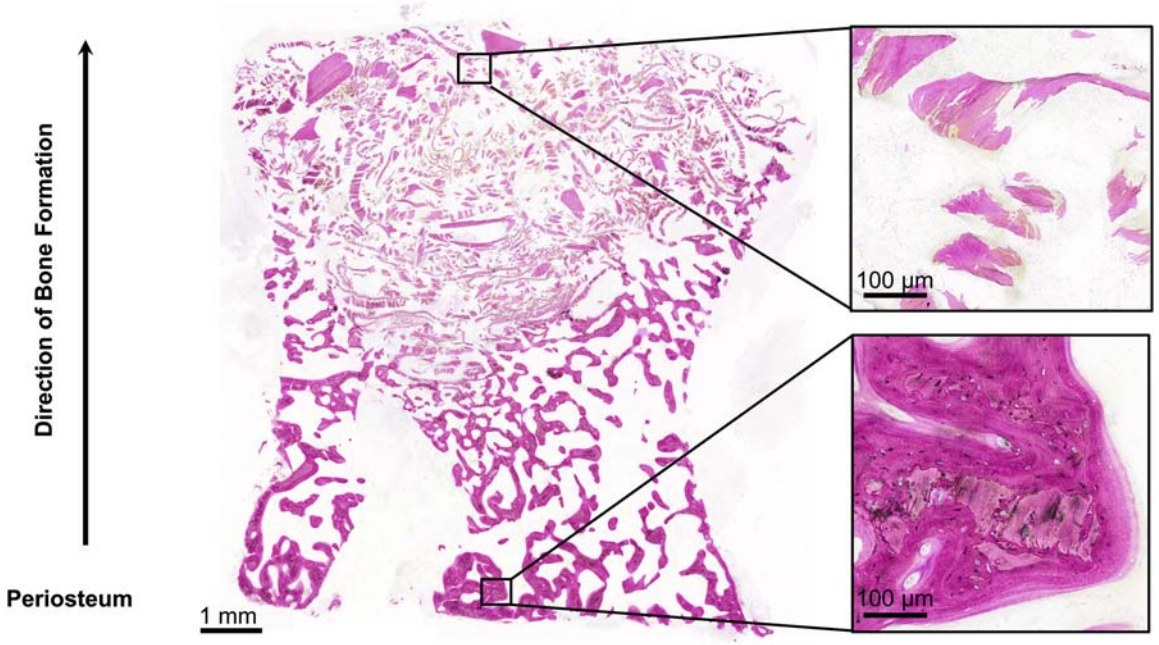

FIGURE 50.3 Histological cross-section of tissue generated within a bioreactor (initially filled with morcellized autologous graft) after implantation against the sheep periosteum for 9 weeks. High-magnification images taken adjacent periosteum and distal to the periosteum can be found on the right (magnification, 10x). *Courtesy Alexander Tatara, MS, PhD; doctoral thesis.*

capabilities. The graft can also serve as a scaffold and a barrier to the ingrowth of nonosteogenic tissue. Techniques for reconstructing segmental bone defects using tissue engineering principles are described later in this chapter.

As described in the strategies for promoting periodontal regeneration, inflammation and infection have significant roles in the regenerative capabilities of craniofacial defects. Infection of a graft site is a major factor accounting for a complication rate of 48% in a review of the literature on nonvascularized bone grafting [7]. Strategies for reducing infection through implantation of antimicrobial agents will be described in a later section.

The paradoxical relationship between inflammation and bone formation raises theoretical questions about the significance of inflammatory states, but the negative effect of prolonged inflammation on bone grafting and fracture repair is well-documented [8]. As such, it is essential to treat infected craniofacial defects by physical debridement and antimicrobial agents for healing or regeneration to occur. Newer strategies to deliver antibiotics locally using devices fabricated through tissue engineering will be described later in this chapter.

Other important conditions that can reduce the regeneration of bone include those that compromise the vascularity of the tissue surrounding a bone defect. The role of the vasculature as a source of inducible cells (pericytes), conduit for inflammatory cells (platelets, macrophages, and monocytes) and essential foundation for supporting metabolism in all living tissue is well-known [9]. When the blood supply to a defect site is compromised by therapeutic measures such as radiation therapy, comorbid conditions (e.g., diabetes), and even healing processes (e.g., scarring and fibrosis), the ability of a defect to undergo osteogenic healing is reduced (Fig. 50.2C). Efforts to reconstruct craniofacial defects afflicted by such conditions include adjuvant strategies to mitigate against the compromised vascularity such as the transfer of well-vascularized tissue beds or chemical modulators of angiogenesis. An example of the critical role of the vasculature is provided in this histological section. Fig. 50.3 illustrates bone formation within a chamber filled with autogenous bone particles placed against a vascularized periosteal membrane. New bone formation associated with neovascularization from the periosteum is seen as osteogenesis progresses from the vascularized margin upward.

CURRENT METHODS OF MAXILLOFACIAL RECONSTRUCTION

Maxillofacial reconstruction evolved from the use of nonvascularized grafting to the addition of vascularized free flaps in the late 1980s [10]. Nonvascular autogenous bone grafts were considered the reference standard for the repair of bone defects. However, successful osteogenesis from nonvascularized grafts depended on adequate soft

tissue coverage to isolate the graft site from infection, serve as a source of osteoprogenitor cells, and provide a vasculature supply. Common donor sites for bone harvest included the ilium, tibia, and calvarium [11,12]. Free tissue transfer techniques added the use of vascularized flaps anastomosed to local vessels when defect sites were contaminated or associated with compromised vascularity [13]. The impact of free flap reconstructions has been so profound that it is considered to be one of the most influential advances in head and neck surgery [14]. These flaps are harvested from areas with an axial blood supply that are isolated and anastomosed to vessels close to the defect site to produce an immediately "living" transplant. The most commonly used sites are chosen for their ease in harvest, modest donor site morbidity, and ability to include a large volume and variety of tissue types nourished from a single vascular pedicle [15]. When soft tissue is missing or when a vascularized soft tissue bed is required, the anterior lateral thigh flap or radial forearm flap can be used. For defects requiring composite soft tissue and bony reconstruction, options include the fibula, scapula, and deep circumflex iliac artery—nourished ilium flaps. Technical concerns with these techniques include the morbidity associated with graft harvest, the patency and length of vessels, the duration of surgery, and the recovery time [16]. However, the quality of reconstruction judged by the amount of bone stock is a matter of the patient's anatomy and may or may not be adequate for functional purposes.

TISSUE ENGINEERING TECHNOLOGIES CURRENTLY USED

The field of tissue engineering emerged in the early 1990s as a new way to combine the principles of biology and engineering for the development of functional tissues [17]. Since the inception of tissue engineering, several technologies have entered the marketplace offering hope for patients who have a range of conditions. In the following sections we will review advances in the field of tissue engineering that show promise for the future of craniofacial reconstruction.

Implantable Scaffolds

To allow damaged bone to be replaced with functional tissue, engineers have developed a wide range of materials that serve to stimulate the adherence and proliferation of osteogenic cells. Some of these technologies mimic the biomechanical and/or biochemical properties of native bone, whereas others try to recapitulate the anatomy [18—20].

In 1881, Sir William MacEwen of Rothesay used tibial bone wedges from three donors to reconstruct a humeral defect in a 3-year-old child, which represented the first published account of interhuman bone grafting [21]. The procedure was unsuccessful; however, later studies identified the factors affecting graft acceptance and rejection and established the parameters of allogeneic grafting. Nevertheless, despite advancements in developing allogeneic, xenogeneic, and artificial substitutes, autogenous bone grafts remain the reference standard for reconstructing segmental bone defects [22]. By definition, bone grafts can be classified as an autograft, allograft, or xenograft, depending on the source [23]. In contrast, alloplastic implants are synthetically manufactured, inorganic, and biocompatible [24]. Whereas autologous bone grafts produce the most predictable results, alloplastic materials offer several advantages over biologically derived materials. They can be fabricated to fit a patient-specific defect and the resorption rate can be controlled by adjusting material properties and compared with autologous grafts, to provide more material than can be typically harvested from a patient while avoiding a second surgical donor site. For oral and maxillofacial surgery procedures, the US Food and Drug Administration has approved a number of alloplastic materials that can be broadly divided into ceramics and polymers.

Ceramics

Numerous ceramics are available; calcium phosphate (CaP)-based ceramics represent the most widely used bioactive ceramic. CaPs offer excellent biocompatibility, possess remarkable osteoactivity, and have a chemical and crystalline structure close to those of native bone mineral [25]. Since becoming available for clinical use in 1992, CaP ceramics have been used with success within craniofacial surgery [26,27]. There are two commonly used CaP ceramics: slow-resorbing hydroxyapatite ($Ca_{10}[PO_4]_6[OH]_2$) and resorbable tricalcium phosphate (TCP) ($Ca_3[PO_4]_2$) [28]. Both of these formulations can be produced as a paste, which enables the surgeon to inject and mold the cement before final setting occurs, and which makes CaPs an attractive option for dental and orthopedic applications. Depending on the formulation of the CaP, the pore and particle size, and the metabolic activity of the

recipient site, CaP cement can take 3–36 months to be completely replaced with bone [25]. To accelerate the degradation of CaP-based scaffolds, several studies have investigated the introduction of macropores to increase the surface area of the implant and accelerate tissue integration [29–31]. The use of macroporosity has gained a lot of interest owing to improved degradation kinetics and improved tissue infiltration. Potential applications of CaP-based scaffolds have improved as several studies have investigated techniques to manufacture CaP-based scaffolds through AM techniques. This allows the engineer to improve degradation kinetics further, reproduce tissue architecture more precisely, and improve tissue infiltration [32–34]. Klammert et al. explored the ability to powder-print CaP implants to repair craniofacial defects [34]. In that study, the authors fabricated custom implants by using three-dimensional powder printing to repair defects in human cadaver skulls. The physical and mechanical characteristics of the implants were tested [34]. Whereas the four-point bending strength was in the range of 3.9–5.2 MPa, which is significantly lower than the bending strength of native compact bone (115–209 MPa), these implants could be used to reconstruct the craniofacial skeleton in non–load bearing areas [35]. A porosity of approximately 28–35% could be achieved, increasing the degradation rate and with sufficient fidelity to size and shape so that a printed implant would be able to fit the defect accurately [34].

Polymers

Polymeric-based biomaterials first emerged within the field of surgery as a material for suture and fixation devices [36]. Although numerous synthetic polymers have been tried in craniofacial surgery, only a few are extensively used in the clinical setting. Unlike natural polymers, in which degradation depends on enzymes present within the host, synthetic polymers degrade in a uniform and predictable manner by simple hydrolysis [37]. Altering the reaction environment during synthesis can precisely control the observed degradation rate, and even other properties such as mechanical properties, by altering the average molecular weight and size distribution [38]. Specifically within the field of craniofacial surgery poly(glycolic acid), poly(lactic acid), and their copolymer poly(lactic-*co*-glycolic acid) (PLGA) have been successfully used clinically [39]. Landes et al. examined the efficacy of using PLGA-based implants for maxillary and mandibular osteosynthesis [40]. In that study, five patients (6%) had an apparent foreign body whereas 75 (94%) had no observable reaction. At 24 months, histology revealed few macrophages, giant cells, and minimal bleeding residuals [40]. This demonstrated that PLGA has excellent biocompatibility but there is need for further investigation into the efficacy of bone integration. PLGA has been used as a delivery vehicle for bioactive factors. Several studies investigated the effect of using PLGA microparticles to produce a sustained release of growth factors, signaling molecules, and/or antibiotics [41–44]. These studies demonstrate the applications PLGA microparticles may have in the clinical setting.

In addition to PLGA, poly(ε-caprolactone) (PCL) has been investigated extensively within craniofacial tissue engineering owing to some of its unique properties. For example, PCL can form a wide array of biocompatible composites, blends, and copolymers [38]. If one combines PCL with other lactones, the degradation time dramatically decreases from that of the homopolymer of PCL, which is roughly 2–3 years [45]. Hollister et al. showed that the concentration of copolymer can be varied so that it has the ability to support bone formation [46]. Finally, the unsaturated linear polyester, poly(propylene fumarate), can be fabricated into scaffolds by UV-initiated photocross-linking. Although this polymer has been extensively characterized, it has been mainly used within bone tissue engineering applications [47–49].

Bioactive Molecules

Just as materials can be leveraged to promote bone growth, bioactive molecules can be introduced to craniofacial defect sites to encourage osteogenesis or angiogenesis. Growth factors are peptides that bind to receptors on a cell, leading to a cellular response. These responses vary by growth factor, cell type, the cell receptor bound, and the time course of growth factor exposure [50]. Clinically, growth factors are used in several applications. They can be employed to augment bone grafting systems, such as with the bone marrow aspirate concentrate (BMAC) technique [51,52]. Growth factors can also be used to stimulate bone formation in heterotopic sites [53–56], an important concept discussed in depth in the section on Bioreactors. Finally, growth factors can be used to form bone without using grafts, employing resorbable scaffolds such as collagen sponges, as seen with sinus augmentation procedures [57–60]. The following section focuses on bone morphogenetic proteins (BMPs) and platelet-derived growth factors (PDGFs), early animal studies, and clinical applications. Many other growth factors (i.e., transforming growth factor-β family, fibroblast growth factor family, insulin-like growth factor, and vascular endothelial growth factor) are important in tissue engineering and regenerative medicine; however, evaluation of these factors in human craniofacial defects is limited and will not be discussed here.

Bone Morphogenetic Proteins

BMPs are a large family of peptides that have a crucial role in bone and cartilage development, as well as some other functions of embryogenesis such as heart and kidney formation [61]. The family acts via two distinct type II and type I serine/threonine kinase receptors; both types are required for signal transduction. BMPs act by stimulating osteoblasts. BMP-2, BMP-4, and BMP-7 show efficacy with bone formation in vivo including in critical-sized defects [62]. The US Food and Drug Administration approved recombinant human BMP-2 and BMP-7 in 2002 for spinal fusion surgeries. In addition, BMP-14 is being tested clinically as a growth factor alternative [63]. There is controversy regarding the use of BMPs in spinal fusion surgeries; a metaanalysis showed efficacy similar to autograft but with more complications, especially when used in the cervical spine [63].

Despite controversy about the use of BMPs in spinal fusion [63], they show great potential for use in the craniofacial area [64–68]. In a rodent study, BMPs have been shown to aid in the healing of critical-sized cranial defects [64]. After loading BMP-2 into PLGA microparticles within a scaffold in a critical-sized, 1-cm defect cranial defect, total union was found in three of eight animals, and the bone volume generated significantly increased over the blank group [65,66]. Larger animals show similar trends. In baboons, a 2.5-cm, critical-sized cranial defect was formed [65]. A collagenous bone scaffold loaded with BMP-7 was introduced to the defect. Groups receiving high doses of BMP-7 (2.5 mg/g scaffold) had extensive osteogenesis, whereas those with low doses (0.1-mg/g scaffold) showed significant increases in bone growth over control animals. A box-type dehiscence defect in the edentulous region of dogs was employed to compare the use of synthetic bone substitute (SBS) and BMP-2–loaded hydrogel [66]. After 8 weeks, the animals were killed and the defects examined. Significantly increased bone volume was seen in the groups containing BMP-2 (14.7 mm^3 for the BMP-2–loaded hydrogel and only 2.01 mm^3 for the SBS-loaded hydrogel).

Several clinical studies were conducted to evaluate the efficacy of recombinant human BMPs (rhBMPs) in human craniofacial defects [67]. In 47 identified case studies in the systemic review, rhBMP-2 was shown to be effective in enhancing bone formation in socket healing and in sinus lift procedures, and BMP-14 was shown to be effective in sinus lift procedures [67]. In one maxillary floor sinus augmentation study, 160 human subjects were enrolled and treated with rhBMP-2 on a collagen sponge or autograft [57]. At 6 months, there was no difference in the change of height between the two groups (7.83 ± 3.52 and 9.46 ± 4.11 mm for the rhBMP-2 and autograft groups respectively), but the density of the bone in the rhBMP-2–treated group was significantly higher. Another clinical study analyzed the effects of rhBMP-2 on the repair of buccal wall defects [68]. Groups received rhBMP-2 (1.5 or 0.75 mg/mL) on an absorbable collagen sponge, just the collagen sponge, or no treatment. The assessment of the alveolar bone showed significantly increased adequacy (as calculated by height and width measured computed tomography [CT] scans and number of repeat procedures needed) over the control or untreated groups.

Platelet-Derived Growth Factor

PDGF is a dimer composed of PDGF A, B, C, or D joined by sulfide bonds [69]. Several homodimers (PDGF-AA, PDGF-BB, PDGF-CC, and PDGF-DD) and one heterodimer (PDGF-AB) exist. Two isotypes of the receptor exist, α and β, with different binding affinities. PDGF-BB can bind to all receptor isotypes and is often considered the universal PDGF [69]. In vitro studies have shown PDGF is produced by osteoblasts and inhibits osteoclastogenesis [70]. In vivo, PDGF is important in new bone formation and in fracture healing [70].

In humans, PDGF is expressed naturally in the course of fracture healing [71]. PDGF-A chains were found expressed by a variety of cell types throughout the healing process. PDGF-B chains were expressed in a more selective pattern: by osteoblasts at the time of bone formation [71]. Several clinical studies investigated the use of PDGF on the healing of craniofacial defects [72,73]. One study investigated intrabony periodontal defects of greater than 4 mm depth treated with β-TCP alone or β-TCP with recombinant human (rhPDGF)-BB [72]. In the group treated with β-TCP and 0.3 mg rhPDGF-BB, the clinical level of attachment was found to be greater and gingival recession was found to be less at 3 months than that of control patients who received only β-TCP. The clinical level of attachment was not significant at 6 months. Given the significant difference at the early 3-month evaluation with loss of significant differences at the 6-month appointment, rhPDGF-A-BB increased the rate of attachment in the treated groups, providing an advantage for treated patients soon after the surgery. A similar defect treated with rhPDGF-BB was analyzed for the rate of bone turnover [73]. Pyridinoline cross-linked carboxyterminal telopeptide of type I collagen, a well-known biomarker of bone turnover, was shown to be increased at the early study time points of patients treated with rhPDGF-BB, which again indicated advantages for patients with decreased recovery times. rhPDGF has also been evaluated in humans for the treatment of sinus augmentation and ridge preservation [59,60]. Both studies involved using inorganic bovine bone material with rhPDGF-BB as the treatment method, and both studies exhibited good bone growth.

Bone Marrow Aspirate Concentrate Technique

As described in the preceding sections, the principal efforts in tissue engineering have focused on stimulating cell multiplication and differentiation and the development of artificial scaffolds with tunable properties to enhance cell adhesion, vascular ingrowth, and scaffold degradation in coordination with new tissue formation. To meet the goal of reconstructing bony defects, another approach was devised to combine several of the more important contributions in tissue engineering methodology in vivo to take advantage of the body's established vascular system.

In keeping with the classical tissue engineering paradigm, the three essential components are provided with clinically available materials. This technique uses allogeneic bone to maintain space and support the ingrowth of vessels and adhesion of bone-forming cells. Differentiation and regenerative signals are provided by inductive bone proteins such as rhBMP-2, which promotes the differentiation of stem cells and migrating osteogenic cells [74]. Finally, a concentrated regenerative cell population composed of autogenous BMAC is introduced into the defect site. The aspirate contains a highly concentrated population of mesenchymal stem cells (MSCs) (Figs. 50.4 and 50.5) and migrating osteogenic cells that serve as a source of cells for differentiation into osteoblasts. By combining these agents, bone regeneration is promoted, which can lead to successful reconstruction of a bony defect (Fig. 50.6). Several studies reported the efficacy, safety, and ability of rhBMP-2 when combined with osteoconductive grafts to accomplish mandibular reconstruction [51,52]. The use of osteoprogenitor or stem cells from a bone marrow aspirate has improved results and offered another technique to reconstruct craniofacial bone defects.

Bone marrow aspirate serves as a rich and readily available source of bone-forming cells (MSCs), which otherwise would not be present in sufficient quantities in a traditional bone harvest. It is easily harvested with simple aspiration through large-bore needles and concentrated with centrifuge devices without significant donor site morbidity [75,76]. Bone marrow transplant/aspirate was first used to treat hemopoietic and oncologic diseases, but it has found additional uses as a cell source in the regeneration of other tissues in the body. Several studies have shown bone marrow−derived stem and progenitor cells to be capable of regenerating bone in both animal and human models [77,78]. BMAC has also been used with spine, long bone, and myocardial regeneration [77,79−81]. Of the mixed population of cells collected in an aspirate, Marx and Harrell suggested that CD34+, CD44+, CD90+, and CD105+ cells are the main types of osteoprogenitor cells collected in the concentrate [82].

In a comparison of osteogenic activity, Gimbel et al. studied patients undergoing alveolar cleft repair with different graft materials. A total of 69 patients were divided into three groups. Group 1 underwent grafting with bone marrow aspirate seeded onto a resorbable collagen matrix (n = 21); group 2 received autogenous cortical and cancellous bone harvested from the ilium through a traditional open approach (n = 25); and group 3 received autogenous cancellous bone that was collected from the ilium with a cannula (n = 23) [83]. Whereas alveolar bone formation was comparable in all three groups, the BMAC plus scaffold group experienced significantly less morbidity, operative time, duration of hospital stay, and cost.

A study conducted by Hendrich et al. described 101 patients treated with BMAC injections for various bone healing disturbances of the femur including necrosis of the head of the femur (n = 37), avascular necrosis (n = 32), nonunion of fractures (n = 12), and other problems (n = 20) [81]. After an average of 14 months (2−24 months),

FIGURE 50.4 Aspiration of bone marrow from ilium.

FIGURE 50.5 Aspirate after centrifuging, demonstrating separation of cells from plasma and red blood cells.

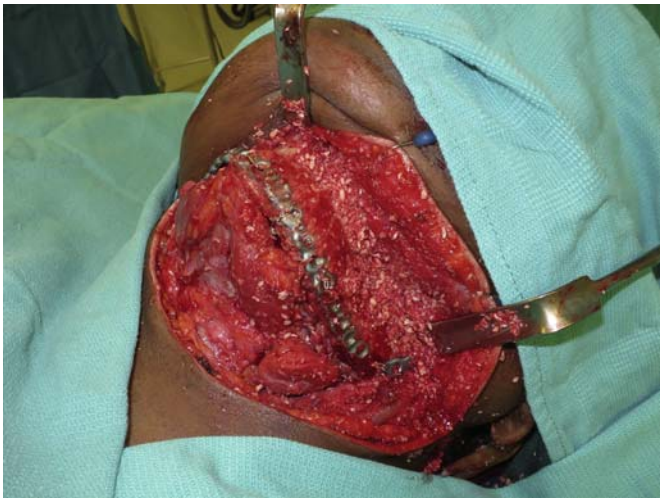

FIGURE 50.6 Tissue engineered graft for mandibular reconstruction: mixture of bone marrow aspirate concentrate, allogeneic bone, and recombinant human bone morphogenetic protein-2.

the patients were reexamined clinically and radiologically and interviewed. Of the 101 patients, only 2 required additional surgery to correct a nonunion or inadequate bone formation; no additional complications such as infections, excessive bone formation, or harvest site morbidity were observed. The researchers' conclusion was that BMAC therapy was a suitable alternative to open treatment but required additional studies to determine the full benefits of this treatment modality.

One of the most exciting applications of the BMAC technique in maxillofacial reconstruction lies in treating large segmental defects of the mandible. Marx and Harrell reported on a series of 40 patients who underwent mandibular reconstruction using this method [75]. All 40 patients achieved successful mandibular continuity that was functionally useful. Melville et al. conducted another study with five patients who underwent immediate intraoral reconstruction with the BMAC technique after resection of benign mandibular tumors [84] (Figs. 50.7 and 50.8). All patients achieved excellent bone quality both clinically and radiographically and were successful candidates for endosseous dental implant placement (Figs. 50.9 and 50.10). This case series demonstrated that composite allogeneic

bone, BMAC, and rhBMP grafts constitute an effective and predictable technique for immediate reconstruction of mandibular continuity defects. In addition, there was no donor site morbidity, intraoperative time was reduced, hospital stay was shorter, and total costs were lower compared with more traditional methods of mandibular reconstruction.

Bioreactors

If the desire is to use living biological tissue and avoid donor site morbidity, another strategy employs bioreactors to grow tissues in geometries matching the defect in either in vitro or in vivo environments [85]. In vitro bioreactors have been used to engineer tissues such as the temporomandibular joint (TMJ) or ear perichondrium [86,87]. Using human MSCs obtained from fresh bone marrow aspirate, researchers were able to observe confluent layers of lamellar bone and osteoids on the decellularized bone scaffold [86]. This required the use of a bioreactor of the same size and dimensions as the TMJ and a constant flow of media across the scaffold. Other types of in vitro bioreactors are also capable of generating viable tissue. A rotating wall bioreactor has been successfully used to cultivate elastic cartilage [87]. Tissue obtained from patients were differentiated into cartilage progenitor cells and injected into a porous scaffold of collagen, hydroxyapatite, and chondroitin sulfate. After culture for 6 weeks, differentiated chondrocytes and elastic fibers were observed in histology.

Although the formation of tissue engineered grafts is possible in vitro, it is important to consider how these tissues will obtain nutrients in vivo. For small tissues, the transport of nutrients and byproducts may be adequate; however, for large tissues, the diffusion rates may not be adequate for the tissue to survive [88]. By introducing vasculature into the construct, cells deep within the tissue can receive appropriate nutrition and gas exchange. In vivo bioreactors have been used to generate vascularized flaps that match the geometry of the defect [85,89–91].

Using strategies previously discussed, in vivo bioreactors can be designed to encourage bone growth in a chamber of desired dimensions. As with osteopromotion strategies, growth factor incorporation or cell seeding can be used directly within the defect to encourage bone growth. These techniques can be used to grow bone in bioreactors in animal models [89–91]. Using MASTERGRAFT, a clinically available scaffold consisting of hydroxyapatite and β-TCP, bone can be grown adjacent to rib periosteum in a large-animal model [89]. Because of the close proximity to the intercostal arteries and veins running below the ribs, tissue from the bioreactor chambers could be removed with the nearby vasculature and transferred to a mandibular defect as a vascularized flap. Whereas some chambers were filled with autograft (requiring harvest from elsewhere in the body), those filled with synthetic graft allowed for the formation of mineralized tissue and reconstruction of large mandibular defects. Incorporation of growth factors to in vivo bioreactors can also be used to promote advantageous ectopic bone growth [90]. BMP-7 was added to Bio-Oss (a scaffold derived from bovine bone) and placed in a pouch created within the latissimus dorsi muscle. After 6, 12, and 24 weeks, tissue was harvested and analyzed. Analysis showed the formation of new bone with vascular supply that could be used for mandibular reconstruction. As an alternative to loading scaffolds with growth factors, cells can be seeded onto scaffolds to promote tissue growth in in vivo bioreactors [91]. Porous, degradable PCL scaffolds were seeded with MSCs from neonatal rats. After 4 weeks of in vitro culture, the cell-seeded scaffolds were implanted in the omenta of rats. Four weeks later, the scaffolds were harvested

and mineralization was observed throughout the scaffold. However, the formation of vasculature allowing for flap transfer was not investigated.

With strong support for the efficacy of in vivo bioreactors in animal models, several bioreactor systems have been used clinically [53–56,92]. The earliest reported case involved angle-to-angle mandibular resection owing to a recurring ameloblastoma [53]. The mandibular-shaped chamber was loaded with autologous bone harvested from the iliac crest and BMP before implantation within the fascia above the scapula. After 4 months, the flap was harvested and transferred with vasculature to the mandible. Competence was restored for liquids and solids, but the patient did not regain the ability to swallow solids. Another clinical case study involved Bio-Oss, bone marrow, and rhBMP-7 within a titanium mesh [54]. The titanium mesh was shaped using CT scans to ensure a close match with the native patient architecture. After 7 weeks within the latissimus dorsi muscle, the mineralized tissue, titanium mesh, and adjacent vasculature were transferred to the mandible. The flap showed remodeling after transfer and the patient had an improved level of mastication after reconstruction completed. Unfortunately, after 13 months, the mesh fractured and the gingiva became disrupted, resulting in infection and necrosis of the mandible replacement [92]. The patient died soon thereafter of cardiac arrest. Many of the human in vivo bioreactor studies require the need for morcellized autograft or bone marrow. Hydroxyapatite with rhBMP-7 was capable growing mineralized tissue in the pectoralis muscle [55]. This tissue was then transferred to the mandible. The patient could talk and eat food; however, 5 months after transfer, the flap became infected. Another clinical study used CT images to shape a titanium mesh cage [56]. Bone blocks, rhBMP-2, and bone marrow aspirate were placed within the cage before implantation in the gastric omentum. After 3 months within the gastric omentum, the free tissue flap was harvested and used to reconstruct the mandible. Three months after transfer, the patient could talk and eat normally.

Adjuvant Therapies

Antibiotics

When repairing craniomaxillofacial tissue defects, proximity to bacterial flora is an important consideration. The oral cavity hosts over 500 bacterial species, including many species of *Streptococcus* [93], and the nasal cavity has been shown to be colonized by *Staphylococcus aureus* in 21% of patients at admission [94]. Although native bacteria generally do not cause problems, trauma or the following reparative surgery can shift the bacterial balance in favor of pathogenic bacteria or permit the passage of bacteria to previously aseptic sites. In facial fracture repair, infection rates can be as high as 42% if no antibiotics are received before surgery [95].

The use of cefazolin sodium has been shown to reduce the rate of infection to 9% during the surgical repair of facial fractures [95]. Although antibiotics are commonly provided systemically before many craniofacial surgeries, a systemic review and metaanalysis of endoscopic sinus surgeries showed no statistical difference in infection rate between patients who receive antibiotics and those who do not [96]. The authors noted that the amount of available data may have limited the statistical power of their analysis, however. For clean-contaminated wounds such as those commonly seen in patients with head and neck cancers, antibiotic prophylaxis becomes mandatory [97]. In cases in which the upper aerodigestive track is entered, the infection rate is much greater. In addition, these infections are often polymicrobial, and the chosen antibiotic should cover aerobic, anaerobic, and gram-negative flora [97].

From a tissue engineering perspective, local antibiotic release is an exciting avenue for exploration. A scaffold designed to promote bone growth, by material properties or the incorporation of bioactive molecules, could potentially deliver antibiotics to a local area, thereby alleviating some of the systemic effects of the antibiotic. Using an infected composite defect in a rabbit mandible, clindamycin-loaded poly(methyl methacrylate) space maintainers were shown to clear infection [98]. The study investigated both burst and extended release kinetics, but the inoculated bacteria were not recovered from any group. Several clinical products exist for local antibiotic release [99]. These clinically available products include gels, chips, fibers, and polymers consisting of a range of antimicrobials such as tetracycline, metronidazole, and doxycycline. After several days of controlled drug release to the site of the periodontal disease, degradation occurs for many of these products whereas others must be surgically removed [99].

Although the species distribution of craniofacial infection has not changed much over the years, the antibiotic resistance of these organisms is growing [100]. The production of β-lactamases has limited the efficacy of penicillin against some gram-negative species, and others are increasingly resistant to clindamycin. This growing resistance has led researchers to explore other potential methods of combatting infection [101,102]. Human saliva contains antimicrobial peptides that can cause bacterial cell death [102]. Although over 45 such peptides have been found,

efficacy in human trials has been limited. Antimicrobial peptides can be designed with different functional groups and can be modified to bind hydroxyapatite selectively [101]. A modest minimum inhibitory concentration (125 μg/mL) was seen against *Streptococcus mutans* and *Lactobacillus acidophilus* when bound to hydroxyapatite. Although this particular antimicrobial peptide was designed to bind to tooth surfaces to combat biofilm formation, the in vitro studies were conducted on hydroxyapatite scaffolds, a major component of the CaP cements discussed earlier.

Patient-Specific Technology

Tissue engineering scaffolds have classically been fabricated from techniques such as electrospinning, phase separation, gas foaming, and particulate leaching [103]. Although researchers have worked to optimize and refine these techniques further, there are intrinsic limitations to the architecture and topography that can be achieved with these conventional techniques. Furthermore, techniques such as electrospinning require the use of organic carcinogenic solvents [104]. The field of tissue engineering has embraced AM or rapid prototyping techniques to bypass these limitations and produce scaffolds with superior reproducibility, more sophisticated structural features, and even patient-specific constructs [105]. Tissue engineers have leveraged AM to control the internal architecture of scaffolds, whereas surgeons have adopted AM to produce solid biomodels that reproduce the patient's anatomy. The field of craniomaxillofacial surgery first adopted AM techniques to produce patient-specific models for surgical planning [106]. This proved to be an invaluable tool for surgeons, because an operation could be planned beforehand. In addition, it allowed the surgeon to predict physical outcomes of the procedure [106]. AM techniques have been extended to produce patient-specific implants. These custom implants precisely fit within a defect site, reducing surgical time and improving aesthetics [107,108].

To generate a patient-specific implant, a fine-cut CT study must be obtained that is acquired according to a special protocol. The radiographic data are first processed with software such as 3D Doctor, to creates a three-dimensional model of the defect. This model is then transferred to design software that allows the engineer to create the implant design. The implant is manufactured from this dataset by subtractive or AM techniques before sterilizing, packaging, and delivery to the surgeon. Initially, the fabrication of patient-specific implants was hindered by limitations within the fields of design and manufacturing. However, technological advances have led to customized cranial, dental, and facial implants in addition to space holders for grafts [58,109–111].

Chacon-Moya et al. published a case report of a 63-year-old female patient diagnosed with esthesioneuroblastoma [111]. The patient underwent an anterior craniofacial resection and radiotherapy. After treatment, the patient developed secondary complications of osteomyelitis and osteoradionecrosis that resulted in loss of the anterior cranial vault [111]. After resolution of the infection, the patient underwent frontal bone reconstruction using a computer-generated poly(ether ether ketone) (PEEK) implant. The patient was observed for 5 months after the PEEK implantation and no complications were observed. This case serves to demonstrate that reconstruction using PEEK implants is an excellent option in patients with large bone defects. Alternatively, computer-aided design–based technology can be leveraged to fabricate customized jigs and cutting guides (Fig. 50.11A and B). This allows the surgeon to create osteotomies in the fibula, resulting in an autogenous graft that approximates the defect contour (Fig. 50.12). Hou et al. used three-dimensional model simulation to contour vascularized fibular osteomyocutaneous flaps to repair mandibular defects in 15 patients [112] (Fig. 50.13). In this report, all patients experienced uneventful healing and were satisfied with the functionality and esthetics when questioned 6 months after surgery. These examples further illustrate the beneficial role AM has within the field of craniofacial surgery.

CONCLUSION

The field of tissue engineering continues to make important strides toward the goal of producing biological tissue of high functional and esthetic fidelity to replace anatomical structures lost to trauma or disease. The field has developed sophisticated biomaterials that leverage manufacturing techniques, characterized and manufactured cell signaling proteins, and developed strategies to deliver therapeutic doses of antibiotics locally to improve tissue regeneration further. In addition, clinicians trying to apply this technology have gained new appreciation for the underlying cause of a defect, which has a significant role in the success of tissue regeneration. Although there have been significant advancements in the field, new directions of investigation into regenerating composite, vascularized, and innervated constructs are required to account for all the tissue types present within the craniofacial region.

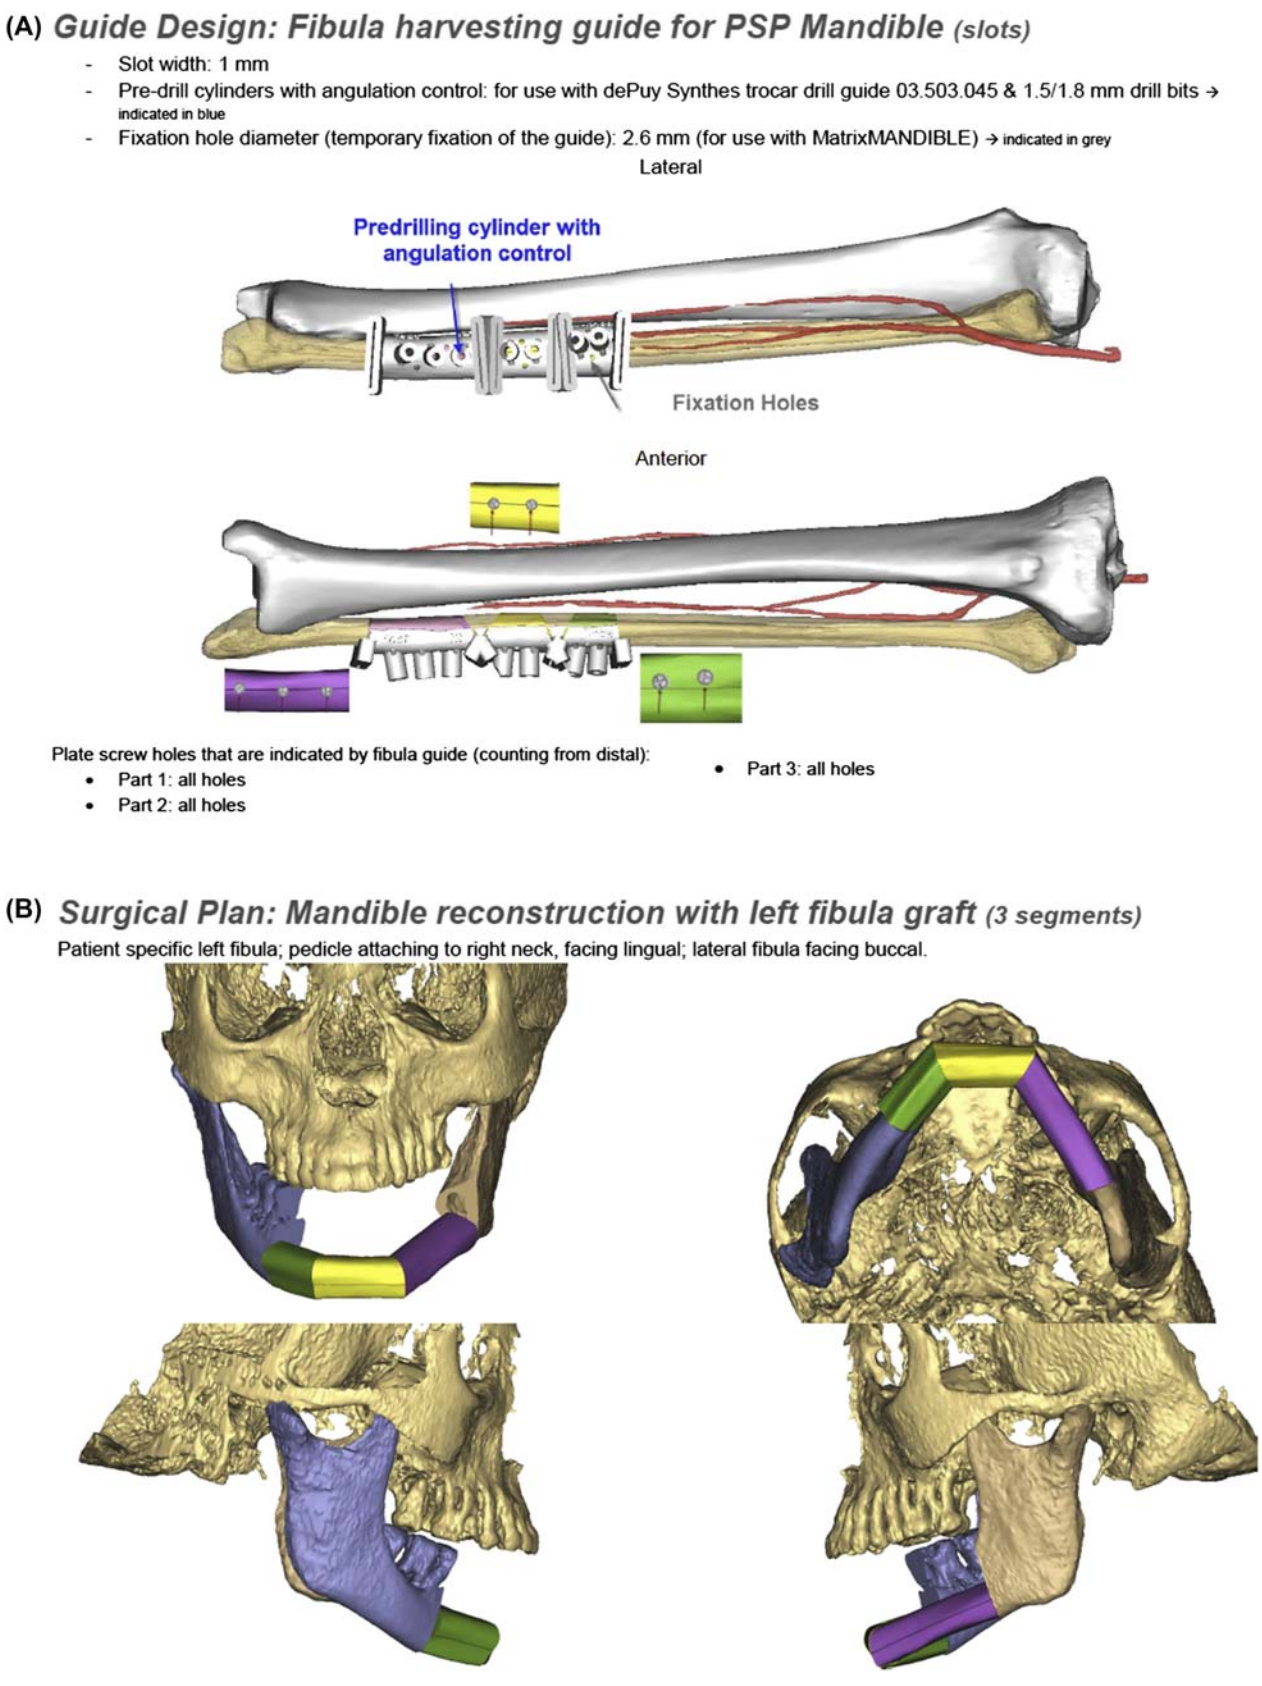

FIGURE 50.11 (A) Virtual surgical planning (VSP) matches the geometry of the fibula to the planned mandibular defect for reconstruction. (B) VSP plan shows final mandibular reconstruction using the fibula, which has been contoured to fit the defect through osteotomies and ostectomies.

FIGURE 50.12 Custom-fabricated plastic jigs applied to the fibula to guide the creation of osteotomies to contour the bone.

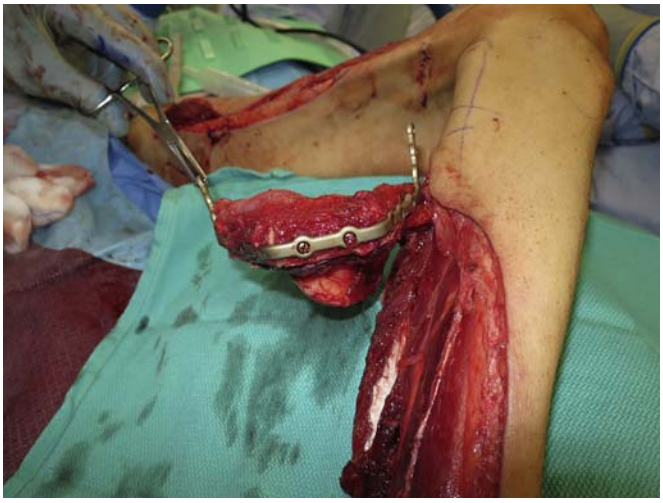

FIGURE 50.13 Fibula contoured with custom jigs is plated to maintain its shape before transplantation to the mandibular defect.

List of Abbreviations

AM Additive manufacturing
BMAC Bone marrow aspirate concentrate
BMPs Bone morphogenetic proteins
CaP Calcium phosphate
CT Computed tomography
MSC Mesenchymal stem cells
PCL Poly(ε-caprolactone)
PDGF Platelet-derived growth factor
PLGA Poly(lactic-*co*-glycolic acid)
rhBMP-2 Recombinant human bone morphogenetic protein-2
rhPDGF Recombinant human platelet-derived growth factor
TCP Tricalcium phosphate
TMJ Temporomandibular joint

Acknowledgments

We acknowledge support toward the development of new technologies for craniofacial regenerative medicine by the National Institutes of Health (NIH) (R34 DE025593) and the Army, Navy, NIH, Air Force, Veterans Administration, and Health Affairs to support the AFIRM II effort, under Award No. W81XWH-14-2-0004.

Dental Tissue Engineering

Nelson Monteiro[1], *Pamela C. Yelick*[2]

[1]University of Connecticut Health, Farmington, CT, United States; [2]Tufts University School of Dental Medicine, Boston, MA, United States

INTRODUCTION

Dental caries, trauma, genetic disorders, and periodontal diseases may cause damage and loss of dental tissues, and ultimately loss of the whole tooth [1]. Despite advancements in dental therapies, loss of dental tissues and teeth is a concern both to individuals and to their professional health care providers and remains a highly prominent public health issue [2,3]. It was reported that the public health burden associated with dental treatment of root canals represents a significant fraction of all expenses related to dental care, which totaled $100 billion in 2009 in the US alone [3]. Approximately 150 million adults experience tooth loss, and it is expected that over 10 million new cases of edentulism will have arisen in one decade [2]. Another highly significant population and of particular concern to the field of regenerative medicine and the US Department of Defense is the military. In 2000, a cost of $1.9 billion was estimated for active duty personnel and $203 million for recruits; periodontal disease accounted for the greatest proportion of active duty treatment costs (47%) and oral surgery for the greatest proportion of recruit treatment costs (32%) [4]. Therefore, the health of both military and civilian populations would significantly benefit from the development of new, improved, and alternative functional dental tissue replacement therapies.

Treatments for deep carious lesions include pulp capping or partial pulp amputation to preserve the pulp tissue [5,6]. However, in the case of irreversible pulpitis, root canal treatment or extraction of the tooth is necessary. Root canal therapy involves complete removal of the infected pulp tissue and replacement with inert material [7]. There are some limitations associated with root canal treatment, including pulp tissue devitalization and excessive enlargement of the pulp chamber; in addition, debridement of infected root canals and the preparation of a post to support a synthetic tooth crown can increase the possibility of tooth root fracture and tooth loss. Dental prosthetic procedures such as dental implant placement have been used as tooth replacement therapies for many centuries [8]. Dental implants function through osseointegration, which is direct integration of the implant with the surrounding alveolar bone [9]. Dental implants have improved significantly over the years, based on innovations from basic and translational research, material sciences, and clinical techniques [8]. However, they are not equivalent to natural teeth in either function or aesthetics. They lack periodontal and cementum tissues, which function to cushion and modulate the mechanical stresses of mastication [9]. These disadvantages have driven an ongoing search for alternative strategies to overcome both the need for root canal and dental implant treatments. This search has led to the development of dental tissue engineering (TE) technologies, which consist of combined TE and clinical approaches to bioengineer dental tissues and whole teeth. Dental TE has demonstrated the potential use of dental stem cells (DSCs), biodegradable scaffolds, and bioactive agents such as growth factors (GFs) to control the spatial and temporal organization of regenerated dental tissues [8,10]. It is expected that dental TE will soon emerge as the preferred solution to root canal and dental implants therapies. Here, we summarize advances in dental TE to regenerate dental tissues including dental pulp, dentin, periodontal tissues, alveolar bone, and whole teeth.

TOOTH DEVELOPMENT

Tooth development is a tightly regulated process mediated by dental epithelial–mesenchymal cell interactions, Fig. 51.1. The dental mesenchyme and dental epithelium are derived from the neural crest and the ectoderm, respectively [11]. Tooth organogenesis is regulated by a complex and intricate network of cell–cell signaling, gene expression, and GF signaling pathways [12]. Progress in elucidating the roles of molecular signals in natural tooth development has shed light on new approaches to control better the cell migration, growth, and differentiation of regenerated tissues [8,12,13]. It is known that at least 12 transcription factors are expressed in odontogenic mesenchyme [12], and more than 200 genes have been identified that are expressed in the oral epithelium, dental epithelium, and dental mesenchyme during the initiation of tooth development [14]. Tooth organogenesis is initiated by the formation of the dental lamina within the dental epithelium. The dental epithelial placode exhibits localized proliferative activity leading to dental epithelial outgrowths into the ectomesenchyme. The developing tooth organ proceeds through bud, cap, and bell stages [11,12]. In the bell stage, species-specific cusp patterns emerge, forming either a single or a multicusped tooth. The bell stage is followed by the differentiation stage, in which final growth and matrix secretion occur as the inner enamel epithelium differentiates into enamel-producing ameloblasts, whereas adjacent dental mesenchymal cells differentiate into dentin-producing odontoblasts [11,13].

The dental pulp is the soft connective tissue in the center of the tooth, which is enclosed by dentin [12]. Dental pulp has a variety of functions: (1) to support nerves that provide sensitivity to the tooth, (2) to nourish the avascular dentin, and (3) to produce the dentin that surrounds it. Dental pulp differs from other craniofacial structures in that it is extensively vascularized and innervated. Pulp vascularization is established by vasculogenesis during embryonic development of the tooth, and angiogenesis occurs during regeneration and therapeutic processes. Pulp innervation occurs at a relatively late postnatal stage and is innervated primarily by nociceptors [15]. Dentin is a resilient and elastic tissue that forms the bulk of the tooth, supports the enamel, and compensates for the brittleness of the highly mineralized enamel tissue. Dentin is a sensitive tissue that is capable of limited self-repair [12]. Odontoblasts and dental mesenchymal cells present in the tooth pulp can be stimulated to deposit new dentin in response to mechanical injury, termed reparative dentin. Enamel is the most highly mineralized tissue in the body; it consists of greater than 96% hydroxyapatite (HA) and exhibits a complex crystalline lattice organization [11,12]. Ameloblasts,

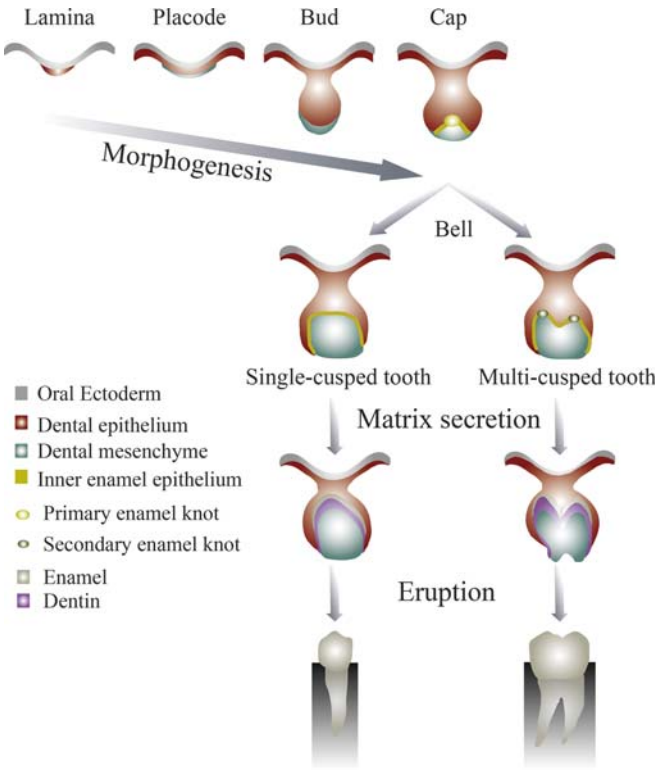

FIGURE 51.1 Principal stages of tooth formation [1].

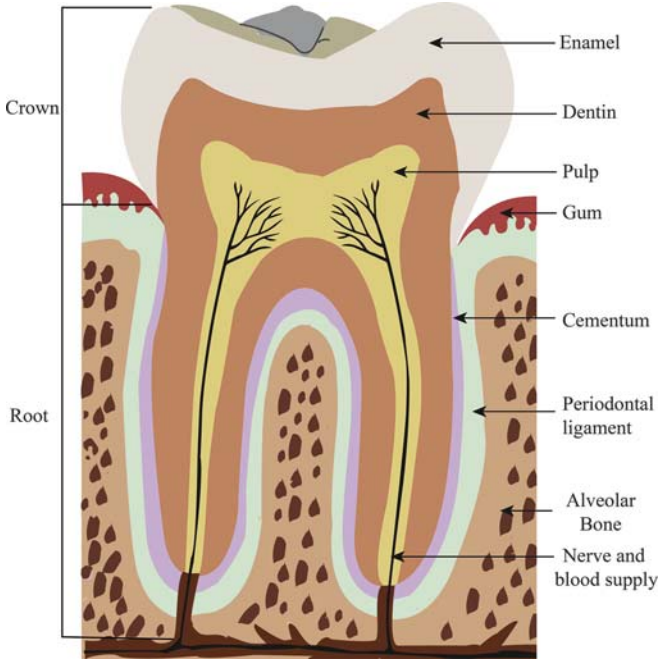

FIGURE 51.2 Adult human tooth morphology.

which secrete the enamel, largely undergo apoptosis before the tooth emerges into the oral cavity, with only a few dental epithelial cell remnants remaining in the periodontal ligament (PDL), termed the epithelial rests of Malassez. The tooth is attached to the jaw by specialized supporting tissues that consist of the PDL, the cementum, and the alveolar bone, all of which are derived from the neural crest cell–derived dental mesenchyme and which are protected by the gingiva (Fig. 51.2). To date, vital vascularized and innervated human adult teeth cannot be regenerated or regrown once damaged or lost. Therefore, the development of effective therapies to regenerate and repair lost or damaged teeth is a major goal of dental TE and regenerative medicine.

DENTAL STEM CELLS

DSCs can be collected from a variety of embryonic and postnatal or adult dental tissues. Embryonic stem cells (ESCs) are pluripotent stem cells that have the capacity to form all tissues of the body, including dental tissues [1,10]. ESCs can be obtained from the inner cell mass of a blastocyst in the 4- to 5-day-old embryo and from the embryonic germ in the 10- to 15-day-old embryo [10,16,17]. In contrast to ESCs, postnatal DSCs are multipotent stem cells that can develop into a restricted number of differentiated dental cell types [18]. The main functions of DSCs in natural teeth are to repair damaged dental tissues and maintain normal dental tissue turnover. Five different mesenchymal stem cell (MSC) populations have been identified in dental tissues, including dental pulp stem cells (DPSCs), stem cells from human exfoliated deciduous teeth (SHEDs), PDL stem cells (PDLSCs), dental follicle precursor cells (DFPCs), and stem cells from apical papilla (SCAPs). Each type of DSC population has specific characteristics and advantages for application in regenerative medicine and dentistry.

In 2000, Gronthos et al. were the first to report the isolation and identification of DPSCs in adult human dental pulp [19]. They showed that DPSCs can produce densely calcified nodules in in vitro tissue culture, but did not exhibit the capacity to form adipocytes, compared with bone marrow mesenchymal stem cells (BMSCs), which do. However, in 2002, Gronthos et al. reported the capacity of DPSCs to differentiate into both adipocytes and neural-like cells [20]. Periodontal ligament stem cells (PDLSCs) are found in PDL tissues located between the tooth and the alveolar bone and can be isolated from the roots of extracted teeth. PDLSCs have the capacity to differentiate into cementoblast-like cells, adipocytes, osteoblasts and collagen-forming cells [21]. Moreover, they were shown to regenerate a cementum–PDL-like structure and contribute to periodontal tissue repair [21]. SHEDs are isolated from an accessible tissue resource: autologous baby teeth [22]. They were identified as a population of highly proliferative, clonogenic cells capable of differentiating into a variety of cell types including neural cells,

adipocytes, and odontoblasts [22]. SHEDs showed the capacity to induce bone formation, generate dentin, and survive in mouse brain after in vivo transplantation. DFPCs can be isolated from the dental follicle, which surrounds the developing tooth and supports the formation of cementum, PDL, and alveolar bone [23]. DFSCs have the capacity to differentiate into osteoblasts, adipocytes, and nerve-like cells in in vitro culture [24–26]. DFPCs expressed higher amounts of insulin-like growth factor-2 transcripts than human BMSCs, and after in vivo transplantation in immunocompromised mice, DFPCs expressed osteocalcin (OCN) and bone sialoprotein (BS) but did not exhibit cementum or bone formation [23]. However, other studies showed that DFSCs transplanted into mice contributed to the formation of a new PDL and cementum tissues [27,28]. SCAPs can be isolated from the dental papilla, which normally develop into the tooth dentin and pulp. It was reported that SCAPs proliferate two- to threefold more rapidly than stem cells obtained from the pulp organ [29]. Also, SCAPs were demonstrated to differentiate into osteoblasts, odondoblasts and adipocytes in in vitro culture, and when implanted in vivo, they were shown to differentiate into osteoblasts and odontoblasts [30,31]. Immunophenotypically, SCAPs are similar to DPSCs with respect to osteogenic or dentinogenic and GF receptor gene profiles, and they also express the stem cell marker STRO-1 and dentinogenic markers including bone sialophosphoprotein, OCN, and the GFs fibroblast growth factor (FGF) recombinant 1 (FGFR1) and transforming growth factor (TGF)-β [29]. Moreover, upon stimulation with a neurogenic medium, SCAPs express a wide variety of neurogenic markers including nestin and neurofilament M.

Based on the promising characteristics of DSCs, dental TE efforts are focused on using DSC populations to bioengineer dental tissues, tooth supporting structures, and bioengineered whole teeth. Moreover, DSCs are considered to be a promising treatment method for several clinical conditions including Alzheimer disease, Parkinson disease, and spinal cord injury [32]. Here, we describe advances in dental TE to regenerate whole tooth and dental tissue structures, including dental pulp, dentin, PDL, and alveolar bone.

DENTAL TISSUE ENGINEERING

The basic principle of TE employs the use of cells, scaffolds, and bioactive agents to regenerate tissues similar to native human tissues (Fig. 51.3). In vivo delivery exposes cells to a host of survival challenges, including immune issues related to inflammation and autoimmunity [33]. To survive the initial onslaught of the immune response

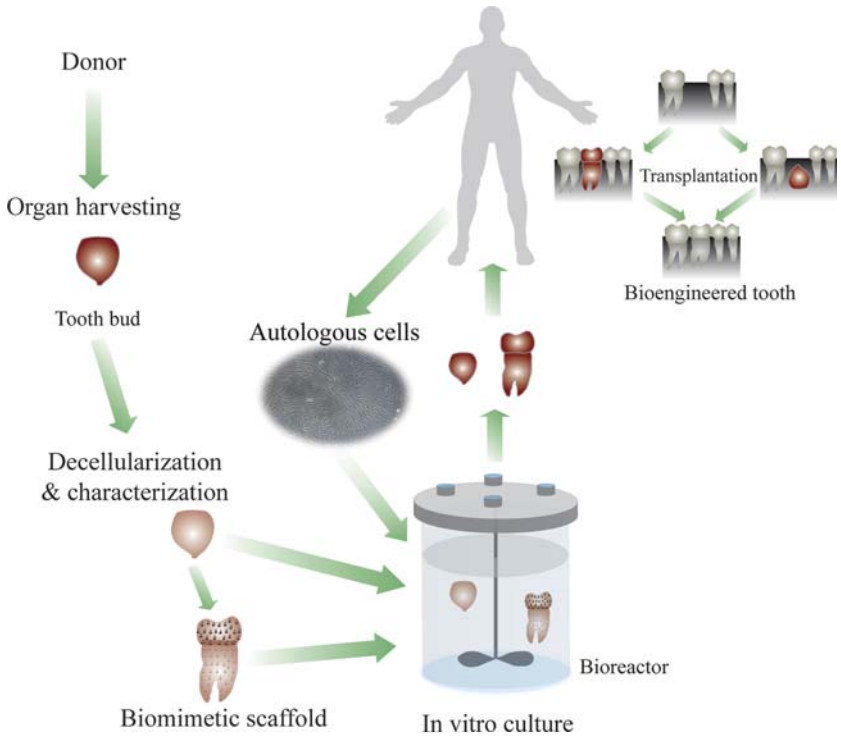

FIGURE 51.3 Dental tissue engineering approach [1].

better and avoid death, in vivo–delivered cells can be seeded in or onto a biodegradable scaffold before implantation when they are used to repopulate a tissue defect and/or restore function [34]. Ideal TE scaffolds mimic the properties and functions of the natural extracellular matrix (ECM), providing appropriate physical characteristics to support the development of new functional tissues. Therefore, it is important to consider the mechanical integrity and surface functionality of any given biomaterial scaffold, to ensure appropriate cell adhesion, proliferation, and differentiation [35,36]. Both natural and synthetic biomaterial scaffolds have been proposed for dental tissue regeneration [1,35,37–40]. The advantage of using natural scaffolds (i.e., collagen, alginate, fibrin, chitosan, gelatin, silk) is the ability to fine-tune their degradation rates by varying the concentration of the polymer and/or cross-linking agents. Synthetic scaffolds (polylactic acid, polyglycolic acid (PGA), PLLA, PLGA, PCL, etc.) have advantages including processing flexibility and the ability to be manufactured in any shape or size and with the desired predefined architecture and structural parameters [35]. Hydrogels are a specific class of scaffolds that exhibit huge potential for applications in dental tissue regeneration, owing to their versatility and adaptability [41,42]. Hydrogels offer several advantages including injectability, easy incorporation of therapeutic agents and cells under mild conditions, minimally invasive local delivery, and high contourability [42,43].

Bioactive agents such as GFs and nucleic acids have an important role in odontogenesis [12] and can be used to functionalize scaffolds to initiate the formation of new tissues [1]. As such, scaffolds can provide a multitude of advantages for bioactive agents, including safe delivery profiles, protection from biodegradation, and the ability to deliver the bioactive agents locally to where they are needed [13,44–46]. GF are critical to the development, maturation, maintenance, and repair of craniofacial and dental tissues [12]. It is therefore important to understand which of the GFs resident in the DSC niche provide appropriate cues to control their fate. For instance, GFs produced by DSCs during tooth development are responsible for the regenerative capacity of the dentin, which maintain cell proliferation and differentiation potential [12]. GFs function by binding to the extracellular domain of an appropriate target GF receptor, which in turn activates intracellular signal transduction pathways [47]. Several GFs (i.e., bone morphogenetic proteins [BMPs], sonic hedgehog [SHH], TGFs, FGFs, brain-derived neurotrophic factor [BDNF], and VEGF) are expressed during tooth formation and repair [1,15]. Therefore, dental tissue regeneration may be facilitated by incorporating GFs into scaffolds to promote dental cell differentiation. Also, because GF protein expression is the result of their gene expression [12], incorporating nucleic acid expression constructs into scaffolds has been proposed as a means to overcome certain limitations of GF delivery, including their short half-lives, denaturation during encapsulation processes, the time-consuming and expensive problem of GF production, the requirement for supraphysiological doses and GF combination for the most effective approach, the extended times required for cell differentiation, and difficulties in differentiating cells toward specific lineages [47–49]. Gene delivery of transcription factors can be used to ensure proper expression of particular splice variants in a coordinated time and sequence, and the ability to regulate a cascade of multiple genes, all from a single delivered construct [1]. Moreover, interference RNA (RNAi), a gene silencing mechanism, can be used to induce DSC differentiation [50].

Several approaches have been developed to incorporate a variety of bioactive agents into scaffolds and control their release profiles [45,46]. For instance, covalent immobilization of bioactive agents offers additional control over the spatiotemporal distribution of a particular agent compared with physical adsorption [1]. Immobilized bioactive agents can be released upon degradation of the matrix or by the hydrolysis of degradable links. Another way to entrap bioactive agents into scaffolds is by incorporating microparticles and nanoparticles [51–54]. The nanoscale properties of nanoparticles enable the ability to fine-tune release kinetics for improved transport properties, diffusivity, solubility, regulated biodistribution, minimization of toxic side effects, and the enhanced therapeutic index of bioactive agents. The combination of DSCs, biomaterial scaffolds, and bioactive agent delivery systems allows for the creation of multifunctionalized systems that can be used to facilitate dental tissue regeneration [1].

Notably, decellularized scaffolds and scaffold free approaches have created new areas of research in addition to the previously used natural and synthetic scaffold approaches [55–58]. Decellularized scaffolds, created by gently removing immunogenic cells from natural tissues such as heart, lung, bone, liver, and tooth buds, preserve the structure, shape compatibility, mechanical integrity, and bioactive molecule gradients that facilitate cell–cell interactions, cell adhesion, and ECM formation [55,59]. As such, detailed characterizations of ECM composition and organization in natural dental tissues could also facilitate dental TE efforts [56,60]. Finally, cell sheet technologies have been proposed to facilitate the regeneration of dental tissues including tooth root, pulp, dentin, and periodontal tissues [57,61–63]. This technique enables the creation of intact sheets of cells that can be harvested without trypsinization and preserves the ECM formed by the cells, including adhesive proteins such as fibronectin. Application of these TE approaches in dental tissue regeneration are discussed subsequently.

Whole Tooth Engineering

Several approaches to engineering entire biological teeth have been proposed, including dental TE, stimulation of third dentition formation, cell–tissue recombination, chimeric tooth TE, and gene-manipulated tooth regeneration [1]. The two major approaches used for tooth regeneration are cell–tissue recombination and dental TE approaches. Dental cell–tissue recombination approaches rely on replicating the natural processes of tooth development, in which cultured progenitor stem cell–tissue constructs are directly implanted in the defect site (Fig. 51.4). Many studies have reported the bioengineering of functional teeth from embryonic stem cells cultured in vitro and/or implanted in vivo [16,17,64–66]. Ohazama et al. showed that embryonic day (E)10 oral epithelium stimulated an odontogenic response in cultured neural and BMSCs [16]. Moreover, BMSC-derived recombinants were demonstrated to form tooth crown structures composed of enamel, dentin, and pulp. In contrast, tissue recombinants derived from ESCs and neural stem cells did not form teeth but expressed odontogenesis-related genes [16]. In another study, high cell–density suspensions generated from E14.5 incisor epithelial and mesenchymal tissues cultured in vitro or implanted into the subrenal kidney capsule subsequently formed bioengineered teeth when implanted in the extraction socket of a rat mandibular incisor [17]. These studies demonstrate the potential for using ESCs for tooth regeneration. However, the potential tumorigenic nature of transplanted ESCs, ethical issues regarding the use of human embryos, and the potential for allogeneic immune rejection are all major concerns of ESC-based therapies [10,67].

Adult DSCs, BMSCs, umbilical cord–derived MSCs, and induced pluripotent stem (iPS) all exhibit potential for use in dental TE [10,68]. Young et al. demonstrated the first successful use of adult DSCs seeded onto PGA–PLLA scaffolds to generate tooth crowns containing dentin and enamel; this demonstrated the presence of adult dental epithelial and MSC populations in pig third-molar tooth tissues [69]. Another study demonstrated that bioengineered pig tooth crowns containing dentin, pulp, and enamel formed in 25–30 weeks, whereas rat tooth crowns formed in just 12 weeks [70]. Honda et al. harvested dental cells from canine first-molar tooth buds, seeded them onto PGA scaffolds, and implanted them into tooth sockets of extracted teeth [71]. Subsequent analyses of harvested implants showed the formation of dentin and bone, but no enamel tissue or dental-root formation was observed. The same authors reported that dental epithelial and mesenchymal cells harvested from porcine third molar teeth seeded onto collagen scaffolds and implanted in vivo formed a single tooth in each scaffold that was morphologically similar to natural teeth [72]. In another interesting study, comparison of bioengineered dental tissues grown in the mandible versus the omentum revealed that both implant sites supported the formation of bioengineered dentin, enamel, pulp, and periodontal tissues [73]. However, omental implant dental tissues appeared to be more organized than those grown in the mandible. Yang et al. reported the formation of a complete tooth, consisting of a tooth crown, root, pulp, enamel, dentin, odontoblasts, cementum, blood vessels, and PDLs when tooth bud cells were suspended in fibrin glue and autografted back into the original alveolar sockets of a pig [74]. Smith et al. demonstrated the use of gelatin methacryloyl (GelMA) hydrogels, combined with postnatal porcine dental epithelial and dental mesenchymal progenitor cells, to support the formation of mineralized and functionally vascularized tissues of specified size and shape [75]. Also, the same model was improved by incorporating dental epithelial and dental mesenchymal cell sheets that expressed appropriate tooth marker expression patterns including SHH, BMP-2, Runt-related transcription factor 2, tenascin, and syndecan in vitro and in vivo [57]. Yang et al. reported whole tooth regeneration using DPSCs combined with epithelial cells isolated from gingival epithelium implanted into the mandibular alveolar socket of a pig for 13.5 months [66]. Seven of eight pigs developed two teeth containing crown, root, and pulp structures. Subsequent histological analyses demonstrated the formation of enamel-like tissues, dentin, cementum, odontoblasts, and periodontal tissues. All of the pig hosts formed regenerated molar teeth regardless

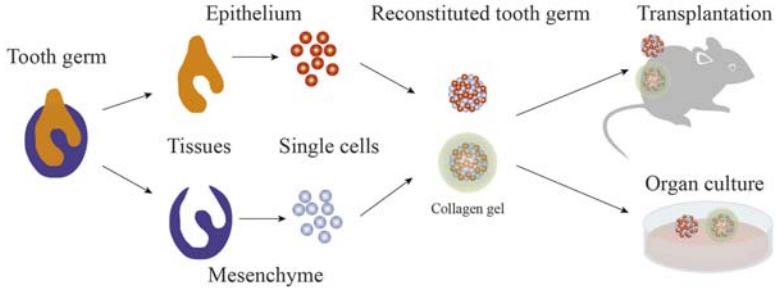

FIGURE 51.4 Dental cell tissue recombination approach [1].

of the original tooth type used to procure the DPSCs, whereas pig hosts that had tooth germs removed or received acellular scaffold implants did not develop new teeth. The authors also reported that the implant location may have influenced the morphology of the regenerated tooth.

More detailed characterizations of tooth expressed ECM molecules, including their respective developmental and spatial organization, may facilitate the design of effective scaffolds for tooth regeneration. One approach to achieving this goal included devising methods to decellularize and demineralize porcine molar tooth buds effectively while preserving natural ECM protein gradients [56]. This report showed that the collagen I, fibronectin, collagen IV, and laminin gradients present in natural tooth tissues were retained in decellularized tooth bud samples. Second harmonic−generation image analysis and three-dimensional (3D) reconstructions showed that natural tooth tissue exhibited higher collagen fiber density and more organized collagen fibers compared with decellularized tooth tissue. That report showed that dental cells seeded back into the decellularized tooth bud scaffolds were able to establish residence within the scaffold and to elaborate and remodel the matrix. Ongoing research has focused on detailed 3D characterizations of tooth pulp tissue to examine collagen fiber destruction and remodeling as a consequence of the decellularization and reseeding processes.

Dental Pulp and Dentin Regeneration

Dental pulp consists of DPSCs, odontoblasts, endothelial cells, neurons, immune system cells, GFs and the ECM, all of which are crucial for maintaining the functions of healthy teeth. Dentin, which encases the dental pulp, is a mineralized form of the collagen-based predentin matrix; its crystalline structure primarily consists of HA and water [76]. Creating an in vitro tissue model that takes into account all of the aspects of a pulp−dentin microenvironment is challenging. Nonetheless, adopting a deconstruction strategy to reduce the pulp−dentin ecosystem to a few of the main components anticipated to be involved in maintaining functional pulp−dentin biology may be sufficient to establish in vitro models capable of pulp−dentin regeneration. Because interactions between tissue vasculature and nerves is critical to maintaining dental pulp homeostasis, dental TE strategies for pulp regeneration must recreate a microenvironment that supports the cellular cross-talk needed to maintain the healthy, functional tissue heterogeneity of natural tooth pulp [76]. Advances in the field of TE have made dental pulp regeneration a realistic, attractive, and alternative therapy for endodontic treatments to restore damaged teeth [5,6,77−81]. The goal is to replace the damaged pulp−dentin complex with a bioengineered, functional biological tissue surrogate that can integrate with remaining healthy host tissues. The first evidence of novo pulp regeneration was demonstrated using human tooth slices or root segments (RSs) injected with DSCs combined with scaffolds [79]. In that report, Cordeiro et al. showed that SHED cell-seeded PLLA scaffolds placed within human tooth slices and transplanted into immunodeficient mice created bioengineered tissue architecture and cellularity closely resembling those of physiologic dental pulp [79,81], including SHED cell differentiation into odontoblast and endothelial-like cells. When supplemented with VEGF, SHED cells expressed VEGF receptor2, CD31, and vascular endothelial cadherin and organized into capillary-like sprouts [81]. These studies demonstrated that the VEGF signaling pathway is an important regulator of endothelial cell−controlled differentiation of DSCs, and therefore that scaffold biomaterials could be used to control the delivery of GFs such as VEGF for dental TE [13]. Another study consisted of SCAPs and DPSCs seeded onto PLG scaffolds, inserted into tooth RSs and transplanted in mice. Analyses of harvested implants showed that the root canal space was filled entirely by a pulp-like tissue exhibiting well-established vascularity, and the formation of a continuous layer of dentin-like tissue deposited along the dental wall of the tooth root canal. The newly formed dentin like tissue was elaborated by a layer of newly formed odontoblast-like cells expressing dentin sialophosphoprotein, BS, alkaline phosphatase, and CD105.

For optimized clinical translation, dental pulp regeneration will require the use of injectable scaffolds. Rosa et al. tested the hypothesis whether SHED encapsulated in PuraMatrix hydrogel or collagen I, could regenerate a functional dental pulp when injected into full-length root canals and implanted in vivo [77]. The authors reported the formation of pulp-like tissues, including the presence of odontoblasts capable of generating new tubular dentin throughout the root canals. The engineered pulp tissue exhibited cellularity and vascularization similar to those of natural human dental pulps. Therefore, this strategy might successfully facilitate the completion of tooth root formation in damaged, necrotic, immature permanent teeth. In another study, autologous DPSCs encapsulated in collagen were transplanted into a root canal along with stromal cell−derived factor-1 (SDF-1) after pulpectomy of mature teeth with complete apical closure in dogs [82]. The results showed that by day 14, the root canal was successfully filled with regenerated pulp tissue, including nerves and vasculature, followed by new dentin formation along the dentinal wall. Khayat et al. also defined a reliable method to regenerate pulp-like tissues within tooth RSs using 5% GelMA hydrogel-encapsulated human DPSCs−human umbilical vein endothelial cells

(HUVECs) implanted subcutaneously in nude rats for 4 and 8 weeks [6]. Analyses of harvested implants showed that hDPSC−HUVEC-encapsulated GelMA constructs formed pulp-like tissue that adhered to the inner dentin surface of the RS, including odontoblast-like cells exhibiting cell extensions into the dentin tubules. Moreover, that report showed that GelMA hydrogels supported hDPSC−HUVEC cell attachment, proliferation, and infiltration of host cells and promoted the establishment of well-organized neovasculature formation. This study identified GelMA hydrogels combined with DSCs as a promising, clinically relevant pulpal revascularization treatment to regenerate human dental pulp tissues. Another study showed that SHEDs and DPSCs cultured in peptide−amphiphile hydrogel scaffolds exhibited cell proliferation and differentiation within the scaffolds, and that SHEDs formed a soft tissue whereas DPSCs deposited mineral [43]. These hydrogel scaffolds are desirable for clinical applications for pulp regeneration, because they are easy to handle and can be introduced into small defects or root canal. Hyaluronic acid sponge scaffolds also exhibit an appropriate structure, biocompatibility, and biodegradation for dental pulp regeneration [83]. In vivo studies using hyaluronic acid−based scaffolds in an amputated dental pulp of rat molar showed dental pulp proliferation and blood vessel invasion. Prescott et al. investigated the role of DPSCs, collagen scaffold, and dentin matrix protein 1 (DMP1) in a simulated furcal perforation, in vivo mouse model [84]. The successful formation of organized pulp tissue was observed in the group containing the triad of DPSCs, a collagen scaffold, and DMP1. In another report, a chitosan bilayer membrane containing TGF-β1 releasing microspheres was developed to promote reparative dentin formation in a pulp-capping dog model [85]. Analyses of in vivo implanted constructs showed that TGF-β1−releasing chitosan membranes generated reparative dentin three to six times thicker than those generated by chitosan bilayer membrane alone. In another study, decellularized human dental pulp ECM supported the proliferation and differentiation of SCAP into odontoblast-like cells near pulp chamber dentinal walls [86]. That study demonstrated that human dental pulp from healthy extracted teeth can be successfully decellularized and subsequently used to differentiate reseeded DSCs, potentially improving clinical outcomes and ultimately promoting the survival and function of injured teeth. Ravindran et al. also demonstrated the odontogenic differentiation of both human DPSCs and human PDLSCs when cultured on a decellularized 3D pulp ECM scaffold, without the need for the exogenous addition of GFs. Subcutaneous implantation of ECM scaffolds containing DPSCs showed the formation of dental pulp-like tissue containing cells expressing DSP and dentin phosphophorin . These results showed that a decellularized dental pulp ECM scaffold can be used as a biomimetic scaffold for dental tissue regeneration and as tool to study the extracellular function of multifunctional proteins [60].

Kim et al. reported the regeneration of dental pulp-like tissue in human teeth by cell homing and without cell transplantation [80]. Human teeth implanted in the mouse dorsum and delivering basic FGF (bFGF) and/or VEGF formed recellularized and revascularized connective tissue that integrated with native dentinal walls of tooth root canals. Also, the combined delivery of bFGF and VEGF, or platelet-derived growth factor (PDGF) combined with a basal set of nerve growth factor and BMP-7, generated cellularized and vascularized tissues and neodentin formation over the surface of native dentinal walls. In another study, scaffold-free 3D tissues were engineered from DPSC sheets, placed into the canal space of human tooth RSs, and implanted subcutaneously into mice for pulp regeneration [87]. Histological results indicated that after 3−5 months, implanted tooth roots containing 3D scaffold-free engineered tissues exhibited vascularized fibrous tissue formation throughout, whereas empty tooth roots remained predominantly empty.

Periodontal Regeneration

Periodontal tissue regeneration strategies aim to restore the supporting periodontal tissues of teeth, including the formation of new cementum, PDL, and alveolar bone [88]. Clinical studies show that transplantation of autologous PDL progenitor (PDLP) cells may be a useful therapy to repair periodontal defects [89]. It was shown that PDLPs were similar to PDLSCs with respect to their ability to exhibit high proliferation rates, express mesenchymal surface molecules, and regenerate in vivo tissue; this provides clinical and experimental evidence supporting the efficacy and safety of using autologous PDL cells in treating human periodontitis. In another study, human PDLSCs were transplanted into immunocompromised mice and rats to assess their capacity for tissue regeneration and periodontal repair [21]. Using defined in vitro culture conditions, PDLSCs were shown to differentiate into cementoblast-like cells, adipocytes, and collagen-forming cells. When transplanted into immunocompromised rodents, PDLSCs exhibited the capacity to generate cementum−PDL-like tissues and contribute to periodontal tissue repair. Therefore, transplantation of PDLSCs may hold promise as a therapeutic approach for reconstructing tissues destroyed by periodontal diseases. It was also reported that autologous PDLSCs, combined

with HA−β-TCP scaffolds and transplanted into surgically created periodontal defects in pigs, were capable of regenerating periodontal tissues, leading to a favorable treatment for periodontitis [90]. Using a similar approach, it was shown that transplanted human SCAPs and PDLSCs, combined with HA−TCP ceramic particles and implanted in an in vivo swine model, regenerated a functional tooth root and periodontal complex capable of supporting a porcelain crown [91]. As such, this approach led to the recovery of both tooth strength and appearance.

Zhou et al. reported a PDL cell-sheet delivery system to promote periodontal tissue healing in a canine model [62]. After root canal treatment, the tooth roots were wrapped with PDL fibroblast-derived cell sheets and replanted back into the same tooth socket for 8 weeks. Subsequent analyses of the in vivo implanted teeth showed that multilayered PDL cell sheet constructs attached to the tooth root and that most cells of the PDL sheet-tooth constructs were viable after replantation. The PDL cell-sheet group showed a significantly higher occurrence of healing (88.4%) than the control group without cell sheets (5.3%). PDL and cementum tissue regeneration was observed in the experimental group and the regenerated tissues expressed high levels of collagen type III, collagen type I, and fibronectin expression. In a similar study, three-layered PDL cell sheets supported by PGA nanofibers were transplanted to dental root surfaces exhibiting a three-wall periodontal defect while filling existing bone defects with porous β-TCP. PDL cell sheet transplantation resulted in regenerated new bone formation as well as the formation of cementum containing embedded, properly oriented collagen fibers. These results suggested that PDL cells exhibit the ability to differentiate into periodontal tissues composed of both hard and soft PDL tissues, and that PDL cell sheet transplantation may be useful for periodontal regeneration in clinical settings [92]. In another study, Lei et al. characterized the cell properties of DPSCs and PDLSCs after in vivo implantation [93], showing that DPSCs and PDLSCs can maintain MSC-like characteristics after in vivo implantation compared with PDLSCs, DPSCs appear to be much more stable under in vivo conditions. These findings provide additional cellular evidence supporting and expanding the use of dental tissue−derived stem cells in dental TE.

In another study, intrabony defects were created in rats to evaluate the regenerative potential of an injectable macroporous calcium phosphate cement (CaP) combined with BMP-2 or FGF-2. Results from that study showed that the combined topical application of FGF-2 with an injectable CaP may prove to be a promising treatment for periodontal regeneration [94]. Another study, by Kim et al., tested the hypothesis that anatomically correct teeth can be regenerated in scaffolds without the need for cell transplantation. Anatomically shaped human molar and rat incisor scaffolds were fabricated by 3D bioprinting of hybrid PCL−HA with 200-μm-diameter interconnecting microchannels. SDF1 and BMP-7 were delivered into the microchannels of the scaffold, which were then implanted orthotopically after mandibular incisor extraction in the case of rats, or by using human molar-shaped scaffolds implanted ectopically into the rat dorsum. Analyses of explanted constructs showed the regeneration of PDL and new bone, which formed at the interface of the rat incisor scaffold and the native alveolar bone. This study showed that SDF1 and BMP-7 delivery recruited significantly more endogenous cells and also induced a greater angiogenesis response compared with growth factor−free control scaffolds [95]. Porous chitosan−coral composites combined with plasmid-encoding PDGF-B gene were also tested for periodontal regeneration, showing that subcutaneous implantation of gene-activated scaffolds supported greater cell proliferation than pure coral scaffolds, and that PDGF-B and type-I collagen expression was upregulated in gene-activated scaffold. Therefore, coral scaffolds combined with PDGF-B gene delivery may also serve as a suitable approach for periodontal tissue regeneration [96]. In another study, a mesoporous bioglass−silk fibrin scaffold combined with BMP-7 and/or PDGF-B adenovirus synergistically promoted up to twofold greater regeneration of PDL, alveolar bone, and cementum compared with each adenovirus used alone [97]. Ex vivo BMP-7 gene transfer was used to stimulate the repair of large mandibular alveolar bone defects in a rat wound repair model [98], consisting of syngeneic dermal fibroblasts transduced ex vivo with adenoviruses encoding green fluorescent protein, BMP-7 (Ad-BMP-7), or an antagonist of BMP bioactivity, noggin (Ad-noggin). These studies demonstrated that Ad-noggin treatment inhibited osteogenesis compared with the control- and Ad-BMP-7−treated specimens. Furthermore, the osseous lesions treated with Ad-BMP-7 gene delivery demonstrated rapid chondrogenesis and subsequent osteogenesis, cementogenesis, and predictable bridging of the periodontal bone defects [98]. In another study, a thermosensitive chitosan hydrogel was used as a small interfering RNA (siRNA) reservoir to silence receptor activator of nuclear factor-κB signaling and promote PDL regeneration [50]. The cumulative in vitro release of siRNA from the hydrogel was 50% over 14 days, and high PDL cell viability was observed for cells seeded on the siRNA-loaded scaffold. In vivo studies showed that the fluorescent signal from siRNA within hydrogel was maintained for up to 14 days when subcutaneously implanted in mice [50].

Alveolar Bone Regeneration

Jaw reconstruction can be challenging because both teeth and bone must be restored [99]. Autologous bone graft techniques followed by the placement of dental implants is one approaches being used to repair jaw defects. However, undesirable limitations to this approach include associated donor-site morbidity for harvested bone, insufficient quantities of available bone, and difficulties in dental implant placement owing to inadequate size, shape, and quality of the reconstructed alveolar ridge [100,101]. Because of high rates of progressive periodontitis, which can alter alveolar bone morphology and destroy surrounding tooth-supporting tissues, alveolar bone is highly susceptible to inflammation, which may result in necessary tooth extraction. The alveolar ridge may continue to resorb even after dental implant placement, and dysregulated bone remodeling in response to mechanical loading (mastication forces) may occur owing to uneven strain distributions caused by resorbed alveolar bone tissues [101]. Therefore, reliable tooth and alveolar bone regeneration strategies are needed to repair jaw defects effectively.

Inorganic materials such as CaP ceramics, bioactive glass, and ceramic−polymer composites have been especially developed for bone TE applications [39,101]. HA ceramics, β-TCP cements, and biphasic calcium phosphates are examples of synthetic CaP bone substitutes [101]. Although they lack the mechanical properties of naturally formed bone, they exhibit osteoinductive or osteogenic abilities, and these ceramics gradually acquire mechanical strength similar to that of cancellous bone [101,102]. For alveolar bone regeneration, biodegradable granular forms of ceramics are preferred, such as β-TCP, because they are easy to shape and can easily adopt the 3D size and shape of the bony defect, an important consideration for proper aesthetics [102]. Advantages of combining ceramics with polymers include improved biodegradability, biocompatibility, and an ability to readily bind GFs critical for osteoinduction. PCL scaffolds coated with CaP or HA exhibit improved osteoblast adhesion, spreading, and proliferation and promote alveolar bone formation in periodontal defects [101]. Goh et al. used a monkey model to examine periimplant bone regeneration and implant stability after immediate implant placement into tooth sockets containing facial wall defects [103]. In the control group, the bony defect was reconstructed with autogenous particulate bone, whereas in the test group, PCL−TCP scaffolds were used. Histological analyses showed better maintenance of facial bone contour in the test group; however, bone regeneration was observed only in areas adjacent to the bony wall of the defect. Implant survival was 100% 6 months for both groups, but the use of a PCL−TCP scaffold showed better maintenance of the alveolar contour compared with autogenous particulate bone at 6 months, although there was minimal bone regeneration within the defect [103].

Aquino et al. reported the use of autologous human DSPCs combined with a collagen sponge scaffold for oral maxillofacial bone tissue repair in patients requiring third-molar extraction [104]. Three months after autologous DSPC grafting, they reported that patient alveolar bone showed optimal vertical repair and complete restoration of periodontal tissue. Moreover, optimal bone regeneration was still evident 1 year after grafting. This clinical study demonstrated the effectiveness of DSCs combined with scaffolds to restore dental tissues such as alveolar bone and periodontal tissues [104]. In another study, bone implants created from pig iliac crest−derived MSCs seeded onto lattice scaffolds and grown in a rotational oxygen-permeable bioreactor system (ROBS) reactor were then combined with dental epithelial and dental mesenchymal cell−derived tooth constructs created from unerupted tooth buds harvested from the same pig [105]. Analyses of harvested implants revealed the formation of bioengineered mineralized tooth tissues, including primary and reparative dentin and enamel in the tooth portion of the hybrid tooth−bone implants, and the formation of OCN and BS-positive mineralized bone in the bone portion of the hybrid tooth−bone constructs. Collagen type III−positive connective tissue resembling PDL and tooth root structures were also present at the interface of the bioengineered tooth and bone tissues. These results demonstrate the potential use of hybrid tooth−alveolar bone constructs for clinical treatment of tooth loss accompanied by alveolar bone resorption [105]. In a similar study, tooth−bone constructs were prepared from third-molar tooth tissue and iliac crest bone marrow−derived osteoblasts isolated from, and implanted back into, the same pig as an autologous reconstruction [100]. Subsequent analyses showed the formation of small tooth structures consisting of organized dentin, enamel, pulp, cementum, and PDL surrounded by newly formed bone, indicating the possibility of tooth regeneration and associated alveolar bone in a single procedure [106].

Cai et al. studied which differentiation approach (e.g., maintenance of stemness, osteogenic or chondrogenic induction) was most suitable for periodontal regeneration, using in vivo implanted, rat BMSC-seeded PLGA−PCL electrospun scaffolds. Their results showed that BMSCs exhibited chondrogenic differentiation, followed by regeneration of alveolar bone and ligament tissues [107]. Successful regeneration of alveolar bone and surrounding

periodontal tissues using gene therapy vectors such as adenoviral BMP-7 (Ad-BMP-7) was also achieved in vivo [98]. Mesoporous Bioglass−silk fibrin scaffolds combined with BMP-7 and/or PDGF-B adenovirus synergistically promoted periodontal regeneration by enabling up to twofold greater regeneration of PDL, alveolar bone, and cementum tissues compared with each adenovirus used alone [97].

CONCLUSIONS

Root canal therapy and prosthetic dental procedures such as dental implants are the only clinical treatments available to treat necrotic dental pulp tissue defects and tooth replacement. These treatments present numerous disadvantages, including loss of tooth vitality and the inability to mimic properties and functions of natural teeth. Based on the promising characteristics of DSCs for regenerative tissue applications, dental TE efforts are focused on using these stem cell populations to bioengineer tooth supporting tissues and whole tooth. Although a variety of studies support the potential use of ESCs for tooth regeneration, the possibility of malignant tumorigenesis, ethical issues regarding the use of embryos, and the potential for allogeneic immune rejection make this approach problematic and unrealistic at present. In contrast, adult DSCs and iPS cells both exhibit significant potential for utility in dental TE. Successful use of DSCs for applications in dental tissue regeneration requires the combination of appropriate scaffolds and GF signals to induce dental cell differentiation and dental tissue formation. In addition, the concepts of scaffold-free approaches and cell homing have also been developed, suggesting alternative approaches using dental cell sheets and the recruitment of endogenous MSCs for dental tissue by GFs.

These reports demonstrate that it is possible to regenerate correct teeth anatomically using a combination of dental cells, scaffolds, and signals. Indeed, the tooth organ is a highly complex biological organ whose formation requires the intricate regulation of a cascade of molecular signals and gene expression. As such, a better understanding of the biological processes and interactions of important GFs and gene expression patterns regulating natural tooth development is critical for successful dental tissue regeneration. Methods to differentiate DSCs successfully into tooth specific lineages, to create all of the tissues that comprise a functional living tooth, is a main challenge in DSC research. New and effective methods for delivering bioactive agents such as GFs and nucleotides (i.e., plasmid DNA and RNA interference) combined with optimized biomaterials scaffolds, are anticipated to provide the means for successful alveolar bone and tooth regeneration in the foreseeable future, to meet the challenge of generating functional, living, bioengineered dental tissues.

Cell Therapy for Blood Substitutes

Shi-Jiang Lu[1], *Robert Lanza*[2]

[1]Vcanbio Center for Translational Biotechnology, Natick, MA, United States; [2]Astellas Institute of Regenerative Medicine, Marlborough, MA, United States

INTRODUCTION

RBCs, the oxygen-carrying component of the blood, are transfused in over half of all anemic patients admitted to intensive care units in the United States [1–3]. It is estimated that nearly 5 million patients receive approximately 14 million units of RBCs per year in the United States alone [4,5]. Limitations in the supply of RBCs can have potentially life-threatening consequences for patients, specifically for those who have rare or unusual blood types with massive blood loss caused by trauma or other emergency situations. Unfortunately, the supply of transfusable RBCs, especially the "universal" donor type (O)Rh-negative, is often insufficient, particularly in the battlefield environment and/or major natural disasters owing to the lack of blood type information and the limited time required for lifesaving transfusion. Moreover, the low prevalence of (O)Rh-negative blood type in the general population (<8% in Western countries and <0.3% in Asia) further intensifies the consequences of blood shortages for emergency situations in which blood typing may not be possible.

Platelets, anucleate discoid-shaped cell fragments released from megakaryocytes (MK), are essential to hemostasis, the biological process by which bleeding stops. Platelets adhere to damaged blood vessels and trigger a series of biochemical changes that stimulate clot formation and vascular repair. In cases of thrombocytopenia (platelet counts $< 150 \times 10^3/\mu L$), the increased risk of bleeding can have life-threatening consequences [6]. In the United States, approximately 1.5 million platelet transfusions are performed annually to protect patients, including those treated with chemotherapy or stem cell transplantations, from the risk of thrombocytopenia and its related dangers [7]. Unfortunately, refractoriness occurs in approximately one out of every three patients who require repeated platelet transfusions [8,9] and whereas both immunological and nonimmunological complications may be to blame, HLA alloimmunization is the primary cause of refractoriness [8]. Over the past few decades, the steady increase in demand for platelets combined with their limited shelf life has presented a constant challenge for blood centers and donor-dependent programs. As with RBCs, there is a vast and continuous need for functional, transfusable platelets, especially in times of emergency.

HSCs located within the bone marrow are multipotent stem cells discovered more than half century ago by Till and McCullogh [10] that have the ability to self-renew indefinitely and are responsible for replenishing all mature cells within the adult blood system including RBCs, platelets and myeloid and lymphoid cells. More than 30,000 patients with malignant blood diseases after chemotherapy received HSC transplantation; however, difficulty in finding an HLA-matched HSC donor, especially for individuals from a mixed or minority ethnicity, is the major obstacle to HSC regenerative therapy.

PSCs, including human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs), are capable of expanding indefinitely in culture without losing their pluripotency; this makes them an attractive cell source to be used for the large-scale production of a variety of therapeutic cell types [11–13]. The advent of human iPSCs may allow patient-specific therapies to be produced, thus circumventing potential issues with HLA mismatching and immunoincompatibility. Although each has its own advantages and disadvantages, hESCs and iPSCs represent two types of PSCs that may be able to serve as an alternative source for producing transfusable RBCs and platelets,

and HSCs with long-term engraftment capability. Here, we will review progress in developing these lifesaving blood substitutes, including some of our own efforts in unlocking the potential use of hESCs and iPSCs in these endeavors.

RED BLOOD CELLS

Erythropoiesis

Erythropoiesis is a highly regulated, multistep process by which the body generates mature RBCs or erythrocytes. During mammalian development, erythropoiesis consists of two major waves: (1) primitive erythropoiesis, which is initiated in the yolk sac with the generation of large *nucleated* erythroblasts, and (2) definitive erythropoiesis, which arises from the fetal liver with the development of smaller *enucleated* erythrocytes [14]. Definitive erythropoiesis in fetal liver features the production of enucleated RBCs that quickly become dominant in embryonic circulation. The switch of hemoglobin to fetal types ($\alpha_2\gamma_2$) also occurs at the initiation of definitive erythropoiesis [15–17]. However, reports show that yolk sac–derived primitive erythroblasts can also enucleate in the circulation of a mouse embryo and persist throughout gestation [18,19].

In adults, all blood cell types, including lymphocytes, myeloid cells, and RBCs, are derived from HSCs residing in the bone marrow. The initial differentiation of a multipotential HSC into a common myeloid progenitor (CMP) determines its capacity to differentiate further into granulocytes, erythrocytes, megakaryocytes, and macrophages, but not lymphoid cells. As the CMP continues to differentiate, it undergoes significant expansion and will eventually commit to one particular lineage. Erythroid unilineage commitment leads to the appearance of the pronormoblast (also called the proerythroblast or rubriblast). The pronormoblast will then pass through early, intermediate, and late normoblast (erythroblast) stages before expelling its nucleus and becoming a reticulocyte. Upon exiting the bone marrow, reticulocytes enter the blood circulation and become fully mature RBCs, expressing adult forms of hemoglobin ($\alpha 2\beta 2$) and delivering oxygen to tissues of the body. They circulate for about 120 days before they are engulfed by macrophages and recycled [20]. The various stages of erythropoiesis can also be distinguished by characteristic morphological features in the cell cytoplasm and nucleus, which become evident after Wright–Giemsa staining. In addition, using an in vitro colony-forming assay, CMP progenitors can be identified by their ability to form a characteristic colony-forming unit (CFU), called the CFU–granulocyte, erythroid, macrophage, megakaryocyte (GEMM) whereas early erythroid progenitors develop into burst-forming units–erythroid (BFU-E), and late erythroid progenitors become CFU-erythroid (CFU-E) in this assay [14].

"Universal" Blood Generated by Modifying Red Blood Cell Surface Antigens

Dr. Lansteiner's Nobel Prize–winning discovery of ABO blood groups occurred over a century ago. Now 30 known human blood group systems and complicated issues surrounding blood type incompatibility continue to frustrate clinicians and scientists. To circumvent these issues, researchers have been trying to develop "universal" blood for decades, primarily through chemical modifications on the surface of RBCs. Among these efforts, Goldstein and coworkers demonstrated that group B erythrocytes can be enzymatically converted to group O, and that the converted cells survived normally in A, B, and O individuals [21]. Since this groundbreaking discovery, there have been coordinated efforts to identify both clinically and economically viable alternative enzymes. New classes of bacterial exoglycosidases have been discovered that can enzymatically perform group O conversions with faster kinetics [22,23]; yet the likelihood of this technology having a major role in blood transfusion practice is unclear. There are no reports showing the enzymatic conversion of other important blood typing groups such as the Rh factor. With the momentum of the rapidly advancing stem cell field, the concept of (O)Rh- negative RBCs derived from PSCs clearly offers an attractive option for the future of blood transfusions.

Red Blood Cells Generated From Adult Stem Cells In Vitro

Erythrocytes have been derived from a variety of primary stem cell sources including umbilical cord blood (CB), peripheral blood (PB), and bone marrow (BM). $CD34^+$ cells from CB, PB, and BM have been isolated and differentiated into erythrocytes with 95% purity after a little over a week of culture using erythropoietin (EPO), stem cell factor (SCF), and interleukin-3 [24–26]. Coculturing with a mouse MS-5 stromal cell line or human mesenchymal stem cells facilitates enucleation, the hallmark of mature RBCs. The stem cell–derived erythrocytes have properties similar to normal RBCs, including membrane deformation capacity, intrinsic enzymatic activity, and balanced adult

or fetal forms of hemoglobin that can bind and release oxygen. In addition, these erythrocytes have been found to survive in vivo in NOD/SCID mice and were detectable 3 days after transplantation. Douay and colleagues showed that autologous RBCs generated under good manufacturing practices (GMP) conditions from PB $CD34^+$ cells behaved the same as did their natural counterparts when reinfused into the autologous recipient [27]. This first preclinical study provided proof of principle for transfusion of in vitro–generated RBCs and the necessary safety data that could support an investigational new drug application. Stem cells from PB and BM have limited expansion capacity (29,000- and 16,500-fold, respectively) compared with those from CB (140,000-fold). Yet, cells from adult PB and BM are often easier to obtain and display mature forms of hemoglobin, whereas CB sources are more difficult to obtain and cells derived from them express only fetal globins. Despite their potential utility and substantial in vitro expansion using bioreactors [28], however, these primary cells still represent donor-limited sources of blood substitutes.

Red Blood Cells Generated From Human Embryonic Stem Cells

The expansion capacity of hESCs far exceeds that of BM, PB, or even CB. Hematopoietic precursors as well as more mature progeny representing erythroid, granulocyte, macrophage, megakaryocytic, and lymphoid lineages have all been identified in differentiating hESC cultures [29]. Therefore, many groups have focused their efforts on trying to steer the in vitro differentiation of entire hESC cultures into specific blood cell types such as RBCs or megakaryocytes and platelets [30–36].

The controlled differentiation of hESCs into erythrocytes has primarily been achieved by either embryoid body (EB) formation or coculturing with stromal cells followed by the isolation of $CD34^+$ cells and further expansion or differentiation. Although somewhat different in approach, both systems have encountered the same obstacles in generating fully mature adult RBCs. For example, Chang et al. [37] generated erythroid cells from hESCs by isolating and expanding nonadherent cells of day 14 EBs for an additional 15–56 days. The resulting cells coexpressed high levels of embryonic ε- and fetal γ-globins but few or no adult β-globins. In addition, the cells had not enucleated. Using a stroma coculture method, erythroid cells could be generated by cultured with human fetal liver stromal cells (FHB-hTERT) for 14–35 days, isolating $CD34^+$ cells and further differentiating them in a four-step culture system. In steps 1 and 2, cocktails of cytokines were used to promote the proliferation and maturation of erythroid precursors. In steps 3 and 4, erythroid cells were transferred onto mouse BM stromal cells (MS5) to facilitate terminal maturation [38]. Although these erythrocytes were generated on a relatively large scale ($0.5–5 \times 10^7$ cells), the resulting cells had problems similar to those generated by the EB method: they mainly expressed embryonic ε- and fetal γ-globin isoforms, with only a trace amount of adult β-globin being detected. Despite these reports, other studies suggest that specific types of stroma can in fact facilitate the expression of adult β-globin in developing erythrocytes. Immunostaining with globin chain-specific monoclonal antibodies [39] showed that almost 100% of hESC-derived erythrocytes expressed the adult β-globin chain after coculture with murine fetal liver derived stromal cells; however, the β-globin content and identity were not verified by an accurate physical method such as high-performance liquid chromatography or mass spectrography. Yet, most of the cells still had not enucleated, a problem that does not seem to have an easily explainable mechanism or simple solution. For example, a study published in 2005 showed that coculturing $CD34^+$ CB, PB, and BM cells on MS5 stroma produced RBCs with up to 100% enucleation [24], whereas a year later, Miharada et al. [26], reported that up to 77% of CB-derived erythrocytes could achieve enucleation without the use of stromal cells.

The mechanism(s) by which stromal cells may facilitate erythrocyte enucleation are largely unknown; therefore, it remains to be determined whether stroma coculture will be absolutely required for the enucleation of hESC-derived erythrocytes. Stroma may secrete important soluble factors, provide critical cell–cell contact, and/or engulf of nuclei and other organelles. Some studies suggest that the process of enucleation involves a critical asymmetric cell division [40] and that Rac GTPases and their effector, mDia2, extrude the pyknotic nucleus during this process [41]. Other studies show that in vivo, contact with macrophages is important and that the erythroblast-macrophage-protein Emp has a critical role in enucleation [42–44]. Clearly, further studies will be required to determine how to improve the efficiency of both enucleation and globin switching in vitro. Coculture with stroma may circumvent problems with the processes, but production of clinical-grade RBC substitutes will demand stroma-free culture conditions.

Not only must in vitro–generated RBC substitutes be fully matured and enucleated for use in the clinic, they must also be capable of large-scale production. Related to this issue, we have developed a strategy that generates functional hemangioblasts (the common precursor cell to all hematopoietic and endothelial cell lineages) efficiently and reproducibly using a serum-free culture system, and have been able to do so with high purity (>95%) and on a

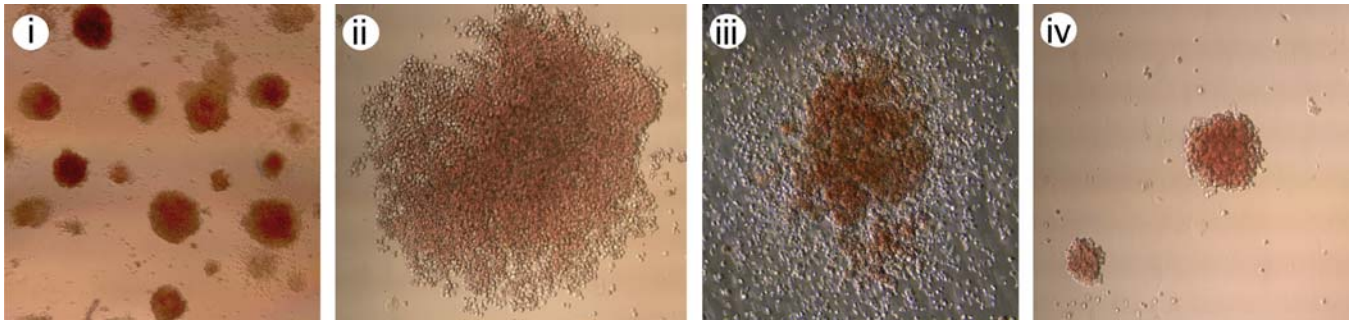

FIGURE 52.1 **Erythroid differentiation potential of human embryonic stem cell–derived hemangioblasts.** These cells showed tremendous colony-forming unit (CFU) capability when cultured in Cephalothin–Fucidin–Cetrimide medium. (i, ii): early burst-forming unit–erythroid (×40, ×100), (iii): large CFU- granulocyte, erythroid, macrophage, megakaryocyte (×200); and (iv): late CFU- erythroid (×100).

relatively large scale [45,46]. A characteristic of the primitive hemangioblast cell is its highly efficient generation of large BFU-E (Fig. 52.1-i and 1-ii), CFU-GEMM (Fig. 52.1-iii), and CFU-E (Fig. 52.1-iv) colonies when cultured in a methylcellulose-based medium. This prompted us to investigate whether hemangioblasts could be used as an intermediate cell source to generate large, clinically relevant quantities of blood components such as erythrocytes and platelets.

Using the hemangioblast system, we generated functional RBCs (blood types A, B, O, and both Rh^+ and Rh^-) on a large scale from multiple hESC lines [33]. Three critical elements allowed us to do this: (1) the efficient generation of hemangioblasts without disruption of their colony-forming environment; (2) expansion of hemangioblasts to erythroblasts in a high cell density (Fig. 52.2i and 2ii); and (3) culture in semisolid methylcellulose-based media to provide optimal conditions for maximum expansion and high erythroid purity (Fig. 52.2i). We generated approximately 10^{10}

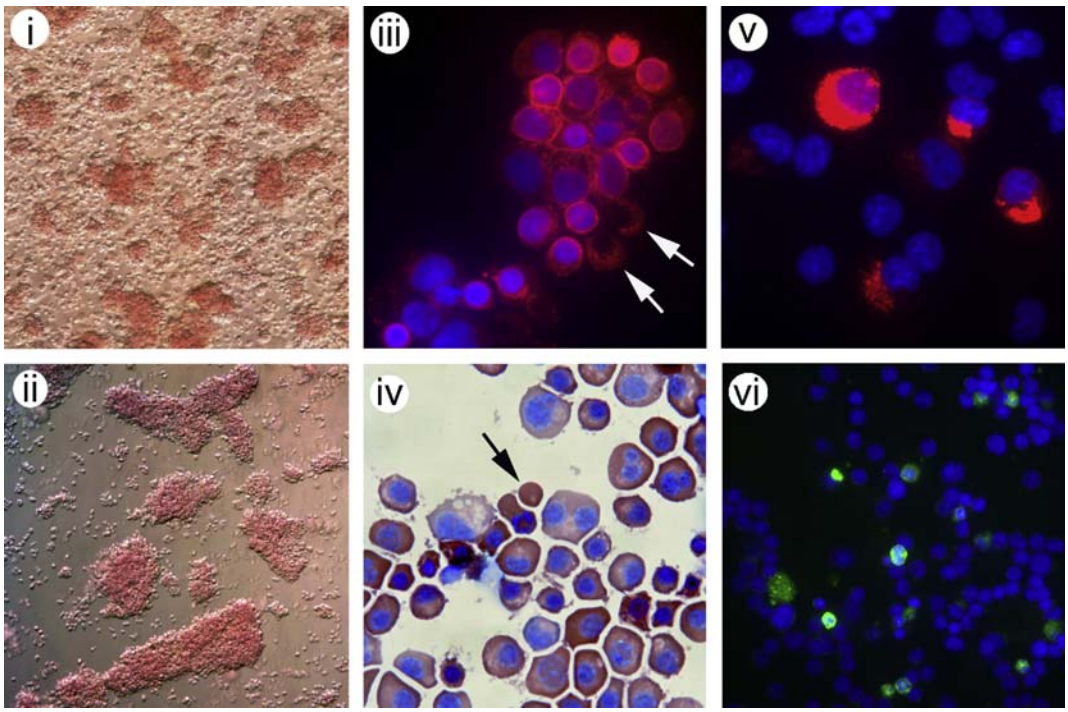

FIGURE 52.2 **In vitro characterization of human embryonic stem cell (hESC)-derived erythroid cells.** (i, ii): Morphology of typical high-density expansion/differentiation of immature hESC-derived erythrocytes cultured with medium containing methylcellulose (×10); (iii): Maturing hESC-derived erythrocytes stain positive for erythrocyte marker CD235a, with a small fraction of cell showing enucleation (*arrows*); (iv): Giemsa–benzidine double staining of maturing hESC-derived erythrocytes showing a high content of intracellular hemoglobin (*brown*). *Arrow* indicates fully enucleated red blood cells (×100); (v): Maturing hESC-derived erythrocytes express A-type surface antigen (*red*, ×100 magnification); (vi): Some hESC-derived erythrocytes express β-chain hemoglobin (*green*, ×100) after elongated culture in vitro. Cellular nuclei in all fluorescence images were stained with DAPI (*blue*).

to 10^{11} erythroid cells per six-well plate of hESCs [33], which is over a thousand-fold more efficient than previously reported methods [38]. Oxygen equilibrium curves of erythroid cells from days 19–21 of differentiation were comparable to normal transfusible RBCs and responded to changes in pH and 2,3-diphosphoglycerate. During the course of our studies, we found that extended in vitro culture facilitated further maturation of these erythroid cells, inducing a progressive decrease in size, increased expression of the erythrocyte cell surface marker, glycophorin A (CD235a), as well as chromatin and nuclear condensation. When the extended culture was performed on OP9 stromal cells, it resulted in the extrusion of the pyknotic nucleus in up to 65% of cells and the generation of enucleated erythrocytes with a diameter of approximately 6–8 μm (Fig. 52.3). At this stage, the erythrocyte population was nearly 100% positive for glycophorin A (Fig. 52.2iii), it had a high content of hemoglobin (Fig. 52.2iv), and it expresses ABO antigen (Fig. 52.2v). Although the cells were found to express fetal and embryonic globin chains, globin chain–specific polymerase chain reaction and immunofluorescent analyses showed that after extended culture, expression of adult β-globin increased from 0% to 15% (Fig. 52.2vi). Overall, these results showed that it is feasible to differentiate and mature hESCs into functional oxygen-carrying erythrocytes on a large scale. The identification of an hESC line with an (O)Rh^- genotype would permit the production of ABO and Rh-compatible (and pathogen-free) "universal donor" RBCs. Considerable effort is still needed to bring hESC-derived RBCs to clinical trials, but these efforts certainly provide a promising lead.

Red Blood Cells Generated From Human Induced Pluripotent Stem Cells

The successful reprogramming of somatic cells into a pluripotent state has been achieved by ectopic expression of various combinations of transcription factors [11,13]. The derivation of these iPSCs is less controversial than that of hESCs; thus, they open up an exciting new route to obtain PSCs. Moreover, that iPSCs can be produced in a patient-specific manner will eliminate the issue of immunorejection in cell, tissue, or organ replacement therapies in the future. A number of groups including our own have published methods for generating RBCs from iPSCs

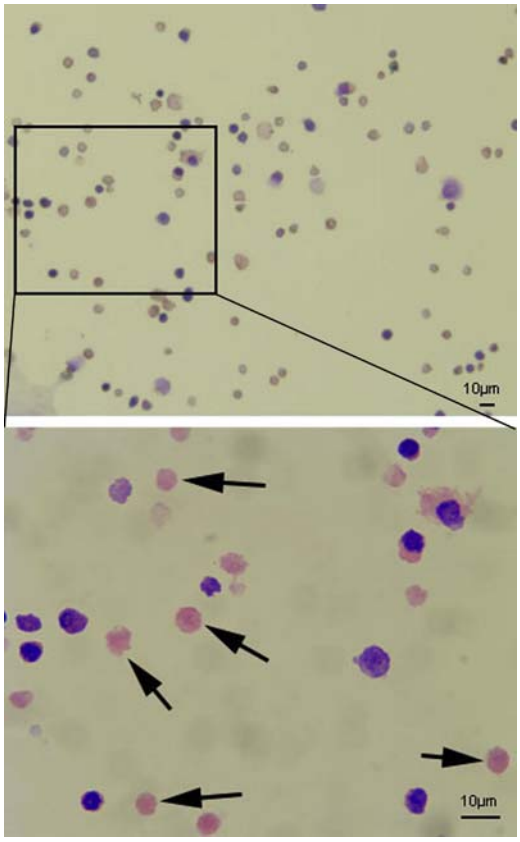

FIGURE 52.3 **Enucleation of erythrocytes derived from human embryonic stem cells in vitro.** (*Top*): Low-magnification image of Giemsa-stained enucleated erythrocytes (×20); (*bottom*): High-magnification (×100) image of enucleated erythrocytes (*black arrows*).

[47–59]. These erythrocytes possess classic morphology, express glycophorin A, and have abundant hemoglobin content. As observed in the hESC differentiation systems, regardless of their origin, iPSC-generated RBCs express mostly fetal hemoglobin (hemoglobin F). RBCs expressing hemoglobin F are slightly less efficient than those expressing adult hemoglobin for oxygen delivery. However, patients who retain expression of hemoglobin F in adult life are not anemic. Thus, the fetal phenotype of RBCs generated from iPSCs that are derived from patients with hemoglobinopathies is not necessarily a barrier for autologous transfusion. Kobari et al [52] and Yang et al. [57] reported the switch from fetal to adult hemoglobin after infusion of iPSC-derived nucleated erythroid precursors into mice, which indicates that these cells possess the potential to turn on the expression of the globin gene under appropriate in vivo conditions. Giani et al. [60] demonstrated that targeted suppression of SH2B3 in primary human hematopoietic stem and progenitor cells enhanced the maturation and overall yield of in vitro–derived RBCs. Olivier et al. [61] described a GMP-compatible, feeder-free, and serum-free method to produce large numbers of erythroid cells from human PSCs. This multistep protocol combines cytokines and small molecules to mimic and surpass the early stages of development and produces more than 99% of CD235a-positive cells. Moreover, their protocol supports extensive expansion, with a single human PSC producing 50,000–200,000 erythroid cells. The erythroid cells produced exhibit a definitive fetal hematopoietic type, with 90–95% fetal globin and a variable proportion of embryonic and adult globin proteins.

Although these studies provided proof-of-principle, our study revealed some intrinsic molecular and cellular abnormalities in the iPSC derivatives, such as increased apoptosis, limited CFU capability, and limited expansion [51]. The exact cause(s) of these abnormalities is unclear but may result from alterations caused by the modified genome of virally reprogrammed cells. Despite transgene silencing after reprogramming, Dias et al. [50] reported a background of transgene expression in differentiated cells obtained from transgenic iPSCs and showed that it can affect their properties. However, Dias et al. [50] observed no difference in erythroid differentiation between transgene-free and transgenic hiPSC lines. Our study [30] and unpublished data showed that viral-free, especially iPSCs generated with messenger RNA (mRNA) transfection, have much improved hematopoietic differentiation and expansion capability compared with human iPSCs carrying viral DNA. Both large-scale RBCs and megakaryocytes and platelets were produced with mRNA-generated iPSCs, which is comparable to hESC-derived counterparts. More research will be needed to figure out the mechanism underlying the disparate observations.

Red Blood Cell Generation by Direct Conversion of Somatic Cells

Another new approach to RBC generation involves the direct dedifferentiation or conversion of human somatic cells to multipotent hematopoietic progenitors, thus bypassing the need for PSC-like hESCs or iPSCs altogether [32,62]. Forced ectopic expression of OCT4 directly transdifferentiates fibroblasts into $CD45^{+}$ hematopoietic progenitors, and after exposure to EPO, these cells were able to produce erythroid lineage cells that expressed high levels of adult β-globin and low levels of fetal γ-globin and were capable of enucleation [62]. Similarly, Liu et al. [32] reported a method to generate erythrocytes from human hair follicle mesenchymal stem cells by enforcing OCT4 gene expression and cytokine stimulation. Erythroid cells generated from human hair follicle mesenchymal stem cells expressed mainly the adult globin chain with minimum levels of the fetal globin chain. Furthermore, these cells also underwent multiple maturation events and formed enucleated erythrocytes with a biconcave disc shape and the morphology of mature and functional RBCs. The limitation of this approach is the high level of OCT4 expression in somatic cells, which can be achieved only by viral infection. Viral integration in the genome limited the usefulness of this approach.

Where Do We Go From Here?

The manufacture of safe and effective RBC substitutes will alleviate many of the risks, complications, and hardships associated with donor-dependent RBC sources. Significant progress has been made by manipulating the differentiation potential of hESCs and iPSCs and driving them toward erythrocyte development. In vitro differentiation systems that can be scaled up for the mass production of RBC substitutes have been developed. The hemangioblast methodology described in this chapter represents one such possibility. Despite many exciting advances with in vitro culture systems, problems associated with the final stages of erythrocyte maturation, namely enucleation and globin switching, will still need to be fully resolved before hESC- and iPSC-derived RBCs can be produced in a stroma-free manner, scaled up for mass production, and brought to the clinic. Direct conversion of somatic cells into RBCs represents an alternative to solving the globin-switching dogma, but the low efficiency

and use of viral vector limits its clinical application. Another obstacle to applying all of these methods is that they are expensive to produce the sufficient number of RBCs that are applicable in the clinic.

MEGAKARYOCYTES AND PLATELETS

Megakaryopoiesis

Because of their role in clot formation and blood vessel repair, platelets are essential for the cessation of bleeding; to maintain an abundant supply of them is vitally important. MK, the large multinucleate precursors to platelets, provide a constant, renewable source of platelets to the blood system and are themselves produced through a process called megakaryopoiesis. As previously mentioned, HSCs differentiate into CMPs, which then undergo significant proliferation and expansion as they further mature and differentiate. Once exclusively committed to the MK lineage, however, they retain only limited expansion capacity. On a cellular level, MK maturation involves many changes such as an increase in expression of the cell surface markers GPIIb/IIIa (also known as CD41 or αIIb/βIII integrin receptor) and GPIb/GPIX/GPV receptors and an increase in cytoplasmic and nuclear mass, with cells expanding to 50−100 μm in diameter, resulting in nuclear polyploidization and cells up to 128 N [63,64]. On a molecular level, thrombopoietin (TPO) is the primary physiological regulator of MK and platelet generation [7]. However, numerous other cytokines, growth factors, and small molecules have been found to be important as well. Multiple cytokines have been reported to stimulate the proliferation of MK progenitors synergistically [65,66], whereas transforming growth factor-β1 and platelet factor 4 have been found to inhibit their development and maturation [67]. Downstream of cytokine signaling pathways, various transcription factors orchestrate the progressive lineage commitment and maturation of developing MKs [68−72].

Biogenesis of Platelets

Although not mutually exclusive, two models have been proposed to describe the assembly and release of platelets from MKs into the bloodstream, a process known as thrombopoiesis [6,73]. In the global fragmentation model, cellular processes termed proplatelets undergo mutual detachment to produce small functional platelets within the MK cytoplasm, which then explodes and releases the cell's entire content of platelets simultaneously. This theory, conceived in the 1970s, is supported by electron microscopy of mature MKs, as well as in vivo and ex vivo observations of platelet release. More recent experimental evidence lends support to the proplatelet model of platelet biogenesis. In this model, proplatelets actually extend from the mature MK cell body, traverse the vascular endothelium, and enter the BM sinusoids, where the shear force of the bloodstream facilitates release of nascent platelets from proplatelet ends. On a molecular level, thrombopoiesis is thought to be a highly coordinated process, with sophisticated reorganization of membrane and microtubules and precise distributions of granules and organelles [74]. It also appears as though localized apoptosis may have important roles in proplatelet formation and platelet release [75]. Despite these advances in our understanding of platelet biogenesis, mechanistic details remain to be elucidated.

Generation of Megakaryocytes and Platelets From Adult Stem Cells and Somatic Cells

Various sources of adult HSCs have been used to study MK and platelet differentiation. Choi and colleagues were the first to report that functional platelets could be produced from $CD34^+$ cells isolated from PB [76]. During 10−12 days of culture, aplastic canine serum was used to promote in vitro MK lineage commitment and maturation and was then replaced by human serum to enhance platelet production from the MKs. Platelets generated from this system demonstrated aggregation capacity when stimulated with either adenosine diphosphate or thrombin, the physiological agonists for normal blood platelets. Subsequent studies showed that HSCs from PB, BM, and CB are also all capable of producing MKs and functional platelets [77−79]. Several groups reported the direct conversion or dedifferentiation of somatic cells into MKs and platelets [79a,80,80a], although the in vivo function of these platelets was not examined. Another strategy is to generate an immortalized MK progenitor cell lines from hematopoietic progenitors with virally transduced genes [81], but the methods involving viral transduction may not be considered appropriate for clinical-grade manufacturing. Yet, the limited in vitro expansion capabilities of primary $CD34^+$ and somatic cells make these cells unable to replace donation as a source of platelets. For this reason, human PSCs may be a better starting cell population for large-scale in vitro production.

Megakaryocytes and Platelets Generated From Human Pluripotent Stem Cells

After initial success with murine ES cells [82–84], MK differentiation from human PSCs including both hESCs and iPSCs was achieved in coculture systems with animal stromal cells [31,35,36]. In these studies, Takayama et al. [35,36] cocultured hESCs or iPSCs on C3H10T1/2 stromal cells for 14–15 days and then handpicked sac-like structures containing hematopoietic progenitors and replated single cell suspensions onto fresh stroma in medium containing TPO, SCF, and heparin for 9–23 days. During this time, polyploid, CD41a/CD42b double-positive MKs emerged and produced platelets with characteristic morphology, as assessed by electron micrography. A variety of in vitro tests confirmed PSC-platelet functionality. In another study by the researchers, a laser-induced vascular injury model was used to show that their iPSC-derived platelets readily incorporate into newly developing thrombi in vivo [36].

The use of both serum and animal feeder layers throughout these studies hinders the ability of these methods to be adapted for clinical use. In addition, because handpicking of PSC sacs is both time- and labor-intensive, alternative methods will likely have to be developed for large-scale production. Pick et al. [85] and Liu et al. [32] reported feeder-free and xeno-free systems to generate MKs from PSCs. Several crucial reagents were also replaced with US Food and Drug Administration–approved pharmacological reagents. However, the generation of functional platelets was not reported in these two studies. We were able to use the serum- and feeder-free hemangioblast system, as described earlier for RBCs, to generate MKs efficiently [34]. Yet, similar to the studies by Takayama et al., we found that efficient platelet generation from hemangioblast-derived MKs still requires a conventional stroma coculture. To this end, we developed a well-defined and completely serum- and feeder-free system to differentiate human PSCs into MKs and functional platelets in less than 20 days, which greatly increases its ability to be developed for clinical use [30]. Using this method, large quantities of cryopreservable MK progenitors were produced from human PSCs, which allowed billions of platelets to be produced rapidly upon thawing of these cells. The improved scale of in vitro–generated PSC platelets provided enough materials to perform light transmission aggregometry (LTA), which is the most common method used in clinical and research laboratories to assess platelet function [86]. LTA has not been performed with platelets generated from human PSCs in vitro, presumably owing to its requirement for a large quantity of fresh platelets. As shown in Fig. 52.4C, human PSC platelets responded to thrombin stimulation in forming aggregates. However, the process was slow and aggregation was weak compared with PB platelets, but stronger and faster than human CB platelets, which is consistent with previous observations [87–89]. These results are a significant improvement over in vitro $CD34^+$ cell-derived platelets, which showed no aggregation by LTA [90]. Differential-interference contrast and electron microscopy analyses showed that ultrastructural and morphological features of PSC-derived platelets were indistinguishable from those of normal blood platelets (Fig. 52.4A). Human PSC platelets form aggregates, lamellipodia, and filopodia after activation and circulate in macrophage-depleted animals and incorporate into developing mouse thrombi in a manner identical to human platelets (Fig. 52.4B; [30]. By knocking out the β2-microglobulin gene, we generated platelets that are negative for the major histocompatibility antigens (Fig. 52.5). The scalable generation of HLA–ABC-negative platelets from a renewable cell source represents an important step toward generating "universal" platelets for transfusion as well as a potential strategy for managing platelet refractoriness.

Improving the Efficiency for In Vitro Platelet Production

These studies provide an important proof of principle for the in vitro manufacturing of functional platelets from different cell sources. However, the efficiency of platelet production will need to be significantly improved to achieve clinically relevant yields [91]. Reems et al. [92] used an in vitro culture system to demonstrate the feasibility of producing functional platelets for clinical use. Using this protocol, the calculated yield of platelets from 5×10^6 $CD34^+$ cells is $1.26–1.68 \times 10^{11}$, which is equivalent to approximately 3 units of donor-derived platelets. However, these calculations are based on extrapolating data from experiments using just 500 starting $CD34^+$ HSCs. A three-dimensional culture system described by Sullenbarger et al. [93] provides additional evidence that it is possible to produce platelets in scalable quantities. In this system, about 20 platelet-like particles were produced from each input $CD34^+$ cell. Thon et al. [94] developed a scalable microfluidic platelet bioreactor that reproduces the BM microenvironment ex vivo, synchronizes proplatelet generation, and strikingly increases the yields of functional platelets by a magnitude of two compared with static conditions from different sources of MKs; this represents the critical next step in creating an alternative source of functional human platelets for infusion. Although this progress is significant, the efficiency is still low compared with greater than 2000 platelets/MK in BM, which remains the biggest challenge to reaching a clinically relevant scale of ex vivo platelets. Considering the optimal in vivo capacity

(B) Comparative kinetics of human blood platelets (hPLT), human embryonic stem cell platelets, and iPSC platelets in immune-deficient mouse blood system (mean ± SD, n = 5). (C) Aggregation assay of platelets from human peripheral blood (PB), umbilical cord blood (CB), and iPSC platelets stimulated with 1 U of thrombin using Chronolog aggregometer. *PSC*, pluripotent stem cell. *This research was originally published in Stem Cell Reports: Feng, Q. et al. (2014). Scalable generation of universal platelets from human induced pluripotent stem cells. Stem Cell Reports 3, 1–15.*

of MK development from HSCs and platelet production from MKs, both the initial hematopoietic amplification stage and downstream platelet biogenesis could stand to be optimized. Strategies to increase the efficiency of MK and platelet production include the development of novel culture systems that mimic the in vivo BM microenvironment as well as the optimization of media formulations including concentrations of cytokines, small molecule mimetics, and nutrients [91,95]. In addition, physiological parameters such as pH, media viscosity, and oxygen levels all may be optimized for increased platelet biogenesis. Finally, in vivo observations that helped to formulate the proplatelet model of platelet biogenesis suggest that shear force could have an important role in platelet release [6,74]. Adaptation of such a mechanical force in culture systems may also significantly promote proplatelet growth and platelet release, as demonstrated by Thon et al. [94].

HEMATOPOIETIC STEM CELLS

Hematopoietic cancers, including leukemia, Hodgkin and non-Hodgkin lymphoma, myeloma, and myelodysplastic syndromes, result from the unregulated proliferation of hematopoietic cells. A promising treatment for hematopoietic malignancies is the transplantation of HSCs collected from PB, BM, or CB of HLA-matched donors into patients after radiation or chemotherapy. Allogeneic HSC transplantation is the only treatment that can cure

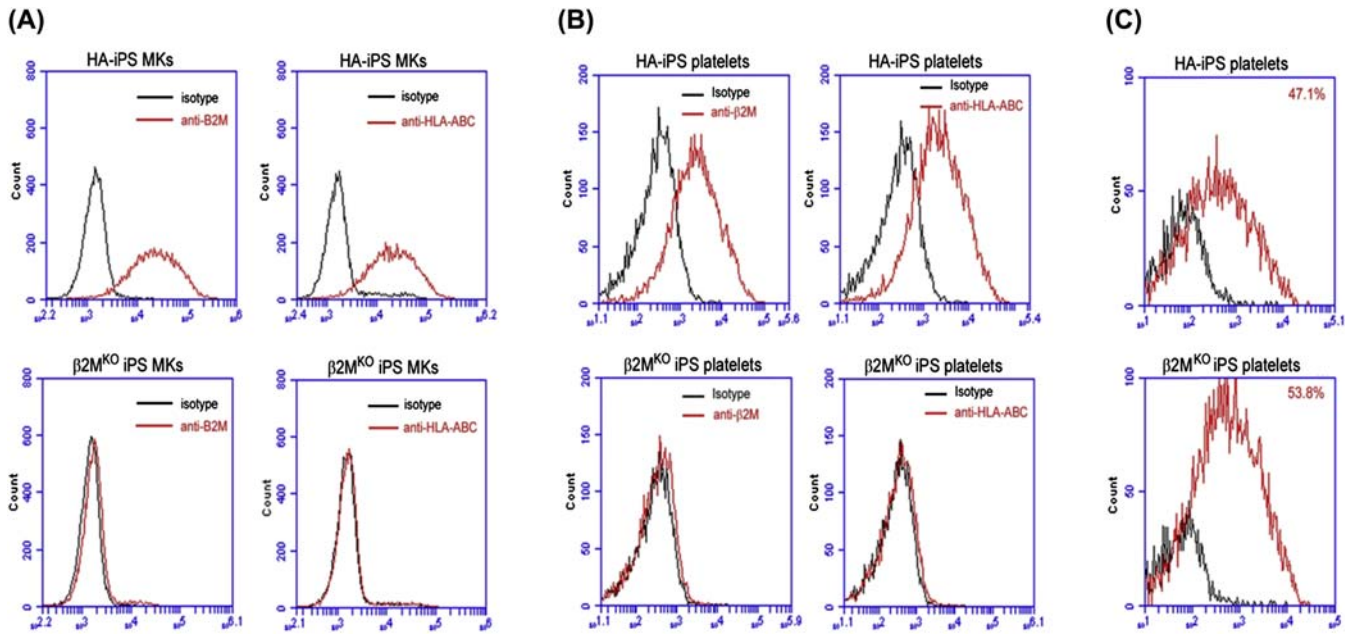

FIGURE 52.5 **Generation and characterization of universal platelets from human induced pluripotent stem cell (iPSCs).** (A) human leukocyte antigen (HLA)-ABC and β2-microglobulin (β2M) expression in wild-type hemophilia A (HA)-iPSCs and $\beta2M^{KO}$ iPSC-derived megakaryocytes (MKs); (B) HLA-ABC and β2M expression in wild-type HA-iPSCs and $\beta2M^{KO}$ iPSC-derived platelets; (C) Platelet activation measured by PAC-1 binding with (*red histogram*) or without thrombin (*black histogram*) in wild-type HA-iPSC platelets and $\beta2M^{KO}$ iPSC platelets. *This research was originally published in Stem Cell Reports: Feng, Q. et al. (2014). Scalable generation of universal platelets from human induced pluripotent stem cells. Stem Cell Reports 3, 1–15.*

chronic myelogenous leukemia. However, HSCs from HLA-matched donors are often scarce, which has been a bottleneck for treating blood cancers, especially for patients from minor ethnic groups.

Several strategies have been developed to generate HSCs from human PSCs [29,96], which possess the potential to serve as an inexhaustible and donorless source of HSCs for transplantation therapy. In addition, iPSCs have the potential for curative treatment for a variety of genetic diseases that affect PB and BM-derived cells. Hematopoietic cells derived from PSCs have been successfully transplanted into immune-deficient NOD-SCID mice, which showed short-term as well as long-term BM engraftment capabilities [97–102]. Similarly, Amabile et al. [103] and Suzuki et al. [104] independently demonstrated that $CD34^+$ $CD45^+$ cells isolated from teratomas formed by human PSCs in immune-deficient mice were able to engraft and reconstitute hematopoietic cells in serial transplantation experiments. These studies suggest that functional HSCs can be derived from human PSCs. However, in all of these studies, BM repopulation was invariably low, only rarely exceeding 1–2%.

The causes for the observed consistently poor engraftment of PSC-derived hematopoietic cells in immune-deficient mice may be multifactorial. First, the PSC-derived hematopoietic cells themselves may be defective, losing some properties that are critical for engraftment, such as the potential of differentiating into endothelial cells. It has been demonstrated by several groups that functional HSCs derived from CB and BM exhibit hemangioblastic activity, producing both hematopoietic and vascular cells in response to vascular injury [105–107]. Hooper et al. [108] found that irradiation caused severe regression of BM sinusoidal endothelial cells, whereas HSC transplantation into these myeloablated mice induced rapid regeneration of the regressed sinusoidal endothelial cells with robust HSC engraftment. However, regeneration inhibition of the damaged sinusoidal endothelial cells prevented engraftment and replenishment of HSCs, leading to hematopoietic failure in these animals.

Second, PSC-derived hematopoietic progenitor cells are of embryonic origin and might have decreased potential for BM engraftment in the marrow microenvironment of adult animals. Experimental evidence supportive of this possibility was presented by Yoder et al. [109]. These investigators observed that mouse yolk sac hematopoietic cells failed to engraft when transplanted into congenic adult recipients but produced durable engraftment and multilineage reconstitution of peripheral blood cells when infused into myeloablated newborn pups. This suggests that the cellular microenvironment has a critical role in proliferating and differentiating hematopoietic progenitor cells.

In effort to overcome challenges associated with HSC generation from human PSCs, several groups took the strategy of directly reprograming adult somatic cells into hematopoietic cells. Riddell et al. [110] demonstrated

that transient expression of six transcription factors (Run1t1, Hlf, Lmo2, Prdm5, Pbx1, and Zfp37) converted mouse committed hematopoietic progenitors into induced-HSCs that possess multilineage differentiation potential, reconstitute stem and progenitor compartments, and are serially transplantable. Similarly, Sandler et al. [111] showed that enforced expression of transcription factors FosB, Gfi1, Runx1, and Spi1 directly converted human endothelial cells into cells consisting of HSCs with long-term engraftment potential. Cheng et al. [112] reported that hematopoietic transcription factors Scl, Lmo2, Runx1, and Bmi1 converted mouse fibroblasts into "induced hematopoietic progenitors" that engrafted immune-deficient mice, generating myeloerythroid and B-lymphoid cells for up to 4 months in vivo. These studies suggest that enforced expression of a small number of transcription factors can reprogram adult somatic cells into engraftable HSCs, but the use of viral or DNA-based vectors confers another threat to clinical application.

PERSPECTIVES

Limitations in the supply of RBCs and platelets can have potentially life-threatening consequences for transfusion-dependent patients with unusual or rare blood types, particularly those who are alloimmunized. Although CB, BM, and PB have been investigated as sources of progenitors for the generation of large-scale transfusable RBCs and platelets [24–26,92,93], it is clear that even after expansion and differentiation, these progenitors represent donor-limited sources of RBCs and platelets. Human PSCs, especially virus-free human iPSCs [113–115], represent a new source of stem cells that are donorless source of RBCs and platelets for human therapy. Advances in gene editing technology allow the generation of PSC cells that can be used to produce (O)Rh-negative "universal" RBCs and O-type HLA major–negative "universal" platelets, which could eliminate tissue incompatibility issues altogether [116]. As for HSCs, de novo generation from human PSCs remains the most challenging obstacle. Further studies will be needed to understand the basic mechanism of HSC development in vivo and to apply this knowledge to develop a system that mimics the events accurately in vitro. The success of generating engraftable HSCs from human PSCs will be a "Holy Grail" for HSC fundamental biology and hematopoietic malignancy therapy.

Financial and Competing Interest Disclosure

S.-J. Lu and R. Lanza are employees of the Vcanbio Center for Translational Biotechnology and the Astellas Institute for Regenerative Medicine, respectively, companies in the field of regenerative medicine and cell therapy.

CARTILAGE AND CARTILAGE REPAIR

Cartilage is a connective tissue that functions to provide form, strength, and support. Three types of cartilage are distinguished by their molecular components in the extracellular matrix (ECM), their anatomical location, and their function. Hyaline (articular) cartilage has a white glassy appearance and is found primarily in articulating joints. Its ECM is mainly composed of water, hyaluronate, proteoglycans, and type II collagen. Hyaline cartilage functions to provide stable movement with minimal friction. It has high viscoelasticity and demonstrates an excellent ability to provide resistance to compression and cushion the impact caused by physical load during movement [1]. Elastic cartilage is distinguished by the presence of elastin in the ECM. Elastic cartilage provides a structural function; it is represented by the support it provides in the external ear. Finally, fibrocartilage has a higher proportion of type I collagen in its ECM. Fibrocartilage is found in the meniscus and intervertebral disc and at the distal region of tendons and ligaments in apposition to bone. It provides tensile strength and counters compression and shear forces [2].

All three types of cartilage feature a sparse cellularity, limited blood supply, and lack of neural innervations. These cartilages have intrinsically poor reparative capabilities owing to their purported inability to form a clot to attract the necessary fibroblasts and start subsequent tissue synthesis for repair [3]. Once defects, even small ones, are initiated in cartilage, the degradation process is progressive [4]. One irreversible consequence of the destruction of articular cartilage is arthritis, a leading cause of disability. Osteoarthritis (OA), the most common type of arthritis, is characterized by articular cartilage loss and degeneration, subchondral bone thickening, osteophyte formation, and joint inflammation [5]. OA is widespread globally in 60–70% of people aged older than 65 years [6–8]. Over 21 million people have this disease in the United States and 10% of cases are estimated to be caused by previous trauma to weight-bearing joints, which is classified as posttraumatic OA (PTOA) [9]. PTOA develops not only in elderly people, but also in young people experiencing the results of previous trauma. Once a cartilage defect is present, cartilage matrix continues to be lost while the surrounding tissues become more inflamed and contribute to further cartilage matrix destruction [10]. This causes significant pain, disability, and morbidities, strongly affecting an individual's capacity to live a full and active life.

Surgical treatment options available for focal cartilage repair include microfracture and osteochondral autografting. Microfracture may be considered a current standard for cartilage repair and is a low-cost and minimally invasive procedure [11,12]. This technique employs subchondral drilling to initiate cartilage repair by inducing bleeding, enabling mesenchymal progenitor cells from the bone marrow to migrate into the lesion site. After this procedure, the repair tissue appears to be a cartilage-like substitute but is primarily composed of fibrocartilage. Unfortunately, the repair fibrocartilage has inferior quality and longevity compared with the native hyaline cartilage, thus delaying cartilage degeneration for only a few years [12]. Osteochondral autografting or mosaicplasty is a technique of autotransplantation in which osteochondral plugs are harvested from non–weight bearing or low–weight bearing regions of the joint and implanted into defects that have been prepared and sized. In clinical testing, survival of the transplanted hyaline cartilage has been reported in 85% of patients, with a 91% good to excellent clinical outcome reported by patients observed for 3–6 years [13,14]. In addition, follow-up 10 years after surgery demonstrated improved clinical outcomes compared with microfracture [15]. However, the cartilage autografts have many problems including limited donor tissue availability, donor site injury, scarring, and pain, prompting

the development of an innovative bioengineered therapy called autologous chondrocyte implantation (ACI), which will be discussed later in this chapter [16,17]. Allograft tissue transplants address the donor tissue availability challenge and are a fast-growing therapy.

TISSUE ENGINEERING FOR CARTILAGE REPAIR

To overcome the treatment obstacles of available surgical options for cartilage repair, the reconstruction of cartilage using tissue engineering techniques has attracted tremendous attention. Tissue engineering is a multidisciplinary field that applies the principles of engineering, life sciences, and cell and molecular biology to the development of biological substitutes that restore, maintain, and improve tissue function [18]. The historical approach to cartilage engineering is to select and optimize the following components to be used individually or in combination to regenerate organs or tissues [1]: reparative cells that can form a functional matrix [2], an appropriate scaffold for transplantation and support, and [3] bioreactive molecules such as cytokines and growth factors that will support and choreograph formation of the desired tissue [19]. Biological cues and important biological factors that promote tissue repair in the local in vivo tissue environment continue to be discovered and developed, propelling the field forward. For example, the innate and adaptive immune systems are newly appreciated factors for successful tissue engineering. The immune system participates in many facets of tissue repair via scavenging dead cells and debris, inducing vascularization of injured tissue, and recruiting progenitor cells to tissue [20–22]. More specifically, Badylak discovered that macrophage phenotype is important in muscle remodeling, and that macrophage phenotype is influenced by ECM scaffolds implanted into a muscle wound [23]. Sadtler found that $CD4^+$ T-helper 2 cells were necessary for proregenerative macrophage polarization and subsequent muscle regeneration after treatment with ECM scaffolds, and concluded that the adaptive immune system as well as the innate immune system are important for functional tissue regeneration with a scaffold [24]. Although little is known about how either innate or adaptive immune cells may be involved in cartilage regeneration, it is likely to be a future focus for the field (Fig. 53.1).

Cartilage Surface Modification

Engineering therapies aimed to prevent cartilage deterioration after injury are valuable considering that cartilage is extremely difficult to repair. Because lubrication of the cartilage surface is extremely important for its proper

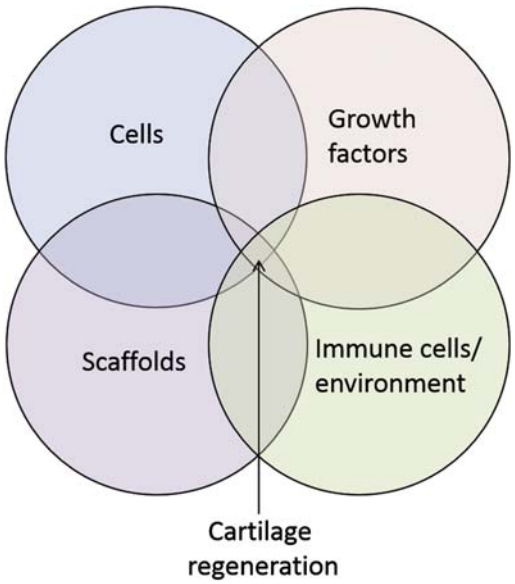

FIGURE 53.1 Revised approach to tissue engineering triad. Cells, growth factors, scaffolds, and immune cells and the immune environment contribute to engineered cartilage regeneration. The immune system contributes inflammatory and antiinflammatory signals, as well as antigen-specific and nonspecific recognition of the engineered scaffold, which may dictate engineered tissue success.

movement without friction and mechanical degradation, viscosupplementation is a common procedure. Viscosupplementation replenishes the molecules in the synovial fluid that naturally lubricate the cartilage surface, most commonly hyaluronic acid. One strategy is to enhance viscosupplementation with synthetic molecules such as a hyaluronic acid (HA) binding peptide to enhance the retention of HA further at the joint surface [25,26]. Synovial fluid can also be enhanced with synthetic charged polymers and synthetics with large molecular brush structures [27]. Synthetic lubricin, synthetic mimics of lubricin, and recombinant lubricin have also been created to replenish lubricin lost at the beginning of cartilage degeneration before major structural cartilage changes have occurred [28]. These lubricin mimics bind HA to the cartilage surface, increasing boundary layer lubrication. Synthetic scaffolds for directing cartilage tissue repair will be covered in the scaffold section.

Cell Types for Cartilage Repair

Different cell sources are available to provide reparative tissue including differentiated cells, mesenchymal stem cells (MSCs), and embryonic progenitor cells. Chondrocytes and MSCs are the two most investigated cell sources for cartilage tissue engineering. Chondrocytes can be isolated from tissue biopsies and cultured ex vivo to achieve the required cell number for engineering new tissue. Chondrocytes have been expanded ex vivo for clinical applications as a US Food and Drug Administration (FDA)-approved therapy [17]. However, a major limitation of chondrocytes is their need to be expanded because of the small amount of cartilage that can be biopsied and the tendency of the chondrocytes to dedifferentiate rapidly in monolayer culture during expansion [29,30]. Tissue culture material and scaffold type can influence chondrocyte phenotype. Culturing cells on hard, flat surfaces results in a loss of the typical chondrocyte rounded morphology, decreased cartilage-specific gene expression, and increased fibrotic gene expression [31]. Three-dimensional (3D) culture and scaffolds preserve the round shape and chondrocyte phenotype to promote chondrogenesis and increased type II collagen and decreased type I collagen synthesis compared with chondrocytes in monolayer culture [32,33].

MSCs represent an alternative to chondrocytes as a cell source for cartilage tissue engineering [34]. MSCs have the advantage of being able to be expanded in vitro in an undifferentiated state while retaining the ability to differentiate after exposure to suitable stimuli [35]. Like chondrocytes, a 3D culture environment for cartilage engineering with MSCs is superior to monolayer culture. Winter et al. compared chondrogenic gene expression and morphology from MSCs derived from bone marrow and adipose tissue [36]. That study demonstrated only partial cell differentiation in monolayer culture; however, bone marrow–derived MSCs showed improved chondrogenesis in 3D culture. In addition to their ability to differentiate into chondrocytes, MSCs have immunomodulatory properties, can migrate to sites of inflammation, and can modulate lymphocyte cell function through several growth factors and cytokines including transforming growth factor-β1 (TGF-β1), nitric oxide, and interleukin-10 (IL-10) [37]. This immunomodulation is especially important when considering the destructive environment in which a cartilage construct is likely to be implanted. MSC therapies for OA are undergoing clinical trials, but not many long-term results are available. Therapies being tested include injection of MSCs isolated from different sources, MSC injection with additional biological factors, and injection of ex vivo expanded MSCs [38]. A clinical trial of bone marrow–derived MSC injections showed improved *Western Ontario* and McMaster Universities Arthritis Index scoring over 1 year after treatment, indicating decreased pain and increased function. In addition, X-ray and magnetic resonance imaging findings indicated that MSC treatment may halt the progression of cartilage loss [39]. However, a common problem with MSC therapy is the poor delivery and retention of MSCs at the cartilage defect site. There are preclinical models aimed at optimizing MSC delivery; however, most clinical trials inject MSCs free of scaffold [38].

Bioscaffolds in Cartilage Repair

Tissue engineering scaffolds are designed to provide a 3D environment to support and direct cellular processes in their migration, proliferation, and differentiation toward functional tissue. Scaffolds can be applied with cells; however, applying scaffold without cells is becoming more attractive because cell therapy is more costly. The selection of bioscaffolds for cartilage engineering requires complex mechanical properties that can support cellular functions, biocompatibility, capability of waste and nutrient transport, and sufficient structural integrity for joint reconstruction. Both natural and synthetic materials have been applied as cartilage tissue engineering scaffolds in a variety of forms, including fibrous structures, porous sponges, woven or nonwoven meshes, and hydrogels.

Natural Scaffolds

Collagen

Collagen is the primary structural protein found in both bone and cartilage [40,41]. As such, collagen-based scaffolds are theoretically capable of supporting chondrocyte attachment and function. They are also biocompatible and biodegradable. Collagen scaffolds have been used in a wide variety of forms such as gels, membranes, and sponges into which cells and/or bioactive factors may be introduced [42,43]. Pieper et al. employed a cross-linked porous type II collagen sponge to support the proliferation and differentiation of chondrocytes under cell culture condition up to 14 days [42]. Yokoyama et al. cultured MSCs in a collagen gel matrix in a chondrogenic medium supplemented with bone morphogenetic protein-2 (BMP-2), (TGF-β3), and dexamethasone [44]. The constructs were characterized by a downregulation of type I collagen and upregulation of type II collagen and the cartilage-related proteoglycans aggrecan, biglycan, and decorin. The maximum size of cartilaginous tissue produced was 7 mm in diameter and 0.5 mm in thickness, still too small for partial-thickness cartilage repair. These cell-based studies indicate some of the disadvantages of collagen scaffolds. Collagen gels allow for uniform mixing of cells and matrix, and for extensive molding and shaping of tissue, but they tend to be fragile until new matrix is laid down. Solid collagen scaffolds such as membranes or sponges exhibit greater initial mechanical strength, but at the cost of less flexibility in shaping and a greater risk of nonuniform cell seeding. Collagen remains a useful scaffold with which to study 3D cell culture, but these disadvantages noted weigh against its use in clinical applications.

Hyaluronic Acid

HA is a polysaccharide that is naturally found in the ECM of articular cartilage and in synovial fluid; it is responsible for the high lubricity of the cartilage surface. It is composed of alternating residues of *N*-acetyl-D-glucosamine and D-glucuronic acid. As with collagen, interest focused on HA as a potential scaffold for cartilage engineering results from its intimate association with chondrocytes in vivo. Intraarticular HA injection has been used to treat symptoms of OA with large world markets and sales and enhances cartilage lubrication and exerts many biologic effects on cells. HA has been shown to have a stimulatory effect on chondrocyte production of type II collagen and proteoglycan [45]. HA also has many immunomodulatory properties. HA less than 50 kDa is considered to be low–molecular weight (LMW), inflammatory HA; at 10^3–10^4 kDa and greater, it is antiinflammatory [46]. HA interacts with many cell receptors including receptor of hyaluronan-mediated motility, CD44, and the immune-related receptors Toll-like *receptors* 2 and 4, giving it the ability to affect inflammation and cell migration, both of which are important aspects of wound healing [47]. It is also thought that LWM HA may provide a danger signal to immune cells to attract them to the site of tissue degeneration to aid in tissue debris clearance, which can damage tissue when occurring chronically [48]. These properties make HA a highly dynamic and important molecule to include in scaffold designs, especially considering that HA makes up a significant part of the chondrocyte pericellular matrix [49] Clinical trials using HA to treat OA have found variable results in the efficacy of HA to reduce OA progression. More research on how variation in different HA products such as molecular weight and cross-linking affects clinical outcome is needed to optimize HA therapeutic effect [50].

Alginates

Alginates are polysaccharides derived from seaweed. They are composed of a family of linear mannuronate/guluronate copolymers that differ in their specific sequences and overall compositions [51]. When exposed to a divalent cation (usually calcium, for the sake of biocompatibility), the linear alginate polymers ionically cross-link to form a porous hydrogel. This allows the uniform seeding of chondrocytes and bioactive factors within the alginate hydrogel, as well as their release, if desired, by exposure to a cation chelating agent such as ethylenediamine tetraacetic acid. Alginates may also be covalently modified to enhance properties such as cell adhesion [51–53] or to fix bioactive factors in place [54–56].The clinical translation of alginates as in vivo scaffold for cartilage repair may be limited by the potential calcification of the constructs [56]. On the other hand, compared with the monolayer cell culture of chondrocytes, alginate matrices provide a convenient means to preserve or reestablish the characteristic chondrocyte phenotype and matrix production during in vitro expansion [57–60].

Chitosan

Chitosan is a polysaccharide derived from chitin (found in arthropod exoskeletons) that has been partially or fully deacetylated. It is composed of linear chains of β-linked D-glucosamine residues. Chitosan has been studied as both a scaffold and a controlled delivery system for bioactive factors [61,62]. There is interest in chitosan as a cell delivery

vehicle because it demonstrates good biocompatibility, and some formulations exhibit the property of temperature-dependent gelation, in that they are liquid at room temperature but gel when exposed to physiological temperatures [63]. In addition, the degree of deacetylation of chitosan directly influences the degradation rate of the constructs as well as the host inflammatory response. A lower degree of deacetylation was associated with an increased degradation rate and host inflammatory response. Thermosetting chitosan constructs injected subcutaneously into nude mice supported chondrocyte growth and matrix production, although the constructs were mechanically inferior to native cartilage [62]. Chitosan constructs were also injected into osteochondral defects created in rabbit knees. Retention of the constructs in the defects was observed at 1 week despite full mobility and weight-bearing. BST-CarGel, a chitosan scaffold used in conjunction with microfracture, is in Phase III clinical testing in the United States and has been approved in several other countries including Australia, Canada, and most of Europe. This treatment resulted in improved lesion filling and cartilage repair quality compared with microfracture alone [64,65].

Composite scaffolds using chitosan combined with alginate and/or HA have also been investigated. Li et al. cultured HTB-94 chondrocytes in interconnected 3D porous chitosan−alginate scaffolds and found promoted cell proliferation and enhanced phenotype expression of chondrocytes in these scaffolds compared with chitosan-only scaffolds [66]. Yamane et al. observed higher cell adhesion, proliferation, and aggrecan synthesis in the HA-coated chitosan hybrid polymer fiber sheet than that in the chitosan fiber sheet [67]. Tan et al. developed injectable in situ−forming composite hydrogels consisting of chitosan and HA for cartilage tissue engineering [68]. Hsu et al. evaluated a chitosan−alginate−hyaluronate scaffold modified with a protein containing an arginine-glycine-aspartic acid (RGD)-modified adhesion peptide motif [69]. It was noted that glycosaminoglycan and collagen synthesis was greater in the chitosan−alginate−HA−RGD scaffold compared with chitosan−alginate and chitosan−alginate−HA scaffolds.

Synthetic Scaffolds

Bioscaffolds derived from natural materials are generally considered more favorable in terms of the biological response they can elicit from cells compared with synthetic scaffolds [70]. However, biological materials can be difficult to generate in large quantities with acceptable consistency and often exhibit poor mechanical characteristics [43]. Synthetic materials are generally less expensive than biologics and are created de novo and provide more precise control over the structural properties, mechanical properties, and rates of resorption with a great deal of batch-to-batch consistency [71].

The most common synthetic polymers and traditional tissue engineering scaffolds are polyglycolic acid (PGA), polylactic acid (PLA), polyethylene oxide, and various derivatives and copolymers based on these entities including poly-lactic-co-glycolic acid (PLGA) [43]. These biodegradable polymers have a long history of medical use and are able to be fabricated and processed in a variety of ways [19]. These materials serve as the basis of scaffolds for the adherence, growth, differentiation, and matrix production of chondrocytes or MSCs [72−75]. In general, the materials exhibit many beneficial properties for the production of engineered tissue: a high surface area to volume ratio if processed correctly, sufficient porosity to allow for nutrient and waste diffusion, the potential for surface modification, and the ability to control their degradation rate via selection and modification of their chemical composition [76]. In particular, the ability specifically to control the rate of degradation is important for scaffold survival in vivo. The scaffold must provide sufficient mechanical strength when first implanted, but it should optimally degrade at the same rate as new tissue generation. If degradation is too rapid, there is a risk of cell loss, scaffold failure, and inflammation and the death of surrounding tissue owing to the rapid release of acidic breakdown products [72,77]. Conversely, an overly slow rate of scaffold degradation would likely impede tissue incorporation. The question remains, how do we determine the replacement rate of the cartilage tissue? This depends on a number of factors including the scaffold itself, but more important, the age of the patient and the level of inflammation in the joint. Articular cartilage changes with age, including increased collagen cross-linking, decreased synthesis of type 2 collagen and aggrecan, and reduced tensile strength [78]. Moreover, senescent cells contribute to the poor reparative abilities of aging cartilage. Senescent cells do not divide but instead cause chronic inflammation in the aging tissue [79]. Chondrocytes can also become senescent, slowing down the rate of scaffold replacement with new cartilage, further affecting the rate of new tissue growth.

Synthetic scaffolds have been processed in a variety of configurations from preformed fibers, meshes, and membranes to photopolymerized injectable gels. Preformed solid scaffolds are seeded in vitro by incubation in a cell suspension. These scaffolds may be applied to large, shallow, or open defects. Li et al. manufactured an electrospun nanofibrous PLGA/poly-ε-caprolactone (PCL) amalgam to mimic the natural extracellular architecture of cartilage better [80]. Their study found that a nanofibrous scaffold was more favorable to promoting cell expansion and matrix deposition over microfibrous scaffolds for cartilage tissue engineering [81]. Solid synthetic scaffolds have the

potential to be modified with natural materials to improve biological characteristics. Enhanced cell attachment and proliferation have been achieved in various composite scaffolds combining synthetic polymers with natural materials, including PLA sponge incorporated with cell-seeded alginate [82], PLGA or a poly-L-lactic acid sponge filled with collagen microsponge [83,84], macroporous PLGA scaffold conjugated with HA on the porous surface [85]. Generally, natural materials have difficulty making mechanically strong engineered cartilage with thickness comparable to partial-thickness and full-thickness articular cartilage defects. Chen et al. successfully prepared a unique composite web with adjustable thickness from 0.2 to 8 mm featuring web-like collagen microsponges formed in a mechanically strong knitted PLGA mesh [86].

Achieving adequate cell densities and uniform cell seeding continues to be challenging [72]. A considerable amount of work by our group and others has focused on liquid polymer solutions that are polymerized or cross-linked in situ after incorporating cells and bioactive factors. Such solutions allow the uniform incorporation of cells throughout the scaffold and the development of minimally invasive application techniques [87–89]. Finally, these in situ polymerizable solutions offer the possibility of precise control of the final shape and composition of the scaffold. For example, there has been considerable work by our group and others studying bilayered constructs in which one layer contains MSCs and the other contains chondrocytes, to approximate the cell–cell interactions that would occur in native tissue. Recapitulating the zonal architecture of native cartilage has also been investigated using sequentially photopolymerized hydrogel layers to generate an engineered tissue that more closely approximates normal cartilage [88,90–92].

Novel polymers based on self-assembling synthetic peptides have been studied as a potential scaffold with an internal microstructure closely resembling ECM for cartilage tissue engineering. These peptides spontaneously form hydrogels in response to changes in their environment, such as alterations in pH or ionic strength [93]. The nanofiber structure in these hydrogels is approximately three orders of magnitude smaller than that of most polymer fibers and more closely approximates the structure of native ECM. These materials have the potential for extensive modification by incorporating peptide domains that influence cell adhesion, differentiation, and proliferation [94]. 3D culture of chondrocytes in peptide hydrogels results in the maintenance of chondrocyte phenotype and secretion of cartilage-specific matrix, with increased proliferation and improved mechanical characteristics compared with chondrocytes cultured in agarose [93,95].

Biological Factors

Growth factors, cytokines, protein gradients, cell–cell interactions, and ECM–cell interactions control cellular differentiation, migration, adhesion, and gene expression. How growth factors control cartilage development, maintenance, and changes during diseased states has been investigated intensively. The primary growth factor families that control cartilage homeostasis are the TGF-β superfamily, BMPs within the TGF-β superfamily, insulin-like growth factors (IGFs), and fibroblast growth factors (FGFs). The role of each of these factors in cartilage growth and homeostasis, as well as effects on stem cells, is varied and diverse. TGF-β and IGF generally exert anabolic effects on chondrocytes including inducing increased type II collagen and glycosaminoglycan synthesis, maintaining chondrocyte phenotype, and promoting chondrocytes proliferation, whereas FGF suppresses proteoglycan synthesis and encourages chondrocytes to take a fibroblast morphology [96]. Although TGF-β signaling generally maintains chondrocyte phenotype and encourages chondrocyte growth, TGF-β signaling is altered in OA, resulting in deleterious effects [97]. Both TGF-β and BMP-2 induce human embryonic stem cells to undergo chondrogenic differentiation [98]. Consequently, cell choice will influence the choice of growth factors applied to an engineered cartilage construct, or vice versa. Most growth factor–only related approaches to preventing cartilage loss involve modulating either anabolism or catabolism of the cartilage tissue and/or inhibiting proinflammatory cytokine signaling. Examples include intraarticular injection of TGF-β, IL-1β inhibitors, and matrix metalloproteinase-13 inhibitors [99,100]. However, the diverse roles of growth factors cause difficulty in attempting to implement them in cartilage engineering. For example, BMP-2 causes chondrogenic differentiation in early embryonic distal digit formation, but it causes cell death in a later phase [101,102]. Some anabolic growth factors may cause osteophytes in OA or do not induce a response in older cells, or they may not be enough to combat the degratory enzymes present in a diseased joint [103].There are also additional signaling molecules, integrins, which are molecules that span the cell membrane and connect the cell cytoskeleton to the ECM. This allows the cell environment, including material stiffness and mechanical forces, to influence cell morphology, migration, and signal transmission [104].

Growth factors can also be broadly administered to a cartilage defect via platelet-rich plasma (PRP), an autologous blood product containing platelet-derived growth factors. PRP contains TGF-β1, IGF-1, vascular endothelial

growth factor, and platelet-derived growth factor. PRP can be made with or without leukocytes. The mechanism of how PRP coordinates an antiinflammatory, proliferative, or remodeling response in cartilage is unknown but is thought to result from stimulating cell proliferation, migration, and matrix synthesis [105,106]. Despite the lack of FDA approval, the components that form PRP are approved, and PRP has been used in cartilage defects clinically, in many cases combined with microfracture or scaffolds [107]. There are many proposed mechanism of action for PRP, including that the growth factors secreted by platelets are responsible for at least part of the cartilage repair and pain relief; however, more research is needed to define PRP's mechanism of action further [108]. Once a mechanism is defined, it will be easier to optimize PRP to treat OA.

Biological scaffolds composed solely of tissue ECM and formed into particles also show benefits in reducing OA progression in animal models. Treatment of diseased joints with biological particles exhibited decreased IL-6 and IL-1β and increased type II collagen and aggrecan expression [109,110]. ECM and PRP demonstrate the power in leveraging nature in engineering. Discovering exactly how these therapies work will be pivotal in determining concentrations and ratios of growth factors and ECM components that are needed for cartilage regeneration, which remain unknown. A final consideration for the use of growth factors in engineering cartilage is the difficulty in their administration. Because most growth factors have limited half-lives, it is difficult to achieve therapeutic concentrations at sites of cartilage damage. Gene therapy techniques are being developed to deliver therapeutic genes encoding necessary gene products to cells at the site of cartilage injury to synthesize biological factors of interest for sustained local expression [111]. In contrast to measuring and monitoring growth factor administration, gene transfer provides a local and sustained supply of bioactive proteins. Gene therapy has encountered obstacles with delivery methods; however, upon development of a reliable delivery technique, genetic engineering may interface with tissue engineering [112].

Bioreactors

A fundamental characteristic of many musculoskeletal tissues is their responsiveness to mechanical stimuli [113]. Articular cartilage is subject to complex forces through its range of motion, including shear, compression, and hydrostatic pressure. These forces affect the growth and functioning of chondrocytes via direct cell deformation, alteration of cellular microenvironment, alteration of cell−matrix interactions, and enhanced mass transport within the matrix [30]. Mechanical stimulation influences chondrocyte morphology, biochemistry, and biomechanical and electrochemical properties, including upregulating chondrocyte expression of aggrecan and type II collagen synthesis compared with chondrocytes grown in a static environment [114,115]. These factors imply that developing a transplantable piece of cartilage in vitro will be more successful in a 3D bioreactor than in a 2D culture system, which will be discussed further [116]. High cell densities within a scaffold (on the order of $20-100 \times 10^6$ cells/ml) are also needed to create a transplantable piece of cartilage in vitro [72]. The need for high cell density and 3D culturing can lead to potential problems with nutrient and waste transport, particularly as the constructs get larger and more matrix is deposited. Static culture that relies on passive diffusion of nutrients and waste may be inadequate to serve the needs of metabolically active tissue.

To enhance the biochemical and mechanical properties of engineered cartilage tissues before implantation, bioreactors have been developed to provide adequate mass transfer and mechanical stimulation. Culture of chondrocytes in 3D bioreactors is also beneficial for measuring the effect of mass flow and dynamic mechanical loading on cartilage formation in an isolated manner [117]. Various bioreactor systems have been applied, including rotating-wall vessel, direct perfusion bioreactor, compression bioreactor, and spinner flask [118]. These configurations are illustrated in Fig. 53.2 [119]. Pei et al. cultured bovine chondrocytes in a variety of preformed scaffolds in static conditions and in a rotating bioreactor system [120]. Constructs cultivated in the rotating bioreactor system demonstrated more uniform cell seeding, greater cell numbers, and enhanced chondrogenesis compared with their static counterparts. Raimondi et al. used a novel forced-perfusion bioreactor system to expose the inner portions of their chondrocyte constructs to bulk fluid flow and hydrodynamic stresses, as opposed to rotating bioreactors that expose the surface only to fluid stresses and convective mass transport [121]. The constructs cultivated in this bioreactor also demonstrated greater cell proliferation and better structural integrity than in static conditions. Vunjak-Novakovic et al. demonstrated that dynamic laminar flow patterns on chondrocytes grown on a PGA scaffold resulted in higher fractions of collagen and glycosaminoglycan and improved mechanical and electromechanical properties compared with chondrocytes grown in static culture or turbulent flow conditions [114]. Kisiday et al. used alternating-day mechanostimulation on chondrocytes to increase proteoglycan accumulation [95]. Waldman et al. compared shear with compression stimulation and demonstrated a greater effect on ECM molecule synthesis with shear forces [122]. Increased ECM translates to an increased load-bearing capacity and stiffness by the cartilage

Bioreactor type	General descriptions	Mass transfer mechanism	Shear stress	Special usage	Tissue	Considerations
Static culture	Batch culture with no flow of nutrient	Diffusion (high)	Very low	Cell proliferation	—	Homogeneous structure of cell constructs and nutrient diffusion limitations
Stirred flasks 	Magnetically stirring of medium	Convection (high)	High	Dynamic seeding of scaffolds	Cartilage	Appropriate scaffold and balance between increasing mass transfer and modulating shear stresses
Rotating wall 	Rotating at a speed so the construcsts in the reactor are maintained "stationary" in a state of continuous free fall	Convection (high)	Low	Tissue constructs which need dynamic laminar flow	Cartilage, bone and skin	Operating conditions (e.g., speed of rotating) especially for growing large tissue mass
Perfusion 	Flow of medium over or through a cell population or bed of cells	Convection (moderate) and diffusion (high)	Moderate	Tissues physicochemicaly and environmentally relevant to human tissues	Epithelial cells, intestinal, bone, cartilage, and arteries	Seeding and attachment of human cells especially within the scaffold body

Engineering parameters in bioreactor's design: a critical aspect in tissue engineering. BioMed Res Int 2013;2013:762132. Copyright (2013) by Hindawi Publishing Corporation, Open access.*

construct [114,122,123]. Nevertheless, high shear conditions promote apoptosis in chondrocytes, resulting in matrix degradation [124].

Hung et al. demonstrated that mechanical stimulation affected gene expression and biochemical and mechanical properties of bovine articular chondrocytes cultured in agarose. It was shown that the effect was proportional to the frequency of stimulation (which varied between 0.005 and 1 Hz) and was synergistic with TGF-1 and IGF-1 [113]. Benya theorized that dynamic stimulation maintains the chondrocyte's round cell shape, which promotes protein synthesis [32]. Shieh and Athanasiou proposed a number of cellular methods for mechanotransduction [1]: transduction of biochemical signals in chondrocytes by changing physicochemistry including the osmotic pressure, pH, fluid flow, and electric potential of the matrix environment [2]; conformational change of ion pumps and channels [3] via integrins that mediate cell–matrix interaction [4]; nuclear deformation changes in the nuclear pore complex influencing DNA available for transcription; and [5] deformation of the cytoskeleton [125]. Further clarification of the signaling pathways involved in mechanotransduction could yield better design of therapies for cartilage repair.

Additive manufacturing technologies have also reached the field of cartilage tissue engineering, in which 3D printing has been employed to create customizable scaffold designs. These 3D printed scaffolds can be used to grow and differentiate cells for tissue engineering, similar to scaffolds processed with more traditional methods. Pati et al. printed decellularized cartilage matrix seeded with human adipose-derived stem cells onto a PCL framework and found satisfactory cell viability and type 2 collagen expression. In addition, cartilage ECM provided a superior microenvironment for cell proliferation over other printable materials including alginate [126]. Because decellularized ECM maintains its complex microstructure, it is likely to become a popular material for 3D printing combined with synthetic materials to provide improved mechanical properties.

Combining mechanical stimulation of chondrocytes with growth factor administration enhances matrix synthesis to a greater degree than either variable alone. Mauck et al. demonstrated that dynamic deformational loading combined with TGF-1 or IGF-1 increased ECM production in a 3D scaffold [123]. The synergy may be a result of mechanical compression causing increased transport and accessibility of growth factors [125]. In addition, Bhumiratana et al. showed that culturing human MSCs (hMSCs) in a well with the addition of TGF-β enabled the hMSCs to condense into cellular bodies [127]. These cell bodies were induced to fuse and form centimeter-sized, mechanically functional cartilage that fused and integrated with bone scaffold. These mesenchymal cell bodies were also tested for their ability to fill a cartilage defect, in which they fully integrated with the existing cartilage owing to collagen II and aggrecan. Moreover, Eng et al. constructed intricate 3D hydrogels designed to predict chemotactic directions of cell migration in MSC and endothelial cell cocultures [128]. Just as sequential administration of growth factors increases chondrocyte proliferation, the investigation of mechanical stimulation and growth factor administration timing could yield future advancements in cartilage engineering [129].

Translation of Cartilage Tissue Engineering

Preclinical Translation

There are many important aspects to consider in designing preclinical ("in vivo") studies for translating engineered scaffolds/cell/peptide therapies, including the clinical indication, animal, and disease model. The type of therapy will also dictate the study design and approach. For example, initial studies for cell-seeded scaffolds often start with simple subcutaneous implantation to examine their ability to generate cartilaginous tissue in vivo. If these studies show that the in vivo environment and tissue scaffold are not hostile to the development of cartilage and osteochondral tissues, the therapy is then tested in the target tissue to determine therapeutic efficacy.

The choice of animal model and the application of the material are crucial to moving therapies to the clinic successfully. For example, if an engineered cartilage construct is intended to fill articular cartilage defects, it is likely that the person receiving the cartilage construct will have OA or some chronic inflammation. Thus, not only is the promotion of new cartilage formation and lack of rejection by the animal important, because the presence of disease will have many implications for the success of the therapy, preclinical testing of materials needs to take into account the disease state. In the case of OA, there are several mouse as well as rat and guinea pig models of OA requiring mechanical loading of the knee joint, transecting the ACL or meniscus, or injecting monoiodoacetate to induce cartilage damage [130].

Animal models still have room to improve. Many therapies, such as *inducible nitric oxide synthase* inhibitors and COX inhibitors, were shown to decrease cartilage lesions and osteophytes in separate OA animal models but did not show clinical efficacy in humans [131]. This problem may be partly because most preclinical testing is performed early in OA disease progression; however, people treated clinically are in late-stage OA. Also, animals used experimentally are generally young adults as opposed to most patients with OA, who are adults aged over 60 years [131]. Studies evaluating the biological differences in OA between young and old animals are needed to advance the utility of animal models in screening therapies.

Clinical Translation

There are many different cartilage bioengineering therapies in clinical testing. Most therapies consist of scaffold alone or scaffold plus cells (MSCs or chondrocytes), MSC-only therapies, PRP injections, and viscosupplementation [132]. ACI is meant for localized cartilage injuries and applies the patient's own expanded chondrocytes in solution to the defect under a surgically closed periosteal flap [16,17]. This allows the autologous articular chondrocytes to synthesize new cartilaginous matrix in the defect site. ACI is clinically approved (Carticel), but the clinical outcomes of the standard ACI methods have disadvantages including donor-site morbidity, risk for leakage of transplanted chondrocytes, complexity of the surgical procedure [133], uneven distribution of the cell suspension in the transplanted site [134], periosteal hypertrophy [135], and dedifferentiation of the chondrocyte phenotype during

in vitro monolayer culture [32,136]. These problems prompted matrix-induced ACI (MACI), second-generation ACI to be developed. MACI involves applying cell-seeded constructs instead of cell suspensions for cartilage repair. Vericel MACI therapy has been approved clinically by the FDA and is the first autologous cellularized scaffold approved in the United States for the repair of cartilage defects. This MACI technique uses an implant with a bioresorbable type I/III collagen membrane with approximately 1,000,000 cells/cm^2. This therapy has been found to improve the Knee Injury and Osteoarthritis Outcome Score more significantly than microfracture but to have similar histological repair outcomes in Phase III clinical testing [137].

Variations of the MACI approach include a technology in which the in vitro chondrocyte expansion was performed using a 3D scaffold made from modified HA [138]. The scaffold was then implanted into cartilage defects via a miniarthrotomy or arthroscopic approach. Their cohort includes 141 patients observed for 2−5 years. Their results appear impressive, with improvement in subjective symptoms reported in over 90% of patients. Second-look arthroscopy was performed in 55 patients, and the cartilage repair was graded as normal or near-normal in over 95% of these patients. Biopsies were taken in 22 of these 55 patients, which revealed a hyaline appearance in 12 of 22; the remainder were a mixed or fibrocartilaginous appearance. Histogenics has the most advanced engineered cartilage therapy in the United States. This MACI therapy, NeoCart, expands chondrocytes, after which they are seeded on a collagen scaffold that is matured in a bioreactor before implantation in a cartilage defect. In Phase III clinical testing in the United States, results demonstrate reduced pain, increased function, and imaging-confirmed defect filling with NeoCart treatment [139].

Biomaterials alone are also being implanted in conjunction with microfracture or other autologous cell or tissue sources for focal cartilage repair to provide a simplified off-the-shelf therapeutic. Various approaches have been developed to incorporate biomaterials with microfracture, e.g., using polymer scaffold combined with minced cartilage from a biopsy [140,141], implanting collagen membranes microfracture [142], and applying chitosan mixed with blood after microfracture [143,144]. These biomaterial-guided tissue repair methods may be more economical and provide an off-the-shelf therapy that is more efficacious than surgical intervention alone.

Achieving integration of engineered tissue with host cartilage is still a troublesome problem for cartilage reconstruction, especially for long-term cartilage repair [145]. Cartilage integration failure was common and probably caused by a variety of factors, including limited chondrocyte mobility in the cartilage extracellular matrix, chondrocyte cell death at the wound edge, chondrocyte dedifferentiation in the engineered tissue, the type of biomaterial scaffold, and the origin and stage of the cells used for cartilage tissue engineering. Corresponding solutions have been reported to enhance the construct, including cartilage integration by pretreating the cartilage interface enzymatically to break down collagenous matrix [146,147], inhibiting the chondrocyte death at the lesion edge [148], and using immature constructs instead of mature constructs [146]. We developed a mechanically strong biological glue to bridge native cartilage with biomaterial scaffolds [149]. This glue is based on chondroitin sulfate, a major component of the cartilage ECM, functionalized with methacrylate and aldehyde groups to react chemically with the biomaterials and cartilage proteins. Using this glue, full integration was achieved in full-thickness chondral defects after marrow stimulation. Studies suggest that PRP can improve cartilage integration of explants [150,151] and that immunomodulation has an important role in successful explant integration.

CURRENT AND FUTURE TRENDS IN CARTILAGE ENGINEERING

These tissue engineering techniques show great potential advantages over conventional surgical options and are being applied to clinical practice intensively [152]. The ultimate aim of articular cartilage tissue engineering is to design an engineered tissue that can regenerate to hyaline cartilage with normal knee functions and integrate fully with the surrounding native cartilage. To date, no engineered tissue construct fulfills this criterion; thus, there is considerable ongoing work in various aspects of cartilage tissue engineering research from cell type to bioscaffold, biological factor, bioreactor, and tissue translation. It would be nearly impossible to summarize the vast body of this research in a single chapter, so the range of studies outlined here is necessarily only a brief summary of the past and current literature on selected topics.

The recurring theme throughout much of the current literature is that the engineered tissue has the histological appearance and biochemical makeup of cartilage of varying stages of maturation. However, it has been reported that mechanically, most of these constructs are inferior to native cartilage. As the basic techniques of chondrocyte, osteoblast, and MSC culture are elucidated, the focus is shifting toward improving the mechanical properties of engineered tissues. One concern is that, to achieve complete reconstruction of cartilage defects, the transplanted tissue can initially have mechanical strength inferior to native cartilage temporally to allow the tissue to mature

and integrate to the surrounding cartilage ultimately under the in vivo environment. A large gap should be considered to exist between in vivo studies and in vitro testing and optimization for the clinical translation of engineered cartilage. In vitro methods should be standardized to provide clear results to develop successful clinical applications for cartilage tissue engineering [35]. Several important basic questions that remain to be answered: What are the optimal types, amounts, and timing of the growth factor milieu? Perhaps PRP will answer this question after further characterization. Will small molecular drugs work effectively for cartilage tissue engineering, because many biological factors are complex and exhibit delivery problems? In vitro models provide the isolated environment necessary to define genetic programming clearly and signaling pathways that are involved in chondrocyte maintenance fail to compensate for all the dysregulated signaling pathways in vivo, which will ultimately dictate the success or failure of a bioengineered therapy. More preclinical models of cartilage defects need to be used to determine the impact of the host environment on bioengineered therapies.

Other areas of intense scrutiny include exploring ways to implement complex tissue elements such as spatial organization and vasculature in engineered tissues. Work on osteochondral tissue generation has been discussed here. However, as the effects of 3D organization of tissues become more fully appreciated, there will be a need to regenerate those structures for the purposes of controlled laboratory study and clinical application. With the use of novel polymers that form hydrogels under controlled conditions, there is the potential for fine control of the shape of engineered tissue as well as the 3D spatial arrangement of heterogeneous cell populations within the scaffold. This has already been demonstrated using photolithographic methods to control hydrogel configuration and cellular organization [153]. A clinical application was demonstrated by Naumann et al., in which computer-aided design techniques were used to fashion an HA scaffold seeded with chondrocytes into the shape of a human ear. The construct demonstrated an acceptable shape as well as evidence of cartilage production in vitro, but mechanical properties were not tested [154]. Another clinical application of computer-assisted arthroplasty was shown by Sidler et al., in which a bony defect was made in the talus of a human cadaver ankle joint. The defect was then analyzed by computed tomography and an implant was fashioned using a computer-aided manufacturing device [155].

An overlooked aspect to cartilage engineering is the use of cytokines and manipulation of the immune cells that produce them. The immune system has typically been viewed as being responsible only for material rejection and tissue destruction, with immune suppression considered ideal. However, in light of work showing the importance of the innate and adaptive immune system in tissue repair, future work will most likely focus on modulating the immune system, not simply suppressing it.

OA treatments such as nonsteroidal antiinflammatory drugs and steroids suppress the immune system and are widely used to reduce pain. However, neither reduces disease progression, which suggests that suppressing the immune system does not improve OA outcome. Harnessing macrophages and T cells for tissue regeneration would be a logical strategy, considering that they already have many functions in tissue remodeling. In addition, because T cell therapies are already used in other diseases such as cancer immunotherapy, they could be adapted for use in cartilage regeneration to guide macrophage polarization and direct the tissue repair process.

Of course, many more questions and challenges remain before the promise of tissue engineering is fully realized. The contributions of scientists in fields as diverse as cell and molecular biology, materials science, chemistry, and mathematics will be required to answer these questions.

Stem Cell Therapy for Musculoskeletal Diseases

Benjamin B. Rothrauff, Alessandro Pirosa, Hang Lin, Jihee Sohn, Mark T. Langhans, Rocky S. Tuan

University of Pittsburgh School of Medicine, Pittsburgh, PA, United States

INTRODUCTION

Musculoskeletal Diseases: A Need for Improved Therapies

Disorders of the musculoskeletal system constitute the most common cause of disability in the developed world and account for 25% of all operating room procedures, the largest percentage by organ system [1]. Musculoskeletal disorders can be caused by acute trauma (e.g., fractures, sports injuries), tissue degeneration (e.g., osteoarthritis, spinal stenosis), genetic aberrancies (e.g., muscular dystrophy), and autoimmunity (e.g., rheumatoid arthritis), with frequent interaction among these etiologies. Joint and back pain, often the result of degenerative osteoarthritic changes, together represent the most frequent cause for a physician visit. Whereas total joint replacement of arthritic hips and knees is a remarkably effective treatment to alleviate pain and improve function, there are fewer treatment options for other chronic musculoskeletal disorders. Furthermore, the population is increasingly engaged in physical activities (notably sports) that increase the risk of orthopedic injury. Even if successfully treated to permit return to physical activity, these injuries often predispose the patient to early-onset osteoarthritis. However, given the finite life span of joint prostheses, surgeons are reluctant to offer total joint replacement to a younger patient. Similarly, a myriad of other musculoskeletal disorders have proven recalcitrant to surgical intervention, no matter how sophisticated the surgical technique. For these reasons, it has been the hope of patients, clinicians, and scientists alike that the relatively new disciplines of tissue engineering and regenerative medicine might provide solutions to these formidable challenges of musculoskeletal disorders.

Perhaps no aspect of orthopedic regenerative medicine has been more promising, and equally disappointing, as stem cell therapies for musculoskeletal diseases. That is, although an ever-increasing pace of basic research is developing novel stem cell–based therapies, with promising results consistently found in animal models, relatively few stem cell therapies have been applied clinically. Where they have, the subject number has been small and the study quality has been poor, limiting conclusions regarding the efficacy of these putative therapies. As discussed subsequently, the slow pace of translating stem cell therapies from the bench to bedside is partly the result of financial and regulatory challenges.

Regulatory and Financial Challenges to Stem Cell Therapies

Cell-based therapies represent a relatively new technology and their regulatory purview is still being determined. The US Food and Drug Administration (FDA) issued a set of regulations (21 CFR 1271) in 2001 governing cellular and tissue-based therapies. The underlying principle of these guidelines was that cellular and tissue therapies that require minimal to no manipulation of autologous tissues do not require FDA approval, whereas those that involve any significant modification or treatment, including genetic manipulation, require it. Despite the subsequent issuance of a series of guidance documents, FDA approval necessitates substantial time, effort, and financial investment for the performance of the clinical trials needed to demonstrate safety and efficacy and has effectively limited the implementation of cellular or tissue-based therapies to those with minimal manipulation of autologous

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00054-0

cells and tissues. Allograft tissues, which contain allogeneic cells, have been implemented in clinical practice by maintaining their classification as transplant tissues that are subject to different regulations. There is ongoing debate about whether mesenchymal stem cells (MSCs) qualify as biologic drugs subject to FDA approval or human cellular or tissue products. Along these lines, in February, 2014, The US Court of Appeals for the District of Columbia Circuit upheld a 2012 ruling that a patient's cells for therapeutic use fall under the aegis of the FDA. The appeals case involved the company Regenerative Sciences and their Regenexx procedure, which involved the use of autologous cells to treat musculoskeletal pathologies.

Most insurance companies have been reluctant to cover the cost of cell-based therapies for musculoskeletal pathologies because outcome studies have been small in number and often of insufficient quality. However, this has not deterred patients from spending up to $10,000 out-of-pocket per treatment for "stem cell" therapies. The success of cell-based therapies with more extensive cellular manipulation, such as genetic engineering, in areas with greater room for dramatic improvement of clinical outcomes, such as orphan diseases of inborn metabolism and cancer, may clear the path for implementing more sophisticated cellular therapies in musculoskeletal pathologies. That is, demonstrated safety and efficacy in treating grave diseases with high morbidity and mortality may ironically facilitate broader implementation of related cell-based therapies for more prevalent, but often less dire, musculoskeletal disorders. On the other hand, promising preclinical studies as reviewed subsequently, demonstrate safety and efficacy of stem cell–based therapies, which it is hoped will prompt clinicians and researchers to partner with regulatory administrators to seek broader application of these technologies to treat human diseases.

Chapter Overview

This review focuses on stem cell therapies for musculoskeletal diseases. In particular, we highlight stem cell applications for individual tissues of the musculoskeletal system (bone, articular cartilage, tendon and ligament, meniscus, intervertebral disc, and skeletal muscle) as well as transitions between tissues (osteochondral interfaces and tendon–bone interfaces). For each, the relevant structure and function are described. Because embryological development of these tissues and the phenotypic characteristics of their resident cells are described in detail in other chapters, only a succinct discussion of tissue-specific endogenous cells is included. There is emphasis on findings of preclinical and clinical studies when possible. However, a comprehensive review of all available stem cell therapies for a given tissue or disease is beyond the scope of this chapter; readers are referred to more extensive reviews for further detail.

STEM CELL THERAPIES FOR MUSCULOSKELETAL DISEASES

Cell-based therapies include numerous cell phenotypes, including adult differentiated cells (e.g., chondrocytes), progenitor cells (e.g., satellite cells, SCs), multipotent stem cells (e.g., MSCs), and pluripotent stem cells (e.g., embryonic stem cells [ESCs], induced pluripotent stem cells [iPSCs]). For all phenotypes, allogeneic, autologous, and xenogeneic cells may be considered. Although adult differentiated cells ostensibly possess the greatest homology to the endogenous cells of the target tissues, autologous cell isolation is associated with the creation of an iatrogenic defect with associated donor site morbidity. Furthermore, these cells often possess a limited expansion potential ex vivo and frequently undergo dedifferentiation during the process [2]. On the other hand, pluripotent stem cells, including ESCs and iPSCs, present several ethical (especially for ESCs) and technical challenges (i.e., need for feeder cells) that have limited their broader use in regenerative applications. Therefore, the MSC has been the workhorse for most investigations of stem cell therapies for musculoskeletal diseases. Although often described as a single-cell phenotype with particular cell surface markers, the term "MSC" is used loosely in the literature to include a multipotent, plastic-adherent population of cells capable of forming colonies. Although MSCs were originally thought to aid tissue regeneration by synthesizing the extracellular matrix (ECM) that would constitute new musculoskeletal tissues [3], studies showing diminished MSC viability and retention at musculoskeletal lesions over time (despite improved healing) suggested that MSCs might also function by secreting paracrine factors [4]. The phenotype and function of MSCs are still an area of active investigation, but as detailed in other chapters, their utility for enhancing healing of musculoskeletal tissues has been demonstrated in preclinical studies, as described subsequently.

Bone

Bone diseases can be caused by different factors, including nutrient deficiencies, genetic alterations, and vasculature disorders, causing bone loss or decreased density, with resulting reduction in bone strength. Congenital bone defects, fracture malunion or nonunion, osteogenesis imperfecta, bone resection caused by osteosarcoma or tumor metastasis, osteoporosis, osteonecrosis, and osteomyelitis are just a handful of musculoskeletal problems affecting bone. Moreover, alterations in bone vascular supply have a critical role in increased susceptibility to osteoporosis, osteonecrosis, and osteomyelitis. These multifactorial pathologies are concerning, especially in the context of an aging population and increased incidence of trauma-related injuries. When the innate regenerative capacity of bone is compromised, as is often the case in these pathologies, there are few biological options to promote new bone growth. Bone autografts are still considered the current reference standard, but they have limitations in terms of size of the defect to be grafted and the need for a second surgical site for the bone harvesting, often the iliac crest of the pelvis. Autografting increases patient morbidity, including increased postoperative pain and risk for infection. Allografts avoid the pitfalls of autografts but do not possess the same strength and cellular component. Because current treatments do not provide optimal outcomes, tissue engineering and regenerative medicine strategies, which use stem cells often in combination with biodegradable scaffolds, represent a possible alternative.

The successful development of clinically relevant engineered bone relies largely on the choice of stem cells, which are the main players for the actual production of the bone tissue. Another critical component is the scaffold, which should possess osteoconductive, osteoinductive, and sufficiently strong mechanical properties, as well as the ability to integrate with the host vascular network. Main vascularization strategies have included the delivery of angiogenic factors within with three-dimensional (3D) scaffolds, in vitro prevascularization strategies, and the use of coculture systems [5].

Several materials have been employed as stem cell carriers for engineered bone. Calcium phosphates such hydroxyapatite (HAp) and β-tricalcium phosphate are known for their osteoconductive properties and stiffness. Bioactive glasses are another class of inorganic materials exploited in bone engineering, owing to their ability to support bone formation in vivo. Apart from inorganic matrices, natural and synthetic polymers have been extensively used for bone engineering. Biopolymers (e.g., collagen, silk, chitosan, polyhydroxyalkanoates) offer low manufacturing/disposal costs, can be obtained from renewable resources, and provide natural cues for cell signaling, adhesion, and remodeling. On the other hand, synthetic polymers (e.g., polyglycolic acid [PGA], poly-lactic acid [PLA], poly-ε-caprolactone, biodegradable polyurethanes) can be manufactured and tailored with desired physiochemical and degradation properties. Biological scaffolds can be prepared by decellularizing bone or specific ECM preparations.

Biologically inspired scaffolds contain signals that can induce the simultaneous development of bone and vasculature within the construct. Technological advancements in the rapid prototyping and additive manufacturing field have given researchers powerful tools to model these materials in various shapes to address clinically relevant issues [6]. Although osteoinductivity and osteoconductivity usually depend on a material's chemical nature, these technologies allowed the development of scaffolds with controlled ultrastructure (e.g., interconnected macroporosity for optimal osteoblast differentiation and vasculature development) as well as stiffness matching the mechanical properties of native bone. A novel fabrication technology that is gaining relevance for bone tissue engineering is bioprinting, which consists of the precise deposition of cell-laden biomaterials (referred to as bioinks) in predefined 3D structures. The use of computer-aided design and manufacturing allows for the production of specific constructs exactly matching the dimensions of the target defect. Vasculature can be bioprinted, too; for example, it can be used to dispense smooth muscle cells, endothelial cells, and fibroblasts as single- and double-layered vascular tubes.

The design of a stem cell–based technology for engineering bone requires the selection of suitable cell sources, which should possess self-renewing capacity and ease of maintenance and manipulation in vitro for subsequent implantation into the defect or lesion. One benchmarked cell source for bone tissue engineering is the MSC, owing to its well-defined capacity to undergo osteogenic differentiation. Together with bone marrow–derived MSCs (BM-MSCs), adipose-derived MSCs (ASCs) are an accepted cell source for engineered bone. MSCs have been thoroughly investigated, in combination with several types of scaffolds, in preclinical settings using small animal models such as mice [7], as well as critical-size defects in rabbits [8] and in more relevant ovine models [9,10].

An example of the clinical use of MSCs in bone engineering was documented in a pilot study treating five patients with unilateral cleft lip and palate. MSCs were used in combination with a commercially available collagen and HAp scaffold (Geistlich Bio-Oss), showing bone formation spanning the previous alveolar cleft

after 6 months in all patients. Despite this early clinical success, myriad investigations suggested that improved fabrication of biomimetic engineered bone is augmented by the use of endothelial stem cells. Blood-derived endothelial progenitor cells are a good candidate for this aim, and they have been used in cotransplantation studies with MSCs to improve neovascularization and bone regeneration in rats [11]. iPSCs can also be identified as cell sources for bone tissue engineering because they can be differentiated into osteoblasts and osteoclasts capable of producing mature bone–like tissue both in vitro and in vivo [12,13]. iPSCs have also been shown to form vasculature [14].

To optimize cell seeding and mass transport within a scaffold, bioreactor technology is also being pursued. Several setups have been developed in the past years, such as spinner flasks, rotating wall vessels, and perfusion bioreactors. Although these systems provide fine control over the experimental parameters, they often fail to produce sufficient quantity and quality of bone; hence "in vivo bioreactor" technologies have been developed to produce clinically relevant volumes of vascularized bone. These techniques rely on the ectopic cultivation, usually in a periosteal flap, of sizeable bone grafts, exploiting the body's regenerative capacity as a living bioreactor to cultivate stem cells, scaffolds, and growth factors. Once sufficiently matured, these functional bone grafts then can be implanted into a defect.

Despite promising results in preclinical application of MSCs for bone regeneration, their clinical use remains nascent and their effects need to be investigated further. Increased therapeutic applications of stem cells for enhanced bone repair will come with elucidating the complex interactions among all of the cellular components of bone. Moreover, bone tissue engineering would be upgraded by automation and standardization, increasing the likelihood of delivering an effective and economically viable technology.

Articular Cartilage

Three types of cartilage exist in human body, including hyaline cartilage, elastic cartilage, and fibrocartilage. In these tissues, glycosaminoglycan (GAG) binds to protein fibrils to form a highly hydrated matrix that is flexible and resilient to bearing. In hyaline cartilage, the fibrils are mainly formed from collagen type II, compared with an elastin–collagen type II mixture in elastic cartilage and collagen type I/II in fibrocartilage. Hyaline cartilage exists in the nose, surfaces of long bone ends, the rib tips, and the rings of the trachea. The cartilage in the epiglottis and pinnae shaping the outer ear are elastic cartilage. The meniscus and temporomandibular joint are typical fibrocartilage. In this chapter, we will primarily focus on cell therapies for the repair of articular cartilage (AC) defects.

AC is the smooth surface that covers bone ends, allowing frictionless movement as well as load bearing. Under physiological conditions, AC has a glassy appearance, thus its name (*hyalos* is Greek for "glassy"). The avascular and aneural nature of cartilage prevents the tissue from receiving sufficient nutrients and reparative cells necessary for wound healing, which limits AC self-repair [15]. For example, a study reviewing knee arthroscopy results reported that the incidence of chondral defects was higher than 60%, although many patients did not report pain or compromised mobility [16–19]. In a review of 993 consecutive knee arthroscopies, 11% of knees were found to have one or multiple full-thickness cartilage lesions (International Cartilage Repair Society Grades 3 and 4) [17]. In a systematic review of multiple databases, the prevalence of full-thickness focal chondral defects in athletes was strikingly higher than that of nonathletes (36% versus 11%) [20].

No treatments are available to regenerate stable hyaline cartilage completely in a chondral defect. In addition to conventional palliative treatments, some surgical protocols such as microfracture and autologous chondral transplantation have been shown to result in filling of the lesions, with associated pain reduction and improved cartilage function. However, critical challenges remain. For small cartilage defects, the microfracture technique is commonly employed to induce bleeding and allow migration of reparative stem cells and cytokines from the bone marrow [21,22], which has been shown to improve joint functionality and pain relief for over half of patients when applied in those who are young. However, the cartilage formed is usually fibrocartilage, which eventually fails owing to structural and mechanical properties inferior to those of hyaline cartilage. Thus, alternative regenerative techniques are being developed to improve microfracture.

Cell-based therapies, such as autologous chondrocyte implantation (ACI), have shown the most promise for the regenerative repair of cartilage [23]. ACI is a two-stage procedure involving chondrocyte isolation and in vitro expansion, followed by implantation [24]. ACI is the only FDA-approved cell-based therapy for focal cartilage defect repair (marketed as Carticel by Genzyme Biosurgery). However, harvesting of autologous cartilage results in donor site morbidity, and the chondrocyte phenotype is reduced or even lost upon culture expansion in vitro, thus

impairing or compromising the outcome [25]. Consequently, it remains uncertain whether ACI provides a superior outcome in cartilage repair over other treatments such as microfracture [26,27].

As alternative cell sources for cartilage regeneration, ESCs present ethical issues and potential immunorejection. iPSCs are often excluded owing to safety concerns, notably tumorigenicity. Therefore, the use of autologous MSCs continues to receive the most attention because of their relatively easy access and efficient chondrogenesis upon stimulation [28]. There are two major avenues to using MSCs for the treatment of chondral defects: the differentiation of MSCs into chondrocytes and the application of factors produced by MSCs.

Adult tissue-derived, multipotent MSCs have the ability to differentiate into chondrocyte-like cells and have been considered a promising candidate cell type to replace chondrocytes for cartilage tissue engineering [22,29]. For example, direct intraarticular injection of MSCs showed improvement in cartilage healing and regeneration [30,31]. In our studies [32–34] as well as those of others, the reparative potential of ASCs was well-demonstrated in cartilage regeneration.

To become chondrocytes, MSCs must undergo a chondroinductive process. Embryonic chondrogenesis in the developing limb bud begins with mesenchymal cell recruitment, proliferation, and condensation. In this sequential process, cell condensation is a critical step that is initiated by several growth factors, including transforming growth factor-β (TGFβ), fibroblast growth factor (FGF), Wnt, and bone morphogenetic proteins (BMPs), acting in concert [35–37]. In particular, TGFβs and BMPs are the most potent inducers of MSC chondrogenesis, characterized by the enhanced expression of SOX9, collagen type II (COL2) and aggrecan and the deposition of collagen and proteoglycans rich in sulfated GAGs. For human MSCs, TGFβ2 and TGFβ3 were shown to be more active than TGFβ1 in promoting chondrogenesis [38]. In fact, the TGFβ family is the most used to direct MSC chondrogenesis. In addition to soluble factors, a variety of both natural and synthetic scaffolds have been used to serve as carriers for the cells or to provide a chondrosupportive microenvironment [39].

Interestingly, in cultures of MSCs undergoing chondrogenesis in vitro, the expression of chondrocyte hypertrophy-associated genes has been widely reported. Hypertrophy refers to the process seen in endochondral ossification of growth plate cartilage, in which chondrocytes undergo enlargement, glycolytic metabolism, altered matrix production, and eventual matrix mineralization [40]. These activities are also associated with osteoarthritis chondrocytes [40,41]. Hypertrophy is characterized by an upregulation in the expression of COL10, specific matrix metalloproteinases, and vascular endothelial growth factor (VEGF), and an increase in alkaline phosphatase activity, which are regulated by the Runt-related transcription factor 2 (Runx2) transcription factor, a marker typically associated with osteogenic differentiation [42]. The ECM deposited by hypertrophic chondrocytes is structurally inferior to that of hyaline chondrocytes, eventually leading to poor cartilage regeneration or formation of nonhyaline cartilage [43,44]. Hypertrophy is not related to the tissue source of the MSCs; it is observed in adult MSCs from all origins. These observations point to the deficiency of currently practiced methods of MSC chondroinduction. Hence, the major challenge of applying MSCs for hyaline cartilage repair is to produce stable articular-like, hyaline chondrocytes that are resistant to hypertrophic conversion and subsequent ossification.

The mechanism of the abnormal hypertrophy is not completely understood. It may result from inherent chondro-hypertrophic and osteogenic tendencies of MSCs, because the insufficiency of current formulas in controlling the hypertrophic process is observed in adult MSCs from all tissue sources. Chen et al. well-summarized the pathways associated with chondrocyte hypertrophy and strategies to inhibit such an unfavorable phenotype [45]. In particular, Wnt/β-catenin signaling was proposed to be associated with hypertrophy, because blocking DKK1 and FRZB, endogenous Wnt inhibitors, increases hypertrophic differentiation. Cao et al. explored the effects of xanthotoxin on MSC hypertrophy and found that xanthotoxin reduced the activation of p38 mitogen-activated protein kinase, leading to the increased expression of histone deacetylase 4, which finally suppressed Runx2 and the expression of hypertrophic marker genes [46]. The PI3K–Bapx1 pathway and Notch signaling have also been shown to be involved in the hypertrophy process [47]. Interestingly, coculture of MSCs with articular chondrocytes may also suppress hypertrophy [48,49]. However, this method would involve the isolation and expansion of (autologous) primary chondrocytes, which is thus hampered by the same limitations as ACI, described earlier.

Eighteen clinical trials using live MSCs to treat cartilage defects are registered at ClinicalTrials.gov. However, few of the completed studies reported results. In a clinical study employing 14 patients, autologous MSCs were used to treat full-thickness chondral lesions of the knee greater than 2 cm^2, with ACI as the control. At all follow-up intervals of up to 24 months, patients treated with MSCs displayed significantly better functional outcomes than those treated with ACI ($P < .05$), including greater range of motion and straight leg raise strength. Subjective subscale scores for pain, activities of daily living, and osteoarthritis outcome scores ($P < .05$) in the MSC-treated group were also superior to those with ACI. No adverse effects from the implants were observed in either group [50].

The safety of autologous MSC implantation was further confirmed in other 2-year follow-up studies [51,52]. To enhance the reparative outcome, multiple cell injections have also been tried. Three intraarticular injections, each containing 20×10^6 MSCs, were performed 4–6 weeks after femoroacetabular impingement. Results showed that modified Harris Hip, Western Ontario McMaster University Osteoarthritis Index, and Vail scores increased from 64.3, 73, and 56.5 at the beginning, to 91, 97 and 83, respectively, at month 24 ($P < .05$). Around 20% of patients reported pain after cell injection [53]. MSC injection has been combined with other surgical methods. For example, after arthroscopic subchondral drilling into grade 3 and 4 chondral lesions, Saw et al. [54] injected hyaluronic acid together with autologous peripheral blood stem cells and found that such combined treatment resulted in hyaline cartilage formation with enhanced quality compared with cell-free treatment.

In addition to their potential to generate chondrocytes, there is substantial evidence to suggest that MSCs produce a wide range of secreted factors that influence the injured tissue microenvironment and orchestrate tissue repair processes. In fact, in many cases in which the positive effects of MSC injection have been observed, the transplanted MSCs are not found at the lesion site at follow-up [4,55]. Therefore, against the initial assumption, increasing evidence suggests that the main therapeutic function of MSCs may not be to replace tissues cells; rather, they may have paracrine effects. As such, the use of MSC secretome, which includes soluble factors as well as extracellular vesicles (EVs) [56,57], has been proposed as a safer and more advantageous approach compared with live MSC-based therapy.

EVs, as well as exosomes, have been applied in many clinical conditions [58], but there are few studies on EVs in the treatment of chondral defects. Although MSC EVs have been shown to have positive effects in treating artificial injury or insult-initiated (secondary) animal osteoarthritis models [59–67], most functions of exosomes are associated with their immunomodulatory properties. In a study using chondrocytes from rats, exosomes from immortalized embryonic day 1-myc 16.3 human ESC–derived MSCs not only promoted chondrocyte proliferation but also enhanced chondrogenic gene expression, as well as GAG deposition [61]. After being incorporated into an acellular tissue patch, stem cell–derived exosomes were able to integrate with native articular cartilage tissues and promoted cell migration at the defect sites, ultimately leading to enhanced tissue regeneration [59]. A study further indicated that such chondrosupportive function may be caused by the high levels of sphingosine-1-phosphate (S1P), which activated S1P receptor 1 on chondrocytes. Blocking S1P with a neutralizing antibody depleted the beneficial effects of EVs in promoting cartilage formation in vivo [68].

Osteochondral Tissue

Defects of both AC and the underlying subchondral bone are often associated with joint pain and instability, risk factors for the development of osteoarthritis. The hallmark of osteoarthritis has been traditionally defined as the progressive degeneration of cartilage; however, several studies reported that subchondral bone is critical in the pathogenesis of osteoarthritis. The continuous mechanical and functional interaction of articular cartilage with the subchondral bone during movement creates reciprocal effects between the two tissues. In fact, antiresorptive drugs that limit bone remodeling have a positive effect on cartilage, whereas antidegradative treatment on cartilage alleviates bone remodeling. During the pathogenesis of osteoarthritis, communication between bone and cartilage is significantly increased owing to vascular infiltration into the cartilage, formation of microcracks and microchannels from bone and bone marrow reaching the cartilage, fragmented tidemark, and fissures. Increased vascularization has been indicated as another hallmark of osteoarthritis, revealing VEGF as an important player in osteoarthritis pathogenesis, because its expression is elevated in arthritic chondrocytes compared with healthy chondrocytes. Treatments of osteoarthritis are mostly symptomatic and based on pain and antiinflammatory medications. Because of the degenerative and chronic nature of this disease, total joint replacement is ultimately necessary in most cases.

Morphological and functional differences of the two main components of the osteochondral complex have always challenged researchers in the development of tissue engineering constructs for the regeneration of this interphase. Most studies have been traditionally focused on the production of gradient structures with different mechanical and chemical properties. Hydrogels are most frequently used for cartilage engineering, owing to the highly hydrated nature of cartilage ECM, whereas stiffer scaffolds are needed to match native bone mechanical properties. A comprehensive review by Nooeaid et al. [69] describes the main materials and scaffolds used for osteochondral regeneration.

The choice of stem cells for osteochondral tissue engineering is also challenging, because bone and cartilage cells are specialized and are characterized by different biological properties. In this case, MSCs are valuable, owing to their ability to differentiate into both cartilaginous and osseous lineages. However, as stated in the earlier section on Bone, engineered bone must also contain an endothelial component to satisfy a clinically relevant engineered

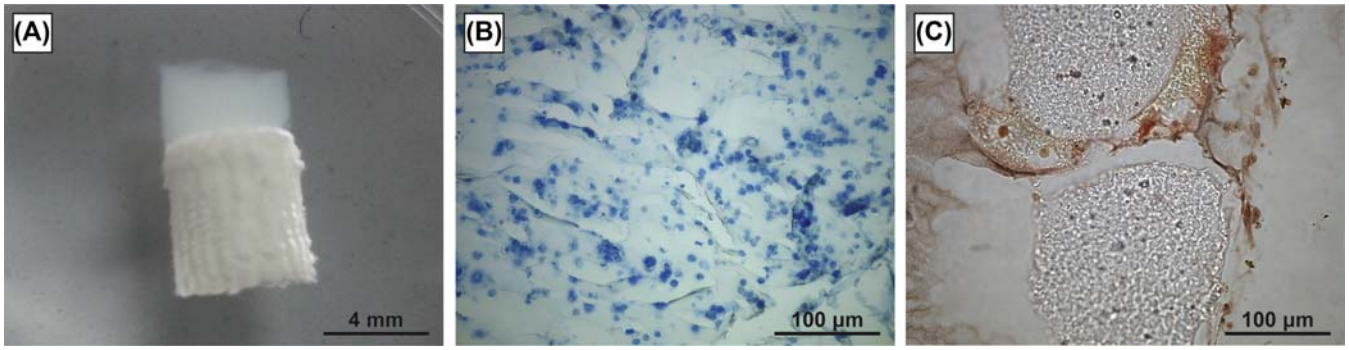

FIGURE 54.1 Engineered osteochondral interphase obtained using a dual-chamber perfusion bioreactor. (A) Macroscopic image of the construct showing photocrosslinked gelatin methacrylate as the cartilage tissue (*top*) and an additively manufactured poly(ε-caprolactone) scaffold as the subchondral bone (*bottom*): both compartments were seeded with human mesenchymal stem cells (hMSCs) and cells were separately yet simultaneously differentiated using two different media streams. (C) Alizarin red histological staining showing calcium depositions by hMSCs in the osseous tissue.

construct for regeneration in vivo. Technical issues associated with the development of an engineered osteochondral interface include the different biochemical compositions of AC and subchondral bone, as well as the different media compositions required to direct MSC differentiation into either lineage. These issues may be solved by the use of bioreactors; in our laboratory, we developed a dual-chamber perfusion bioreactor that allows the simultaneous yet separate flow of two different media to induce MSCs to differentiate specifically into chondrocytes and osteoblasts [70] (Fig. 54.1).

Although much research has focused on the treatments of osteoarthritis, a satisfactory strategy to alleviate or stop disease progression is unavailable. Preclinical studies have employed stem cells to stimulate the regeneration of the osteochondral interphase and halt the progressive destruction of the joint. These studies have used animal models that develop osteoarthritis caused by targeted genetic perturbations, surgically induced damage, or spontaneous age-associated degeneration. Stem cells can be directly injected into the defect site, usually in the early stages when the defect is limited to the cartilage only, or combined with scaffolds, in the case of exposure or degradation of subchondral bone, thereby providing mechanical support [71]. Preclinical studies for osteochondral repair have employed a handful of biphasic and triphasic scaffolds, combined with different types of differentiated or stem cells [72]. Usually small animals such as rodents and rabbits are used for proof-of-concept studies, but of course, they lack the mechanical load that can be found in humans. A few studies have employed large models, such as ovine, porcine, or equine models. The take-home message of these studies is usually a superior histological score of bone and cartilage regeneration in the experimental group compared with controls, with no sign of chronic inflammation. Stem cell–based treatment of osteochondral lesions in animal models has shown the potential to promote tissue regeneration and limit disease progression. However, osteoarthritis progression in humans is slow compared with rodents or rabbits, so the clinical use of MSCs in human is still at early stages and needs to be improved.

Tendon and Ligament

Tendons and ligaments respectively connect muscle to bone and bone to bone, producing joint motion through the transmission of contractile muscle forces and stabilizing the joint. Sharing a similar ultrastructure and biochemical content, tendons and ligaments are composed predominantly of aligned fibers of collagen type I, between which elongated fibroblasts extend in parallel. While recent studies have begun to elucidate the nascent cell populations and molecular mediators that contribute to tendon and ligament development [73], less is known about the biological events governing intrinsic healing following injury to these tissues.

Like many other musculoskeletal soft tissues, tendon and ligament possess a poor innate regenerative capacity. Rather than reconstitution of the aligned COLI fibers seen in native adult tendons and ligaments, the healing neotissue resembles a fibrovascular scar similar to that seen during wound healing, in which there is an elevated COLIII:COLI ratio, and the collagen fibrils possess a disorganized orientation [74]. Although the biochemical composition and ultrastructure remodel over years, once torn, tendons and ligaments almost never regain the structure and function they possessed before injury. Even worse, tendons and ligaments exposed to the intraarticular

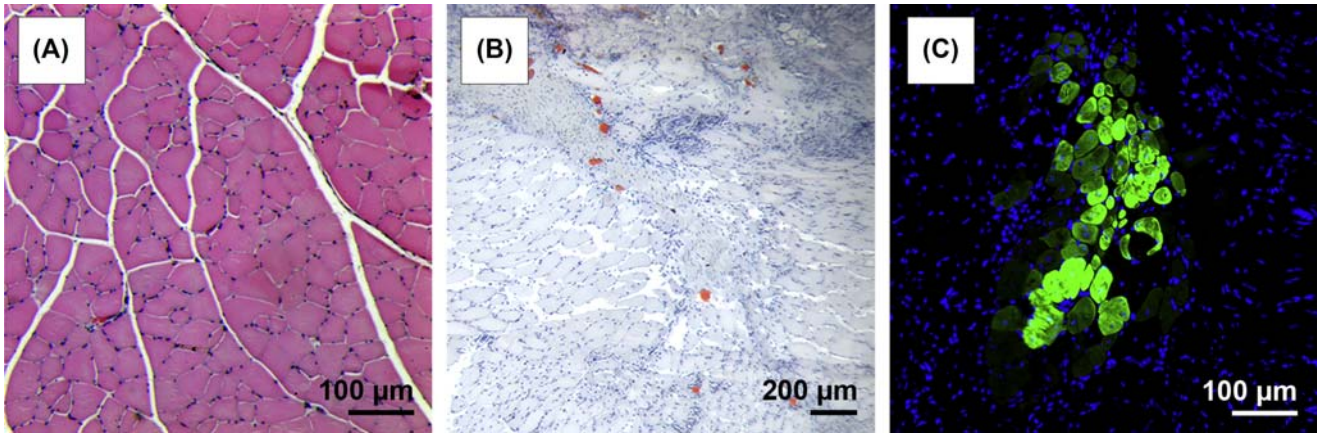

FIGURE 54.2 **Stem cell therapies for skeletal muscle diseases.** (A) Hematoxylin-eosin staining of healthy muscle in cross-section showing polygonal myofibers with multiple peripheral nuclei and minimal interstitial space between fiber bundles. (B) Oil Red O staining of degenerated muscle showing fat droplets (*red*), myofiber atrophy, and inflammatory infiltrate. environment (which contains synovial fluid) often undergo negligible healing, with the resulting instability predisposing the joint to further damage, including accelerated osteoarthritis progression and damage to adjacent structures.

Because tendons and ligaments are relatively hypocellular, cell-based therapies have been explored in an effort to provide a sufficient number of reparative cells, or, as in the case of MSCs, to secrete proregenerative paracrine factors [75]. As detailed in comprehensive reviews [76,77], numerous preclinical studies have demonstrated benefit when applying stem cells to damaged tendons and ligaments. However encouraging, it must be remembered that tendon and ligament injuries are heterogeneous in character, spanning degenerative changes associated with overuse and aging (i.e., tendinopathy) to acute lacerations (i.e., flexor tendon transection). Furthermore, the tendon and ligament microenvironment, including a broad range of mechanical forces experienced in vivo, is equally diverse, from extraarticular collateral ligaments of the knee (which spontaneously heal) to the intraarticular anterior cruciate ligament (which does not heal) to the flexor tendons on the hand, which are enveloped in a sheath to which the healing tendon forms adhesions, thereby preventing normal tendon gliding. All of these details must be considered in the context of surgical or conservative treatments when developing cell-based therapies to improve tendon or ligament healing.

Such heterogeneity of injury characteristics may partly explain the paucity of studies examining the efficacy of cell-based therapies on tendon/ligament healing. A systematic review [78] identified only four studies in which stem cells were applied to damaged tendons. Two case series in which allogeneic ASCs and BM-MSCs were injected into the midsubstance of degenerated lateral epicondylar tendons [79] and patella tendons [80], respectively, showed improvements in pain and functional scores over time. However, the absence of controls limited further interpretation regarding the benefit of the stem cell injection. Similarly, Ellera Gomez et al. [81] and Hernigou et al. [82] augmented arthroscopic rotator cuff repairs with BM-MSCs injected at the repair site. Compared with the literature and/or historical controls, both studies suggested a reduction in repair failure (i.e., re-tear) and improved function. However, because those studies were also case series, Pas et al. [78] concluded that there was insufficient evidence to support the use of stem cell therapies for tendon disorders.

Tendon–Bone Interface: Enthesis

Despite a limited number of clinical studies exploring stem cell–augmented rotator cuff repair, rotator cuff tears constitute one of the greatest orthopedic challenges; over 25% of patients aged over 60 years presenting with full-thickness tendon tears [83]. Rotator cuff tears most frequently occur at the tendon–bone interface (i.e., enthesis), which normally possesses a complex architecture including a mineralized fibrocartilage gradient that serves to reduce stress concentrations in the transition from compliant tendon to stiff bone [84]. Reattaching tendon to bone is particularly challenging because the native enthesis structure is not regenerated during healing, which predisposes the surgical repair to failure and occurs at rates exceeding 90% in severe cases [85]. As a result, there has been considerable interest in applying tissue engineering principles to improve enthesis healing.

As detailed by Patel et al. [86], there have been promising tissue engineering efforts to fabricate scaffolds that mimic the gradients in cell phenotypes, ECM composition, and mineral distribution, as seen at the native enthesis. Although these emerging biomaterials may ultimately serve to guide reparative cells, whether exogenously delivered or endogenous recruited, in reconstituting the structure and function of the healing tendon−bone interface, few studies have investigated the effect of these scaffolds in vivo. On the other hand, numerous preclinical studies have been performed in which stem cells, most frequently encapsulated in a biodegradable hydrogel (e.g., fibrin, collagen), are localized between the tendon and bone, as manually apposed during surgical repair. Results have been equivocal; a review of the collective body of work suggested that stem cell therapies are most efficacious when combined with biochemical signals normally present during enthesis development (i.e., chondrogenic factors) [87]. When the molecular events underlying enthesis development are more fully elucidated, it can be expected that stem cell therapies will be modified by biochemical signals or genomic engineering to mimic the spatiotemporal expression pattern observed during the formation of this complex interface. Lessons learned in promoting enthesis healing of the rotator cuff might then by applied to other tendon−bone interfaces (e.g., ACL reconstruction), which is frequently the site of early surgical failures.

Meniscus

The menisci of the knee are crescent-shaped fibrocartilaginous structures interposed between the femur and tibia. When the knee is loaded during ambulation, the menisci serve to distribute compressive forces across the articular surfaces, thereby reducing contact stresses and facilitating joint motion. The menisci also serve as secondary stabilizers of the knee. As structure matches function, the menisci possess region-specific biochemical and ultrastructural characteristics: the inner meniscal regions, which sustain compressive forces under joint loading, are composed of an ECM rich in COLII and proteoglycans, whereas the resident cells have a round morphology and gene expression pattern similar to articular chondrocytes. Compressive loading of the inner regions creates hoop stresses that are borne by the aligned COLI fibrils of the outer meniscal regions, between which aligned fibroblastic cells are interposed. In adults, only the outer 10−30% of the meniscal width is vascularized. The hypocellularity and avascularity of the menisci, particularly the inner regions, provide a poor innate healing capacity to the meniscus when injured [88].

Unfortunately, the meniscus is the most commonly injured structure of the knee; partial removal of torn meniscal tissue (i.e., meniscectomy) constitutes the most commonly performed orthopedic surgical procedure [88,89]. Since the seminal publication of Fairbank in 1948, it has been known that meniscectomy induces the onset, and accelerates the procession, of joint degeneration (i.e., osteoarthritis) [90]. Nevertheless, the poor intrinsic healing capacity of the meniscus has limited the use of primary repairs as a treatment strategy [91]. Past efforts using blood products to enhance the healing environment, including fibrin clots [92] and trephination [93], provided inconsistent benefit, spurring the search for biological or synthetic materials that could serve as meniscal substitutes. While meniscal allograft transplantation and engineered menisci have been clinically implemented, inclusion criteria to qualify for these technologies greatly limit their widespread use [94]. Bioengineers have fabricated biological meniscal substitutes using a patient's (i.e., autologous) cells [95,96]. These technologies may ultimately offer the surgeon the option of an engineered autograft to transplant, but high fabrication costs and demanding surgical technique will likely remain challenges for the foreseeable future.

On the other hand, numerous preclinical studies have investigated the putative benefit of augmenting meniscectomies or primary repairs with stem cells, most commonly MSCs, delivered in one of two ways: (1) intraarticular injection of an MSC suspension, or (2) localized delivery to the tear site in an MSC-seeded biomaterial. For example, Hatsushika et al. [97] injected 10×10^6 allogeneic synovial MSCs suspended in phosphate-buffer saline intraarticularly 2 weeks after transection of the anterior half of the medial meniscus in a rabbit model. The regenerated meniscus in the MSC-treated group was larger than the control (no MSC) group at 1 and 3 months postinjection, but not 4 and 6 months, but it exhibited superior histological properties and chondroprotective effects at all time points. Nevertheless, the innate regenerative response of the rabbit meniscus is dissimilar to the minimal healing response seen in larger mammals, including human patients. To that end, Nakagawa et al. [98] augmented suture repairs of longitudinal tear lesions in microminipigs by intraoperatively injecting a suspension of 20×10^6 allogeneic synovial MSCs into the tear site. At 12 weeks, the MSC-treated group demonstrated improved healing, as evaluated grossly, histologically, and biomechanically, and by T1rho magnetic resonance imaging (MRI) mapping analysis. For both studies, MSCs were found at the tear site at early time points.

These preclinical studies, among others, demonstrated that MSCs could home to the meniscal lesion and improve healing. However, it has been reasoned that delivery of an MSC-seeded biomaterial to the tear site may improve

MSC localization while providing a microenvironment capable of promoting fibrocartilage formation. In support, Zellner et al. [99] reported that suture repairs augmented with MSC-seeded hyaluronan-gelatin sponges in a rabbit model enhanced fibrocartilage formation, with associated increases in biomechanical properties, compared with unrepaired defects or defects treated with acellular sponges. Similarly, Kondo et al. [100] found that aggregates of autologous synovial MSCs localized in place of the transected anterior half of the medial meniscus in aged primates promoted meniscal regeneration.

Although these studies demonstrate a clear benefit of MSCs for enhanced meniscal healing and/or regeneration, only two related clinical studies have been performed. After in vitro optimization and corroboration of benefit in an ovine model, Whitehouse et al. [101] augmented five suture repairs of meniscal tears (bucket-handle, n = 3; bucket-handle with radial extension, n = 1; and vertical flap, n = 1) with a collagen matrix (Avitene Ultrafoam collagen sponge) seeded with autologous BM-MSCs. By 15 months, two of five patients underwent meniscectomy owing to re-tear or nonhealing; the remaining three patients demonstrated MRI evidence of healing at 24 months' follow-up. Mixed results were also noted in a similar study by Vangness, Jr. et al. [102], in which intraarticular injection of 50×10^6 or 150×10^6 allogeneic BM-MSCs after subtotal meniscectomy significantly increased meniscal volume (defined a priori as a 15% threshold) in 24% and 6% of patients, respectively, as evaluated by MRI at 12 months postmeniscectomy. No patients in the control group (no MSCs) met the 15% threshold for increased meniscal volume.

Although a preponderance of preclinical studies supports the application of MSCs for improved healing, heterogeneity in study designs has prevented identification of the optimal tissue source, delivery method (i.e., intraarticular injection versus seeded biomaterial), and cell number. It also remains unclear whether allogeneic MSCs will perform worse than autologous MSCs [103]. To our knowledge, neither minimally manipulated autologous cells (derived intraoperatively, most commonly from the iliac crest bone marrow or adipose tissues) nor iPSCs have been applied in augmented meniscus repair [103].

Intervertebral Disc

The intervertebral disc (IVD) shares many structural and functional features with the meniscus. Separating each vertebrae of the spine, the fibrocartilaginous IVDs experience complex loading patterns consisting of compressive, torsional, and shear stresses. The nucleus pulposus (NP) forms a highly hydrated gelatinous core composed of COLII, proteoglycans, and chondrocyte-like NP cells, surrounded by the annulus fibrosis (AF) consisting of orthogonally oriented lamellae of aligned collagen fibers with interposed fibroblastic cells [104]. When the spine is loaded, high hydrostatic forces created in the NP are resisted by the tensile strength of the surrounding AF. In addition, IVDs possesses cartilaginous end plates on both their superior and inferior surfaces, through which oxygen and nutrients diffuse from capillaries of the subchondral bone of vertebrae. Although the outer region of the AF is vascularized, the IVD is largely avascular and hypocellular, which limits its innate healing capacity [105]. In the context of a complex interplay of genetic and environmental factors, this feature is thought to predispose the IVD to degenerative changes beginning as early as the second decade [106].

IVD degeneration is one of the principal contributors to low back pain, which is the leading cause of disability in the developed world and is estimated to affect 75–80% of people at some stage [107]. Although the molecular mechanisms governing IVD degeneration are incompletely understood, early loss of proteoglycan content from the NP is associated with decreased disc height, concurrent with weakening of the AF in the context of increased catabolic and inflammatory mediators. Upregulated inflammation, coupled with aberrant neovascularization and innervation of the IVD, is thought to contribute to discogenic pain and deterioration of spine mobility. Furthermore, the weakened AF can eccentrically bulge or fail, permitting herniation of NP contents, causing radiculopathy pain by aggravation of adjacent nerve roots. At present, there are no efficacious treatment options between conservative measures (i.e., physical therapy, nonsteroidal antiinflammatory drugs, epidural corticosteroid injection) and surgical intervention (i.e., microdiscectomy, total discectomy, disc arthroplasty, spinal fusion) [104]. Therefore, regenerative and tissue engineering strategies have been explored as a means of reversing or preventing further disc degeneration.

In a comprehensive review of cell-based therapies for lumbar degenerative disc disease, Oehme et al. [107] identified 25 preclinical studies in which stem or progenitor cells were applied to promote IVD regeneration. Although 20 of 25 studies investigated MSCs, the cell phenotype was variable (i.e., autologous versus allogeneic versus xenogeneic, bone marrow- versus adipose-derived), as was the intradiscal delivery method (i.e., suspension versus hydrogel). Furthermore, the animal models included species from rats to sheep, yet most involved nucleotomy or NP aspiration from the disc of a previously young, healthy animal. Compared with untreated controls, MSC-treated

groups generally enhanced disc regeneration, as demonstrated by increased disc height, improved ECM synthesis, and superior morphology, as evaluated by MRI [107]. Where degenerative disc disease has progressed beyond any reasonable hope of cell-augmented repair, disc replacement with a tissue-engineered graft may ultimately be possible. As highlighted by Bowles and Setton [108], composite strategies for tissue engineered IVD replacements have largely used biomaterials consisting of fibrous polyesters (e.g., PLA) for the AF and MSC-seeded hydrogels for the NP. Preclinical results have been encouraging, although limited in the number and length of follow-up.

Only four clinical studies have explored cell-based treatment of IVD degeneration. In the earliest report, Yoshikawa et al. [109] implanted collagen sponges seeded with autologous MSCs (isolated from iliac crest bone marrow 2–4 weeks earlier) into a single degenerative disc in two patients. Both patients experienced improvement in pain and diminished radicular symptoms by 6 months, which persisted to the final follow-up at 2 years. T2-weighted MRI at 2 years suggested increased water content compared with preoperative MRI. Similar findings were subsequently reported in cases series by Orozco et al. [110] and Pettine et al. [111], in which degenerated IVDs were injected with suspensions of BM-MSCs or bone marrow concentrate, respectively. Using a more extensive coculture protocol, Mochida et al. [112] injected autologous NP cells culture expanded in direct contact (i.e., cell-to-cell) with autologous BM-MSCs into degenerative IVDs immediately adjacent to a spinal fusion (the discarded disc rendering the autologous NP cells). Compared with the studies employing MSCs, only one of nine patients demonstrated mild improvement in disc morphology as evaluated by MRI. That said, experimental design varied substantially across studies, limiting rigorous comparison. Furthermore, none of these clinical studies included a control patient population.

Skeletal Muscle

Despite remarkable regenerative ability, skeletal muscle integrity and function are often compromised in muscular dystrophy [113–115]. Muscular dystrophy describes a heterogeneous group of approximately 40 inherited disorders characterized by progressive muscle weakness, degeneration, and wasting. Duchenne muscular dystrophy (DMD) is one of the most common and severe childhood muscular dystrophies; however, there not yet effective treatments available for DMD patients [116]. In addition to diseases, loss of skeletal muscle through trauma, tumor ablation, and prolonged denervation represent common clinical challenges. To treat traumatic muscle loss, free tissue transfer is an option, but autologous muscle transfer not only causes donor site morbidity, it can produce loss of function at the donor site [117]. Tissue engineering of skeletal muscle to replace functional muscle tissue could offer an alternative.

Engineering functional skeletal muscle would require the recapitulation of functional motion and integration with host connective tissues [118]. At the cellular level, it is also important to achieve parallel alignment of fibers and integration of functional neuromuscular junctions. As with other musculoskeletal tissues, mechanical stimulation is essential during myogenesis; it influences metabolic activity and gene expression, as well as fiber alignment. Also, myoblasts, which are similar to many types of cells, lose their differentiation capacity as they are culture-expanded [119,120]. Therefore, understanding the biology of precursor cell types such as SCs and other muscle progenitor cells, is crucial. Although SCs act as local regenerative cells in muscle, their limited expansion potential in vitro limits their current usefulness relative to other stem cell sources [121]. Such stem cells include, but are not limited to, ESCs, iPSCs, BM-MSCs, ASCs, hematopoietic stem cells (HSCs), and muscle-derived stem cells (MDSCs) [120,122,123].

ESCs and iPSCs, which are pluripotent cells (PCs), are considered the most promising cell source for cell-based therapies. Studies have reported that these cells can be induced and successfully converted into skeletal muscle cells to repair acutely and chronically injured muscle [120,122]. Pyle and colleagues reported that iPSCs derived from DMD patients' skin fibroblasts were successfully reprogrammed to muscle progenitor cells. Upon transplantation of these human iPSCs, they underwent efficient fusion and improved ultrastructural organization and the expression of adult myosin in mice [124]. However, concerns regarding tumorigenic potentials and complex biological and ethical issues correlated with PCs have dampened their use in favor of stem cell therapies.

Most research thus far has focused on MSCs from bone marrow, fat, and blood. Starting with the study of Ferrari et al. in 1998, which involved the transplantation of BM-MSCs [125], several studies have reported that transplantable ASCs also could be recruited to injured muscle and take part in repair and regeneration [123]. Transplantation of HSCs has shown to result in increased dystrophin gene expression in dogs with DMD [126]. In addition to their role in differentiating into myofibers, MSCs have been shown to impose paracrine effects on differentiation and tissue regeneration of host resident muscle progenitor cells [120,127].

Besides MSCs, MDSCs show promise for stem cell–based therapies for the treatment of DMD (Fig. 54.2) [128]. MDSCs are isolated from late-plating mononucleated muscle cells and are long-term self-renewing cells [129]. It was previously reported that compared with myoblasts, the MDSCs demonstrated a higher intramuscular engraftment capability in vivo [130,131]. The exact mechanism involved in the improved regenerative potential of the MDSCs remains unclear; however, several studies suggested that their high survival property owing to elevated resistance to stress is critical, as well as their release of soluble factors such as VEGF [132,133] (Fig. 54.2).

In vivo, the ECM of muscle provides fibers with the architecture to support development and function. Therefore, for skeletal muscle tissue engineering, a scaffold may be needed to mimic the matrix and maximize the potential therapeutic effects of cells [134]. A suitable biomaterial should be used to fabricate the scaffold to guide proper tissue reorganization, provide optimum microenvironmental conditions for cells, and coordinate in situ tissue regeneration. The most commonly used materials for scaffold preparation are collagen, naturally derived materials, and embedded 3D collagen with muscle stem cells, which has been shown to enhance cell attachment, expansion, and differentiation. Most synthetic scaffolds used for skeletal muscle tissue engineering are fabricated from polyesters such as PGA and polylactic glycolic acid, which can easily be tailored into shape- and size-specific scaffolds with easy control over mechanical, structural, and physicochemical properties. Injectable, cell-compatible hydrogel is often used as a cell carrier because of its capacity to promote myogenic cell differentiation in vivo [118,135]. The presence of growth factors, including VEGF, insulin-like growth factor-1, hepatocyte growth factor, stromal cell-derived factor-1, and FGF, is also an important element of muscle engineering, because these growth factors can accelerate muscle stem cell activation, proliferation, and differentiation [136].

Although clinical trials on muscle tissue engineering of human subjects are limited, several clinical trials in patients with muscular dystrophy involving these stem cells have progressed (ClinicalTrials.gov). Table 54.1 summarizes clinical trials from 2004 to 2019.

CHALLENGES AND PROSPECTS

Now some time after the seminal publications of Langer and Vacanti [137] and Brittberg et al. [24], respectively, popularizing the concept of tissue engineering and describing the application of autologous chondrocytes for AC regeneration, the clinical impact of stem cell therapies for musculoskeletal diseases remains limited. Although numerous in vitro and preclinical studies demonstrated the potential of stem cell therapies, as highlighted previously, there are numerous challenges preventing clinical translation, including obvious outstanding technological and biological questions, but also regulatory and financial considerations [138].

An alternative approach to current cell-based therapies involving two-step surgical procedures with intervening ex vivo cell expansion is to bolster the reparative functions of endogenous stem cells. Because nearly all tissues contain endogenous stem cells that contribute to normal homeostatic function, it is hypothesized that directed modulation of the stem cell niche may overcome the microenvironmental cues in injury or degeneration that otherwise inhibit complete regeneration [139]. Furthermore, the immune response to disease or damage is increasingly recognized as a principal determinant of subsequent healing; targeted modulation of the immune response by novel biomaterials and/or biologics and pharmaceuticals may promote synergism with stem cell therapies, thereby improving stem cell viability and synthetic function [140]. Along the same vein, emerging biomaterials localized at the musculoskeletal lesion have been shown to be capable of recruiting endogenous stem cells to the scaffold where embedded bioactive growth factors can drive site-appropriate differentiation [141].

Exogenous stem cell therapies may still prove valuable, either to reconstitute damaged tissues directly or to enhance healing indirectly by secreting regenerative paracrine factors. Because MSCs have been the most commonly used cell phenotype for cell-based therapies, better characterization of their phenotype and mechanism of action will be required to maximize their benefit [142]. To that end, it remains an open question whether allogeneic MSCs induce an adverse inflammatory response [143]. Although limited in number and scope, studies suggest that matching of major histocompatibility complex (MHC) between donor and recipient patients may be necessary. If MHC-matched allogeneic MSCs indeed prove equivalent in efficacy to autologous MSCs, they would represent an off-the-shelf source for cell-based therapies, obviating the current need for two-step procedures and ex vivo cell expansion.

Alternatively, but not mutually exclusive, it may be possible through emerging genome editing technologies to silence otherwise immunogenic elements of donors cells. At the same time, these technologies may allow for the creation of autonomously regulated, closed-loop delivery of biological drugs. For instance, using the Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-associated-9 system, Brunger et al. [144]

TABLE 54.1 Clinical Trials of Cell Therapies in Muscular Dystrophies From 2004 to 2019

ClinicalTrials.gov Identifier	Number of Patients	Muscular Dystrophy	Cell Therapy	Patient Age	Study Start and End Dates	Effects
NCT00773227 Phase 2	30	OPMD	Autologous myoblast	18–75	Apr. 2004–Oct. 2015 [151]	Improvement in video endoscopy and video fluoroscopy of swallowing
NCT02241434 Phase 1	245	DMD	Autologous BM mononuclear cells	3–25	Jan. 2009–Jun. 2016	No report
NCT02285673 Phase 1/2	10	DMD	Umbilical cord mesenchymal stem cells	7–20	Nov. 2013–Nov. 2015	Primary outcome will be assessed by DMD gene expression, no report
NCT01834040 Phase 1/2	30	DMD	BM-derived autologous cells	4–30	Sep. 2014–Oct. 2016	Primary: Improvement of daily living scale Secondary: improvement of muscular dystrophy specific functional rating scale
NCT01834066 Phase 1/2	25	DMD	BM-derived autologous cells	6–25	Sep. 2014–Dec. 2016	No report
NCT02208713 Phase 1	21	FSHD	MDSCs and ASCs	18–50	May 2014–Dec. 2017	No report
NCT02196467 Phase 1/2	10	DMD	Myoblast	16+	May 2014–Feb. 2019	No report

ASCs, adipose derived stem cells; *BM*, bone marrow–derived; *DMD*, Duchenne muscular dystrophy; *FSHD*, Facioscapulohumeral muscular dystrophy; *MDSCs*, muscle-derived stem cells; *OPMD*, oculopharyngeal muscular dystrophy.

program iPSCs to respond to proinflammatory cytokines interleukin-1 and tumor necrosis factor α (TNF-α) by synthesizing and secreting their soluble inhibitors (e.g., soluble TNF receptor 1). By engineering these feedback loops into the iPSC genome, the soluble inhibitor was synthesized only when cultured in the presence of its respective cytokine. Although the concern for tumorigenicity for iPSCs is real, it is possible to differentiate the iPSC into an MSC (or further into a specific cell phenotype, e.g., chondrocyte) [145], thereby mitigating the risk of teratoma formation upon in vivo application. If proven safe and effective, iPSCs, with or without further genetic engineering, might provide the ultimate off-the-shelf source for cell therapies, including diseases of every organ system.

Successful translation of cell therapies to the clinic would also be facilitated by improved model systems, both animal and in vitro, which reflect the clinical scenario and human physiology more accurately. Whereas many musculoskeletal diseases amenable to stem cell therapies are chronic conditions in aged patients, most animal models have used young, healthy animals in which an iatrogenic damage is acutely induced in a tissue, immediately followed by the experimental intervention. Fortunately, the discrepancy between established animal models and human patients is increasingly recognized, with ongoing development of models of chronic diseases in aged animals. Alternatively, companion animals (i.e., pets) often experience naturally occurring diseases and injuries similar to those of humans, which offers opportunities to investigate stem cell-based therapies in a model of greater clinical relevance [146]. That said, no animal model perfectly matches human disease; drug therapies developed through extensive animal testing ultimately prove ineffective or even harmful when translated into clinical therapies. As a result, there has been an increased emphasis on developing microphysiological in vitro models (i.e., organs-on-a-chip) using only human cells [70,147]. It is hypothesized that human-specific microphysiological models will allow greater fidelity to human pathology while also obviating the challenges, including biological, financial, and ethical considerations, of animal models. First-of-kind models of IVDs [148] and osteochondral interfaces of joints [149] have shown promise; the latter were discussed earlier.

When stem cell therapies, whether optimized in microphysiological or animal models, are translated into human patients, higher-quality clinical studies are needed to validate their efficacy. Most clinical trials of stem cell therapies for musculoskeletal diseases are case series that do not include adequate controls. In addition,

evaluation of stem cell–mediated enhancement of tissue regeneration would be facilitated by novel noninvasive metrics of tissue quality, whether biochemical or imaging-based [150]. These technologies would allow real-time monitoring of tissue healing, compared with histological evaluation after death in an animal model. In turn, this would facilitate the researcher's ability to investigate stem cell therapies in human patients.

List Abbreviations and Acronyms

AF Annulus fibrosis
ASC Adipose-derived stem cell
BM-MSC Bone marrow–derived mesenchymal stem cell
DMD Duchenne muscular dystrophy
ECM Extracellular matrix
ESC Embryonic stem cell
HAp Hydroxyapatite
HSC Hematopoietic stem cell
hMSC Human mesenchymal stem cell
FGF Fibroblast growth factor
iPSC Induced pluripotent stem cell
IVD Intervertebral disc
MDSC Muscle-derived stem cell
MHC Major histocompatibility complex
MSC Mesenchymal stem cell
NP Nucleus pulposus
PGA Polyglycolic acid
PLA Poly-lactic acid
SC Satellite cell
TNF-α Tumor necrosis factor-α
VEGF Vascular endothelial growth factor

CHAPTER

55

Myoblast Transplantation in Skeletal Muscles

Daniel Skuk, Jacques P. Tremblay

Axe Neurosciences, Research Center of the CHU de Quebec—CHUL, Quebec, QC, Canada

INTRODUCTION

Cell transplantation, which is frequently called "cell therapy," is an approach under study to treat different skeletal muscle disorders. The starting point of this therapeutic approach can be traced to 1978, when Partridge and colleagues proposed that "in subjects suffering from inherited recessive myopathies, muscle function might be restored if normal myoblasts could be made to fuse with defective muscle fibers" [1]. Among these myopathies, Duchenne muscular dystrophy (DMD) was the first target and has being the main objective of this experimental therapeutic strategy. This is because of the relative frequency of this disease (a prevalence of 50 cases per million in the male population) and its severity: progressive skeletal-muscle degeneration in the limbs and trunk during childhood and adolescence, leading to motion loss, respiratory insufficiency, and ultimately death by respiratory or cardiac complications. Other clinical applications subsequently sought the treatment of individual muscles affected by different processes, such as the cricopharyngeal muscle in patients with oculopharyngeal muscular dystrophy [2], the tibialis anterior in patients with fascioscapular muscular dystrophy [3], the urinary sphincter in patients with stress urinary incontinence [4], and the external anal sphincter in patients with anal incontinence [5].

The saga of cell transplantation in clinical myology is an example of the importance of the preclinical basis for designing new therapeutic protocols. After a few animal experiments in the 1980s, mostly in mice, several groups undertook clinical trials of cell transplantation in the 1990s [6]. Lacking adequate preclinical data to plan the strategies of cell implantation and even the strategies to control acute rejection, these clinical trials reported scarce and modest results on the molecular level. In fact, these trials were conducted in the hope that some muscle precursor cells injected in a few sites of a skeletal muscle would be able to diffuse throughout the muscle and spontaneously fuse with so many myofibers that a therapeutic effect would be obtained. Subsequent research demonstrated that this hope was unrealistic, and the lesson to take from this experience is that clinical researchers need to know the behavior of the grafted cells in appropriate experimental conditions to design efficient clinical protocols.

This chapter addresses current knowledge that could be useful for future clinical applications of cell transplantation to treat skeletal muscle pathologies. For this reason, and considering warnings regarding the poor clinical predictability of studies in mice [7,8], priority will be given to observations made in humans and nonhuman primates. The chapter is organized to address three main questions: (1) why myoblasts meet the properties needed for the aim of the treatment, (2) how the muscle precursor cells can be properly delivered to the target tissues, and (3) how to ensure the long-term survival of the graft.

SATELLITE CELL–DERIVED MYOBLASTS MEET THE PROPERTIES NEEDED FOR TRANSPLANTATION IN SKELETAL MUSCLES

The term "myoblast" defines the proliferating mononuclear progenitor cells that fuse with analogous cells to form myotubes, the syncytial stage in the process of myogenesis that, under adequate conditions, precedes myofiber formation. This applies to every case in which this phenomenon occurs; that is, during skeletal muscle embryogenesis, in postnatal myofiber regeneration, and in vitro culture of skeletal muscle cells. To be specific in the terminology, avoiding confusion between myoblasts involved in postnatal muscle regeneration or proliferated in vitro from

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00055-2

skeletal muscle biopsies (both derived from satellite cells) and somite-derived myoblasts involved in muscle embryogenesis, we will use the term "satellite cell–derived myoblasts" (SCDMs) for the first two cases.

Any cell transplantation strategy involves the graft of either differentiated cells or precursor cells with the ability to differentiate into the former. In the skeletal muscle, the differentiated cells responsible for muscle contraction, that is, the myofibers, are not proper for transplantation in clinical regenerative medicine because they are long multinucleated syncytia that cannot be proliferated in vitro or adequately implanted to rebuild a muscle. The possibility of a more efficient cell transplantation in this context is offered by the specific stem cell of the skeletal muscle: that is, the satellite cell. The main function of satellite cells is to repair myofiber damage. They are normally quiescent in the periphery of myofibers until an injury produces focal or total necrosis of a nearby myofiber, triggering a process that involves the removal of myofiber debris by phagocytic cells and the activation of dormant satellite cells, which differentiate into proliferating SCDMs. Murine models demonstrate that muscle regeneration is not possible when satellite cells are depleted [9–11], which confirms that the mainstay of muscle regeneration is the sequence: satellite cells → SCDMs → myotubes → myofibers. Satellite cells can be isolated from skeletal muscle biopsies by standard cell-culture techniques and can be expanded as SCDMs in vitro, maintaining their capacity to fuse into myotubes that will differentiate into myofibers under appropriate conditions. This relative simplicity to obtain and proliferate these cells in vitro facilitated the use of SCDMs for cell transplantation.

Relevant Properties of Satellite Cell–Derived Myoblasts for Cell Transplantation in the Skeletal Muscle

Lipton and Schultz reported for the first time in 1979 the two main myogenic properties of exogenous SCDMs implanted into skeletal muscles [12]: (1) they fuse with the recipient's myofibers, and (2) they form new small myofibers by fusing the grafted cells among themselves. The first property allows gene complementation, that is, myofibers in which exogenous myogenic cells are incorporated express proteins coded by the exogenous and endogenous myonuclei [13], which are thus referred to as "mosaic" or "hybrid" [14]. Through gene complementation, grafted SCDMs can act as vehicles of therapeutic genes, for example by introducing normal genomes in the genetically abnormal myofiber of a patient with a recessive genetic myopathy. The second property opens the door to the possibility of forming new myofibers in patients in which the skeletal-muscle parenchyma has been lost. A third property of SCDM transplantation, which was reported later, is the possibility of developing into new graft-derived satellite cells. Fig. 55.1 illustrates the properties, in terms of myogenic outcomes, of SCDM transplantation.

Gene Complementation

The first experimental demonstration of this phenomenon as a consequence of cell transplantation in the skeletal muscle was reported by Partridge et al. in 1989 [15]. They transplanted normal mouse SCDMs in *mdx* mice (which, as patients with DMD, have a myopathy caused by the deficiency of the protein named dystrophin) and observed several myofibers expressing dystrophin a few weeks later. The same observation was repeated soon by other researchers [16,17] and is now routine in research in this area. Other proteins restored by normal SCDM transplantation in mouse models of muscular dystrophies were merosin in *dy/dy* mice (a model of merosin-deficient congenital muscle dystrophy) [18] and dysferlin in SJL mice (model of limb-girdle muscular dystrophy 2B) [19]. In humans, occasional observations of increased dystrophin expression after allotransplantation in DMD patients of SCDMs from nonmyopathic donors were reported during clinical trials conducted in the 1990s, but these observations were not conclusive and most patients gave negative results [6]. It was not until more recent clinical trials, based on translational preclinical studies in nonhuman primates, that it was shown that donor-derived dystrophin can be expressed systematically in the muscles of patients with DMD locally injected with normal SCDMs (Fig. 55.2) [20–23], provided certain conditions are met (as explained subsequently).

A critical factor complicating the protocol of intramuscular cell implantation (in the cases in which we sought to obtain a homogeneous and significant genetic complementation in a whole large muscle) is that the intracellular proteins encoded by a single myonucleus remain localized near the nucleus of origin, in a region named the "nuclear domain" [24]. This restriction is produced by the limited diffusion of both the messenger RNA (mRNA) [25] and protein [26]. Consequently, proteins from graft-derived myonuclei are expressed only in the myofiber segments where fusion of the grafted cells was produced (Fig. 55.1E). The size of the nuclear domain depends on the capacity of a given protein to diffuse or remain anchored to stationary cellular components [26]. As an example, single injections of ß-galactosidase–labeled normal SCDMs into *mdx* mice produced dystrophin expression throughout

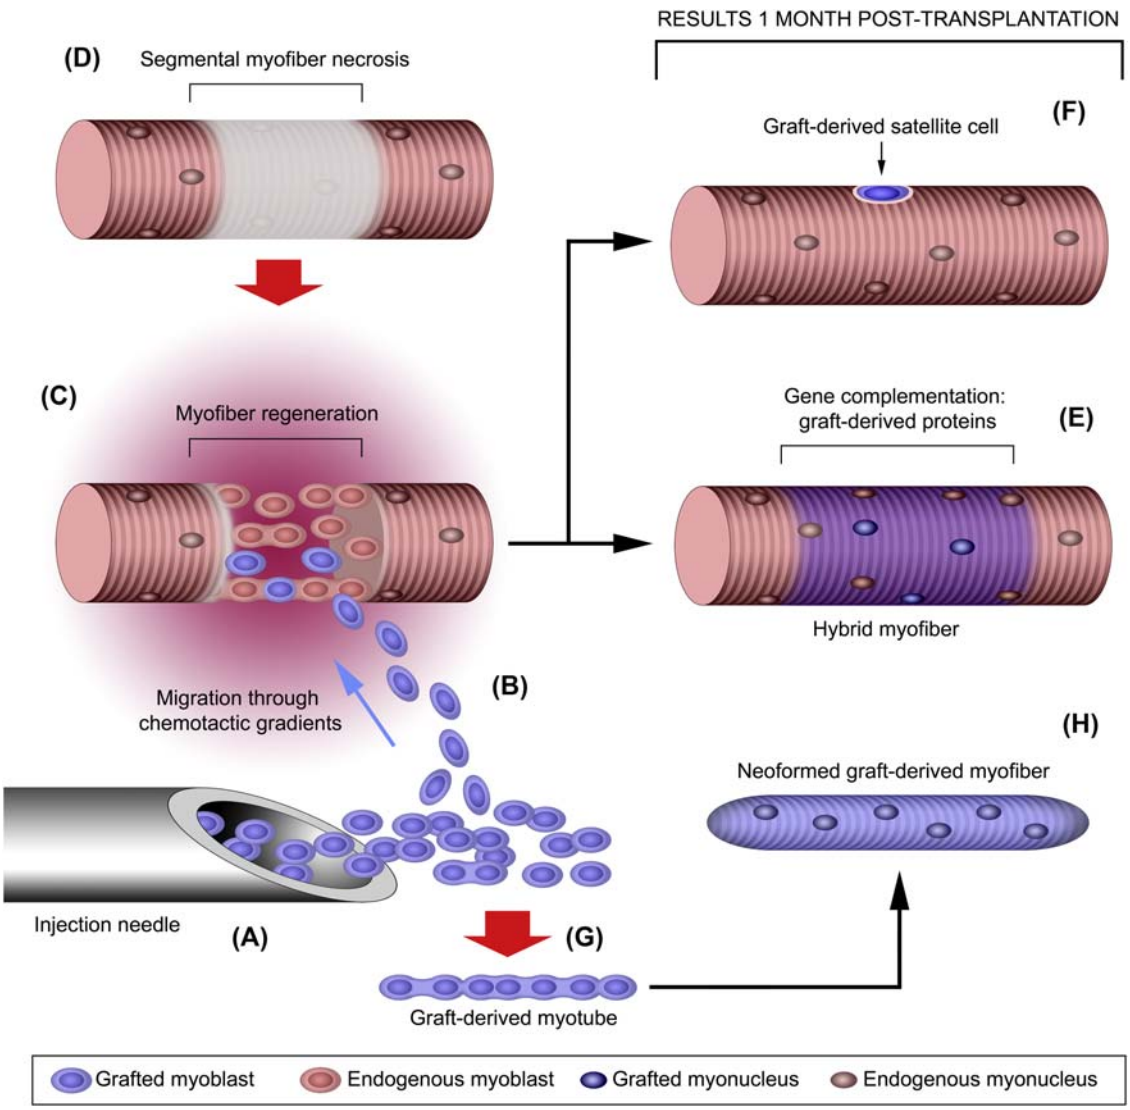

FIGURE 55.1 Myogenic properties of satellite cell–derived myoblasts (SCDMs) after injection in a skeletal muscle. Grafted elements are represented in *blue* and endogenous in *red*. After their intramuscular injection (A), some SCDMs migrate (B) through chemotactic gradients (*pink gradation*) toward regions of myofiber regeneration (C), which is the consequence of myofiber damage leading to segmental necrosis (D). Grafted SCDMs are recruited in this myofiber regeneration, fusing with the endogenous SCDMs (C). When regeneration is completed, the coexistence of grafted myonuclei with endogenous myonuclei leads to a hybrid myofiber (E), in which genetic complementation leads to the expression of graft-derived proteins around the graft-derived myonuclei. Some grafted cells, on the other hand, can develop into new graft-derived satellite cells (F). Finally, some grafted SCDMs can fuse among themselves to form myotubes (G) that under adequate conditions become new graft-derived myofibers (H).

roughly 500 μm of the myofiber, in contrast with 1500 μm for β-galactosidase [27]. This difference was even more striking when dystrophin expression was compared with green fluorescent protein [28]. The longer domain of β-galactosidase and green fluorescent protein should be attributed to the solubility of these proteins, resulting in spreading more than dystrophin, which remains attached to the cytoskeleton.

Formation of New Myofibers

In DMD and other degenerative myopathies, progressive worsening of muscle weakness is produced by the steady and irreversible loss of myofibers. An ideal treatment for the advanced stages of these diseases may include not only molecular correction but also restoration of functional myofibers.

The potential of SCDM transplantation to restore skeletal muscle mass and strength was reported in mice after acute severe muscle destruction [29–31]. These experimental conditions, however, are not similar to those of a

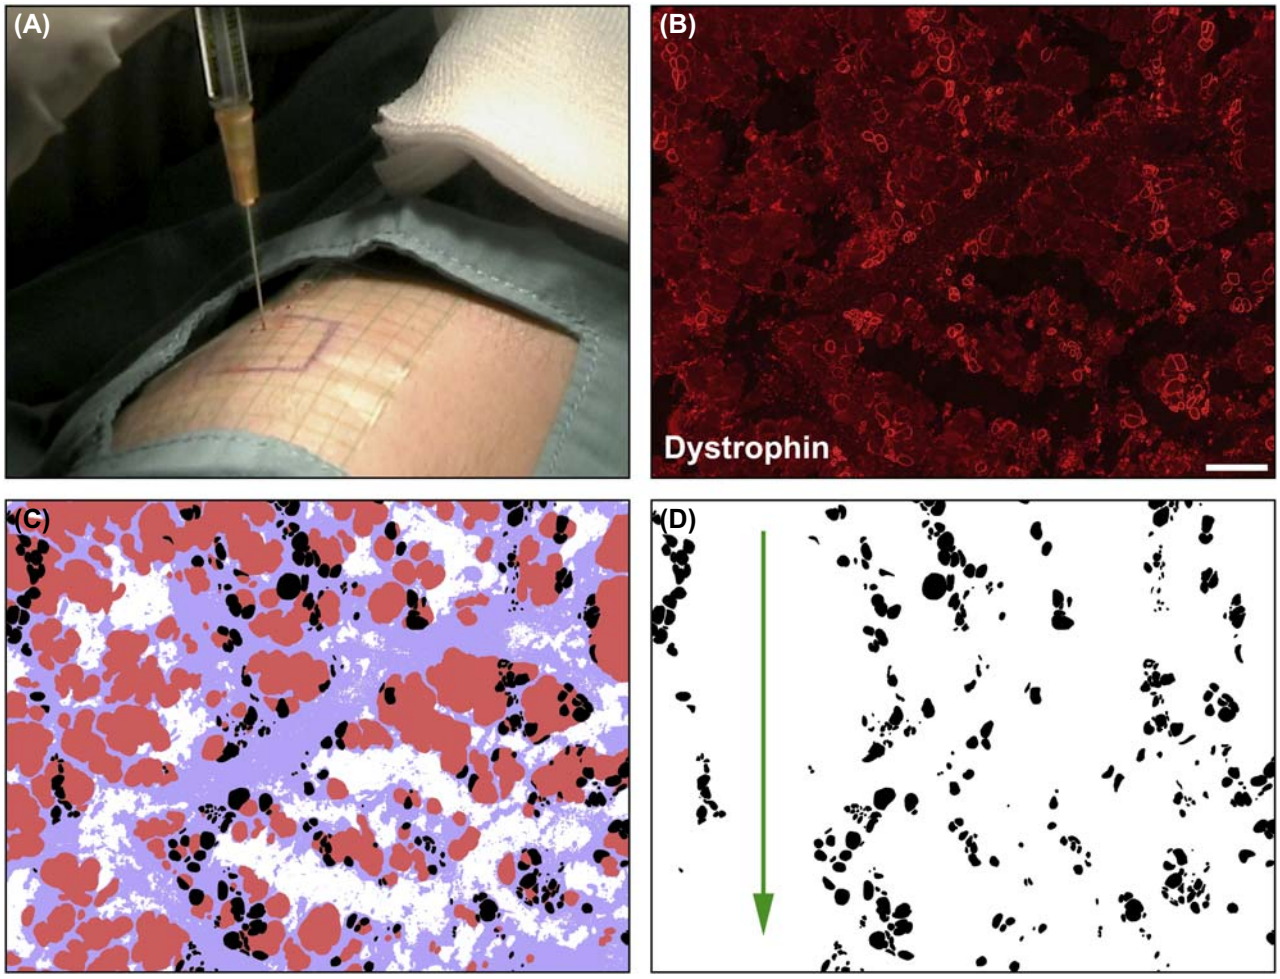

FIGURE 55.2 Allotransplantation of normal satellite cell–derived myoblasts in 1 cm^3 of the tibialis anterior of a patient with Duchenne muscular dystrophy, in a Phase 1A clinical trial conducted by the authors. (A) Several parallel intramuscular cell injections are being done with a 100-μL Hamilton syringe. The cells are delivered homogeneously during the needle withdrawal, and the density of cell injections is controlled with the help of a sterile transparent dressing with a grid. (B) The cross-section of a biopsy performed 1 month later in a cell-grafted site is shown stained for the red fluorescent immunodetection of dystrophin. (C) The schematic representation of the histological image in (B) illustrates the distribution of the dystrophin-positive myofibers in this biopsy: in *black*, dystrophin-positive myofibers; in *red*, muscle tissue; in *blue*, connective tissue; the *white spaces* correspond essentially to fat tissue. (D) Isolating the dystrophin-positive myofiber profiles of the previous image, it can be seen that they are distributed roughly in parallel axes corresponding with the original trajectories of the injections (indicated by the *arrow*). (B) Scale bar = 500 μm.

degenerative myopathy in which the damage is progressive and leads to a loss of the tissue scaffold owing to the fibrotic and fat replacement [6]. The tissue scaffold, which remains preserved in the acute muscle damage experiments in mice but is lost in degenerative myopathies, seems essential for the regeneration of myofibers [32]. How cell transplantation might form new functional myofibers in skeletal muscles that have degenerated to fibrosis and/or fat substitution remains insufficiently studied. A study in mice suggested that it could be possible to create myotubes within the adipose tissue [33]. Otherwise, neoformation of small ectopic muscles was observed after subcutaneous implantation of SCDMs in mice, despite the absence of a previous endomysial support [34]. In *mdx* mice, formation of new myofibers through the fusion of the implanted SCDMs among themselves was observed after irradiation of the recipient muscle [35].

Progressing from these few observations to a clinically functional procedure remains a challenge, among other factors, because these results were obtained in mice, which have intrinsically greater muscle regeneration capacity than do primates [36]. A clinical observation encouraging this research is the presence of small dystrophin-positive myofibers, putatively neoformed, in patients with DMD who were transplanted with normal SCDMs (Fig. 55.3) [20].

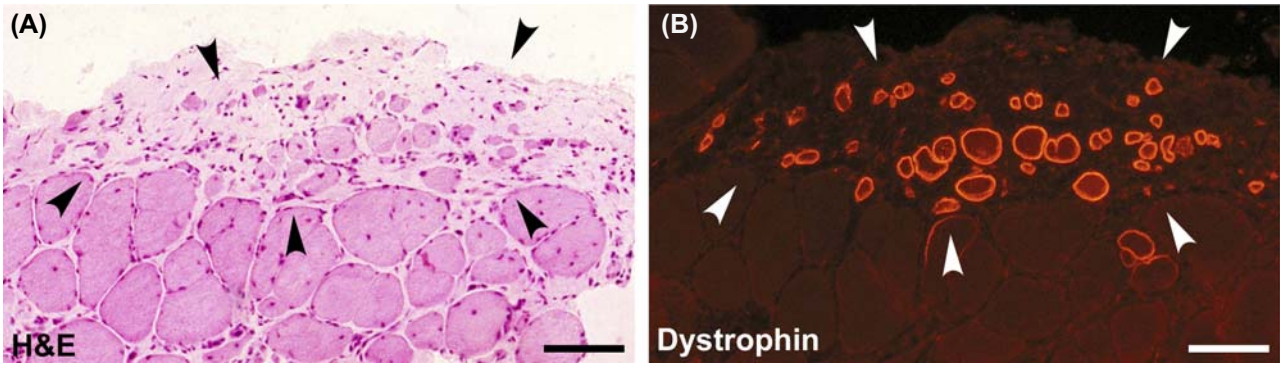

FIGURE 55.3 Probable neoformation of small graft-derived myofibers after satellite cell–derived myoblast (SCDM) transplantation in a patient with Duchenne muscular dystrophy (DMD). The figure shows serial cross-sections of a muscle biopsy performed in the tibialis anterior of a 16-year-old patient with DMD, transplanted 1 month before with SCDMs proliferated in vitro from a muscle biopsy from his father. Sections were stained with hematoxylin-eosin (H&E) (A) and for fluorescent immunodetection of dystrophin with MANEX50, an antibody that detects an epitope coded by exon 50 of the dystrophin gene (B). Because this was the exon deleted in this patient, this antibody confirms that this dystrophin is of donor origin. A cluster of small myofibers dispersed into an extrafascicular accumulation of connective tissue is indicated between *arrowheads*. All of these small myofibers exhibit donor-derived dystrophin. Studies in nonhuman primates supported the interpretation that this corresponds to myofiber neoformation caused by the fusion of the grafted SCDMs among them in the connective tissue. Scale bars = 100 μm.

Formation of Graft-Derived Satellite Cells

Transplants of mouse and human SCDMs into mouse muscles showed that some grafted SCDMs remained as mononuclear cells able to participate later in muscle regeneration and also proliferate and form myotubes in vitro [37–39]. Morphological studies showed specifically that graft-derived satellite cells were produced by the transplantation of mouse SCDMs [31,34,40] and human SCDMs [41,42] in mouse muscles (Fig. 55.4). Some observations suggest that this phenomenon could also occur after SCDM transplantation in humans: Donor-derived mononuclear cells were detected in the muscles of patients with DMD who received SCDM allotransplantations from nonmyopathic donors, and some of the donor-derived nuclei were in locations susceptible to corresponding to satellite cells [20,43].

This may imply that the potential therapeutic effect of SCDM transplantation is not limited to the early fusion of the implanted cells, but should also ensure a permanent source of normal satellite cells to participate in muscle hypertrophy and regeneration. Moreover, this could mean that the percentage of myofibers expressing donor-derived dystrophin may increase over time, if a process similar to that described in *mdx* mice regarding the expansion of clusters of myofibers expressing revertant dystrophin is produced [44].

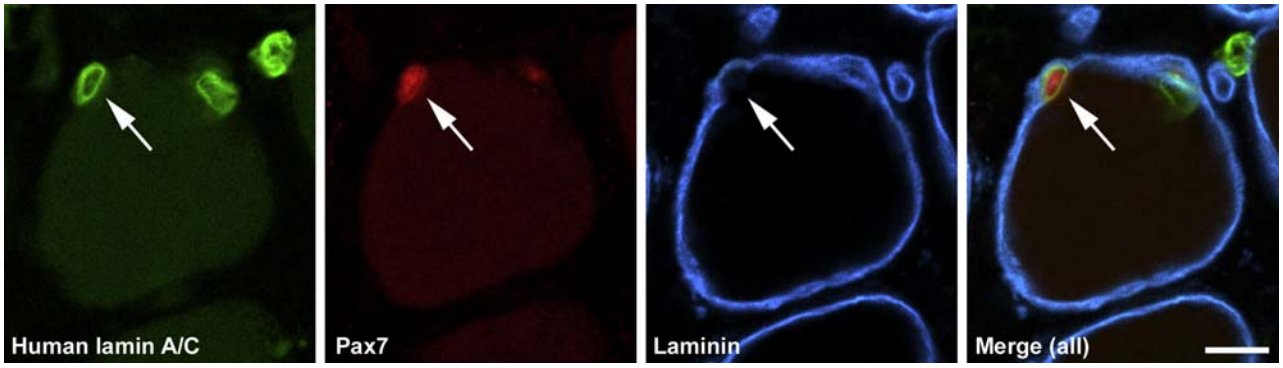

FIGURE 55.4 Graft-derived satellite cells formed by the transplantation of human satellite cell–derived myoblasts (SCDMs) in immunodeficient mice. The figure shows a single myofiber in a cross-section of a skeletal muscle of an immunodeficient mouse transplanted 4 weeks before with SCDMs from an adult human. Different elements are evidenced by fluorescent immunodetection in confocal microscopy. The peripheral nuclear labeling of human lamin A/C (*green fluorescence*) evidences two human nuclei in the periphery of the myofiber (visible by contrast enhancement). One of them (*arrow*) shows a typical intranuclear staining of Pax7, a marker of satellite cells (*red fluorescence*). Immunodetection of laminin (*blue fluorescence*) evidences that this nucleus is in the periphery of the myofiber inside the basal lamina: that is, in the anatomical position of a satellite cell. Scale bar = 10 μm.

CELL ADMINISTRATION

Once appropriate cells for transplantation are produced, the following step is to deliver them to the target tissue in such a way that the cell graft will reach a therapeutic objective. Two main routes have been explored for cell transplantation in myology: local intramuscular injection and intravascular infusion.

Intravascular administration, essentially by the intraarterial route, was reported to produce significant levels of gene complementation using some cell types under specific experimental conditions in mice and dogs [45–48]. Among these cells, the so-called "mesoangioblasts" were considered the most attractive for cell therapy in myology, given the excellent results of gene complementation reported in mice and dogs by one group [45,46]. In contrast, a clinical trial of intraarterial administration of mesoangioblasts in patients with DMD gave negative results [49], questioning the clinical predictability of the previous animal studies. With regard to SCDMs, few studies of intraarterial infusion have been performed in rats [50] and nonhuman primates [51]. In both cases, it was observed that the SCDMs were able to fuse with myofibers, depending on a concomitant mechanical damage in the muscles [50,51]. The analysis of nonhuman primate tissues showed that the intraarterially injected SCDMs were mostly trapped in the capillary network of the limb irrigated by the injected artery (in all tissues analyzed) and that the production of microemboli in the arterioles produced small muscular microinfarcts [51].

Because the only positive results confirmed in humans have been obtained with local administration of SCDMs by intramuscular injections, the rest of the chapter will be dedicated to this route of administration.

Density of Cell Injections

The main constraint of the intramuscular route is that the injected cells contribute to muscle regeneration essentially around the injection trajectories, and mostly in the myofibers damaged during the injection. This is clearly observed in nonhuman primates, in which each SCDM injection leads an irregular "strip" of hybrid myofiber profiles in histological muscle cross-sections [52–55], constituting a histological pattern called "bands of engraftment" [55] (Figs. 55.5 and 55.6). An almost similar pattern, although sometimes less defined, was observed after injections of normal SCDMs in patients with DMD (Fig. 55.2) [20,22].

Because protein expression is limited to nuclear domains, which are short in the case of dystrophin, as mentioned earlier, cell injections must be placed close to each other and must reach the whole muscle to obtain a homogeneous expression of graft-derived proteins throughout a muscle in which the only myofiber regeneration that occurs is produced by the injection damage. Consequently, the extent of gene complementation in a muscle will depend on the density of the matrix of cell injections: that is, on the number of injections per surface of the matrix (Fig. 55.5C and D) [53]. The highest percentages of dystrophin-positive myofibers after normal SCDM transplants in DMD patients were indeed obtained when at least 100 cell injections/cm^2 were performed [20–23]. This form of cell implantation was denominated "high-density injections" [6], to make a distinction from the earlier clinical trials of SCDM transplantation, which performed few injections distant from each other.

Technical Approaches for Intramuscular Transplantation

In a clinical context, a high-density injection protocol performed with precision syringes operated manually is adequate only for small volumes of muscle [20,22]. Done in that way, the method is slow and needs much concentration to ensure the depth of the intramuscular cell delivery permanently; it becomes excessively time-consuming and technically exigent for large volumes of muscle. A first attempt to alleviate this problem partially was to adapt for cell injection some laboratory dispensers initially developed for the repetitive delivery of small volumes of liquid [56]. A monosyringe dispenser became a routine instrument for SCDM transplantations in monkeys (Fig. 55.5B) [57] and was used for SCDM transplants in a patient with DMD [21]. However, its clinical use is limited to relatively small muscles and the precision needed to deliver the cells through a thick skin remains a challenge. Consequently, we determined the need to develop specific instruments for the percutaneous intramuscular injection of cells in a clinical setting. A first semimanual device was created to deliver very small quantities of cell suspension, homogeneously throughout the intramuscular trajectory of six needles at the same time, which avoids wasting in skin and hypodermis [58] (Fig. 55.7).

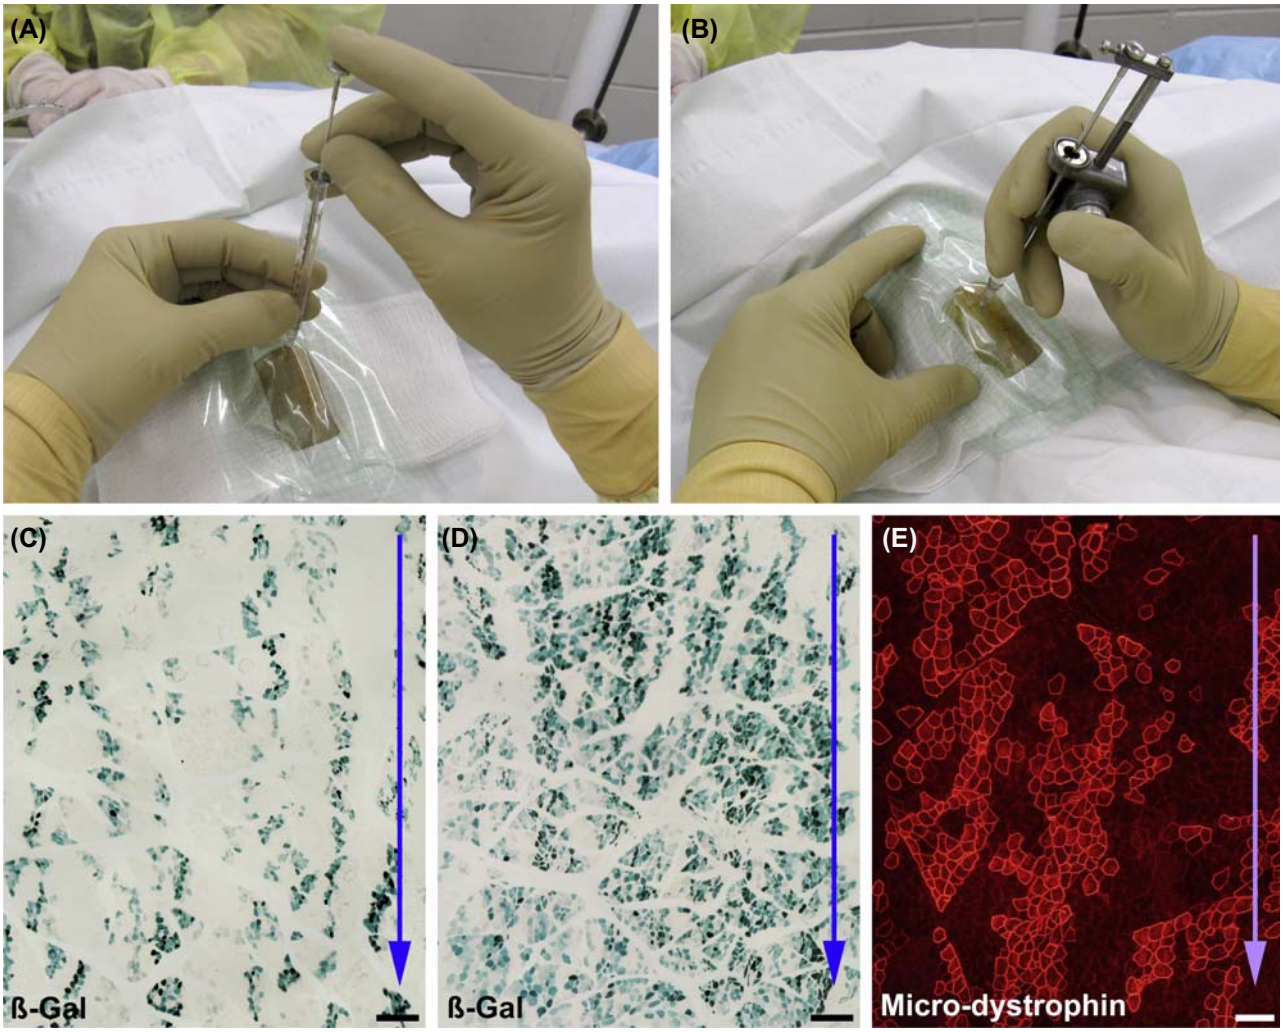

FIGURE 55.5 Examples of intramuscular satellite cell–derived myoblast (SCDM) transplantations in nonhuman primates. In most studies, SCDMs are delivered through parallel, close intramuscular injections using either a precision syringe operated manually (A) or a repeating dispenser with a precision syringe (B). As in some clinical trials (see Fig. 55.2), the density of cell injections is controlled with a sterile transparent dressing with a 5-mm grid. After 1 month, fusion of the grafted cells with the recipient's myofibers is analyzed in cross-sections of muscle biopsies using histological techniques to detect transgenic proteins that labeled the grafted cells (C–E). Histological images show cross-sections of macaque muscles grafted with transgenic SCDMs labeled either with β-galactosidase (β-Gal) (C, D) or a micro-dystrophin coupled to a peptide tag (E). Myofibers expressing donor-derived proteins are respectively detected by histochemical detection of β-Gal (C, D, *greenish blue staining*) or fluorescent immunohistological detection of the peptide tag (E). The distribution of the myofibers expressing donor-derived proteins reproduces the pattern of the original cell injection trajectories (indicated by *arrows*). The density of β-Gal–positive myofibers is higher in (D) than in (C) because the density of cell injections was higher: 25/cm^2 in (C) and 100/cm^2 in (D). Scale bars: (C, D) = 500 μm; (E) = 200 μm.

Potential Risks of the Cell Injection Procedure

A protocol of high-density injections may involve risks that need to be avoided or controlled. These risks could be local and systemic, and according to experience in nonhuman primates, they are limited to the first posttransplantation days.

Locally, a monkey's biceps brachium is swollen the first day after transplantation, but it reaches its pretransplantation diameter after 5 days [52]. This implies risks for a compartment syndrome in muscles enclosed in a rigid osteofascial space. The monkey's biceps brachium tolerates this treatment well, but for muscles such as the tibialis anterior it may be necessary to proceed cautiously in humans. The first tests in some arm muscles of a

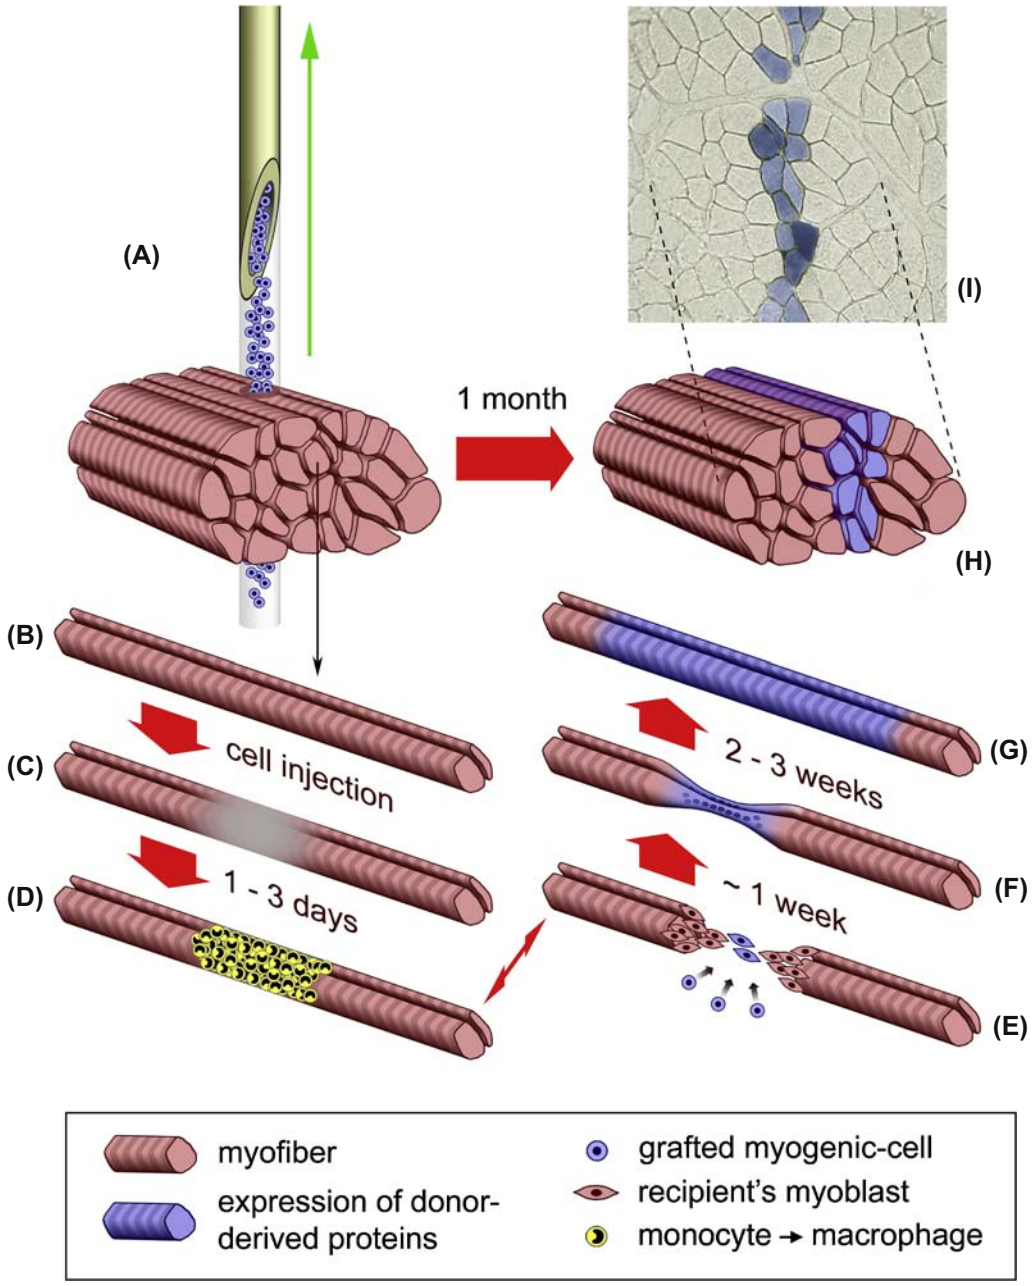

FIGURE 55.6 Representation of how the pattern of bands of engraftment is formed after the injection of satellite cell–derived myoblasts (SCDMs) in the muscles of nonhuman primates. (A) Cell injection traversing a muscle fascicle and delivering the cells homogeneously during the needle withdrawal. (B–G) The process of grafted-cell uptake in two myofibers isolated from this fascicle. Myofibers are damaged by the injection needle (B) and experience segmental necrosis (C). The necrotic region is invaded by circulating monocytes (D), which become macrophages with two main functions: phagocytosis of the necrotic debris and release of factors helping myofiber regeneration. Myofiber regeneration is done by activating the recipient satellite cells, which proliferate as SCDMs that fuse together (E). The regenerative process recruits grafted SCDMs (E). The nuclei of the grafted cells that participated in SCDM fusion are integrated in the myotubes that fill the gap led by segmental myofiber necrosis (F). Later, these graft-derived nuclei allow the expression of graft-derived proteins throughout a restricted length of the myofiber (G). This process leads to restricted regions of donor-protein expression in the fascicle (H), which are observed as bands of engraftment in cross-sections of the cell-grafted muscle (I). In this case (I), as in most SCDM transplantation studies in nonhuman primates, the grafted cells were labeled with a gene coding for β-galactosidase and the result of the graft after 1 month is evaluated through β-galactosidase expression (*greenish blue staining*) in the myofibers.

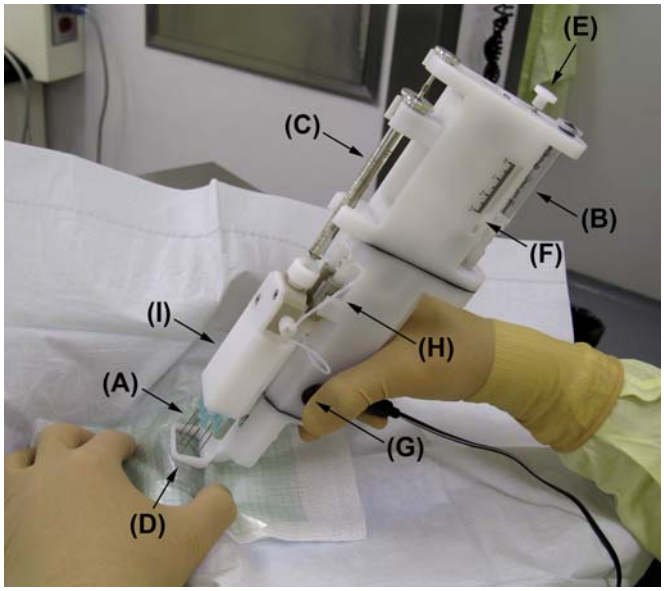

FIGURE 55.7 First device designed for the percutaneous transplantation of cells by a high-density injection protocol, shown during satellite cell–derived myoblast (SCDM) transplantation in a biceps brachium of a macaque. This prototype delivers very small quantities of cell suspension through up to six standard disposable needles (A), from a container incorporated into the device (B). From this container, the cell suspension circulates toward the injection needles during the up-and-down movements of a precision syringe (C). To deliver the cells in the muscle and not the skin, the operator can set the adjustable foot (D) to leave the needle length necessary to go through the skin and hypodermis (estimated by ultrasound analysis). The amplitude of the needles' excursion into the muscle can be set with a knob (E), using the indicator of injection depth as a reference (F). The operator then introduces the needles until the foot touches the skin surface (D); thus, the tips of the needles should be at the muscle surface. Pressing the push button (G), the needles penetrate the muscle and the precision syringe (C) is filled with cell suspension. Once the needles reach the depth of injection, they are automatically retracted to their original position and the cells are delivered into the needles' trajectory during this movement. Then the operator withdraws the needles and restarts the sequence in another position. Two valves (H) control the appropriate circulation of the cell suspension. The container, syringe, and needles are linked by a plastic support (I) that includes the flow divisor. An electromechanical system into the device's body governs the injection sequence. *Reproduced from reference Skuk D. Cell transplantation and "stem cell therapy" in the treatment of myopathies: many promises in mice, few realities in humans. ISRN Stem Cells 2013;2013:25, Article ID 582689.*

patient with DMD were well-tolerated [21], although in this case the muscles were largely replaced by fibrosis and fat tissue.

Systemically, extensive muscle damage releases intracellular metabolites such as myoglobin and potassium. This implies risks for cardiac arrhythmia in the case of severe hyperkalemia and acute renal failure in the case of myoglobinuria. However, both phenomena were not observed after high-density cell injections in the biceps brachii of monkeys [52]. Indeed, maintaining muscle damage in each transplant session under the potentially hazardous limits might prevent this problem. As an example, high-density injections throughout two biceps brachii in monkeys increased serum creatine-kinase to 2000 U/L [52] whereas the risk for acute renal failure is considered to be at 16,000 U/L [59]. This problem was not observed in a first test in a human, but the volumes of muscle injected were proportionally smaller than those used in monkeys, and as indicated earlier, these muscles were largely replaced by fibrosis and fat tissue [21].

Improving the Efficiency of Cell Injections

A lower density of cell injections is desirable, but to reach this objective, the volume of muscle expressing a therapeutic protein (e.g., dystrophin) after each single-cell injection must be increased. This could be achieved by (1) making the implanted cells to fuse with myofibers other than those around the injection trajectory, or (2)

increasing the nuclear domain of the therapeutic protein. This last possibility has rarely been investigated: only one study in *mdx* mice reported a threefold increase in the nuclear domain of dystrophin after transplantation of SCDMs overexpressing dystrophin [27].

Making the grafted cells to fuse with myofibers other than those close to the injection trajectory implies first knowing why this happens. Two factors were previously mentioned to explain why the grafted SCDMs fuse mostly with the myofibers in the trajectory of injections: (1) the grafted SCDMs lack the capacity to move through the tissue and therefore remain in the injection trajectories to fuse with the neighboring myofibers; and/or (2) the grafted SCDMs have the capacity to move through the tissue but myofiber regeneration is mandatory to attract the transplanted SCDMs to fuse with them, and in a normal muscle this occurs only in the myofibers damaged by the injection.

Addressing the first factor, various studies wanted promotion of the intramuscular diffusion of the grafted SCDMs by inducing in them the secretion of enzymes that degrade the extracellular matrix [60–63]. Several of these studies improved the migration capacity of SCDMs under experimental conditions in vitro and in vivo in mice, and even enhanced the transplantation outcome. However, the first tests in monkeys were disappointing and suggested that an increasing migration capacity in the implanted SCDMs does not augment the success of their transplantation per se [63]. Subsequent experiments in nonhuman primates demonstrated that grafted SCDMs have an intrinsic capacity to migrate several millimeters into the muscle, but that they migrate essentially to fuse with regenerating myofibers in a mechanically damaged tissue [64].

Addressing the second factor, other experiments increased the number of regenerating myofibers to favor the uptake of the grafted SCDMs. Local injection of myotoxins such as phospholipases derived from snake venoms [17,65] and local anesthetics [66,67] are efficient in small rodents for this purpose. Intense muscular exercise produced extensive myofiber necrosis and almost doubled the success of SCDM transplantation in dystrophic mice [68]. Conjointly, inhibiting the proliferation of the recipient's satellite cells favors the participation of the grafted SCDMs in myofiber regeneration. This is achieved in mice by exposing the recipient muscles to high doses of ionizing radiation before cell transplantation [17,69]. Cryoinjury of recipient muscles necroses myofibers and satellite cells and has been used in mice as a pretreatment to favor the implanted cells [30,31,41].

In nonhuman primates, the coinjection of SCDMs and myotoxic phospholipases improved the outcome of SCDM transplantation but only when SCDMs and myotoxins were highly concentrated in the muscle [52,70]. A method that was especially efficient in inducing extensive myofiber regeneration in the large muscles of nonhuman primates, with the consequent increase of the SCDM engraftment in extensive zones, was intramuscular electroporation [71]. In the event that one of these methods could be translated to the clinic, it should be taken into account that increasing muscle damage would reduce the volume of muscle to be treated in one session, considering the risk for a rhabdomyolysis-like phenomenon as mentioned earlier.

CELL-GRAFT SURVIVAL

Once a good delivery of the appropriate cells is obtained, their survival in the recipient must be ensured. The posttransplantation survival of myogenic-cells should be analyzed for two periods: the initial (the first week) and the long-term (the life span of the patient).

Initial Survival

There is a consensus that an important mortality occurs among grafted SCDMs rapidly after their intramuscular implantation, essentially within the first week posttransplantation. This was deduced by the progressive loss of different grafted-cell markers after SCDM transplantation in mice [72–74]. In addition, morphological evidence of apoptosis and necrosis was found among the grafted SCDMs early after implantation [74].

This early cell death does not prevent the outcome of SCDM transplantation, because not all cells die, and in some mouse experiments the proliferation of the surviving cells compensated totally [74] or partially [73] the cell death. This initial cell death is not well-understood, and studies approaching this topic show contradictions, probably because of methodological differences [74]. An early study in mice blamed cells of the acute inflammatory reaction for killing the implanted SCDMs [72], but later experiments found no evidence of neutrophil, macrophage, or natural killer cell responsibility in this death [75]. It was also postulated that the survival of the graft could be caused by a special small subpopulation of cells that specifically avoid early cell death and proliferate greatly [73]. Other mechanisms proposed to be responsible for causing apoptosis among SCDMs grafted in mice were hypoxia [76] and anoikis [77].

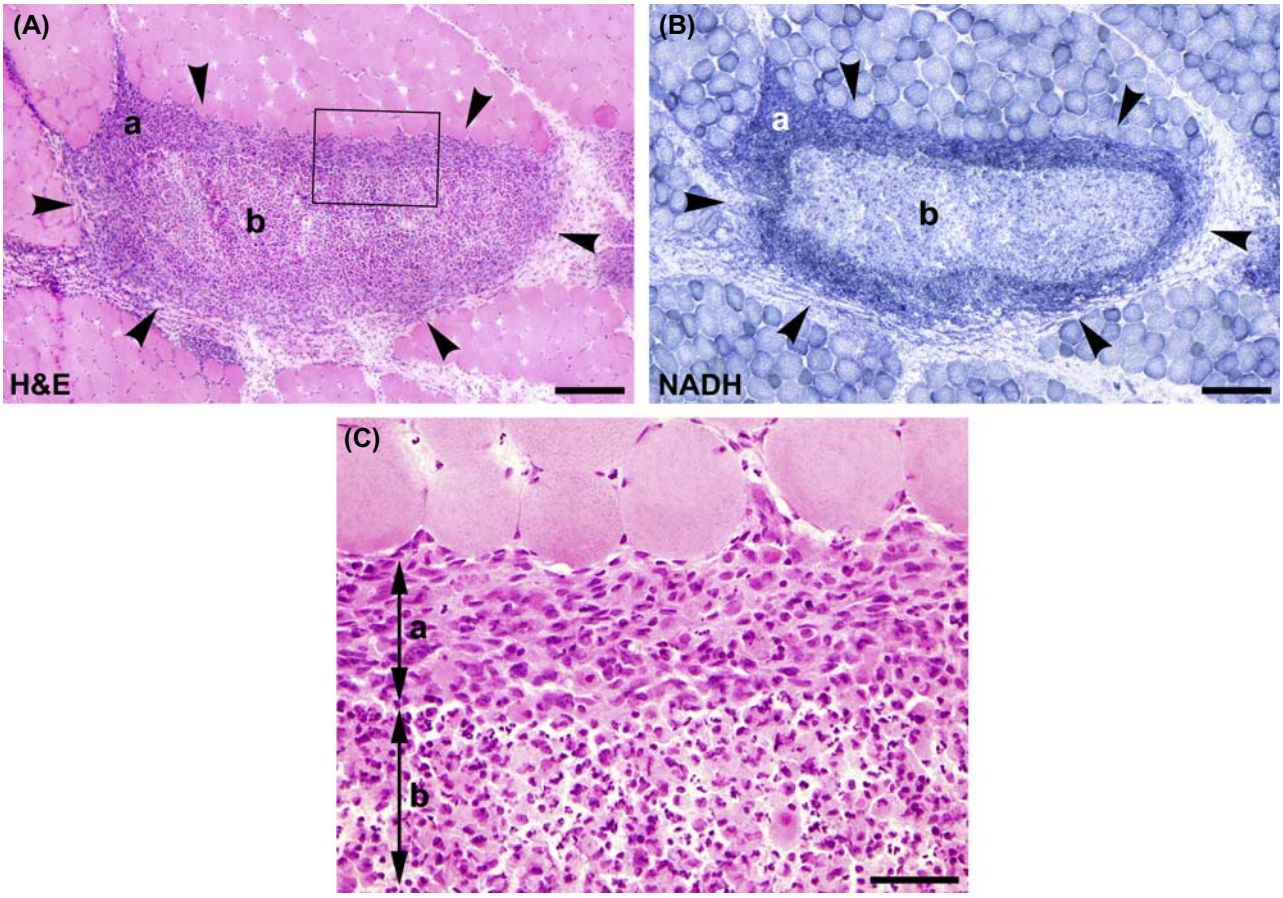

FIGURE 55.8 Ischemic necrosis in an intramuscular accumulation of grafted satellite cell–derived myoblasts 1 day after their transplantation in the skeletal muscle of a nonhuman primate. *Arrowheads* in (A) circumscribe the intramuscular accumulation of grafted cells in a section stained with hematoxylin-eosin (H&E). Two regions with different staining characteristics can be observed in this cell accumulation: a darker peripheral ring (a) and a paler core (b). In a serial section (B) stained for histochemical detection of the oxidative enzyme nicotinamide adenine dinucleotide reduced diaphorase (NADH), the two regions are more clearly delimitated: a peripheral ring strongly stained (a: living cells with oxidative activity) and a central region almost devoid of oxidative reaction (b: necrosed cells with a loss of oxidative activity). A detail of this accumulation of grafted cells (*rectangle* in [A]) is shown at higher magnification in (C). (C) The peripheral layer (a) is composed of cells with normal characteristics, whereas the core (b) has smaller cells with pyknosis, karyorrhexis, and in several cases, loss of cytoplasmic staining. Scale bars: (A, B) = 200 μm; (C) = 50 μm. *Reproduced from reference Skuk D. Cell transplantation and "stem cell therapy" in the treatment of myopathies: many promises in mice, few realities in humans. ISRN Stem Cells 2013;2013:25, Article ID 582689.*

Otherwise, a well-determined mechanism of rapid grafted-cell death detected in monkeys is the ischemic necrosis of the central part of the intramuscular accumulations of grafted SCDMs (Fig. 55.8) [78]. Injected cells form avascular accumulations and their survival depends on the oxygen and nutrients diffusing from the surrounding tissue. Because this diffusion is limited, only a peripheral cell layer of about 100–200 μm survives. For this reason, the amount of central necrosis depends on the size of the grafted-cell clusters [78].

Long-term Survival

The principal threat to the long-term survival of SCDM grafts is acute rejection in inadequately immunosuppressed allogeneic transplantation, as confirmed in nonhuman primates [79]. Acute rejection in the context of SCDM transplants was extensively studied in mice since the first description of lymphocyte infiltration and grafted SCDM disappearance soon after allogeneic transplantation [80]. Subsequent studies identified CD8+ and CD4+ lymphocytes in these infiltrates [81,82], and expression of interleukin-2 receptors, T-helper 1 cytokine, and granzyme B confirmed that these were activated lymphocytes [83,84]. Incompatibility in minor antigens can also trigger acute rejection of hybrid myofibers, as observed in mice after syngeneic transplantation into females of SCDMs obtained from males [85].

However, observations in mice were not useful in the analysis of immune responses and acute rejection in clinical trials of SCDM transplantation [20,21]. For this purpose, studies in nonhuman primates defined the histological features of acute rejection of hybrid myofibers [79]. Independent of the way to induce acute rejection of the hybrid myofibers (withdrawal of immunosuppression, low immunosuppression, or progressive reduction of immunosuppression) and of the posttransplantation period in which rejection occurs, graft loss was associated in all cases with myositis characterized by dense focal accumulations of CD8+ and CD4+ lymphocytes and a more diffuse component of macrophages [79]. Typically, these lymphocyte accumulations were mainly endomysial, totally or partially surrounding some myofibers and often invading them. Some mechanisms by which the immune system eliminates the hybrid myofibers were identified: There was evidence of sarcolemmal damage in the myofiber regions invaded by lymphocytes, together with myofiber necrosis and caspase 3 activation in some of the myofibers attacked by CD8+ lymphocytes [86].

Ensuring Cell Survival in the Recipient

Early cell death among grafted SCDMs is misunderstood. For that reason, it has not been prevented efficiently. However, because this death does not devastate the population of implanted SCDMs, which seems well-restored by the proliferation of the surviving cells, the only potential benefit of inhibiting it would theoretically be a reduction in the number of cells to be injected [87]. This would not be totally insignificant, because it has been estimated in nonhuman primates that the number of SCDMs to be injected per cubic centimeter of muscle, using matrices of 100 injections/cm^2, is between 10×10^6 and 100×10^6 cells [55]. Conversely, massive ischemic central necrosis can be prevented or reduced by ensuring the formation of accumulations of grafted SCDMs in which most cells are within 100–200 μm of the surrounding tissue [78].

Acute rejection, on the other hand, precludes the survival of an SCDM allograft. Whereas acute rejection is efficiently controlled by pharmacological immunosuppression, careful selection of the drugs is required for SCDM transplantation because some of them kill and/or inhibit differentiation of the grafted SCDMs [6]. Because the best results of SCDM allotransplantation in mice were reported using tacrolimus for immunosuppression [17], this drug became the immunosuppressant of choice for SCDM allotransplantation in monkeys [57] and consequently in humans [20–23]. The first clinical trial of SCDM transplantation with tacrolimus immunosuppression involved follow-up of only 1 month [20,22], but a patient in whom tacrolimus was continued for 18 months showed preservation of donor-derived dystrophin during that time [21].

Because pharmacological immunosuppression has severe secondary effects, a main objective in clinical transplantation is to create immune tolerance: that is, long-term specific unresponsiveness to grafts with preservation of immune reactions against other foreign antigens. In mice, a transient immunosuppression can be sufficient to develop immune tolerance to SCDM allotransplants in some strains or to delay acute rejection for months in others [30,88] but in nonhuman primates, immunosuppression withdrawal causes rapid acute rejection of the hybrid myofibers [79,86]. This is another example of how immune tolerance is more easily obtained in mice than in monkeys or humans [89]. Some protocols to develop immune tolerance were tested for SCDM transplantations in mice. Central tolerance via mixed chimerism [90,91] was more successful than peripheral tolerance combining donor-specific transfusion and administration of anti-CD154 antibodies [92]. However, central tolerance in the context of myogenic-cell allotransplantation may not include neoantigens appearing in the hybrid myofibers and would also need peripheral-tolerance mechanisms to avoid acute rejection [93].

Another approach to avoiding immunosuppression in this context is the autotransplantation of SCDMs genetically corrected ex vivo [94]. Tests in mice with different viral vectors or transfection approaches to introducing the therapeutic transgene in SCDMs were considered to be promising for future development with this approach [94], and the feasibility of this strategy was also tested in macaques [54]. However, some of these tactics leave open the possibility of a rejection owing to incompatibility of minor antigens, essentially neoantigens from the product of the transgene incorporated in the cells [95].

CONCLUSIONS

To reach a therapeutic objective, cell transplantation basically needs three conditions: a cell that meets the properties required for the treatment, a method of cell administration that ensures that the treatment could be clinically relevant, and conditions to ensure the survival of the graft throughout the life of the recipient. So far, SCDMs are the only myogenic cells that have passed a clinical test of cell transplantation in skeletal muscles, restoring dystrophin in

variable amounts of myofibers in patients with DMD. Intramuscular implantation through a protocol of high-density injections is the only method that has produced relevant percentages of hybrid myofibers in humans. Finally, a tacrolimus-based immunosuppression is the only method that has been successfully tested in nonhuman primates and humans to ensure the survival of the hybrid myofibers produced by SCDM allografts.

Some important challenges remain to render this technique applicable in clinics with any expected benefit for patients. A main challenge is to enhance the success of SCDM transplantation further while reducing the density of cell injections. Another challenge is a main problem in the global context of transplantation: that is, minimizing as much as possible the toxicity of the methods needed to control graft rejection. This could be achieved by refining immunosuppressive protocols or developing efficient approaches to immune tolerance. Cell transplantation also offers the alternative of manipulating cells before transplantation to avoid immunosuppression, which opens the possibility of autotransplantation of genetically corrected cells. Finally, the capacity to restore the functional parenchyma in skeletal muscles that have degenerated to fibrosis and/or fat substitution remains unsolved and barely studied. However, this would be the only possibility of restoring muscle function in degenerative muscular pathologies such as DMD.

Glossary

Myoblast Proliferating mononuclear progenitor cell that fuses with analogous cells to form myotubes: that is, syncytial multinucleated cells with central nuclei, a small diameter, and few myofibrils, which under adequate conditions (essentially motor innervation) precedes myofiber formation.

Myofiber Syncytial multinucleated cells of cylindrical shape that are the terminally differentiated contractile units of the skeletal muscle, composed essentially of contractile proteins (myosin and actin) organized in sarcomeres and that have a specialized system for excitation−contraction coupling.

Satellite cell Mononuclear myogenic precursor cell located in the periphery of myofibers, between the basement membrane and the sarcolemma, where it remains quiescent while the muscle myofiber remains intact, and is activated when the myofiber is damaged, reentering the cell cycle to: (a) generate myoblasts to regenerate the myofiber and (b) give rise to other satellite cells to maintain the pool of muscle progenitors.

Satellite cell−derived myoblasts Myoblasts involved in postnatal myofiber regeneration that are generated by the activation and proliferation of satellite cells, either in vivo, in response to a myofiber injury that causes segmental or total necrosis and therefore needs to be repaired or in vitro, during the cell culture of skeletal muscle biopsies.

CHAPTER

56

Islet Cell Transplantation

Juliet A. Emamaullee, Andrew Pepper, A.M. James Shapiro

Department of Surgery, University of Alberta, Edmonton, AB, Canada

INTRODUCTION

Background

Diabetes is a disease that results from impaired glucose metabolism. Approximately 90% of diabetes is caused by a defect in insulin production and/or use (type 2 diabetes mellitus [T2DM]), whereas the more severe form, type 1 diabetes mellitus (T1DM), is caused by a complete loss of insulin-producing β cells within the islets of Langerhans of the pancreas. Diabetes affects more than 200 million patients worldwide and is projected to afflict at least 5% of the global adult population by 2025 [1]. As the incidence of diabetes has increased, the cost of treating these patients has skyrocketed, consuming between 7% and 13% of health care expenditure in developed countries [2]. Since the discovery of insulin in 1921, diabetes has become a treatable condition and the life expectancy of patients with diabetes has been greatly improved. However, even with diligent blood glucose monitoring and insulin administration, metabolic abnormalities associated with diabetes often lead to many chronic secondary complications, including nephropathy, retinopathy, peripheral neuropathy, coronary ischemia, stroke, amputation, erectile dysfunction, and gastroparesis [3]. In the United States, patients with diabetes represent 8% of those who are legally blind and 30% of all patients receiving dialysis caused by end-stage renal disease, and 20% of all patients receiving kidney transplants [3]. The Diabetes Control and Complications Trial (DCCT) was conducted to determine whether intensive blood glucose regulation by frequent insulin injection or pump could prevent these long-term complications in patients with diabetes [4–6]. Results from the DCCT and subsequent Epidemiology of Diabetes Interventions and Complications study clearly demonstrated that this approach improved but did not normalize glycosylated hemoglobin (HbA1C) levels and significantly protected against cardiovascular disease, nephropathy, neuropathy, and retinopathy [5–8]. However, the consequence of improved glycemic control was a threefold increased risk for serious hypoglycemic reactions leading to recurrent seizures and coma [5,9]. Improvements in the size and sensitivity of insulin pumps have increased their utility and provide possible alternatives for stabilizing glycemic control in diabetic patients [10]. Insulin pump therapy can improve HbA1C levels compared with multiple daily injections of insulin, but pumps may malfunction and thus still necessitate frequent blood glucose monitoring by the user, and they have not resulted in glycemic stabilization rates achieved in islet transplantation [11,12].

Although advances in the formulation, half-life, and administration of insulin have markedly improved the quality of life and long-term survival of patients with diabetes, it has long been recognized that the restoration of an adequate islet mass would provide maximum benefit to diabetic patients, leading to a true physiological correction of the diabetic state. In the early 1960s, great advances were made in the field of renal transplantation owing to improved immunosuppressive therapies (azathioprine and corticosteroids), which prompted the first attempts in whole-pancreas transplantation [13,14]. First introduced by Kelly and Lillehei in 1966, early attempts were associated with high mortality rates and poor graft survival, with less than 3% graft function at 1 year after transplant [15]. The risk profile and long-term outcomes in whole-pancreas transplantation have been greatly improved by improvements in surgical technique, including portal venous and enteric endocrine drainage and steroid-free maintenance immunosuppression [16,17]. To date, more than 25,000 pancreas transplants have been performed worldwide for end-stage renal disease (simultaneous kidney pancreas or pancreas after kidney transplantation) or less frequently for severe hypoglycemic unawareness (pancreas transplant alone). Data collected in the International

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00056-4

Pancreas Transplant Registry showed that only 50% of patients who have undergone pancreas-alone transplantation remain insulin independent at 5 years despite improvements in surgical technique and immunosuppression [18–20]. Also, less than 30% of the approximately 6000 cadaveric pancreata donated each year are transplanted because of strict donor criteria and requirements for short cold ischemic time [18,21]. The surgical risks and requirement for lifelong immunosuppression have reserved pancreas-alone transplantation only for diabetic patients with the most severe and life-threatening disease, despite strong evidence that the procedure can prolong life, reverse established nephropathy, and improve quality of life. Because the major surgical complications in whole-pancreas transplantation are related to the exocrine function of the pancreas, which is not necessary to restore euglycemia in diabetic patients, it has long been recognized that β-cell replacement could be achieved with implantation of isolated pancreatic islets. This approach involves transplantation of a cellular graft that would be implanted using minimally invasive techniques; thus, it would avoid the risks associated with major surgery, resulting in a more widely available treatment for patients with diabetes.

History of Islet Transplantation

The concept of islet transplantation actually preceded the discovery of insulin in 1921 by nearly 30 years (Fig. 56.1). In 1893, physicians in Bristol, England, attempted to treat a young boy who had diabetic ketoacidosis by transplanting fragments of a freshly slaughtered sheep's pancreas [22]. Although the graft ultimately failed in the absence of immunosuppression, there was temporarily improvement in the boy's state, which suggested that cells within the pancreas could stabilize diabetes. After the discovery of insulin, it was thought that exogenous insulin replacement would be an effective treatment for patients with T1DM, and therefore islet transplantation was not actively pursued. However, as insulin therapy transformed T1DM from an acute health crisis to a chronic disease, it became apparent that insulin injections could not prevent the onset of debilitating and life-threatening secondary complications. Because the first series of whole-pancreas transplants in the late 1960s were associated with poor morbidity and mortality, isolated islet transplantation gained renewed interest [23]. The first successful islet isolations and subsequent transplantation into chemically induced diabetic rodents were pioneered by

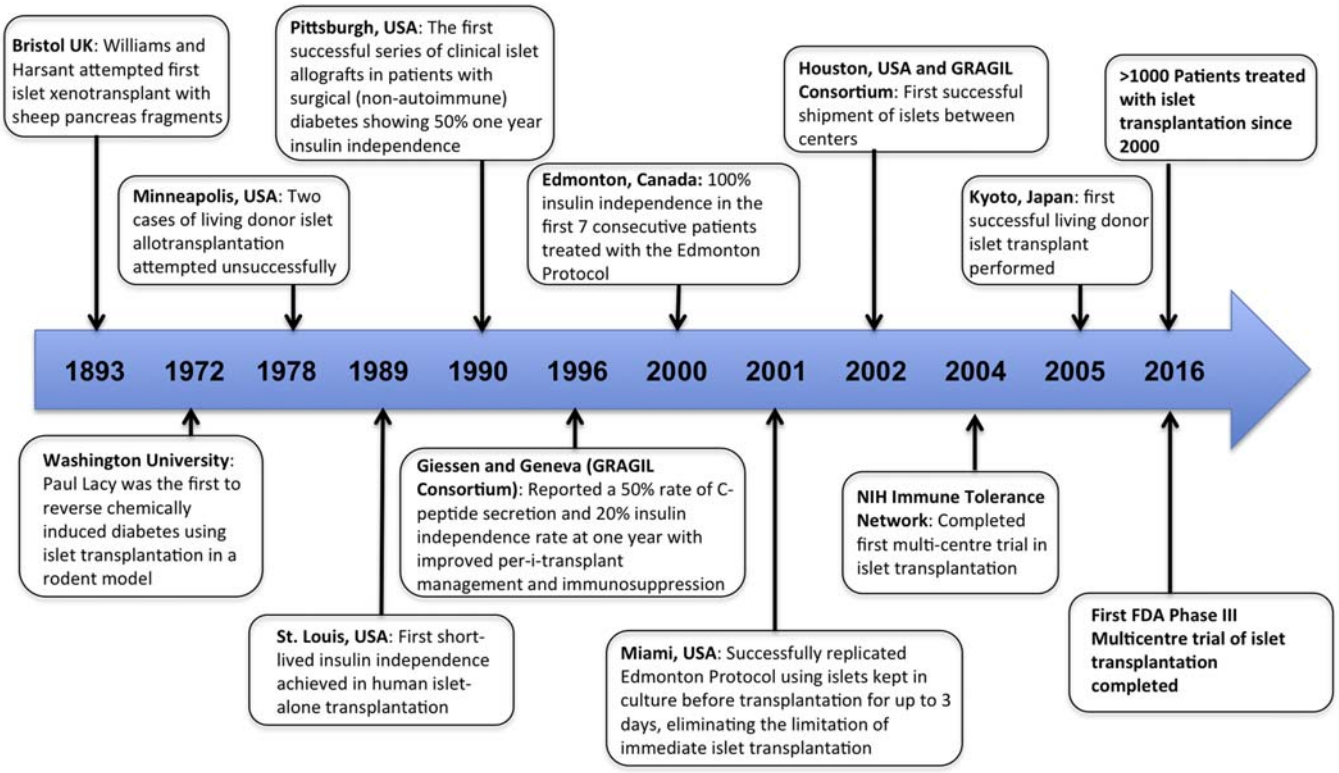

FIGURE 56.1 Timeline of notable advances in the history of islet transplantation. *GRAGIL*, Groupe Rhin–Rhône–Alpes et Genève Pour la Greffe d'Îlots de Langerh.

Dr. Paul Lacy at Washington University in St. Louis, which immediately sparked interest in implementing clinical trials [24–27]. Although euglycemia was routinely obtained in animal models of islet transplantation, clinical islet transplantation struggled to find success for most of the 1970s and 1980s. During that time, unpurified islets were infused into the portal vein, which led to many serious complications including portal vein thrombosis, portal hypertension, and disseminated intravascular coagulation [28]. While working in Lacy's group, Dr. Camillo Ricordi developed the "automated method" for high-yield islet isolation in 1989 [29]. This represented a major turning point in the field and led to the report that Lacy's group had achieved short-lived insulin independence in a patient with T1DM who had received an islet graft after a previous kidney transplant [30]. The following year, the group led by Ricordi at the University of Pittsburgh reported the first series of clinical islet allografts that demonstrated improved insulin independence rates of 50% at 1 year in subjects who underwent cluster islet-liver transplants for abdominal malignancies in the setting of surgically induced (nonautoimmune) diabetes [29,31]. Although this represented a major advance in the field of islet transplantation, these results could not be reproduced in patients with T1DM, the important patient population in need of β-cell replacement [32]. In the late 1990s, the European Groupe Rhin–Rhône–Alpes et Genève Pour la Greffe d'Îlots de Langerhans (GRAGIL) consortium reported the first modestly successful insulin independence rates of 20% at 1 year in patients with T1DM, which could be attributed to improved peritransplant management and immunosuppressive drug regimens [33]. Because the results from Pittsburgh and the GRAGIL consortium were obtained in patients who had previously received a kidney transplant, there was no additional risk in terms of immunosuppression to patients after receiving an islet graft [32,33]. An international registry held in Giessen, Germany, has maintained a comprehensive record of previous clinical attempts at islet transplantation globally, and of the total world experience of over 450 attempts at clinical islet transplantation before 2000, less than 8% of subjects achieved insulin independence [34]. After 3 decades of research, the 1-year insulin independence rates in clinical islet transplantation were still too low to justify the risks associated with portal infusion and lifelong immunosuppression in most patients with T1DM [33–37].

The Edmonton Protocol

Shapiro and colleagues at the University of Alberta developed a protocol in 1999 that was designed for patients with "brittle diabetes" who experienced extreme difficulty in managing blood glucose levels ("glucose lability") and/or severe hypoglycemic unawareness [38]. The so-called "Edmonton Protocol" was unique compared with previous attempts in clinical islet transplantation in its high targeted islet mass, with a mean of approximately 13,000 islet equivalents (IE)/kg recipient body weight, often derived from two (or occasionally more) fresh islet preparations and in its immunosuppression strategy, with emphasized avoidance of corticosteroids and the use of potent immunosuppression with combined sirolimus, tacrolimus and anti-CD25 antibody to protect against rejection and recurrent autoimmunity [38]. This approach led to dramatic improvements in islet allograft survival; all of the first seven patients achieved sustained independence from insulin [38]. Almost 300 consecutive patients have received islet transplants at the University of Alberta since 1999, and the 1-year insulin independence rate remains steady at approximately 80% after completed transplants (<13,000 IE/kg). Results obtained at the University of Alberta have been replicated at other centers including an international multicenter trial through the Immune Tolerance Network, but each center's success has varied greatly depending on its previous experience and skill in islet isolation and immunosuppressive management [39,40]. The Miami group demonstrated that islets can be cultured for up to 3 days before transplant or shipped and transplanted at a remote facility (Houston) with similar success as freshly isolated islets when transplanted using Edmonton-like immunosuppression [41,42] The GRAGIL Network (a Swiss–French consortium) also demonstrated the benefits of centralized islet processing facilities that can service a broader network of centers throughout Europe [33,43].

Based on the success of the Edmonton group, islet transplantation has been funded in Alberta, Canada, as accepted clinical standard of care since 2001. Progress in this area has been challenging in the United States, but large registration trials have been completed, which should facilitate Biological Licensure by the Food and Drug Administration, and therefore reimbursement, which will make a significant difference to the availability of islets for transplantation in that country [44,45]. The success of clinical islet transplantation has encouraged many centers around the world to implement a program, and since 2000 more than 1000 patients have been transplanted using variants of the Edmonton Protocol in almost 50 centers worldwide [46].

Despite this success, the requirement for lifelong immunosuppression in islet-alone transplantation has restricted its availability to patients with T1DM and severe hypoglycemia or glycemic lability. The benefit of islet transplantation in patients with T2DM has not been determined, because many of these patients are overweight and/or insulin resistant and thus would require a large islet mass to meet metabolic demands. Most patients require two

or occasionally three islet implant procedures to achieve insulin independence, although insulin independence after single donor infusion was reported in a cohort of patients at the University of Minnesota [47,48]. In Edmonton, data indicate that C-peptide secretion (>0.5 ng/mL) is maintained in almost 70% of patients in the long term (up to 18 years), and through this, patients derive ongoing benefit in terms of stabilization of glycemic control without hypoglycemic reactions. Overall, a quarter of patients remain completely insulin free at 5 years, but this rises to 50% in patients treated in newer T-depleting and antiinflammatory induction protocols. Although the cause of the discrepancy between insulin independence and maintenance of C-peptide status is not fully understood, it is likely that multiple events hinder graft function and survival over time. Whereas rejection (acute or chronic) and recurrent autoimmunity may be responsible for graft loss, it is probable that other, nonimmune-mediated damage occurs, such as chronic toxicity from tacrolimus. Perhaps the most important component of decaying graft function over time is the concept of islet "burnout" from constant metabolic stimulation, because only a marginal mass of islets actually engraft in most subjects. In clinical islet transplantation, the risks for malignancy, posttransplant lymphoma, and life-threatening sepsis have been minimal, but fears regarding these complications limit broader application in patients with less severe forms of diabetes, including children [46]. Moreover, a number of immunosuppression-related side effects have been encountered, including dyslipidemia, mouth ulceration, peripheral edema, fatigue, ovarian cysts, and menstrual irregularities in female subjects, which can be dose or drug limiting in some patients [49]. Thus, although dramatic improvements in outcomes after islet transplantation have been observed, extensive refinements in clinical protocols are needed to improve safety and enhance success with single donor islet infusions.

CLINICAL ISLET TRANSPLANTATION

Patient Assessment and Selection

Clinical islet transplantation is associated with a series of potential risks, including procedural complications such as bleeding or portal vein thrombosis, or those associated with lifelong immunosuppression, i.e., infection or malignancy. For these reasons, patients selected as islet recipients must have severe, life-threatening diabetic complications that justify the risks of transplantation. Two T1DM patient populations have been identified as suitable candidates for islet transplantation: individuals who experience frequent, severe, and recurrent hypoglycemic unawareness, and those with highly unstable blood glucose control despite an optimized insulin regimen (glycemic lability).

When patients are evaluated for islet transplantation, their metabolic status and diabetes-related secondary complications should be carefully characterized so that those who would receive the greatest benefit despite the requirement for lifelong immunosuppression are selected. First and foremost, islet transplantation is reserved for patients with C peptide−negative (<0.3 ng/mL) T1DM. Recipients with an elevated body mass index (>30 kg/m^2) or those greater than 90 kg are generally excluded, because their metabolic demand may not be met by the transplanted islet mass. As mentioned previously, indications for islet-alone transplantation include severe hypoglycemic unawareness and/or glycemic lability. To assess these symptoms, Ryan et al. developed an objective scoring system to measure the severity of both hypoglycemia (the HYPO score), and the (LI), which is based on changes in blood glucose over time [50]. Selection criteria for islet-alone transplantation include a HYPO score greater than 1047 (90th percentile), LI > 433 mmol/L^2/h · $week^{-1}$ (90th percentile), or a composite with the HYPO score greater than 423 (75th percentile) and LI greater than 329 (75th percentile) [51]. Because patients with poor diabetes compliance or an inadequate baseline insulin regimen are likely to benefit from an improved design of insulin dosing regimens, patients selected for transplant should have a plasma HbA1C less than 10%. In an effort to reduce the risk of serious procedural and immunosuppressive drug-related complications, the patient's cardiac and renal function should be carefully assessed. Selected recipients should have adequate cardiac function including blood pressure less than 160/100 mmHg, no evidence of myocardial infarction in the 6 months before assessment, no angiographic evidence of noncorrectable coronary artery disease and left ventricular ejection fraction greater than 30% as measured by echocardiogram. To eliminate patients who are better candidates for simultaneous kidney−pancreas transplantation or those who may experience adverse renal function as a result of tacrolimus, selected recipients should have no evidence of macroscopic proteinuria (<300 mg/24 h) and a calculated glomerular filtration rate greater than 80 (>70 in females) mL/min/1.73 m^2. Proliferative retinopathy should be stabilized before transplantation, because acute correction of glycemic control may lead to accelerated retinopathy. Finally, to reduce

the risk of antibody-mediated graft rejection, potential recipients should be screened for panel reactive antibody (PRA) assays. It remains unknown whether patients with elevated initial PRA will have worse long-term islet function if they have a negative cross-match to the specific donor cells.

Islet Transplantation Procedure

Although several locations have been tested as potential implantation sites for islet grafts, the high level of graft function and ease of delivery associated with infusion into the portal circulation of the liver have led to this being the transplantation site of choice in clinical protocols [27]. There are two accepted approaches for implanting purified islets into the liver by way of the portal vein. Whereas surgical laparotomy and cannulation of the portal vein was most often used in the early islet transplant programs, current protocols routinely employ the percutaneous transhepatic approach to implant donor islets in cadaveric islet transplantation (Fig. 56.2A) [51]. Compared with surgical laparotomy, this procedure is minimally invasive and thus can be performed using local anesthesia combined with opiate analgesia and hypnotics given as premedication. Access to the portal vein is achieved by percutaneous transhepatic approach using a combination of ultrasound and fluoroscopy to guide the radiologist. A branch of the right portal vein is cannulated and a catheter is positioned proximal to the confluence of the portal vein, which is confirmed with a portal venogram [52]. The risk for portal vein thrombosis is reduced by inclusion of unfractionated heparin (70 U/kg) in the islet preparation. Islets are then infused aseptically into the main portal vein under gravity, with regular monitoring of portal venous pressure (by an indirect pressure transducer) before, during, and after the infusion. An ultrasound examination should be performed at 1 day and 1 week after transplant to rule out intraperitoneal hemorrhage and confirm that the portal vein is patent and has normal flow.

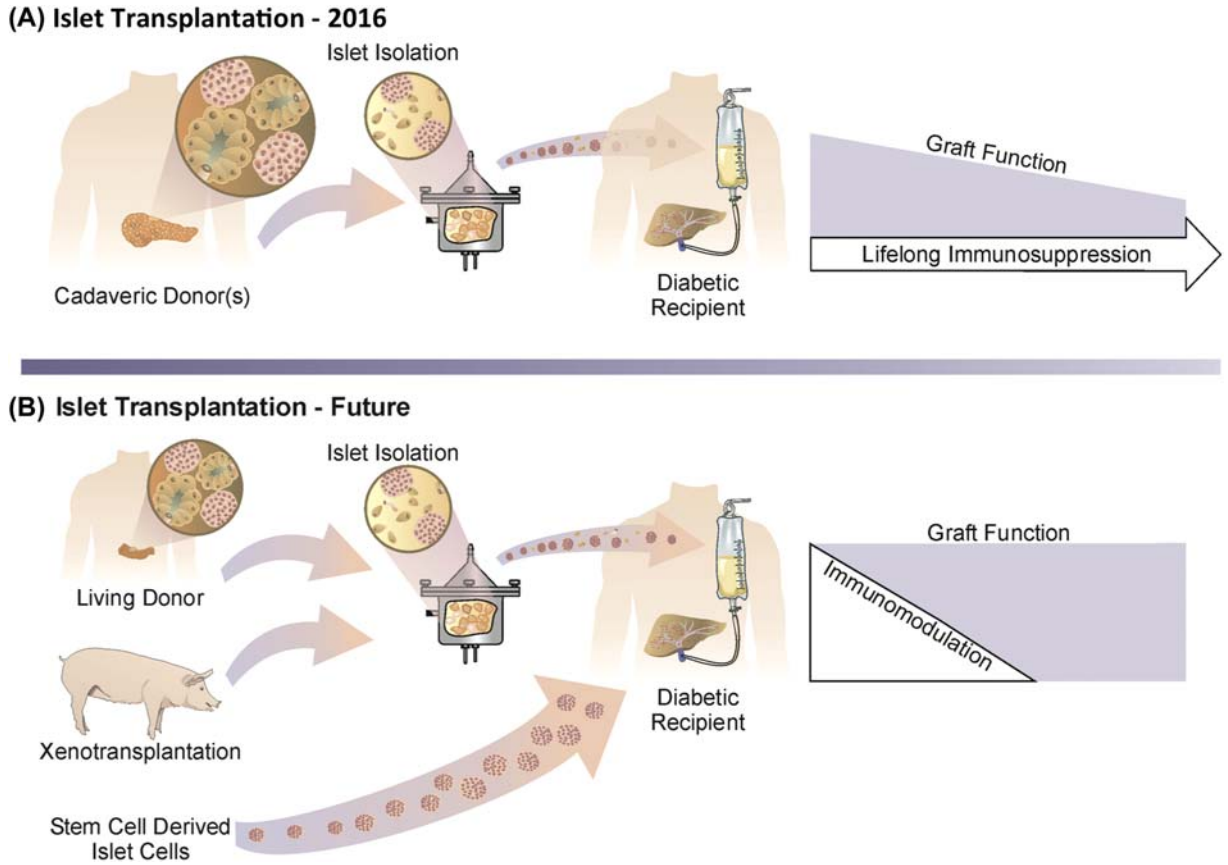

FIGURE 56.2 The islet transplant procedure: present and future. Islet transplantation, in its current form (A), has provided insulin independence in most diabetic patients at 1 year after transplant, but this procedure is limited by the availability of suitable cadaveric donors and the requirement for lifelong immunosuppression. In the future (B), islet transplantation could be made available to a broader range of diabetic patients through the use of alternative tissue sources such as living donors, xenogeneic donors, or stem cell–derived β cells. Also, as novel immunomodulatory therapies are identified, tolerance induction strategies can be developed that will prolong graft function and allow for the reduction or complete withdrawal of immunosuppressive drug therapy.

If the skills of a local expert interventional radiologist are unavailable or if a large hemangioma is present on the right side of the liver at risk for puncture and bleeding if the percutaneous approach were to be used, surgical laparotomy and cannulation of a mesenteric venous tributary of the portal system should be considered. In this situation, complete surgical control is in place to prevent uncontrolled bleeding. Another advantage includes the potential for use of a dual-lumen catheter for cannulation of a mesenteric vein (i.e., dual-lumen 9-French Broviac line), which allows for continuous monitoring of portal pressure during islet infusion. Still, this surgical approach should be considered only when the percutaneous transhepatic approach cannot be used, because it presents several major disadvantages, including the requirement for a surgical incision, formation of adhesions, and the risk for wound infection and wound herniation, which may be exacerbated when the drug sirolimus is used after transplant, because this drug interferes with wound healing.

Risks to the Recipient

Surgical Complications

There are two potentially serious procedural complications in islet transplantation: bleeding from the catheter tract created by the percutaneous transhepatic approach, and portal vein thrombosis, particularly when large volumes of tissue are infused. Adverse bleeding events were noted early in the development of the Edmonton program, but these have been almost completely avoided with the routine use of effective methods to seal and ablate the transhepatic portal catheter tract on egress when the catheter is withdrawn [53]. The combination of coils and tissue fibrin glue (Tisseel) was used previously, but it has been replaced by Avitene paste (1 g Avitene powder mixed with 3 mL radiological contrast media and 3 mL saline; approximately 0.5−1.0 mL of this paste is injected into the liver tract) [54]. The use of purified islet allograft preparations has not resulted in main portal vein thrombosis in the Edmonton program, but thrombosis of a right or left branch or peripheral segmental vein has been encountered in approximately 5% of patients. Other rarely observed procedural side effects have included fine-needle gallbladder puncture, which has been avoided with the use of ultrasound-guided transhepatic portal venous access. Rarely, arteriovenous fistulae (which may require selective embolization) or hepatic steatosis have been observed [55].

Immunosuppressive Therapy and Complications

Islet transplantation for T1DM represents a unique challenge in immunosuppression, because both alloimmunity and islet-specific autoimmunity must be effectively controlled to preserve graft function. An additional important consideration is that many of the immunosuppressive agents used in solid organ transplantation since the 1960s, particularly corticosteroids, are known to be toxic to islets. Previously in the Edmonton Protocol, the induction agent daclizumab (anti-CD25 [interleukin (IL)-2R] antibody) was used, but this was replaced by basiliximab when daclizumab was no longer available for clinical use. Maintenance immunosuppression consisted of sirolimus combined with low-dose tacrolimus. This regimen, described initially at the University of Alberta, has been successfully replicated at other centers as part of a multicenter Immune Tolerance Network (ITN) trial [39,56]. More recently, induction with depletional therapies including thymoglobulin (6 mg/kg total dose) or alemtuzumab (30 mg intravenously) combined with the antiinflammatory agents etanercept (anti−tumor necrosis factor [TNF]) and anakinra (anti-IL receptor [ILR]) have been employed in the Edmonton program. We and others found that the more standard posttransplant combination of tacrolimus (6−10 ng/mL) and mycophenolate mofetil (up to 2 g/day in a divided dose as tolerated) is much better tolerated than sirolimus. The 3- and 5-year outcome data suggest more graft durability in terms of sustained insulin independence with this regimen, which has been encouraging.

In addition to the Edmonton Protocol immunosuppression described earlier, alternative regimens have been reported. The Minnesota Group, led by Dr. Bernhard Hering, used antithymocyte globulin (ATG) and etanercept (anti−TNF-α antibody) induction with a combination of sirolimus and mycophenolate mofetil with or without low-dose tacrolimus for maintenance, or hOKT3γ1 (Ala-Ala) (humanized anti-CD3 antibody) and sirolimus induction with sirolimus and reduced-dose tacrolimus for maintenance [47,48]. In some instances, alternative immunosuppressive agents have been used because of drug intolerance or other side effects. Islet patients often possess mild preexisting renal impairment as a result of long-standing diabetes, and this renal dysfunction may be exacerbated with calcineurin inhibitor therapy, even at the low doses involved in the Edmonton Protocol. The drug sirolimus may also have nephrotoxic side effects, which may be compounded when used in combination with a calcineurin inhibitor drug [57,58]. For these reasons, renal status must be monitored diligently in all patients after islet transplantation. In addition to its recognized nephrotoxicity, tacrolimus is associated with gastrointestinal side effects, which may lead to episodic diarrhea. Neurotoxicity may be seen with tacrolimus but is often avoided in

low-dose regimens [59]. Sirolimus is associated with neutropenia and mouth ulceration, but these side effects can be reduced with lower target trough levels and tablet formulations. In the context of islet transplantation, sirolimus has been linked to a number of side effects including dyslipidemia, small bowel ulceration, peripheral edema, and the development of ovarian cysts or menstrual cycle irregularities in female recipients [51,60]. Combined with the observation that sirolimus is extremely poorly tolerated at high doses in this patient population, this has led to avoidance of this drug within our program.

Although chronically immunosuppressed patients are at risk for developing all types of malignancy, squamous epithelial cancers most commonly occur and are most readily treatable. The Collaborative. Islet Transplant Registry reports an overall rate of less than 2% in islet transplant recipients [46]. The lifetime risk of lymphoma is estimated to be 1−2% in transplant recipients, but this risk is likely to be reduced in islet recipients, because these patients are generally not treated with glucocorticoids or OKT3.

FUTURE CHALLENGES

Overcoming Tissue Shortage

In its current form, islet transplantation is reserved for a small subset of patients with the most severe forms of T1DM. Even with the relatively small patient population selected for islet transplantation, the wait-list time for patients in Edmonton, which has access to organs from a large geographic region, ranges from 6 months to 2 years, depending on blood group. As islet transplantation becomes more suitable for a broader range of diabetic patients and as the incidence of diabetes increases, there will be an even more severe shortage of islet tissue for transplantation. Clinical islet programs rely on the scarce supply of pancreas organs derived exclusively from heart-beating, brain-dead cadavers. Compared with organs procured for whole-pancreas transplantation, which must fall within strict donor criteria, organs obtained for islet transplantation tend to be more "marginal" and come from older, less stable donors. Furthermore, the pancreas is particularly susceptible to toxicity from the circulating products of severe brain injury, hemodynamic instability, and inotropic support in a brain-dead organ or donation after cardiocirculatory death (DCD). The quality of the pancreas is further degraded by cold ischemic injury during transportation, which inevitably results in islet damage and loss. Brain death, with an acute cytokine and injury storm has been associated with islet injury, with consequential reduced islet recovery and viability compared to islet isolation in the absence of injury, at least in small animal models [61,62]. Because of the sporadic islet transplant experience with DCD pancreas donation in North America, a direct comparison with the standard neurological determination of death (NDD) donation has yet to be objectively conducted. A comparison study of clinical islet isolation success rates and transplantation outcomes between DCD and NDD pancreas donors from our center was published in 2015 [63]. Islet yields were similar between NDD and DCD. Likewise, metabolic function was similar between NDD and DCD, as well as the mean decrease in insulin requirement at 1 month after transplantation. Although these results support the broader use of DCD pancreata for islet isolation, a much larger DCD islet experience will be required to determine the noninferiority of both short- and long-term outcomes [63].

Unfortunately, once the pancreas is in the isolation laboratory, the extensive processing and purification steps during processing result in further islet destruction and loss, often resulting in at best 60% recovery of the estimated 10^7 IE/pancreas, [64]. As a result, nearly all islet recipients require islets derived from two cadaveric donors. Thus, a rapidly growing area of islet transplant research involves the development of improved cadaveric or alternative islet tissue sources for transplantation.

Living Donor Islet Transplantation

One approach to alleviating islet tissue demand would be to use living donors for islet transplantation. Living donor programs in kidney, liver, and lung transplantation have moved forward successfully at most leading transplant centers worldwide, in an attempt to meet the growing demand for donor organs and improve clinical outcomes. Long-term clinical outcomes of islet transplantation alone, in specialized centers, mirror the results of whole-pancreas transplant alone; over 50% of patients have achieved insulin independence 5 years after transplant [65]. However, apart from the University of Minnesota experiences [47] and those at the University of California, San Francisco (UCSF) [66,67], the rate of single donor islet transplant success remains low (10−15%) [68]. Therefore, most patients require multiple pancreas donors to achieve insulin independence. In addition, despite remarkable progress in clinical islet transplantation since 1999, islet supply and functional viability remain

significant challenges when islets are derived from cadaveric organ donors, even at the most experienced centers [61]. In the living donor setting, the distal half-pancreas could be procured under "ideal" circumstances without exposing the pancreas to hemodynamic instability or inotropic drugs, and the pancreas would be processed immediately without prolonged cold ischemia. Thus, the potency of islets derived from a living donor source is assumed to be far superior to cadaveric tissue. Living donor islet transplantation represents a unique opportunity to overcome donor organ shortage and procure the islet tissue under perfect conditions, with closer human leukocyte antigen matching between donor and recipient. Furthermore, the living donor islet transplant setting will provide a unique opportunity to develop protocols for pretransplant recipient conditioning for donor-specific tolerance induction.

Although cadaveric islet transplantation has been an active area of clinical research involving more than 1500 patients over several decades, only three cases of living donor islet allotransplantation have been reported [69–71]. Initially, the rationale of pursuing living donor islet transplantation originated from discouraging patient outcomes in the pioneering series of deceased donor islet allografts conducted in the late 1970s [72]; the first attempts at islet autografts (after pancreatectomy for chronic pancreatitis) proved to be more promising [71,73].

The first two clinical attempts at living donor islet allotransplantation were carried out in 1978 by Sutherland and colleagues at the University of Minnesota [70,71,73]. Although neither recipient achieved sustained islet function, these pioneering efforts were truly remarkable given the early stage of clinical islet transplant development at the time. The first recipient's graft was lost owing to a cytomegalovirus infection, and the second recipient lost function because of a sensitizing event as the result of a previously rejected kidney from the same donor (the recipient's sister) [72]. The immunosuppression available was primitive by current standards (azathioprine and high-dose steroids), and the islets were isolated using suboptimal conditions, before the development of the Ricordi chamber and sophisticated purification schemes currently used in clinical islet transplantation.

The dramatic improvement in clinical outcomes obtained in cadaveric islet transplantation since 2000 has renewed interest in developing living donor islet transplantation. The first living donor islet transplantation case attempted since the introduction of the Edmonton Protocol was carried out at the University of Kyoto in early 2005 [69]. The recipient, a 27-year-old woman, developed C peptide–negative, unstable diabetes after chronic pancreatitis as a child. Her 56-year-old mother was approved to be the donor, and islets were purified from the distal pancreas obtained during an open laparotomy. There were no surgical complications in either donor or recipient. The unpurified islet mass (408,114 IE [8200 IE/kg] in a volume of 9.5 mL after tissue digestion) was transplanted into the portal vein using the percutaneous approach under full systemic heparinization. Edmonton Protocol–style immunosuppression was started before transplant using sirolimus and low-dose tacrolimus (started 7 days before transplant), anti-IL2R antibody (given 4 days before transplant and on the day of transplant), and anti-TNF-α blockade induction (infliximab; given 1 day before transplant). Insulin therapy in the recipient was discontinued at 22 days after transplant; this patient continued to be insulin independent with excellent glycemic control and a normal HbA1C more than 1 year after transplant [74]. The donor presented no evidence of glucose intolerance, maintained normal HbA1C values, and was C-peptide positive 30 months after transplant [72,74].

Although no definitive conclusions can be drawn from this single successful case of living donor islet allotransplantation, results from living donor islet autotransplantation suggest that the insulin independence may be achieved routinely with significantly less IE/kg recipient body weight than has been required for cadaveric allografts thus far. It is widely accepted that over 70% of patients will remain insulin free after islet autotransplantation if an islet mass exceeding 300,000 IE ($\geq$2500 IE/kg) is transplanted, compared with the >10,000 IE/kg that is often required to achieve insulin independence with cadaveric islet preparations [75]. Reports from the Minnesota group showed that clinical islet autografts have a significantly lower rate of metabolic decay over time, even with a smaller islet implantation mass (<2500 IE/kg) [76]. The combination of single donor successes in islet allografts and the efficacy of a small islet mass required for insulin independence in islet autotransplantation have provided a stimulus for evaluation and potentially resurgences in living donor islet allograft programs [77].

Globally, living donors compromise a fraction of the pancreas–islet transplant (less than 1%); however, in countries with strict donor criteria and a severe donor shortage, such as Japan, living pancreas donors comprise over 20% of all organ donors [72,78]. Despite the potential risks for a living donor in terms of surgically induced diabetes and surgical complications [79], the demand for islet tissue, and the relative ease of implementing living donor protocols into established islet transplant programs, there is a likelihood that this approach may more forward, especially in countries with strict organ donor criteria.

Xenotransplantation

Living donor islet transplantation may circumvent the wait list for suitable donor tissue in some specialized cases; however, associated risks for the donor and the possibility of an insufficient islet yield to obtain insulin dependence remain significant concerns. Identification of a renewable and limitless xenogeneic source of islets would avoid the requirement for human islet donors altogether and could provide enough tissue to transplant diabetic patients as often as required. Pigs are particularly attractive as a xenogeneic islet source because they are widely available, produce insulin that is functional in humans, and could be selected for certain donor characteristics including genetic manipulation. For a few decades, it has been widely thought that of all of the experimental xenotransplantation strategies, islet transplantation is perhaps the closest to clinical application [80]. The first clinical case of islet xenotransplantation was conducted by Groth et al. in 1994, when fetal porcine islet cell clusters were placed under the kidney capsule [80]. Despite the lack of clinical benefit observed in this pioneering attempt of xenotransplantation, evidence that porcine islets could survive in the human body was demonstrated through the measurement of porcine C-peptide.

A limited small clinical experience was reported with porcine derived islets; however, few have resulted in reduced insulin requirements and no patients have achieved a period of insulin independence [81–83]. Despite these setbacks, islet xenotransplantation using porcine tissue has remained an active area of research, and progress has been made using preclinical nonhuman primate models implementing various genetic donor manipulation and immunosuppressive protocols [82,84–87]. Most notably, experimental studies have demonstrated that nonencapsulated pig islets (both wild-type and genetically engineered) have the capacity to maintain normoglycemia in immunosuppressed diabetic nonhuman primates for more than year after transplant [88,89].

The generation of α-1,3-galactosyltransferase–deficient pigs has provided a source of islet tissue lacking the major xenoantigens causing hyperacute rejection in pig-to-human xenotransplantation [90]. Still, it remains to be determined whether the transmission of endogenous retroviruses or other zoonotic infections from pig to human can be completely avoided in xenotransplantation, even with the establishment of highly monitored "clean" pig colonies [87,91,92].

The first nationally regulated clinical trial of intraperitoneal encapsulated (alginate-poly-L-ornithine-alginate) neonatal porcine islet xenotransplantation in nonimmunosuppressed diabetic patients was carried out in New Zealand and reported in 2014; it demonstrated a marginal reduction in hypoglycemic unawareness [93]. Curiously, the number of islets transplanted did not correlate to the clinical outcome, because the transplantation of 5000 IEq/kg was associated with better results than that of larger doses (15,000 and 20,000 IEq/kg) [88]. The authors speculated that the large islet mass was prone to oxygen and nutrient starvation, resulting in substantial islet loss.

Building on this first study, in 2016, Matsumoto et al. reported the results of a second nationally regulated clinical trial, conducted in Argentina, of encapsulated porcine islet xenotransplantation in nonimmunosuppressed patients with T1DM [94]. Differing from their initial clinical study, the islets were transplanted in two separate infusions 3 months apart, in the hope of reducing the hypoxia associated with large transplant volume. Patients received either 5000 IEq/kg × 2 or 10,000 IEq/kg × 2 of encapsulated neonatal porcine islets in the peritoneal cavity by laparoscopy (n = 4/group). Despite the demonstrated significant improvement in HbA1c and the reduction in hypoglycemic unawareness events for up to 2 years after transplant, the reduction in insulin dose was marginal [88,94]. There was no evidence of complications from the transfer of porcine endogenous retroviruses [95]. This second nationally regulated trial was indeed a progressive step forward for the field of clinical islet xenotransplantation; however, numerous aspects need consideration before large-scale clinical trials should be initiated [87].

Stem Cell Transplantation

Substantial research efforts have been made to identify suitable islet precursor cells that could be differentiated into a potentially unlimited source of insulin-producing β cells. Difficulties in producing physiologically regulated insulin secretion and control of proliferation have made progress in this area difficult to achieve histologically [96,97].

The pursuit of a renewable source of insulin-producing cells has led researchers to consider a multitude of tissue origins to derive these cells. The native pancreas contains progenitor cells capable of β-cell repopulation in the event of injury [98,99]. Given the proper environment and transcription factors, these cells can be directly reprogrammed into cells that closely resemble β cells [98,100]. Despite persuasive evidence that demonstrates the regenerative capacity the adult pancreas retains, it remains uncertain whether this ability is stem cell driven, because specialized cell types within or outside the pancreas indeed retain plasticity in proliferation and differentiation. As such,

inducing reprogramming or transdifferentiation of exocrine cells or other types of endocrine cells in the pancreas may provide a more efficacious approach to deriving insulin-producing cells.

Others have explored using hematopoietic stem cells as precursors to insulin-producing cells. This includes attempts to use bone marrow–derived cells in addition to umbilical cord blood (UCB). This was initially an exciting area of study, because UCB is easily obtained and would avoid some of the ethical implications associated with the use of stem cells. Unfortunately, early animal studies showed no conclusive evidence of endogenous β-cell replenishment after hematopoietic stem cell injection [101,102]. Even so, clinical studies have been conducted in type 1 diabetic patients. Haller et al. used stored autologous UCB infusions in newly diagnosed patients with T1DM, showing reduced insulin requirements and lower HbA1C [103]. A further study employing hematopoietic stem cells resulted in most of the 23 newly diagnosed patients with T1DM who received these cells achieving insulin independence and elevated C-peptide levels [104].

More recently, a prospective clinical study in which 20 adult patients with newly diagnosed T1DM were enrolled and randomized to mesenchymal stem cell (MSC) treatment or to the control group. One-year follow-up demonstrated residual β-cell function, as measured by serum C-peptide in response to a mixed-meal tolerance test, in the treatment patients in contrast to those in the control arm, who showed a loss of C-peptide. No side effects of MSC treatment were observed, which may constituted this procedure as a safe and promising strategy to intervene in disease progression and preserve β-cell function [105].

In addition, a study reported a single-center experience with suppressing T1DM progression by combining immunoablation and autologous hematopoietic stem cell transplantation (AHSCT) in newly diagnosed patients. During the 52-month median time of follow-up, 20 of 23 patients (87%) remained without the use of exogenous insulin for at least 9.5 months. Average HbA1C concentrations were 10.9% at diagnosis, 5.9% at 1 year, 6.4% at 2 years, 6.8% at 3 years, and 7.1% at 4 years after AHSCT. No severe complications of diabetes were seen; however, one patient died of pseudomonas sepsis in the course of neutropenia after AHSCT. Thus, AHSCT may lead to a remission of T1DM with good glycemic control in the vast majority of patients, with the period of remission lasting over 5 years in some [106]. The underlying mechanism of preserving endogenous β-cell mass using MSC has yet to be fully elucidated.

Owing to their pluripotency and ability to self-renew, embryonic stem cells (ESCs) have received an enormous amount of research attention. Since 2000, researchers have attempted to find the optimal set of conditions and signals to differentiate them into an insulin-producing cellular population. A number of the early attempts were conducted using rodent ESCs; although they were initially promising, they were limited by cell homogeneity, immaturity, the low number of insulin-positive cells, and a lack of glucose sensitivity [107–110]. It was not until 2004 and 2006 that an effective differentiation strategy was discovered, which paved the way for the differentiation of human ESCs (hESCs) into pancreatic endoderm cells (PECs) that contained both insulin and C-peptide [111,112]. Further refinement of the strategy allowed these cells to become glucose-sensitive, showing the ability to ameliorate diabetes in a rodent model [113]. Several alternative approaches have been developed to differentiate hESCs into pancreatic progenitor cells, which undertake the final stages of glucose-responsive β-cell differentiation in vivo [111,113–117]. Furthermore, advances in manufacturing PECs for clinical trials [118] and generating insulin-producing cells of increased maturity derived from hESCs or induced pluripotent stem cells (PSCs) in vitro have been reported with the capacity to restore normoglycemia rapidly compared with early progenitor cells [119,120].

In 2014, the US Food and Drug Administration and Health Canada granted ViaCyte Inc., a commercial leader in regenerative medicine technologies, permission to initiate the first-in-human pilot phase 1/2 clinical trial to test their VC-01 combination product in a small cohort of patients with T1DM. This product combines CyT49 hESC-derived PEC contained within a macroencapsulated immune-protective device transplanted subcutaneously (NCT02239354). It is hoped that early pilot results of this ongoing trial will the direct future progression of the field. Ongoing development of extrahepatic sites for stem cell–derived product implantation will likely require further optimization to improve engraftment, oxygen delivery, and metabolic exchange. However, it remains to be seen whether the transplantation of pancreatic progenitors in an immune-isolating device will be preferential to transplanting these or more mature glucose-responsive insulin-secreting cells into a retrievable prevascularized subcutaneous site in the presence of standard clinical immunosuppressive therapy.

In addition to ViaCyte, the commercial entities BetaLogics, and SemmaTherapeutics are continuing to perfect a protocol to differentiate PSCs into insulin-producing cells. ViaCyte's less differentiated PECs may prove longer to reverse diabetes compared with BetaLogics' and SemmaTherapeutics' more mature "β-like" cellular products; however, this time variable may not be the greatest concern for a patient with life-long T1DM, who may not mind waiting a few extra weeks to become insulin independent via stem cell differentiation.

Ethical and religious concerns regarding the use of ESCs remain, in addition to concerns pertaining to the risk of teratogenicity [121–123]. However, if a sustainable stem cell–derived, insulin-producing cellular product can be ethically derived from a donated, discarded human embryonic blastocyst from an in vitro fertilization clinic, a world supply of limitless β cells from one single discarded blastocyst could be achieved. Despite the remaining challenges, the clinical path for stem cell–derived therapeutic products has been paved, providing a tantalizing optimistic future for this β-cell replacement therapy to restore glycemic control to patients with insulin-dependent diabetes.

Optimal Transplantation Site

The intraportal infusion of islets in the liver has become the implantation site of choice, receiving more than 90% of clinical islet graft, and is the only islet microenvironment that routinely results in insulin independence. As the use of stem cell–derived β cells and xenogeneic islet sources becomes a clinical reality, an engraftment site that facilitates harmless retrieval may be compulsory. As a consequence, intensified research effort has been dedicated to pursuing alternative transplant sites [124–126]. It has been suggested that an optimal cellular transplantation site should (1) have an adequate tissue volume capacity; (2) be in close proximity to vascular networks; (3) have dynamic communication between the cellular graft and systemic circulation; (4) facilitate minimally invasive means to transplant, biopsy, and retrieve; and (5) elicit minimal inflammation [126].

The islet isolation process subjects islets to significant ischemic and physical injury, rendering them susceptible to posttransplantation stresses. Islets require ready access to oxygen and glucose and benefit from close proximity to a good vascular supply, because their revascularization is not immediate and their capacity for diffusion is limited. As an endocrine tissue, islets require a means to sample representative glucose levels and need to be able to deliver insulin through a relevant route to target tissues. Ideally, a transplanted islet should reside in a site with minimal immunological attack and low levels of posttransplantation β-cell apoptosis, such as that induced by the instant blood-mediated inflammatory reaction (IBMIR). From a surgical standpoint, it would be advantageous to have a transplant site that afforded minimal procedural complications and allowed one to monitor islets after implantation.

The portal vein–liver site has become the standard site in most islet transplants. An early rodent study showed this site to be superior with respect to the number of autologous islets required to reverse hyperglycemia [27]. However, further studies showed an eventual loss of islet function even in the absence of alloimmune or autoimmune attack [127]. Despite marked improvement in patient outcomes after intraportal islet infusion, the achievement of single-donor engraftment success has been challenging, because most recipients require at least two donors to achieve insulin independence [47,48]. The death of significant numbers of intraportal islets in the immediate posttransplant period from tissue factor–triggered platelet injury, the IBMIR, compounded by ischemia from immature revascularization contribute to impaired islet survival and function in the long term [128]. Various additional factors contribute to acute islet loss and graft attrition, particularly in the intraportal hepatic site, resulting in an estimated 70% loss of transplanted β-cell mass [129]. Finally, although islet infusion is relatively straightforward, there are possible complications, including bleeding and thrombosis. This site has indeed allowed islet transplantation to reach amazing clinical success, but there are clear reasons for a search to identify a clinically relevant, non–blood exposed extrahepatic site to optimize β-cell engraftment further.

Although the kidney subcapsular space has become the site of choice for many researchers employing a mouse islet transplant model, it has not shown promise in clinical practice. Major limitations of this strategy are surgical invasiveness, its systemic nature, nonphysiological glucoinsular response, hypoxia, and limited transplant volume capacity, coupled with differences in the renal capsule architecture between rodents and humans [130–133]. Although it is theoretically a tempting site, with its high oxygen content and proximity to endogenous islet location, the pancreas is relatively invasive to access and may potentiate the autoimmune attack of transplanted islets through the priming of local lymph nodes. Although the latter has not yet been proven, the usefulness of this site is nullified in the case of islet autotransplantation. Furthermore, limiting this site of islet implantation is the limited ability to retrieve and image, and the finite transplant volume capacity [134–136]. The formation of an omental pouch, created surgically using omentum and the parietal peritoneum, has shown efficacy in both rat [137] and dog [138] models of diabetes. Although necessitating a higher number of islets to reverse diabetes (compared with the renal subcapsular site), the omentum is a vascular, portal insulin delivery site and a possible location for implanting islet encapsulation devices [139–142]. A potential drawback to this site is the inability to retrieve and image and provoke an inflammatory response effectively. However, success in the first clinical patient at the University of Miami using BioHub technology has instilled a sense of renewed optimism for this site. A related structure in mice, the epididymal fat

pat, has been used successfully to transplant embryonic endocrine progenitor cells [113]. In addition, a pouch could be created laparoscopically, which minimizes the morbidity of surgery. Further research needs to be completed to determine the long-term survival of islets at this potentially useful site.

Researchers have shown that islets can be transplanted into the gastric submucosal space (GSMS) [143–146]. This site has many potential benefits including avoiding the IBMIR, a rich oxygen supply, and a high oxygen tension. In a preclinical animal study [143], it was shown that diabetic pigs receiving islets endoscopically into the GSMS fared better than did pigs receiving intraportal islets. Pigs in the former group showed less early islet loss and received less insulin to maintain normoglycemia. More recently, a technique of endoscopic-assisted biopsy of porcine islet allografts in this site demonstrated an additional benefit of the potential easy access for graft monitoring and biopsy [143–145]. This has become an exciting possibility for an extraportal site of islet graft deposition; further research should shed light on the potential for long-term graft survival at this site. Various immune privileged sites have also been investigated, including the brain [147–149], testis [150,151], thymus [152–155] and anterior chamber of the eye [156], which demonstrate promising preclinical results. However, the use of such a strategy to avoid chronic immunosuppression has yet to be translated to clinical islet transplantation.

In theory, subcutaneous transplantation should be superior to portal vein infusion because it provides ready access to the graft and the possibility of monitoring function through imaging [157–159]. However, transplantation of islets into an unmodified subcutaneous site has universally failed to reverse diabetes in animal models or in humans, owing to poor oxygen tension and inadequate vascularization [160]. Stimulation of angiogenesis is critical to successful subcutaneous islet transplantation [125,126,159,161]. Oxygen generators, polymers, meshes, encapsulation devices, matrices, growth factors, and cotransplantation of MSCs have all been explored with variable success.

Pepper et al. demonstrated the successful restoration of euglycemia using mouse and human islets in preclinical animal models, by using the subcutaneous deviceless transplant approach, which modifies subcutaneous tissue into a highly vascularized engraftment site by temporally exploiting the natural foreign body reaction to an implanted catheter [162]. This site was also efficacious in reversing diabetes after transplant in mice at a marginal islet dose [163]. This technical was further optimized and demonstrated the long-term durability of syngeneic islet grafts in mice [164]. The use of this transplant technique will be explored in a first-in-human trial planned at the University of Alberta.

Improving Engraftment Posttransplant

In clinical islet transplantation, islets derived from multiple donors are often required to achieve insulin independence, which suggests that a significant portion of the transplanted islets must fail to engraft and become functional. It has been estimated that up to 70% of the transplanted β-cell mass may be destroyed in the early posttransplant period [51,129]. Because this profound loss has been observed in both immunodeficient and syngeneic islet transplantation models, islet survival is likely regulated by non–immune mediated stimuli. After isolation, the islet microvasculature is completely disrupted, and upon implantation into the portal circulation, hypoxia persists whereas the islets revascularize, which can take up to 2 weeks [165–167]. During this engraftment period, the islets are continuously exposed to immunosuppressive drugs including tacrolimus and sirolimus, which are known to affect β-cell survival and function adversely [168,169]. These negative effects are likely compounded by the proximity of the transplanted islets and high concentrations of these drugs in the hepatoportal circulation, further degrading β-cell mass over time [170].

A critical process that may influence islet engraftment and survival in the early posttransplant period has been termed the IBMIR. Islets have been shown to express tissue factor naturally, a protein that acts as a receptor and cofactor for factor VII, an important mediator of the coagulation cascade [171]. Isolated human islets release tissue factor along with glucagon and insulin, which ultimately leads to platelet activation and binding at the surface of the islets. This causes the formation of a fibrin capsule around the islet and disruption of the islet morphology [128,129,171,172]. Most of this process has been characterized using an in vitro tubing loop model, so the true impact of this process in the clinical setting has yet to be fully characterized. However, examination of serum in patients undergoing islet transplantation has shown that a statistically significant increase in the serum concentration of thrombin–antithrombin complexes is present almost immediately after portal infusion, with peak levels occurring at 15 min, even when there was no clinical evidence of portal hypertension or intraportal thrombosis [171]. Because platelet activation is a primary contributing factor in the generation of an inflammatory response, IBMIR is probably an important early process in islet transplantation that elicits an immune response [128,129,171,172].

Many studies targeted at enhancing islet survival during the early posttransplant period have been published, and a variety of different strategies have been tested. Some groups aimed to enhance revascularization with vascular

endothelial growth factor, but these studies have not yet demonstrated that this approach significantly improves islet graft survival [173]. Anticoagulation strategies using injection of activated protein C or inhibition of thrombin have been studied as a means to inhibit IBMIR, but these interventions have shown only a modest benefit in a series of in vivo studies in animal models [172,174,175]. Anticoagulation with insulin−heparin peritransplant has aided in reducing the impact of IBMIR and increased single-donor islet engraftment success rates from 10% to 40% [176]. Clinical studies designed to prevent IBMIR, such as low−molecular weight dextran sulfate, are under investigation.

Because these processes described involve both extracellular (i.e., IBMIR) and intracellular (i.e., hypoxia) stimuli leading to β cell death, another approach to preserving β-cell mass in the early posttransplant period has been to directly inhibit the apoptotic triggers that ultimately lead to loss of islet mass after transplant. A variety of strategies have been explored in the experimental setting; although promising data have been generated in vitro, demonstration of in vivo benefit to islet graft survival has been more elusive [177−180]. Many studies have described inhibition of a variety of apoptosis-associated proteins, including cellular FLICE-inhibitory protein (prevents caspase-8 activation), A20 (inhibits nuclear factor-κB activation), Bcl-2, and Bcl-XL (mitochondria-associated antiapoptotic proteins) [177−182]. A20 has shown promise, because its overexpression reduced the islet mass required in syngeneic islet transplantation in mice [182,183]. Investigations using X-linked inhibitor of apoptosis protein, which inhibits the downstream effector caspases that function in the final common pathway of apoptosis, have demonstrated promise in both human and rodent models of engraftment and in promoting murine islet allograft survival [184−186]. However, this area of research is limited by its requirement for the genetic manipulation of islet tissue before transplant, which has proven to be variable and difficult to achieve in human islets. Also, these genetic alterations are most often regulated with viral vectors, which represent a highly controversial reagent for clinical use, especially in immunosuppressed transplant recipients.

Our group has investigated the use of small-molecule peptidyl pan caspase inhibitors to promote β cell survival during the posttransplant engraftment period. These data demonstrate that euglycemia can be achieved in more than 90% of transplant recipients after an 80−90% reduction in islet implant mass using mouse or human islets in a nonallogeneic transplant model in addition to porcine autografts [187−189].

Next-generation pan-caspase inhibitors, including EP1013 and IDN-6556, demonstrated augmented long-term engraftment using a marginal islet dose capable of restoring euglycemia effectively in transplant recipients in both small- and large-animal models [187]. We described the ability of the potent pan-caspase inhibitor F573 to reduce apoptosis effectively in murine and human islets. Furthermore, the authors demonstrated that F573 treatment could differentially augment islet engraftment in intraportal and extrahepatic transplant sites using full and marginal islet transplant doses in mice [190]. These data further suggest the therapeutic benefit of novel inhibitors in the clinical islet transplant setting. As such, the Edmonton group is investigating the use of next-generation pan-caspase inhibitor in their clinical islet program (NCT01653899).

Improved Immunomodulation: Toward Donor-Specific Tolerance

One unique component of islet transplantation in patients with T1DM is the possibility of recurrent autoimmunity, which may elevate the demand for immunosuppression. Indeed, it has been well-established using a rodent model of T1DM, the nonobese diabetic (NOD) mouse, that control of recurrent autoimmune reactivity to β cells is one of the most difficult obstacles to overcome in islet transplantation [191−193]. Although it has been challenging to study recurrent autoimmunity in clinical patients, some evidence exists suggesting that levels of autoantibodies to glutamic acid decarboxylase (GAD) and IA-2 increase after islet transplantation, although the direct impact of this phenomenon on graft survival has yet to be fully elucidated [194,195]. As such, translation of findings in animals to clinic has been challenging, as highlighted by a trial demonstrating that GAD65 immunization was ineffective in preventing islet destruction in patients with recent diabetes onset [196].

If recurrent autoimmunity alters immunosuppressive drug functional thresholds, this presents yet another problem in the context of islet transplantation, because many of the drugs are directly β cell toxic. Direct control of recurrent autoimmunity may enhance long-term graft function in islet transplantation. Attempts have been made to control autoimmunity at the time of diabetes onset using various immunosuppressive agents such as azathioprine, prednisone, cyclosporin A, or antithymocytic globulin, but no significant benefit was observed [197]. Clinical studies using a modified anti-CD3 (Ala-Ala) in patients with new-onset T1DM have demonstrated that this treatment significantly improved C-peptide responses in these patients, which persisted for up to 2 years after treatment [198]. More recently, the ITN reported the findings of the Autoimmunity-Blocking Antibody for Tolerance in Recently Diagnosed Type 1 Diabetes (AbATE) trial. This trail was the fourth with the monoclonal antibody teplizumab (anti-CD3) and demonstrated preservation of β cell function [199]. The AbATE trial demonstrated that in

responders, mean preservation of C-peptide continued at baseline levels for 2 years [200]. These results make a persuasive case for full-scale phase 3 trials designed with adequate doses to preserve C-peptide in newly diagnosed patients with T1DM [199].

Incorporation of this induction agent into clinical islet transplant protocols suggested that it may enhance insulin independence rates after single-donor infusion, which may be related to its ability to curtail β-cell autoimmunity in these patients [48]. Continued development of therapies targeted at regulation of autoimmunity will allow further refinement of immunosuppression protocols for islet transplantation in the future.

In all types of transplantation, the ultimate goal is to develop therapeutic protocols that involve a brief period of treatment only during the initial posttransplant period, followed by the complete withdrawal of all immunosuppressive drugs. This phenomenon has been termed "operational tolerance," because it may involve passive ignorance of the graft or a more active T-cell tolerance to the graft antigens. In experimental transplantation, the difference in these two types of response is important and can be measured using retransplantation of donor-type or third-party tissue, with tolerance resulting in acceptance of the donor-type graft and rejection of the third-party graft. In the clinical setting, however, the distinction may not be as critical, because both ignorance and tolerance would allow for reduction or withdrawal of immunosuppressive therapies. The most widely studied pathway to tolerance induction involves the inhibition of T-cell costimulation after T-cell receptor ligation. During an immune response, a T cell must receive "signal 2" through interactions between its surface molecule CD28 and CD80 or CD86 on the antigen-presenting cell to become fully activated. To disrupt this interaction, the extracellular portion of CTLA-4, which has a higher affinity for CD80/CD86 than CD28, has been artificially fused with human Fcγ to produce the soluble molecule CTLA4-Ig, designed for therapeutic purposes. CTLA4-Ig has been recognized for its potent immunoregulatory activity in murine models of T1DM, in which treatment of young NOD mice dramatically reduced the incidence of T1DM [201]. Our program and others demonstrated that CTLA4-Ig treatment in allogeneic islet transplantation can prolong graft survival but does not induce tolerance [202–204]. A high-affinity version of CTLA4-Ig called belatacept or LEA29Y has been developed for clinical use and has shown considerable promise in promoting allograft survival in nonhuman primates and in clinical renal transplantation [205,206]. Two compounds have been approved for use: abatacept (CTLA4Ig) and belatacept (LEA29Y), which block T-cell interaction with CD80/CD86 on antigen-presenting cells. The group at UCSF reported promising results with belatacept costimulation blockade combined with thymoglobulin (thymo)-based therapy [66]. This protocol allowed a calcineurin inhibitor–free maintenance therapy strategy and even permitted single-donor engraftment success. This same group studied the benefit of an anti-LFA-1 antibody called efalizumab [67]. Although effective in allowing tacrolimus-free maintenance therapy, it was withdrawn from clinical use owing to concerns regarding progressive multifocal leukoencephalopathy, and thus impeded the long-term follow-up.

A second costimulatory pathway that was examined in transplantation involves the interaction between CD40 on antigen-presenting cells and CD40L (CD154) on T cells, leading to T-cell activation. This interaction also promotes B-cell differentiation and the activation of antigen-presenting cells including macrophages and dendritic cells. Blockade of this pathway using anti-CD154 therapies demonstrated considerable promise in promoting tolerance induction in primate models early on, but further testing of the potent anti-CD154 blocking antibody (Hu5C8) was halted owing to unexpected thromboembolic complications in clinical trials [207–209]. The development of therapeutic antibodies targeting the CD40 molecule appears to avoid this negative side effect and should prove to be important in future clinical tolerance induction protocols in islet transplantation [210].

The combination of multiple immunotherapy approaches may prove to be most efficacious in achieving desirable, durable, long-term transplant outcomes. Blockade of IL-1 with anakinra, an IL-1 receptor antagonist, has become important in treating inflammatory conditions including rheumatoid arthritis [211]. In clinical islet transplantation, improved efficacy was demonstrated when combined iodixanol-based islet purification, thymoglobulin induction, and blockage of IL-1β and TNF-α was implemented [212]. Our own laboratory investigated the combination of TNFα and IL-1 blockade and found them to be synergistic in promoting islet engraftment in mice [213].

Bellin et al. reported a comprehensive study in which patients receiving anti-CD3 monoclonal antibody alone or ATG or alemtuzumab plus TNF-α inhibition exhibited substantial long-term insulin independence compared with patients treated with anti-IL-2R [214]. Furthermore, these outcomes were comparable to that seen with pancreas transplant alone. Findings support the potential for long-term insulin independence after transplant using potent induction therapy, with anti-CD3 Ab or T-cell depletion with TNF-α blockage [214].

SUMMARY AND CONCLUSIONS

β-cell replacement through islet transplantation presents the best opportunity to treat T1DM and prevent long-term serious complications associated with this disease. The concept of islet transplantation is not new, but investigators struggled to find success in achieving insulin independence until the introduction of the Edmonton Protocol in 2000. This has provided hope for many patients with diabetes, but in its current form, islet transplantation is reserved only for patients with the most severe disease. Restoration of endogenous-regulated insulin by the liver through intraportal islet transplantation has been highly effective in mitigating hypoglycemic reactions, and current data from Edmonton indicate that almost 70% of patients continue to secrete measurable C-peptide by 18 years after transplant, which greatly improves the quality of life for many patients [45]. Although up to 80% of recipients may attain insulin independence at 1 year after transplant, insulin independence has tended to wane over time. Protocols from the leading centers suggest that insulin independence may be maintained in up to 50% of patients by 5 years after transplant, but Collaborative Transplant Registry data collected across a larger number of participating centers still suggests that insulin independence is maintained in a much lower proportion over time.

However, the requirement for islets derived from two or more cadaveric donors severely limits the availability of this procedure. There are multiple opportunities for intervention throughout the entire process, from pancreas procurement, shipment, and islet processing to strategies for enhanced islet survival after implantation. Priority areas for clinical trials include the expansion of living donor protocols, interventions to impede the IBMIR process, and the use of nondiabetogenic and more "islet-friendly" immunosuppressive and tolerance-induction strategies to control both autoimmunity and alloimmunity effectively. Strategies targeted at preserving β-cell mass throughout the process will have a substantial and immediate impact on islet transplantation by reducing the amount of islet tissue necessary to reverse diabetes. Once some of these obstacles are overcome, islet transplantation will become available to a broader population of patients with T1DM, especially those early in the progression of the disease who will benefit most because the development of serious chronic secondary complications could be avoided.

Prenatal Cell- and Gene-Based Therapies for Regenerative Medicine

Graça Almeida-Porada, Christopher D. Porada

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

Regenerative medicine promises the restoration of structure and/or function of deficient or damaged tissues and organs, with the goal of finding a way to cure previously untreatable injuries and diseases [1].

When contemplating the use of regenerative medicine during the prenatal period, one must first consider which diseases could benefit the most from such treatment. For example, in inherited metabolic diseases such as Lesch–Nyhan, Tay Sachs, and the acute neuropathic forms of Gaucher, a considerable amount of irreversible neuronal damage occurs during embryonic and fetal development [2]. The damage that these diseases exert during gestation cannot be entirely reversed after birth, causing even the most advanced treatments given to these patients postnatally to fall short of full therapeutic benefit [3]. Hence, the most compelling rationale for using regenerative medicine approaches during gestation is the ability to treat diseases early enough in development to prevent the onset of structural or metabolic damage, and thereby avoid the devastating manifestations that would otherwise occur before birth. Even in patients with diseases that can be cured postnatally, a persuasive argument can be made for the psychological and financial benefits of performing correction in utero, because it would allow the birth of a healthy infant who ideally would require no further treatments.

Remarkable advances in prenatal imaging, such as high-resolution ultrasonography and high-throughput molecular techniques, have improved the ability to identify diseases early in gestation by using fetal cells, or cell-free fetal DNA present in the maternal blood [4], the latter of which essentially eliminates any risk to the fetus during diagnosis. Importantly, these technical advances have not only improved the ability to identify diseases early in development, they have made it possible to deliver therapies safely to precise anatomic sites within the early-gestation fetus. Therefore, preemptive fetal regenerative medicine would entirely transform the current treatment of genetic disorders [5], allowing physicians to intervene before clinical manifestations of disease. It is also worth mentioning that the environment within the uterus provides a sterile platform in which to manipulate a fetal recipient. For instance, if one considers the treatment of an immunodeficiency, the maternal womb functions as a sterile incubator, allowing immune reconstitution before exposure to pathogens [5].

In this chapter, we review the therapeutic rationale for using in utero stem cell transplantation (IUTx), and/or in utero gene therapy (IUGT) in the context of regenerative medicine and examine crucial experimental data to support their use. We discuss the fetus as a target for regenerative medicine and the biological barriers that have thus far precluded more widespread clinical application/success of prenatal regenerative medicine, and we illustrate some of the unique advantages the fetal patient possesses, as well as some of the potential risks that will need to be addressed before clinical implementation.

FETAL DEVELOPMENT AND REGENERATIVE MEDICINE

There are several biological advantages unique to fetal development that provide compelling evidence to believe that for certain genetic disorders, regenerative medicine approaches such as stem cell transplantation and/or gene

therapy would be far more efficient and effective if administered during fetal life rather than postnatally. Because hematopoietic stem cells (HSC) were the first cell type tested for IUTx and they are the cell type that has been used in most IUTx studies, this chapter will focus on the use of HSC in IUTx. However, other cell types have also been explored in the context of IUTx. The choice to use HSC for IUTx was based on the ability of HSC to self-renew and differentiate into all of the mature hematopoietic lineages, which make them well-suited for treating a broad range of hematopoietic disorders. Equally important, their property of self-renewal allows successful HSC transplantation to result in lifelong correction. HSC have been the subject of intense study for decades and are the most comprehensively characterized stem cells in the body. They are one of the only stem cells in the body that has been isolated to relative purity, and much of what we know about the biology and behavior of stem cells in general is based on the paradigm that experiments with HSC established.

The initial rationale for performing HSC IUTx was based on the expectation that normal developmental events such as (1) the lack of a fully functional immune system, (2) migration of HSC from the liver to the marrow, and (3) the development of new hematopoietic niches occurring during the emergence of the hematopoietic/immune system would collectively create the proper setting to facilitate engraftment of allogeneic cells, thereby avoiding the complications and toxic myeloablative conditioning associated with postnatal bone marrow (BM) transplantation [6].

Definitive hematopoiesis commences in the yolk sac and/or aorta−gonadal−mesonephric region, migrates to the fetal liver, and finally transfers to the BM, where it resides postnatally for the remainder of life [7]. In addition, during fetal development, large-scale migration of stem cells occurs to seed tissue compartments [8]. It was therefore expected that the normal fetal biology would allow transplanted cells to piggyback onto the naturally occurring processes of migration, engraftment, differentiation, and expansion. Looking specifically at hematological disorders, it was presumed that donor reconstitution of the defective hematopoietic compartment would occur without the need for cytotoxic myeloablation, which is a primary cause of the severe morbidity and mortality associated with postnatal BM transplantation. Unfortunately, it is now recognized that the fetal hematopoietic system is highly competitive and represents a daunting barrier to engraftment of transplanted adult HSC [9−11]. However, if postnatally derived HSC possessing proliferative capability similar to that of fetal sources were able to be identified, or the regulatory signals controlling the migration of HSC and their seeding of nascent marrow niches were better understood, it is likely that these processes could ultimately be manipulated to drive the engraftment of donor cells [12].

A distinct advantage of delivering either cellular or genetic therapies during the fetal period, over a pediatric or adult patient, is the very small size of the fetus. At 12 weeks of gestation, the point in development at which prenatal therapy would commence, the human fetus only weighs roughly 35 g [4]. Therefore, it is possible to administer much higher cell or vector doses on a per-kilogram basis than could be achieved after birth. The ability to achieve much higher vector-to-target cell ratios should greatly enhance the efficiency of transduction. In addition, the ability to administer a small volume of vector and achieve the desired rate of transduction is of additional benefit from a technical and logistical standpoint, because the large-scale production of certain vectors under good manufacturing practice conditions is often extremely difficult.

Additional aspects of the developing fetus that make it a more suitable gene therapy recipient than the adult are the highly proliferative state of the stem or progenitor cells present throughout the body and the accessibility of these cells. γ-retroviruses and lentiviruses have received a great deal of attention as gene delivery vectors, owing to their ability to integrate into the genome of the host cell. This unique property allows transduction of a long-lived cell to provide lifelong therapy. In the adult, most stem cell populations are relatively quiescent, and they are often inaccessible, because of their tissue distribution and/or the presence of anatomic barriers. As a result, these promising vectors have often yielded fairly low levels of initial transduction and only a limited degree of expansion of transduced adult cells occurs after gene therapy, which have often prevented therapeutic levels of gene correction. During specific developmental periods, however, stem and progenitor cell populations are present at a relatively high frequency in most tissues and may be accessible to gene transfer, providing a unique window of opportunity for gene transfer to these expanding nascent stem cell populations, which will be inaccessible later in life [6,13]. In the fetus, the cells in all of the organs are actively cycling to support the continuous expansion that occurs throughout gestation. Thus, most cell types that are largely quiescent in the adult are far more mitotically active in the fetus. As such, these cells should be far more amenable to genetic correction with vectors requiring cell division. Although the active cell cycling in the fetus enables efficient transduction with vectors that require mitosis, this ongoing proliferation in all of the fetal organs is also beneficial when using vectors that do not have an absolute requirement for mitosis. The active cycling of the cells in all of the organs to support the continuous expansion that occurs throughout gestation should result in expansion of the gene-corrected cells during the remainder of gestation,

allowing initial transduction of even small numbers of target cells to result in significant levels of gene correction by birth. Clearly, being able to take full advantage of this fetal expansion will likely require the use of vectors that integrate into the host genome, because vectors based on nonintegrating viruses, such as adenovirus, or those that integrate only rarely, such as adeno-associated virus (AAV), will largely be lost during cellular division, causing cessation of a therapeutic effect.

In addition to the ability to access nascent stem cell populations, fetal biology provides one of the most compelling reasons to deliver cellular or gene therapies in utero: the possibility of inducing donor-specific immune tolerance [14]. Early in gestation, the emerging immune system is shaped by a process of self-education. In the fetal thymus, prelymphocytes that recognize "self"—major histocompatibility complex (MHC) are preselected, and any of those that exhibit the ability to recognize, with high-affinity, any of the myriad self-antigens in association with self-MHC, undergo deletion [15]. This process thus strives to create an immune system devoid of self-reactive lymphocytes (which could later lead to autoimmunity) and is populated with a diverse repertoire of lymphocytes that are able to recognize foreign antigens in association with self-MHC [6,16]. Therefore, the introduction of allogeneic cells or foreign proteins by IUTx, with subsequent presentation of exogenous antigens in the thymus, before the completion of thymic education, should lead to the deletion of alloreactive T cells, creating donor-specific or protein-specific immune tolerance.

Looking specifically at IUGT, the immature immune system of the fetus should enable the delivery of immunogenic transgenes or viral vectors that would be rejected by the intact immune system of a postnatal patient. For example, most of the world's population has been exposed to, and harbors antibodies to, the capsid proteins in various serotypes of AAV, which makes postnatal gene delivery with these valuable vectors difficult. Intervening in utero, before maturation of the immune system, would likely allow efficient gene transfer with these vectors, because these antibodies are not present. With respect to the transgene, many patients have the genetic diseases that are targeted with postnatal gene therapy because they do not produce a specific protein. As a result, their immune system has never "seen" this protein, and, after gene therapy, the cells of the immune system seek to eliminate any cells in the body that are expressing the very protein that could cure the patient of his or her disease. The low levels of gene delivery to the desired target cells and the immune response combine to yield low levels of expression of the therapeutic protein, and even these small amounts are often produced only for a short time. Performing IUGT could induce a state of tolerance to the transgene and perhaps to the vector itself, which not only ensures long-term, stable transduction and expression but should make it possible to administer postnatal "booster" treatments (if required) with the same vector and transgene without eliciting an immune response. An important caveat to inducing tolerance to the vector, however, is that such tolerance could potentially render the individual susceptible to postnatal infection with the wild-type virus on which the vector was based. Such an outcome is clearly undesirable; preclinical animal studies will be needed to determine whether this risk exists.

PRECLINICAL ANIMAL STUDIES OF IN UTERO STEM CELL TRANSPLANTATION

In 1945, Owen [17] described for the first time that the shared placental circulation present in monochorionic dizygotic cattle enabled an intrauterine exchange of circulating HSC that resulted in lifelong hematopoietic chimerism and donor-specific tolerance to the twin [17—19]; reports of natural chimerism in both nonhuman primate and human twins followed years later [20,21]. The presence of hematopoietic chimerism led to a lack of alloreactivity between the two siblings, and in the case of dizygotic human twins, the frequency of chimerism was relatively high (8% for twins and 21% for triplets) [22,23]. Because these levels of chimerism would be sufficient to exert a therapeutic effect in most hematologic diseases [6], these findings provided compelling evidence that allogeneic hematopoietic cells could engraft and induce durable immune tolerance if introduced early during fetal development; they inspired scientists decades later to consider using IUTx to treat hematopoietic disorders.

Although these "experiments of nature" hinted at the therapeutic potential of IUTx, these natural chimeras result from placental vascular anastomoses. As such, there is a continuous exchange of blood and contact with allogeneic cells and antigens beginning very early and persisting throughout gestation [24]. Unfortunately, it would likely be impossible to recreate this process experimentally, or ultimately, in a clinical setting to treat human patients. With this caveat in mind, however, these exciting findings provide the scientific basis for the therapeutic promise of IUTx, and for its ability to induce donor-specific immune tolerance, and they have served as the impetus to realize IUTx's clinical potential.

These observations in dizygotic twins are important because they provide compelling evidence that the immunological tolerance induced by IUTx can facilitate maintenance of the donor hematopoietic cells. Perhaps even more

exciting has been the realization that even if the levels of donor cell engraftment after IUTx are insufficient to be curative or therapeutic, one could exploit the antigen-specific tolerance induced by IUTx and administer postnatal "booster" transplants of same-donor HSC to achieve therapeutic engraftment without having to employ toxic myeloablation [25–27], or possibly even transplant same-donor solid organs.

With respect to using IUTx to induce donor-specific tolerance to permit subsequent transplantation of a same-donor organ, Billingham and colleagues performed groundbreaking experiments in the 1950s [14] that provided the first experimental evidence that IUTx with allogeneic cells could indeed induce donor-specific tolerance that permitted successful postnatal grafting of skin in mice. Given the robust nature of the immune response that is formed to third-party skin [28], this was a remarkable achievement and provided unequivocal proof of the durability of the induced state of tolerance. However, despite the demonstrated potential for in utero hematopoietic chimerism to induce immune tolerance, it was not until nearly 20 years later that Fleischman and Mintz began to explore the possibility of performing experimental IUTx with the goal of engrafting donor (allogeneic) HSC. Using a line of c-kit–deficient mice with genetic anemia, these innovative investigators showed that performing IUTx with allogeneic adult BM HSC reversed genetic anemia [29]. These important studies revealed another interesting aspect of donor cell engraftment after IUTx: the extent to which the donor cells repopulated the erythroid compartment of the recipient was directly correlated to the degree of anemia present. As a result, the erythroid compartment of lethally anemic homozygous mice was rapidly and completely replaced with donor-derived erythropoiesis, whereas donor-derived erythropoiesis was far less in mice with mild anemia. Mintz continued his work with IUTx, and ultimately made the striking discovery that erythroid reconstitution could be achieved in this model following IUTx with just a single HSC [30].

These early studies were predominantly performed with the goal of gaining a better understanding of HSC biology rather than trying to develop IUTx as a potential therapy. Nevertheless, these studies provided the first evidence that host cell competition could act as a barrier to donor cell engraftment after IUTx, a realization that would ultimately prove critical to successful clinical implementation of IUTx. It was almost 20 years from Mintz's initial report before independent confirmation came for the ability to achieve robust hematopoietic chimerism after IUTx in stem cell–deficient recipients [31], when Bruce Blazar demonstrated that only cells of the lymphoid lineage were reconstituted when mice with a T-cell defect were treated by IUTx [32,33]. These studies reaffirmed the concept that in the presence of a lineage deficiency, IUTx is able to reconstitute the defective lineage, but donor cells contribute minimally, if at all, to other hematopoietic lineages. These findings thus suggested that achieving clinically meaningful levels of donor cell engraftment after IUTx in recipients with a competitive hematopoietic compartment was likely going to be far more difficult than initially appreciated. Indeed, early IUTx studies in immunocompetent, wild-type mice consistently reported very low engraftment rates, and it was soon reported that immunodeficient mice engrafted much more efficiently than wild-type [33,34].

Since these initial pioneering murine studies nearly a half century ago, the field of IUTx has made substantial advances, moving first to large-animal models and ultimately to human trials. The first report of the engraftment of allogeneic cells after fetal transplantation in a large-animal model was made in sheep [35]. Among the various animal models for studying IUTx, sheep have proven to be particularly valuable as a preclinical tool. Fetal sheep provide a natural, unperturbed environment in which to study IUTx. Moreover, if IUTx is performed early enough in gestation, xenogeneic cells are not rejected, which makes it possible to study the engraftment and differentiation capacity of a variety of human stem cells [36]. Although it may not be readily apparent, sheep actually share many important physiological and developmental characteristics with humans. Importantly, the results of extensive studies of mammalian development and fetal physiology obtained in the sheep model have been directly applicable to an understanding of human fetal growth and development [37]. In contrast to most large animals, e.g., dogs and pigs, that tend to have large litters, sheep, like humans, typically have only one or two offspring in each pregnancy. In addition, sheep are similar in size and weight to humans during gestation, at birth, and even as adults. This makes it possible to develop and test clinically relevant doses of cells and vectors in this model, and then to translate the outcome directly to the clinic without the need for costly and often complicated scale-up. In addition, their immune system and hematopoietic development during fetal ontogeny have been thoroughly delineated and parallel those of humans [38–41], which make this model ideal for investigating the immune facets of IUTx (and IUGT). Also, sheep in captivity normally live for 8–10 years. This long life span allows important issues such as long-term efficacy and safety to be carefully evaluated.

The fetal sheep model has also had a critical role in defining the phenotype of long-term engrafting human HSC and was responsible for identifying several novel human stem cell markers/phenotypes, such as $CD34^{+}CD38^{-}$, $HLA\text{-}DR^{-}$, $Thy\text{-}1^{+}$, CD133, KDR, and $CD34^{-}$ [42–46], which underscores the high translational value of data obtained with this model. The sheep model has made it possible to define the role of the marrow microenvironment

in the engraftment of HSC after IUTx [37,47–49] and has also proven to be a valuable preclinical model in which to study HSC mobilization; engrafted human hematopoietic cells respond to human cytokines similarly to their native counterparts [50]. These data collectively support the utility of the fetal sheep model to develop and test IUTx (and IUGT) approaches and obtain clinically relevant results.

Like sheep, the canine model has been shown to accept xenogeneic transplants, and low-level multilineage hematopoietic engraftment has been demonstrated in hematologically normal dogs [27]. More recently, Flake and colleagues showed that the levels of hematopoietic engraftment in canine recipients after IUTx are sufficient to (1) ameliorate or cure the clinical phenotype of the canine analog of human leukocyte adhesion deficiency (canine leukocyte adhesion deficiency), and (2) induce donor-specific tolerance in some animals that is adequate to facilitate postnatal "boosting" of chimerism using a low-dose, busulfan-conditioning regimen, followed by transplantation of same donor T cell–depleted BM [27,51–53]. In addition to sheep and dogs, IUTx has been performed in pigs [54] and goats [55,56], and low-level engraftment has also been achieved after IUTx in nonhuman primates [57–60]. Subsequent studies in the pig model provided compelling evidence that IUTx with adult BM-derived HSC induced immune tolerance that enabled postnatal transplantation of a solid organ (kidney) allograft [61]. These exciting studies suggest that one day it may be possible to use IUTx to induce immune tolerance in fetuses with congenital abnormalities that require postnatal organ transplantation.

Despite the unquestionable clinical value of large-animal models, the low cost, simplicity of handling and housing, and ease of genetic manipulation have led investigators to use mouse models extensively to probe various components of the immune system to understand the mechanism(s) better by which IUTx induces immune tolerance. Flake, MacKenzie, Peranteau, Shaaban, Nijagal, and colleagues have performed elegant studies that collectively have provided compelling evidence that clonal deletion, anergy, and induction of donor-specific T regulatory cells (Tregs) all have important roles in establishing chimerism and inducing tolerance after IUTx [62–65]. These murine studies also revealed that even very low levels of allogeneic HSC (1–2% engraftment) are often sufficient to induce postnatal tolerance successfully across full MHC barriers, as long as a certain "threshold" level of chimerism is achieved and maintained [66]. Subsequent work by Shaaban et al. provided evidence that this engraftment threshold is likely governed by natural killer (NK) cell tolerance [67].

Collectively, these results in small and large animals have clearly demonstrated the technical feasibility of IUTx, validated its ability to induce donor-specific tolerance, and clarified some of the pathways that are required for tolerance induction. Although it is possible that the human immune system will present its own unique challenges, these animal studies establish an essential foundation for the ultimate clinical application of IUTx.

Barriers to In Utero Stem Cell Transplantation Success

One of the driving assumptions behind IUTx was that a so-called "window of opportunity" existed before the appearance of mature T cells in the fetal thymus and peripheral circulation (~12–14 weeks of gestation in the human fetus) [16] during which the fetus should be "preimmune" [68]. However, accumulating data from numerous experimental studies made it increasingly clear that significant barriers existed that prevented successful engraftment after IUTx unless the recipient possessed a lineage-specific defect, e.g., anemia or severe combined immunodeficiency (SCID), that could confer a competitive advantage to the donor cells [68–73]. It was the surprising findings of Peranteau [74], however, that conclusively dispelled the belief that the fetus is truly "preimmune," by showing (in mice) that IUTx with congenic cells produced more consistent engraftment and at higher levels compared with phenotypically identical allogeneic cells. These studies provided some of the first concrete evidence that the fetal immune system poses one of the major barriers to engraftment after IUTx. Further analysis of these congenic and allogeneic IUTx recipients revealed that although 100% of allogeneic and congenic recipients maintained high levels of engraftment up to 3 weeks after IUTx, 70% of allogeneic animals lost their engraftment between 3 and 5 weeks whereas congenic animals all remained chimeric [74].

The authors confirmed the presence of an adaptive cellular and humoral alloresponse that was quantitatively higher in nonchimeric versus chimeric animals, which placed these results at odds with a wealth of prior data, much of which was from this same group, and demonstrated long-term chimerism in a percentage of recipients (both mice and other animals) after IUTx and the presence of deletional tolerance. A possible explanation for this seeming discrepancy came from the authors' subsequent observation that allo-IUTx pups placed with surrogate mothers maintained their chimerism in the long term, and they became tolerant to the donor via a mechanism of partial deletion of donor-reactive T cells and the induction of a potent Treg response [63,75]. These findings suggested that IUTx can trigger maternal alloimmunization and that subsequent transfer of alloantibodies to the pup via breast milk resulted in the loss of chimerism.

In an independent, contemporaneous series of murine IUTx studies, Nijagal, MacKenzie, and colleagues provided further evidence that fetal intervention can trigger maternal alloimmunization. However, data from these studies led the authors to conclude that the trafficking of maternal T cells to the fetus was responsible for the loss of chimerism rather than alloantibodies in the breast milk [64,76]. Of course, one must recognize that placentation, maternofetal antibody−cell trafficking, and the time course of events after IUTx are likely to differ considerably between mice and large animals or humans. Nevertheless, these findings raise the important question of whether maternal immunization can limit engraftment after IUTx, and it may be an issue that needs to be considered when applying IUTx clinically. Until this question is addressed in clinically predictive large-animal models, the prevailing consensus in the field is that it may be prudent to use maternal cells in any clinical application of IUTx to eliminate the possibility of triggering a maternal immune response.

Although the preceding studies were well-designed and the data appear to be beyond reproach, Shaaban and colleagues made the astute observation that the maternal immune system has been intact in all human patients who have thus far undergone IUTx for a variety of diseases, despite the nature of the clinical outcome (success or failure). This group logically contends that these clinical data argue strongly against maternal immunity having an important role in engraftment failure after IUTx [67,77]. This group spent several years investigating the ontogeny of the fetal immune system in an effort to establish which cells or pathways present at the time of IUTx could account for the apparent immune barrier to engraftment of allogeneic cells. These authors identified a subset of early alloreactive NK cells within the fetal liver, which they thought might pose a barrier to engraftment of transplanted cells as early as the end of the first trimester in humans. This conclusion is supported by subsequent work from the same group, showing that it is possible to achieve engraftment of allogeneic cells reliably and consistently after IUTx if NK cells are depleted from the fetus, but not from the mother [67,77,78]. Intriguingly, the authors also found that the levels of early chimerism required to induce NK cell tolerance agree precisely with the threshold levels of engraftment that were discussed earlier. In further work, this same group established a possible mechanistic link between the induction of prenatal NK cell tolerance and the process of trogocytosis, which explains how levels of engraftment of only 1−2% could result in the exposure of donor antigens to a sufficient number of NK cells to induce donor-specific tolerance reliably [79]. Although these important findings have not yet been reproduced in large-animal IUTx models, these sophisticated studies collectively argue persuasively for the import role fetal NK cells have in achieving engraftment of allogeneic cells after IUTx, as occurs in postnatal HSC transplantation.

In addition to the possible immune response of the fetus and/or mother to the donor cells, host cell competition presents a significant barrier to engraftment of allogeneic HSC after IUTx. In postnatal HSC transplantation, the recipient is myeloablated before infusion of the donor cells to suppress endogenous hematopoiesis and create space within the BM niches for the infused cells. After IUTx, the situation is drastically different, however; the infused donor cells must compete against the robust endogenous fetal hematopoietic system. Studies in c-kit−deficient mice have lent strong support to the idea that donor (adult) cells may have a competitive disadvantage in the fetal environment by showing that in the absence of host competition, as few as one or two normal HSC can fully reconstitute the hematopoietic compartment after IUTx [29]. Similarly, IUTx studies performed in SCID mice illustrate the importance of host cell competition [32], in that donor cells completely repopulate the defective lymphoid lineage of the recipient. However, when no defect is present, the scale tips dramatically in favor of the endogenous fetal HSC, which have a marked competitive advantage over their adult-derived counterparts [9] owing to their accelerated or enhanced cycling and expansion kinetics. Data from the congenic mouse model of IUTx provide a striking example of how profoundly this competition from endogenous hematopoiesis can limit long-term donor cell engraftment. In this setting in which no immune barriers exist, even when investigators delivered massive doses of 2×10^{11} donor cells/kg, levels of long-term donor cell engraftment never exceeded 10% [74].

The limited number of available niches and the proliferative capacity of the fetal environment have also been suggested to serve as a barrier to successful IUTx [80]. For donor cells to engraft successfully, they must be able to compete favorably with the host cells for available hematopoietic niches. Support for this concept was provided by studies in which more competitive fetal donor cells or larger doses of adult cells were shown to enhance the success of IUTx [12,81]. Selective depletion of host HSC before BM transplant resulted in high rates of engraftment in adults, so it stands to reason that improved competition for available host niches after IUTx should also lead to higher levels of early chimerism. However, no evidence was found to suggest that quantitative or qualitative differences exist in the number of HSC or available niches in patients with SCID compared with patients with the range of other disorders that have proven refractory to correction by IUTx [82,83]. The absence of such data makes it hard to explain the marked difference in donor cell engraftment after IUTx in immunodeficient versus nonimmunodeficient recipients by invoking a competitive niche model [67]. Nevertheless, it is reasonable to assume that the fetal marrow indeed possesses a finite number of hematopoietic niches that are available for donor cells after IUTx,

given studies in an allogeneic and xenogeneic fetal sheep model showing that a plateau of engraftment efficiency is eventually reached as one increases the dose of donor cells administered [84]. Along these same lines, another study also performed in the sheep model showed that administering busulfan to the pregnant ewe 6 days before IUTx led to a significant increase in donor cell engraftment [85]. Although instructive, it is doubtful that using a highly toxic myeloablative agent during pregnancy would be deemed acceptable in humans. Studies from MacKenzie's group demonstrated that it was possible to achieve therapeutic levels of engraftment after neonatal transplantation [86] with none of the cytotoxic effects of an agent such as busulfan, by selectively depleting the host HSC in utero using an antibody to the c-kit receptor. Although these two studies collectively support the notion that chimerism can be significantly enhanced after IUTx by emptying host HSC niches before donor cell infusion, additional studies are clearly needed to identify ways to optimize the beneficial effects on donor HSC engraftment while minimizing fetal and maternal risks.

Preclinical Animal Studies of In Utero Gene Therapy: Hemophilia A as a Model Genetic Disease for Correction by In Utero Gene Therapy

Multiple outstanding reviews have been written discussing IUGT in detail [5,6,87,88]. For this reason, in this section we will briefly highlight some of the key advantages and risks to this approach, focusing much of our discussion on hemophilia A (HA), using this disease as a paradigm to illustrate the utility of IUGT for treating or curing a wide array of genetic diseases. Gene transfer using viral vectors exploits the natural ability of the parent virus to attach to a target cell efficiently and transfer its genetic material to the host cell nucleus. However, viral vectors are engineered to be devoid of most if not all viral genes, thereby rendering the vector incapable of replication and avoiding the expression of potentially immunogenic and/or toxic viral genes. Although a complete vectorology discussion is beyond the scope of this chapter, the specific vector to be used for a given IUGT application will depend largely on one's goals and the disease and/or cell type being targeted and should be selected after careful consideration of factors such as the ability to integrate into host genomic DNA, tissue tropism, packaging capacity, and potential immunogenicity. An "ideal" vector should possess the ability to target a specific cell type/organ selectively and to mediate sufficient levels of gene transfer (and subsequent transgene expression) to produce a therapeutic effect with only a single treatment. Clearly, however, the ideal vector tropism will vary depending on the disease to be treated. As we will discuss in detail shortly, when targeting diseases such as the hemophilias, tissue-specific expression of the corrective gene is not required. As such, the use of a vector that is capable of widespread transduction and gene expression within the developing fetus is desired because it would lead to far greater therapeutic benefit.

When one considers initial target diseases for exploring the therapeutic potential of IUGT, the diseases that would be most amenable to treatment by IUGT are those caused by a mutation in a single gene. To contemplate in utero treatment, testing for the target disease must be in place to allow diagnosis before birth, and there must be compelling reasons to pursue prenatal treatment rather than waiting until after birth. Using a variety of animal model systems and rodent models of human genetic diseases, IUGT, using a wide variety of viral vectors, has been targeted to multiple organs. Moreover, in several disease models, phenotypic rescue has been accomplished with IUGT [87,89–97]. In the interest of brevity and for the purpose of illustrating the profound therapeutic potential of IUGT and the ease with which it could be implemented clinically to cure disease, the next section of this chapter will focus on HA, presenting HA as a paradigm for genetic diseases that could be corrected by IUGT, the rationale for pursuing its treatment before birth, the feasibility of doing so, and clinical, societal, and financial advantages IUGT could offer over existing treatments for this disease.

The Need for Better Hemophilia A Treatments

HA is the most common inheritable coagulation deficiency [98]. Its clinical severity varies based on factor VII (FVIII) plasma levels. However, up to 70% of patients with HA have a severe, life-threatening phenotype [99] and frequent spontaneous hemorrhaging, which leads to hematomas, chronic painful and debilitating arthropathies, and potentially life-threatening internal bleeding [99]. The current standard of care for HA is prophylactic factor infusion, which consists of intravenous infusions of recombinant or plasma-derived FVIII two to three times a week to maintain hemostasis. Although this "protein-replacement therapy" has greatly improved quality and length of life for many patients with HA, it is far from ideal. Patients are condemned to a lifetime of frequent intravenous infusions and are financially burdened with treatment costs that can exceed $300,000/year. Even among the approximately 25% of patients with HA worldwide who are fortunate enough to have access to FVIII prophylaxis,

approximately 30% will mount an immune response (inhibitors) to the infused FVIII [100]. In the best-case scenario, these inhibitors reduce the effectiveness of subsequent infusions of FVIII; in the worst-case scenario, they can lead to treatment failure, putting the patient at risk for a life-threatening bleed. These significant shortcomings highlight the need for novel therapies that can promise longer-lasting correction or permanent cure of HA.

In marked contrast to protein replacement, a single gene therapy treatment could promise lifelong correction of HA; indeed, several aspects of HA make it an ideal target disease for gene therapy [101,102]. First, FVIII does not need to be expressed in either a specific tissue or cell type to produce a therapeutic effect. Although the liver is thought to be the major site of FVIII synthesis within the body [103], FVIII can be expressed and perform its clotting function, as long as it is produced by cells that can release the synthesized FVIII into the circulation. Second, even if FVIII levels could be restored to only 3–5% of normal, this seemingly minimal change could exert a marked clinical effect in patients with severe HA, converting them to a moderate or mild phenotype and dramatically improving their quality of life [102]. This knowledge led the American Society of Gene and Cell Therapy to include the hemophilias in the most promising, "target 10" diseases in their roadmap (www.ASGCT.org).

Preclinical Animal Models to Study In Utero Gene Therapy for Hemophilia A

Fortunately, FVIII-deficient mice produced via gene targeting or knockout [104] and colonies of HA dogs in which spontaneous mutations occurred within the FVIII gene [105,106] are both available to study the biology of FVIII and to explore and develop gene-based strategies to treat HA. The phenotype in the HA mice is mild, in contrast to that of most human patients, and therapeutic benefit has been demonstrated in multiple postnatal murine gene therapy studies [107–115]. Postnatal gene therapy has also been shown to be capable of phenotypically improving HA dogs, but therapeutic benefit in this more clinically predictive model has proven far more difficult than in mice [116,117]. Despite these promising preclinical results, however, no therapeutic benefit has yet been seen in any of the clinical gene therapy trials that have been conducted for HA. This is in striking contrast to the successes in clinical gene therapy trials for hemophilia B (HB) [118]. Although the precise reasons for this marked difference in the ability of gene therapy to correct HA versus HB are not clear, this discrepancy is particularly vexing when one considers that roughly 80% of all clinical hemophilia cases are HA.

The difficulties seen thus far in translating success in animal models into therapeutic benefit in human patients highlight the importance of preclinical animal models that both precisely mimic the disease process of HA and closely parallel normal human immunology and physiology. To this end, we used a variety of reproductive technologies to reestablish and then clinically characterize a line of sheep successfully that possess a spontaneous frameshift mutation causing severe HA [119]. FVIII activity is undetectable in plasma of these sheep using a highly sensitive chromogenic assay, and if not treated at birth, these sheep die within the first hours or days of life [120,121]. All 10 affected animals that have been born have experienced multiple spontaneous episodes of severe bleeding, including muscle hematomas, hematuria, and hemarthroses, all of which have responded to infusion of human FVIII. In contrast to other animal models of HA, just like human patients with severe HA, these sheep experience frequent spontaneous bleeds into their "knees," which produce crippling arthropathies over time that ultimately lead to decreased movement, difficulties walking, and eventually symptoms of pain just to stand up. Also similar to human patients, some of these sheep developed inhibitors after administration of FVIII.

As discussed in detail in the section on IUTx, sheep possess many characteristics that make them an ideal preclinical model for IUGT. An additional unique advantage to using sheep in the context of HA treatment is that like humans, most of the FVIII carrier protein, von Willebrand factor (vWF), is stored or located within their platelets. This is in contrast to dogs, in which vWF circulates freely in plasma [122]. This important difference makes the sheep a highly relevant model in which to test the efficacy of platelet-targeted gene therapy approaches for HA [123].

Feasibility and Justification for Treating Hemophilia A Before Birth

Even if costs dropped sufficiently to enable most HA patients to afford FVIII prophylaxis, these patients would still require frequent, lifelong intravenous infusions and would still face the possibility of treatment failure owing to inhibitor formation. These problems, as well as many of the hurdles that have impeded gene therapy from curing patients with HA (and those with many other diseases as well), could be overcome or eliminated by performing gene therapy in utero. In 75% of HA cases, a family history exists that makes it possible to screen before birth. Prenatal diagnosis for HA is feasible and available, and is both encouraged and cost-effective, even within developing countries [124,125]. Moreover, it is now possible to diagnose HA in utero by performing digital polymerase chain reaction (PCR) on cell-free fetal DNA present in the mother's blood, which makes the prenatal diagnosis of HA effectively risk-free [126]. Despite the availability of prenatal screening, however, about 1 in 5000 boys born throughout the world each year have HA [98]. Corrective IUGT could remove the heavy physical, psychological,

and monetary burden on patients, their families, and the health care system. The estimate for the lifetime cost of prophylactic treatment for one HA patient is $20 million. Curative IUGT would thus save approximately $4.8 billion over the lifetime of the patients with HA in the United States.

Whereas after birth any intervention places a patient with HA at risk for bleeding, during early fetal life, activation of factor X occurs primarily via tissue factor activity, making it largely independent of the factor IXa (FIX)–FVIIIa phospholipid complex [127]. As a result, the fetus develops without hemorrhage despite having little or no expression of FVIII and FIX [127–129]. The unique hemostasis of the fetus should thus allow IUGT to be performed safely for HA; indeed, 1 of the 46 human patients who received IUTx was transplanted in the hope of correcting HA, or at least inducing immunological tolerance to FVIII [130]. Although only this one patient with HA was treated, he experienced no untoward effects as a result of the in utero intervention, he exhibited a reduced severity of disease compared with his siblings, and in contrast to his siblings, he did not develop inhibitors with FVIII treatment [130]. This remarkable case thus provides clinical validation for prior experimental studies demonstrating that exposure to vector-encoded proteins (including coagulation factors) during early immunologic development induces stable immune tolerance [131–134]. The lifelong tolerance to FVIII induced by an IUGT-based HA treatment should therefore prevent the development of FVIII inhibitors that plague patients treated with replacement therapy [121,135]. In this one clinical case, Dr. Touraine relied on the ability of unpurified fetal liver cells to produce sufficient levels of FVIII endogenously, after transplant, to mediate correction. The only partial correction that was observed in this patient supports the approach of using gene transfer to ensure adequate levels of FVIII are obtained for full phenotypic correction.

We showed that by administering a single intraperitoneal injection of a small volume of γ-retroviral vector during gestation, it is possible to achieve gene transfer levels within the hematopoietic system of 5–6% [94,136,137], levels that would certainly be beneficial in HA. Subsequent studies in which we selected $CD34^+$ cells from these IUGT recipients and performed serial transplantation or repopulation [94,137,138] provided compelling evidence that this approach successfully modified bona fide HSC, indicating this method could provide lifelong disease correction.

Results from these studies also demonstrated that hepatocytes and hepatic endothelium were transduced at levels that would be therapeutic in HA and defined the period of gestation for optimal transduction of these cells [93]. IUGT experiments performed by other investigators during the same period using sheep, rodent, and nonhuman primate models, and employing a variety of viral vectors, produced similar results [87,89,90,93,94,132,133,139–154]. These collective results clearly support the ability of this method to deliver an FVIII transgene to the nascent liver with adequate efficiency to convert patients with severe HA to a moderate or perhaps even mild phenotype.

As discussed at the beginning of this section, one of the most frequent and most dangerous clinical problems when treating severe HA by protein replacement is the formation of inhibitors in about 30% of patients. We have spent several decades performing IUGT studies in the sheep model and have demonstrated that it is possible to take advantage of the unique temporal window of relative immunonaivety during early gestation to deliver exogenous genes efficiently to a variety of fetal tissues and induce durable cellular and humoral tolerance to vector-encoded gene products [131]. Further mechanistic studies demonstrated that early in fetal development, IUGT exploits both central and peripheral tolerogenic avenues in the fetus [134]. These results strongly imply that even if it is not curative, IUGT would still be an ideal approach to treating HA, because the state of immune tolerance induced by IUGT would ensure that postnatal therapy, whether it is protein- or gene-based, could proceed safely with none of the immune-related problems that plague HA treatment.

Interestingly, although the incidence of HA is about seven times that of HB, the only experimental studies to test the ability of IUGT directly to correct the hemophilias have targeted HB (factor IX [FIX] deficiency) [89,132,133,139,150,152–156]. The choice to target HB rather than A most likely results from the greater ease with which FIX can be cloned into a variety of viral vectors and efficiently expressed upon transduction of appropriate target cells. The treatment of HB by IUGT has been extensively studied in murine models, with different groups performing gene transfer at differing gestational ages via different routes of injection and using different vector types. Sabatino et al. reported low-level human FIX expression after intramuscular injection of fetal mice with either AAV-1 or AAV-2. As predicted, the injection of AAV-1 induced tolerance and allowed the postnatal readministration of the FIX-encoding AAV-1 vector, increasing FIX levels sufficiently to reach the therapeutic range. Surprisingly, however, injection of AAV-2 did not induce immune tolerance [157]. In other studies, Schneider et al. compared various routes of administration for delivering adenovectors and AAV-2 vectors encoding human FIX into mouse fetuses and found that adenovectors resulted in initially higher levels of FIX. Mice injected in utero with nonintegrating adenovectors also maintained therapeutic levels of FIX for 6 months, and no antibodies developed against either vector or transgene [154].

Without a doubt, Waddington and colleagues achieved the most clinically promising results of IUGT in hemophiliac mice by showing that the injection of an FIX-encoding lentiviral vector into embryonic day 15 mouse fetuses resulted in levels of FIX that were 9–16% of normal and improved coagulation for 14 months after IUGT. Furthermore, no immune response developed to FIX, even when the authors attempted to break tolerance by repeatedly injecting the protein postnatally [133].

Collectively, these murine studies have provided compelling evidence that IUGT can result in the expression of FIX at levels that not only have therapeutic significance but are often sufficient to induce tolerance, thus allowing postnatal administration of the same vector or the FIX protein without eliciting an immune response. Because patients with HA have at least a 10-fold higher likelihood of developing inhibitors than do HB patients [158,159], these studies, although encouraging, leave unanswered the critical question of whether IUGT will also induce stable immune tolerance to FVIII, given its higher inherent immunogenicity.

Risks of In Utero Gene Therapy

Despite the great promise IUGT holds for treating the many genetic diseases that can be diagnosed prenatally, several important safety concerns must be addressed before its clinical application. There are two sets of potential safety concerns when contemplating IUGT: those associated with fetal intervention and those owing to the gene transfer itself. As with any fetal intervention, infection, preterm labor, and fetal loss are all theoretically possible. In reality, however, a wealth of clinical data exist demonstrating that the human fetus can be safely accessed multiple times with an extremely low procedure-related risk [75,88]. Any manipulation of the fetus obviously has the potential to alter normal organ development, and the possibility for deleterious effects owing to the injection and from any inherent toxicity of the vector itself need to be considered and carefully evaluated. Nonhuman primates injected with lentiviral vectors in utero via either the intrapulmonary or intracardiac route showed no adverse effects on postnatal heart and lung development [148], which suggests that IUGT exerts minimal if any effects on organ development. In contrast, Flake and colleagues reported that expression of fibroblast growth factor-10 in the developing rat lung after IUGT led to cystic adenomatoid malformations; this illustrated how forced expression of a specific transgene can lead to malformation [160]. These findings suggest that strategies involving the expression of growth factors, transcription factors, or other regulatory molecules will need to be carefully examined because they may have significant potential to alter normal organ development, particularly early in gestation. One study also showed that AAV vectors administered to the fetus can cross the placenta, enter the maternal circulation, and transduce multiple tissues within the mother [156]. Because this study was performed in nonhuman primates, whose placentation is similar to that of humans, this is an issue that will likely need to be explored in greater detail and with other commonly employed vectors to better define or quantitate the risk of inadvertent gene transfer to maternal tissues and ascertain what risk, if any, this will pose to the mother.

In addition to the general risks associated with fetal intervention, two unique risks have raised the most concern regarding the use of IUGT: vector-mediated insertional mutagenesis and germline transmission [161]; each of these will now be discussed.

Genomic Integration-Associated Insertional Mutagenesis

Insertional mutagenesis is a major concern with all of the integrating viral vectors and has been subjected to intense scrutiny since four cases of T-cell leukemia occurred in human pediatric patients with X-SCID 31–68 months after they received γ-retroviral vector-modified autologous HSC. This concern was further heightened when linker-mediated PCR analysis of lymphocytes from these patients revealed that insertional mutagenesis had occurred in all four patients and was at least partially responsible for the observed leukemogenesis [162–164]. A later study in which genotoxicity or leukemogenesis was also observed after γ-retroviral or HSC-based gene therapy to treat Wiskott–Aldrich syndrome [165] heightened this concern. Importantly, in our long-term IUGT studies in fetal sheep, we also employed γ–retroviral vectors and achieved significant levels of gene transfer to bona fide HSC [94,136–138], yet we did not observe leukemogenesis in any of these animals. Because sheep have a life span of roughly 10 years, this study should more or less approximate a 35-year follow-up in "human years." A major difference between our study and the clinical trial that likely explains the markedly different outcome is the transgene that was delivered via the retroviral vector. In our experimental proof-of-concept studies, we employed marker genes to enable us to track and quantitate transduction and transgene expression easily in various tissues. In the clinical trial for X-SCID, the vector encoded the therapeutic common γ chain (γc) gene (interleukin-2 receptor subunit γ), because this was the gene defect causing X-SCID. Subsequent studies revealed that the observed leukemogenic event in these patients likely arose from a combinatorial effect of both the insertion of the vector in close proximity to the LIM only protein 2 oncogene and a growth advantage that was conferred on the transduced

cells expressing high levels of the therapeutic γc gene [166–169]. This clinical trial thus provides a valuable lesson in the complexities of risk assessment in gene therapy, which is still a relatively new and rapidly evolving field.

Looking specifically at IUGT, there has been only one report of oncogenesis after in utero delivery of a viral vector. In these studies, Themis, Waddington, Buckley, and colleagues reported a high incidence of postnatal liver tumors in mice after prenatal injection with a third-generation equine infectious anemia virus–based lentiviral vector. These tumors were not seen in mice that received a nearly identical vector that was constructed on an HIV backbone [170–172]. The authors did not identify the genomic insertion sites in these animals, so it remains unclear whether insertional mutagenesis was the cause of the observed tumor formation. Nevertheless, this important study demonstrates that the fetus may be particularly sensitive to tumorigenesis induced by certain vectors. The findings of Themis and the results of the clinical trial for X-SCID collectively suggest that preclinical assessment of the risk of insertional mutagenesis after IUGT will require carefully designed preclinical studies with the actual vector to be employed for the pending clinical trial in an animal model that has been thoroughly validated in the setting of the target disease.

Potential Risk to Fetal Germline

Although gene transfer to the vast majority of fetal tissues would be desirable for correcting diseases that would benefit from widespread systemic release of a secreted transgene product (such as HA), gene transfer to cells of the developing germline would raise major ethical issues. In the human fetus, the primordial germ cells (PGC) are compartmentalized within the gonads at 7 weeks of gestation [173]. The germline should be accessible only through the vascular system, so targeted gene therapy that is administered after this period in gestation should not affect the germline. Nevertheless, the possibility of inadvertent gene transfer to the germline is clearly a major safety concern and a bioethical issue, and studies have demonstrated that both the embryonic germline [174–177] and isolated PGC [178] can readily be infected with γ-retroviral vectors and pass the vector genetic material to subsequent generations in a Mendelian fashion as part of the permanent genome. For this reason, we used a three-tiered approach to examine this important issue in detail in the sheep model of IUGT. We performed (1) immunohistochemical staining on reproductive tissue from the in utero–treated animals, (2) genetic analysis on the sperm cells from the treated males, and (3) breeding experiments in a limited number of animals [94,137,141,142]. These studies indicated that although the fetal ovaries appeared to be largely unaffected by this approach to IUGT, numerous cells within the developing fetal testes were modified, including interstitial cells, Sertoli cells, and small numbers of both immature germ cells within the forming sex cords and the resultant sperm cells. Importantly, however, gene-modified germ cells were observed in only two of the six animals examined, and the incidence of germ cell modification in these two animals was about 1 in 6250, a frequency that is well below the theoretical level of spontaneous mutation within the human genome [179]. This low frequency of modification, coupled with observations that genetic alterations to the germ cells may produce deleterious effects, placing them at a disadvantage during fertilization, suggests that the likelihood that any genetic alterations present would be passed to subsequent offspring would be extremely unlikely. In agreement with this supposition, we did not observe transfer of the vector sequences in any of the 10 offspring we studied, even when mating animals that had both received IUGT. Nevertheless, this is clearly an issue that will need to be addressed in greater detail before clinical application of IUGT. This need for further investigation was underscored in other IUGT studies performed by Tarantal and colleagues, who employed lentiviral vectors in nonhuman primates and observed modification of the female germline but no effect on the male germ cells [140]. Thus, the issue of germline safety will likely have to be investigated in more than one preclinical model, employing the specific vector being considered for clinical use, to obtain an accurate assessment of the risk posed by the procedure.

Genome Editing

The field of gene therapy is rapidly advancing, and the development of genome-editing technologies such as zinc finger nucleases, transcription activator-like effector nucleases, and Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-associated genes [180,181] promises to revolutionize the way in which gene therapy is conceptualized. The ability to modify a specific sequence of DNA in its native genomic locus offers remarkable advantages in terms of both safety and efficacy, over current "gene addition" and should largely eliminate existing concerns related to random genomic integration, inappropriate levels or tissue distribution of transgene expression, and inadvertent germline alteration. One would therefore expect that these newer gene-editing technologies will be an important component of future IUGT studies and trials. However, these systems will likely introduce their own unique set of risks and concerns, and further study will be required to define and fully understand what these risks may be and evaluate whether the benefits these systems can offer over "traditional"

viral vectors outweigh these risks. In addition, well-designed experimental studies in suitable preclinical models will be required to determine whether these genome-editing systems should be administered directly to the recipient to mediate gene correction (which will likely require the use of viral vectors to achieve sufficient efficiency), or whether modifying suitable cell populations in vitro, followed by the infusion of these gene-corrected cells, will prove the safer mean to move these technologies toward clinical application.

CLINICAL EXPERIENCE WITH IN UTERO STEM CELL TRANSPLANTATION

Early successes with experimental IUTx in animals discussed in the preceding sections quickly led to attempts around the world to treat various human hematologic disorders with IUTx. In 1989, Touraine performed the first successful human IUTx for bare lymphocyte syndrome [182]. After this seminal case, several centers reported the successful transplantation of fetuses with SCID [183–186] using a variety of fetal and adult sources of HSC and transplanting the fetus between 16 and 26 weeks' gestation. In each case, IUTx resulted in readily detectable engraftment of donor cells at birth and clinical improvement. IUTx has been performed on 46 human patients for 14 different genetic disorders [4], collectively providing definitive proof that the early human fetus can be accessed multiple times with an extremely low procedure-related risk [75,88].

Although the successful treatment of immunodeficiencies provided clinical proof of the vast therapeutic potential of IUTx, the clinical experience thus far with IUTx for a wide range of other disorders has unfortunately been largely disappointing. The tremendous success with SCID is a function of the unique nature of this disorder, which provides a survival and proliferative advantage for donor HSC-derived T cells. Indeed, in these patients, the only hematopoietic lineage reconstituted by the donor cells has been the T-cell lineage (split chimerism) [88], echoing the findings in Blazar's early murine studies [32]. The results of the 46 clinical IUTx cases have proven that using current methods, IUTx is unable to achieve therapeutic levels of engraftment in recipients whose hematopoietic system possesses a normal level of "competitiveness." That these transplants were performed at different centers, at variable gestational ages, and used donor cells from different sources and/or with different phenotypes, has made it difficult to identify common factors that may be responsible for the poor levels of donor engraftment. The inherent inconsistency in these studies has made it necessary to perform many of the more carefully controlled animal studies that were previously described to identify the nature of the barriers that limit engraftment after IUTx and to develop means of overcoming them to achieve clinical success.

The hematopoietic system and marrow microenvironment of patients with hemoglobinopathies, lysosomal storage diseases, and the vast majority of the other disorders that are being considered for treatment with IUTx are competitively normal during fetal development. As such, clinical success with IUTx for these diseases will require the development of methods to overcome endogenous host cell competition. To this end, Flake and colleagues showed [53] in the canine model that administering large doses of highly enriched HSC via a novel ultrasound-guided, intravascular (intracardiac) route produced significantly higher engraftment levels than the intraperitoneal route that has traditionally been employed for IUTx in human patients. This study generated a good deal of excitement in the field, because the levels of donor cell engraftment the authors obtained with the new route would likely be therapeutic in most candidate diseases. However, studies performed by Tanaka et al. in the sheep model have shown that the intravascular route is no better than the intraperitoneal route, which led the authors of this other study to conclude that the markedly greater safety afforded by the intraperitoneal route will likely make this the clinical route of choice [187].

One particular area that has received a great deal of attention is the idea that the best immediate clinical application for IUTx may be to use it to induce prenatal tolerance, thus making it possible to perform a curative postnatal BM transplantation without the need for highly toxic cytoablation and immunosuppression [6,13]. This approach greatly lowers the threshold of donor cell engraftment that would be required for clinical success, because, as discussed previously, induction of donor-specific immune tolerance can reliably be obtained with stable levels of donor chimerism of only 1–2%. The therapeutic merit of this approach was experimentally validated by Peranteau et al [26]. In this landmark study, the authors demonstrated that low-level hematopoietic engraftment to induce tolerance, followed by postnatal nonmyeloablative same-donor "boosting" BM transplantation, resulted in high levels of donor cell engraftment and phenotypic correction in murine models of β–thalassemia and sickle cell disease, two diseases that had previously proven completely refractory to correction by IUTx. These promising results led the authors to conclude optimistically that "if adequate engraftment can be achieved to consistently induce donor-specific tolerance without [graft-versus-host disease] in a preclinical model, then clinical trials of

IUTx for treating genetic disorders that can be prenatally diagnosed and treated by mixed hematopoietic chimerism, such as the hemoglobinopathies and selected immunodeficiency disorders should be initiated" [26].

CONCLUSIONS AND FUTURE DIRECTIONS

Great progress has been made over the past few decades in the fields of IUTx and IUGT. However, multiple hurdles still need to be overcome for these therapies to become well-established clinical approaches. Challenges for IUTx are primarily related to overcoming the competitive barriers to engraftment in the "hematopoietically fit" fetus and better defining the innate and adaptive immune limitations to engraftment in large animals and humans. As our understanding of stem cell biology, developmental hematopoiesis, and the ontogeny of the hematopoietic niche advance, the therapeutic applications of IUTx will likely expand from their narrow focus to include the treatment of nonhematopoietic diseases. Although the strategy of prenatal tolerance induction for the facilitation of postnatal HSC transplantation is nearing clinical application and has great potential to benefit many patients, the development of an IUTx strategy that allows a single-step treatment to achieve therapeutic levels of engraftment would be ideal and would likely propel this promising therapy into the clinic.

IUGT holds even greater promise for treating and curing essentially any inherited genetic disease. From the results of countless studies exploring IUGT in sheep, mice, and nonhuman primates, it is clear that the direct injection of viral vectors into the developing fetus can efficiently deliver an exogenous gene and achieve long-term expression in multiple tissues. As such, one can envision a day when IUGT becomes a viable therapeutic option for diseases affecting any of the major organ systems. Importantly, even if it is not curative, IUGT would be an ideal approach for diseases such as HA, because lifelong immunologic tolerance could be induced to the missing FVIII protein, thus overcoming the immune-related hurdles that hinder postnatal treatment of this disease. Despite its great potential, however, IUGT is still in the experimental stages, and several important safety concerns need to be extensively investigated in appropriate preclinical animal models before initiating studies in human patients.

IUTx and IUGT stand at a critical juncture [188] and have vast potential for dramatically improving human health care. Many of the most intimidating obstacles have been overcome in animal models or are at least better understood, which has revitalized this exciting field. There is no doubt that surpassing the few remaining hurdles to allow clinical implementation of these therapies will dramatically change the whole paradigm for the way in which the world perceives and treats genetic disorders.

INTRODUCTION

Cardiovascular diseases (CVDs) such as aortic disease, coronary artery disease (CAD), and peripheral artery diseases (PAD) are the leading causes of mortality worldwide [1]. In 2011, the age-standardized death rate attributable to all CVDs was 229.6 per 100,000 in the United States. Based on 2011 death rate data, more than 2150 Americans die of CVDs each day, an average of one death every 40 s [1]. Atherosclerosis is one of the most important causes of CVDs; it induces stenosis, occlusion, and calcification of arteries in patients with CAD and PAD. Aortic aneurysm or dissection often occurs in patients with aortic disease. In addition, chronic kidney disease is reaching epidemic proportions because patients have risk factors for CVDs such as hypertension, hyperlipidemia, smoking, and diabetes. Many patients with end-stage renal disease (ESRD) require vascular shunts for hemodialysis. Clearly, CVDs impair the quality of life for many individuals.

There are various therapeutic strategies for CVDs. In particular, lifestyle modifications and pharmacological therapies have important and fundamental roles in treating CVDs. In addition, more invasive endovascular intervention such as thrombectomy, balloon dilatation, stent implantation, and/or surgical procedures may be recommended for more severe cases of CVDs. Surgical procedures typically involves graft replacement and/or bypass procedure. In CADs, patients with left main coronary disease or three-vessel disease typically undergo percutaneous coronary intervention or coronary artery bypass grafting (CABG). Second-generation drug-eluting stents have been developed to improve patency and reduce major adverse cardiac events, but CABG should remain the standard therapy for high-risk patients [2]. Common graft sources for CABG are the autologous bilateral internal thoracic arteries or the saphenous vein. In contrast, the use of a synthetic vascular graft such as expanded polytetrafluoroethylene (ePTFE) (Gore-Tex) or polyethylene terephthalate (Dacron) is common for patients with aortic disease. In PAD, autologous venous grafts are primarily used for peripheral arteries below the knee, whereas synthetic grafts also are used for larger arteries such as iliac, femoral, and popliteal arteries (above the knee). In ESRDs, typical vascular access for hemodialysis is provided by autologous arteriovenous (AV) shunts. Graft selections depend on the patency. In smaller arteries such as the coronary artery and below-the-knee arteries, synthetic grafts have shown unfavorable results owing to high incidences of thrombosis. In medium-size arteries, such as the femoral and popliteal arteries, polytetrafluoroethylene (PTFE) grafts have shown patency rated of 60% and 27% compared with 89% and 85% when using the saphenous vein at 1 and 5 years, respectively [3]. Therefore, it is recommended that synthetic grafts be used only when autologous grafts are unavailable. In aortic diseases, there are no suitable autologous substitutes. In general, synthetic materials have shown limitations associated with thrombosis, stenosis, calcification, infection, a lack of durability, the need for anticoagulation therapy, and the inability to regenerate native tissue. Suitable autologous tissues are in short supply, which makes it difficult to perform multiple or repeat operations.

To overcome the limitations associated with autologous and synthetic grafts, the concept of the tissue engineered vascular graft (TEVG) was proposed. Vacanti et al. defined tissue engineering as the fabrication of alternative materials that integrate with a patient's native tissue for the purpose of restoring biological and physiologic function [4]. In 1986, the first tissue engineered blood vessel was reported by Weinberg and Bell and consisted of bovine endothelial cells (ECs), smooth muscle cells (SMCs), and fibroblast cultures embedded in a collagen gel integrated with a Dacron mesh [5]. To date, hundreds of TEVGs have been developed and evaluated in animal models and

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00058-8

clinical studies. It is promising technology for pediatric cardiologists who treat congenital heart diseases because TEVGs can regenerate and remodel new vessels and provide growth potential. In 2001, the first TEVG clinical trial was performed in children with congenital heart disease [6]. Similarly, TEVGs have attracted attention from nephrologists looking for alternatives to AV shunts. Niklason et al. reported that their clinical study, which used TEVGs to provide hemodialysis access, produced favorable safety and patency results [7]. In this chapter, we look at the status of large-diameter TEVGs in large-animal models and clinical studies and share the outlook for the future of TEVGs.

MATERIALS FOR AND APPROACHES TO FABRICATING TISSUE ENGINEERED VASCULAR GRAFTS

A large number of fabrication materials have been proposed to construct large-diameter TEVGs that have the potential to integrate with and remodel into native. There are currently three strategies regarding materials, scaffold, and TEVGs: (1) biological-based, (2) biodegradable synthetic-based, and (3) hybrids (Fig. 58.1). A large number of biological-based and biodegradable synthetic-based matrix combinations have been evaluated, but few have been applied clinically.

Biological-Based Scaffolds

When designing and constructing an arterial TEVG, it must be durable enough to withstand high arterial pressures. With this in mind, the use of natural matrices from animal or human arteries may provide advantages with regard to structure and mechanical properties. However, when xenogenic and allogenic matrices are transplanted, immunological rejection often sets in. Therefore, they require a decellularization process to avoid adverse immunological reactions.

Natural Decellularized Matrices

Xenogenic Matrices

Vessels and nonvascular tissues harvested from animals or cadavers are two distinct sources when fabricating decellularized vascular matrices. Decellularized vascular grafts sourced from animals or cadavers have a structure similar to native vessels; therefore, they have inherent advantages with regard to mechanical properties. Nonvascular tissues such as the small intestinal submucosa (SIS) and amniotic membrane also contain natural extracellular matrix (ECM). However, the SIS and amniotic membrane must be shaped into tubular constructs. They have been used as the materials for TEVGs, but neither have reached clinical trials or preclinical animal studies to investigate their efficacy as large-diameter TEVGs. All nonautologous natural matrices require decellularization to remove most cellular antigenic components. Different decellularization methods have been proposed and typically involve a combination of physical approaches and chemical and biological agents. Physical approaches include freeze-thawing, mechanical abrasion, hydrostatic pressure, and nonthermal irreversible electroporation [8]. Acids and bases, hypotonic and hypertonic solutions, detergents, and alcohols are common chemical agents. Enzymes such as DNases and trypsin, nonenzymatic agents such as ethylenediaminetetraacetic acid, and serine protease inhibitors such as phenylmethylsulfonyl fluoride are common biological agents. The ideal combination of decellularization methods and agents must be selected carefully and will successfully maintain the three-dimensional (3D) structure and mechanical properties of ECM while removing cell remnants. Therefore, the merits and limits of each respective method must be understood.

Decellularized vessel grafts have the longest history with regard to the development of TEVGs. Since the 1960s, many decellularized TEVGs have been developed and some have been marketed commercially. Most of these TEVGs have been produced for AV shunts. The most popular decellularized vessel graft that is available commercially is Artegraft. This xenogenic TEVG is composed of a decellularized bovine carotid artery graft for hemodialysis access; the primary patency rate was significantly higher than in ePTFE grafts at 1 year (60.5% versus 10.1%; $P = .0062$) [9]. Furthermore, fewer percutaneous angioplasties were performed in upper-arm Artegrafts than in ePTFE grafts (1.30 ± 0.27 versus 2.49 ± 0.43 times per patient-year; $P = .014$). Therefore, the authors concluded that Artegrafts were an excellent option for hemodialysis AV shunts. Another popular xenogenic graft is SynerGraft Model 100, which is based on decellularized bovine ureters [10]. In a clinical study, 29 patients were implanted with SynerGraft and 27 received ePTFE grafts as AV shunts; they showed similar patency (28% versus 48%; $P = .290$) and infection rates (4% versus 9%; $P = .410$) between SynerGraft Model 100 and ePTFE after

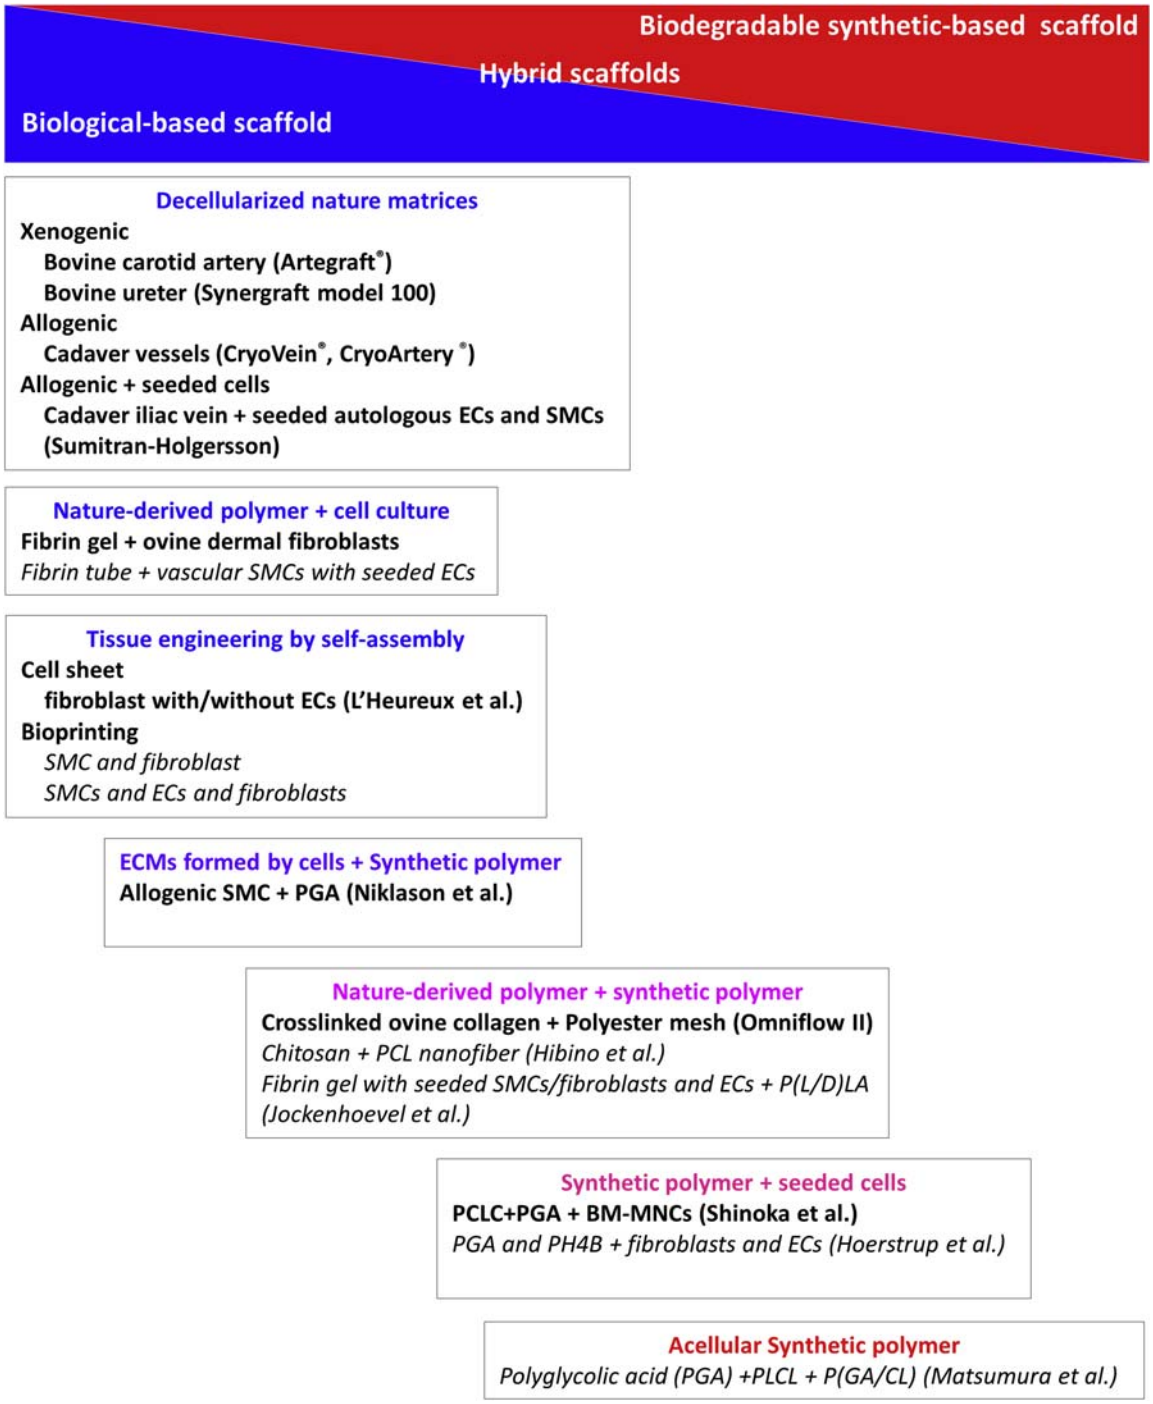

FIGURE 58.1 Large-diameter graft classification by scaffold materials in large-animal model and clinical studies. Various combinations of biological-based scaffolds and biodegradable synthetic-based scaffolds have been developed and evaluated in large-animal models and clinical studies. Large-animal model studies are shown in *italics* and clinical studies are shown in *bold*. *BM-MNCs*, bone marrow mononuclear cells; *EC*, endothelial cell; *PH4B*, poly-4-hydroxybutyrate; *PCL*, poly(ε-caprolactone); *PGA*, polyglycolic acid; *P(GA/CL)*, poly(glycolide-*co*-ε-caprolactone); *PLCL*, poly(L-lactide and ε-caprolactone); *P(L/D)LA*, poly(L/D)lactide; *SMC*, smooth muscle cells.

1 year. Unfortunately, advantages for SynerGraft Model 100 were not seen. To improve patency, decellularized xenogenic grafts seeded with cells have been developed in animal models. For example, in ovine models, decellularized porcine carotid artery grafts seeded with endothelial progenitor cells (n = 6) remained patent up to 4.4 months as AV shunts [11].

SIS may be a promising source of TEVG matrices. SIS is a kind of natural ECM that has been shown to retain a porous scaffold suitable for tissue reconstruction. The porous scaffold allows for easy cell infiltration. SISs have been applied in many clinical areas such as the ileum, diaphragm, rotator cuff, and bladder [12–14]. Various SIS-derived TEVGs have been developed. In a large-animal study, 24 SIS grafts obtained from pigs were implanted as ovine carotid arteries [15]. However, patency at 3–4 months was 30%. In general, the patency rates of decellularized xenogenic grafts do not exceed those of ePTFE in many clinical and animal studies. Andreadis and Swartz et al. reported that SIS TEVGs coated sequentially with heparin and vascular endothelial growth factor showed successful endothelialization, remodeling, and development of vascular function in ovine carotid artery models [16]. The patency was 92% in 12 sheep at 1 weeks (n = 3), 1 month (n = 4), and 3 months (n = 4). However, SIS grafts have not been used clinically.

Allogenic Matrices

Allogenic vascular grafts are provided by human cadavers. CryoVein, which is composed of cryopreserved saphenous vein allografts, has been evaluated for many years. Farber et al. reported the results of 240 infrainguinal revascularization procedures with CryoVein [17]. The primary patency rate was not sufficient (50% at 6 months and 18% at 24 months) [17]. Similarly, CryoGraft has been used for hemodialysis access, compared with PTFE shunts, and revealed a similar primary patency at 2 years between the two groups. CryoGraft showed more resistance to infection but was also more susceptible to aneurysm [18]. Cryopreserved arteries (CryoArtery) have been developed to treat infected aortic prosthetic grafts or mycotic aneurysms. Evaluations of CryoArtery revealed an overall treatment mortality rate of 21% at 12.5 months, and graft-related complications were acceptable at midterm follow-up regardless of the disease severity risk [19]. An advantage to using decellularized allogenic and/or xenogenic matrices is that they can address the limited availability of autologous grafts, but the advantage is limited by their lack of cellularity. The lack of cellularity may lead to graft thrombosis, infection, and aneurysm. Therefore, cell seeding technologies have been developed to modify grafts. In a first case report, a cadaveric allogenic iliac vein graft seeded with autologous bone marrow–derived ECs and SMCs was implanted into a patient with extrahepatic portal vein obstruction as a bypass between the superior mesenteric vein and the intrahepatic left portal vein (meso Rex bypass) [20]. The graft was patent at 9 months after the operation but narrowed owing to mechanical obstruction by the surrounding tissue and required a second operation to be performed. The authors stated that the advantage of this graft is that it is unnecessary to use immunosuppression therapy because the decellularized allogenic graft is seeded with autologous cells. However, human donor cadaver vessels are in short supply and result in complicated ethical issues. In addition, inadequate decellularization has caused cases of adverse immune response and graft failure. On the other hand, aggressive decellularization may destroy the structural integrity of the ECM and lead to decreased mechanical properties. Therefore, allogenic vessel-derived TEVGs are not commercially widespread.

Nature-Derived Polymers

ECMs are composed of collagen, proteoglycan, fibronectin, elastin, etc., and therefore are good candidates as TEVG scaffold materials. Many researchers have studied these different nature-derived polymers as TEVG scaffolds. In sheep models, Tranquillo et al. fabricated 4-mm-diameter grafts composed of ovine dermal fibroblasts and fibrin gel. The fibrin gel from bovine fibrinogen and ovine dermal fibroblasts was combined and cultured into a tubular mold for 2 weeks and the grafts were subsequently transferred to a pulsed flow-stretch bioreactor for an additional 3 weeks and then decellularized. The grafts were implanted interpositionally in the femoral artery of six sheep; all were patent and showed no dilatation or calcification at 24 weeks [21]. In addition, the researchers implanted grafts fabricated in the same manner to replace the pulmonary artery in three young lambs. The lambs displayed normal growth after 50 weeks [22]. Andreadis et al. also reported a conceptually similar TEVG in which fibrin tubes with entrapped vascular SMCs were implanted as vein interposition grafts in lambs [23]. The graft was seeded with ECs in the luminal TEVG surface before implantation; subsequently, they showed patency for 15 weeks. Silk-derived fibroin, collagen, and chitosan are also potential nature-derived polymers as TEVG scaffolds. However, these combination strategies have been evaluated only in vitro and in small-animal model.

Tissue Engineering by Self-assembly

The Tissue Engineering by Self-Assembly (TESA) design approach, which L'Heureux et al. developed, is a promising and unique fabrication method of TEVGs [24]. TESA does not use nature-derived polymers or synthetic scaffolds but is based on cell sheet tissue engineering. The cell sheets are formed by culturing autologous fibroblasts from a biopsy. Cell sheets are wrapped around a 4.8-mm-diameter stainless-steel mandrel and then matured. After taken off the mandrel, the TEVG is dehydrated and luminally seeded with autologous ECs. The production time for

these grafts ranges from 6 to 9 months. According to published data, the first 10 patients underwent AV shunt graft implantation and primary patency rates were 78% at 1 months (7/9) and 60% at 6 months (five of eight patients; one patient withdrew and another patient died of unrelated causes) [25]. The authors stated that this patency was acceptable because patients enrolled in the study had a high probability of failure and had at least one previous access failure. Thus, the study group represented a particularly challenging patient population in which AV shunt failure was expected to be far higher. L'Heureux et al. also reported that nonendothelialized TEVGs were implanted into three patients as AV shunts [26]. Two patients required intervention for stenosis and occlusion (both eventually failed) within a year and one patient died of sepsis. The authors suggested that an endothelium may not be required to maintain the patency of this TEVG because thrombogenic failures appeared to result from stenosis. Removing the EC seeding process simplifies the fabrication of TEVGs and saves on cost and time. Furthermore, they developed a novel assembly method termed thread-based tissue engineering (TBTE) to save production time compared with TESA. TBTE technology uses the cell-synthesized matrix of fibroblasts to form strong threads that can be assembled into complex 3D structures using classic textile technologies such as weaving, braiding, or knitting. Preclinical studies are investigating TBTE grafts for canine AV shunt and CABG [27].

Other TESA technologies include microtissue aggregation and 3D cell printing. Forgacs et al. fabricated prototype biological self-assembly bioprinted grafts in vitro [28]. Multicellular spheroids or cylinders 300−500 μm in diameter were made from SMCs and fibroblasts. Subsequently, agarose rods and the uniform multicellular spheroids were deposited layer by layer. With this method, various tubular and branching structures can be fabricated into TEVGs. Itoh et al. manufactured another type of 3D bioprinting TEVG using multicellular spheroids and implanted the constructs into rat abdominal aorta ($n = 5$) [29]. Their unique method skewered the multicellular spheroids into a needle array according to a predesigned 3D structure. They implanted the grafts into rat aortas and evaluated their histologies 5 days after implantation. These technologies have not yet reached clinical application. The major limitations of these technologies are that they require long times to culture and they have difficulty attaining suitable mechanical strengths. However, the technologies can fabricate bifurcated TEVGs or grafts with different-sized ends. Therefore, many researchers are continuing to investigate them.

Hybrid Scaffolds

Hybrid scaffolds combine biologically based and biodegradable synthetic materials. Many synthetic materials have been used as TEVG scaffolds. Originally, biodegradable synthetic scaffolds were developed to reinforce and maintain the mechanical strength of TEVGs. In the 1980s, Weinberg and Bell produced the first TEVG. It consisted of cultured bovine ECs, SMCs, and fibroblasts in a collagen gel and subsequently was shaped into tubes. However, this TEVG lacked sufficient mechanical strength and required a Dacron mesh support. Since then, various approaches have been investigated. Niklason et al. produced a novel approach using a biodegradable synthetic scaffold for cell culture. The synthetic scaffold was designed to degrade as ECMs obtain the appropriate mechanical strength during cell culture within a bioreactor. Therefore, the final TEVG product is composed only of ECMs formed by cells.

Extracellular Matrices Formed by Cell Culture and Synthetic Polymers

As described earlier, Niklason et al. reported a unique approach to fabricating TEVGs. In vitro−fabricated human decellularized TEVGs using allogenic human vascular SMCs have undergone a multicenter clinical trial [7]. In brief, human vascular SMCs were derived from deceased organ and tissue donors and met eligibility requirements set forth by US Food and Drug Administration regulations. SMCs were isolated with 1−60 million cells from individual donors. After expansion, 1 million cells/cm were seeded onto polyglycolic acid (PGA) polymer scaffolds within flexible bioreactors. Pulsatile flow was applied to the grafts for 8 weeks in the bioreactors, and then subsequently were decellularized (Fig. 58.2). The grafts were implanted into the arms of patients with ESRD for hemodialysis access and showed favorable results. Of the 60 patients with ESRD who underwent TEVG implantation, primary patency was 63% and 28% at 6 and 12 months, respectively, and secondary patency, which included preceding successful interventional or surgical procedures, was 97% and 89%, respectively. The patency was higher than that reported in multicenter studies of ePTFE (55−65% at 1 year). In addition, the grafts displayed no significant potential immunogenicity, aneurysm, or structural degradation. This TEVG will require longer follow-up observations in addition to prospective, randomized, and large clinical trials. However, this TEVG is perhaps the closest to being clinically translated and serving as a readily available off-the-shelf conduit in large-diameter graft applications. In this chapter, the TEVG developed by Niklason et al. is classified as a hybrid scaffold even though the

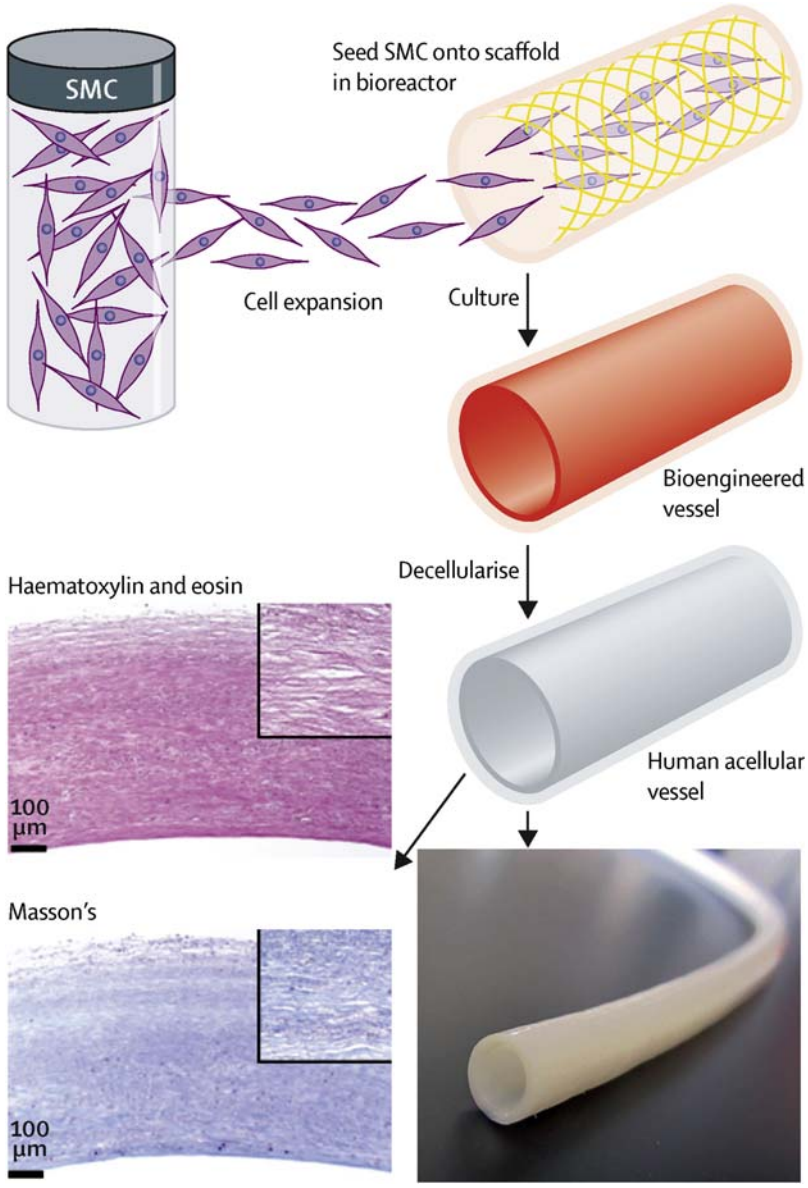

FIGURE 58.2 Production of arteriovenous shunt grafts by Niklason et al. Smooth muscle cells are seeded onto a biodegradable scaffold within a single-use bioreactor. During culture, a cellular bioengineered vessel is grown that is then decellularized to produce the human acellular vessel. Gross appearance is an off-white uniform tubular structure. Hematoxylin-eosin stain and Masson trichrome stain show a dense extracellular matrix without cellular or nuclear remnants. *SMC*, smooth muscle cell. *Lawson JH, Glickman MH, Ilzecki M, Jakimowicz T, Jaroszynski A, Peden EK, et al. synthetic scaffold degraded before the grafts were implanted into patients. However, it is also reasonable to classify their graft as a biological-based scaffold.

Nature-Derived Polymers and Synthetic Polymers

The oldest hybrid TEVG applied clinically is Omniflow II, which is composed of cross-linked ovine collagen and a polyester mesh endoskeleton. Since the 1990s, several favorable study results have been published on this graft [30,31] and have led to its use in many European countries and several South American and Asian nations. Conceptually, a hybrid scaffold is one in which biological-based materials enhance biocompatibility and cell infiltration, whereas synthetic-based materials provide the graft with overall structure reinforcement. Many biological-based scaffolds have been investigated, including fibrin, collagen, elastin, chitosan, and gelatin. Synthetic-based scaffold approaches are primarily biodegradable. Poly(ε-caprolactone) (PCL) is well-used as a biodegradable synthetic-

based scaffold material and has been investigated in small-animal models [32,33]. Weiss et al. reported successful results with a bilayered scaffold composed of an inner layer of recombinant human tropoelastin and an outer layer of PCL in a rabbit model [32]. Another group demonstrated good results with an acellular hybrid vessel of PCL, polyurethane, and collagen in canine models [33]. In a large-animal model, Hibino et al. investigated an electrospun PCL−chitosan nanofiber TEVG as ovine carotid artery replacements [34]. The TEVG showed 67% patency (four of six) and there was no evidence of aneurysm or calcification. Electrospun nanofiber scaffolds are a promising method for fabricating arterial TEVGs that may be capable of withstanding high flow and pressure blood flow. Electrospun nanofiber scaffolds that resemble ECM structures can be fabricated relatively easily. In small-animal models, however, several studies revealed that an electrospun scaffold with small pore sizes can inhibit cell infiltration into TEVGs. Therefore, many researchers are searching for optimal scaffolds with regard to selecting the materials, electrospun fiber diameter, pore size, and alignment [35,36]. When blended into a TEVG, rapidly degrading chitosan is considered to promote better cell infiltration and rapid neovessel remodeling owing to pore size enlargement. Jockenhoevel et al. developed fibrin scaffold grafts encapsulated with autologous SMCs/fibroblasts and ECs. The construct was then reinforced with a poly(L/D)lactide 96/4 mesh. They implanted the TEVGs into sheep carotid arteries and observed them for up to 6 months [37]. Eighteen grafts ($n = 6$ for 1, 3, and 6 months' follow-up) were patent and there was one significant case of stenosis (3 months). There was no evidence of thrombus, aneurysm, or calcification. In addition, explanted grafts were observed to contain remodeled cellular distribution and mature autologous proteins. However, these TEVGs are associated with higher costs and longer production times owing to cell culturing compared with cell-free TEVGs. In addition, these carotid artery TEVGs diameters are about 4−5 mm and are not strictly included in large-diameter TEVGs.

Synthetic Polymers With Seeded Cells

This type of TEVG consists of a biodegradable synthetic polymer seeded with cells. A biodegradable synthetic scaffold must maintain the graft's mechanical properties until the new vessel is reconstituted by host-derived cells over the course of its inflammation-mediated process. Various cell populations such as SMCs, fibroblasts, and ECs have been cultured and seeded onto TEVGs to mimic the structure of native vessels. Stem cells have also been identified as a potential source for cell seeding because they have important roles in tissue regeneration, remodeling, and maturation. Several types of stem cells, such as embryonic stem cells (ES cells), induced pluripotent stem cells (iPS cells), and bone marrow−derived cells, have been seeded onto the biodegradable synthetic polymer for study. In the past, a TEVG seeded with ECs derived from ES cells was developed. However, research on human ES cells has been limited because of political and ethical concerns. On the other hand, iPS cells do not have these concerns, and opportunities in tissue engineering have been recognized for cell sheet TEVGs in mice inferior vena cava [38]. The TEVGs showed favorable patency, but seeded iPS cells primarily exerted a paracrine effect to induce neotissue formation and showed no direct change to vessel cells. The benefit to using iPS cells is that they do not require immunosuppressive therapy, but it is a complex process to fabricate TEVGs using this particular cell population.

The feasibility of using a tissue engineered pulmonary arterial graft with seeded vascular cells in an ovine model was demonstrated in 1997 [39]. The same group switched to using autologous bone marrow mononuclear cells (BM-MNCs) instead of vascular cells for clinical applications and developed a venous TEVG that consisted of a woven fabric made of a 50:50 mixture of poly(L-lactide and ε-caprolactone) (PLCL) reinforced with PGA. Previously, it was reported that multipotential cells existed in bone marrow and had the ability to differentiate into several cells types and organs in vivo [40]. In addition, several studies revealed that endothelial progenitor cells derived from bone marrow contributed to angiogenesis. However, Shinoka et al. revealed in a mouse model that the number of seeded BM-MNCs in the TEVGs decreased rapidly in the first few days after implantation and disappeared altogether within 1 week after implantation without differentiating into vascular cells [41]. BM-MNCs contain an abundance of cytokines that can enhance neovessel formation, and they likely act in a paracrine manner to recruit additional host cells during the remodeling process. With regard to BM-MNC harvest and seeding of Shinoka's TEVG, approximately 4−5 mL/kg body weight BM-MNCs were aspirated into a syringe from the anterior superior iliac spine of a patient with a puncture needle under general anesthesia. After several washing and concentration steps, BM-MNCs were seeded onto biodegradable polymer scaffold by pipetting. The outer surface of the seeded scaffolds was then sprayed with fibrin glue. In 2001, the group started a clinical trial implanting the TEVGs for extracardiac total cavopulmonary connections to 25 Japanese children. Their biodegradable TEVGs were thought to be particularly suitable in children because they have the potential to grow and remodel. Midterm (median, 16.7 months) and long-term results (mean, 5.8 years) revealed no evidence of aneurysm, graft rupture, graft infection, ectopic calcification, or graft-related mortality [42,43]. However, four patients died of graft-unrelated causes during the long-term follow-up and four required percutaneous angioplasty owing to stenosis. In one patient, the

TEVG was replaced with a PTFE patch 2 months after the original surgery because of unexpectedly slow tissue growth on the patch used for a lateral tunnel procedure. Histological findings of the explanted graft showed collagen-rich fibers and a surface covered with ECs [42]. Of 20 patients who were contacted for long-term follow-up, eight (40%) required no daily medications. Patients who are implanted with nonbiodegradable synthetic grafts such as ePTFE often require long-term anticoagulation and antiplatelet therapy. Shinoka's group is collecting long-term follow-up data (median, 13.0 years) (unpublished data); eight patients have died owing to graft-related causes and seven have undergone percutaneous angioplasty (seven have undergone percutaneous angioplasty (six balloon dilatation and one stent implantation)). This long-term mortality rate appears to be reasonable because most patients with congenital heart disease typically originally have severe conditions and are at high risk. Comparisons between postoperative and long-term follow-up angiography (11 years later) showed that the neovessels behaved and functioned like normal vessels without stenosis and aneurysm (Fig. 58.3).

The female patient presented in Fig. 58.3 was diagnosed with complex congenital heart disease including double outlet right ventricle, subaortic ventricular septal defect, small tricuspid valve and right ventricle, Juxtaposition of right atrial appendage, persistent left superior vena cava, and total anomalous pulmonary venous return. She underwent pulmonary artery banding at age 1 month and total cavopulmonary connection (TCPC) with enlargement of the pulmonary vein orifice using autologous pericardium at age 3 years. A 16-mm-diameter PLCL and PGA TEVG seeded with BM-MNCs was implanted between the inferior vena cava and pulmonary artery. Angiography after graft implantation showed that the TEVG was patent (Fig. 58.3, left, indicated by *arrows*). Furthermore, long-term follow-up (11 years later) angiography showed that the TEVG remained patent without aneurysm and displayed growth as the child grew older (Fig. 58.3, right, indicated by *arrows*). More recently, Shinoka et al. presented the first report of late-term (12 years) histological findings of our TEVGs [44]. This female patient was diagnosed with a single right ventricle, pulmonary stenosis, pulmonary stenosis, bilateral superior vena cava, a hemiazygos connection, and a common atrium with mild to moderate regurgitation from a common atrioventricular valve, and underwent TCPC with a common atrioventricular valve plasty when she was 4 years old. A 12-mm-diameter biodegradable synthetic TEVG seeded with BM-MNCs was implanted between the hepatic vein and pulmonary artery. Unfortunately, she died at age 16 years owing to multiple organ failure, low cardiac output syndrome, disseminated intravascular coagulation, pancytopenia, and brain abscessation. Histological examinations of ECs, SMCs, elastic fiber and collagen fiber layers from the patient's autopsy report revealed that the synthetic scaffold had completely degraded, remodeled, and generated neotissue that seamlessly integrated with native vessel (Fig. 58.4).

In the United States, Drs. Breuer and Shinoka started a pilot study investigating the clinical use of the TEVGs in congenital heart surgery (NCT01034007). If the pilot study proves to be successful, this TEVG technology will be the first to be commercially applied clinically in the world. Several studies have already shown excellent long-term

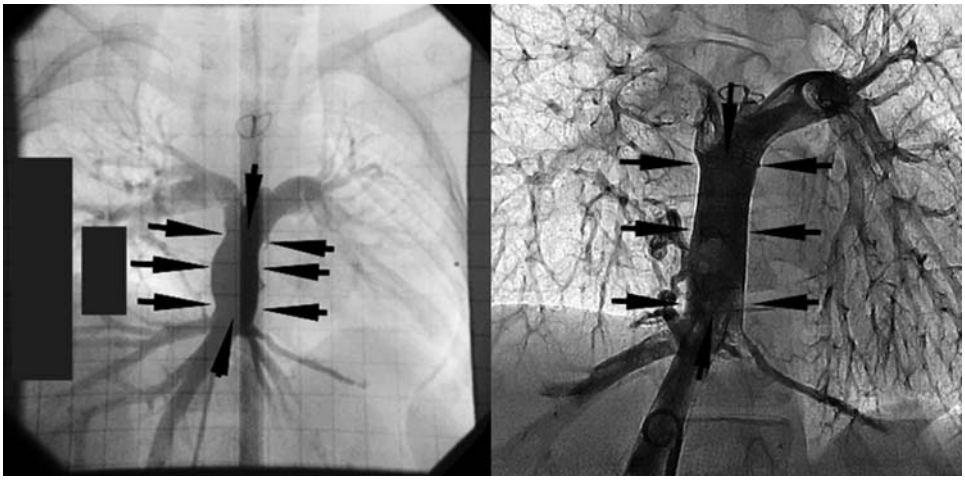

FIGURE 58.3 Angiographic comparison between postgraft implantation and long-term follow-up (11 years later). A 3-year-old girl with a double-outlet right ventricle, who underwent pulmonary artery banding at age 1 month, underwent a total cavopulmonary connection with enlargement of the pulmonary vein orifice using autologous pericardium. Poly(L-lactide and ε-caprolactone) (16 mm in diameter) and a polyglycolic acid tissue engineered vascular graft (TEVG) seeded with bone marrow mononuclear cells was implanted between the inferior vena cava and pulmonary artery. An angiography after graft implantation showed that the TEVG was patent (*left*) (*arrows*). Long-term follow-up angiography (11 years later) was patent with no aneurysm and displayed growth as the patient grew older (*right*) (*arrows*).

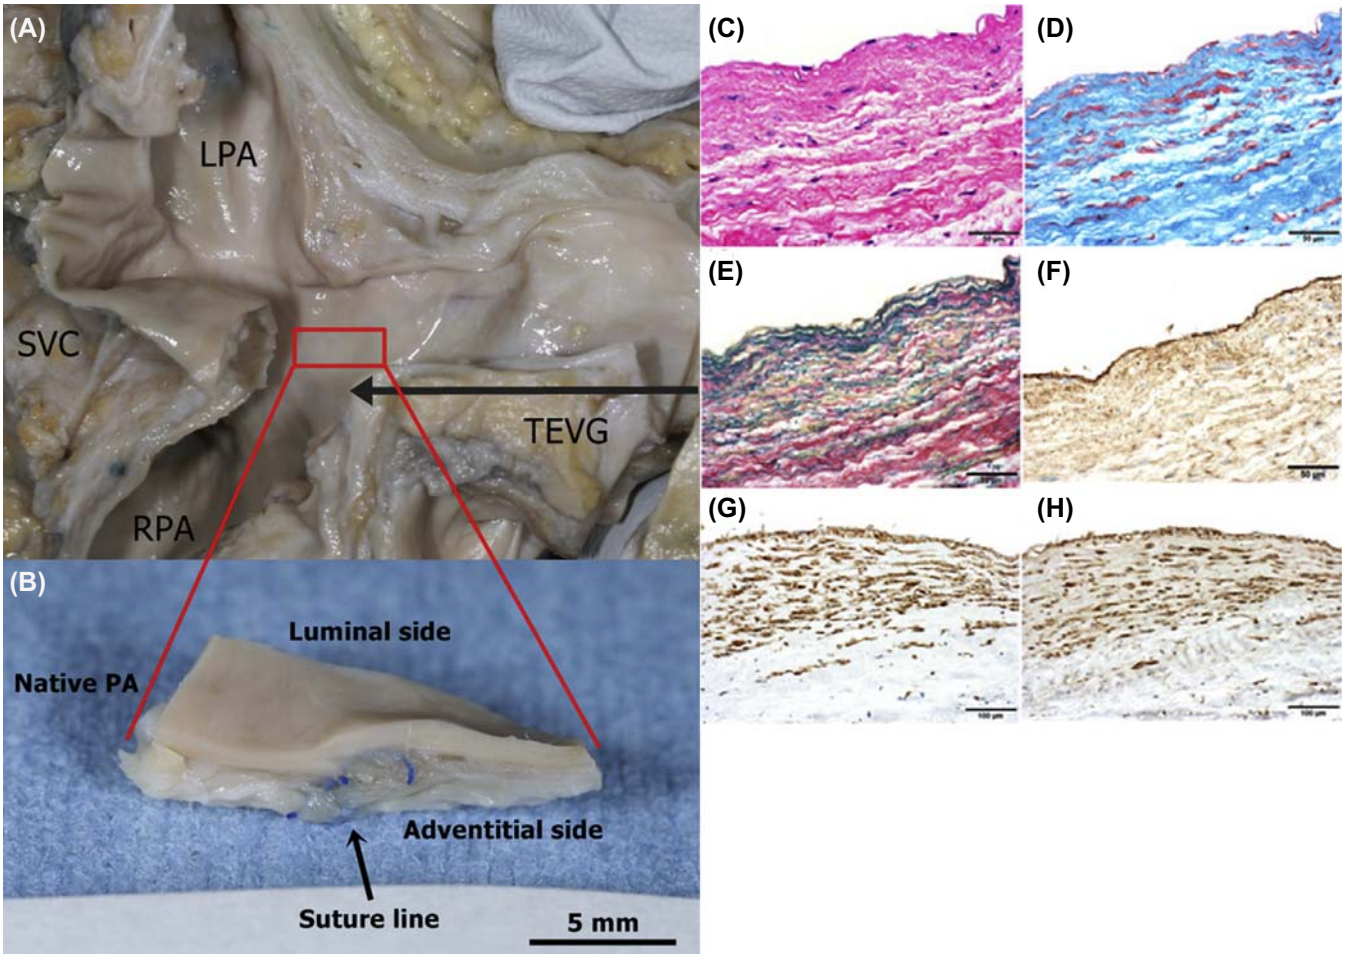

FIGURE 58.4 Macroscopic and histological images of explanted human TEVG. A female patient with a single right ventricle underwent TCPC with common atrioventricular valve plasty at age 4 years. A 12-mm-diameter biodegradable synthetic TEVG with BM-MNCs was implanted between the hepatic vein and pulmonary artery. Unfortunately, she died 12 years later and an autopsy was performed. (A) Macroscopic imaging of the TEVG. No difference appears between native PA and TEVG. (B) Cross-section view of the border between native PA and TEVG. (C) Hematoxylin-eosin staining. clinical outcome after TCPC using nonbiodegradable PTFE grafts [45,46]. This makes the superiority of biodegradable TEVGs much more difficult. Furthermore, the TEVGs used in TCPCs were implanted in high-flow and low-pressure environments. Therefore, the future will look at developing small-diameter TEVGs that are able to endure the high-flow and high-pressure environments of the arterial system.

Many researchers have investigated various combinations of scaffold materials, fabrication methods, seeded cells, and culture protocols. Beside the Breuer–Shinoka and Niklason groups, no clinical trials are using hybrid scaffolds. In ovine models, Hoerstrup et al. have shown patency of up to 100 weeks in pulmonary artery replacement with nonwoven PGA scaffolds coated with a thin layer of poly-4-hydroxybutyrate seeded with autologous myofibroblasts and ECs [47,48]. The scaffolds were fabricated by a heat-application welding technique. Thereafter, myofibroblasts were seeded in three steps at 24-h intervals onto the scaffolds and cultured under static culture conditions. After 2 days, the grafts were seeded with ECs. After another 3 days of static culture, the grafts were transferred into a pulse duplicator system and cultured for 14 days. Therefore, the total culture period is about 3 weeks and biodegradable synthetic materials remain in the grafts. This fabrication method is similar to that of Niklason et al., but there are major differences in the culture period and the fact that biodegradable synthetic materials remain when the graft is completed. Hoerstrup's hybrid TEVGs remodeled into a functional vasculature that mimicked native vessels and displayed growth as the sheep aged.

Biodegradable Synthetic-Based Scaffolds

The ideal TEVG is thought to remodel, generate neovessels, grow, and be easy to fabricate. With this in mind, TEVGs fabricated from acellular synthetic scaffolds are the closest approach to producing the ideal graft. Acellular synthetic scaffolds do not require in vitro cell cultures and can eliminate the risk for adverse immunological reactions. Therefore, cell-free biodegradable synthetic grafts have been investigated in small- and large-animal models. Poly(lactic acid), PGA, and PCL are the most widely used synthetic scaffold materials and have different degradation periods and mechanical properties. Attempting to combine the best various individual characteristics of single polymers, copolymers such as PLCL and poly(L-lactic-*co*-glycolide) have been proposed and developed. However, cell-free synthetic scaffolds are disadvantaged because they have no cell populations, like SMCs, fibroblasts, and ECs, to promote TEVG remodeling and antithrombogenicity. Therefore, acellular synthetic grafts have not yet reached clinical trials. Matsumura et al. have developed TEVGs consisting of knitted PGA fibers and a PLCL sponge with outer poly(glycolide-*co*-ε-caprolactone) monofilament reinforcement. These constructs were implanted into canine left pulmonary arteries and showed 100% patency up to 12 months [49]. This favorable patency is unsurprising because pulmonary artery reconstruction surgery generally results in satisfactory outcomes. The next generation of acellular synthetic scaffold will focus on arterial TEVGs studied in large-animal models. In arterial vasculature, lots of research has focused on small-diameter TEVGs because many patients have CVDs that require arterial bypass grafts or surgical procedures.

CONCLUSION

Historically, the development of TEVGs has faced many difficulties. To overcome these obstacles, different fabrication methods, techniques, and approaches have been proposed. TEVG materials introduced in this chapter are biologically or synthetic-based scaffolds. With regard to the development of TEVGs, it was rational to focus on the venous system at first, because large-diameter venous grafts do not need to endure the high pressures of the arterial system. In the 2000s, after Shinoka et al. published clinical results investigating the use of venous biodegradable synthetic grafts seeded with BM-MNCs in children with congenital heart disease, many researchers turned their attention to creating AV shunt TEVGs for hemodialysis access. This is the next logical progression in TEVG technologies because although the AV system has higher pressures than the venous system, it is still subject to lower pressures than the arterial system, which makes it much more likely and easy to fabricate. However, AV shunt TEVGs must be more durable than venous TEVGs and able to withstand repeated cannulation. Niklason et al. showed the viability of acellular biological-based TEVGs for patients with ESRD requiring dialysis access. The final frontier in vascular grafts will be to develop arterial TEVGs. Several research groups have developed arterial TEVGs and demonstrated their efficacy in animal models, but no groups have progressed to clinical trials. Most biodegradable synthetic arterial TEVGs are using electrospun nanofiber to withstand the high pressures of the arterial system. However, biodegradable synthetic TEVGs must be completely reconstituted by host-derived cells before the synthetic scaffold degrades and loses mechanical integrity. The neovessel remodeling process should include confluent endothelialization, the construction of SMC layers, and abundant ECM deposition. Therefore, the balance between scaffold degradation and neovessel formation has an important role in the long-term viability of a TEVG. Electrospun nanofibers are promising scaffold materials for arterial TEVGs. PCL electrospun nanofiber grafts have shown good mechanical properties with high patency rates in small-animal models [36]. However, thin-fiber and small-pore electrospun nanofiber scaffolds inhibit cell migration into the scaffold, which causes delayed neotissue formation. In contrast, thicker-fiber and large-pore electrospun grafts can enhance the neovessel formation and remodeling process by mediating macrophage polarization toward an M2 phenotype [36,50]. However, electrospun grafts with too-large pores can leak blood and lose their mechanical properties. Therefore, it is critically important to find the optimal blend of fiber diameter and pore size in electrospun nanofiber scaffolds when fabricating the ideal arterial TEVG. The clinical translation of small-diameter arterial TEVGs is greatly anticipated based on market forces and the many patients who have atherosclerotic CVD that require such grafts.

Important factors to consider when rationally designing a TEVG are that it should be less invasive, cost-effective, time saving, and readily available off-the-shelf. Unfortunately, venous and AV shunt TEVGs are not yet widely accepted in the clinical setting because not all of these factors have not yet been satisfied. Furthermore, the cell culture and seeding processes for producing TEVGs are technically complicated, and they have high costs and require extra time. With this in mind, cell-free synthetic TEVGs are the most cost- and time-effective approach but are limited by their inability to control cell migration, which often leads to aneurysm or occlusion. Therefore, technologies for TEVGs that elute and/or release drugs and proteins such as chemokines, cytokines, and growth

factors might be the source of important future studies and research. Several decades have passed since the first TEVG was developed. However, no one has developed a TEVG that is widely and commercially used in the clinical setting. To achieve clinical translation, multidisciplinary collaborations among clinicians, cardiovascular surgeons, engineers, chemists, and biologists will be needed in addition to further progress and advances in diverse technologies.

List of Acronyms and Abbreviations

AV Arteriovenous
BM-MNCs Bone marrow mononuclear cells
CABG Coronary artery bypass grafting
CAD Coronary artery disease
CVD Cardiovascular disease
EC Endothelial cells
ECM Extracellular matrix
ES cell Embryonic stem cell
ePTFE Expanded polytetrafluoroethylene
ESRD end-stage renal disease
iPS cell Induced pluripotent stem cell
PAD Peripheral artery diseases
PCL Poly(ε-caprolactone)
PGA Polyglycolic acid
PLCL Poly(L-lactide and ε-caprolactone)
PTFE Polytetrafluoroethylene
SIS Small intestinal submucosa
SMC Smooth muscle cells
TBTE Thread-based tissue engineering
TCPC Total cavopulmonary connection
TESA Tissue engineering by self-assembly
TEVG Tissue engineered vascular graft

Regenerative Medicine Approaches for Tissue Engineered Heart Valves

James K. Williams, James J. Yoo, Anthony Atala

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

Heart Valve Disease: A Local and Global Problem

More than 5 million Americans are diagnosed with heart valve disease (HVD) each year. HVD can occur in any single valve or a combination of the four valves, but diseases of the aortic and mitral valves are the most common in adults [1–4]. Nearly 30% of all adults aged over 65 years have a sclerotic aortic valve, 10% of whom have accompanying stenosis (narrowing) [1–4]. Valvular heart disease is also a global issue. Approximately 1 million people aged over 65 years are affected by HVD in the United Kingdom [5]. US research also suggests that there could be undiagnosed HVD in the United States and United Kingdom populations [6]. Whereas the prevalence of valvular heart disease is estimated at 2.5% in industrialized countries, the prevalence in developing countries is unknown, but most likely it is much higher owing to the number of people (mostly children) with rheumatic heart disease (RHD). RHD is responsible for about 233,000 deaths annually [7,8]. At least 15.6 million people are estimated to be affected by RHD; a significant number of these are children and require repeated hospitalization and often unaffordable heart surgery over the ensuing 5–20 years [9–11]. In addition, RHD still represents 22% of valvular heart disease in Europe [7–11].

Adult Populations

As much as 90% of patients with severe aortic valve stenosis have a life expectancy of less than 10 years unless treated, and 50% of these patients with heart failure will die within 1 year [12]. The most common heart valves replaced in adults are the aortic and mitral valves; they represent three out of four cases of valvular disease in this cohort of patients [12,13]. Replacement of diseased heart valves by mechanical prostheses or bioprostheses is common and lifesaving and enhances quality of life in many patients. However, there are important limitations to available substitute heart valve technology, including (1) the need for long-term anticoagulation to reduce thromboembolic complications in all patients with mechanical prosthetic valves and the consequent significant risk of hemorrhagic complications with this therapy, and (2) progressive immune-based degradation of biological valves (including xenogenic and allogenic valves).

Young Populations

Congenital heart disease occurs in about 1% of births and more than one-third of these abnormalities involve the aortic or pulmonary valves. There is a significant need for valve replacement in children and adolescents [7–11]. A major problem with heart valve replacement in children is that mechanical or bioprosthetic devices are incapable of growth. Thus, children with congenital heart disease and other children who need valve replacement often require multiple valve replacement operations to implant successively larger valves to accommodate somatic growth.

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00059-X

Indeed, difficulties associated with valve replacement in children have provided strong motivation to the tissue engineering approach to valves, the goal of which is to have a living and dynamic valve, with structure, function, and homeostatic and adaptive mechanisms as close as possible to those of the natural valve. Tissue prostheses are readily available and come in different ranges. However, they are unavailable in sizes smaller than 19 mm and hence are unsuitable for small children even if annular enlargement techniques were used.

CLINICAL OPTIONS

More than 100,000 heart valve surgeries are performed in the United States each year, and over 300,000 worldwide [1–4]. At a mean cost of $140,000 per procedure, this indicates an annual cost of $14 billion in the United States alone [1–4]. HVD surgery is the second most common cardiovascular procedure and is expected to triple (exceeding 1 million worldwide cases annually) by 2050 [3]. Because of its important hemodynamic position, a sclerotic aortic valve increases risk for death from other cardiovascular diseases (e.g., heart attack, stroke, and cardiomyopathy) by 50% [1–4]. The invention and implantation of prosthetic heart valves to treat patients with dysfunctional, diseased valves started in the 1950s [1–4]. Since then, a wide variety of valve prostheses have been developed and can be divided into mechanical or biological.

Mechanical

Several designs of mechanical heart valves have been developed over the years [14,15]. The most common mechanical valve is the bileaflet valve introduced in 1977 [15]. Mechanical valve prostheses are usually recommended for patients aged under 60 years, because these prostheses are durable with the potential to last over 20 years and often do not require replacement surgeries [16–18]. However, mechanical heart valves increase the risk for thromboembolism and require lifelong anticoagulation therapy, which exposes them to higher risks for bleeding and hemorrhages associated with this therapy [18]. For infants born with congenital valve defects, mechanical valves are not ideal because they do not come in sizes small enough (16–29 mm in diameter) for newborns and do not grow with the patient.

Biological

Biological tissue-based valve replacements were developed to eliminate the need for anticoagulation treatment in patients who have undergone valve surgeries. Since the late 1950s, many different types of biological valves have been created, ranging from valves coming from the patient's own body (autografts and autologous valves) to valves from human donors (homografts) and to valves from other animal species (xenografts). Advantages of biological valves are their excellent hemodynamic profile, lack of anticoagulation therapy, and ability to grow and integrate with the patient [19]. Since their production in 1965, xenografts have become the most frequently implanted biological valve [20]. Two common classes of xenografts include porcine aortic valves and bovine pericardial valves [14]. Although biological heart valves eliminate the need for anticoagulation therapy, they are not as durable as mechanical heart valves. Patients must undergo valve replacement surgery within 10–15 years, because biological valves degrade over time. Thus, biological heart valves are often recommended for patients aged more than 60–70 years [21]. Biological heart valves are available for pediatric patients, but they have a higher rate of degradation and do not grow, and thus require repeat procedures [22,23]. Advantages and disadvantages of mechanical and biological valves are depicted in Table 59.1.

TISSUE ENGINEERED HEART VALVES

Tissue engineered heart valves (TEHVs) can potentially address the shortcomings of current implants by providing an unlimited supply of heart valves in a variety of sizes. The general approach to producing TEHVs is to incorporate biomaterials with autologous cells that enable growth and biological integration. The ideal heart valve prosthesis should be antithrombogenic, biocompatible, durable, and resistant to calcification, and exhibit a physiological hemodynamic profile [24]. In addition, the valve's capability to integrate and grow with somatic growth would eliminate the need for multiple surgeries. The overall goal of TEHVs is to demonstrate excellent hemodynamics and match patient anatomy. At a cellular level, biomaterials used for the TEHV construct should promote cellular integration by enabling cell adhesion, proliferation, extracellular matrix (ECM) production, and remodeling. Most important, the scaffold

Implant	Advantages	Disadvantages	References
Mechanical	Durable	Lifelong anticoagulation	[16]
	Low reoperation rates	Risk for hemorrhage and embolism	[17]
		Does not grow	[16,18]
		Infection risk	[18]
Biological	"Natural" material	Limited supply for pediatrics	[18,19]
	Better hemodynamics	Less durable	[19]
	No anticoagulants	Immune-based deterioration	[18,19]

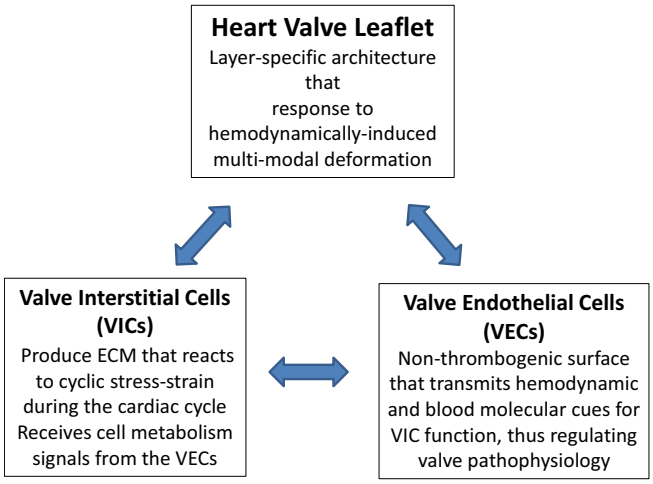

FIGURE 59.1 Schematic representation of the interaction of valvular endothelial cells (VECs) and valvular interstitial cells (VICs) on heart valve leaflet structure and function [25–28]. *ECM*, extracellular matrix.

must promote the physiological cell phenotype and degrade at a rate that matches ECM production. Despite advances, no currently available TEHVs meet all of these requirements. Thus, the challenge to bioengineering TEHVs is to develop commercially available implants that can meet all or most of these criteria. This will require the collaboration of biomechanical engineers, cell biologists, physiologists, pathologists, and cardiothoracic surgeons.

Biomaterials suitable for TEHVs fall into several classes: decellularized ECM (xenografts or homografts), natural polymers, and synthetic polymers. When designing a TEHV, there are three main design considerations for choosing a biomaterial: (1) cell–scaffold interactions, (2) the fabrication process and its impact on the microarchitecture of scaffold, and (3) the durability of structure and function in a physiological setting. This is especially important when designing valve replacements for the mitral or aortic position, in which pressures and shear stresses are much higher than the pulmonary position.

There are several design criteria for tissue engineering heart valve scaffolds. All of these need to focus on how best to recapitulate the basic structure of the valve leaflets. This consists of cellularization (either ex vivo or in situ) of a bilayer of valvular endothelial cells (VECs), surrounding valve interstitial cells (VICs), which have properties of both fibroblasts and myocytes (myofibroblasts). These cell interact both physically and biologically to form and maintain valve structure and function [25–28]. The basic biology of the heart valve leaflets is depicted in Fig. 59.1.

Considerations for Cell Source

There are several considerations for selecting a cell source. First, the type of cells is important to consider because there are three main options: xenogeneic, allogenic, and autologous. Although xenogenic sources may be readily available, they are not a viable clinical option. Allogenic cells are also not ideal because they can invoke immune

responses and would require long-term immunosuppressive therapy. However, allogenic sources may be possible if used to create stronger matrix, followed by decellularization and implantation. Thus, autologous human cells are the most desirable option for creating a TEHV.

The ideal cell source for seeding of TEHVs would be one that can be expanded sufficiently and has the potential to be differentiated into the two main cell types found in heart valves (VECs and VICs). If these cells are to be differentiated, it is important to characterize their phenotype and biological function [28]. VECs regulate permeability, immune and inflammatory responses, and VIC phenotype through paracrine signaling [27]. Meanwhile, VICs maintain tissue homeostasis by high proliferation activity and ECM repair and remodeling [27]. To recapitulate the long-term durability and function of a TEHV, it will be necessary to produce an implant that can reproduce these cell functions and spatial distribution within the valve leaflet.

A number of cell types have been applied to TEHVs. These include VICs, VECs, endothelial progenitor cells, bone marrow progenitor cells, autologous amniotic fluid cells, myofibroblasts, and smooth muscle cells [27]. The important takeaway from past studies is that each cell type has advantages and disadvantages. Although these studies are promising, the direct application of primary cells for TEHVs may not be suitable for clinical translation, because allogenic cells can induce an immune response in the recipient of the TEHV. Primary cells have limited proliferation capabilities whereas stem cells can result in uncontrollable proliferation and differentiation. These are some limitations that need to be considered when selecting a cell source for TEHVs.

Scaffold Design

The design of any implant will depend on the implant position within the heart and must recapitulate the leaflet structure. There are four heart valves: the tricuspid and mitral valve control blood flow from the atrium to the ventricles while the pulmonary and aortic valves regulate blood from the ventricles to the pulmonary artery and the aorta, respectively. The tricuspid, pulmonary, and aortic valve are composed of three leaflets. Meanwhile, the mitral valve has two cusps. Each leaflet is composed of three layers known as the fibrosa, spongiosa, and ventricularis. The fibrosa layer has collagen fibers aligned in the circumferential direction, whereas the ventricularis is composed of elastin fibers aligned in the radial direction. Valve endothelial cells line the outer layers of the fibrosa and the ventricularis, and within the valve leaflet, there are valvular interstitial cells [29].

Despite efforts, the ability to replicate the trilayer leaflet structure in TEHVs successfully remains challenging. One of the most important design criteria for developing functional leaflets is the different orientations of collagen and elastin fibers. To replicate this property, a fabrication process that can reproduce these unique orientations will need to be identified and implemented. Furthermore, the overall mechanical properties need to be within physiological parameters.

With newer fabrication techniques, several groups have developed and tested multilayer scaffolds for TEHVs. For instance, the electrospinning technique using materials such as poly-ε-caprolactone (PCL) enables the formation of aligned nanofibers [30]. These aligned scaffolds introduce anisotropic properties similar to native valve leaflets. In addition, modification to electrospun scaffolds and addition of other materials have since been introduced to generate more complex structures that resemble the three layers of the leaflet [31,32].

Once developed, consideration needs to be given to the interaction between layers of the valve implants. One study demonstrated that a trilayer hydrogel quasilaminate can be generated using poly(ethylene glycol) (PEG) diacrylate and a sandwich fabrication method [33]. The scaffold was composed of two stiff hydrogel outer layers and one soft hydrogel component to represent the spongiosa layer. The scaffold experienced no issues between the interfaces of the layers and did not vary in bending moduli compared with its single-layer counterpart. However, addition of cells to the trilayer scaffold reduced the modulus [33]. Three-dimensional (3D) printing also permits the fabrication of a leaflet structure that enables anisotropic properties to be introduced. However, 3D printing is still in the early development stage [33].

Implant Function

Proper and long-term implant function is the ultimate goal of valve replacement. In an average lifetime, a person's heart valves will open and close nearly 3 billion times, allowing 3–5 L of blood to circulate through the body continuously and efficiently [34,35]. The semilunar valves (pulmonary and aortic) prevent blood from flowing back into the ventricles, while the atrioventricular valves (tricuspid and mitral) prevent blood from flowing back into the atria from the ventricles. To sustain function, heart valves must be able to withstand many forces of the hemodynamic environment in both the right and left sides of the heart. Meeting these criteria is the challenge of TEHVs.

Hemodynamically, the leaflets of the aortic valve are closed during diastole, slightly overlapping in a region called the lunula to allow filling of the left ventricle. The valve annulus then expands in radius until a small orifice is present

and blood begins to flow through the orifice as the ventricle contracts during systole [34]. During this contraction, the aortic valve opens and blood flows through the valve, traveling up to 1.35 ± 0.35 m/s [36]. At the end of systole, the deceleration of blood flow allows for coaptation of the valve cusps [34,35]. As one can imagine, redeveloping these complex hemodynamic functions is a particularly difficult job using TEHVs, and further studies need to be performed.

The biomechanics of the implant are critical to valve hemodynamics. During the cardiac cycle, valves experience stresses and strains as a result of blood flow and pressure gradients between the chambers of the heart. Arjunon et al. described three mechanical stimuli experienced by heart valves: shear stress, pressure, and leaflet strain [25]. Shear stress in valves is defined as the frictional stresses that the leaflets experience owing to blood flow during the cardiac cycle. Strain is a measure of deformation. Strain in aortic valve leaflets is largely determined by tissue structure. Strains in the circumferential and radial directions were reported to be 10% and 40%, respectively [25]. The highest shear stresses experienced by the ventricularis are 70 dyn/cm^2 during systole; during diastole, the fibrosa experienced shear stresses of about 23 dyn/cm^2 [25].

Biomechanics and hemodynamics cannot be considered separately in implant design. In a diseased or defective state, leaflets may experience higher levels of shear stress owing to altered hemodynamics [25]. During diastole, heart valves experience transvalvular pressure gradients ranging from 10 to 120 mmHg [35]. The aortic valve, in particular, experiences a transvalvular diastolic pressure gradient of 80 mmHg [25]. The ability to sustain this pressure is caused by circumferentially aligned collagen fibers in the fibrosa layer of the leaflets [29,36]. Therefore, the hemodynamics and biomechanics are closely intertwined.

Implant Design Goals

TEHVs must be designed to offer a significant increase in function compared with the diseased valve while integrating with the patient's body, a task not yet accomplished by mechanical or biological valve implants. Above all, TEHVs must ensure long-term functionality of the valve by passively maintaining unidirectional blood flow. To achieve this functionality, TEHVs must be designed with several considerations in mind. They must be able to withstand the inertial forces of blood flow in the hemodynamic environment of the heart location in which they are implanted. Blood flow out of the left ventricle during systole should passively open the TEHV. By mimicking the general anatomy of the valve leaflets and sinuses, the pressure gradients between heart chambers should cause the TEHV to close fully. Continued and oscillating changes should not cause damage to the leaflets, nor should they stimulate the progression of disease, such as calcification. Finally, leaflets should display anisotropic properties, particularly regarding strain in the circumferential and radial directions, because these properties are important in ensuring valve functionality and preventing pathological conditions from developing on the cellular level [25].

Testing Tissue Engineered Heart Valve Function

There are two approaches for testing TEHVs: one is in vitro (before implantation or explantation) and the other is in vivo. Engelmayr et al. [37] used a bioreactor to simulate cyclic flexure to test heart valve scaffolds made of poly(glycolic acid) (PGA) fibers and a 50:50 blend of PGA and poly(lactic acid) (PLLA) fibers, coated in the β-subunit of prolyl 4-hydroxylase (P4HB) to allow molding into different shapes. From this study, they determined that dynamic flexure significantly decreases the stiffness of their scaffolds after 1 week compared with those under static conditions, owing to fiber fragmentation observed in scanning electron microscopy images of the scaffolds. This finding is significant in that dynamic testing is necessary to evaluate the functionality of TEHVs in a physiological setting, because TEHV behavior may not be truly represented under static testing conditions. Driessen et al. [38] measured the biomechanics of TEHV leaflets and created them in a diastolic pulse duplicator. Over 4 weeks, the conditioned leaflets became thinner. Uniaxial tensile tests were performed on the conditioned leaflets and the results were used to develop a model to analyze TEHV mechanics. In addition to less coaptation of the engineered scaffolds, these results indicated that the tissue engineered leaflets were stiffer and less anisotropic compared with native porcine valve leaflets These studies demonstrate the importance of testing the functionality of TEHVs under dynamic conditions and indicate a need for more appropriate scaffold designs to replicate the functionality of native valves.

Only a few in vivo studies involving TEHV implantation have been conducted. Sodian et al. created polyhydroxyoctanoate (PHO) scaffolds with ovine carotid arterial cells and implanted the scaffolds into six sheep. These valve scaffolds resulted in no stenosis or thrombosis for 20 weeks, but they degraded slowly, resulting in prolonged bioabsorption of PHO [39]. Hoerstrup et al. created a PGA mesh coated with P4HB, which resulted in faster degradation of the scaffold that was higher in strength and flexibility. These valve scaffolds resembled native heart valves in structure, mechanics, and composition, and they remained functional in sheep for 5 months [40]. More recently,

Kluin et al. implanted an electrospun polycarbonate *bis*-urea valve into the pulmonary position of sheep for up to 12 months. During that time, the subjects showed no signs of valve failure and the implanted scaffolds had cell infiltration into the porous microstructure. The evidence of collagen, glycosaminoglycans (GAGs), and elastin deposition similar to native valves was thought to contribute to the successful functionality of these valves [41]. Williams et al. [42]. transplanted porcine decellularized scaffolds, conjugated with CD133 into the pulmonary position of sheep and reported that these constructs had similar biomechanical and matrix composition as native leaflets 3 months after implantation. Furthermore, these CD133-conjugated valves could be cryogenically preserved and maintain their viability [43]. However, many TEHVs have yet to be studied for functionality. As more groups are successful in designing functional TEHV scaffolds, studies regarding the mechanical properties and the effect of hemodynamics on these scaffolds must be conducted to determine their suitability for implantation in humans.

Bioreactors

In vitro testing and conditioning of THEVs has required the development of bioreactors. Because hemodynamic behavior around valves is complex, many different bioreactors have been created to mimic the conditions that native valves experience, including cyclic stretch and flexure, oscillatory shear stress, and pressure. In 2000, Hoerstrup et al. developed a pulsatile flow bioreactor to stimulate TEHV scaffolds to increase in mechanical strength through ECM production while enabling a more complete degradation of the polymeric scaffold [44]. For less mechanically robust TEHVs made of materials such as hydrogels, Jockenhoevel et al. created a bioreactor consisting of a laminar flow chamber to introduce shear stress to fragile scaffolds [45]. Soon afterward, Engelmayr et al. reported a bioreactor design to provide cycle flexural stimulation to TEHV scaffolds to observe changes in effective stiffness of the scaffold resulting from unidirectional cyclic flexure [37]. To study the effects of conditioning scaffolds with only some of the mechanical cues present during the cardiac cycle, Mol et al. designed a diastolic pulse duplicator, a bioreactor that mimics only the diastolic phase of the cycle and conditions scaffolds using a strain-based approach [46]. Berry et al. and Lee et al. [47,48] developed a computerized pulsatile bioreactor to condition-seeded endothelial cells physiologically on a decellularized porcine scaffold. Alternatively, Engelmayr et al. designed the flex–stretch–flow bioreactor to study the coupled effects of cyclic flexure, stretch, and flow on TEHVs [49]. In addition, Syedain et al. created a cyclic stretch bioreactor consisting of the TEHV mounted in a latex tube that is cyclically pressurized by culture media, stretching the valve root and leaflets with the latex. More recently, Ramaswamy et al. designed a more physiologically relevant bioreactor that would allow for higher fluid velocities and subject scaffolds to higher shear stress while maintaining laminar flow [50]. From a regulation standpoint, bioreactor-required TEHVs represent a challenge because resterilization and reuse increases the risks of disease transmission between scaffolds during seeding and conditioning. This hinders the clinical development of patient-specific TEHVs, so alternative designs (disposable) must be pursued to make this process clinically translatable.

In Vivo Conditioning and Testing

Several approaches have been devised to rely on the body to reseed and condition implanted TEHVs, because the body is the best incubator and bioreactor. In vivo testing is difficult in small animals. For this reason, larger mammals are used, such as dogs, pigs, calves, and sheep, in which ultrasound, computed tomography, and magnetic resonance imaging of cardiodynamics are available. The most commonly used animal model for studying TEHVs is the adult sheep. Sheep have been widely used because they have a high calcium metabolism, which makes them valuable for observing TEHVs for durability and sustained performance under "worst-case" conditions [51]. Gallo et al. [52] reported on the potential use of the Vietnamese pig to evaluate TEHVs because they possess anatomic features that are similar to those of humans. Compared with common farm pigs, Vietnamese pigs are smaller and do not grow as rapidly; they reach about 70 kg during adulthood. Vietnamese pigs are also suitable because their cardiac output, stroke volume, mean arterial pressure, heart rate, and myocardial blood flow are similar to those of human beings.

BIOMATERIALS FOR TISSUE ENGINEERED HEART VALVES

Decellularized Bioscaffolds

One method for tissue engineering living, functional heart valves is to decellularize xenogeneic heart valves and then recellularize them with autologous cells with or without conditioning in a bioreactor before implantation. Several approaches to decellularization have been developed over the years. Each has advantages and

disadvantages. These include the use of detergents, enzymes, and osmotic buffers. Two commonly used decellularization detergents are sodium dodecyl sulfate (SDS), an anionic surfactant, and Triton X-100, a nonionic surfactant [53]. Enzymatic decellularization by trypsin−ethylenediaminetetraacetic acid is also commonly studied [53]. There are different protocols, which usually consist of removing the cellular material using one of these agents.

One problem with these decellarization procedures is structural changes within the scaffold biomaterials. Several studies have been conducted regarding the different methods of decellularization and their resulting impact on valve structure and mechanics. Decellularization using Triton X-100 has been shown to cause the largest increase of extensibility compared with treatment with trypsin or SDS [53]. However, these methods all had a significant effect on the stiffness of the leaflets. Treatment with SDS has also been shown to cause elastin fibers to curl, whereas collagen fibers lost structural details [54]. In this same study, trypsin decellularization resulted in decreased elastin and Triton X-100 caused collagen fibers to misalign. SDS was the only treatment that resulted in complete decellularization without the loss of elastin or collagen structure. A study reported that valves treated with SDS or Triton X-100 and trypsin did not show a significant decrease in elastin, but it resulted in a decrease in collagen and GAGs [55]. The results of these experiments failed to provide an optimal protocol for decellularization, which has yet to be developed. Recellularization of a decellularized scaffold involves coating the inner and outer surfaces of the valve with a cell solution [55]. After seeding, valves are preconditioned in a bioreactor to improve cell migration and proliferation, as well as cell alignment to flow conditions.

Natural Materials for Tissue Engineered Heart Valves

In addition to preformed decellularized scaffolds, there are numerous approaches using biomolecules to form TEHVs. Collagen is the most abundant protein in the body, with multiple genetic variants [56]. The most common type of collagen is collagen type I, which has been extensively studied in tissue engineering applications [57]. The other types of collagen are II, III, and V; these make up components of skin, muscle, bone cartilage, and tendons, respectively. Collagen can be fabricated into several different forms such as collagen sheets, sponges, hydrogels, pellets, or nanospheres. In the case of heart valve tissue engineering, collagen is high interesting mainly because the leaflets of the valve are primarily composed of collagen type I. Collagen can be extracted and purified from different tissue sources [58]. The mechanical properties of collagen hydrogels can be tuned through manipulations of the concentration of monomer, temperature, pH, and ionic strength [58,59]. These conditions can influence the diameter of collagen fibers and the overall mechanical properties of the hydrogel [60]. Although the mechanical properties are tunable, the elastic moduli of collagen hydrogels are limited to 10−30 kPa and have an ultimate tensile strength of 5−10 kPa [61]. However, these properties of collagen hydrogels are not representative of natural ECM because lower protein concentrations must be used to ensure proper diffusion of nutrients to the surrounding cells [34,62].

Heart valve collagen scaffolds have been molded in 2D or 3D hydrogels to better understand heart valve biology and the progression of valve disease [63,64]. To develop a scaffold with physiological properties, variations in the temperature, pH, and cross-link concentration have been used to modulate the scaffold properties [65−67]. These properties of collagen have been used to study the metabolic activity of VICs [68] and determine the effects of anisotropic strain on VIC phenotype and behavior [69].

There are both advantages and disadvantages to using collagen as a biomaterial for TEHVs. One advantage of collagen is that it is a native biomaterial with which cells normally interact [70]. One major disadvantage of collagen is variability depending on the source [71]. Another problem is that collagen from other species or even other humans can elicit an immunogenic reaction if antigens are present [58]. Importantly regarding TEHV use, collagen can activate the blood coagulation pathway through platelet adhesion and aggregation [72]. There are surface treatments to make the collagen less thrombogenic [73]. However, a major limitation is its mechanical properties; it must be combined with other materials for heart valve tissue engineering.

Fibrin

Fibrin is another natural biomaterial that has been used for TEHVs. Fibrin scaffolds support cell growth and proliferation and enable a number of biological active molecules to bind to fibrin [73]. This enables specific cell−matrix interactions that can promote tissue regeneration. Fibrin-based heart valves were created by molding [74]. In that study, Jockenhoevel et al. demonstrated that fibrin could be used to generate an autologous biodegradable tricuspid valve conduit using injection molding. The degradation rate of valve conduits was controlled by aprotinin, which halted fibrinolysis by inhibiting plasmin. Although injection molding of fibrin enabled a complex structure to be

made easily, there were two major limitations: scaffold shrinkage after long-term culture and poor mechanical properties. Another application of fibrin for TEHVs was when Flanagan et al. generated fibrin-based valve conduits, which were subsequently implanted into an adult sheep model for functional studies. The study used echocardiography to generate animal-specific valve models. The fibrin-based valves were generated by injection molding using a mixture of autologous fibrin, myofibroblasts, and endothelial cells [75]. Valves were conditioned mechanically for 28 days before implantation into the pulmonary trunk of adult sheep. Although the valves remained intact with no signs of thrombosis, calcification, or stenosis, valve insufficiency was observed in all implants owing to contraction of the leaflet structures [75].

There have been additional studies using fibrin-based TEHVs, but these involved hybrid constructs with fibrin and other biomaterials to address the issue of tissue shrinkage, contraction, and strength. The BioTexValve, developed by Moreira et al. is a bio-inspired textile-reinforced TEHV. The valve conduit is reinforced with electrospun fibers of poly(L/DL)-lactide and poly-lactide-*co*-glycolide (PLGA) to improve the leaflet burst strength; it closed with no problems under physiological aortic conditions in a flow-loop for 21 days [76]. Most fabrication of fibrin TEHV scaffolds has been limited to molding because fibrin cannot be manipulated after gelation and it does not have the shear-thinning properties for extrusion-based 3D printing [77]. The only method for 3D bioprinting fibrin is to use two-component printing, in which fibrinogen and thrombin are mixed on the print platform to form a hydrogel. Thus, fibrin alone is not suitable for 3D bioprinting, and it must be combined with other biomaterials for successful printing. Thus, fibrin can be used to make valve conduits that promote healthy cellular ECM production and remodeling without resulting in thrombosis or calcification. However, the major limitations of fibrin are the poor mechanical properties and scaffold contraction caused by cell-mediated contractions [73].

Alginate

This anionic polymer has been used in a wide range of biomedical applications owing to its biocompatibility, nonthrombogenicity, and low cost [78]. The overall mechanical and degradation properties of alginate hydrogels can be controlled via chemoreversible ionic gelation or covalent cross-linking [79,80]. Alginate hydrogels have been used in a variety of biomedical applications such as wound healing, drug delivery, and scaffolds for tissue engineering [71,78,80]. The main application for alginate in the area of TEHVs is to serve as a thickening agent for 3D bioprinting [30,81]. For instance, Duan et al. combined alginate with gelatin. This combination enabled valve conduits to be 3D printed with high shape fidelity and spatial placement of encapsulated cells [81].

There are many advantages and disadvantages to using alginate as a natural biomaterial for TEHVs. First, alginate is biocompatible, inexpensive, and easily implemented into the 3D bioprinting process [78]. A major drawback of using alginate is that there can be large batch-to-batch variation, and biosynthesis of alginate through bacteria is expensive and not yet scalable. Furthermore, its hydrophilic properties make it difficult for protein adsorption and cellular recognition. As a result, alginate scaffolds must be chemically modified to enable cellular function. Finally, there is concern that the presence of calcium ions can promote calcification of alginate scaffolds [80].

Hyaluronic Acid

Hyaluronic acid (HA) is a nonsulfated glycosaminoglycan that is a major constituent of the ECM. It is biosynthesized from bacteria (*Bacillus subtilis*) to produce highly pure human-grade batches [82,83]. Although the properties of HA can be used for tissue engineering, its poor mechanical properties require chemical modifications or the addition of other biomaterials to develop stable and durable scaffolds [84]. One application for HA scaffolds is to study VIC behavior under conditions mimicking the native valve [85]. The transition of HA into hybrid scaffolds permitted even more biological and mechanical control over the scaffolds. In addition, HA can be used to test a myofibroblast-like phenotype [86]. Thus, HA may be useful for understanding valve biology and pathogenesis. Skardal et al. demonstrated that HA can be used in conjunction with PEG derivatives to bioprint vessel-like structures [87]. They also generated a two-step bioprinting process with photocross-linkable hyaluronan and gelatin hydrogels [88]. HA lacks the mechanical properties necessary for physiological function as a scaffold for heart valve leaflets.

Gelatin

Gelatin is a partially hydrolyzed collagen that was originally investigated for its application as a cell culture platform. Gelatin has been incorporated into polymer blends to improve the viscosity for 3D extrusion-based printing and to introduce biologically active sites for enhanced cell viability [81]. The advantage of using gelatin is its similarity to collagen, in that it contains bioactive molecules that promote cell adhesion, proliferation, and migration. However, gelatin is mechanically weak and requires chemical modification or the addition of other materials for it to form a hydrogel. Thus, the best application of gelatin, like HA, is to introduce biological activity to a scaffold or to be used as an additive to modify the physical properties of a polymer blend for 3D bioprinting.

Chitosan

Chitosan is another natural biomaterial that has been applied to TEHVs. An interesting property of chitosan is that it is antimicrobial and has been investigated to treat biological prosthetic heart valves to make them antimicrobial and less prone to calcification [89]. An advantage of chitosan is its molecular structure, which is similar to GAGs. Furthermore, the biocompatibility and its ability to be degraded under physiological conditions are promising. However, chitosan is mechanically weak, similar to all other natural biomaterials, and thus must be modified or combined with other materials for its application in TEHVs.

Polyhydroxyalkanoates

Polyhydroxyalkanoates (PHAs) are a family of natural polyesters biosynthesized from microorganisms or modified plants, or through chemical reactions [90,91]. They are biocompatible, biodegradable, and tunable. They have been applied to the field of tissue engineering [92,93]. One of the first applications of PHA to TEHVs was the development of a composite valve conduit containing PGA. The scaffold was seeded with autologous ovine vascular and endothelial cells. Afterward, valves were implanted at the pulmonary valve position. The results of this study demonstrated that no thrombus formation occurred and there was evidence of cellular matrix production and remodeling [94] However, valvular regurgitation occurred after 24 weeks of implantation. Other studies include the use of PHA foam to generate a valve conduit seeded with autologous vascular cells [95]. The scaffolds were implanted into the pulmonary artery and after 17 weeks there was no sign of thrombus formation and minimal regurgitation compared with acellular scaffolds.

The benefit of PHA is that elasticity can be introduced to stiffer materials such as PGA or poly(lactic acid) (PLA). Previous studies combined chondroitin sulfate, HA, and bioactive glass to improve the bioactivity of PHA scaffolds [96–98]. However, issues that remain with PHA are shrinkage and valve regurgitation. This will likely require blending PHA with other biomaterials or introducing chemical modifications for a more useable scaffold. Table 59.2 outlines the most commonly used natural biomaterials in TEHV construction.

Synthetic Biomaterials

Because of their supply, consistent and reproducible content, and tunability, synthetic biomaterials have been pursued for TEHV fabrication.

Poly(ethylene glycol) Hydrogels

PEG hydrogels are used commonly for various tissue engineering applications because they are biocompatible, nonimmunogenic, and approved by the US Food and Drug Administration for internal use. They are also versatile, because their mechanical, structural, and degradation properties can be tuned using a variety of methods [73]. However, cells will not readily attach to PEG biomaterials because they are hydrophilic. Therefore, tissue engineering using PEG hydrogels requires the addition of bioactive molecules to the hydrogel, such as arginine-glycine-aspartate, a peptide found on fibronectin that promotes cell adhesion and migration [99]. Many studies have been conducted on the ability of PEG hydrogels to maintain the phenotype of native cells in heart valves as well as promote the production of ECM. One example is a study by Wang et al. [100], which demonstrated that VICs from porcine aortic valves maintain their quiescent fibroblast phenotype much better when cultured on PEG hydrogels as opposed to stiff plastics and suggested that the fibroblasts sense the elasticity of the surfaces by the phosphatidylinositol-4,5-bisphosphate 3-kinase–AKT pathway.

Several studies have also been conducted regarding the structure and functionality of PEG hydrogels in TEHVs. Durst et al. was the first group to study the bending mechanics of PEG hydrogels. They conducted three-point bending tests using a custom-designed bending tester on cell-seeded PEG hydrogels of different concentrations and molecular weights. The reported that the flexural stiffness of these constructs matched the native valve leaflets [101]. Other studies tested the importance the role of PEG in designing valve leaflet scaffolds that mimicked the trilayer structure of native leaflets [33], their use in 3D printing [102], and the importance of patterning PEG hydrogels in such a way that the anisotropic properties of native leaflets could be preserved [103].

Polyvinyl Alcohol

Polyvinyl alcohol (PVA) is a hydrophilic synthetic polymer generated by the hydrolysis of poly(vinyl acetate), which is formed by the polymerization of vinyl acetate [73]. This material has been pursued for tissue engineering

TABLE 59.2 Overview of Advantages and Disadvantages of Natural Biomaterial in Tissue Engineered Heart Valve Bioengineering

Biomaterials	Use in Heart Valve Engineering	Advantages	Disadvantages	References
NATURAL MATERIALS				
Collagen	Molded as hydrogels to study valve biology and disease progression, frequently combined with other materials	Most abundant protein in body Good cell interaction	Tensile strength Inconsistent batching Blood coagulation Immune reaction	[57,58] [70–73]
Fibrin	Used in molding heart valves and to test heart valve cell functions	Cell interactions Biodegradable Common natural protein	Poor mechanical properties and scaffold contraction caused by cell-mediated contractions Better combines with other biomaterials	[73–77]
Alginate	Thickening agent for three-dimensional bioprinting	Biocompatibility, nonthrombogenicity, and low cost	Large batch-to-batch variation Expensive to produce Hydrophilic properties make it difficult for protein adsorption and cellular recognition	[78–81]
Hyaluronic acid	Major constituent of extracellular matrix Study valve cell biology Bioprinting	Cell-friendly Used in bioprinting when mixed with other biomaterials	Poor mechanical properties	[82–87]
Chitosan	Treating biological prosthetic heart valves to make them antimicrobial and less prone to calcification	Biocompatibility and its ability to be degraded in physiological conditions are promising	Mechanically weak Must be modified or combined with other materials for its application in tissue engineered heart valves	[89]
Polyhydroxyalkanoates	Aids in introducing elasticity to stiffer materials such as poly(glycolic acid) or poly(lactic acid)	Biocompatible, biodegradable and tunable	Shrinkage and valve regurgitation	[92–98]

because it is nontoxic, biocompatible, biodegradable, and widely available [104]. In the development of TEHVs, PVA hydrogels have been studied for their cellular, structural, and functional compatibility. Wan et al. initially studied the fabrication of PVA hydrogels using the freezing and thawing technique to develop a bioprosthetic heart valve stent. They discovered that after the fourth freezing and thawing cycle, the stress–strain curve of the PVA hydrogel matched that of native porcine aortic roots in the physiological pressure range [105]. In other studies, PVA was used to attach fibronectin covalently to PVA to examine National Institutes of Health 3T3 fibroblast attachment and proliferation [106] to create photocross-linkable and degradable hydrogels [104]. A single-piece trileaflet valve made entirely of PVA molded using the freezing and thawing method was fabricated by Jiang et al. to develop a PVA-based composite hydrogel that mimicked the mechanical properties and anisotropic behaviors of native porcine aortic valve leaflets [107].

Hydrolytically Degradable Polymers

Hydrolytically biodegradable polymers such as PGA, PLA, PCL, poly(glycerol sebacate) (PGS), and polyurethanes (PUs) have shown promise for use in TEHVs because they are biocompatible and exhibit good mechanical properties suitable for withstanding the stresses and strains experienced by valves in a hemodynamic environment. Using techniques such as electrospinning, these polymers can be fabricated into fibrous scaffolds similar to the native valve ECM structure [92].

One of the most commonly studied biodegradable polymers is PGA. PGA has a high modulus and degrades rapidly, losing mechanical strength within 2–4 weeks; the accumulation of glycolic acid has been shown to cause inflammation months to years after implantation [92].

Another biodegradable polymer similar to PGA is PLA. PLA is more hydrophobic and stable against hydrolysis and it degrades more slowly compared with PGA. In tissue engineering applications, PLA has been blended or

copolymerized with other polymers to decrease degradation time [108]. PGA, PGA−PLA hybrids, and their copolymer PLGA have been used in a variety of studies regarding the fabrication of functional, bioresorbable leaflet scaffolds [109]. One group studied bone marrow stem cells seeded on PGA−PLLA scaffolds under different stress conditions and found that the cells exhibited endothelial and myofibroblast phenotypes similar to valves under combined steady flow and cyclic flexure [110]. Another group found that prolonged tissue culture reduced retraction of the tissue engineered leaflets that typically lose mechanical integrity owing to rapid degradation of the PGA scaffold, and suggested that this resulted from an increased amount of GAGs in the tissue [111].

PCL has a slower rate of degradation in vivo compared with PLA. As such, it has been used to contribute mechanical stiffness to tissue engineered valve leaflets. An early study that used PCL as a valve scaffold was conducted by Lieshout et al., in which a PCL filament was knitted into round leaflet patches that were sutured into a tube made of the same knitted PCL. The knitted structure was fitted on a mold and a fibrin solution was poured over the mold. The knitted scaffolds showed complete coaptation and durability over 10 million cycles. There was significant leakage, likely caused by areas of the scaffold where the fibrin detached [112]. In another study, seeded and unseeded scaffolds of PCL were fabricated and cultured for up to 6 weeks. From this study, the researchers determined that PCL scaffolds resulted in the most tissue formation over 6 weeks and the formation of tissue also increased the stiffness of the scaffolds. The tissue that formed on PCL scaffolds contained ECM components in amounts similar to those in native leaflets [113].

PGS is another biodegradable synthetic polymer that has been used to develop heart valve leaflets. The mechanical properties of PGS can be adjusted by altering the curing temperature, curing time, and molar ratio of glycerol to sebacic acid [114,115]. PGS undergoes surface degradation, slowly losing mechanical strength as a result of mass loss. Attempts have been made to create PGS scaffolds that mimic native valves in structure and function. Masoumi et al. designed and microfabricated PGS scaffolds by laser ablation, computationally determining the conditions necessary to create scaffolds that would best match the anisotropy and modulus of native bovine aortic valve leaflets. They observed moduli in the scaffold that were similar to the native valves in the circumferential and radial directions, as well as the presence of collagen and DNA in the scaffolds that were seeded with fibroblasts [116]. In a different study, Masoumi et al. used a micromolding technique to create trilayered scaffolds with PGS sandwiched between two layers of electrospun fibers of a PGS and PCL mixture. These trilayered scaffolds mimicked native valve leaflets in a number of ways, from promoting the deposition of ECM to mimicking their anisotropy and elastic moduli, and to displaying sufficient diastolic coaptation in the pulmonary position of pig hearts. However, the scaffolds lacked fibrous microstructure, which is a hindrance to tissue formation [31].

PUs are a class of elastomers that display good biocompatibility and tunable mechanical properties [117]. Some groups have worked to incorporate degradable linkages in the polymer to make it suitable for tissue engineering [108]. PUs have been used in TEHVs. Thierfelder et al. [118] fabricated PU scaffolds using a spraying technique and obtained homograft scaffolds, seeding both types of scaffolds with human fibroblasts and endothelial cells to compare their behavior after conditioning in a dynamic bioreactor for 5 days. Compared with the homografts, they found that PU scaffolds showed continuous, confluent layers of fibroblasts and endothelial cells on their surfaces, as well as decreased expression of genes associated with inflammation, interleukin-6 and monocyte chemoattractant protein 1, and the production of ECM. Table 59.3 outlines the most commonly used synthetic biomaterials used to construct TEHVs.

These are the biomaterials most commonly used to fabricate TEHVs. They all have advantages and disadvantages. The advantage of decellularized scaffolds is the premade 3D structure and "natural components." However, they have been shown to elicit an immune reaction and are limited in their supply and sizes. The advantages of synthetic polymers are their unlimited supply, consistent components, off-the-shelf possibilities, and ability to be made into multiple sizes and shapes. However, controlled degradation and tensile strength continue to plague their clinical application.

Tissue Engineered Heart Valve Fabrication Techniques

There are many techniques for fabricating natural or synthetic scaffolds. Scaffolds can be fabricated through molding, which is a process in which precursor solution is dissolved, poured into a mold, and then gelled. This technique is often used to generate tubular or planar scaffolds [58]. Another method for generating scaffolds is electrospinning. This fabrication process involves subjecting a polymer solution to an electric field. A charged polymer solution is generated when the electrostatic repulsion overcomes the surface tension between the polymer and syringe. Once this occurs, jets of polymer travel toward a surface, during which the solvent evaporates to generate continuous filaments of a natural or synthetic material [119]. Bioprinting is a more recent approach used to generate

TABLE 59.3 Overview of Advantages and Disadvantages of Synthetic Biomaterial in Tissue Engineered Heart Valve Bioengineering

Biomaterials	Use in Heart Valve Engineering	Advantages	Disadvantages	References
SYNTHETIC MATERIALS				
PEG	Used to maintain phenotype of native cells in heart valves, as well as promote production of extracellular matrix Used to modify flexural properties of implants	Biocompatible, nonimmunogenic, and approved by US Food and Drug Administration for internal use Versatile because as their mechanical, structural, and degradation properties can be tuned using a variety of methods	Cells will not readily attach to PEG biomaterials because they are hydrophilic. Therefore, tissue engineering using PEG hydrogels requires the addition of bioactive molecules	[73,99–103]
Polyvinyl alcohol	Used to develop bioprosthetic heart valve stents Used to create photocross-linkable and degradable hydrogels. Freeze–thaw capabilities	Nontoxic, biocompatible, biodegradable, and widely available	Poor strength on own. Must be used in conjunction with other biomaterials	[104–107]
Poly(glycolic acid) PLA	Functional, bioresorbable leaflet scaffolds. Behavior of cells on stiff biomaterials	Bioresorbable Made into many shapes and sizes	Fast biodegradation rates	[109–111]
Poly-ε-caprolactone	Scaffolds with slower degradation Add mechanical stiffness	Slower rate of degradation in vivo compared with PLA	Can make scaffolds too stiff and nondegradable unless tested in vivo	[111–113]
PGS	To adjust biomechanical properties of bioengineered heart valve leaflets	Biodegradable Maintains flexure properties similar to native valves	PGS-based scaffolds can lack fibrous microstructure and hindrance to tissue formation	[31,116]
Polyurethanes	Fabricate scaffolds using spraying technique and obtained homograft scaffolds, seeding both types of scaffolds with fibroblasts and endothelial cells	Good biocompatibility and tunable mechanical properties	Used only as addition to other biomaterials	[117,118]

scaffolds for heart valve tissue engineering. 3D bioprinting is an additive manufacturing technique that enables complex 3D structures to be generated through layer-by-layer deposition of biomaterials, cells, and growth factors [120,121]. The most common types of 3D bioprinting are inkjet, extrusion-based, and laser-assisted printing.

Future Direction in Tissue Engineered Heart Valves

Although the field has progressed significantly, no TEHV is being used clinically. As highlighted in this review, different cell types, recellularization methodologies, and biomaterials have been researched each with its own advantages and disadvantages. Fabrication techniques have evolved to develop more complex structures closely resembling native valves, but a main takeaway point is that a single biomaterial, cell type, or cellularization method may not be sufficient for TEHVs. The combination of several biomaterials and fabrication techniques may be the solution to addressing the limitations of using a single biomaterial. There are also the overriding problems of cost and patient accessibly to this complex bioengineering process. As reviewed in the Introduction, many people around the world do not have access to advanced bioengineering, surgical, or advanced cell processing facilities.

To address surgical facility limitations, transcatheter deployment of heart valves has become increasingly popular owing to its relative ease of implantation. Transcatheter valve prostheses consist of tissue mounted on an expandable stent; they are introduced into the body in a variety of ways, such as via the femoral artery, the aorta, or the subclavian artery, and transapically. All transcatheter valves are composed of biological tissue because this is necessary for the leaflets to be crimped into a catheter. Newer designs are being developed (Stephan and Petra). Regardless, there are concerns that the crimping may cause damage to the tissue and possibly affect long-term durability [122,123]. As a less invasive alternative to heart valve replacement surgery, transcatheter valve replacement allows patients who pose a high surgical risk to receive valve replacements they would not otherwise receive. Despite advances in the transcatheter delivery mechanism, stroke remains the major complication for transcatheter valve replacement

[124]. Although over 50,000 adult patients have received transcatheter valve implants since 2002, transcatheter technologies for pediatric patients with congenital heart disease are severely lacking [125]. However, the minimal invasiveness and fast recovery time of transcatheter valve replacement can be advantageous for younger patients, especially because valve-in-valve procedures are an option to replace damaged or degraded valve prostheses [124].

To make TEHVs more readily accessible to a wider patient population, an "off-the-shelf" approach may be needed. This involves a scaffold with the ability to remodel and form new tissue in the body through its recruitment of endogenous cells. This approach is advantageous over the traditional in vitro approach because it does not require preconditioning of the scaffold before implantation, which can take up to 6 weeks. During this preconditioning time, there are risks of bacterial and fungal contamination. The logistics of maintaining good manufacturing practice and infrastructure for translating an in vitro scaffold comes with an enormous cost [126].

One tested method of developing off-the-shelf TEHVs involves in situ heart valve scaffolds formed through foreign body reaction and decellularized TEHVs. Kishimoto et al. [127] developed an autologous heart valve scaffold using in-body tissue architecture technology. This involved placing a mold into the subcutaneous space, where the body forms a fibrous scaffold surrounding the mold. The stentless mold was tested in a goat model, where the valve performed well under systemic circulation. This approach enables off-the-shelf scaffolds to be created; however, it is in the initial stages of preclinical animal work. More assessment of the immune reaction to a foreign scaffold such as this is needed along with its long-term performance under physiological conditions.

Another approach involved first creating a biodegradable synthetic scaffold seeded with homologous cells. Then scaffolds were subjected to decellularization, in which the process is gentle enough not to alter the collagen or tissue structure. These researchers demonstrated that decellularized TEHVs could be stored for up to 18 months with no alterations to the tissue structure [128]. In addition, these off-the-shelf scaffolds have the ability to be reseeded with stem cells and maintain good cell viability through the crimping process for minimally invasive procedures [129]. Researchers have also demonstrated the feasibility and long-term functionality of homologous off-the-shelf TEHVs in a sheep and nonhuman primate model [130,131]. The concept of off-the-shelf TEHVs may be the fastest method to clinical application. Although this approach is promising, more research is needed for the recellularization, remodeling, and growth potential of off-the-shelf scaffolds. Concerns regarding thrombogenicity and calcification in the long term will also need to be assessed.

Other research groups have used hybrid tissue engineering approaches to develop off-the-shelf scaffolds with biological and mechanical properties capable of active remodeling after implantation. Janhavi et al. developed a biohybrid valve using electrospinning to create aligned nanofibrous scaffolds composed of decellularized bovine pericardium and PCL−chitosan. The scaffold was optimized to mimic the anisotropic and microstructure properties of native valves. The biohybrid scaffold was 20 times stronger than the native valve and demonstrated ECM deposition and cell proliferation when seeded with human VICs [132]. Although promising, this hybrid TEHV was not evaluated under physiological conditions.

Other investigators have taken the approach of developing a decellularized scaffold implant with alterations in surface characteristics that promote in situ recellularization and valve maturation [42]. This study decellularized porcine heart valves that were conjugated with the endothelial progenitor marker CD133. When placed in the pulmonary position of sheep, these constructs rapidly recellularized with both VECs and VICs. The conjugated valves displayed native valve-like biomechanical properties and interstitial matrix composition. Conjugated valves could be cryopreserved and maintained their recellularization properties when thawed [43]. These valves also displayed characteristics of growth that may make then desirable for pediatric patients [42]. However, they were tested only in the pulmonary position and for 3 months. It is unknown whether the implant can withstand the pressures and sheer of the eft side of the heart and if they continue to mature long-term.

Several studies have used modified biomaterials to attract cells for better regeneration and function. These include employing nanoparticles for a variety of uses [133,134]. Alternations in fibrospinning and coating strategies have also been used to attract cells to biomaterials [135,136]. Table 59.4 outlines the tested TEHVs and their advantages and disadvantages.

CONCLUSIONS

This review outlines the progress in and challenges of developing a clinically available TEHV. As discussed, there are several limitations to each option. These setbacks are particularly detrimental to younger patients who require a living valve with the ability to grow. Thus, the need remains for TEHVs. This review covered the design considerations for heart valve tissue engineering and assessed the application of biomaterials, fabricating techniques,

TABLE 59.4 Status of Current TEHV Constructs

Current TEHV Constructs	Advantages	Disadvantages	Status
Seeded (preseeded) natural biomaterial TEHVs	Three-dimensional architecture Cell compatible Natural hemodynamics	Immune response, degradation Lengthy, complicated, and expensive Cell viability can be low Do not grow Limited availability and sizes	Preclinical testing
Self-, or enhanced-seeding natural biomaterial TEHVs	Less time, cheaper, more off-the-shelf capabilities. This uses nanotechnology, biomolecules to alter characteristics	Unclear whether mobilized cells form durable growing valves	Preclinical testing
Synthetic biomaterial-based TEHVs	Multiple sizes, shapes and supply Less immunogenic Controlled degradation rates	Strength and durability	Preclinical testing
Seeded synthetic biomaterial-based TEHVs	Enhanced maturation Can use nanotechnology or biomaterial combinations to increase cell survivability and biomechanics	Strength and durability	Preclinical testing
Textile-reinforced TEHVs	Increase strength and durability Can incorporate cell seeding	Possible reduced degradation Possible reduced remodeling capabilities	Preclinical testing
Stent-delivered TEHVs	Wider clinical application Potential to enhance reseeding Less traumatic	Mitral valve still difficult to reproduce Postoperative slipping	Clinical application of unseeded implants, especially in Europe

TEHV, tissue engineered heart valves.

and emerging technologies for developing TEHVs. Despite enormous progress, a clinically available TEHV remains to be realized. A large class of natural and synthetic biomaterials has been investigated for TEHVs. However, as researchers have learned, using a single biomaterial may not be sufficient to match the demanding mechanical and biological properties of native valves. It seems that important progress has been made in developing biomaterials that could be off-the-shelf and stimulate self-reseeding and maturation into implants with long-term function and structure. It will be critical to develop a TEHV that has the capability to self-heal and remodel with growth. This is the challenge to address unmet medical needs.

CHAPTER

60

Regenerative Medicine of the Respiratory Tract

Sarah E. Gilpin[1,2], *Philipp T. Moser*[1], *Harald C. Ott*[1,2]

[1]Massachusetts General Hospital, Boston, MA, United States; [2]Harvard Medical School, Boston, MA, United States

Rebuilding or regenerating the respiratory tract requires a combined understanding of lung development, essential repair mechanisms, and the role of the supporting microenvironment. The primary function of the lung is to exchange gas to deliver oxygen to the circulating blood and remove carbon dioxide from it. Maintenance or reestablishment of this function is the fundamental goal of pulmonary tissue engineering and regenerative medicine. Although a seemingly simplistic job, many tightly controlled mechanisms are essential to permit and sustain this essential physiologic capacity. This chapter will review the lung's endogenous mechanisms for repair, as well as state-of-the-art approaches to harnessing this capability for tissue engineering and regenerative medicine of the respiratory tract.

LUNG DEVELOPMENT: A ROAD MAP TO REGENERATION

During development, the lungs, in addition to the trachea, arise from the anterior foregut endoderm, a tissue that ultimately leads to the creation of multiple organs, including the respiratory system, esophagus, thyroid, and liver [1]. In mice, lung specification is first noted at embryonic day 9 (E9.0) and is identified by expression of the transcription factor Nkx2.1 (Fig. 60.1). The primordial lung begins to form during the embryonic stage (E9.5–E12.5; weeks 4–7 in humans) and the original lung bud then splits into two bronchial buds. Separation of the posterior part of the trachea from esophagus also occurs. The process of branching morphogenesis occurs during the pseudoglandular stage (E12.5–16.5, weeks 7–17 in humans). This intricate process results in controlled development of the conducting airways and terminal bronchioles. The fibroblast growth factor (FGF) family of signaling proteins is an important driving force during development. Interactions with the surrounding mesenchyme have an essential role during airway morphogenesis, acting as the source of many important growth factors and promoting epithelial proliferation in the branching bud [2]. Lung branching can be partly recapitulated when the mesenchyme is removed but substituted with critical growth factors, including FGF10 [3]. During the canalicular stage (E16.5–17.5, weeks 17–26 in humans) and saccular stage (E18.5 to birth, weeks 27–36 in humans), the distal lung parenchyma develops, with the emergence of alveolar pneumocytes and the creation of the respiratory units of the lung. The glucocorticoid receptor is expressed during lung development and functions to stimulate the production of surfactant-associated proteins and phospholipid synthesis by enhancing the activity of phosphatidylcholine [4]. Surfactant production can be measured in the amniotic fluid during the saccular stage; it also prepares the lungs for breathing by reducing the surface tension of the alveolar unit. This milestone has clinical relevance because the ratio of the surfactant glycoproteins lecithin and sphingomyelin measured in the amniotic fluid can be used to indicate lung maturity, with rising lecithin levels correlating with gestational age [5]. As the understanding of pulmonary surfactant and its essential function evolved, the development of surfactant replacement therapy has greatly improved survival for preterm infants with immature lung function [6]. Lung development continues in the late and postnatal periods as the lungs undergo the process of alveolarization. This mechanism functions to increase the gas exchange surface area dramatically as the lung further refines the immature alveolar structure and undertakes secondary septation to generate a greater number of smaller alveoli [7]. The distal microvascular network also develops at this time to ensure that each alveolar unit is connected to the requisite blood supply. Postnatal lung development and alveolar remodeling continue through the first years of human life. This is coupled with

normal tissue growth mechanisms to increase the functional capacity of the mature lung further. Morphometric data suggested that between birth and young adulthood, the total lung volume can increase 23-fold [8].

An understanding of lung development and the nuanced signaling pathways that dictate its successful manifestation provides an important foundation for appreciating the closely related processes of tissue repair and regeneration.

REPAIR AND REGENERATION IN THE NATIVE LUNG

Although adult lung tissue is often described as being largely quiescent, a remarkable capacity for repair remains after development is complete. As an organ that is constantly subjected to injury from the outside environment, a number of facultative repair mechanisms exist, which together act to maintain lung function and homeostasis. Furthermore, a healthy airway epithelium provides an important first line of defense against inhaled toxins and microbes, relying heavily on innate immune mechanisms to prevent pathogen colonization and mediate repair [9]. Maintenance of the lung epithelial barrier is accomplished by a number of regenerative cell populations that exist in specialized niches and can become activated after tissue injury.

Cell phenotypes that line the respiratory tract vary along a proximodistal axis. The bronchial epithelium largely functions to clear mucous and protect against immediate insult or prolonged inflammation. A continuous intact cell barrier is essential for this defense against environmental infiltrates and infections. The trachea and bronchi are lined with pseudostratified columnar epithelium consisting of ciliated, club, basal, and abundant goblet cells. The mucous secreted by goblet cells is a complex mixture of water, glycoproteins, and lipids designed to trap pollutants and aid clearance [10]. The accompanying ciliated cells are terminally differentiated columnar epithelium with coordinated cilia that beat to move the viscous mucous upward toward the pharynx, maintaining airway balance. The bronchial epithelium also functions to release cytokines, chemokines, and other mediators to recruit inflammatory cells and initiate host defense pathways when necessary. The secretory club cells are less abundant in the larger airways and account for 15% of proliferating cells during normal tissue homeostasis [11]. Club cells are further responsible for metabolizing inhaled toxins, which is accomplished by the cytochrome P450 isoform 2F within their smooth endoplasmic reticulum, which also makes them susceptible to ablation by treatment with the drug naphthalene [12]. Their major secreted product, the club cell secretory protein, 10 kD (CC10) (also known as secretoglobulin 1A1 and uteroglobulin) is also reported to possess antiinflammatory and immunomodulatory properties [13] and can be used as a noninvasive indicator of acute or chronic lung injury [14]. The basal epithelial cell lies superficial to the basal lamina and functions to aid attachment of the epithelium to the basement membrane. Basal cells can be identified by expression of transformation-related protein 63 (p63), cytokeratins 5 and 14, and the epidermal growth factor receptor in both mice and human airways [15]. Basal cells possess the ability to act as an endogenous adult stem cell population; they are capable of self-renewal and multilineage differentiation. Early experiments showed

that basal cells can function to reconstitute a differentiated mucociliary epithelium when seeded onto denuded tracheas and transplanted subcutaneously into nude rats [16]. Lineage tracing experiments further confirmed that basal cells can differentiate to club and ciliated cells in the trachea, both in steady state and after injury [17]. Loss of the basal stem cell population prevents proper epithelial tissue repair, resulting in pathologies similar to bronchiolitis obliterans syndrome, with alternating regions of epithelial denudation and progressive collagen deposition [18]. Similarly, impaired basal cell reparative function may contribute to the pathogenesis of chronic obstructive pulmonary disease in smokers [19]. Mathematical models suggest that a heterogeneous population of basal stem cells exists within the lung tissue and propose that approximately equal numbers are multipotent stem cells and committed precursors [20]. There is also evidence that rare CC10-positive cells can differentiate back to a basal cell lineage after tracheal injury in rats [21].

As the conducting airway branches toward the respiratory bronchioles, the cell composition progressively changes. The simple columnar ciliated epithelium of the terminal bronchioles develops into simple cuboidal epithelium. The smaller airways and bronchioles consist of basal, club, and ciliated cells, whereas goblet cells are no longer found and neuroendocrine cells appear. Neuroepithelial bodies (NEBs) appear, which have been shown to sequester regenerative cells capable of repairing the bronchiolar epithelium after selective depletion of club cells by the toxin naphthalene [22]. A subpopulation of cells within the NEB that are resistant to naphthalene, termed variant club cells, are also critical for preservation of this stem cell population and maintenance of epithelial renewal after injury [23].

The simple squamous epithelium of the distal lung consists of the flat, elongated alveolar type 1 pneumocytes (AT1), contributing 95% of the gas-exchange surface area, and the cuboidal alveolar type 2 pneumocytes (AT2), comprising the remaining 5%. AT2 cells are responsible for producing the pulmonary surfactant proteins (SP) A through D, whereas the AT1 cells interface with the pulmonary vasculature to facilitate gas exchange. Early experiments first provided evidence that AT2 cells serve as endogenous progenitors for the distal lung, which become type 1 cells in response to injury [24]. This observation was further confirmed using more sophisticated genetic lineage tracing techniques, demonstrating the clonal proliferation of AT2 cells during long-term homeostasis and after bleomycin injury [25]. A distinct population of cells at the bronchoalveolar duct junction has been described to have unique regenerative properties, with a bilineage potential for repair. These bronchioalveolar stem cells are reported to coexpress CC10 and SP-C and to proliferate in response to epithelial damage in vitro [26]. In vivo, lineage-tracing studies found that CC10-positive cells did not significantly contribute to the alveolar epithelium during postnatal growth [21]. After bleomycin injury, CC10-labeled SP-C−negative cells have been shown to develop into AT2 cells, combined with self-renewal of the native AT2 population [27]. Together these studies continue to redefine the multilineage potential of traditionally proximal or distally restricted cell populations and to be an important and expanding area of research. It has been shown that during development, the distal AT1 and AT2 cells arise from a bipotent progenitor, in contrast to the traditional hierarchy shown after birth [28]. In adult lungs, AT1 cells marked by the transcription factor HOPX have the potential to act as a facultative progenitor capable of becoming SP-C$^+$ AT2 cells and contribute to compensatory lung regrowth after pneumonectomy in mice [29]. As new experimental evidence continues to provide new insight into how the lung maintains and repairs itself, the established paradigms must also shift.

The continued evolution of traditional cell hierarchy and potential for repair will be important in developing new cell-based therapies for lung regeneration. The ability to reactivate and exploit these complex endogenous cell repair mechanisms for therapeutic benefit continues to be a major goal of regenerative medicine (Fig. 60.2).

NOVEL CELL POPULATIONS FOR LUNG REPAIR

As an internal organ that allows for direct and noninvasive access to the respiratory tissue, delivery of regenerative cells as therapy for airway disease is an attractive concept. However, innate epithelial defense and clearance mechanisms mean that delivered cell engraftment is generally low and transient in nature. Robust methods are required to track and quantify any surviving cells, which often includes luciferase or fluorescent transgene expression coupled with ex vivo tissue analysis by quantitative polymerase chain reaction or histology [30]. These methods are prone to error owing to sampling methods and the potential for identifying false-positives, which makes the conclusions difficult to interpret. The field continues to advance toward the goal of directed cell therapy to the airways as new methods are developed and new cell populations are identified. Intravenous infusion is an alternate route to achieving cell delivery of regenerative cell populations to the lung. The pulmonary capillaries have a mean diameter of 5.5 μm, which means that as larger cells pass through the vascular network, a high percentage can be retained

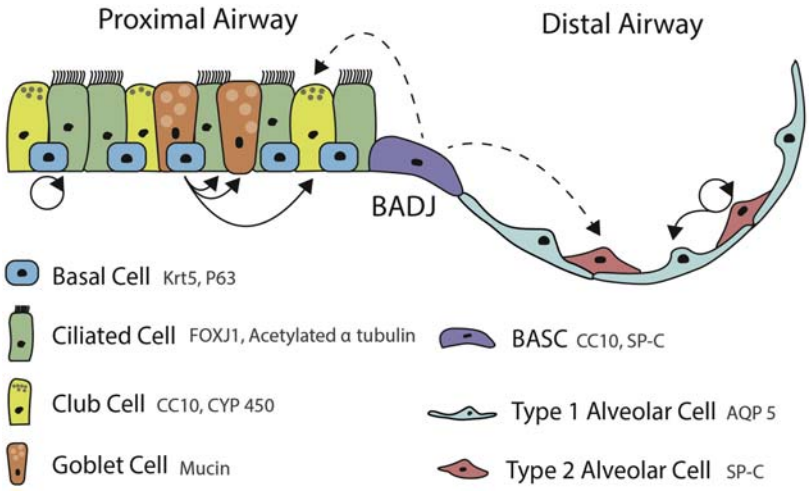

FIGURE 60.2 **Endogenous lung epithelial repair.** Schematic of the lung epithelium from a proximal to distal location. The location and function of important endogenous lung epithelial stem/progenitor cell populations are listed, which can be activated to differentiate and self-renew to maintain tissue homeostasis. *Arrows* indicate well-established (*solid*) and novel (*dashed*) differentiation pathways. *AQP 5*, aquaporin 5; *BADJ*, bronchoalveolar duct junction; *BASC*, bronchoalveolar stem cells; *CYP 450*, cytochrome 450; *SP*, surfactant protein.

within the lung and can exert local effects [31]. In addition, many reports have suggested that exogenous cells arising from the bone marrow can be mobilized into the peripheral blood and may engraft to repair injured lung tissue. This paradigm remains controversial, and robust conclusions from these studies also require rigorous experimental analysis. Cell lineage-tracing experiments have suggested that the long-term contribution of bone marrow−derived cells to the lung epithelium [32] or endothelium [33] is low or undetectable.

A separate population, the mesenchymal stem/stromal cells (MSCs), have been widely studied as a reparative population for lung cell therapy. This nonhematopoietic multipotent stromal population can be isolated from various biological sources, including bone marrow, peripheral blood, adipose tissue, dental pulp, and umbilical cord blood, and are initially defined by plastic adherence in vitro [34]. These cells, marked by CD105, CD73, and CD90 expression, also secrete antiinflammatory cytokines, including interleukin (IL)-10 and can decrease proinflammatory cytokine expression, such as IL-1β, IL-6, and interferon-gamma [35]. When delivered intravenously, MSCs can act in a targeted way onto the lung after injury. Treatment with MSCs has shown benefit in animal models of fibrosis after bleomycin induced lung injury, significantly reducing inflammation and collagen deposition within lung tissue [36,37]. Use of these cells is also being translated to clinical application. A proof-of-principle trial was completed that demonstrated the feasibility of treating pulmonary fibrosis by intravenous infusion with MSCs [38], and many clinical trials are ongoing. MSC may also have the potential to treat sepsis and acute respiratory distress syndrome in patients [39] and have shown benefit in repairing donor lungs deemed otherwise unsuitable for transplantation [40]. Taken together, this multifaceted ability to regulate the immune response and enhance tissue repair after lung injury makes MSC-based therapy a promising and advancing area of regenerative medicine.

Epithelial injury is an important driver for regenerative cell activation and is a critical component of many experimental models. Tissue damage may in fact be essential for regeneration, which suggests that preconditioning injury of the lungs may be required before cell therapy. One study of endogenous lung repair during the canalicular stage of development used sublethal radiation injury to vacate the putative lung progenitor niche [41]. It was reported that intravenous infusion of lung-derived cell populations resulted in long-term lung chimerism, which was identified in clonal donor-derived patches. Treatment with these cells after injury resulted in a marked improvement in lung function compared with untreated controls. In addition, injury has been shown to activate specific facultative progenitor populations, which can also be used for therapeutic treatment. A study of lung repair after H1N1 influenza-induced lung injury showed that lineage-traced keratin (Krt)5^+ cells undergo a proliferative expansion to regenerate the damaged tissue. After isolation of these cells and subsequent intratracheal delivery 5 days after influenza infection, tissue analysis revealed that multiple epithelial lineages in the regenerating lung were derived from the transplanted cells. These included both AT1 and AT2 pneumocytes at 40 and 90 days after influenza infection [42], which suggested that traditionally proximally specified $Krt5^+$ cells take on a bilineage potential after injury. Parallel work identified a rare lineage-negative $Krt5^+$ cell population in normal distal lung tissue that is also activated after influenza- or bleomycin-induced lung injury and could also migrate to repair the injured tissue [43]. After orthotopic

transplantation of these cells to influenza-injured lungs, multicellular structures were identified in areas of active regeneration, which also observed differentiation toward SP-C$^+$ distal epithelial fate. These studies further revealed that the Notch signaling pathway has a critical role in proximal versus distal epithelial fate decisions during regeneration and tissue repair. These new insights into epithelial cell potential and regenerative capacity further refine the optimal cells for therapeutic use.

The directed differentiation of pluripotent stem cells toward defined lung lineages is another exciting option for generating cells suitable for use in lung tissue engineering. These cells also offer a valuable opportunity to model lung development and respiratory disease using human cells. Much research and progress have been accomplished using both embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) to recapitulate the developmental program and drive specification of lung-specific cells. Early studies first attempted to a drive a lung epithelial phenotype from ESCs by culture in small airway growth media [44] and transition to an air−liquid interface (ALI) culture [45]. Coculture with digested fetal lung mesenchyme was able to induce differentiation of a distal SP-C$^+$ epithelial population from murine ESCs, which also highlights the critical role of growth factor cross-signaling during development [46]. Increased lung differentiation efficiency can be accomplished by first stimulating the Nodal pathway with activin A treatment, to induce a definitive endodermal germ layer fate directly [47,48]. Additional patterning of the endoderm toward the anterior foregut by inhibiting the transforming growth factor-β and bone morphogenic protein signaling pathways further aids specification of a lung-specific fate [49]. Two important and parallel reports described the successful differentiation of NK2 homeobox 1 transcription factor (Nkx2.1)-expressing lung/thyroid progenitor cells from this anteriorized foregut population [50,51]. Further differentiation of a lung-specified population can generate varying degrees of mature proximal (CC10$^+$ and p63$^+$) and distal (SP-C$^+$) epithelial lineages in vitro. Ideally, for use in cell therapy or tissue engineering applications, the differentiation methods would be able to generate a large number of homogeneous cell populations. The continued optimization of targeted and robust protocols to generate specific epithelial cell lineages is a challenge in this rapidly advancing field.

An important study reported that after a differentiation period of 48 days, human ESCs were able to produce basal, goblet, Clara, ciliated, and both type I and type II alveolar epithelial cells. When the progenitor cell potential was tested in vivo by implantation under the kidney capsule in mice, cystic and tubular structures were found lined by an epithelial layer of both pseudostratified and elongated morphology [52]. Human iPSCs can also be differentiated to create a functional multiciliated proximal epithelium after 28 days of culture at ALI [53]. In this study, expression of the cystic fibrosis transmembrane receptor (CFTR) could be visualized at the apical surface of polarized cells. These results demonstrate the capacity of defined stem cell populations to create functional tissue and the exciting potential these cells can have in regenerative medicine for lung diseases. Starting with a patient-specific pluripotent cell affords the possibility of correcting or enhancing these populations before differentiation. This is particularly attractive for pulmonary diseases resulting from monogenic mutations, such as cystic fibrosis (CF). It has been shown that starting from a small CF patient skin biopsy, iPSCs can be generated and corrected for the ΔF508 mutation in the endogenous CFTR gene, using the Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-associated protein 9 system. Subsequent differentiation of these iPSCs to a proximal airway epithelial fate, including culture at ALI, further showed the ability to restore the CFTR chloride current by patch clamp studies [54]. The potential for CFTR gene correction using zinc-finger nucleases combined with homology-directed repair has also been successfully demonstrated [55]. These exciting advances in cell and molecular biology have great promise in patient-specific regenerative medicine. The combination of these novel technologies with parallel advances in cell therapy and tissue engineering has the potential to have a meaningful impact for patients in need.

BIOLOGICAL SCAFFOLDS TO SUPPORT REGENERATION

As knowledge of regenerative cell populations advances, the challenge of engineering a functional three-dimensional (3D) tissue still faces many hurdles. The use of biological scaffolds can further support these cells in creating lung tissue ex vivo by providing a platform to enhance regeneration in an anatomically correct environment. The choice of biomaterial and the methods used to create these lung scaffolds are important considerations that are integral to the ultimate function of the regenerated tissue.

Artificial scaffolds have been used for lung and airway tissue engineering. In one study, fetal rat lung cells were combined with Gelfoam and injected into normal healthy lung parenchyma; they showed cell survival for 35 days and provided a supportive environment for recipient-derived cells to engraft [56]. Scaffolds can also be used to sequester cell-derived growth factors for targeted delivery. This was demonstrated with adipose-derived MSCs

grown on a polyglycolic acid felt sheet, which secreted large amounts of hepatocyte growth factors and resulted in enhanced compensatory lung growth after surgical resection. Also of note are the efforts to create a synthetic, implantable tracheal graft. The relatively simple tissue, which is composed of a hollow tube with compatible mechanical properties, seems a promising first goal toward patient-specific regenerative medicine. The minimal requirements for any biomaterial used for this purpose would be biocompatibility to the recipient and suitability as a substrate for cell attachment and survival [57]. A large number of biocompatible materials have been tested for this purpose, including biodegradable polymers (polyglycolic acid, polylactic acid, and polycaprolactone), and hydrogels (Pluronic F-127 and collagen gel). Important progress has been made using the nanocomposite biomaterial polyhedral oligomeric silsesquioxane poly(carbonate-urea) urethane. This material has been shown to be biostable, to have favorable mechanical properties, and to support the growth of various cell types, including human bronchial epithelial cells [58]. In addition to synthetic materials, decellularized native tracheas are promising scaffolds for airway engineering. Decellularized tissue engineered tracheas have been investigated in a number of studies using various species, with mixed results [59]. Although good epithelialization was observed in many reports, grafts were structurally unstable, leading to airway obstruction and subsequent collapse. An important consideration for large airway engineering is the long-term maintenance of biomechanical integrity and lumen patency, to prevent the need for subsequent dilatation or stenting of the implanted graft.

When aiming to create more complex tissues such as functional lung parenchyma, the ability to create a suitable scaffold with adequate tissue architecture and resolution presents significant challenges. The concept of whole-organ decellularization provides a promising option. Removal of all the cells from a tissue, leaving the only the extracellular matrix (ECM), is a long-standing technology, and acellular ECM scaffolds are used in clinical practice for many applications [60]. Many of these are products derived from the dermis, pericardium, small intestinal submucosa, and urinary bladder of bovine and porcine sources. The ability of these ECM scaffold to facilitate constructive tissue remodeling in vivo makes them a valuable tool for regenerative medicine.

Building on this concept and stemming from a seminal article on whole-heart regeneration [61], this approach was first applied to whole lungs in an exciting series of reports in 2010 [62–64]. By perfusing a detergent through the native vasculature of the lungs, ideally at a controlled pressure, the intact organ can be fully decellularized, leaving only the ECM scaffold. Detergents used include sodium dodecyl sulfate, sodium deoxycholate, and 3-([3-cholamidopropyl] dimethylammonio)-1-propanesulfonate. Comparative analyses of these detergents for use in decellularization have not provided a consensus and suggest that many approaches are valid [65–67]. Lung decellularization has been upscaled and applied across many species including mice [68], rats [69], pigs [66], nonhuman primates [70], and humans [66,71]. It has been confirmed that the acellular scaffolds retain essential collagens, laminin, elastin, and glycosaminoglycan to support cell reattachment [66,72]. The relevant importance of the ECM composition versus structure is an area of active study and interest. Proteomic mass spectrometry has been applied to analyze and compare the protein scaffold that is retained after decellularization [66,72,73]. These studies provide important insight into the composition of the bioactive scaffold upon which new tissue will be created. If essential proteins are lost through the decellularization process, or if immunogenic proteins are retained within the matrix, there can be significant consequences for the regeneration process both during ex vivo recellularization and after in vivo implantation [74]. A quantitative comparison of the acellular scaffold with the ECM of native lung tissue was achieved by applying a stable isotope-labeled concatemer approach, in which known concentrations of labeled peptides were incorporated to generate a standard reference curve [75]. Further refinement of these techniques, as applied to diverse biological scaffolds, will provide more precise information about the relationship between protein composition and overall tissue regeneration and function.

The source of native lung tissue used to prepare scaffolds can have a direct impact on subsequent regeneration. Several studies have shown that underlying lung pathologies can cause changes in the ECM that are retained after decellularization and can perpetuate during tissue repair [76]. Remodeling of the ECM is a hallmark of pulmonary fibrosis characterized by increased collagen deposition and changes in the alveolar architecture. When normal human lung fibroblasts were grown on ECM scaffolds derived from fibrotic lung tissue, genes associated with fibrotic changes became activated [77]. This suggests that the origin of the ECM can have a great impact on cellular function and fate. It has also been shown that culture on fibrotic ECM can drive myofibroblast differentiation from normal lung fibroblasts [78]. Emphysema also dramatically affects the lung matrix composition and structure. In a murine model of emphysematous lung injury induced by treatment with porcine pancreatic elastase, the subsequently decellularized lungs portrayed a unique pattern of ECM retention compared with uninjured lungs. Despite these histologic and compositional differences, no significant differences were noted when MSCs or $CC10^{+}$ epithelial cells were redelivered to the emphysematous lung scaffolds [79]. Similar changes in scaffold architecture were reported in human emphysematous lung scaffolds; in these studies, subsequent cell attachment and survival were significantly

decreased in the diseased scaffolds compared with those from normal lungs [80]. Interestingly, when the acellular lung ECM was solubilized and prepared as a coating to support 2D cell grown in vitro, no differences in survival were found, which suggests that the 3D architecture of the acellular lung scaffold is the main effector of these changes. The age of the lung can contribute important differences to the decellularized scaffold. In one study of aged versus young mouse lung scaffolds, cells grown on the older ECM were found to express a significantly lower level of laminins α3 and α4, which recapitulates the laminin deficiency that is observed in aged lung ECM. These data further highlight the deep biological information that is contained with lung scaffold and the feedback loops that can exist between reparative cell populations and the underlying ECM [81].

There has not been a systematic analysis of these ECM-associated variables, and those that were studied varied across methodology, species, and the cell type used. This level of investigation will be necessary before clinical translation of decellularized lung scaffold-based tissue engineering, to standardize and optimize the biological source of lung ECM and exclude factors that may be detrimental to regeneration.

One possible way to reduce variation in the lung ECM scaffold would be to use animal sources of donor organs. The ability to control age, size, and any variation in environmental exposure or potential pathology would standardize the starting material for clinical lung tissue regeneration. One widely explored option is the porcine lung, because pig organs are anatomically similar to human organs. Yet, there are also many important differences between the species. One study comparing decellularized scaffolds from rat, pig, primate, and human lungs found that human and primate lungs were stiffer, contained more elastin, and retained fewer glycosaminoglycans than did pig or rat lung scaffolds [82]. Adhesion of human endothelial cells in the vascular network of the lung scaffold was also markedly enhanced in human and primate tissues compared with porcine and rat matrices. These finding reaffirm that the ECM composition can have an important role in tissue regeneration after recellularization. There are also anatomic and morphologic differences between human and porcine lungs [83]. Of note, porcine lungs lack interalveolar connections known as pores of Kohn, which facilitate collateral ventilation and prevent atelectasis. When choosing sources of lungs for xenotransplantation, it may be important to consider whether the animals are quadruped or bipedal, because the mode of ambulation can also affect breathing mechanics.

The use of porcine lung xenografts for transplantation is also complicated by hyperacute rejection, mediated by antibodies anti-Gal (Galα1-3Galβ1-(3)4GlcNAc-R), an epitope that humans do not express. Exciting research has suggested that this rejection may be overcome with the use of genetically modified Gal knockout animals [84]. Proof-of-concept studies demonstrated that decellularized wild-type and α-Gal knockout pig lungs can be comparably decellularized and are biocompatible with human lung cells despite some differences in retained proteins [85].

Another intriguing source of scaffolds for lung regeneration is 3D printing, also termed stereolithography, to create complex solid organ matrices [86]. This approach would allow for custom-designed organs to be created for the intended recipient, further augmenting the concept of personalized medicine. Through bioprinting, the biomaterial can also be combined with cells in a controlled and localized manner, which provides a potential advantage over the random repopulation of a decellularized scaffold. Major challenges facing adoption of this technology for whole-lung regenerative medicine are resolution, scale, and the composition of the construct.

ADVANCES IN REBUILDING FUNCTIONAL LUNG TISSUE

Higher-level tissue function is a critical step in regenerating tissue for clinical application. To engineer complex tissue ex vivo, the cells used must retain their regenerative capacity for repair and differentiation when recombined. Several in vitro methods have been developed to study and validate the regenerative capacity of important cell populations. This ability is a function of not only of the cells themselves, but also of the microenvironment in which they are placed. The ability for cells of the respiratory tract to form tight junctions is critical for maintaining fluid balance and controlling solute transport. In vitro, barrier function is typically measured by growing cells on semipermeable inserts and quantifying transepithelial electrical resistance (TEER) [87]. The application of an ALI culture environment further drives tissue maturation and cellular differentiation toward a ciliated phenotype, which can be used to further enhance tissue regeneration.

A 3D culture system can also be used to test the regenerative capacity of specific lung cell populations in vitro. In one model, isolated and purified basal epithelial cells demonstrated the ability to formation of clonal "tracheospheres" containing both ciliated and secretory cells [17]. Single, isolated murine AT2 cells can also create 3D alveolar-like structures termed "alveolospheres" [27]. In this model, the presence of primary platelet-derived growth factor receptor α-positive mesenchymal support cells was essential to recapitulate the regenerative niche and support 3D tissue formation. Airway organoids have also been created by combining human adult primary bronchial

epithelial cells, lung fibroblasts, and lung microvascular endothelial cells, which demonstrated self-organization into discrete structures and recapitulated limited aspects of branching morphogenesis [88]. These methods provide a useful experimental tool to study the ex vivo potential of specific cell types and assess their ability for complex tissue regeneration. In this context, the surrounding microenvironment and exogenous factors can easily be tested and manipulated to better define and enhance the stimuli needed to drive tissue regeneration. Such 3D models can also be used to study lung development. Murine E17.5 lung cells can be isolated and cultured in 3D collagen hydrogels to create distal proSP-C–expressing epithelial structures surrounded by a capillary-like endothelial network [89]. This system can be used to test the influence of critical growth factors and ECM components on lung morphogenesis. The establishment of multilineage lung organoids from iPSC-derived progenitors has also been reported, by directing differentiation along the defined steps of lung development [90]. The successful engraftment, long-term survival, and maturation of organoid-derived lung epithelium in vivo is also important for therapeutic applicability. The use of synthetic scaffolds to support survival and regeneration may confer an important advantage to cells after implantation [91].

Small matrix slices can also be used to study tissue regeneration in a high-throughput manner. After decellularization, small pieces of lung tissue can be sectioned (250 μm) and placed into traditional 2D culture. Recellularization of these thin lung matrix slices demonstrated biocompatibility and integrin-mediated cell attachment to the ECM [66]. The effect of ECM composition on tissue regeneration can also be investigated using the lung matrix slice model. In one study, when ESC-derived definitive anterior endoderm cells were cultured on ECM that was pretreated with Heparitinase I to remove matrix-associated heparan sulfate proteoglycans, cellular organization and differentiation were compromised [92]. This suggests that retention of important ECM components after decellularization may be required to support mature tissue regeneration and function. Native 3D lung ECM was further shown to promote lung lineage specification from human iPSCs, as identified by Nkx2.1 expression, compared with traditional 2D in vitro differentiation [93]. Cells can also be delivered to whole rodent lung scaffolds in a mixture of agarose, creating a semisolid tissue that can be further sectioned and maintained in vitro, as described using lung-specified murine ESCs [50]. A method of excising small segments ($\sim$1–3 cm^3) of human decellularized lung tissue that retains 3D vascular and airway conduits has been described and used for recellularization in a high-throughput in vitro model [72]. The clear benefits of these smaller-scale models to test cell differentiation and tissue regeneration is the ability to test more conditions with less variation while also reducing experimental time and costs.

The native lung scaffold is particularly well-suited for recellularization because it retains the anatomical separation between the airways and vasculature network while enabling direct access to both compartments. Epithelial or mesenchymal cell populations can be delivered to the respiratory tract via the trachea, and endothelial cells can be delivered via the pulmonary artery and vein, ultimately repopulating all of the essential cell types in the lung without compromising the underlying organ structure. The first studies to prove biocompatibility of the whole decellularized scaffold used a heterogeneous mixture of pulmonary epithelial cells isolated from neonatal rats [63,64]. This important proof-of-principle has evolved to include studies using a wide range of primary and pluripotent-derived cell populations. This methodology has been successfully applied to regenerate human lung scaffolds repopulated with donor tissue-derived basal epithelial stem cells and pulmonary artery endothelial cells. These recellularized tissues were maintained in ex vivo culture for over 7 days, confirming cell viability and continues proliferation while reforming the complex lung tissue architecture along the native matrix [94]. A challenge remains to derive the optimal cells for use in regenerating these scaffolds. Primary epithelial cells are a convenient possibility because they can be isolated from small tissue biopsies or airway brushing, but expansion to an adequate cell number in vitro can be limiting. The modification of important cell pathways, including the Rho-associated protein kinase and SMAD, can be achieved by adding targeted small molecules inhibitors to the culture media to reduce cell senescence and maintain proliferation [95,96]. An additional challenge inherent in patient-derived cells is the contribution of underlying pathologies, which may compromise cell isolation, expansion, or function.

Combined with advances in cell and matrix biology, the feat of bioengineering fully functional lungs and airways for transplantation will require the continued optimization of many additional factors. Implementing these advances to recreate higher-level tissue function will also depend on developing successful methods to culture and mature the organ ex vivo before implantation. When creating systems for lung culture outside the body, much can be learned from the ex vivo lung perfusion technology, which is used in clinical lung transplantation to expand the donor pool [97]. This procedure maintains cadaveric donor lungs with physiologic protective ventilation and perfusion, with the aim of facilitating more accurate assessment of the graft. This system, which is typically applied for 3–4 h before transplant, can also serve as a platform to recondition lungs that would otherwise be deemed unsuitable for transplantation, or to apply novel treatments such as gene therapy with the immunosuppressive

cytokine IL-10 [98]. These clinically relevant advances in ex vivo lung preservation have provided important benefits to patients but are still limited by a relatively short time in which the lung remains stably functional.

Applying some of these concepts to ex vivo lung engineering has guided the development of lung bioreactor systems to support the recellularization and culture of biological scaffolds with the aim of establishing and maintaining lung function on the scale of days to weeks. Effectively recapitulating the biomimetic events associated with breathing and blood perfusion in an ex vivo environment is a critical component of successful lung bioengineering. The optimal choice of perfusate is an important consideration that has not yet been robustly evaluated or defined. Not only must the perfusate facilitate nutrient delivery and waste removal through the regenerating vessels, it must prevent unwanted vascular permeability and tissue edema, for which traditional cell culture medias are not optimal. Methods for lung vascular regeneration have been described using both primary and iPSC-derived endothelial cells, which require specific alterations to the perfusion media composition to induce angiogenesis or vascular barrier function during defined phases of regeneration [99]. Further development and improvement in vascular regeneration are important and complementary component of respiratory tract tissue engineering. It has been shown that during whole rodent lung recellularization, the coculture of human lung-derived endothelial cells with primary basal cells imparts a proliferative advantage to the regenerating epithelium [94]. An additional challenge of using traditional cell culture media for complex tissue engineering is defining a composition that is optimized to support multiple cell types (Fig. 60.3).

Many versions of ex vivo lung bioreactors have been developed and tested, ranging from the rodent to the human scale [100–102]. The minimal requirements are to provide a controlled environment with proper temperature and humidity, and to maintain sterility. The application of specific biomechanical stimuli during organ culture in the bioreactor can have direct effects on the tissue and cells, and so careful control of both perfusion and ventilation are important design parameters. Sheer stress applied to the regenerating vasculature by perfusion can act to align and stimulate pulmonary endothelial cells after redelivery to the scaffold [103]. Perfusion must also provide

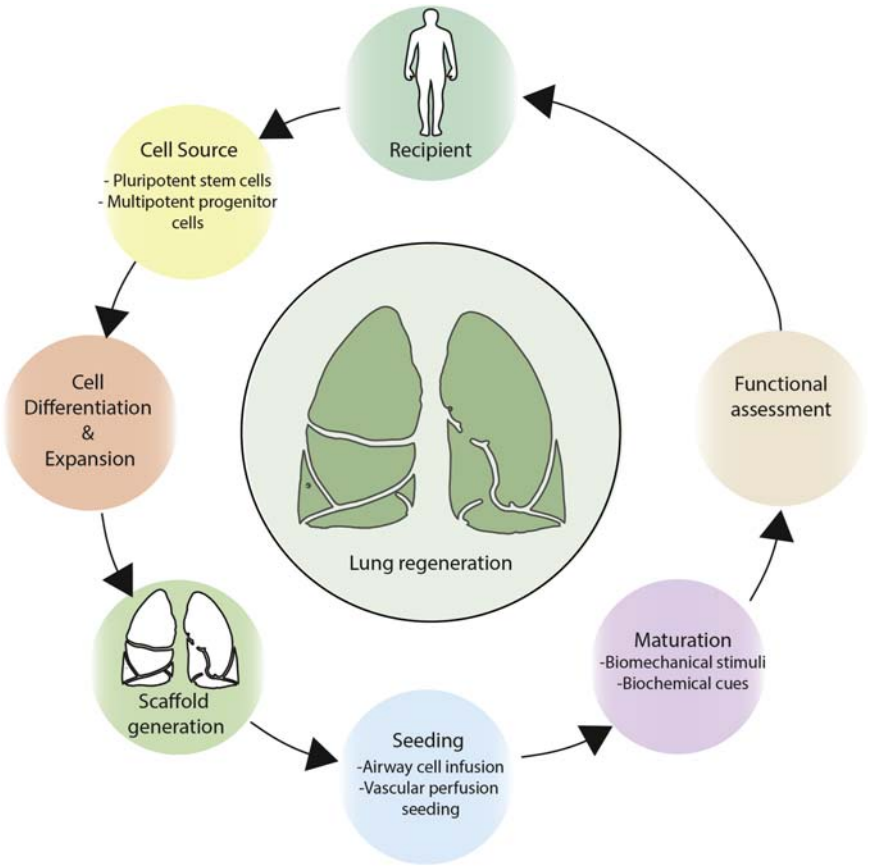

FIGURE 60.3 **A road map for lung regeneration.** Essential steps and current challenges in personalized regenerative medicine for the lung are listed, with the aim of bioengineering functional lung tissue for therapeutic use.

adequate delivery of oxygen and nutrients to the regenerating tissue. The cyclic stretch and relaxation that is created during mechanical ventilation can induce biological changes in lung epithelial cells, including surfactant secretion, differentiation, and cytokine release [104]. As described in vitro, the inclusion of an ALI between the perfused vasculature and the inflated airways during whole-organ culture can also be used to induce ciliation of the proximal airway epithelium. The protocols dictating when to apply these biomimetic stimuli and at what magnitude are not yet defined. Establishment of robust methods will also require sufficient analysis techniques to assess for cell viability and tissue regeneration in a noninvasive manner during culture. One reported method uses a resazurin-based reduction assay delivered through the vascular perfusate. Fluorescence of resazurin-containing medium can be used as a correlate of cellular metabolism, which is consistent with histological assessment of the regenerating tissue [105]. Measurement of glucose consumption and lactate production in the media during organ culture can also be used as noninvasive indicator of cell viability. Biological tests such as these, combined with a functional analysis of graft gas exchange capacity and perfusability, can be used to establish meaningful, quantitative criteria for transplant readiness.

CLINICAL TRANSLATION AND FUTURE CONSIDERATIONS

Lung transplantation remains the only curative treatment for advanced lung diseases; yet, insufficiencies in donor lung availability and long-term challenges with graft rejections continue to limit the therapeutic utility. Although advances in organ preservation, reconditioning, and immune tolerance provide important benefits, the ability to harness regenerative medicine to create lung tissue for clinical use is an exciting and possibly complementary option. To this end, many challenges have been discussed in this chapter. This includes harnessing endogenous cell repair mechanisms, improving methods to derive pulmonary cells from pluripotent progenitors, and developing methods to create new tissue constructs based on clinical-scale biomaterials, in addition to validating protocols for maturing and evaluating the regenerated tissue. The role of in vivo factors that drive repair has been mostly described in the context of animal lung injury models. The contribution of these mechanisms to tissue repair after implantation of an engineered tissue is widely unstudied in the lung and will likely have an important role in regenerating the respiratory tract.

The ability to direct regeneration, either ex vivo or in vivo, from patient-derived cells, would have significant benefit to people with lung disease. The capacity to apply these regenerative medicine approaches in an on-demand fashion is an additional advantage of these novel technologies. Much work is still required to coalesce the fields of lung development, cell biology, and tissue engineering fully, but promising advances have already been realized. Important questions regarding cell potential and the contribution of the microenvironment are being studied and applied to advance the goal of functional regenerative medicine for the lung.

List of Acronyms and Abbreviations

2D/3D two or three dimensions
ALI Air–liquid interface
AT 1/2 Alveolar type 1/2 pneumocyte
CC10 Club cell secretory protein, 10 kD
CF Cystic fibrosis
CFTR Cystic fibrosis transmembrane receptor
CRISPR Clustered Regularly Interspaced Short Palindromic Repeats
ECM Extracellular matrix
ESC Embryonic stem cell
FGF Fibroblast growth factor
H1N1 Influenza A virus
IL Interleukin
iPSC Induced pluripotent stem cell
Krt Keratin
MSC Mesenchymal stem or stromal cell
NEB Neuroendocrine body
Nkx2.1 NK2 homeobox 1 transcription factor
p63 Transformation-related protein 63
SP Surfactant protein

INTRODUCTION: FROM TISSUES TO ORGANS: KEY GOALS AND ISSUES

Nearly 8 million people in the United States have experienced a myocardial infarction (MI). Each year, 665,000 new cases occur [1]. MI results in the substantial death of cardiomyocytes in the infarct zone, followed by pathological remodeling of the heart. The remodeling process involves cardiac dilation, wall thinning, and severe deterioration of contractile function, leading to congestive heart failure in more than 900,000 patients each year in the United States [1]. Conventional therapies are limited by the substantial inability of myocardium to regenerate after injury [2] and the shortage of organs available for transplantation. This chapter will focus on describing approaches that have been considered as novel treatment options after MI [3].

Regardless of the approach to regenerative medicine or the scope of the application (a vascular graft, a pediatric valve, or an entire heart), there are three overlapping therapeutic goals: the three R's:

- Increase the safety of tissue and organ **replacement** and its effectiveness, and make it more widely available;
- **Repair** tissues and organs without having to replace them; and
- Enable tissues and organs to **regenerate** so that repair and regeneration become one and the same.

Furthermore, the problems of reaching these goals can be summarized (Table 61.1) in three categories (here largely in the context of tissue engineering) [4,5]:

- **Cell number**: What is the source of cells to be used and how will large numbers be generated? How will they be supplied with nutrients and oxygen (and have wastes removed) within a device of reasonable volume?
- **Cell function**: How will the scaffold, extracellular matrix (ECM), and diffusible factors interact to generate the desired cell phenotype? How will the engineered tissue or organ integrate with the host to ensure a functional outcome?
- **Cell durability**: What will happen over the long term as remodeling and/or the host immune or inflammatory system responds to the new tissue?

To replace, repair, or regenerate cardiovascular tissue, these central issues of regenerative medicine will need to be addressed. Some of these issues (Table 61.1) reflect the fundamental nature of how an organ is different from a tissue: the large size and three-dimensional (3D) structure, and the presence of multiple cell types that work in unison. A number of cell sources are available for cardiac tissue engineering, ranging from primary cardiac cells to stem cell differentiated cardiac cells. Advantages and disadvantages of cell sources are listed in Table 61.2. Beyond these largely scientific challenges, there are the no less critical, practical questions of manufacturing, sterilization, storage, and distribution, and the regulatory and public policy issues that will need to be addressed before such therapies can be made available to the patients who are expected to benefit. Furthermore, we will need new imaging or other noninvasive strategies to monitor the success (or not) of these therapies: i.e., to enable the translation into clinical practice.

TABLE 61.1 Critical Issues Associated With Tissue Engineering a Heart [5]

	Objective	Critical Issues
Cell number	• ~300 g cells (3×10^{11} cells) • ~200 mL O_2/h[a]	• Cell source/purity • Vascularization
Function	• Cellular phenotype (multiple cell types) • Coordinated muscle contraction • Pump blood • Connect to circulation	• Microenvironment (soluble and insoluble factors) • Pacemaker and electrical conduction • Valves and conduits • Biomechanical elasticity and strength • Nonthrombogenicity
Durability	• Fatigue resistance • Hypoxia and disease tolerance • Host tolerance	• Biocompatibility • Remodeling • Innate/adaptive immune response
■ Manufacturing and quality control		
■ Ethical, legal, and social issues		
■ Imaging and noninvasive diagnostics		
■ Regulatory and public policy issues		

[a]*Based on moderate activity [5a].*

TABLE 61.2 Cell Sources for Cardiac Tissue Engineering and Some of Their Advantages and Disadvantages [5]

Cell Sources	Advantages	Disadvantages
Adult cardiac cells	Target cell source	Little proliferative or developmental potential; limited resources
Fetal cardiac cells	Some proliferative potential, appropriate developmental potential; demonstrated efficacy	Limited resources; ethical considerations
Endothelial progenitor cells	Some proliferative potential; may elicit in vivo healing through indirect mechanisms	Appropriate developmental potential yet to be demonstrated; may not be appropriate for larger tissue replacement or in vitro tissue engineering
Adult bone marrow–derived cells	Significant in vitro proliferative potential; some demonstration of efficacy	Appropriate developmental potential to be demonstrated; safety tolerance after in vitro culture to be determined
Embryonic stem cells Induced pluripotent stem cells	Significant in vitro proliferative potential; demonstration of efficacy; appropriate developmental potential; sustainable resource	In vitro culture may introduce genetic changes; safety tolerance after in vitro culture and differentiation to be determined

ENGINEERING OF CARDIAC PATCHES USING CELLS, SCAFFOLDS, AND BIOREACTORS

Whereas small infarcts may be treated with cell therapies, larger areas of damaged tissue may require replacement with a cardiac patch. The time after an infarction is critical in the success of any regeneration strategy. Upon MI, a vigorous inflammatory response is elicited and dead cells are removed by marrow-derived macrophages. Over the subsequent weeks to months, fibroblasts (FBs) and endothelial cells (ECs) proliferate, forming granulation tissue and eventually a dense collagenous scar. Formation of scar tissue severely reduces the contractile function of the myocardium and leads to ventricle wall thinning and dilatation, remodeling, and ultimately heart failure. Thus, the best regeneration strategy depends on the length of time passed since the incidence of the infarction; i.e., new and old infarcts most likely cannot be treated using the same approach.

Cell injection strategies, will work best if applied shortly after MI. Application of cells and growth factors within hours and days after the MI has the potential to direct the wound repair process so that the minimum amount of scar tissue is formed, the contractile function is maintained in the border zone, and pathological remodeling is

attenuated. Tissue engineering strategies will work in the acute phase as well, but may be more necessary after a scar has formed. In these cases, larger areas of the heart must be replaced or augmented, and this is potentially where a scaffold-based approach may be most useful.

Scaffold-based therapy can be divided into two approaches: (1) a hydrogel, in which cells are either encapsulated and cultivated in vitro or injected directly into the MI area without preculture; or (2) porous and fibrous 3D scaffold, in which scaffolds are seeded with cells and in most cases cultivated in vitro before use as cardiac patches. Natural ECM may also serve as a scaffold. In addition, repair of the heart with biomaterials alone or constructs made by cell self-assembly has also been examined and performed.

Patients with large transmural akinetic scars often benefit from the Dor procedure (endoventricular circular patch plasty) [6,7]. In some cases, however, the success of this procedure is temporary, thus motivating the need for viable tissue patches. In this procedure, the scar tissue is excised and the ventricle is closed using a circular Dacron (polyethylene terephthalate) patch lined with endocardium.

In a pioneer study, Taylor and colleagues used the ECM of the native rat heart as a scaffold for cardiac tissue engineering [8]. This approach enabled them to preserve the underlying geometry and create an ideal natural template for tissue engineering of the heart (Fig. 61.1). The authors decellularized adult (12-week-old) cadaveric Fisher rat hearts by coronary perfusion with detergents (Fig. 61.1A). In addition to conserving the ECM, the vasculature was preserved and was perfusable (Fig. 61.1B). The structure of the ventricles, atria, and heart valves was also preserved. Cardiomyocytes were then isolated from neonatal rats and reseeded onto the structure. Vascular perfusion with the oxygenated media was provided via a peristaltic pump. In a subgroup of samples, rat aortic ECs were injected into the aorta to recellularize the vasculature. Macroscopic contractions were observed by day 4 of cultivation, whereas a pump function of about 2.4 mmHg was generated at day 8 under electrical

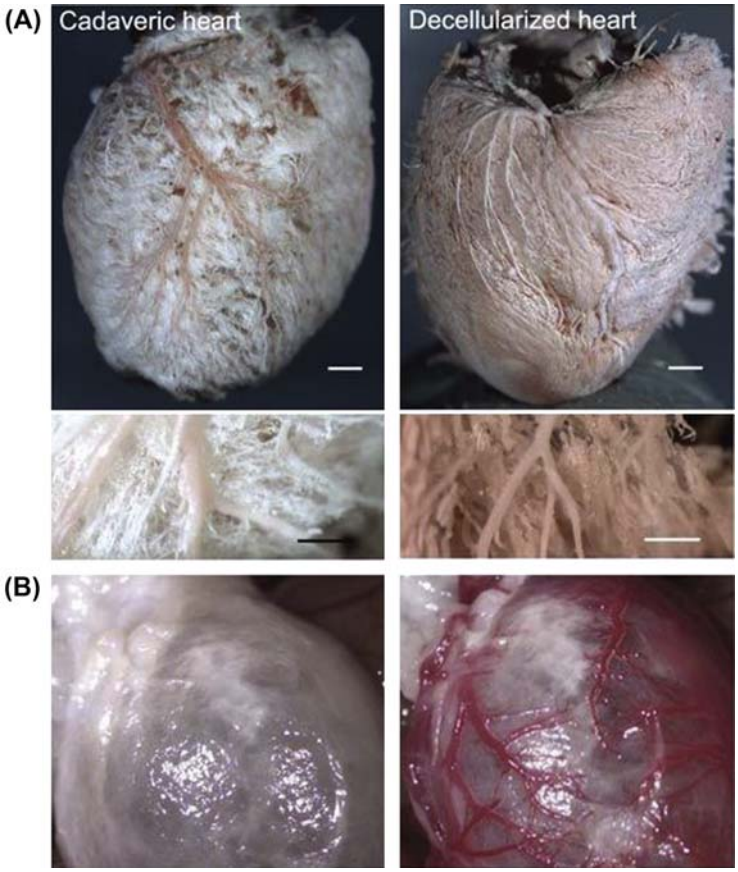

FIGURE 61.1 **Native heart extracellular matrix can serve as a suitable substrate for tissue engineering of a whole heart.** (A) Low-magnification (upper row; scale bar = 1000 mm) and high-magnification views (lower row; scale bar = 250 mm) of coronary corrosion casts of cadaveric and decellularized whole adult rat hearts. (B) Upon heterotropic transplantation of the decellularized whole rat heart before (left), blood can be seen flowing through the preserved decellularized vascular structures shortly after unclamping of the host aorta (right) [8].

stimulation. Clearly, the performance was only a small fraction (~2%) of the native heart; nonetheless, this was a milestone in cardiac tissue development.

In a similar approach, Guyette et al. decellularized human cadaveric hearts, leaving behind the ECM components [9]. The decellularized heart had with mechanical properties similar to those of the cadaver tissue. The remaining human cardiac matrix was perfused with induced pluripotent stem cell (iPSC)-derived cardiomyocytes. After 14 days of culture, although it was immature, the repopulated human heart was metabolically active and responsive to electrical stimulation. Further work involving full recellularization of the myocardial matrix and valves, as well as long-term organ culture to assist in tissue maturation is required before this technique can be brought to the clinic; however, it serves as foundational work in the path to full organ regeneration and repair.

In cardiac tissue engineering approaches, most studies suggest that some type of scaffold, an inductive 3D matrix, is necessary to support the assembly of cardiac tissue in vitro. An important scaffold-free approach includes stacking confluent monolayers of cardiomyocytes [10]. Although cardiac patches obtained in this way generate a high active force, engineering patches more than two to three cell layers thick remains a problem. Shimizu and colleagues described a polysurgery approach in which vascularized cardiac grafts can be created by sequentially layering cell sheets in multiple surgeries spaced at 1- to 3-day intervals [11]. Although this approach demonstrates that thick tissues (~1 cm) can in principle be created from cell sheets, the approach will be difficult to implement in the clinical setting. Murry and colleagues managed to obtain a cardiac patch based on human embryonic stem cell (ESC)-derived cardiomyocytes by the self-assembly of isolated cells in orbitally mixed dishes [12], essentially creating cell aggregates that could be deployed as a patch.

The most important example of hydrogel-based cardiac tissue engineering includes the work of Eschenhagen and colleagues. Cardiomyocytes were cast in growth factor–supplemented collagen gels and cultivated in the presence of cyclic mechanical stretch [13–16]. The main advantage of the hydrogel approach is the higher active force generated by such cardiac tissues, compared with the force generated by tissues on porous or fibrous 3D scaffolds. In addition, collagen and laminin are the main components of the myocardial ECM; thus, they are supportive of cardiomyocyte attachment and elongation. However, the main challenge remains in tailoring the shape and dimensions of such tissues. One interesting approach to addressing this issue is the use of extruded collagen type I tubes [17].

The use of porous scaffolds is another popular approach employed in cardiac tissue engineering. 3D cardiac tissue constructs were successfully cultivated in dishes using a variety of scaffolds, among which collagen sponges were the most common. In the pioneering approach of Li and colleagues, fetal rat ventricular cardiomyocytes were expanded after isolation, inoculated into collagen sponges, and cultivated in static dishes for up to 4 weeks [18]. The cells proliferated with time in culture and expressed multiple sarcomeres. Adult human ventricular cells were used in a similar system, although they exhibited no proliferation [19]. In another study, fetal cardiac cells were cultivated on porous alginate scaffolds in static 96-well plates. After 4 days of culture, the cells formed spontaneously beating aggregates in the scaffold pores [20]. Cell seeding densities on the order of 10^8 cells/cm^3 were achieved in the alginate scaffolds using centrifugal forces during seeding [21]. Neonatal rat cardiomyocytes formed spontaneously contracting constructs when inoculated in collagen sponges (Tissue Fleece) within 36 h after seeding [22] and maintained activity for up to 12 weeks. The contractile force increased upon addition of Ca^{2+} and epinephrine.

In a classical tissue engineering approach, fibrous polyglycolic acid (PGA) scaffolds were combined with neonatal rat cardiomyocytes and cultivated in spinner flasks and rotating vessels [23]. The scaffold was 97% porous and consisted of nonwoven PGA fibers 14 μm in diameter. This material has advantages from a clinical perspective because it is found in biodegradable sutures. Neonatal rat or embryonic chick ventricular myocytes were seeded onto PGA scaffolds by placing a dilute cell suspension in the spinner flasks and mixing for 3 days (50 rpm) [23]. Mixing in the spinner flasks (0, 50, or 90 rpm) had a significant effect on the construct metabolism and cellularity. Constructs cultivated in well-mixed flasks had a significantly higher cellularity index and metabolic activity compared with constructs cultivated in the static flasks. After 1 week of culture, constructs seeded with neonatal heart cells contained a peripheral tissue-like region (50–70 μm thick) in which cells stained positive for tropomyosin and organized in multiple layers in a 3D configuration [24]. Electrophysiological studies conducted using a linear array of extracellular electrodes showed that the peripheral layer of the constructs exhibited relatively homogeneous electrical properties and sustained macroscopically continuous impulse propagation on a centimeter-size scale [24]. Constructs based on the cardiomyocytes enriched by preparing in a well-mixed flask exhibited a lower excitation threshold (ET), higher conduction velocity, higher maximum capture

rate (MCR), and higher maximum and average amplitude of contraction. Laminar flow conditions in rotating bioreactors further improved the PGA-based constructs. The cells in the peripheral layer expressed tropomyosin and had a spatial distribution of connexin-43 comparable to that of the neonatal rat ventricle. The expression levels of cardiac proteins connexin-43, creatine kinase-MM, and sarcomeric myosin heavy chain were lower in rotating bioreactor cultivated constructs compared with the neonatal rat ventricle but higher than in the spinner flask–cultivated constructs [25]. In both spinner flasks and rotating bioreactors, the center of the constructs was mostly acellular owing to the oxygen diffusional limitations.

Electrospun scaffolds have gained significant attention because they enable control over the structure at submicron levels as well as over mechanical properties, both of which are important for cell attachment and contractile function. Microsized to nanosized fibers are created by electrically charging a stream of polymer that is then collected as a network of fibers. Electrospun fibers have a 3D fibrous structure and a high surface area to volume ratio that allows them to mimic the native ECM closely [26]. Another attractive property of electrospinning is the ability to make both random and highly aligned fibers. In one study, random poly(glycerol-sebacate) (PGS) and gelatin composite fibers were fabricated by collecting the fibers from a charged stream of polymer on a glass slide on a collector plate, whereas aligned fibers were collected on aluminum parallel electrodes (Fig. 61.2A). The tunable fiber alignment was demonstrated with different PGS–gelatin ratios and the microstructure was able to direct neonatal rat cardiomyocyte alignment, thus demonstrating the relationship between scaffold structure and cell morphology (Fig. 61.2B). Furthermore, the different fiber alignment and compositions possessed different mechanical properties, which were further shown to influence the contractile behavior of the cells, which allowed them to conclude that softer, more aligned fiber mats resulted in more synchronous beating [27].

The electrospinning protocol has been optimized for a wide range of biomaterials. Entcheva and colleagues [28] used electrospinning to fabricate oriented biodegradable, nonwoven poly(lactide) (PLA) scaffolds. Neonatal rat cardiomyocytes cultivated on oriented PLA matrices had remarkably well-developed contractile apparatuses and exhibited electrical activity. In a study by Parker and colleagues, a method known as rotary jet spinning, which allows for the fabrication of highly aligned fibers, was optimized for a variety of biomaterials. The polymer is fed through a syringe pump and collected on a rotating cylindrical collector. The ease of fabrication and resulting aligned fibers make this technique promising [29,30].

One hurdle that must be overcome in the area of electrospun scaffolds is the transport of oxygen and nutrients. Hasirci and colleagues attempted to overcome this by wrapping a biodegradable polyester electrospun aligned mat around a porous biodegradable tube composed of poly(L,D-lactide)lactic acid–PGS (Fig. 61.2C). The mat was cultured with mesenchymal stem cells before formation of the vascular construct and the tubing was perfused with cell culture media. This preliminary study can be used to develop thicker patches that can be integrated later with the existing vasculature of the heart [31].

Another common cardiac tissue engineering technique is to combine the benefits of the naturally occurring ECM and the stability of a porous scaffold. Freed and colleagues reported on the mechanical stimulation of hybrid cardiac grafts based on knitted hyaluronic acid–based fabric and fibrin [32]. The grafts exhibited mechanical properties comparable to those of native neonatal rat hearts. In a subcutaneous rat implantation model, the constructs exhibited the presence of cardiomyocytes and blood vessel ingrowth after 3 weeks. Another group inoculated collagen sponges or synthetic PGS scaffolds using Matrigel with neonatal rat cardiomyocytes [33]. The main advantage of a collagen sponge is that it supports cell attachment and differentiation. However, the scaffold tends to swell when placed in culture medium; therefore, the creation of parallel channel arrays resembling a capillary network is difficult. For that purpose, a biodegradable elastomer [34] with a high degree of flexibility was used.

Cardiac patches based on synthetic scaffolds are becoming highly sophisticated. They are able to stimulate and record electrical activity of the cardiac tissues relying on built-in electrodes. Dvir and colleagues engineered an electronic cardiac patch composed of gold electrodes embedded in a thin SU-8 mesh. An electroactive polymer capable of releasing proteins or small molecules upon electrical stimulation was loaded onto select electrodes. This sensor was then deposited with electrospun polycaprolactone-gelatin fibers, thus creating an electrospun biomaterial-electrode patch (Fig. 61.2D). The patch was then seeded with neonatal rat cardiomyocytes and cardiac FBs (Fig. 61.2E). They revealed that their device was able to support a homogeneous distribution of cells that interacted with the electronic fibers. Finally, an important function of an electronic patch is the ability to control the tissue remotely. Application of an electrical signal allowed the group to manipulate the direction of tissue contraction and propagation. Techniques that combine the fields of electronic sensors and biomaterials present an interesting approach in the attempt to develop, monitor, and control cardiac tissue [35].

BIOPRINTING

3D bioprinting is a technique that has quickly gained popularity for its ability to create highly aligned tissues. Biopolymers can be encapsulated with cells and printed into lattice structures for the analysis for cardiac function. A technique that can potentially combine the advantages of the hydrogel approach with ease in tailoring tissue shape and size is inkjet printing. Cardiac constructs based on feline cardiomyocytes were created by printing cell

solutions onto alginate and using calcium as a cross-linking agent [36]. This approach may be particularly useful for coculture because it enables precise control over cell location in the tissue construct.

Pati et al. developed a novel decellularized ECM bioink capable of printing various tissues. The ink, which consists of decellularized heart tissue, had a positive effect on cardiac tissue maturation. They demonstrated that there was an upregulation of fast myosin heavy chain and α-sarcomeric actinin compared with the control gel [37]. Alternatively, a gelatin-based bioink encapsulated with gold nanoparticles was developed by Zhu et al. (Fig. 61.3A). The conductive bioink was loaded with neonatal rat cardiomyocytes and was printed into a lattice structure. The cardiac scaffolds showed synchronous beating as early as day 2 of culture. Immunostaining showed increased connexin-43 gap junction proteins and sarcomeric structures, which suggested that the conductive bioink aided in tissue maturation (Fig. 61.3B) [38].

Another bioprinting approach consists of printing a mosaic hydrogel sheet. The sheet is composed of alternating bioinks containing cells and can be printed in an aligned fashion to mimic the heart's structure (Fig. 61.3C). This method will allow for design in cell alignment as well as the controlled incorporation of other cell types. This method

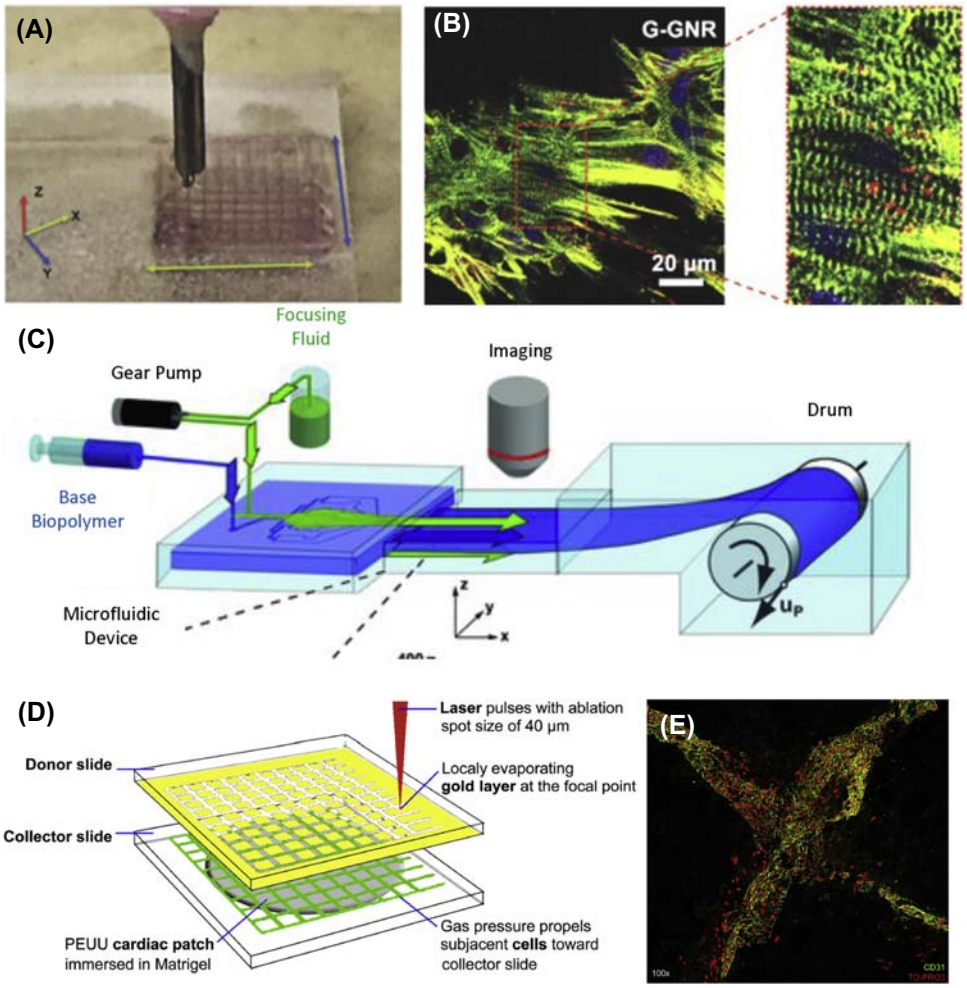

FIGURE 61.3 Applications of bioprinting to create anisotropic and vascularized scaffolds. (B) Immunostaining of neonatal rat cardiomyocytes embedded in a gold nanoparticle gelatin methacryloyl three-dimensionally (3D) bioprinted construct for sarcomeric α-actinin (*green*), Cx-43 (*red*) and 4′,6-diamidine-2′-phenylindole dihydrochloride (DAPI) (*blue*) [38]. (C) Schematic of a bioprinting approach that can be used to print a mosaic hydrogel sheet. Using microfluidics, a base polymer is extruded for a flat sheet. This method can be modified to print numerous polymer compositions simultaneously [39]. is still fairly new; further optimization is required to increase the resolution. However, it presents a novel approach in the development of a full-sheet cardiac patch [39].

Incorporation of human iPSC-derived cardiomyocytes into any cardiac platform is a desirable property; however, the shear stresses typically associated with bioprinting increase the complexity of such a task. Therefore, a method is needed that can accurately print a structure similar to the native ECM. Zhang and colleagues developed the method of multiphoton-excited 3D printing that enabled them to generate an ECM-mimicking construct. The scaffold was generated by depositing gelatin methacrylate in a grid-shaped pattern modeled after the native deposition of fibronectin. Human iPSCs were differentiated into cardiomyocytes, smooth muscle cells, and ECs and seeded on the bioprinted scaffold. The bioprinted patches were then engrafted into a murine model of MI. The patch was shown to improve cardiac function of the treated animals; however, further work is required to confirm electromechanical integration of the patch [40].

In addition to creating biomimetic scaffolds, bioprinting can be used to create vascularized patches. The human umbilical vein endothelial cell (HUVEC)-laden patch was created through laser-induced forward-transfer cell printing (Fig. 61.3D). Briefly, HUVEC cells were seeded on a prepatterned polyurethane cardiac patch that was deposited onto a collector plate by short laser pulses (Fig. 61.3E). The patch was implanted in an MI rat model and rats with the HUVEC-laden patches showed significantly improved heart function. In addition, the vascularized patches resulted in a higher capillary density around the infarct area suggesting vascular integration [41].

Therefore, many techniques have arisen in the field of cardiac tissue engineering. Each technique has its own advantage and disadvantage, but there seems to be a general trend of increasing complexity in an effort model the native cardiac environment to more accurately.

CARDIAC ORGANOIDS AND ORGAN-ON-A-CHIP ENGINEERING

Cardiac organoids, microphysiological systems, and organ-on-chip platforms have become popular for their ability to recapitulate properties found in the native tissue. These devices are sought as models in drug toxicity studies and disease modeling. In early work, contractile organoids 24 mm long and 100 μm thick were fabricated by self-organization [42]. Cardiomyocytes were cultivated on a polydimethylsiloxane (PDMS) surface coated with laminin. As laminin degraded, the confluent monolayer detached from the periphery of the substrate, moving toward the center and wrapping around a string placed in the center of the plate until a cylindrical contractile organoid was formed.

A significant step toward a clinically useful cardiac patch was the cultivation of ESC-derived cardiomyocytes on thin polyurethane films. Cells exhibited cardiac markers (actinin) and were capable of synchronous macroscopic contractions [43]. The orientation and cell phenotype could be improved further by microcontact printing of ECM components (e.g., laminin), as demonstrated for neonatal rat cardiomyocytes cultivated on thin polyurethane and PLA films [44,45].

We have used microfluidic patterning of hyaluronic acid on glass substrates to create thin (10- to 15—μm-diameter), several millimeter−long cardiac organoids that exhibited spontaneous contractions and stained positive for troponin I, a cardiac marker [46].

Feinberg et al. seeded a layer of neonatal rat ventricular cardiomyocytes on a PDMS membrane that could be detached from a thermosensitive poly(isopropylacrylamide) layer at room temperature. Called muscular thin films, these cell-covered sheets could be designed to perform tasks such as gripping, pumping, walking, and swimming by careful tailoring of the tissue architecture, thin-film shape, and electrical-pacing protocol [47].

Scaffold structure can be used to guide the orientation of cardiomyocytes effectively and yield an anisotropic structure similar to the native myocardium even in the absence of specific physical cues such as electrical or mechanical stimulation. Freed and colleagues created an accordion-like scaffold using laser boring of a 250-μm-thick PGS layer [48]. The accordion-like honeycomb was designed by overlapping two 200 × 200-μm squares at an angle of 45 degrees. The pore walls and struts were about 50 μm thick. The scaffolds were pretreated with cardiac FBs followed by the seeding of enriched cardiomyocytes. During pretreatment, rotating culture was used, whereas static culture was used upon cardiomyocyte seeding. At the end of cultivation, the authors obtained contractile cardiac grafts with mechanical properties closely resembling those of the native rat right ventricle. In addition, the cells in the pores were aligned along the preferred direction.

Badie et al. investigated yet another method to replicate the microstructure of heart tissue in vitro. The two-step method first involves imaging the heart using diffusion tensor magnetic resonance imaging (DTMRI). From the 3D reconstructed image, a specific 2D plane is chosen and the cardiac fiber directions on this plane are converted into soft-lithography photomasks, and later into fibronectin-coated PDMS sheets. Fibronectin patterns consisted of a matrix of 190-μm^2 subregions, each composed of parallel lines 11–20 μm wide, spaced 2–8.5 μm apart, and angled to match local DTMRI-measured fiber directions. By adjusting fibronectin line widths and spacing, cell elongation, gap junctional membrane distribution, and local cellular disarray were altered without affecting the cell direction. This approach enabled the systematic studies of intramural structure–function relationships in both healthy and structurally remodeled hearts [49,50].

Bursac and colleagues developed a cell–fibrin hydrogel micromolding approach in which PDMS molds containing an array of elongated posts were used to fabricate relatively large neonatal rat skeletal muscle tissue networks. As the cells compacted in the hydrogel, the presence of high–aspect ratio posts forced them to elongate and align, thus imparting a high degree of anisotropy to the cells and the tissue. This approach is being extended to the cultivation of cardiac patches based on mouse ESC-derived progenitor cells [51,52].

Interestingly, a high degree of anisotropy correlating with the high propagation velocities in the longitudinal direction (~35 cm/s) was achieved by cultivation of neonatal rat cardiomyocytes of micromolded poly(ethylene glycol) hydrogels with submicrometer features, specifically alternating 800 × 800-nm grooves and ridges. The submicrometer features forced the cells to align focal adhesions along the groove and ridge direction and the cytoskeleton followed [53].

Typical culture platforms are limited in their ability to develop mature tissue, because iPSC/ESC-derived cardiomyocytes are immature after differentiation, and therefore are limited in their ability to truly model the cardiac environment. Another prominent heart-on-a-chip cardiac model is called the Biowire (Fig. 61.4A). The Biowire platform combines electrical and architectural cues, thus creating a microenvironment capable of fostering mature cardiac tissue. The platform consists of human ESC (hESC)-derived cardiomyocytes seeded in a collagen gel around a surgical suture, which is embedded in a PDMS template. Throughout culture, the cardiomyocytes and collagen gel compacted around the wire, forming a dense tissue. The tissue was electrically stimulated for 7 days and had highly organized sarcomeric banding, which suggested maturation of the tissue (Fig. 61.4B). Stimulation during culture was also shown to improve Ca^{2+} influx and the electrophysiological properties, which further supported the hypothesis of improved tissue maturation upon electrical stimulation. Future iterations of the model should support the use of vascular cells to aid in oxygen and nutrient diffusion [54]. The platform was later modified to support seeding around a polytetrafluoroethylene tube. The tubing can be perfused with various drugs and the surrounding tissue can be monitored to test for cardiotoxicity [55].

Cardiac organoids and organ-on-a-chip devices can also be used for disease modeling applications. A model aims to study diseased myocardium by creating arrays of ventricular tissue subjected to cyclic stress. Their goal was to induce diseased and failing myocardium by mimicking mechanical overload. The chip consisted of flexible micropatterned substrates placed inside a chamber ring that stretched the samples to 10% strain by a custom system. The group found that they were able to induce myocardium failure by studying genetic, structural, and function response, suggesting a novel platform to study the response of diseased tissue. In future studies, they hope to extend the platform to include drug toxicity testing [56].

Another model attempts to reproduce the hallmarks of cardiomyopathy associated with the mitochondrial disease Barth syndrome. Barth syndrome is the result of a gene mutation that results in abnormalities in the sarcomeric assembly and contraction of the heart. Using iPSCs from patients with Barth syndrome, cells were seeded onto micropatterned fibronectin sheets to examine sarcomeric organization. The sarcomeric structure of the Barth syndrome cells was incomplete and sparse compared with healthy control cells. This allowed the group to confirm that sarcomeric organization depends on proper functioning of the mitochondria. To characterize the contractile response of the tissue, the cells were integrated into their heart-on-a-chip model, which consists of a flexible PDMS cantilever; this allowed the researchers to confirm impaired cell contractility (Fig. 61.4C). Once validated, the model was used to evaluate the effect of possible therapies, thus proving the effectiveness and need of disease models for therapeutic testing [57].

In another effort to model dilated cardiomyopathy, Chen and colleagues attempted to determine how a genetic mutation affects the sarcomeric protein, titin. Human iPSC-derived cardiomyocytes were seeded onto microarray post detectors, which allow for robust observation of contractile activity. Unsurprisingly, sarcomeres were not

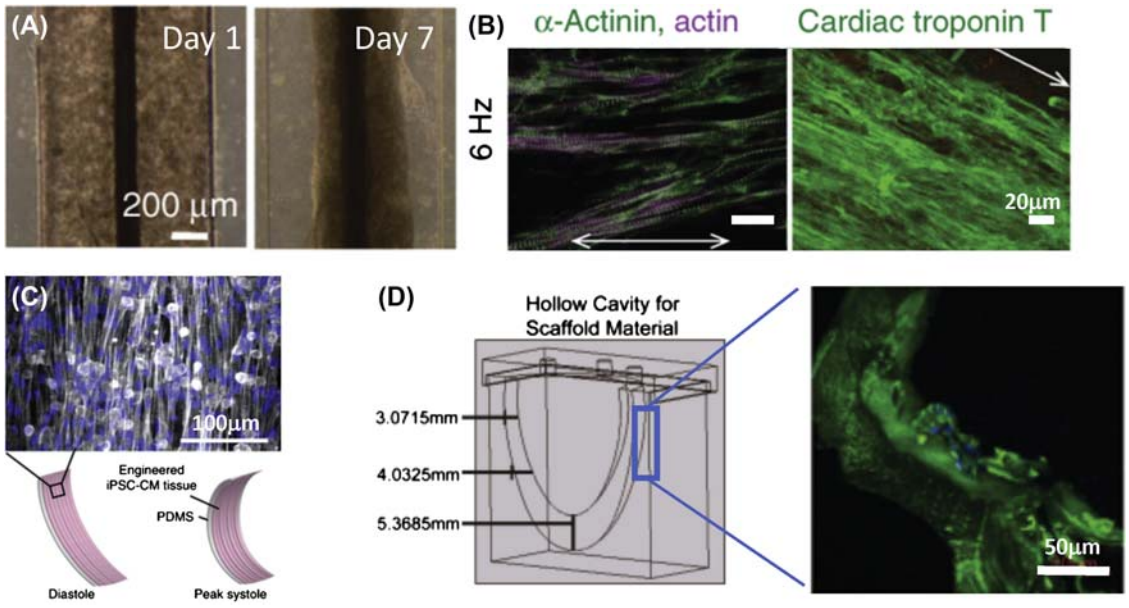

FIGURE 61.4 **Cardiac organoids and heart-on-a-chip engineering.** (A) Microscopic image of a heart-on-a-chip platform called the Biowire showing the contraction of human embryonic stem cell (ESC)-derived cardiomyocytes and cardiac fibroblasts contracting over 7 days [54]. (B) Immunostaining of human ESC-derived cardiomyocytes and cardiac fibroblasts after 7 days of electrical stimulation at 6 Hz showing strong cardiac specific marker expression and sarcomeric formation [54]. (C) Organ-on-a-chip cantilever platform used to model Barth syndrome, a mitochondrial disease (bottom). The platform is patterned with fibronectin lines to allow for anisotropic organization. Sample has been immunostained for sarcomeric α-actinin (*white*) and 4′,6-diamidine-2′-phenylindole dihydrochloride (DAPI) (*blue*) [57]. (D) An approach using three-dimensional (3D) printing to develop a mold modeled after the left ventricle. The mold is injected with chitosan and lyophilized before seeding. Immunostaining (right) shows poor spreading and clustering of cells. Sarcomeric α-actinin (*green*), and DAPI (*blue*) [62,63].

only shorter but more disorganized in titin-deficient samples. Furthermore, the model was used to identify other missense variances that resulted in a mutated titin protein. This approach can be used for further gene expression modification of not only titin but also other cardiac proteins to model various diseases [58].

A universally accepted cardiac model cultured in serum-free media is necessary in the field for disease modeling and the pharmaceutical industry. Zimmermann and colleagues developed a proof-of-concept system that could be scaled up and used in applications ranging from disease modeling to a cardiac patch. Using a 1:1 ratio of human iPSC-derived cardiomyocytes and nonmyocytes, the cells are seeded around a cantilever post structure. The cells are cultured in serum-free media, thus complying with Current Good Manufacturing Practice standards. This platform was found to foster the maturation of the cells better as opposed to a conventional monolayer. Finally, in an effort to demonstrate the scalability of the platform, the cardiomyocytes and nonmyocytes were seeded around a custom array of posts. The array of posts supported the formation of a functional tissue sheet that, when sutured over the epicardium of a rat heart, exhibited signs of vascularization. Such a platform, as described earlier, should be taken only as a proof-of-concept model. Further work is required to develop standardized models that support disease modeling and tissue repair [59].

One major limitation to heart-on-a-chip platforms is evaluation of tissue functionality, because a main means of measuring tissue response is by microscopy and measuring the amplitude and frequency of the beating tissue. An alternative approach consists of combining sensors in the microphysiological system for continuous monitoring. Lind et al. combined 3D printing and microphysiological systems to develop a platform capable of tissue contractile stress. They developed six inks based on piezoresistive, high-conductance, and biocompatible soft materials. This chip, which is printed using these materials, consists of a cantilever system with micropatterns on top to direct cell alignment. The microphysiological system provided long-term, continuous data acquisition, thus proving its usefulness for drug studies [60].

ENGINEERING THE ENTIRE VENTRICLE

Using a collagen-based hydrogel, Lee et al. developed an in vitro ventricle chamber. Briefly, isolated neonatal rat cardiomyocytes were suspended in collagen and pipetted into a cup-shaped mold around a balloon catheter. After collagen gel polymerization, the organoid was cultured in cell media until testing. Their approach allowed them to create a 3D cardiac encapsulated ventricle chamber that was able to contract spontaneously and expel a measurable volume. However, they noted that the cells maintained an immature and random orientation, unlike the aligned anisotropy found in native heart tissue [61].

Another cardiac ventricle, developed by Patel et al., consists of a ventricle-shaped chitosan tissue formed by freezing chitosan in a 3D printed computer-aided design (CAD) model of the left ventricle (Fig. 61.4D). The chitosan was then lyophilized and rehydrated before seeding. Neonatal rat cardiomyocytes were injected intermittently throughout the scaffold and a cardiac seeded patch was wrapped around the outside. However, there are considerable differences between the scaffolds and the CAD models, and the injected cells remained in clusters and failed to spread throughout the scaffold. Further work is required before the platform can be used to examine the pressure–volume response of the cardiac ventricle [62,63].

BIOREACTORS AND CONDITIONING

Major efforts in the development of bioreactors for tissue engineering of myocardium focus on (1) providing sufficient oxygen supply for the highly metabolically active cardiomyocytes, and (2) providing appropriate physical stimuli necessary to reproduce a complex structure at various length scales (subcellular to tissue).

The most common culture vessels used for tissue engineering of the myocardium include static or mixed dishes, static or mixed flasks, and rotating vessels. These bioreactors offer three distinct flow conditions (static, turbulent, and laminar) and therefore differ significantly in the rate of oxygen supply to the surface of the tissue construct. Oxygen transport is an important factor for myocardial tissue engineering owing to the high cell density, limited cell proliferation, and low tolerance of cardiac myocytes for hypoxia. In all configurations, oxygen is supplied only by diffusion from the surface to the interior of the tissue construct, yielding an approximately 100-μm-thick surface layer of compact tissue capable of electrical signal propagation and an acellular interior [64].

Oxygen Supply

In an attempt to enhance mass transport within cultured constructs, a perfusion bioreactor that provides interstitial medium flow through the cultured construct at velocities similar to those found in the native myocardium (~400–500 μm/s) was developed [65]. In such a system oxygen and nutrients were supplied to the construct interior by both diffusion and convection (Fig. 61.5A). Interstitial flow of culture medium through the central 5 mm–diameter × 1.5 mm–thick region resulted in physiologic dense, viable, differentiated, and aerobically metabolizing cells. In response to electrical stimulation, perfused constructs contracted synchronously, had a lower ET, and recovered their baseline function levels of ET and MCR after treatment with a gap junctional blocker. On the other hand, dish-grown constructs exhibited arrhythmic contractile patterns and failed to recover their baseline MCR levels. These studies suggested that the immediate establishment and maintenance of interstitial medium flow markedly enhanced the control of oxygen supply to the cells and thereby enabled engineering of compact constructs. However, most cells in perfused constructs were round and mononucleated, indicating that some of the regulatory signals (either molecular or physical) were not present in the culture environment.

In another approach, a separate compartment for medium flow was created by perfusing channeled scaffolds in a configuration resembling the capillary network in vivo. Neonatal rat heart cells were inoculated into the pores of an elastic, highly porous scaffold (PGS) with a parallel channel array and perfused with a synthetic oxygen carrier (Oxygent in culture medium, perfluorocarbon [PFC] emulsion) [33]. Constructs cultivated with PFC emulsion had significantly higher DNA content, significantly lower ET, and a higher relative presence of cardiac markers troponin I and connexin-43 (Western blot) compared with the culture medium alone. Cells were present throughout the construct volume. In this configuration, the presence of PFC emulsion further enhanced the

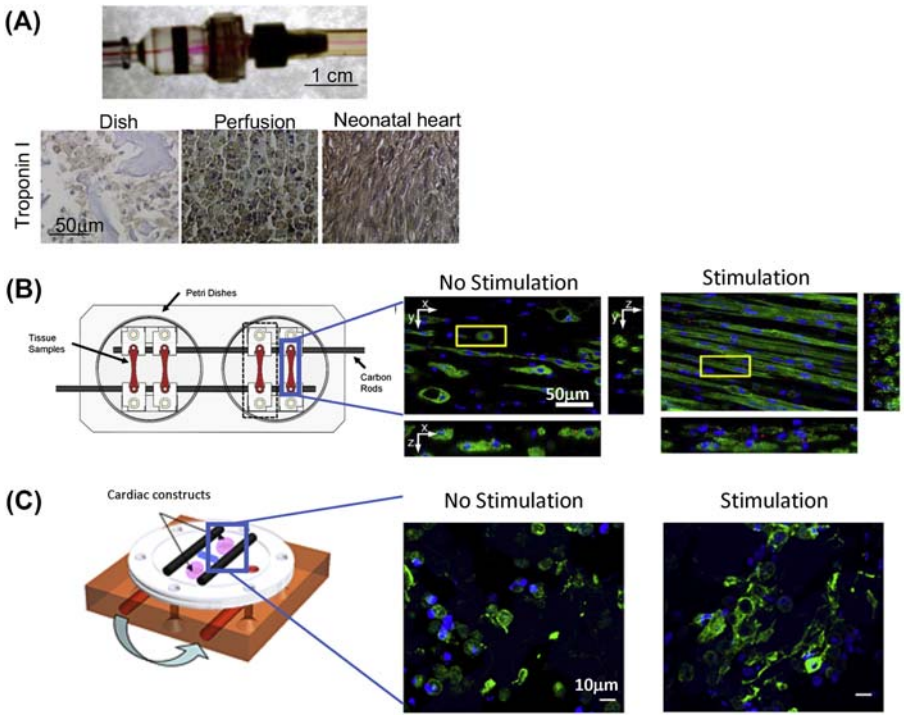

FIGURE 61.5 **Cardiac tissue engineering culture systems.** (A) Direct culture medium perfusion of constructs based on neonatal rat cardiomyocytes inoculated into collagen sponges using Matrigel. Medium perfusion resulted in uniform cell distribution and maintenance of cell viability. Immunohistochemical staining illustrated cross-sectional distribution of cells expressing cardiac troponin I [73]. (B) Bioreactor designed to stimulate the sample. Immunostaining for sarcomeric α-actinin (*green*), Cx-43 (red), and 4′,6-diamidine-2′-phenylindole dihydrochloride (DAPI) (*blue*) reveals elongated sarcomeric structures and expression of Cx-43 similar to the native adult myocardium [76]. (C) Hybrid bioreactor designed to electrically stimulate the samples and subject the constructs to a flow rate of 0.1 mm/s. The stimulated samples were more elongated and had a stronger expression of troponin I (green) [77].

oxygen supply to the cells by improving both axial (convective term) and radial (effective diffusivity) transport properties [64].

Kofidis et al. supplied pulsatile flow to cardiomyocytes encapsulated in fibrin glue around a rat artery in vitro [66]. Dvir et al. designed a novel perfusion bioreactor that employs a distributing mesh upstream from the construct to provide homogeneous fluid flow and maximum exposure to perfusing medium [67]. This convective supply of oxygen led to increased cell viability in alginate scaffolds seeded with physiologically relevant cells [67]. In addition, pulsatile culture medium flow resulted in physiological cardiac hypertrophy via stimulation of the Erk pathway [67,68]. We combined mechanical stimulation and perfusion in a single system by using a normally closed pinch valve at the outlet from the perfusion chamber. The valve was set to open at the frequency of 1 Hz. The buildup of the culture medium during the closed period resulted in tissue compression followed by relaxation at the valve opening [69].

Differentiation

Mechanical Stimulation

One significant approach to cardiac tissue engineering, established by Eschenhagen and colleagues [13,14,16,70], involves cultivating neonatal rat heart cells in collagen gel or Matrigel in the presence of growth factors. The cultured tissues are subjected to sustained mechanical strain. Under these conditions, cardiomyocytes and nonmyocytes form 3D cardiac organoids, consisting of a well-organized and highly differentiated cardiac muscle syncytium that exhibited contractile and electrophysiological properties of working myocardium. First

implantation experiments in healthy rats showed survival, strong vascularization, and signs of terminal differentiation of cardiac tissue grafts [15].

In the state-of-the art approach by Eschenhagen and colleagues, neonatal rat cardiac cells were suspended in the collagen−Matrigel mixture and cast into circular molds [16]. After 7 days of static culture, the strips of cardiac tissue were placed around two rods of a custom-made mechanical stretcher and subjected to either unidirectional or cyclic stretch. Histology and immunohistochemistry revealed the formation of intensively interconnected, longitudinally oriented cardiac muscle bundles with morphological features resembling adult rather than immature native tissue. Primitive capillary structures were also detected. Cardiomyocytes exhibited well-developed ultrastructural features: sarcomeres arranged in myofibrils, with well-developed Z, I, A H and M bands, specialized cell−cell junctions, T tubules, as well as well-developed basement membranes. Contractile properties were similar to those measured for native tissue, with a high ratio of twitch to resting tension and strong β-adrenergic response. The action potential characteristics of rat ventricular myocytes were recorded.

Another way mechanical stimulation assists in tissue maturation is through improved orientation of gap junction proteins. Connexin 43 is a gap junction protein specific to cardiac tissue and is responsible for intercellular communication. In a study led by Dhein and colleagues, neonatal rat cardiomyocytes were cultured on silicon membranes that were subjected to uniaxial cyclic stretch for 24 h. The samples were stained for connexin-43 and other cardiac markers and the cells exposed to the mechanical stretch were elongated in morphology. Connexin 43 was found to be polarized transversely in the direction of cyclic stress [71].

Electrical Stimulation

In the native heart, mechanical stretch is induced by electrical signals. Contraction of the cardiac muscle is driven by the waves of electrical excitation (generated by pacing cells) that spread rapidly along the membranes of adjoining cardiac myocytes and trigger the release of calcium, which in turn stimulates contraction of the myofibrils. Electromechanical coupling of myocytes is crucial for their synchronous response to electrical pacing signals, resulting in contractile function and pumping of blood [72].

We prepared cardiac constructs by seeding collagen sponges with neonatal rat ventricular cells that were electrically stimulated using suprathreshold square biphasic pulses (2 ms in duration, 1 Hz, 5 V) [73]. The stimulation was initiated after 1−5 days of scaffold seeding (a 3-day period was optimal) and applied for up to 8 days. Over only 8 days in vitro, electrical field stimulation induced cell alignment and coupling, increased the amplitude of synchronous construct contractions by a factor of seven, and resulted in a remarkable level of ultrastructural organization. The development of conductive and contractile properties of the cardiac constructs was concurrent, with a strong dependence on the initiation and duration of the electrical stimulation. Aligned myofibers expressing cardiac markers were present in stimulated samples and neonatal heart. Stimulated samples had sarcomeres with clearly visible M and Z lines, and H, I, and A bands. In most cells, Z lines were aligned and the intercalated discs were positioned between two Z lines. Mitochondria (between myofibrils) and abundant glycogen were detected. In contrast, nonstimulated constructs had poorly developed cardiac-specific organelles and poor organization of ultrastructural features.

Subsequently, we applied biphasic electrical stimulation to mimic conditions in the heart further and demonstrated that electrical stimulation enhances the assembly of cardiac organoids based on multiple cell types, including FBs, ECs, and cardiomyocytes [74]. We also developed cardiac microchips that combine electrical field stimulation and topographical cues. Specifically, micrometer-sized grooves and ridges were created by hot-embossing polystyrene placed between gold electrodes on a single chip. Simultaneous application of topographical cues and electrical field stimulation resulted in a remarkable level of cardiomyocyte alignment, elongation, and assembly of contractile apparatus [75].

Further applying this work, Hitchcock and colleagues used electrical stimulation to engineer mature cardiac tissue, similar to a native phenotype. In the native heart myocardium, connexin-43 is concentrated at the end of cells; however, in unstimulated heart myocardium, connexin-43 is typically sporadically expressed, thus providing motivation for electrical stimulation. The authors developed a specialized bioreactor in which neonatal rat cardiomyocytes were seeded around two posts to form an engineering cardiac tissue fiber (Fig. 61.5B). After 3 days of culture, the samples were electrically stimulated by carbon electrodes. The group found that the stimulated samples were more elongated and had a stronger expression of sarcomeric structures, which was similar in morphology to the native heart myocardium. Connexin 43 expression was found to be significantly

increased in the stimulated sample compared with the unstimulated one and was expressed at levels similar to native adult myocardium [76].

In an attempt to mimic adult native myocardium more accurately, more complex bioreactors are being developed to stimulate the tissue. A combination bioreactor designed to stimulate electrically and provide biomimetic perfusion rates was developed by Vunjak-Novakovic and colleagues (Fig. 61.5C). Neonatal rat cardiomyocyte tissue constructs were subjected to a flow velocity of 0.1 mm/s and were stimulated with a 3-Hz monophasic square wave. The stimulated samples were the most abundant and were more elongated compared with unstimulated samples. A limitation of the study was the spread of neonatal cardiomyocytes. The group used PGS for the tissue scaffold, which does not readily support cell attachment. As a result, the cells appeared to cluster on the tissue. However, this study serves as an example of the advantages of mimicking environmental cues in cardiac tissue engineering [77].

Hence, the in vitro application of a single but important in vivo factor progressively enhanced the functional tissue assembly and improved the properties of engineered myocardium at the cellular, ultrastructural, and tissue levels.

TISSUE AND ORGAN FUNCTION

Successful implantation of engineered tissues requires both maintenance of the cellular phenotype and the functional integration of the construct within the host tissue. As progress is made from the state of the art described earlier to the final goal, it will be necessary to ensure that engineered cardiac cells and tissue contract in unison with the surrounding native myocardium to produce the desired force, but also that the graft is electrically integrated with the host to prevent arrhythmogenesis.

Underlying such integration and the implicit control of the construct phenotype is the creation of arborized networks (vessels, lymphatics, and nerves) needed to sustain large and complex tissue structures. Then there are issues associated with blood compatibility, tissue remodeling, and more generally immune and inflammatory responses to the new tissue or cells. Using autologous cells is an approach that is immunologically preferable, but it likely precludes the "off-the-shelf" concept behind much of the attraction of tissue engineering.

Mechanical Elasticity and Strength Development

A critical feature of a heart is its mechanical characteristics. Simply speaking, the heart must pump blood at a mean pressure of roughly 100 mmHg. Hence, heart muscle must stretch in response to capillary filling pressure and eject a volume of blood that varies with demand. The latter requires a uniform and well-coordinated contraction that generates the required power. The mechanical fatigue limitations of a heart that must beat 3×10^8 times over 10 years must be compared with the flexural fatigue life of synthetic elastomeric materials that are typically much lower.

It will be a significant challenge to replicate the complex architecture of the myocardium and its nonlinear viscoelastic properties in both resting and activated states [78]. Although some constructs exhibit a significant burst strength and some groups are advanced in the use of the tools of biomechanics to advance vascular graft [79] or heart valve development, this area has received less attention than it deserves [80].

Tissue Architecture and Electrical Conduction

The complexity of the electrical conduction pathways in the heart is just starting to gain attention in tissue engineering literature. The cells need to form the appropriate intercellular connections and matrix arrangements to enable the directed beating of contracting cells to generate the forces required to pump blood [81]. The proper formation of the intercalated disks between myocytes is also critical in enabling electrical pulses to be transmitted in the correct direction at normal speeds and in allowing suitable force transmission. The heart also contains specialized cells that participate in the electrical conduction routes found throughout the heart. These specialized cells are crucial to coordinating the heart's contractile effort; including them in the proper places in a regenerated substitute may be critical. There are clear differences between the rhythmic twitching of cultured cardiac cells en mass and the

organized, efficient, regulated beating of the heart; only the latter will generate the force required to pump blood at systolic pressure levels. It is not difficult to envision the problems yet to be faced. Given the variety of electrical conduction–related diseases in a normal myocardium, there is good reason to suspect that simple mimicry of heart muscle may fall short of the goal. The protocol for directed differentiation of human pluripotent stem cells, specifically hESCs and iPSCs, has sufficiently advanced to enable differentiation of preferentially ventricular cells [82] as well as more specialized cells of the conduction system, e.g., sinoatrial nodal cardiomyocytes [83]. These advances are paving the way to engineering cardiac tissues with specialized cardiomyocyte subtypes to reproduce the complexity of the native tissue composition.

Thrombogenicity and Endothelialization

The need for blood compatibility is another crucial characteristic of cardiovascular constructs. All biomaterials lack the desired nonthrombogenicity and most ECMs initiate thrombosis; hence, endothelialization of the construct is another critical issue. ECs have a reversible plasticity [84–86] and can become activated (proliferative or adhesive to leukocytes) upon exposure to inflammatory cytokines (e.g., interleukin-1 [IL-1], tumor necrosis factor [TNF]) or to growth factors such as vascular endothelial growth factor (VEGF). Flow and the associated shear stress, normally in the range of 5–20 dyn/cm^2, elongate and align cells in the direction of flow [87,88] and modify gene expression [89] as well as many other functions including markers of antithrombogenicity.

ECs provide a hemocompatible surface by producing molecules that modulate platelet aggregation (e.g., prostacyclin), coagulation (thrombomodulin [90,91]), and fibrinolysis [92] (e.g., tissue plasminogen activator). They can be transformed into a prothrombotic surface: for example, by the action of thrombin or through exposure to some biomaterials [93–96]. Blood compatibility has been an important issue in the development of vascular grafts. Clinical success [97] has renewed enthusiasm for seeding grafts with ECs. In some protocols, many of the preseeded cells are lost upon implantation owing to insufficient adhesion [98], and thus protection from thrombosis provided by the cells is limited because of incomplete cell coverage. The potential to exploit the presence of circulating EC progenitors has only begun to be explored [99].

It is also worth noting the effects of the endothelium on the neighboring tissue and the corresponding effects on EC phenotype. With vascular smooth muscle cells (VSMCs), this bidirectional cross-talk is thought to be a critical regulator of vascular homeostasis [100]: Secretion and expression of molecules such as nitric oxide [101], prostacyclin [102], and endothelin [103] act on VSMCs to regulate vessel tone. Meanwhile, VSMCs inhibit EC endothelin 1 production to increase EC nitric oxide and endothelial nitric oxide synthase expression [104]. Many other relevant systems (e.g., matrix metalloproteinase [MMP] secretion and matrix remodeling) are also affected by the interactions between EC and other cell types. Moreover, VEGF inhibits pericyte coverage under conditions of PDGF-mediated angiogenesis [105], complicating vascularization strategies built around VEGF delivery (see subsequent discussion).

Vascularization

The intrinsic nature of large cell-based constructs and the corresponding difficulty of supplying cells deep within the construct with nutrients are yet other problems. Diffusion is fine for 100 μm or so and low cell densities can extend this limit, but at the cost of making constructs too large to be useful. Thin or essentially 2D constructs (e.g., a tube) are feasible without an internal blood or nutrient supply. However, it is hard to combine cells at tissue densities ($>10^8$ cells/cm^3) into large tissues without some sort of prevascularization or its alternative. Thus, a capillary network (and a lymphatic network) needs to be "engineered" as part of the creation of a larger structure.

In a cell-free approach, vascularization and improvement of left ventricular (LV) function after MI were achieved by the sustained release of basic fibroblast growth factor (bFGF) incorporated into gelatin microspheres [106], acidic fibroblast growth factor (FGF) from ethylene vinyl acetate copolymer [107], and bFGF from heparin-alginate beads [108]. Mooney and colleagues incorporated an endothelial cell mitogen (VEGF) into 3D porous poly(lactide-*co*-glycolide) scaffolds during fabrication [109] to promote scaffold vascularization. Sustained delivery of bioactive VEGF translated into a significant increase in blood vessel ingrowth in mice and the vessels appeared to integrate with the host vasculature. We use microencapsulated $VEGF_{165}$-secreting cells (prepared

by transfection of L929 cells) as a means of exploring this strategy, at least for microcapsules [110]. Of course, VEGF is but one angiogenic factor [111] and issues associated with the functional maturity of the vessels and the need for multiple factors may limit this strategy. In a third approach, Vacanti et al. micromachined a hierarchical branched network mimicking the vascular system in 2D. Silicon and Pyrex surfaces were etched with branching channels ranging from 500 to 10 μm in diameter [112] that were then seeded with rat hepatocytes and microvascular ECs.

We covalently immobilized VEGF165 and angiopoietin-1 to porous collagen scaffolds to enhance scaffold vascularization in vitro and in vivo [113]. Such covalent immobilization offers the advantages of prolonged signaling and lowers the total amount of growth factors required; it also offers the possibility of generating capillary-like structures in the tissue engineered scaffolds in vitro.

A prevascularized skeletal muscle was created [114] by coculturing skeletal muscle cells with ESC-derived EC and FBs. It appeared that up to 40% of the engineered blood vessels "connected" to the host vasculature upon implantation in this small-animal model. Finally, we adapted endothelial seeding in a modular approach to create scalable and vascularized tissue constructs. ECs were seeded onto submillimeter-sized collagen gel cylindrical modules that contained a second cell (e.g., hepatoma G2, smooth muscle cells, or [most relevant here], cardiomyocytes) [115]. With a view to creating uniform, scalable, and vascularized constructs, these modules were packed into a larger tube, formed into a sheet, or implanted directly with interconnected channels lined with ECs resulting from the random assembly of the modules. These channels connected with the host vasculature in vivo [116], creating a perfusable chimeric vasculature containing both host and donor cells and with host smooth muscle cell involvement. Embedded cardiomyocytes formed "contractile" structures near the periphery of modules, although the density of such structures was relatively low [115]. Remodeling occurred in vivo (after periinfarct injection or use as a patch), resulting in a well-distributed microvasculature (after 2 or 3 weeks in syngeneic animals), but the distribution of cardiac structures was relatively low.

Tissue vascularization is an enduring challenge in the field of tissue engineering and numerous approaches have been devised to tackle it. Advances in microfabrication techniques provided us with increasing control over the spatial arrangement of cells when creating a 3D functional tissue. Building on this progress, we developed a 3D stamping technique based on conventional soft-lithography, which allowed us to pattern thin sheets of synthetic biodegradable polymers and stack them to form a scaffold with a built-in intricate microchannel network mimicking the native blood vessels. The scaffold (referred to as AngioChip) was subsequently populated with ECs within the microchannels and parenchymal cells in the surrounding matrix (Fig. 61.6A) [117]. The stable synthetic scaffold structure supports extensive tissue remodeling, resulting in a free-contracting cardiac muscle and a metabolically functional liver embedded with an internal perfusable vascular network (Fig. 61.6B). The built-in blood vessels were shown to be mechanically stable and permeable, and even allowed vascular sprouting under the guidance of angiogenic growth factors. Furthermore, we surgically connected the built-in vessel network within the engineered tissue to the host circulation system, establishing blood perfusion immediately upon implantation (Fig. 61.6C). This demonstration shows the feasibility of our bottom-up approach to overcome the lack of tissue survival after implantation caused by the absence of vascular perfusion.

Host Response and Biocompatibility

Questions related to the immune and inflammatory response to tissue constructs are starting to draw attention. The host response to a tissue engineered construct is manifested by the innate and adaptive immune systems, involving both plasma (e.g., complement) and cellular components (e.g., macrophages, T cells, etc.), that are directed against engineered cells and grafts or the materials used in tissue constructs. This potent immune response is most often mediated by major histocompatibility complex mismatches between donor and host tissue in allogeneic transplantations. This response can also be manifested in situations in which autologous cells or tissues are engineered to express therapeutic but foreign factors, or if these autologous cells are placed in tissue constructs that themselves negatively affect immune consequences [118].

Immunosuppressants have enabled the successful transplantation of kidneys, hearts, and other organs. With the advent of tissue engineering, new configurations of tissues and organs (often with an added biomaterial component) are being developed and our understanding of the immune and inflammatory response to these new therapies is being shown to be inadequate. Some xenogeneic cell transplants (mice to rat) survive in situations of cardiac repair despite the species differences [119], although this may be specific to the animal model or to cardiac repair. The longevity of a transplant also depends on the ability of somatic cells to withstand and respond to the stresses of

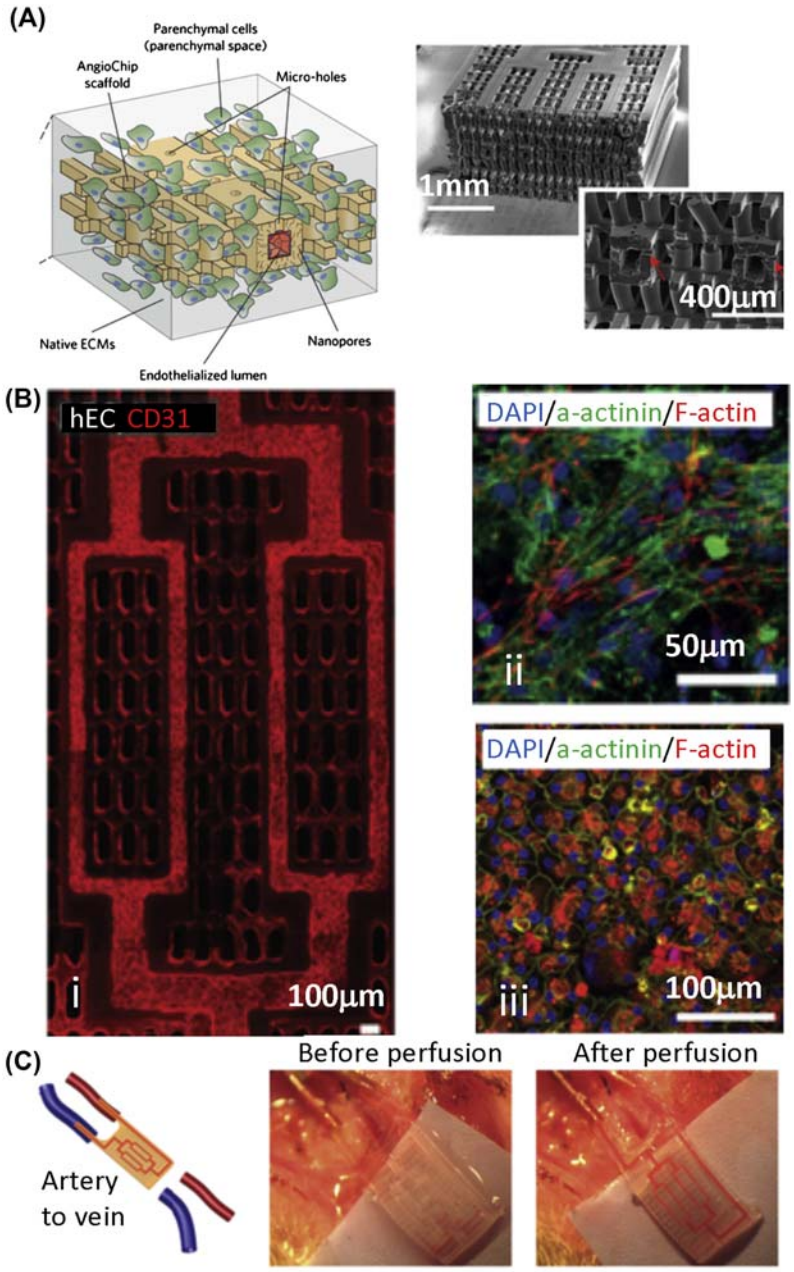

FIGURE 61.6 **Microfabrication of vasculature [117].** (A) Schematic of the AngioChip scaffold illustrating the endothelialized lumen in the parenchymal space (left). implantation, rejection, and other injuries [120]. The classic "foreign body reaction" to biomaterials is well-known, but the details of the molecular signals (complement regulatory proteins and MMPs) that accompany this phenomenon (in the context of biomaterials) are only beginning to be defined.

A variety of approaches have been undertaken or are under development to generate or improve upon graft acceptance [121]. These approaches include methods to block the innate immune response such as by using drugs or transferring genes to block nuclear factor-κB signaling pathways, for example. Other methods to block the innate response include the use of antibodies to IL-1 or TNF or the use of antiadhesion and antielastase antibodies. We must

understand the mechanism of the host response itself better so that we can design better biomaterials, select or engineer more suitable cells, or devise better strategies to control both innate and adaptive immune responses and enable a functional integration of the new tissue with the host.

IN VIVO STUDIES

In Situ Cardiac Tissue Engineering via Injection of Cells in Hydrogels

Hydrogels have gained much attention as vehicles for the delivery of reparative cells into the myocardium owing to their injectability and ability to control cross-linking chemistry. For a hydrogel for use in myocardial regeneration, it needs to be: (1) biocompatible; (2) biodegradable; (3) injectable, so that it can be applied with a syringe in a minimally invasive manner; and (4) mechanically stable enough to withstand the beating environment of the heart. In addition, a biomaterial that can promote the attachment and survival of cells and localize them at the infarction site would address these limitations of poor cell retention and survival.

Early studies relied on cell injection using natural hydrogels such as Matrigel [122,123] or fibrin [124–126] and reported structural stabilization, reduced infarct size, and improved vascularization upon injection of undifferentiated ESCs [122,123] or bone marrow cells [124–126]. Alginate alone was demonstrated to reduce pathological remodeling and improve function [127]. A synthetic, self-assembling peptide hydrogel (AcN-RARADADARARADADA-CNH) was also used, forming a nanofibrous structure upon injection into the myocardium that promoted recruitment of endogenous ECs and supported survival of injected cardiomyocyte (CM) [128]. Insulin-like growth factor-1 bound to the self-assembling peptide was demonstrated to improve grafting and survival of CM injected into MI [129]. Laflamme and Murry demonstrated that targeting of multiple pathways, which was related to cell survival by encapsulating a number of biomolecules in Matrigel, significantly increased the survival and grafting of the hESC-derived CM injected into infarcted rat hearts [130]. They carried on studies using the same hydrogel to deliver hESC-derived cardiomyocytes in guinea pig [131] and nonhuman primates [132], demonstrating that the cells delivered with the hydrogel could indeed integrate, upon a remodeling phase that included the presence of significant ventricular arrhythmias.

Zhang et al. studied the effect of injecting CM in a mixture of collagen type I and Matrigel [133], the material used by Zimmerman et al. to create engineered heart tissue [134], in MI-induced rats. An additional problem with using ECM proteins in this setting may be the immune response exhibited by rats to mouse proteins (i.e., Matrigel is a basement membrane derived from mouse sarcoma). Positive connexin-43 staining was found in cells in the biomaterial, and the biomaterial was also seen to improve the thickness and function of the heart. The main drawback is that the material takes 1 h to gel, which could allow for significant cell loss, although no cell retention studies were conducted in these experiments.

We modified chitosan with the peptide QHREDGS derived from angiopoietin-1, the peptide sequence implicated in the survival response of muscle cells cultivated in the presence of this growth factor [135]. The chitosan was rendered photocross-linkable by modification with azidiobenzoic acid (Az-chitosan) [136]. Neonatal rat heart cells cultivated on cross-linked films of Az-chitosan–QHREDGS attached, elongated, and remained viable whereas they exhibited lower attachment levels and decreased in viability when cultivated on the chitosan substrates modified with the scrambled peptide sequence [137]. Interestingly, cells on Az-chitosan–QHREDGS were capable of resisting Taxol-induced apoptosis, whereas those on Az-chitosan–Arg-Gly-Asp-Ser were not [137]. We also demonstrated that QHREDGS peptide was able to attenuate pathological remodeling and improve cardiac function upon MI in a rat model, acting largely by promoting the survival of spared cardiomyocytes [138].

Other studies collectively indicated that an injection of hydrogel alone, without the reparative cells, may attenuate pathological remodeling upon MI [127,139–141]. For example, injection of alginate or collagen alone improved LV function and reduced cardiac remodeling after infarction [127,142]. Two alginate biopolymers were modified to assess therapeutic potential in rat MI models. Alginate modified with 0.025% v/v polypyrrole, a conductive polymer, injected into the infarct zone showed improved arteriogenesis at 5 weeks posttreatment and significantly enhanced infiltration of myofibroblasts into the infarct area compared with saline and alginate-only controls [143]. Also, Arg-Gly-Asp–conjugated alginate and alginate alone injected into the infarct zone showed improved LV function and increased arteriole density 5 weeks after injection compared with bovine serum albumin in phosphate-buffered saline control [144]. Results from both studies again show the potential for non–cell based therapies to treat chronic heart failure.

An interesting example is the injection of a hydrogel based on decellularized porcine ventricular myocardium, which resulted in improvements in local and global cardiac function [145,146] and thus the initiation of Phase I clinical trials with this hydrogel.

It is suspected that by changing the ventricular geometry and mechanics, hydrogels reduce the elevated local wall stresses that have been implicated in pathological remodeling [147]. Finite element modeling of wall stresses indicated that upon injection of the material of elastic modulus 10−20 kPa in the infarct, the relationship between ejection fraction and the stroke volume/end-diastolic volume was improved. In addition, injections of the material in the border zone decreased end-systolic fiber stress proportionally to the volume and the stiffness of the injected material.

We believe that properly tuning the mechanical properties of a hydrogel and providing bioactive molecules may offer new cell-free treatment options for MI. The death of CM by necrosis and apoptosis peaks at 6 h upon acute MI [148]. However, the persistent and progressive loss of CM in neighboring areas of the infarct continues up to 60 days after the onset of MI. During this process, up to 35% of cells at the borders of subacute and old infarcts may become apoptotic [149], compared with only 1% in the remote regions of myocardium [150]. Studies in rats and dogs demonstrated that CM loss by apoptosis persists for 1−4 months upon MI, which correlates with the progressive worsening of the pump function. Thus, developing hydrogels that specifically prevent apoptosis of the heart cells (e.g., QHREDGS peptide-modified chitosan) may result in new treatment options in the future, in which hydrogel injected alone in the border zone, without reparative cells, would act to mechanically stabilize the ventricle and prevent further apoptosis of cardiomyocytes.

For example, it was shown that EC-induced cardiomyocyte protection after infarction occurs through PDGF-BB signaling. Thus, binding PDGF-BB to the self-assembling nanofibers of RAD16-II (a peptide consisting of alternating RAD domains, AcN-RARADADARARADADA-CNH_2) hydrogel was evaluated as a potential therapeutic option. Sustained, targeted release of this signaling molecule to host myocardium was observed up to 14 days after injection. Injection of nanofibers with PDGF-BB at the site of infarct in rats decreased CM death and preserved systolic function after MI and showed (separately) a decrease in infarct size after ischemia−reperfusion [151].

The relative contribution of cells versus the injected biomaterial to the attenuation of pathological remodeling also needs to be assessed and the mechanism by which various cells induce functional improvements needs to be elucidated. Although with the injection of contractile cardiomyocytes the expectation is that cells will functionally couple to the host myocardium and contribute to contractile function, the same is not possible for noncardiomyocytes. The exact mechanism by which nonmyocytes impart improvement in function and attenuation of pathological remodeling is still under debate, but some researchers suggest that the transplantation of healthy cells results in the release of growth factors and other molecular signals, i.e., the paracrine effect. These help with angiogenesis, cell survival, and recruitment of progenitors. A possible drawback of using the biomaterial is that the scaffold or hydrogel may also take up space that would prevent a high tissue density until the material degrades.

Implantation of Cardiac Patches

Significant progress has been made in constructing in vitro cultivation systems and biomaterial scaffolds, but fewer studies have focused on implanting cell-based cardiac patches onto viable or injured myocardium. In a pioneering study, Li and colleagues [18] implanted a construct based on neonatal rat cardiomyocytes and collagen sponges onto the surface of the cryoinjured myocardium of Lewis rats. The grafts were implanted 3 weeks after infarction. After 5 weeks in vivo, cells survived supported by blood vessel ingrowth and integrated with the surrounding tissue. However, the graft did not improve LV function.

Attenuation of pathological remodeling (i.e., prevention of ventricle dilatation and maintenance of contractile function) was observed in a study by Leor et al. [20], in which cardiac constructs based on neonatal rat cardiomyocytes and porous alginate scaffolds were implanted onto myocardium of Sprague−Dawley rats that underwent permanent main coronary artery occlusion. The grafts were implanted 7 days after MI. After 9 weeks of implantation, the grafts demonstrated integration with host myocardium at the anchorage sites as well as inflammatory infiltrates and the presence of fibrous collagen.

Zimmerman et al. [15] placed cardiac tissue rings cultivated in the presence of mechanical stimulation onto uninjured hearts of Fisher 344 rats for 14 days. They noticed that although both cells and collagen were isolated from Fisher rats, immunosuppression was required to maintain of heart tissue upon implantation. In the absence of immunosuppression, even in the syngeneic approach, cardiac constructs completely degraded after only 2 weeks in vivo. It is unknown what caused the response; it is possible that it was the remainder of serum or chick extract.

Regardless, the finding has significant implications in the potential implantation of cardiac patches in clinical settings.

To decrease the potential immunogenicity of their engineered tissue, Zimmerman and colleagues discarded all xenogenic components from their culture [152]. This included cultivating the engineered heart tissues in serum-free and Matrigel-free conditions. Mixed heart cell populations rather than cardiomyocyte-rich populations were used and the culture medium was supplemented with triiodothyronine and insulin [152]. Other studies also established the need for nonimmunogenic media. Schwarzkopf et al. used autospecies sera, in this case rat, to culture rat cardiomyocytes [153]. The metabolic activity of cells was significantly higher than for the cells cultivated in conventional culture medium with fetal bovine serum.

Zimmermann et al. demonstrated integration and electrical coupling of a complex multiloop graft to native myocardium in rats with left anterior descending coronary artery ligation (Fig. 61.7A and B). Functional improvement was demonstrated not to be merely the result of scar stabilization or paracrine effects [134]. Functional integration of cardiac cell sheets to the heat-injured myocardium was also demonstrated [154].

In a study performed by Weinberger et al., human engineered heart tissue strips composed of fibrinogen and Matrigel with suspended human iPSC-derived cardiomyocytes were created [155]. The engineered strips, which were intended to limit the number of cells that were washed out after a cell injection, were sutured onto the hearts of cryoinjured guinea pigs. Hearts of the guinea pigs treated with the engineered strips had an improved LV function compared with animals that received a cell free patch, and the graft was found to be electrically coupled to the host myocardium. However, 28 days after implantation, cells were found in the spleen and lungs of some of the guinea pigs.

Although cardiac patches still require further development and regulatory approval, there are numerous in vivo studies improving their cell retention and proving their effectiveness. A cardiac patch developed by Zhang and colleagues was transplanted onto an MI porcine model to test whether including multiple cell types and growth factors would aid in cell retention [156]. The patch was composed of fibrin loaded with insulin growth factor and was encapsulated with a combination of human iPSC-derived cardiomyocytes, ECs, and smooth muscle cells. After transplantation, the group saw that the cell-laden patch increased ejection fraction and the ventricular wall thickness while it decreased the infarct size, which suggested that incorporating a growth factor into the cardiac patch and multiple cell types may be required for the success of such a therapeutic approach (Fig. 61.7C and D).

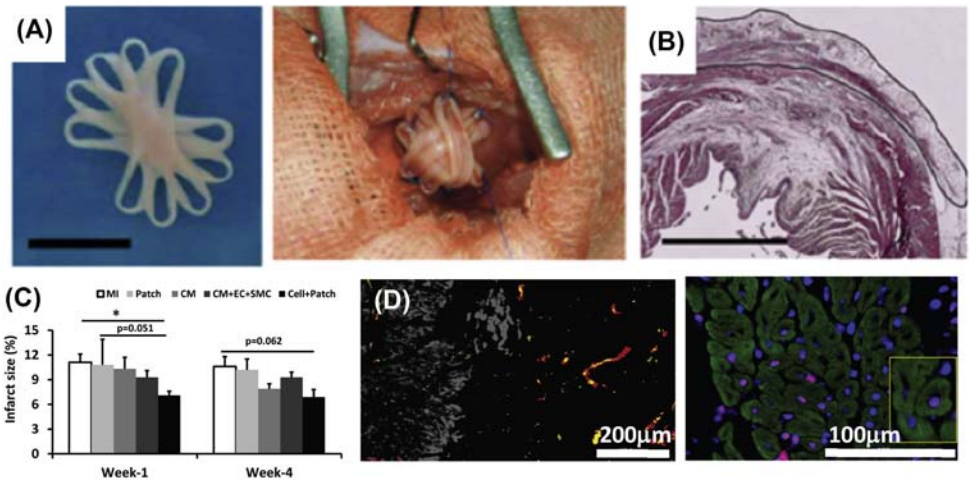

FIGURE 61.7 **In vivo integration of engineered cardiac patches.** (A) A multilooped, mechanically stimulated cardiac construct based on neonatal rat cardiomyocytes and collagen hydrogel was used to repair myocardial infarction (MI) in the rat heart [134]. (B) Histology of the multilooped patch showing integration with the surrounding myocardium [134]. (C) A cardiac patch implanted on an MI porcine model was shown to decrease the infarct size compared with animals not treated with a patch [156]. (D) Immunostaining of the implanted patch shows increased vascular density at the border zone. Image on the left is stained for CD31 (*green*), smooth muscle actin (SMA) (*red*), and cardiac troponin T (cTnT) (*white*). In addition, less apoptotic cells were found at the border zone. Image on the right is stained for apoptotic cells (terminal deoxynucleotidyl transferase dUTP nick end labeling assay) (*red*), cardiac troponin I (*green*), and 4′,6-diamidine-2′-phenylindole dihydrochloride (DAPI) (*blue*) [156].

The first human clinical trial using a patch-based therapeutic was performed by Larghero and colleagues. In this case report, hESC-derived cardiac progenitors were embedded in a fibrin glue scaffold [157]. The pericardium over the infarcted area was retracted, creating a pocket with which the patch was placed. At 3 months after surgery, the patient's ejection fraction had improved from 26% to 36% and a reduction in end-diastolic and systolic volumes was noted. Despite the increase in symptomatic performance, this trial was conducted only on a single patient; therefore, it is difficult to draw conclusions. However, this trial shows the potential for such a treatment and future clinical trials.

In addition to engineering the patches of myocardium, Zimmermann and colleagues designed the first biological assist device [158]. The authors mechanically stimulated a hollow-spherical construct consisting of collagen I and neonatal rat cardiomyocytes until a beating pouch-like structure was created. The pouch was then placed over uninjured rat hearts in such a manner that the right and left ventricles were covered. Fourteen days after implantation, the pouch covered the epicardial surface of the heart and exhibited blood vessel ingrowth.

Roche et al. created an alternative ventricular assist device that uses soft robotics to pump the heart manually. The sleeve consists of actuators aligned helically to mimic the twisting motion of the beating heart. It was tested in vivo on a pig model with acute heart failure and the researchers observed the reestablishment of cardiac output. The group hopes to see the technology used in the clinic as a device to extend the life of a patient waiting for transplant [159].

Badylak et al. implanted ECM derived from porcine urinary bladder into a surgically created 2-cm [2] defect in the LV free wall of dogs. Eight weeks after implantation, the ECM patches showed higher regional systolic contraction compared with the control group in which a material (Dacron) used for myocardial defects was employed. Histological analysis suggested that cardiomyocytes accounted for about 30% of the remodeled tissue in the ECM scaffolds [160]. In another study, this improvement in the heart function was attributed to an increase in the myocyte content in the ECM patches between weeks 2 and 8. The relationship between the myocyte content and the extent of mechanical function was observed to be linear. There was also some evidence (a decrease in cardiomyocyte diameter and an increase in the overall area occupied by cardiomyocytes over time) suggesting the possibility of cardiomyocyte proliferation in the patches [161].

Limitations related to the source of autologous cardiomyocytes motivated studies that used nonmyocyte-based patches for MI repair. Smooth muscle cells seeded with poly (ε-caprolactone-*co*-L-lactide) sponge reinforced with poly-L-lactide fabric were used in a modified endoventricular circular patch plasty procedure (Dor procedure). Cell-seeded grafts resulted in improved LV function (as assessed by echocardiography) compared with cell-free controls [162]. A patch made of dermal FBs seeded onto knitted Vicryl mesh (Dermagraft) was used in an attempt to increase angiogenesis upon MI. When placed over the infarcted regions on the hearts of SCID mice, the grafts improved microvessel density within the damaged myocardium [163].

There appears to be a consensus regarding the requirement for multiple cell types, specifically FBs and ECs, in addition to cardiomyocytes for successful cardiac tissue graft survival and vascularization in vivo. In one approach, omentum was used to prevascularize cardiac patches based on neonatal rat cardiomyocytes and alginate scaffolds modified with angiogenic factors. After excision and implantation into the infarcted rat myocardium, the vascularized cardiac patch showed structural and electrical integration into host myocardium and attenuated pathological remodeling of the ventricle significantly better than did the in vitro cultivated patch alone [164].

In another strategy, a simultaneous triculture scaffold-free approach was used to generate beating cardiac patches based on hESC. Upon implantation into the hind-limb muscle of nude rats, these patches, which were composed only of enriched cardiomyocytes, did not survive to form significant grafts. However, patches containing ECs (either HUVECs or hESC-derived ECs) and FBs in addition to cardiomyocytes persisted in the (noninfarcted) rat heart and resulted in 10-fold larger cell grafts compared with cardiomyocyte-only patches. The preformed human microvessels also anastomosed with the rat host coronary circulation and delivered blood to the grafts [165].

These studies demonstrated the feasibility of cardiac patch implantation, but further studies are necessary to estimate the effect of culture conditions and scaffold type on the in vivo outcome. Although significant progress has been made in the area of biomaterials and bioreactors, it is unknown which cultivation conditions and what biomaterial will best preserve contractile function and prevent pathological remodeling upon implantation. Thus, studies that investigate this systematically and correlate in vitro parameters (e.g., force of contraction) to in vivo outcomes (e.g., fractional shortening) are required. The host response to the patch and the nature of the immunologic situation further complicate these studies.

Delivery Route for Cells and Patches

It remains to be determined how and where in the heart the cells and patches should be applied for optimal therapeutic benefit. The ventricular wall is composed of the *epicardium*, the outer epithelial lining of the muscle; the *myocardium*, composed of working CMs and support cells such as **FBs**; and the *endocardium*, consisting of a specialized endothelial lining that is in contact with blood filling the ventricle. Most cell therapy approaches focus on the direct injection of a cell suspension into the myocardium using either catheters or open chest surgery [166–168]. These approaches are inherently limited by the small volume of free space available for cell engraftment. The cell density in the myocardium is extremely high (10^8 cells/cm^3 [169]); upon injury such as MI the dead cells are replaced by a dense collagenous scar, leaving no space for injected cells to engraft. The injected cells are rapidly washed out or ejected, resulting in a maximal engraftment efficiency of 10% [20,130,170,171], which necessitates the injection of as many as 1 billion CMs for sizable grafts in monkeys [132].

The injection of isolated cells also offers little opportunity to mature or modify the electrophysiological properties of the graft. The immaturity of the injected cells was postulated to have caused malignant arrhythmias in monkeys that received hESC-derived CMs [132]. Thus, cardiac patches may offer a unique solution to the challenges of cell delivery, engraftment, and graft function. The size, shape, and functional properties of cardiac patches can be tailored through in vitro cultivation with electrical field stimulation [54,73] or mechanical stimulation, whereas their application on the ventricular surface could provide sufficient space for implant engraftment to a clinically relevant size. In fact, in a clinical trial, hESC-derived cardiac progenitors were applied during open heart surgery onto the *epicardial surface* of the heart using a fibrin hydrogel and a pericardial patch over the hydrogel [157]. The epicardium is generally considered a safe location for patch deployment, owing to the high risk for embolization and thrombosis associated with patch application inside the ventricle on the endocardial surface of the ventricular wall.

SUMMARY

Functional viable cardiac patches have been engineered based on neonatal rat cardiomyocytes and hESC- and iPSC-derived cardiomyocytes. Various biomaterials have been tested for this purpose and in vitro culture systems have been developed that enhance cardiac construct differentiation (mechanical and electrical stimulation), improve cardiomyocyte survival at high density (medium perfusion), and enhance maturation of cardiomyocytes derived from human pluripotent stem cells, paving the way to engineering autologous cardiac patches of clinically relevant size.

The field of microphysiological organ systems and organ-on-a-chip engineering has emerged and matured to the level required to use these miniaturized 3D cardiac tissues in drug discovery, safety testing, and disease modeling, relying on human cardiomyocytes derived from iPSCs.

Because the in vivo studies conducted thus far used different cell sources, biomaterials, animal models, delivery times after infarction, and experimental time frames, direct comparison cannot be made between methods. Although all reported studies have shown some form of improvement, complete myocardial regeneration has not been achieved. Perhaps a valid question to be answered in the future is: What is the required level of myocardial regeneration in terms of survival and attenuation of symptoms? Complete regeneration is an ambitious goal that may not be required. Future studies must also increase their time frames to assess the long-term effects of these treatments better.

Although the completely artificial heart will remain a dream, the near future may bring a clinically relevant autologous cardiac patch as evidenced by rapid progress in engineering cardiac patches based on stem cell–derived cardiomyocytes. Work on recellularizing decellularized hearts may represent the first step toward "the heart in a box" envisioned several decades ago.

INTRODUCTION

The liver is the largest internal gland in the body and one of the most critical organs in metabolic homeostasis because it is responsible for many essential metabolic exocrine and endocrine functions. Among them, it is responsible for the detoxification and elimination of a variety of substances, regulation of glucose levels, maintenance of blood homeostasis, and production of many products including lipids, proteins, vitamins, and carbohydrates. In addition to this, the liver possesses a unique regenerative capacity; it is able to regenerate most of its function after losing up to three-quarters of its mass as a result of partial hepatectomy or toxic injury. However, in severely ill patients with an end-stage liver disease, this regeneration capacity is severely limited and liver transplantation (LT) becomes the only lifesaving intervention. This also applies to patients with decompensated cirrhosis, hepatocellular carcinoma (HCC), inborn errors of metabolism, and fulminant hepatic failure. Moreover, LT remains the only available cure for a wide range of liver diseases.

Nearly a half century has passed since Dr. Starzl [1] performed the first liver transplant. However, it was not until 1967 when short-term success was achieved with 1-year survival after transplantation [2]. Since then, the success and the survival rates of LT have increased owing to improved immunosuppressive regimens, surgical techniques, and donor–recipient pairing [3]. However, today, the number of patients waiting for a liver transplant far exceeds the number of transplants performed. Although this gap was reduced with the increased use of marginal organs such as steatotic livers, employment of hepatitis C virus (HCV)-positive donor organs for HCV-positive recipients, and donation after cardiac death, the number of patients waiting for a liver transplant continues to exceed the number of available livers.

According to reported by the Organ Procurement and Transplantation Network in 2014, 6729 liver transplants were performed in adults whereas around 14,600 people were on the waiting list to receive a donor's liver. Although 6729 transplants were performed, 1821 patients died while waiting for a donor and 1290 patients were removed from the list because they were too sick for transplantation during that year [4]. Despite attempts to reduce the waiting time, two-thirds of all patients will never receive one.

Liver cell transplantation has also been considered a possible treatment for patients with life-threatening liver diseases. In this case, a preparation of isolated cells is injected directly into the liver via a portal vein or into the spleen. Engraftment of these cells and their therapeutic potential to correct many metabolic deficiencies has also been demonstrated by several studies [5]. In 1992, a group of scientists from Michigan University performed the first successful hepatocyte transplantation into a French-Canadian woman with familial hypercholesterolemia [6]. Afterward, other successful cases followed, but not all patients had noticeable progress [7], which was also observed with other diseases [8,9]. Although the long-term safety of this technique has been confirmed [10,11], the success

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00062-X

of this procedure has not yet been enough to evade the need for whole-organ transplantation. One possible explanation for these results could be the small number of hepatocytes that engraft in the recipient owing to the poor quality and quantity of the cells used [12]. Hence, it is accurate to say that as a result of hepatocytes, the shortage of human liver donors is the limiting factor in the development of this therapeutic approach. Other sources such as hematopoietic stem cells [13], bone marrow–derived mesenchymal stem cells [14,15], and fetal liver progenitors [16,17] have also been used (Fig. 62.1).

In addition to cellular therapies, other experimental approaches are in development with high therapeutic potential. These novel approaches aim to stimulate the diseased liver to regenerate itself or substitute it with a bioengineered liver capable of performing all native liver functions [18]. In this regard, and with the available technology, liver bioengineering comprises the creation and use of a supporting scaffold and large numbers of hepatic and vascular cells to generate functional tissue. Considerable effort has been made in trying to develop biomaterials capable of mimicking the liver extracellular matrix (ECM) to replicate the benefits offered by this structure regarding cell adhesion, growth and viability, and maintenance of the differentiation state and metabolic functions. Despite this, in the first studies performed with synthetic materials, the maintenance of the vascular network was not successfully achieved, resulting in low hepatocyte survival [19]. Some of these obstacles were solved by administering growth factors to promote angiogenesis and increase cell viability [20,21], but also by developing advanced bioreactors to improve hepatocyte seeding [22]. However, the absence of specific hepatic signals for cell growth and differentiation proved to be another critical limitation, probably owing to the lack of a real three-dimensional (3D) environment in which hepatocytes could find or create their native niche. Several research groups have addressed this issue by employing tissue decellularization to prepare bioscaffolds devoid of all cellular material from a harvested tissue or organ. In 2009, Baptista et al. successfully repopulated decellularized rat and ferret livers with

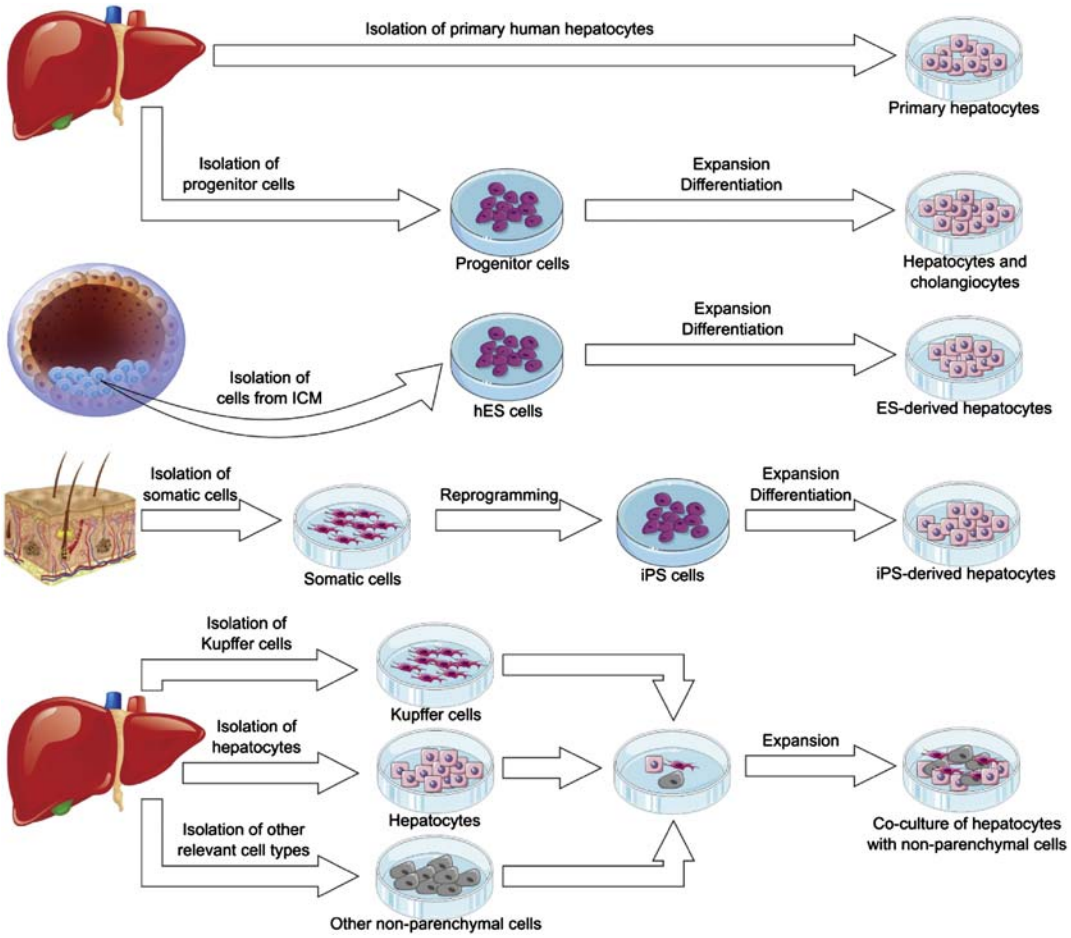

FIGURE 62.1 Available strategies for the isolation and generation of hepatic cells and tissues. *ES*, embryonic stem cells; *hES*, human embryonic stem cells; *ICM*, inner cell mass; *iPS*, induced pluripotent stem cells.

human fetal liver and endothelial cells [23,24]. Immediately afterward, Uygun's group achieved the decellularization of rat livers, which were then repopulated with rat primary hepatocytes and anastomosed ex vivo with a rat for up to 8 h [25]. It is still difficult to know the real value of this technology in clinical applications, but the potential to change transplantation medicine and patients' lives is evident.

Hence, in this chapter, we will describe some of these novel regenerative medicine approaches and the potential applications for these tissue-engineered liver constructs as biologic surrogates for a large variety of biomedical and pharmaceutical applications.

HEPATIC TISSUE ENGINEERING

It is widely accepted today that 3D cultures mimic in vivo natural conditions much better than do traditional 2D cultures, in which cells are grown on a flat surface in Petri dishes. The reason for this is that 3D cultures more closely reflect in vivo cell behavior, providing a physical and mechanical environment that promotes cell proliferation, differentiation, and expression of specific growth factors and other molecules. Hepatic tissue engineering has been able to create bioengineered grafts with the medical purpose of organ replacement, or restoration, which recreate physiological 3D microenvironments that more accurately mimic the in vivo environment. These promising techniques rely on the combination of different disciplines such as engineering, biomaterials, cells, and growth factors.

Starting with the biomaterials used, these can be made of either natural or artificial components capable of supporting 3D cellular growth. Some examples of their applications in tissue engineering are described subsequently.

Chitosan

Chitosan is a natural polysaccharide derived from chitin, a structural polymer of arthropod exoskeletons [26], which has been widely used in tissue engineering because of the structural similarity with glycosaminoglycans, another component of liver ECM [27,28]. Fan et al. [28] combined chitosan with galactosylated hyaluronic acid, making porous 3D sponges that induced hepatocyte aggregation that displayed liver-specific metabolic activities.

Gong et al. used chitosan−gelatin liver scaffolds with a hierarchical predesigned channel network inside, providing a porous structure. They compared this fabricated scaffold with conventional porous ones, obtaining higher proliferation rates (62%) of HepG2 [29]. Jiankang et al. [30] also designed a model of a porous scaffold made of chitosan and gelatin with internal structures such as portal vein, hepatic chambers, well-organized fluidic channels, and central vein, demonstrating improved hepatocyte aggregation and liver-specific functions. In another experiment, Zang et al. [31] determined that 1% of genipin cross-linked with chitosan−gelatin scaffolds present better results in HepG2 performance compared with glutaraldehyde, and r1-(3-dimethylaminopropyl) 23-ethyl-carbodiimide hydrochloride cross-linked scaffolds.

Galactosylated chitosan (GC) is also commonly used, combined with hyaluronic acid, an anionic glycosaminoglycan widely present in mammal ECM, to create porous sponges in which hepatocytes and endothelial cells were cultured [32]. This hybrid scaffold could represent a cell storage and delivery vehicle for a bioengineered liver tissue. Chung et al. [33] combined GC with alginate, creating a highly porous 3D sponge for hepatocyte anchorage. They demonstrated better spheroid formation and higher cell viability compared with scaffolds made only of alginate. Chitrangi et al. compared three different scaffold constructions for the differentiation of human umbilical cord-derived mesenchymal stem cells into hepatocyte-like cells: dextran−gelatin, chitosan−hyaluronic acid, and gelatin-vinyl acetate. They reported better results in hepatocyte differentiation when using those scaffolds made of gelatin, probably owing to its presence in natural ECM composition [34].

Collagens

Type I collagen, a crucial component of mammal ECM, is one of the most used materials in tissue engineering, especially for hepatocyte culture and primary hepatocyte transplantation [35]. Risbud et al. published several articles in which they compared the use of hydrogel scaffolds coated with collagen or with chitosan, demonstrating better human umbilical vein endothelial cell attachment and growth in the first ones. They also suggested that collagen hydrogel-coated textile scaffolds represented an excellent system in which hepatocytes and nonparenchymal cells could be cocultured in parallel [36,37].

Matrigel consists of a complex mixture of ECM proteins (collagen IV), proteoglycans (heparan sulfate), and growth factors (epidermal growth factor and transforming growth factor-β) secreted by Engelbrecht−Holm−Swarm mouse sarcoma cells that resemble the ECM of many tissues. Although the main inconvenience of Matrigel is that it is not a well-defined culture condition, many authors use this compound in vitro. For example, Fan et al. combined Matrigel with agarose to construct a hybrid hydrogel to obtain 3D constructs for tissue engineering [38]. Yarmush et al. also developed 2D culture systems that rely on using mixed collagen I and Matrigel sandwiches. These systems showed that primary hepatocyte function was maintained for several weeks without a noticeable loss of function [39].

Alginate

Alginate, a hydrophilic porous polysaccharide matrix that allows cell growth and differentiation, is also commonly used. Shteyer et al. [40] suggested that alginate scaffolds improve animal survival after an acute hepatic failure owing to an 87% partial hepatectomy in mice, achieving in vivo hepatocellular function of primary hepatocytes. They compared these results with collagen scaffolds and obtained inferior results. Lin et al. used alginate scaffolds for bone marrow−derived mesenchymal stem cell differentiation into hepatocyte-like cells [41]. Tai et al. [42] suggested in vitro differentiation of human mesenchymal stem cells into hepatocyte-like cells using an Arg−Gly−Asp−modified chitosan−alginate scaffold. This construct was implanted in rats with a 70% partial hepatectomy and used for the in vivo delivery of liver-like cells.

Many other related studies describe the power of alginate matrices as scaffolds in liver tissue engineering. They enhance hepatocyte viability, morphology, and function, maintaining hepatocellular performance [43]′ [44].

Polyglycolic Acid, Polylactic-*co*-glycolic Acid, and Polycaprolactone

Synthetic materials have also been used for this purpose, such as polylactic-*co*-glycolic acid (PLGA) or polyglycolic acid (PGA). Lees et al. [45] generated 3D scaffolds made of PLGA coated with laminin in which they seeded human embryonic stem cells. These scaffolds were then transplanted into the liver lobules of mice. The researchers observed the formation of teratomas that produced typical proteins of hepatic lineages and also from pancreatic and neuronal lineages. Furthermore, they found the assembly of an ECM rich in laminin, collagen IV, and collagen I, and positive CD34 endothelial progenitors, which represented vasculature formation.

Barralet et al. [46] developed a PGA fiber mesh scaffold stabilized with polycaprolactone to study the behavior of human biliary epithelial cells. They compared this technique with alternative models as collagen I sandwiches or Matrigel, showing spheroid aggregation, long-term proliferation (6 months), and phenotypic stability, which would represent a good strategy for bile duct tissue engineering. Other studies [22,47] achieved hepatic tissue generation with primary hepatocyte seeding in this PGA scaffolds, with the capacity of albumin and urea secretion.

Decellularized Extracellular Matrix

Decellularization techniques represent a popular technique for generating naturally derived scaffolds. In this process, whole organs are perfused with detergent solutions to remove the cellular contents, preserving an intact ECM and vascular tree. The main advantage of this technique is that there is no need to create an ECM in vitro because the ultrastructure and composition of the native ECM are preserved. In the same way, the vascular network and bile duct system are also well-preserved after liver decellularization [23,24,48].

These scaffolds are then recellularized with different cell types and numbers using different seeding conditions, with the objective of creating functional bioengineered organs able to be transplanted into recipient animals and, in the long-term, into patients with end-stage liver failure.

Human, pig, and rat livers are the scaffolds mainly used for liver tissue engineering, but there are several studies in which spleen was used (Fig. 62.2) [49].

Regarding the decellularization process, there are differences reported by several authors. The most commonly used reagents are sodium dodecyl sulfate [50] and Triton X-100 [23,51,52]. Some other examples are enzymes, proteases, ethylenediaminetetraacetic acid, or deoxycholic acid. There are also multiple concentrations and combinations of these reagents [53,54], several methods of detergent perfusion exist, as reported by several researchers. Some use the portal vein [50], others the portal vein and hepatic artery [23,51,55], and others the inferior vena cava [56]. Cell seeding methods are also variable [53,54]; the portal vein and hepatic vein are the most commonly used.

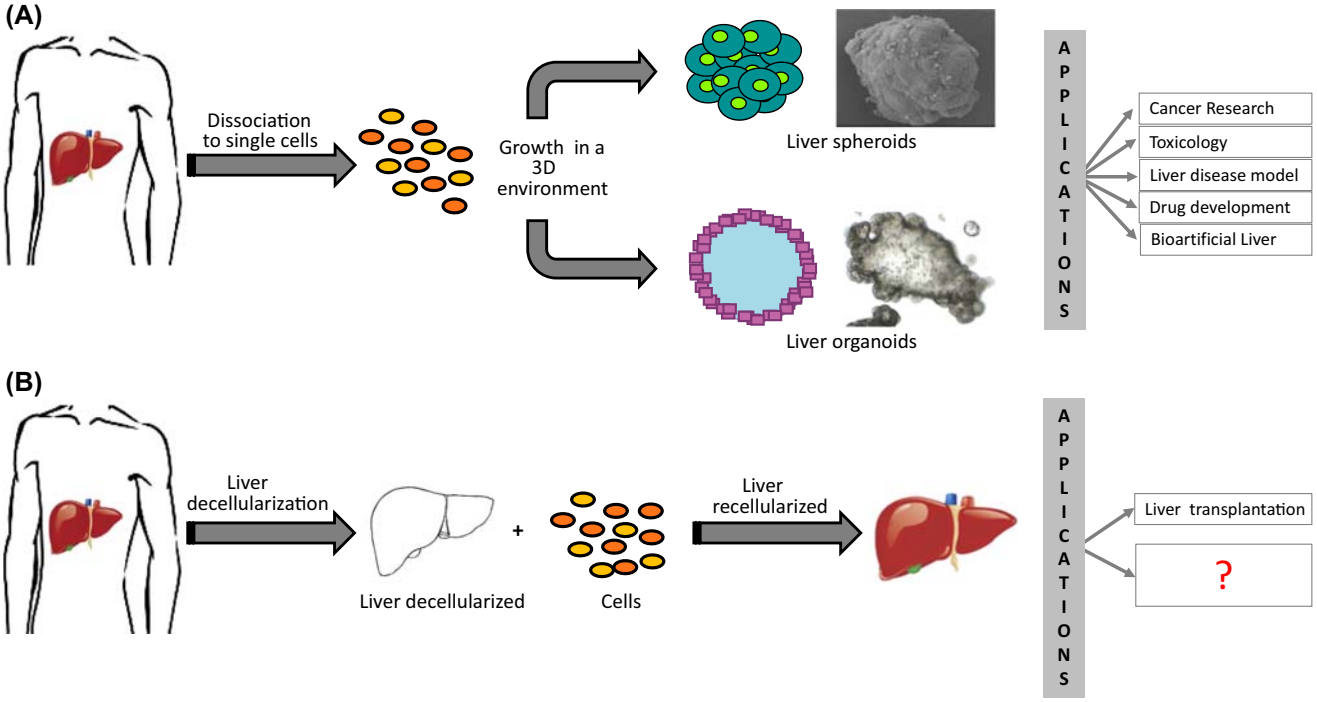

FIGURE 62.2 **Biomedical applications of liver bioengineered tissues**. (A) The resulting single cells isolated from the digestion of human hepatic tissue samples can be seeded in a three-dimensional (3D) environment, originating spheroids and organoids with multiple applications. (B) Cadaveric donor livers can be decellularized and afterward recellularized using the patient's own cells, with the ultimate goal of obtaining a functional liver for transplantation.

Regarding cell types, primary hepatic cells, both parenchymal (hepatocytes) and nonparenchymal cells (sinusoidal endothelial cells, stellate cells, and Kupffer cells), have been used for liver tissue engineering, as well as pluripotent stem cells, fetal progenitor cells, and immortalized cell lines.

Cell number is also a significant variable to take into account [48,57]. To mimic better what is observed in vivo, it is essential to recreate the hepatic spatial distribution (e.g., 80% of the liver parenchyma is composed of hepatocytes). However, there are issues regarding this: not all the cells that comprise the liver structure are easily isolated and maintained in vitro (e.g., hepatocytes do not efficiently expand in vitro, and liver sinusoidal endothelial cells are difficult to obtain) [57]. Furthermore, high cell seeding densities usually provoke cell aggregation, blocking the vascular network perfusion. On the other hand, low cell seeding densities will limit cell−cell interactions, limiting cell growth, affecting both cell viability and survival in the scaffold.

Taking this into account, different recellularization methods have been developed [48,57,58]. Soto-Gutierrez et al. [48] compared three of them regarding better hepatocyte survival and function: direct parenchymal injection, continuous perfusion, and multistep infusion. The first consists of direct cell injection into different lobes of the liver scaffold. In the second technique, the total amount of cells that are going to be seeded are suspended in the culture media and perfused at a determined flow rate. Finally, the cells are added to the culture media in multiple steps, with time intervals between them, and perfused at a determined flow rate. They determined that the best results were using the multistep perfusion system, which not only allowed hepatocyte engraftment around 90%, but also were able to produce albumin and metabolize ammonia and cytochrome P450 (CYP)1A/2 activity for 7 days in vitro.

The flow seeding conditions are also critical. Low flows should be used to allow cell attachment and survival in the scaffold surface. Moreover, every type of cell has its particular cell attachment conditions, with the need to find a particular speed that allows for the most significant cell engraftment as possible, and the delivery into the native spatial location inside a decellularized liver scaffold. Other shortcomings that have to be solved are the long-term cell survival or graft thrombosis after implantation, owing to lack of a functional vascular network in the current generation of bioengineered livers. What can be determined from this is that a lot of relevant issues still need to be addressed in this novel field of liver bioengineering before clinical applications. Although much has been accomplished so far, mimicking in vitro the complexity observed in vivo is still challenging.

Future studies may lead to a better understanding of the production of human-sized transplantable bioengineered livers able to restore diseased organs or replace failed organs.

LIVER SPHEROIDS, ORGANOIDS, AND AGGREGATES: CANCER, BIOARTIFICIAL LIVER, TRANSPLANTATION RESEARCH, AND TOXICOLOGY AND DRUG DEVELOPMENT

Another strategy for the generation of 3D liver tissue constructs is using the hepatocyte capacity to form hepatospheres, which are spontaneous nonadherent spheroid cell aggregations that mimic in vivo cellular environment. The generation of these structures can be achieved by multiple methods such as nonadherent round-bottom wells using methylcellulose-containing medium, rotary and rocked cultures, hanging drops, or 3D matrices [59]. These hepatic structures have revealed higher liver-specific hepatospheres [60,61], which solves the problem of culturing hepatocytes in 2D systems, where dedifferentiation quickly develops. Cocultures with endothelial and other nonparenchymal cells were also developed using this technique (Fig. 62.2A).

Cancer Research

Liver spheroids have emerged as a promising tool in cancer research [62,63]. This 3D culture method has been used as an intermediate model between in vitro and in vivo microenvironments [64]. Studies have demonstrated that liver spheroids preserve a more significant number of liver cells functions better than 2D culture, including albumin and urea production and bile secretion [62,63]. Moreover, the 3D culture conserves cell polarization, resulting in higher concordance with in vivo conditions rather than 2D cultures. This is particularly important in cancer research because 3D cultures better resemble the interplay of the tumor and its microenvironment. This culture configuration allows for the formation of a stable tissue in which cell−cell and cell−matrix interactions are better preserved than in 2D cultures [65]. Hence, liver spheroids more accurately reflect the tumor complexity and heterogeneity and constitute a therapeutically relevant model, displaying pathophysiological gradients of in vivo tumors, such as pH and oxygen gradients, the penetration rate of growth factors, and the distribution of proliferating and necrotic cells [64].

Liver spheroids and aggregates have also been used to evaluate the mechanism of tumor growth, metastasis development, and antitumor therapeutic agents [63,65,66]. Not long ago, unlike other cancers, there was a lack of evidence and data published about the use of liver spheroids in primary liver cancer research. An increase was observed in the number of studies using liver aggregates for in vitro modeling of HCC [67,68]. Song et al. cultivated multicellular tumor spheroids to elucidate the mechanisms of environment-mediated chemoresistance and metastatic transformation in HCC. In that study, the authors created different multicellular spheroids that contained different human HCC lines and stromal cells, including hepatic stellate cells (HSCs). The authors observed that the presence of activated HSCs increased the compactness of spheroids and enhanced resistance to chemotherapeutic agents such as sorafenib and cisplatin compared with other stromal cells. The authors also observed that this increase in drug resistance was related to HSC production of collagen 1A1. On the other hand, the results of the study showed that activation of HSC promoted HCC migration by upregulating matrix metalloproteinase 9. Globally, the authors demonstrated that interaction between HCC cells and HSC induced chemoresistance and gave the tumor a more aggressive and invasive profile; they suggested that HSC could be the target for novel therapeutic strategies [68].

In the same way, Chen et al. used HCC spheroids to screen candidate metastasis-associated genes. The authors built two different HCC spheroids using two different cell lines, one with high-metastatic (MHCC97H) behavior and other with a less aggressive profile (Hep3B). Then the authors evaluated the expression of candidate metastasis-associated genes related to cell adhesion, matrix secretion, and invasion. The results showed an evident change in the gene expression of 123 genes between the two spheroids. In the MHCC97H spheroids, the authors found that the number of upregulated genes related to adhesion molecules mediating cell−matrix interactions and matrix secretion was significantly higher. In contrast, the Hep3B spheroid presented an increased expression of adhesion molecules maintaining cell adhesion. With these data, the authors could identify a specific gene expression pattern that may determine the malignant phenotype of the HCC spheroid [67].

The findings of these studies represent the potential of the liver spheroids in the field of cancer research. 3D culture models offer a more accurate environment of in vivo microarchitecture to study tumor growth and progression.

In the future, the introduction of new biomaterials and biofabrication techniques will also reproduce the interaction between cells and matrices more precisely. For these reasons, the results obtained from studies performed with 3D culture methods are more consistent owing to their similitude with the in vivo reality. A strong implication of liver spheroids in cancer research is their potential in personalized medicine. Future studies in patients with primary liver cancer or liver metastasis may use host-tumor based spheroids to evaluate pharmacologic activity and toxicity.

Bioartificial Liver and Transplantation Research

The liver is a vital organ with complex functions including gluconeogenesis, albumin and urea synthesis, lipid metabolism, drug detoxification, waste removal, and immune and hormonal modulation. Liver diseases are prevalent worldwide; most cases lead to progressive impairment of liver function. The only available treatment for life-threatening conditions such as end-stage liver disease and acute liver failure is LT, but because of donor shortage and an increase in the number of potential LT candidates, alternative measures are needed [69]. Owing to their ability to resemble in vivo structures and preserve organ-specific functions, liver spheroids have also been used in bioartificial livers and transplantation research [62,63]. Liver spheroids have a potential use in this field, directly transplanted or employed in hybrid and bioartificial liver support systems (Fig. 62.2) [70–72].

In 2005, Gan et al. explored the role of a spheroid-based hybrid artificial liver support system (HALSS) for treatment of severe liver failure. In this study, the HALSS consisted of a plasma separator, a hemoabsorbant, and a bioreactor with pig-derived hepatocyte spheroids in its extrafiber space. This system has been used in 10 patients with severe liver failure. The authors observed that after 24 h of spheroid culture, they produced higher levels of albumin and urea in respect to 2D cultures, suggesting better preservation of cell function. The authors also observed that patients treated with HALSS had a better survival rate (30% versus 0%), low levels of total bilirubin and alanine transferase, and improvement in coagulation compared with those in the control group. With these results, the authors concluded that spheroid-based HALSS could be useful in supporting liver function in patients with severe liver failure [71]. A preclinical study by Glorioso et al. evaluated the neuroprotective effect of the spheroid reservoir bioartificial liver (SRBAL) in a porcine model of acute liver failure. In that study, 18 pigs with an acute liver failure caused by a drug overdose were randomized into three groups: standard therapy, standard therapy plus no cell liver support device, and standard therapy plus the SRBAL device. After 90 h of treatment, the authors observed that pigs treated with the SRBAL improved survival compared with standard therapy and no cell device therapy (83%, 0%, and 17%, respectively) and had significant improvement in the rate of ammonia detoxification, peak levels of serum ammonia, and intracranial pressure. The authors also found that hepatocyte spheroids remained highly functional and that survival and device function were directly related to hepatocyte cell dose, treatment duration, and membrane pore size [72]. These studies reflect the potential of the spheroid-based bioartificial liver as a promising treatment for liver failure. Spheroid aggregates offer a readily available source of donor cells and reach the minimal cell dose to obtain a significant clinical effect in animals and humans. Regardless, randomized clinical studies are needed to determine whether these bioartificial support systems are safe and feasible in individuals with acute liver failure, with the aim of expanding its use to clinical practice and avoiding LT.

Other studies have evaluated the effect of direct transplantation of liver spheroids. No controlled trial has yet evaluated the clinical benefit of liver cell therapy in liver diseases in humans, and slightly more than 100 patients have been treated with hepatocyte transplantation [73]. However, the benefit is well-known in animal models. In 2002, Hamazaki et al. demonstrated that intraperitoneal transplantation of microencapsulated multicellular spheroid of rat hepatocytes improved survival in acute liver failure induced by 90% hepatectomy. Nevertheless, data are needed on liver spheroids transplantation in humans [70].

Results from experience with hepatocyte transplantation in humans and with liver spheroids in animals are promising, and cell-based therapies emerged as a “bridge to transplant” for both metabolic liver disease and liver failure. The most significant limiting factor is that sources of hepatocytes for transplant are scarce and tissues that are available come from organs that are unsuitable for LT [74]. To avoid this problem, alternative sources of cells have been evaluated. Pettinato et al. evaluated the differentiation of human induced pluripotent stem cells (hiPSCs) into hepatocyte-like cells through direct Wnt−β-catenin pathway inhibition [75]. The authors developed a new multicellular spheroid-based hepatic differentiation protocol starting from hiPSCs. The resultant spheroids were transplanted into a rat model of acute liver failure. The results showed that transplantation significantly prolonged the mean survival and ameliorated the liver function compared with the control group. These results indicated that this differentiation program is feasible and highly efficient and suggested that the differentiation of stem cells

may provide an alternative source for hepatocyte-like cells with comparable differentiation and function [75]. Once again, these results confirm the power of 3D culture to preserve liver-specific functions throughout time.

Finally, liver spheroid transplantation could also have a role in personalized gene therapy. A study suggested that transplantation of spheroids of cells after genetic modification with nonviral DNA vectors may increase the therapeutic potential of this technique. In their work, Uchida et al. evaluated this hypothesis [76]. The authors transplanted subcutaneously hepatocyte spheroids transfected with erythropoietin DNA in rats. They observed that the spheroid-treated group showed a significantly higher hematopoietic effect than animals transplanted with a cell suspension from monolayer cultures. Moreover, the spheroid system contributed to the preservation of native functions of hepatocytes in the host tissue, confirming once again that 3D culture delays dedifferentiation and loss of functions of these cells [76].

These results introduced a new perspective for liver spheroid transplantation. In the future, genetically modified spheroid transplantation systems may be used to overcome genetic diseases. The actual state of the art suggests that we may soon be able to create and transplant genetically modified spheroids of hepatocyte-like cells derived from the patient's own stem cells, which will represent a revolution in personalized medicine.

Toxicology and Drug Development

The liver is the organ where most drugs are metabolized and transformed into metabolites or active compounds. These substances by-products may become toxic to the liver itself and the rest of the body, a phenomenon known as drug-induced liver injury (DILI). To launch a single drug into the market is a long (12–15 years) and costly ($3–5 billion) process [77]. After an initial screening, lead candidate compounds are characterized in vitro and in vivo for their absorption, distribution, metabolism, excretion, and toxicity properties before proceeding with clinical trials. However, most compounds (>90%) fail during these final stages: 43% of these failures occur owing to a lack of efficacy and 33% to the appearance of adverse effects [78], mainly because of DILI [79]. Hence, drug withdrawals at clinical stages in humans mainly result from the use of inappropriate or inaccurate in vitro and in vivo liver models in the course of drug studies.

On the other hand, the liver is the target organ of some prevalent diseases, such as infectious hepatitis B virus, HCV [80], malaria [81], overnutrition-induced (type 2 diabetes, nonalcoholic fatty liver disease, fibrosis, and cirrhosis) [82–84] or tumoral diseases (HCC represents the sixth most common cancer worldwide) [85].

Considering all of this, liver models' results are necessary for the development of novel drugs, not only for the study of xenobiotics' metabolism and toxicity but also for the development of specific drugs for liver diseases. Hence, more realistic in vitro human liver models are needed that resemble as closely as possible in vivo liver structure, physiology, and the pharmacological response.

Limitations of Current In Vitro Liver Models to Test Drugs

As mentioned before, maintaining liver parenchymal function ex vivo is essential to generating stable systems for efficacy and toxicology drug studies, so fully functional hepatocytes are needed. For that, the 3D relationship of cells within the differential microenvironments of the liver (e.g., periportal versus pericentral), the regional hemodynamic flow patterns, and other physiological factors such as oxygen tension and cytokine profiles have to be simulated in vitro. However, cell-based models that are routinely used in drug testing are simple monoculture systems (typically standard microtiter plate formats) employed under static, nonphysiologic 2D conditions, which make them suboptimal models for drug efficacy and safety testing, unable to mimic or predict more complex mechanisms of action [86].

Hepatocyte viability in suspension decreases significantly after 4 h. Because of that, for years cryopreserved human hepatocytes in monolayer cultures have been the reference standard to test drug metabolism and toxicity [87]. However, cryopreservation also reduced hepatocyte viability, and function and their culture in monolayer downregulates cell receptors involved in cell–cell and cell–ECM interactions, drastically reducing cell functionality over time [87]. The development of 2D culture models such as sandwich culture increased basal and induced drug-metabolizing enzyme activities and simulated in vivo biliary excretion rates [87,88]. However, dedifferentiation of hepatocytes in long-term cultures and the lack of nonparenchymal cells that interact with hepatocytes continued to be inherent disadvantages of these models [89]. The coculture of hepatocytes with other liver cells, such as stellate cells, Kupffer cells, liver sinusoidal endothelial cells, or liver epithelial cells diminishes these limitations to some extent, improving the longevity and functionality of cells and producing the higher expression of CYP and phase

II isoforms compared with monotypic culture [90–93]. Nevertheless, cocultures are usually based on the random mixing of different cell types and thus do not account for their particular anatomical relationship. Looking for more relevant models, to emulate the 3D organization and morphology of hepatocytes within the liver, 3D cultures have been developed. 3D cultures range in complexity from monotypic or heterotypic spheroids [94,95] to 3D scaffold systems [96] and more advanced models using microfluidic in vitro systems [96,97]. Multiple commercial 3D coculture platforms have been developed for drug screening and drug studies such as the "HepatoPac" platform [98], the 3D InSight Human Liver Microtissues of InSphero, the HepaChip in vitro microfluidic system [99], and the HμREL microliver platforms [100].

Although some issues have been addressed for specific applications with these models, others continue to be biologically and technically challenging [88,101].

Organoids in Drug Development

Organoids represent more complex models that try to simulate 3D cell–cell and cell–ECM relationships in more relevant physiological conditions that mimic the liver microenvironment arrangement amenable to the high-throughput screening of compounds feasible enough to guarantee long-term studies.

The optimal liver role depends on the coordinated function of parenchymal and nonparenchymal cells within the hepatic acinus as well as hepatic blood microcirculation. Aspects of the microcirculation can be simulated in vitro via perfusion models to create a dynamic in vivo like environment. Different macroscopic perfused in vitro liver systems initially developed as bioartificial liver devices have been created [97], which provide evidence that perfusion can improve longevity and function in sophisticated hepatic systems, and thus show better in vivo mimicry. Although these models represent the most physiologically practical systems, their size makes them unfeasible for use in drug testing studies because they lack the throughput and analytical flexibility for drug screening. The use of these organoids in drug development involves their miniaturization to a microscopic level. This new class of in vitro tools, often called "on-a-chip" tissue models, can mimic the architecture of small tissue sections and individual characteristics of the dynamic in vivo flow environment, while offering more precise spatial and temporal control of soluble factors. Apart from being amendable to high-throughput screening approaches, these models can be engineered for real-time monitoring of the state of cells and their extracellular environment, which is crucial for determining cellular mechanisms of action in drugs [97].

Several organoid systems have been developed for drug screening and testing. One of the best examples of these organoids is in microfluidic systems. In 2006, Kane et al. developed a microfluidic coculture system of hepatocytes and T3-J2 fibroblasts in an 8×8-well array, demonstrating stable albumin and urea excretion for 32 days. Some years later, HμREL Corporation developed a similar microfluidic in vitro liver platform for drug screening for commercial purposes (HμRELflow) [100]. This platform, formed by multiple fluidically interconnected microscale cell culture compartments, enables simulation of the interaction of test substrates with two or more organs, which provides an enhanced prediction of human response. In fact, in vivo-like absorption, distribution, metabolism, bioaccumulation, and toxicity of naphthalene were demonstrated when lung, adipose, and liver cells were fluidically connected [100]. Furthermore, the size of the system enabled microscopic imaging, oxygen sensing, physiologically appropriate ratios of chamber sizes, hydrodynamic shear stress, and less consumption of media and cells. Even so, some issues such as sample removal, complexity in maintaining recirculation, and cell monolayers on chips and not physiological tissue constructs, significantly limit the model. Some years later, Au et al. developed another microfluidic model, a microfluidic organoid for drug screening (MODS) platform [102]. The novelty of this system compared with the previously developed MODS was the ability to evaluate different conditions simultaneously and the automation of time-consuming processes such as the generation of mixtures and the formation of serial dilution series, which can result in more efficient screening of lead drug candidates. Vernetti et al. developed and characterized a sophisticated system to investigate drug safety and efficacy in liver models of disease. This system includes a human 3D, microfluidic, four-cell, sequentially layered, self-assembly liver model as well as fluorescent protein biosensors for mechanistic readouts and a microphysiology system database to manage, analyze, and model data [103].

Hollow-fiber reactors have also been adapted to drug testing. In 2010, Schelzer et al. developed a microscale prototype of a hollow-fiber reactor. In this model, the bioreactor consisted of four cell chambers, each of which included four compartments (one for cells, two for culture medium, and the last for oxygen supply) connected to provide the cells with a physiologically based environment [104]. The prototype allowed for small numbers of cells and limited reagent use, microscopic evaluation of the cells, and monitoring of oxygen concentrations. Later, a similar system

with coculture of parenchymal and nonparenchymal liver cells was developed for studies of pharmacokinetics and drug toxicity, showing maintained albumin synthesis and CYP activity for 2−3 weeks [105]. Nevertheless, some limitations arise in this kind of systems, such as the lack of physiologic gradients typically seen in liver tissue, the complexity of many tubing lines, and the limited throughput, because only a few different conditions can be assessed simultaneously.

As also mentioned previously, decellularization constitutes a novel approach in liver models [23,25]. This macroscopic model that can be used to investigate liver development and regeneration can also be miniaturized for high-throughput drug studies [106].

Apart from physiological models, organotypic models of liver diseases are being developed for drug testing. Drug metabolism, toxicity, and efficacy in diseased livers differ substantially compared with healthy conditions, so accurate models of disease are required. In this sense, Skardal et al. developed liver-based cell organoids in a rotating-wall vessel bioreactor that inoculated with colon carcinoma cells to generate liver-tumor organoids for in vitro modeling of liver metastasis [65]. Leite et al. developed hepatic organoids with fibrotic features such as HSC activation and collagen secretion and deposition to study drug-induced liver fibrosis [107]. Similarly, Lee et al. generated a reversible- and irreversible-injured alcoholic liver disease model in spheroid-based microfluidic chips in which rat primary hepatocytes and HSCs are cocultured [108].

Although enormous advances have been made to develop more realistic and predictive in vitro liver models for drug testing, the field is still dawning. There are critical issues that should be solved for the field to move forward. Standardizing model and platform characterizations for drug-based studies (viability, secretory capacity, enzymatic and toxicology activities, and drug transporter activity) should be established for each model. Building specificity and sensitivity of the systems, recreating more accurately parenchyma zonation, developing better detection systems and better materials [97], and finding new, unlimited, fully functional cell sources [109] are some challenges in developing in vitro liver models for drug studies.

CONCLUSIONS AND FINAL PERSPECTIVES

This chapter has focused on strategies of liver tissue engineering with potential for developing innovative treatments and efficient models for studying the liver. Knowledge of regenerative biology and medicine has increased exponentially, giving new hope to the development of effective treatments for liver disease. Much work still lies ahead to obtain final therapies or models that accurately represent the liver to its fullest. Standardization of cell isolation protocols and media formulation is needed to achieve a high grade of reproducibility of results among laboratories around the world. Despite the obstacles, some 2D liver culture models, especially cocultures with hepatocytes and nonparenchymal cells (which better represent the in vivo microenvironment of the liver) can be considered useful models for studying the acute phase response, mutagenesis, xenobiotic toxicity, lipid, and drug metabolism in the liver. Liver organoids are also considered a possible tool to assess cell changes that lead to tumorigenesis and cancer progression, and for drug screening and testing. Improvement and standardization of the protocols used are needed to enhance the production rate and ameliorate the features of the obtained organoids.

Regarding the bioreactor systems used in liver tissue engineering, clinical assessment of the efficacy and safety of bioartificial liver systems in treating different end-stage liver diseases is near completion. Then, the field can concentrate on reducing the costs, finding more suitable cell sources, and optimizing bioreactor technologies.

Finally, the use of whole-organ liver scaffolds is promising in the quest of bioengineering a whole liver for transplantation. Livers from different species have been decellularized using various protocols to obtain acellular bioscaffolds. Nonetheless, complete recellularization using all necessary liver cell types, including Kupffer, sinusoidal endothelial, and stellate cells, and the generation of a fully functional liver have not yet been accomplished. Hence, one of the most significant challenges in whole-organ liver bioengineering is an appropriate cell source to repopulate the acellular scaffold and achieve well-defined complete revascularization of the decellularized liver. Induced pluripotent stem cell (iPSC) technology has the potential to provide a source of cells for whole-liver bioengineering for humans. However, bioengineering a fully functional organ with a size comparable to that of humans has yet to be achieved by using iPSC technology.

Altogether, the strategies for liver tissue engineering discussed in this chapter may have an impact on innovative personalized tissue engineering-based treatments as alternative and effective therapies for different liver diseases or pathologies.

INTRODUCTION

Structure and Function of the Cornea

The cornea is the transparent front covering of the eye that transmits and focuses light into the eye for vision. It is composed of three main cellular layers: an outermost stratified epithelium, a middle stroma, and an innermost endothelial layer. The total thickness is approximately 550 μm in the center and 750 μm at the periphery [1]. The epithelium of the cornea forms the outer layer and primary protective barrier. It is composed of stratifying, non-keratinized epithelial cells. Epithelial cells also secrete antiinflammatory and antimicrobial factors as an insoluble layer that maintains the tear film [2]. Because cells are lost on the anterior surface of the cornea, new layers of epithelium originate from a basal layer generated by corneal stem cells in the corneo−scleral limbus [3]. The stroma is composed of a hydrated, largely collagenous extracellular matrix (ECM) containing a network of fibroblast-like cells called keratocytes. The single endothelial layer actively osmoregulates the entire structure and maintains hydration while pumping out excess fluid. The cornea is avascular and relies on its extensive network of sensory neurons and their interaction with the corneal cells to maintain tissue integrity and heal wounds [4].

The external location of the cornea makes it prone to injury and infection. Diseases of the cornea are the fourth largest cause of vision loss globally according to the World Health Organization [5]. Corneal blindness is treated by transplantation with donated human corneas, but there is a severe worldwide shortage of good-quality corneas. Not taking into consideration patients in poorly served remote areas or those contraindicated for conventional surgery, an estimated 12.7 million patients are awaiting corneal transplantation globally [6]. This need is particularly elevated in low- to middle-income countries, e.g., China and India, where 2 million and 7 million patients, respectively, are awaiting surgery.

Treatment Options, State of the Art, and Need for Corneal Regenerative Medicine

The only widespread treatment is corneal transplantation using a full-thickness human donor cornea through a procedure known as penetrating keratoplasty (PK). PK therefore relies on the ability to access donor corneas via eye banks. In 2012, there were 184,576 corneal transplants in 116 countries globally [6]. This means that of 70 patients needing transplantation only 1 is treated, and this is mainly because of a severe global shortage of human donor corneas. However, even with adequate access to donated tissues, although initial graft success rates are high in developed nations, e.g., 90% over 2 years in Sweden [7], only about 64% of grafts survive over 10 years [8]. In developing nations where there is a preponderance of severe pathologies that place patients at high risk for rejection, the graft survival rate over 2 years was 52% [9].

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00063-1

Corneal prostheses known as keratoprostheses (KPros) have been developed mainly as alternatives to donor corneas for high-risk grafts, because these patients are generally contraindicated or not prioritized for conventional donor transplantation in countries where there is a severe donor shortage. The traditional KPro that is used clinically is composed of an optical core, often made from poly(methyl methacrylate) and a skirt that interfaces with the patient's eye. The two most widely used KPros (the Boston KPro and osteo-odonto-keratoprosthesis) and their variants contain a biological interface. However, the irreversible nature of the surgery, potential complications, and the need for sustained antibiotics and immune suppression cause them to remain an option for end-stage eyes, so they are not ideal replacements for donor human corneas [10]. For more detailed reviews of KPros, see Avadhanam et al. [10]and Salvador-Culla et al. [11].

Regeneration of the corneal epithelium from cell-culture expanded limbal epithelial stem cells pioneered by Pelligrini et al. was a major breakthrough in modern corneal blindness treatment and is in clinical application as the first European Commission approved cell-based advanced therapy medicinal product (ATMP) [12,13]. A direct method for limbal cell replacement known as simple limbal epithelial transplantation (SLET) that bypasses stem cell expansion has also entered clinical application [14,15]. However, limbal stem transplantation is most successful when using an autograft, and in cases where the pathology involves deeper layers, follow-on transplantation with a donated cornea is still needed [16].

The first successful regeneration of the cornea using a cell-free method was reported by Griffith and colleagues and resulted from the use of recombinant human collagen (RHCIII) hydrogels [17]. Ten patients underwent the implantation of proregeneration scaffolds by anterior lamellar keratoplasty [17]. Patients were given partial-thickness implants composed of RHCIII cross-linked using 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide–*N*-hydroxysuccinimide, resulting in the regeneration of the epithelium, stroma, and corneal nerves (Fig. 63.1). Because the neocorneas were derived from the patients' own cells growing into cell-free scaffolds, there were no immune problems and patients did not require immune suppression beyond the 6–7 weeks of local steroid eye drops prescribed prophylactically.

Regenerative medicine remains the main option for restoring the structure and function of the cornea to the semblance of a normal cornea. In this chapter, we review current methods used to regenerate the human cornea. Because of the wide variety of methods used, we will review only examples that are in clinical evaluation and are being evaluated preclinically, as well as some novel methods.

REGENERATIVE MEDICINE APPLIED TO KERATOPROSTHESIS DEVELOPMENT

KPros under development and clinical evaluation incorporate elements allowing regeneration. Specifically, devices have been designed to allow the regrowth of corneal epithelium to cover the device to maintain the tear film and prevent infection or extrusion of the implant. This is done by surface modification of the interface opposing the patient's corneal tissues with either surface chemistries or lithographic techniques that pattern the surface on a nanoscale to microscale.

The macromolecules of ECM proteins such as collagen, fibronectin, laminin, their derivative cell adhesive peptides (e.g., isoleucine–lysine–alanine–valine, Tyr–Ile–Gly–Ser–Arg [YIGSR], and Arg–Gly–Asp [RGD]), or other ECM analogs have been evaluated for their ability to modulate epithelial growth over KPros. Previous work has shown that corneal epithelial cell adhesion and growth were significantly enhanced by tethering of laminin or fibronectin adhesion promoting peptide via flexible polyethylene glycol (PEG) chains, more so than by tethering of fibronectin or simple coating of the surface with matrix proteins [18,19]. Modification with fibronectin-based Arg–Gly–Asp–Ser (RGDS) [20–22], laminin-based YIGSR [23,24], and a novel collagen-based peptide, Gly–Pro–Leu [25], was also shown to improve epithelial cell adhesion in vitro. Surface modification peptide combinations, e.g., well-known cell adhesion peptides RGDS and YIGSR together with their synergistic counterparts Pro–His–Ser–Arg–Asn and Pro–Asp–Ser–Gly–Arg, have resulted in surfaces that provide improved corneal epithelial cell adhesion and growth [23].

Growth factors such as epidermal growth factor or insulin-like growth factor-1 have been tethered onto polydimethylsiloxane and polymethacrylic acid-*co*-2-hydroxyethyl methacrylate, respectively [18,26]. Both studies showed that the growth factors enhanced corneal epithelial cell attachment and growth and that the use of a PEG tether has been shown to improve cell coverage of the polymers significantly in vitro. Both sets of results strongly suggested that the spacer molecules provided the correct microenvironment for the epithelial cells by exposing the bioactive motifs to allow the cells to reach confluence, compared with little or no epithelial growth on the surfaces that were coated only with the bioactive factors.

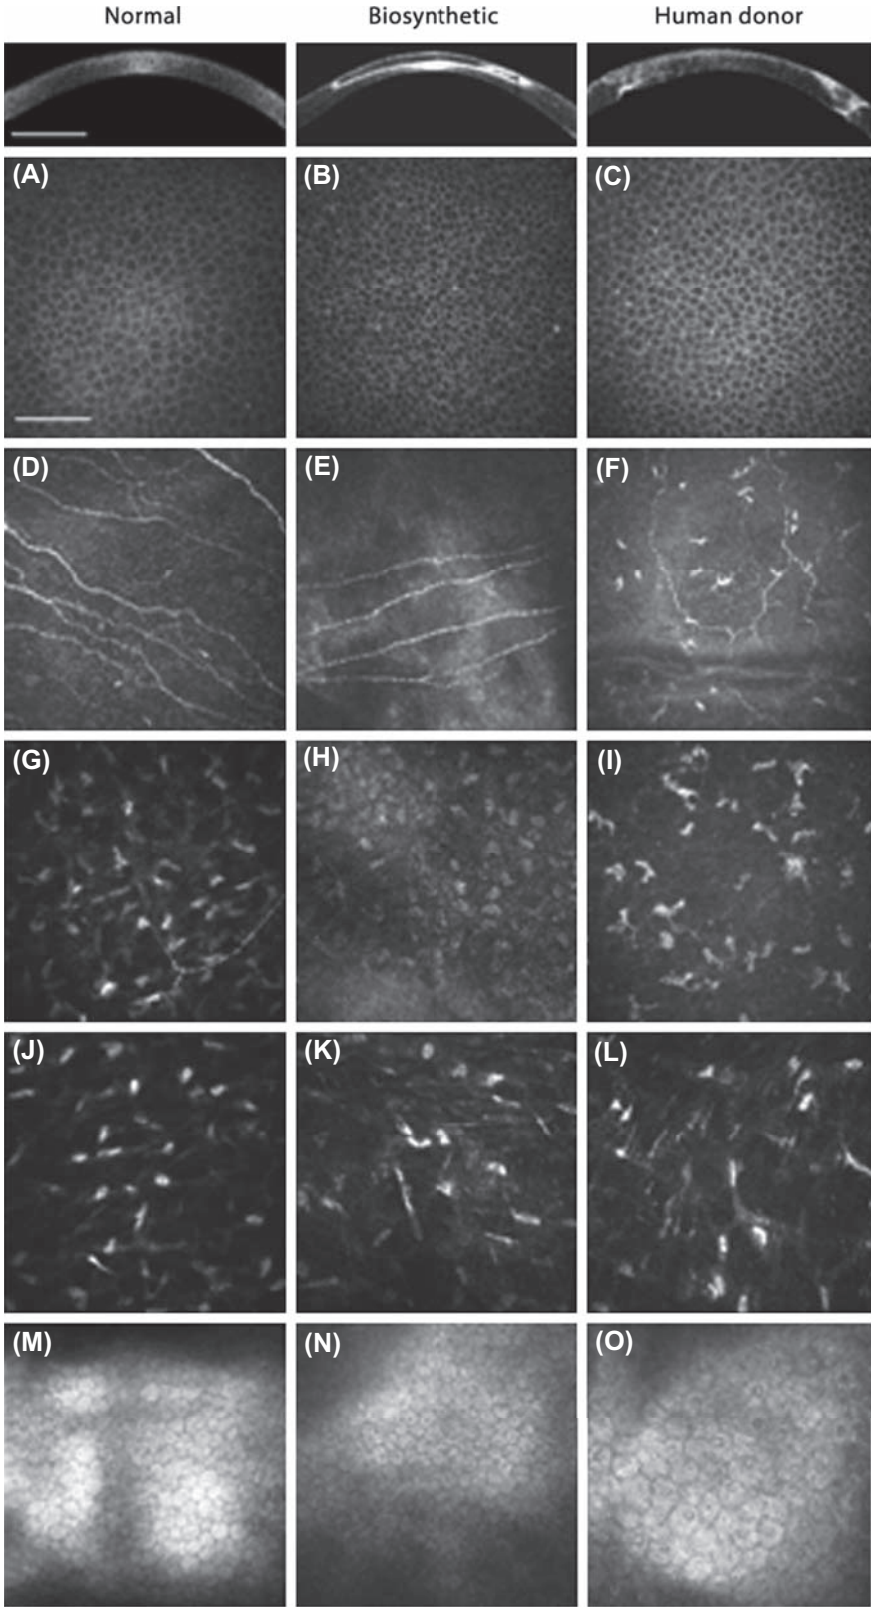

FIGURE 63.1 Corneal features in a healthy, unoperated subject, alongside those of operated patients, at 24 months after implantation of a biosynthetic cornea or a human donor cornea. (Top row) Anterior segment optical coherence tomography (ASOCT) images of a healthy cornea, biosynthetic implant, and human donor transplant by penetrating keratoplasty. Areas of wound-healing activity exhibit high reflectivity (*white areas*). (A–O) In vivo confocal microscopy (IVCM) images. Intact epithelium of the unoperated cornea (A), regenerated corneal epithelial cells on the implant surface (B), and regenerated epithelium of the penetrating graft (C). Regenerated nerves (E) at the subbasal epithelium in an implanted cornea were parallel and morphologically similar to the normal cornea (D), whereas regenerated subbasal nerves were also observed in a cornea transplanted with human donor tissue (F). Anterior stromal cell (keratocyte) nuclei (G–I) and posterior keratocytes (J–L) were present, with varying density, in all corneas. The endothelium (M–O) in all corneas exhibited a characteristic mosaic pattern. *Reproduced from Fagerholm P, Lagali NS, Merrett K, Jackson WB, Munger R, Liu Y, et al. A biosynthetic alternative to human donor tissue for inducing corneal regeneration: 24 month follow-up of a Phase I clinical study. Science Transl Med 2010; 2: 46ra61, courtesy of AAAS.*

Modification of the physical profile of a KPro surface by lithography is another method to enhance the cell–tissue device interface. Surface patterning of a KPro was first reported by Myung et al. using a photolithographically patterned device composed of a PEG–poly(acrylic acid) (PAA) central core and a poly(hydroxyethyl acrylate) microperforated skirt. Type I collagen was then coupled to the hydrogel using photochemical surface modification to promote epithelial migration into the wound site in rabbit models in vitro and in vivo [27]. When the collagen-patterned PEG–PAA hydrogels were implanted into rabbits, the result was good tolerance in 9 of 10 subjects but an optical haze remained at the surgical site [28]. An additional study suggested that the collagen was evenly distributed but cell migration was slower than in surgical controls and took 5 instead of 2.5 days for wound closure [29]. A comparative study of PEG-diacrylate–PAA versus PEG-diacrylamide–PAA hydrogels indicated that the PEG-diacrylamide was more biocompatible than the original formulation [30]. A 2015 study compared porous versus nonporous PEG-diacrylamide–PAA hydrogels with surface modification with type I collagen and fibronectin [31]. The porous hydrogels were synthesized using templates composed of polystyrene microbeads, which were removed after cross-linking by washing in methyl ethyl ketone buffer. Both the porous and nonporous formulations supported the multilayered growth of corneal fibroblasts, which suggested the suitability of porous PEG–PAA hydrogels for KPro skirt material.

REGENERATION OF CORNEAL LAYERS

Corneal Epithelium

Work in regeneration of the corneal epithelium has focused on methods that circumvent the rejection of allogeneic donor cells, because this is a huge problem that necessitates systemic immunosuppression even in patients receiving human leukocyte antigen–matched tissue, which has its own risks and side effects [32]. This includes the development of new therapeutic stem cell sources from transdifferentiation of progenitor cells from other sites such as oral mucosa (or other mucous membranes) to conversion of fibroblasts or mesenchymal stromal/stem cells (MSCs) into corneal lineages by induced pluripotency [33].

Transdifferentiation of oral mucosa has been tested in patients with bilateral corneal epithelial stem cell depletion. In 2004, Nishida et al. reported the first successful human cultivated oral mucosal epithelial transplantation surgeries [34]. The procedure was conducted in four participants with bilateral total limbal stem cell deficiency caused by Stevens–Johnson syndrome (SJS) or ocular cicatricial pemphigoid. The oral mucosal cells were cultured on temperature-responsive cell-culture surfaces with 3T3 feeder cells and transplanted onto one eye of each patient, with successful, stable outcomes. However, all transplanted eyes had some peripheral corneal neovascularization. The procedure was later improved by culture of oral mucosa on human amniotic membrane (HAM) [35]. This technique has been successfully used in patients with SJS, alkali and temperature burns, and aniridia [36–40]. Other stem cells such as umbilical cord lining-derived stem cells have been successfully tested in rabbit models for use in regenerating the corneal surface [41]. MSCs have also been tested as potential sources of corneal limbal epithelial stem cell replacements in rat and rabbit models, but results have been mixed [42–44].

A range of biomaterials have been employed as substrates for corneal epithelial cells for use as implants. Fibrin and HAMs have been the staples. However, materials such as collagen membranes and silk fibroin are being evaluated.

Electrospun poly(D,L-lactide-*co*-glycolide) (PLGA) has also been used as substrate to expand cultured limbal cells and as a human limbal cell explant to restore the stem cell niche [45,46]. PLGA was used at a ratio of 50:50 lactic acid to glycolic acid. The electrospun meshes underwent γ-sterilization and dry storage at −20°C. The meshes degraded at 4–6 weeks in vitro and allowed for the culture of confluent limbal cells. Both cultured and explanted cells generated differentiated and stem cell populations when transplanted into an ex vivo rabbit corneal model.

Corneal Endothelium

The expansion of primary corneal endothelial cells (CECs) in culture before reinjection has been successfully tested in a feline model. CECs were obtained from Descemet membranes excised from feline corneas and expanded for up to two passages after cell detachment. Sixteen animals underwent surgery of the right eye. Eight animals underwent 7-mm central endothelial scraping and injection with 2×10^5 or 1×10^6 cultured CECs, and 100 or 350 μM Rho-associated, coiled-coil containing protein kinase (ROCK) inhibitor (ROCKi). Two underwent

18-mm total scraping followed by intracameral injection of 1 M CECs and ROCKi in 0.2 mL. Six negative controls underwent central or total scraping followed by injection of ROCKi. After surgery, the corneas grafted with CECs performed better than the surgical controls but the endothelium had incomplete functionality and was inferior to the unoperated corneas.

CECs have been differentiated from human embryonic stem cells (hESCs) but in vivo analysis has thus far been limited to animal models. In 2014, Zhang et al. reported human corneal endothelial-like cells derived from the periocular mesenchymal precursor (POMP) phase of hESCs [47]. POMP cells were transferred into coculture with human corneal stromal cells in lens epithelial cell–conditioned media for differentiation into CEC-like cells. The CEC-like cells were sorted using fluorescence activated cell sorting and cultured to generate CEC-like sheets. Transplantation into rabbits undergoing Descemet membrane stripping resulted in gradual restoration of transparency. Two methods of deriving CECs from the neural crest (NC) phase of hESCs have been tested. McCabe et al. derived CEC-like cells from dual Smad inhibitor–generated, feeder-free hESC NC cells with platelet-derived growth factor-β, and Dickkopf-related protein 2 [48]. Song et al. derived CEC-like cells from feeder-supported hESCs differentiated into NC cells cultured in bovine CEC conditional medium and fresh CEC media [49].

Corneal Stroma

Funderburgh and colleagues worked on stroma regeneration and showed that direct injection of stem cells isolated from limbal biopsies can prevent corneal scarring [50]. Limbal stem cell biopsy-derived stromal cells were derived from mesenchymal cells from human cadaveric cornea-sclera rims. In culture, these cells expanded to produce a thick lamellar structure with aligned collagen and proteoglycans resembling the ECM. Grafts in a mouse corneal wound model prevented the formation of scar tissue and were well-tolerated. Corneal stroma sheets have also been constructed in vitro for use as potential replacements for pathologic or thinned stromas. These are discussed subsequently in a discussion on self-assembled corneal constructs.

FULLY CELL-BASED, SELF-ASSEMBLED CORNEAL CONSTRUCTS

Self-assembly of corneal stromal components, largely collagens, has been extensively examined by Germain and colleagues, who used the method of ascorbic acid stimulation of fibroblastic cells to secrete ascorbic acid to prepare a range of tissues. In earlier work, Proulx et al. constructed a corneal stroma by growing stromal fibroblasts in cell culture medium supplemented with ascorbic acid for 28–35 days [51]. The ascorbic acid induces fibroblasts to lay down collagen and other ECM components to form sheets. These 35- to 55-μm-thick sheets are then stacked to form a corneal stroma. After fabrication of a stacked stroma, Proulx et al. added an endothelium and epithelium to construct a three-layered cornea. First, CECs were seeded on top of the reconstructed stroma and allowed to grow into a monolayer in endothelial growth medium. After 2–7 days, a plastic ring was placed on top of the cultured construct that was then turned upside down. Corneal limbal epithelial cells are then seeded on top, after which the entire construct is cultured in epithelial growth medium supplemented with more ascorbic acid. After achieving epithelial confluence, the entire construct is air-lifted and cultured at the air–liquid interface to promote stratification of the corneal epithelium. The resulting cornea was significantly thinner than a native human cornea. However, it was transparent and the authors suggested that full thickness might be achieved by increasing the number of stacked layers of fibroblast–ECM.

A variation on the use of ascorbic acid was reported by Karamichos et al. [52], who employed ascorbic acid with and without transforming growth factor-β to induce elaboration of ECM by human umbilical cord MSCs (cord stem cells) to form a cornea stroma-like structure. The cord stem cells themselves differentiated into stroma-like cells. As reported for the corneal stromal fibroblasts, it took 4 weeks to produce a construct 24 mm in diameter and 30 μm thick. However, in the cord stem cell matrices, 50% fewer cells than fibroblast-produced matrices were present, which showed that the ECM laid down by the cord stem cells was denser.

Self-assembled corneal stromal constructs were tested in animals. The iteration of self-assembled corneal stromal was reported by Syed-Picard et al. [53]. Human cornea stromal stem cells were seeded onto micropatterned PDMS substrates supplemented with stem cell growth medium. After 48 h, the medium was switched to a keratocyte differentiation medium containing ascorbic acid, fibroblast growth factor-2, and transforming growth factor-β3. After 10 days, a sheet was produced that could be detached from the PDMS substrate. After 5 weeks of implantation into stromal pockets in the corneas of immune-competent mice, the sheets were

well-integrated with persistence of human donor cells. They had also acquired transparency during the implantation period (Fig. 63.2).

Thicker sheets can be produced using a similar method, by stacking of self-assembled stromal constructs. Corneal stromal constructs were generated from both feline and human donor corneas and six sheets of stromal cells were stacked to generate each graft, which was then implanted into the corneas of cats in stromal pockets [54]. The animals each received two 4-mm-long and 300-μM-long incisions poles apart in the superior nasal and inferior temporal quadrants, after which a graft was placed in each intrastromal pocket. Four animals received human xenografts and four animals received feline allografts. Contralateral eyes underwent surgery without grafting. Preoperatively, the grafts were slightly hazy but they were restored to complete transparency after day 37. The grafts remained transparent and avascular with reinnervation and showed normal corneal sensitivity (Fig. 63.3). Overall, the surgery was well-tolerated with no symptoms of immune rejection.

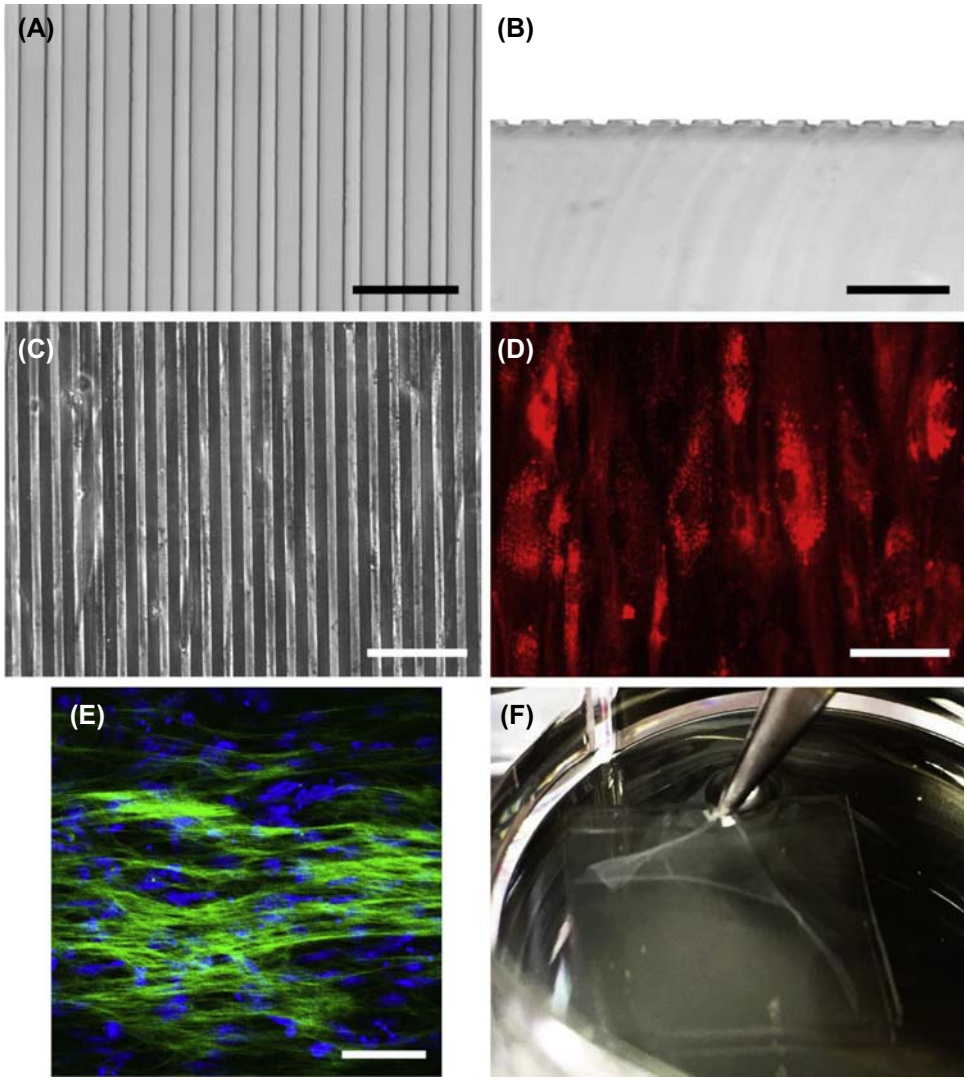

FIGURE 63.2 Formation of scaffold-free tissue sheet with parallel cell and matrix organization. Light micrographs of (A) top view and (B) cross-sectional view of the polydimethylsiloxane substrate show grooves approximately 10 μm wide, 10 μm apart, and 5 μm deep. (C) Phase contrast image shows corneal stromal stem cells (CSSC) cultured on the grooved substrate. (D) For better visualization, CSSC were labeled with DiI (*red*) and cultured on grooved substrate. (E) Two-photon micrograph of 10-day cultures of CSSC on grooved substrates in keratocyte differentiation medium shows deposition of parallel organized collagenous matrix (*green*). Nuclei (*blue*) were stained by SYTOX-green (*blue*). (F) After 10 days of culture, a robust tissue sheet is formed that can be separated from the substrate using forceps. Scale bars: (A) and (B) = 50 μm; (C)–(E) = 100 μm. *Reproduced from Syed-Picard FNN, Du YY, Hertsenberg AJJ, Palchesko RR, Funderburgh MLL, Feinberg AWW, et al. Scaffold-free tissue engineering of functional corneal stromal tissue. J Tissue Eng Regen Med 2016;12(1):59–69, with permission from Wiley and J. Funderburgh.*

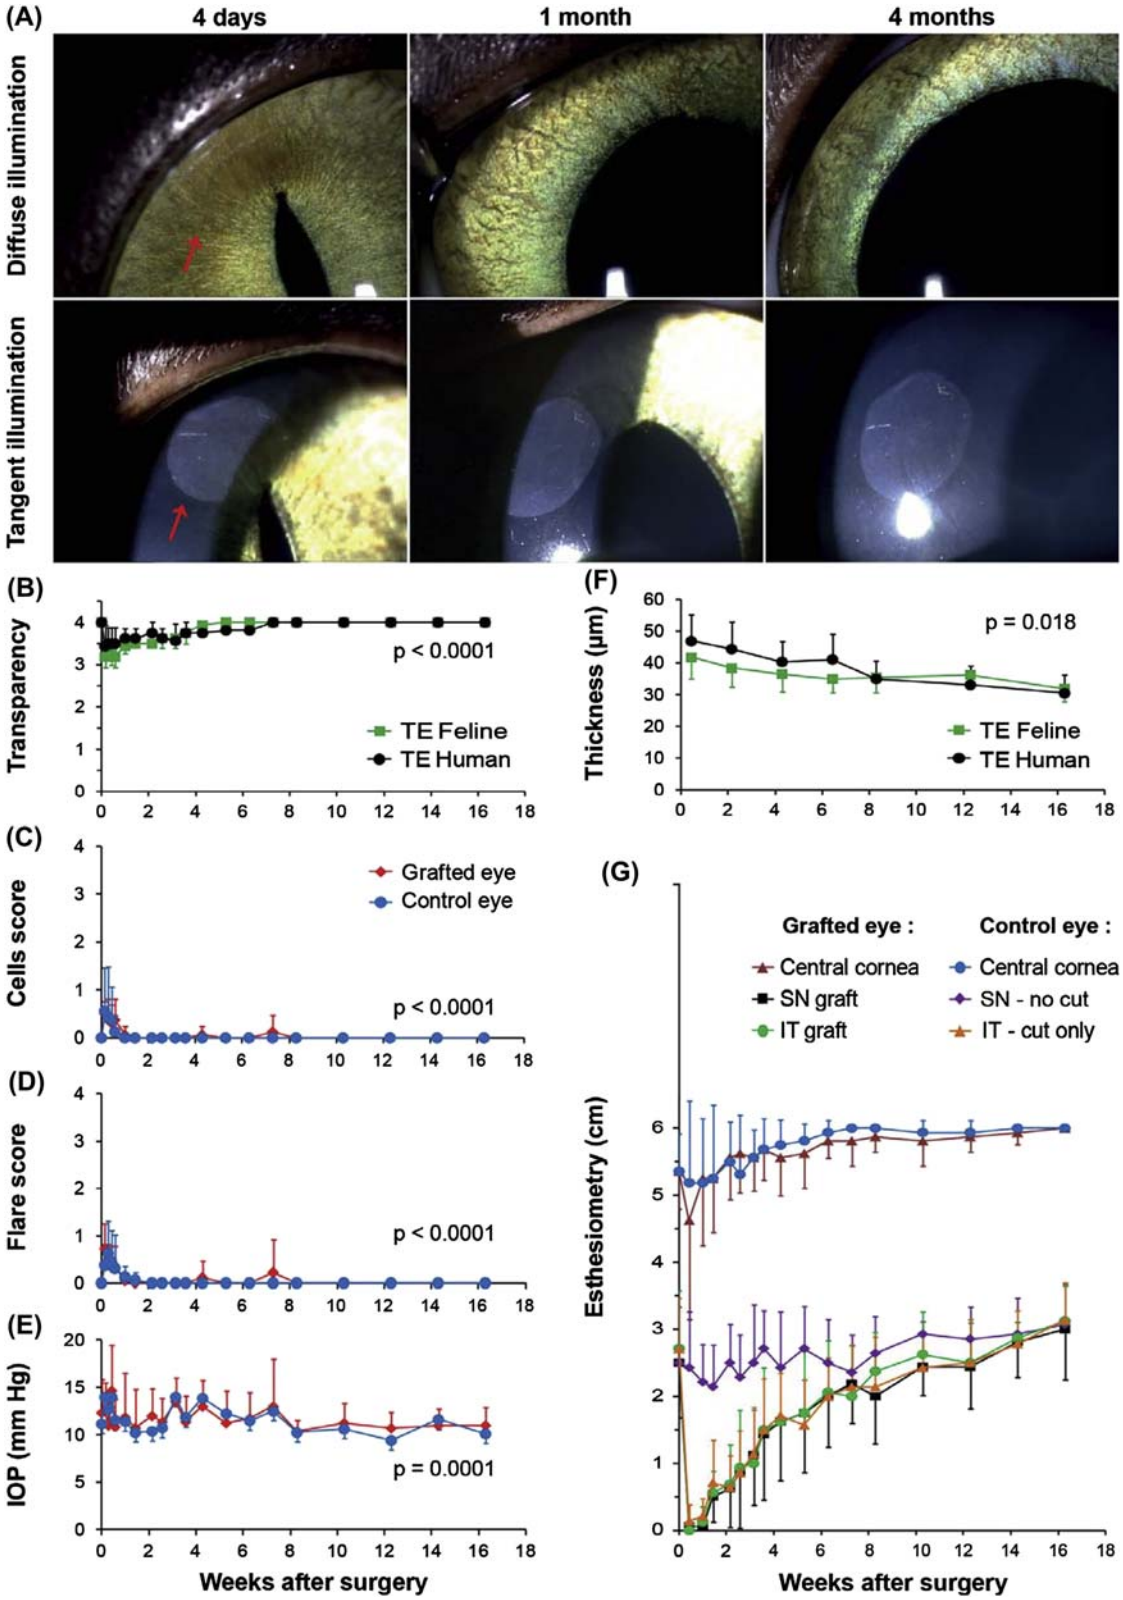

FIGURE 63.3 Clinical outcome of the tissue engineered (TE)—intrastromal grafts. (A) Representative slit-lamp photos at 4 days (column 1), 1 month (column 2), and 4 months (column 3) after transplantation of a TE-stroma in the superior nasal quadrant. Regular diffuse illumination (first row) does not allow visualization of the clear graft, which can only be seen with direct tangential illumination (second row; *arrow*; same graft and ×10 magnification for all six photographs). (B—G) Clinical evolution of grafted and control eyes. (B) Transparency score. (C) Anterior chamber cell score. (D) Anterior chamber flare score. (E) Intraocular pressure (IOP). (F) Graft thickness. (G) Esthesiometry. The parameters described in this figure were measured in all eyes at all indicated time points, with no missing data. The most representative photos are shown. *SN graft*, superior nasal graft; *IT graft*, inferior temporal graft. *Reproduced from Boulze Pankert M, Goyer B, Zaguia F, Bareille M, Perron MC, Liu X, et al. Biocompatibility and functionality of a tissue-engineered living corneal stroma transplanted in the feline eye. Invest Ophthalmol Vis Sci 2014;55(10):6908—20.*

Self-assembled stromal constructs therefore show promise for regenerative medicine applications; however, they have some significant limitations. Allogeneic cells may be problematic in clinical applications, so patient-derived autografts are more likely to be preferred. This poses significant surgical limitations, because patients will need to undergo surgery to isolate the donor tissue and then wait a significant period for the fabrication of a construct. This type of custom construct will then be limited to clinics with on-site cleanroom facilities. The possibility remains of decellularizing the stromal ECM and implanting it, but this has been attempted only in cartilage [55].

CELL-FREE BIOMATERIALS

A range of ECM-based or inspired proregeneration scaffolds have been proposed as alternatives to the largely collagenous corneal stroma. These range from human and xenogeneic decellularized ECM (from pig corneas to fish scales) to matrices made from extracted human and animal collagen, RHC, or short peptide analogs of ECM proteins.

Decellularized Extracellular Matrix as Implants

The aim of decellularization is to remove the cellular content while preserving the native ECM that is believed to promote regeneration when it is used as cell-free or pre−cell seeded implants. A wide range of decellularizing methods have been tested, including agents such as enzymes, chelating agents, chemicals (acid and alkali treatment and alcohols), detergents, hypertonic and hypotonic solutions, and physical methods (freezing, pressure, sonication, and mechanical agitation) [56]. Automated devices for decellularization have also been developed [57].

In 2011, Daoud et al. reported the clinical evaluation results of 150 patients who received anterior lamellar keratoplasty with human decellularized corneas sterilized with γ-radiation [58]. These implants showed high levels of epithelialization within a few days and no postoperative infection or rejection in all but four cases, all of which occurred in patients with preexisting corneal melting. In 2015, Zhang et al. described the implantation of decellularized porcine corneal stromas into the corneas of 47 patients who had corneal fungal ulcers [59]. They reported that 41 of the implants became transparent over time and 34 patients (72%) showed vision improvement. These results are promising, but caution must be exercised for xenogeneic transplantation because severe allergic reactions have been reported [60,61]. The use of poor-quality cadaveric human corneas as decellularized implants instead of living allografts is still caused by cornea shortage problems and requires confirmation of safety, because immunogenicity and risk of disease transmission remain considerations.

The main structural protein in decellularized ECM is collagen. The scales of fish comprise 41−81% of connective tissue protein and collagen and have been examined as collagen implants. Emergency patients with perforated corneal ulcerations or lacerations referred for immediate treatment at European hospitals often receive a temporary human cadaveric donor cornea. This so-called “0-cornea” is used to close the eye only temporarily because it does not meet all requirements of human donor corneas used for PK. However, an “0-cornea” is not always immediately available; hence, the ologen Biocornea was developed (Fig. 63.4) This is a temporary cornea made from decellularized and decalcified fish scales, designed to seal perforated corneas temporarily for up to 72 h while waiting for a donor human cornea to become available. When tested in rat corneas [62], these fish

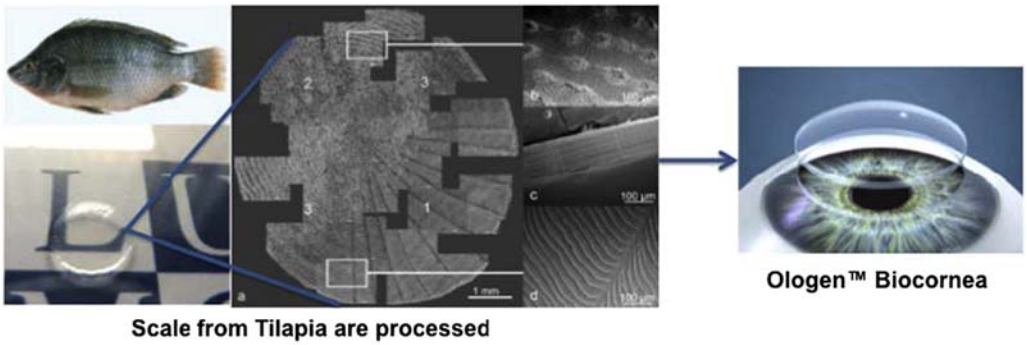

FIGURE 63.4 Ologen Biocornea derived from fish scale has a morphology similar to human cornea extracellular matrix and is transparent. *Courtesy of Aeon Astron Europe B.V.*

scale–derived collagen matrices were not reepithelialized during the 3-week study period and integration was incomplete in two of six animals, leading to the loss of implants. Some melting was also observed. As implants within stromal pockets, the grafts resulted in haziness. The ologen Biocornea was also reported to be able to seal full-thickness cornea perforations in minipig models in which there was no leakage of aqueous humor, the anterior chamber of the eye retained its normal depth, and there was only mild swelling of the wounded cornea [63]. Histopathological examination of the patched cornea showed that the temporary repair did not trigger immune cell invasion and prevented epithelial ingrowths into the wound.

An important consideration for the use of xenoderived, decellularized cornea stromas is the heterogeneity of the decellularization process and the risk for allergic reactions to xenogeneic biomaterials (compared with allogeneic biomaterials) and pathogen transmission if tight processing controls are not adhered to [64]. China Regenerative Medicine International is moving ahead with the industrial-scale use of decellularized pig corneas as alternatives to human donor corneas [65].

Collagen-Based Implants

The 4-year follow-up of the first successful regeneration of multiple cell types in the human cornea showed that implants made from carbodiimide-cross-linked RHCIII were able to engraft stably without immune suppression [66]. Interestingly, even at 4 years after the operation, the regeneration process in several patients appeared to be ongoing. Histopathology of a graft from a patient who elected to be regrafted (owing to a problem with contact lenses needed to correct astigmatism resulting from suturing) showed that the regenerated neocornea had a structure similar to that of a normal, healthy cornea.

For corneas with inflammation or more severe pathologies such as chemical burn, however, implants made from RHCIII alone were not able to prevent neovascularization, as shown in rabbit models of alkali burn [67]. The incorporation of a network of 2-methacryloyloxyethyl phosphorylcholine (MPC), a synthetic lipid with known inflammation suppressing properties [68] properties, blocked neovascularization [69]. When the RHCII–MPC implants were grafted into three patients as tectonic patches for relief of symptoms from chronic corneal ulceration from burns and a previously rejected graft, i.e., individuals with severe pathologies causing pain, severe discomfort, and photophobia who were diagnosed to be at high risk for rejecting conventional donor corneas, RHCIII–MPC implants restored surface integrity and relieved the patients of the symptoms [69]. Two of the three patients also showed improvement in vision. A more recent clinical study of RHCIII-MPC implants as anterior lamellar grafts in six patients over an average of 24 months showed stable restoration of surface integrity, relief of symptoms in patients with ulceration, and improvement in touch sensitivity indicating regeneration of corneal nerves [70].

In Islam et al. patterning RHCIII–MPC hydrogel constructs with microcontact printing, another form of soft lithography, showed that different widths of fibronectin stripes were able to modulate cell adhesion and proliferation characteristics [71].

Peptide Analogs of Extracellular Matrix

Full-length ECM macromolecules are often hard to extract in large quantities and to purify. Animal source material has the risk of pathogen transmission and requires screening before use in humans [72]. In addition, these macromolecules are relatively difficult to functionalize compared with synthetic polymers. Hence, the development and use of short analogs of ECM components would allow for more effective processing and applications. Peptide analogs have been tested for the fabrication of scaffolds.

Peptide amphiphiles (PAs) containing the Arg–Gly–Asp (RGD) cell adhesion motif from fibronectin were developed by Miotto et al. to promote corneal regeneration (PAs) [73]. When assembled into film coatings, such PAs enhanced the adhesion, proliferation, and alignment of human corneal stromal fibroblasts while inducing the formation of three-dimensional (3D) lamellar-like stromal tissue [74]. Uznalli et al. tested PAs based on laminin peptides [75]. When used as injectable scaffolds in rabbit models of corneal wound healing, they reported an increase in keratocyte migration into the surgically induced wounds that led to enhanced stromal regeneration. In addition, PAs using matrix metalloproteinase sequences were developed that self-detach after reaching confluency [76,77]. Finally, a PA based on lumican that forms nanotape structures was reported to support human corneal fibroblasts and increase collagen production [78].

Islam et al. reported the use of a short peptide analog of collagen in fabricating corneal implants [79]. A sequence from O'Leary et al. [80] conjugated to multiarm PEG through thiol-maleimide chemistry through a "C-G" peptide linker resulted in a hybrid hydrogel consisting of the collagen-like peptide (CLP) and PEG. CLP–PEG hydrogels

were successfully tested as a proregeneration scaffold in corneas of minipigs as anterior lamellar grafts. Regeneration of corneal epithelium, stroma, and nerves were recorded over the 12-month observation period (Fig. 63.5). The timing and similarity of the regeneration were comparable to those of control implants made from RHCIII−MPC previously tested in human patients [69,70].

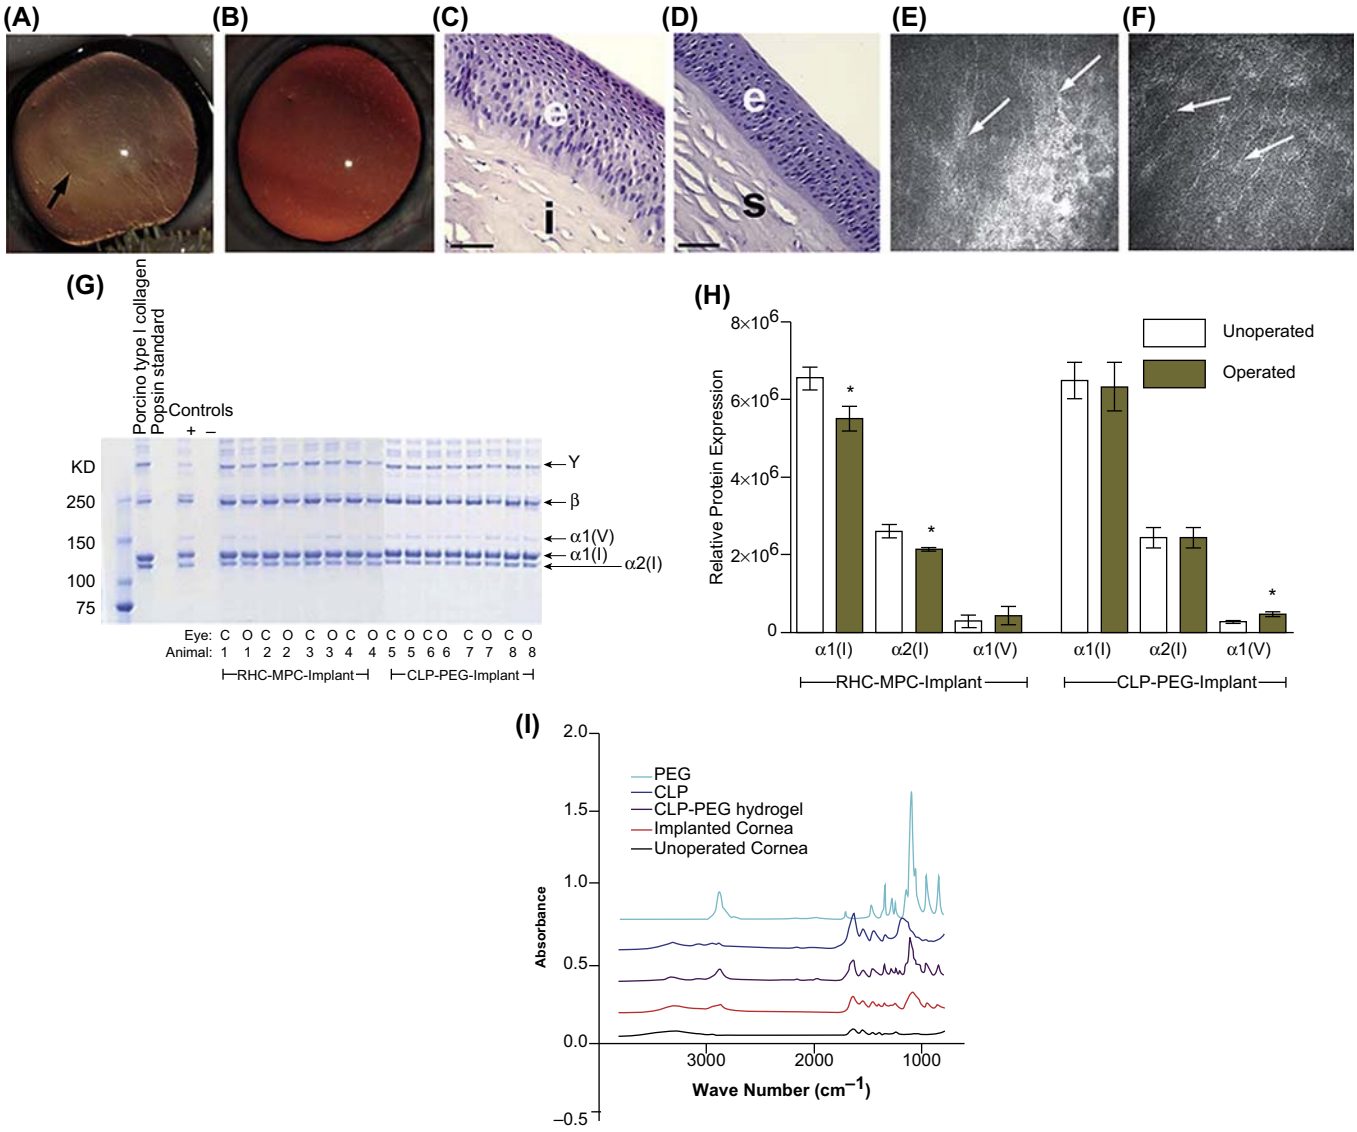

FIGURE 63.5 Postsurgical corneal regeneration at 12 months after collagen-like peptide (CLP)−polyethylene glycol (PEG) implantation. (A) Optically clear CLP−PEG implant (*arrow*) stably integrated within the pig cornea, compared with its healthy, unoperated contralateral cornea (B). Blood vessels are seen in the implanted cornea but stop at the margin of the implant. (C) Hematoxylin-eosin staining of a representative regenerated CLP−PEG neocornea compared with a healthy control cornea (D) showing similar morphology. Scale bars = 50 mm. (E) In vivo confocal microscopy shows the regenerated nerve (*arrows*) in CLP−PEG cornea that follow a parallel pattern similar to that of the unoperated cornea (F). (G) Sodium dodecyl sulfate−polyacrylamide gel electrophoresis separated proteins from the central cornea area of both implanted and control corneas show the presence of α1 and α2 chains for type I collagen (α1[I] and α2[I], respectively) and α1 chain for type V (α1[V]), in the regenerated CLP−PEG implanted cornea, similar to recombinant human collagen (RHC)-2-methacryloyloxyethyl phosphorylcholine (MPC) and the unoperated healthy control corneas. (H) Analysis of normalized, relative protein content shows that the levels of α1(I) and α2(I) in CLP−PEG implanted corneas were similar to those of the control healthy corneas (no statistical significance) whereas the level of α1(V) was higher than that of the control (*$P < 0.05$). In RHC-MPC−implanted corneas, levels of both α1(I) and α2(I) were significantly lower than in the unoperated controls (*) whereas α1(V) were similar. No differences were observed between RHCIII-MPC and CLP−PEG implants in general. (I) Fourier transform infrared analysis of regenerated pig neocorneas 12 months after grafting with CLP−PEG implants shows the presence of both CLP and PEG. *e*, epithelium; *i*, implant; *s*, stroma. *Reproduced from Islam MM, Ravichandran R, Olsen D, Ljunggren MK, Fagerholm P, Lee CJ, et al. Self-assembled collagen-like-peptide implants as alternatives to human donor corneal transplantation. RSC Adv 2016;6(61):55745−9.*

CELL–BIOMATERIAL COMPOSITES

Cell–biomaterial composites have also been proposed as artificial corneas. Collagen has been used to develop composites of epithelium and stroma from isolated stem cells, e.g., as Real Architecture for 3D Tissue equivalents. A first-in-human study is under way.

Silk, particularly the structural protein fibroin derived from the domesticated silkworm *Bombyx mori*, has been explored as potential corneal stromal scaffolds by several groups in conjunction with therapeutic stem cells. Several examples are discussed here. Groove-patterned, RGD-functionalized silk substrates have been fabricated and seeded with human corneal stromal stem cells (hCSSCs) and human corneal fibroblasts (hCFs) as potential human corneal stromas [81]. The hCSSCs effectively differentiated into stromal cells that elaborated a cornea-specific ECM to mimic human corneal stromal tissue. These constructs were 90–100 μm thick and contained ECM components such as collagen, keratin sulfate, lumican, and keratocan. On the other hand, the hCFs differentiated into myofibroblasts that deposited less-organized collagen in a pattern resembling that of corneal scar tissue. In 2016, Wang et al. reported the successful implantation of helicoidal multilamellar RDG functionalized silk fibroin films in rabbits [82]. At 180 days after the operation, the implants were transparent without signs of neovascularization or immunogenic response. Wang et al. reported the construction of a 3D corneal model using silk with endothelium, stroma, and innervation supported on a free-floating PDMS scaffold in culture media [83], which allowed an air–liquid interface. This and previous models using collagen showed that an air–liquid interface enable optimal corneal cell and nerve ingrowth in multilayered corneal constructs [84–86].

Silk fibroin has also been blended with chitosan to form scaffolds [87]. These were seeded with cornea stromal fibroblasts to form constructs that were implanted into the corneas of 15 rabbits for 12 weeks to allow regeneration. The regenerated rabbit corneas were described as being comparable to healthy, unoperated corneas, with expression of K3/12 expression in the corneal epithelial cells and vimentin in the stromal cells.

Hazra et al. reported the creation of a silk fibroin film generated from non–mulberry feeding silkworms, *Antheraea mylitta* (Am) [88]. The Am film supported the proliferation and differentiation of limbal stem cells. After implantation in rabbits, the films were clear and well-tolerated without neovascularization at 2-month follow-up.

COMPOSITE IMPLANTS INCORPORATING SPECIFIC BIOACTIVE FUNCTIONS

Infections are an important cause of vision loss and corneal blindness [2]. Hence, implants that contain nanoparticles designed to combat microorganisms or viruses have been under development. Collagen-based implants incorporating antibiotics (vancomycin) or nanoparticles releasing the antiviral drug acyclovir have been tested and found to be effective at blocking the activity of *Staphylococcus aureus* in rabbit infection models and herpes simplex virus serotype 1 (HSV-1), respectively, in vitro [89,90]. A variant on implants with antiviral properties is a collagen-based implant that incorporates corneal cells engineered by gene transfer to secrete the innate antiviral cathelicidin peptide, LL-37 [91]. The secreted LL-37 was able to inhibit viral binding and reduce the incidence of plaque formation and plaque size in vitro but was insufficient to protect cells completely from HSV-1 infection.

Silver nanoparticles (AgNPs) have been reported to have broad antiinfective and antiinflammatory properties. Collagen implants incorporating AgNPs have also been developed, along with a strategy to prestabilize and incorporate AgNPs with different colors into collagen matrices to fabricate corneal implants of different colors and antimicrobial properties [92].

CHALLENGES

From a regulatory perspective, regenerative implants and grafts in the cornea are primarily classified as medical devices or ATMPs, respectively. The most straightforward type of implant to manufacture is a fully synthetic scaffold, especially one that is thermostable and can be sterilized by γ-irradiation or electron beam. These scaffolds do not have to contend with rules concerning xenografts. Scaffold derived from animals, either through decellularization or by isolating structural proteins, requires more testing to comply with requirements to prevent pathogen transmission. The most complex regulatory submissions are cell and scaffold composites, which are regulated under the ATMP guidelines. Pellegrini et al. successfully initiated the first application for an ATMP

product in Europe, but this remains an area in which there are many safety considerations and few examples to guide both the applicant and the regulatory agencies [93]. It will likely remain incumbent on the applicants to demonstrate that their product is effective, reproducible, and sterile. Extensive risk analysis of all phases of the production and implantation of an ATMP will be required to generate sufficient confidence that the product will be safe for an extended market.

CONCLUSIONS AND FUTURE PERSPECTIVE

There is a wide variety of solutions for regenerating the cornea. Most recently, 3D bioprinting was used to print corneal stromas complete with cells [94]. Progress has been made in cell-based therapies, ECM-based scaffolds, nanomaterials, and combinations of advancements in cell and biomaterials. The challenge to replace human donor corneas and KPros as the current standard of care remains complex. Advances in cell-based therapies have significantly improved the probable efficacy of corneal autografts, and biomaterials have improved the structural properties of ECM-based scaffolds; however, no single therapy has emerged as a stable, affordable solution for the many causes of corneal damage. It is possible that in the future, biomaterial scaffolds may be combined with surgical techniques such as SLET or cultured cell solutions to customize commercially available scaffolds for individual patients. Nanomedicine also opens the door to the possibility of incorporating therapies for eye infections directly into surgical solutions, which may speed postoperative recovery and prevent latent infection recurrence in patients with corneal blindness caused by infections such as HSV.

Alimentary Tract

Richard M. Day

University College London, London, United Kingdom

INTRODUCTION

The alimentary tract is a hollow organ that starts at the mouth and terminates at the anus. It conducts a number of highly complex and diverse functions that are regulated by distinct cellular and functional differences along the tract length, which allow it to provide the body with nutrients, water, and electrolytes. To achieve this, it is essential that the lumenal contents be propelled along at a rate that will allow efficient digestion and absorption to take place while also enabling waste products to be stored and excreted in a controlled manner. In addition to this, an important symbiotic relationship exists between bacterial species that colonize the alimentary tract of the host [1]. Therefore, the surface of the alimentary tract must also provide a barrier against unwanted entry of organisms and toxins. If the barrier function is breached, specialized cells and tissues within the gut wall provide an important component of the immune system to protect the host.

Dysfunction of the alimentary tract may result from a variety of congenital and acquired conditions that can affect any of its physiological functions. This chapter will discuss knowledge regarding tissue engineering different regions of the alimentary tract, highlighting successful strategies as well as failures and some obstacles that have yet to be overcome in this rapidly evolving field.

ESOPHAGUS

The esophagus is a muscular tube measuring approximately 25 cm in length in adult humans. It functions primarily as a conduit to connect the pharynx with the stomach, providing coordinated peristaltic contractions in response to swallowing to propel food into the stomach. The esophageal mucosa is lined by stratified, squamous, nonkeratinized epithelium. The submucosa contains muscle, nerve, blood vessels, lymphatics, and mucosal glands. The muscularis has two layers consisting of an outer longitudinal layer and an inner circular layer. Both layers consist of striated muscle in the upper portion and smooth muscle in the lower third, continuous with the muscle layers of the stomach. The myenteric plexus exists between the muscle layers. The esophagus has no serosa and its vascular supply is less extensive compared with the intraabdominal portions of the gut. Sphincters at the upper and lower ends of the esophagus ensure food is transferred appropriately between it and the pharynx or stomach. The upper esophageal sphincter, found in the upper 3–4 cm of the esophagus, and the lower esophageal sphincter, located 2–5 cm above the gastroesophageal junction, remain tonically and strongly constricted to prevent air from entering the esophagus during respiration between swallowing and reflux of stomach contents into the esophagus between peristaltic waves, respectively. Regenerative medicine techniques are being explored for a number of conditions affecting the esophagus.

Gastroesophageal reflux disease is one of the most common disorders affecting the gastrointestinal tract, resulting from lower esophageal sphincter incompetence. Medical therapy is generally safe and effective in most cases, but for patients for whom this option fails, antireflux surgery or endoscopic procedures that involve injecting bulking materials may be used in an attempt to narrow the lumen of the lower esophagus. Attempts have been made to restore physiological function of the esophagus using regenerative medicine. The feasibility of using a suspension of muscle precursor cells to restore gastroesophageal function in a model of gastroesophageal reflux disease has been explored

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00064-3

[2]. Muscle precursor cells isolated from expanded satellite cells derived from skeletal muscle fibres were injected into the gastroesophageal junction after cryoinjury. Histology showed an increase in myofibers at the site of injection that had fused into newly formed or preexisting myofibers. The need remains to demonstrate that cells injected in this manner can contribute to functional improvement of damaged esophageal sphincter, but the feasibility of using this approach offers a promising therapy for this common condition.

Esophageal reconstruction is a requirement for congenital esophageal atresia, burns, malignancy, or severe benign disease. Surgical techniques include stretching, circular myotomy, and interposition of stomach or colon, but these approaches are frequently associated with complications including stricture, leakage, elongation, and gastroesophageal reflux. An artificial esophageal construct has been sought for many years. To be effective, the construct must be implantable without rejection and biocompatible to support appropriate tissue growth, and retain biomechanical characteristics of native esophageal tissue, i.e., be soft and elastomeric while maintaining a tubular structure when implanted in vivo.

Attempts to tissue engineer replacement esophageal tissue have included both patch and circumferential implantation of constructs composed of synthetic as well as natural scaffold materials. A full-length of tissue engineered esophagus has not been produced, but a number of incremental advances toward this goal have been achieved.

Early attempts exploring the use of a nondegradable prosthetic tubes in canine models were of limited success [3]. Surgical reconstruction techniques of the esophagus after resection for structures and malignancies have involved the transfer of small segments or patches of skin and other tissues on a vascular pedicle, with moderate results [4–6]. Tissue engineered sheets of autologous oral mucosal epithelial cells were successfully transplanted by endoscopy in a canine model [7]. The transplanted sheets adhered to the underlying esophageal muscle layers created by endoscopic submucosal dissection and enhanced wound healing without postoperative stenosis. Because the interaction between the epithelium and mesenchymal cells is thought to reduce fibrosis and scarring that cause stenosis, the investigators suggested that this approach may offer a novel therapy to reduce scarring and prevent painful constriction that can be associated with endoscopic submucosal dissection for the removal of large esophageal cancers.

A variety of scaffold materials to support cell and tissue esophageal constructs have been investigated [8–12]. Acellular scaffolds composed of extracellular matrix components have been explored primarily because they are assumed to be advantageous over synthetic scaffold materials owing to their ability to promote cell attachment, growth, and cell–cell signaling among different tissue components. Decellularized esophageal tissue can be produced via repeated detergent-enzymatic treatment that results in a scaffold with biocompatibility suitable for the growth of esophageal epithelial cells [13,14]. Based on these preclinical findings, it has been envisaged that human donor esophageal tissue might one day be used in a manner similar to that described for the tissue engineering of human airway tissue [15].

Scaffolds derived from small intestinal submucosa (SIS) have been widely investigated for tissue engineering replacement esophageal constructs. SIS consists of extracellular matrix material harvested from porcine small intestine and has been used extensively in tissue engineering experiments since it was originally described by Matsumoto and colleagues in 1966 for use in large vein replacement in dogs [16–20]. It has been successfully applied to regenerative medicine applications in humans, including repair of hernias, diaphragms, and tympanic membranes, and for large wound coverage [21–24].

The success with using SIS as a scaffold to promote tissue regeneration appears to relate to the retention of collagen (types I, II, and V), growth factors (transforming growth factor, fibroblast growth factor 2, and vascular endothelial growth factor), glycosaminoglycans (hyaluronic acid, chondroitin sulfate, and heparin sulfate), proteoglycans, and glycoproteins (fibronectin) during the fabrication process [25,26]. It is thought that the resulting scaffold has a composition closely resembling native extracellular matrix, which makes it ideally suited for the attachment and growth of new tissue.

The extent of circumferential replacement of esophageal tissue appears to have an impact on the outcome of attempts to tissue engineer esophagus, with patches producing better results compared with tubular segments. Lopes and colleagues successfully used SIS patches to repair defects to the anterior wall of cervical or abdominal esophagus in rats without signs of stenosis over 150 days [27]. Likewise, Badylak and colleagues used SIS patches (or urinary bladder submucosa) to repair esophageal defects created in dogs without clinical signs of esophageal dysfunction [28]. However, the latter study reported signs of stenosis in dogs receiving complete circumferential segmental grafts of SIS [10]. Doede and colleagues reported similar findings, with severe stenosis occurring when relatively short tubular lengths (4 cm) of SIS were used in alloplastic esophageal replacement in piglets [28]. Thus, although scaffolds consisting of only extracellular matrix have shown the capacity to promote cell growth in vitro and tissue regeneration of patch defects in vivo, replacement of circumferential defects without stricture

formation remains difficult to achieve. The outcome of repairing full circumferential defects using SIS may be improved by optimizing the poor mechanical properties of the scaffold material. To address this, hybrid scaffolds composed of SIS combined with synthetic polyesters (poly[3-hydroxybutyrate-*co*-3-hydroxyhexanoate] and poly [lactide-*co*-glycolide]) were assessed for their feasibility as a tissue engineering scaffold for esophageal constructs [29]. Improved biocompatibility was observed with the hybrid scaffold compared with scaffolds produced from the synthetic material alone.

Epithelial-mesenchymal cell signaling is likely to have an important role in facilitating reconstruction of the esophageal construct after implantation. A similar effect has been shown in bladder reconstruction, in which the presence of urothelium led to infiltration of fibroblasts into acellular matrices and apparent transdifferentiation into a smooth muscle phenotype [30]. Signaling from the mesenchymal cell population appears to be equally important in promoting growth of overlying epithelium [31]. Complete reepithelialization with little inflammatory response and evidence of skeletal muscle regeneration was observed when bone marrow mesenchymal stem cells were seeded onto the SIS scaffold implanted in a canine model [32]. Moreover, the presence of epithelial-mesenchymal signaling may prevent stricture formation in an esophageal construct, a problem frequently encountered with many of the scaffolds tested [10,33]. Similar signaling properties have been demonstrated in bladder reconstruction in which acellular collagen scaffolds seeded with urothelium and smooth muscle cells prevented tissue contraction [34]. Likewise, the interaction of muscle with the ablumenal surface of esophageal scaffolds at the time of implantation of partially circumferential grafts appears to have accounted for the reduced stricture formation observed in a canine model of esophageal reconstruction described by Badylak and colleagues [11]. It can be concluded from these observations that careful consideration of the order in which cells are added to the tissue engineered construct will improve the likelihood of achieving a successful outcome.

In addition to SIS, gastric acellular matrix was used as scaffold by Urita and colleagues to regenerate esophagus in a rat model [35]. Grafts of gastric acellular matrix were used to patch defects in the abdominal esophagus and animals were killed at points between 1 week and 18 months. Although regeneration of the muscle layer or lamina muscularis did not occur, there was no evidence of stenosis or dilatation at the graft site. The matrix obtained in this study was from whole stomachs, but the investigators suggested that gastric acellular matrix may provide an autologous source of naturally derived extracellular matrix scaffold in a clinical setting, because the portion of stomach destroyed to obtain the matrix is minimal. It remains to be seen whether this approach is feasible in a larger animal model, but the use of autologous acellular matrix scaffolds avoids concerns related to the use of xenogenic scaffold materials such as porcine-derived SIS. In addition to the risk of transmitting viral pathogens and prions, cultural and religious beliefs may need to be considered when using acellular matrix scaffolds derived from certain species. In addition to SIS, other biological materials have been investigated for esophageal tissue engineering. Extracellular matrix scaffold has been generated from ovine forestomach tissue [36]. Moving away from mammalian sources of scaffold material, Franck and colleagues reported that a bilayer silk fibroin matrix composed of porous silk fibroin foam annealed to a homogeneous silk fibroin film exhibited improved cell attachment and spontaneous differentiation of esophageal epithelial cells toward a suprabasal cell lineage compared with SIS scaffolds [37].

Although the esophagus can be considered one of the less complex regions in the alimentary tract, several significant hurdles still need to be overcome before tissue engineering and clinical replacement of full-length esophageal segments become a clinical reality in humans. Unlike patch grafts, replacement of longer lengths of tissue will be unable to rely on adjacent esophagus to cover the surface area of larger scaffolds via guided tissue regeneration. Improved methods from isolating and expanding the different esophageal cell populations will therefore be a prerequisite for successful tissue engineering of larger constructs. Kofler and colleagues identified subsets of ovine esophageal epithelial cells that may help achieve this [38]. PCK-26−positive esophagus epithelial cells demonstrated high proliferative capacity and uniform coverage on collagen scaffolds, which the investigators suggested could have an important role for successfully tissue engineering esophagus. Further refinement of the scaffold material may also improve epithelialization. For example, the inclusion of copper into acellular porcine SIS scaffolds was reported to enhance epithelialization of the scaffold in a canine model of esophageal repair [39].

Failure to regenerate a functioning muscle layer may not be problematic for short or noncircumferential grafts, but for longer lengths of esophagus the presence of an innervated functional muscle layer will be essential. A retrospective study investigating the temporal appearance and spatial distribution of nervous tissue in a canine model of esophageal reconstruction using porcine urinary bladder submucosa showed the presence of nerve tissue within sites of the remodeling scaffold [40]. Although the study was unable to demonstrate whether the nervous tissue was functional or to distinguish among the various subsets of neurons, it opens the possibility of using similar models to identify mechanisms that promote innervation that will facilitate the tissue engineering of functional tissue. Peristalsis of food also depends on the correct orientation of muscle fibers in the wall of the alimentary tract.

To address this, promising results have been obtained with orienting smooth muscle tissue on unidirectional scaffolds for tissue engineered esophagus in rats [41]. Oriented stands of smooth muscle mimicking the configurations found in the native organ were engineered when cells were seeded onto unidirectional scaffolds. These were assembled with esophageal epithelium to create a hybrid approach.

STOMACH

Gastric disease affects approximately 10% of the world's population and includes gastritis, peptic ulcers, and gastric cancer. Insufficient stomach mass, which may arise from gastrectomy or congenital microgastria, is associated with increased patient morbidity.

The stomach functions as a digestive organ and reservoir and is anatomically divided into four regions (cardiac, fundus, corpus, and pylorus). The gastric glands are tubular structures whose cellular composition and function are specialized according to each region of the stomach. Such specialization, combined with the harsh environment created by the lumenal contents, makes tissue engineering of the stomach as whole challenging. The size and shape of the stomach vary, depending on its contents. The stomach wall contains outer longitudinal and inner circular layers of smooth muscle, with an innermost layer of oblique muscle fibers. These layers facilitate important functions including storage of ingested food in the stomach until it can be accommodated in the lower portion of the alimentary tract, mixing of the food to form chyme, and regulation of food transit into the small intestine at an optimal rate for digestion and absorption. Stomach emptying is controlled by the gastric food volume and the release of the hormone gastrin, as well as feedback signals from the duodenum.

Tissue engineered neostomach constructs to patch partial gastrectomy have been explored in a canine model using a two-part sheet composed of an outer layer of collagen sponge and a temporary inner silicone sheet to protect the collagen from degradation by the acidic stomach juices and provide mechanical support [42]. After removal of the silicone sheet at 4 weeks, evidence of stomach regeneration was observed and complete coverage of the scaffold had occurred by 16 weeks, confirmed by the presence of mucosa and a thin muscular layer. Acid production capacity was present in the regenerated stomach wall but the contractile response to acetylcholine was poor [43]. Technical difficulties associated with suturing and endoscopic removal of the silicone sheet in this model were addressed by creating a tissue engineered sheet without silicone that had sufficient strength to allow suturing and resist anastomotic dehiscence [44]. The silicone sheet was replaced by a biodegradable copolymer of poly(D,L-lactide) and ε-caprolactone (PDLCL) on the mucosal side of the collagen scaffold, both of which were completely absorbed at 16 weeks' implantation. Although regeneration of the stomach mucosa was observed, the replacement of the silicone sheet with PDLCL did not provide sufficient mechanical strength to prevent significant shrinkage of the scaffold.

The feasibility of creating new stomach tissue using stomach-derived organoid units harvested from neonatal and adult rats has been investigated [45]. The organoid units were seeded onto polymer scaffold tubes to form constructs that were implanted into the omentum of adult syngeneic rats. At 4 weeks, the construct was anastomosed to the small intestine. Histology of the tissue engineered stomach tissue was similar to native stomach, with gastric pits, squamous epithelium, and positive staining for α-actin smooth muscle in the muscularis and gastrin indicating the presence of a well-developed gastric epithelium. The same approach has been used to tissue engineer stomach neoconstructs in an autologous large animal model [46].

A limitation of approaches using autologous or allogenic organoid units is the tissue source. To address this, three-dimensional gastric organoid tissue from human pluripotent stem cells (PSCs) have been generated by temporal manipulation of the fibroblast growth, WNT, bone morphogenetic protein, retinoic acid and epidermal growth factor (EGF) signaling pathways [47]. The primitive gastric organoids exhibited molecular and morphogenetic developmental stages similar to those observed in the developing antrum of murine stomach. The proliferative zones contained $LGR5^{+}$ cells, mucus-secreting antral and pylorus cells, and gastric endocrine cells; however, the acid secreting (corpus) region was not developed in this model. A critical factor for the development of all the stomach regions from stem cells appears to be the Barx-1 gene [48]. Noguchi and colleagues demonstrated Barx-1—inducing culture conditions generated spheroids of fully functional stomach-like tissue in vitro from mouse embryonic stem cells. The spheroids were able to develop into functional corpus and antrum tissue that secreted pepsinogen and acid.

The relevance of mesenchymal stem cells to optimize and condition the cellular milieu within the tissue engineered construct has also been shown with stomach tissue engineering. Tissue regeneration after the creation of a full-thickness stomach defect in rats was enhanced when SIS scaffolds were used in conjunction with mesenchymal

stem cells [49]. Whereas contractility in response to a muscarinic receptor agonist, a nitric oxide precursor, or electrical field stimulation was observed in all groups, smooth muscle layers were both longer and better structured compared with SIS grafts not seeded with mesenchymal stem cells.

SMALL INTESTINE

The small intestine in adults measures approximately 6 m in length from the duodenojejunal flexure to the ileocecal valve. Its primary function is absorption of nutrients from the lumen, a process facilitated by specialized mucosal surface features (folds of Kerckring, villi, and microvilli) that increase the absorptive surface area about 600-fold to approximately 250 m^2. The mucosa is lined with epithelium overlying lamina propria containing vascular and reticular stroma, large aggregates of lymphoid tissue called Peyer patches, and a strip of smooth muscle called the muscularis mucosa. Intestinal stem cells reside at the base of epithelial invaginations into the mucosa called crypts and develop into all four lineages of epithelial cells that line the intestine [50]. Epithelial cells migrate along the crypt–villus axis, differentiating and maturing toward the lumen of the bowel where they become senescent over the course of a few days and are shed into the lumen of the bowel.

A lack of intestinal epithelial stem cell markers has hampered identification and isolation of pure populations of cells for regenerative medicine purposes. Studies have shown that Musashi-1 may be a marker of intestinal stem cells [51,52], and a Sox9-(enhanced green fluorescent protein [EGFP]) mouse model has been used to enrich multipotent intestinal epithelial stem cells [53]. Using a culture system that mimics the native intestinal epithelial stem cell niche, these cells are capable of generating "organoids" that contain all four epithelial cell types of the small intestinal epithelium. Furthermore, Sox9-EGFP multipotent intestinal epithelial stem cells express CD24, which may facilitate their enrichment by fluorescence activated cell sorting using widely available antibodies.

The submucosa consists of fibrous connective tissue that supplies blood and lymphatic vessels to the mucosa. The muscularis propria consists of an inner layer of circular muscle and an outer longitudinal muscle layer. The muscularis propria is covered by the adventitia, a layer of loose connective tissue, and the serosa, a mesothelial lining of peritoneum.

The function of the small intestine cannot be replaced by transposing another part of the gut. Intestinal ischemia and bowel resection for tumors and inflammatory bowel disease can result in short bowel syndrome when more than 75% of the small intestine is lost. Short bowel syndrome is often associated with intestinal failure and the requirement of lifelong nutritional support (total parenteral nutrition), which is frequently accompanied by severe complications such as liver failure, line sepsis, and poor long-term survival rates. The length of residual intestine is critical for these patients; thus, techniques for increasing absorptive surface area have been sought for many years. Surgical options for increasing the absorptive surface or slowing the transit time to enhance absorption have been reported, but these approaches require longer residual intestinal segments and most have only limited long-term clinical success [54–57]. Small bowel transplantation is a viable option for some patients, but this procedure has limitations including the availability of donor tissue, the need for long-term immunosuppression, graft versus host disease, and potential posttransplant lymphoproliferative disorder [58].

The amount of small bowel required for successful nutritional rehabilitation depends on factors including the patient's age, the amount of small bowel present, the presence or absence of the ileocecal valve, and the amount of large bowel present. Therefore, small bowel elongation of just a few centimeters could allow many patients to become independent of total parenteral nutrition. Distraction enterogenesis has been devised as a novel method to increase intestinal length by applying linearly directed force, resulting in increased surface area and epithelial cell proliferation [59,60]. Devices used for distraction enterogenesis include extralumenal, radially self-expanding shape memory polymer cylinders [61]; biodegradable springs composed of polycaprolactone created to lengthen intestinal segments mechanically while avoiding the need for subsequent retrieval [62]; and double-balloon catheter devices [63]. Biological mechanisms that account for distraction enterogenesis are unknown [64], but the effect can be enhanced by adding exogenous glucagon-like peptide 2 [65] or by codelivering microspheres that provide sustained release of basic fibroblast growth factor (bFGF), which results in improved vascularity [66]. The use of growth factor–embedded scaffold materials is an effective method for improving the short half-lives of growth factors. An example used to achieve growth factor–embedded scaffolds for distraction enterogenesis include subcritical CO_2 to embed heparin-binding EGF-like growth factor into polyglycolic acid/poly-L-lactic acid scaffolds [67]. Local delivery of the trophic growth factor improved structure of the tissue engineered intestine.

Several different approaches, using either guided tissue regeneration or tissue-engineering neotissue constructs, were taken to regenerate small intestine that used combinations of various synthetic and natural scaffold materials, different cell types, and surgical procedures.

Early attempts to patch bowel defects using the serosal surface of another piece of intestine resulted in its being covered with regenerated mucosa [68,69]. This paved the way for other researchers to investigate a variety of scaffold materials, such as polytetrafluoroethylene tubing, for the ingrowth of neointestine via guided tissue regeneration [70]. The use of nonresorbable materials for studying intestinal morphogenesis and regeneration continues to be interesting [71], but the use of resorbable scaffold biomaterials for intestinal tissue engineering has become the predominant approach.

Chen and Badylak used SIS to patch partial defects in the small bowel wall of a canine model [72]. Histological evaluation showed the presence of mucosa, varying amounts of smooth muscle, sheets of collagen, and an outer serosal layer. However, in the same study, attempts to use a tubular configuration of SIS were unsuccessful. The tubes either leaked or became obstructed; this occurred primarily because the SIS was unable to maintain lumenal patency when exposed to the moist lumenal contents. Similar limitations with the mechanical integrity of the scaffold material were reported by Pahari and colleagues, who used guided tissue regeneration to create a segment of new intestine in rats using acellular dermal matrix (AlloDerm) rolled into tubes [73]. Building on the work, elongation of the intestine was achieved using an acellular biologic scaffold to create autologous bioartificial intestinal segments (BIS) [74]. The BIS were demonstrated to have functional absorptive characteristics [75]. Other approaches using biologically derived scaffolds included the use of allogenic aortic graft segments interposed in an excluded small bowel segment wrapped in omentum, which resulted in intestinal-like wall transformation of the aortic graft [76].

In an attempt to maintain an open lumen in the tissue engineered intestine, Hori and colleagues reported that scaffolds composed of sheets of acellular collagen sponge wrapped on a temporary silicone stent and covered with omentum guided tissue regeneration of almost all layers of the gastrointestinal tract in a canine model, but only a thin muscularis mucosa was present and the muscularis propria was absent [77]. The same group explored the addition of mesenchymal stem cells seeded onto a collagen scaffold, which it was hypothesized might differentiate "site-specifically" into muscle cells and regenerate the muscle layer [78]. Intestinal regeneration occurred but muscle regeneration in an organized manner was not observed. Wang and colleagues used a rat model to evaluate the feasibility of regenerating tubular intestine using sheets of rat-derived SIS wrapped around a silicone stent [79]. The tubular graft was interposed in the middle of a Thiry-Vella loop (a defunctionalized segment of ileum that is brought out as a double ileostomy) in Lewis rats. The silicone stent was left in place for 3 weeks to maintain lumenal patency during tissue regeneration. At 4 weeks, an epithelial layer had begun to form and completely covered the lumenal surface by 12 weeks. The neomucosa had a typical morphology containing goblet cells, Paneth cells, enterocytes, and enteroendocrine cells. Although the regenerated bowel contained bundles of smooth muscle-like cells, especially near the sites of anastomosis, the quantity and organization of the muscle layer differed from those found in native small intestine; they were predominantly circular muscle with no longitudinal muscle. The use of a Thiry-Vella loop in the model created by Wang may have facilitated mucosal development in the neointestine by protecting it from alimentary transit and creating an isolated environment that avoided the food stream and digestive enzymes. Lee and colleagues observed only minimal intestinal regeneration in a rat model used to evaluate SIS scaffolds. From this, they concluded that SIS scaffolds alone were insufficient to regenerate small intestine and suggested that the use of appropriate progenitor cells is probably necessary to facilitate the regeneration of small intestine [80].

Many of the studies reporting intestinal tissue engineering strategies are based on methodologies used in the pioneering work conducted by Vacanti and colleagues in the 1980s and 1990s that combined intestinal tissue with scaffolds [81]. Important to these studies were previous investigations by Tait and colleagues that showed intestinal tissue could be separated by enzymatic digestion to produce organoid units [82]. These clusters of cells contained all of the elements of the intestinal mucosa including stem cells and mesenchyme, which could be used to regenerate intestinal neomucosa expressing digestive enzyme activities and glucose transport capacity similar to those of age-matched native intestinal mucosa. When organoid units were subcutaneously grafted, they displayed different epithelial populations consistent with epithelial transit amplifying and stem cell populations [83].

Subsequent studies demonstrated that transplanting organoid units onto biodegradable polymer scaffolds followed by implantation into the omentum of syngeneic adult animals resulted in the formation of neointestinal cysts attached to a vascular pedicle with mucosa facing a lumen that contained mucoid material [84]. The mucosa of the neointestine created with this technique showed morphological similarities to native intestine, including the formation of a primitive crypt–villus axis lined with columnar epithelial cells and goblet cells and a polarized epithelium with the brush border enzyme sucrase expressed at the apical surface and laminin at the basolateral surface, and

transepithelial resistance similar to that of native intestine [85]. For all of these promising findings, it is essential that the tissue engineered construct facilitates nutrient absorption. Anastomosis of the tissue engineered cyst-like structures to native jejunum in adult rats provided continuity with the native intestinal tract, which resulted in a more developed neomucosa containing significant increases in villus number, villus height, and surface length of the cyst compared with nonanastomosed cysts [86]. The investigators postulated that anastomosis may have facilitated neomucosal growth in the cysts by draining lumenal contents or via stimulatory factors present in the lumenal contents of the native intestine in continuity with the neomucosa. The anastomosed neointestine was also shown to express of Na^+-dependent glucose transporter SGLT1 [87] and a mucosal immune system with intraepithelial and lamina propria immune cells similar to that of native jejunum [88]. The native small intestine has a great adaptive and compensatory capacity in response to massive small bowel resection, which is considered to be controlled by humoral factors. The mucosa of the neointestine was also shown to possess this adaptive capacity after massive small bowel resection, resulting in a significant regenerative stimulus for the morphogenesis and differentiation of the tissue engineered intestine [89]. An improvement in intestinal function, capable of facilitating patient recovery after massive small bowel resection, was putatively demonstrated when cysts containing neointestine were anastomosed to native small bowel during an 85% enterectomy in rats [90]. The study showed that animals with tissue engineered intestine returned to their preoperative weight more rapidly compared with animals undergoing small bowel resection alone. These findings significant because they are the first to suggest that tissue engineered intestine may provide a therapeutic intervention for managing patients with short bowel syndrome. Although it is tempting to speculate that the observed effects resulted from neointestine restoring absorptive function after small bowel resection, the mechanism underlying the beneficial effects remain uncertain [91]. It has been postulated that the amount of intestine replaced by the anastomosed neointestine (approximately 4 cm) was far shorter than the amount resected, probably approximately 10% of the original length and is unlikely to have added sufficient mucosal surface area to account for the increase in postoperative weight observed. Furthermore, the improved nutrition may have resulted from the tissue engineered intestine slowing intestinal transit, leading to increased absorption and weight gain, a principle that could be achieved with simpler remedial surgical procedures [91]. To gain a better understanding of the mechanisms underlying the formation of neointestine, the model has been transitioned from a rat to a mouse model, which has enabled the use of transgenic tools for lineage tracing. This demonstrated that epithelium, muscularis, nerves, and blood vessels are derived from multicellular organoid units derived from donor small intestines of transgenic mice [92]. Studies also investigated the effects of donor age and region where intestine crypts are harvested [93]. In mice, higher efficiency of enterosphere formation was observed with crypts harvested from tissue collected from the proximal small intestine, and also in young mice.

A significant drawback with this approach is the need for large amounts of donor tissue to harvest a sufficient number of organoid units to seed scaffolds that will generate a relatively short length of neointestine, which is likely to offer only limited therapeutic value [91]. A solution might exist with the use of yet unexplored alternative sources of intestinal epithelial stem cells, such as bone marrow–derived cells and PSCs circulating in the peripheral blood [94,95]. New methods for generating organoid units that address the limitations of harvesting donor intestinal tissue have also been explored. McCracken and colleagues reported a protocol for differentiating human PSCs into three-dimensional (3D) human intestinal tissue, developing into intestinal tissue containing all major types of intestinal epithelial cells and mesenchymal components [96].

To address challenges associated with the limited availability of autologous donor intestine in patients with short bowel syndrome, protocols exist for generating enteroids from minimal quantities of starting material [97]. Also, refinement of the harvested donor stem cells or manipulation of growth factors in the local environment may provide a method for enhancing the quality of the neointestine. The morphology of tissue engineered intestine was improved by seeding scaffolds with intestinal stem cell–enriched crypts [98]. Greater circumferential mucosal engraftment and an average villous height closer to native intestine were achieved with the purified crypts collected using a filtration-based system compared with scaffolds seeded with a villous fraction containing differentiated epithelial cells. Likewise, manipulation of the expression of growth factors that control the growth and differentiation of the intestine during development might provide a valuable approach for improving the formation of tissue engineered small intestine. Tissue engineered organoid units overexpressing fibroblast growth factor 10 resulted in larger tissue engineered constructs, with longer villi and a greater proportion of proliferating epithelial cells [99].

Organoid units derived from human postnatal, small bowel resection specimens, were seeded onto biodegradable scaffolds and implanted into nonobese diabetic/severe combined immunodeficiency γ chain–deficient mice [100]. After 4 weeks, the tissue engineered small intestine contained the four major types of differentiated intestinal epithelial cells, muscularis, and intestinal subepithelial myofibroblasts.

Bone marrow–derived epithelial cell adhesion molecule–positive, and CD133-positive cells were used to recellularize human cadaveric small bowel specimens that had been chemically decellularized [101]. After recellularization, the tissue engineered small intestine contained mucin-positive goblet cells, cytokeratin 18–positive epithelial cells in villi, and smooth muscle cells in muscularis mucosa.

Cryopreservation of the organoid units could be used to delay production of tissue engineered small intestine, a procedure that could be particularly helpful in patients who are critically ill and require delayed autologous implantation of a tissue engineered construct. Cryopreservation using vitrification led to higher viability of organoid units compared with standard snap-freezing; the thawed organoid units were capable of producing tissue engineered small intestine [102].

Another important aspect of intestinal tissue engineering is the ability for the neointestine to repair, regenerate, and remodel. The latter is particularly important when considering the use of engineered intestinal tissue for children, in whom the length of the intestine increases significantly during development. The trophic effects of glucagon-like peptide-2 (GLP-2) have been evaluated on neointestinal growth [103]. GLP-2 is an endogenous regulatory peptide with potent trophic effects on intestinal mucosal growth and an ability to modulate the expression of Na^+-glucose cotransporter 1 (SGLT1). Adult rats with neointestinal implants that received subcutaneous injections of a GLP-2 analog twice daily for 10 days had enhanced mucosal growth and increased expression of SGLT1 compared with control rats. These findings indicate that the neointestine is capable of responding to external regulator signals that could be used to further expand the surface of the neointestine.

There is a lack of preclinical models for observing intestinal tissue regeneration and improved intestinal function on a scale that can be feasibly translated into humans. Intestinal tissue engineering has been investigated using a large-animal model designed to emulate conditions required for human therapy [46]. Tissue scaffolds were seeded with organoid units isolated from the jejunum of 6-week-old piglets and implanted into the omentum of that animal. However, the study provided only limited information on issues related to the scaling-up of a technique for use in humans because the neointestine was not anastomosed to the native intestine and the scaffolds used were similar in size to those used in previous small-animal models.

A functional mucosal barrier is an essential element of intestinal tissue engineering for which scalability also needs to be considered. Although transepithelial resistance of the mucosa created in neointestinal cysts is similar to that of native intestine [85], the creation of larger intestinal constructs will require rapid coverage of the scaffold surface to ensure the barrier function is established. This process might be accelerated by including materials in the scaffold that promote epithelial cell spreading. Yoshida and colleagues investigated the effect of transplanting organoid units onto denuded colonic mucosa of syngeneic recipient rats [104]. The addition of bFGF facilitated neomucosal growth and improved restoration of intestinal epithelial cell coverage over the denuded mucosa compared with the control group. Other approaches might include including inorganic materials into hybrid scaffolds, such as bioactive glass, shown to increase epithelial cell migration via bFGF in an indirect manner [105]. As well as stimulating regeneration of the mucosa, delivery of growth factors may provide a strategy for regenerating the muscularis propria. Local delivery of bFGF from scaffolds, via either incorporation into the collagen coating of scaffolds or encapsulation into microspheres, was also shown to increase the engraftment and density of seeded smooth muscle cells and blood vessel formation after 28 days' implantation in the omentum of rats [106].

Rapid vascular in growth into the tissue engineered intestine will be essential to maintain the viability and engraftment of cells seeded on the scaffold. Gardner-Thorpe and colleagues observed that tissue engineered intestine exhibited lower levels of bFGF and vascular endothelial growth factor (VEGF) and a fixed capillary density compared with native juvenile bowel [107]. This led that group to evaluate a polymeric microsphere system to deliver encapsulated VEGF and stimulate angiogenesis in the maturing neointestine [108]. Capillary density in the muscular and connective tissue layers was significantly increased in the presence of microspheres containing VEGF, as were the size and weight of the constructs. Interestingly, the rate of epithelial cell proliferation also increased in constructs implanted with VEGF-releasing microspheres, possibly related to the improved vascularization of the construct providing greater nutritional support to the rapidly proliferating epithelium. The need for neovascularization is not restricted to tissue engineering tissues of the alimentary tract. A number of different approaches are being used to tackle this problem [109]. It remains to be seen whether any of these approaches will provide a sufficient stimulus to promote arteriogenesis required for sufficient vascularization of larger tissue constructs. Furthermore, a functional lymphatic system in the neointestine is essential to establish normal nutrient absorption, fluid homeostasis, and immunological functions. Lymphangiogenesis is reported to occur in the neointestine created by the organoid unit-cyst model in rats [110]. Although angiogenesis has been demonstrated in intestinal tissue engineering using small-animal models, it is not certain whether the provision of thin-walled endothelium lined structures will be sufficient to support the functionality of a larger tissue construct. Therefore,

techniques to promote the formation of medium-sized blood vessels via arteriogenesis are likely to be required to facilitate complete integration of large-scale intestinal constructs with a functional capacity. The small bowel has an extensive vascular system fed by arcades of arteries in the mesentery derived from the superior mesenteric artery. Translation of the existing tissue engineering models to a scale suitable for implantation into humans will require the formation of a similar vascular system consisting of medium-sized blood vessels to maintain viability of a larger tissue construct as well as enable absorption of fluid and dissolved nutrient material from the intestine into the portal blood, which will require a vascular system similar to that found in native intestine. One approach to enabling immediate perfusion of the tissue engineered construct might involve using the existing vascular system in decellularized tissue. Preservation of the vascular structure in decellularized porcine small bowel has been used to engineer tissue via innate vascularization [111]. The decellularized scaffold was repopulated by endothelial cells and exhibited patent vessels after arterial and venous microanastomosis.

Improved methods for seeding and maturing larger tissue engineered intestinal constructs will be needed to ensure that the limited cells available are delivered to the tissue construct efficiently and uniformly. These obstacles may be overcome with the development of bioreactor systems that will assist with the long-term culture and bioengineering of tissues by providing an in vitro environment that is similar to normal physiological conditions. Kim and colleagues designed a perfusion bioreactor specifically for intestinal tissue engineering [112]. The use of bioreactors that provide magnetic force may also be used to deliver cells labeled with superparamagnetic iron oxide nanoparticles into hollow tubular scaffolds with more uniform distribution [113]. Techniques used to tissue engineer vascular grafts might also provide solutions that can be translated to intestinal tissue engineering. For example, centrifugal casting onto decellularized laser-porated natural scaffolds has been reported to enable the rapid fabrication of tubular tissue in a bioreactor-free manner [114].

The type of scaffold material chosen for tissue engineering is an important consideration. An optimal scaffold material must be capable of withstanding the intestinal microenvironment, which poses significant challenges in terms of biocompatibility, mechanical properties, and longevity. It must allow transplanted cells to engraft and proliferate rapidly while enabling tissue perfusion of nutrients and remodeling to ensure complete integration with the host. The composition, geometry, and topography of scaffolds used for intestinal tissue engineering may influence the properties of cells grown on their surface.

Compared with natural extracellular matrix–derived scaffolds, biodegradable synthetic polymer scaffolds provide more control over scaffold properties, such as scaffold architecture, degradation rates, and mechanical properties. Boomer and colleagues evaluated a selection of synthetic tubular scaffolds composed of poly(glycolic acid), poly(ε-caprolactone), poly(L-lactic acid), and polyurethane with either nanofiber or macrofiber structures [115]. Implantation of the scaffolds into the peritoneal cavity of rats revealed different rates of tissue infiltration and scaffold degradation. The inclusion of extracellular matrix components such as hyaluronic acid (a nonsulfated glycosaminoglycan found ubiquitously in connective, epithelial, and neural tissue) was found to enhance the physicochemical properties of gelatin–collagen scaffolds, including attachment, growth, and viability of Caco-2 cells [116]. Histological organization of cells resembling intestinal circular and longitudinal smooth muscle has also been achieved using scaffolds that consist of two layers of orthogonally oriented fibers [117].

The function of the geometry of the crypt–villus microenvironment in regulating intestinal cell proliferation and differentiation was explored by Wang and colleagues [118]. Caco-2 cells migrating over microwell structures showed increased metabolic activity and lower levels of differentiation compared with cells cultured on flat surfaces, which suggested that the structure of crypts may have a role in retaining a proliferative phenotype. Likewise, scaffold architecture is a parameter that can be used to enhance cell infiltration and mass transfer of nutrients to ensure the viability of tissue is maintained. The porosity of the scaffold has a critical role in cell survival and ultimately the viability of the tissue construct. This was illustrated in a study looking at the inclusion of 250-μm pores in multilayered electrospun scaffolds [119]. When implanted in vivo, scaffolds with greater macroporosity were associated with increased blood vessel development and improved survival of intestinal smooth muscle cells, which suggested that macropore connectivity can be optimized to enhance angiogenesis and improve cell viability. Compression molding combined with particulate leaching has been used to create multilayered scaffolds with differential porosities and pore sizes [120]. These structural features were found to influence the behavior and interaction (bridging versus penetration) of different cell types found within the small intestine (epithelial and smooth muscle cells).

The impact of the spatial geometry and mechanics of the microenvironment are likely to have an important role in the physiological functionality of tissue engineered constructs. DiMarco and colleagues used a combination of experimental and finite element analysis to investigate critical variables that control intestinal organoid contraction [121]. Adjustment of ambient oxygen concentration, tailoring the density of the collagen type I matrix, addition of R-spondin1, and culture geometry were found to influence contractile behavior of the organoids. Contractile

behavior occurred only within a narrow range of collagen densities, which the investigators suggested acted as a permissive switch to enable contraction. The inclusion of biomimetic topographical features might provide further control of cell behavior. To replicate the irregular multiscale features of native intestine, Koppes and colleagues created replicas of decellularized porcine small intestine by chemically depositing Parylene C to create molds for polydimethylsiloxane (PDMS) substrates [122]. The PDMS substrates exhibited multiscale folds, crypt and villus structures, and submicron features of the basement membrane. Finer control over the impact of microenvironmental cues is likely to improve scaffold performance, which affects tissue formation, development, differentiation, and functional behavior. Culture of primary intestinal organoids in recombinantly engineered extracellular matrix allowed improved physical manipulation of the scaffolds biomechanical cues while retaining the efficiency of organoid formation to match that obtained with natural collagen I matrices [123]. This provided a means to optimize the properties of the scaffolds to achieve improved matrix performance and identification of microenvironmental cues crucial for bioengineering tissue constructs. Porous protein scaffold systems composed of silk fibroin have also been used to replicate the tissue architecture and microenvironments of the intestine [124]. This type of insight into how properties of the scaffold materials influence the functional behavior of cells is crucial if physiological features such as the stem cell niche, crypt−villus axis, and peristalsis are to be achieved in the tissue engineered construct.

Combined with the revolution in additive manufacturing, an icreased understanding of the biochemical and mechanical cues that control tissue regeneration will lead to a step change in state-of-the-art technology available to create scaffolds tailored to replicate the native scaffold of tissues in terms of topographical, mechanical, and biochemical features. Lee and colleagues fabricated scaffolds with a high surface area−to-volume ratio using 3D printing technology [125]. The growth of smooth muscle cells in vitro was found to be influenced by the geometry of the scaffold. Scaffolds with small villi (0.5 mm) had increased cell density compared with scaffolds containing large villi (1 mm) after 14 days of culture. A 3D printable Matrigel−agarose system was described for the printing of intestinal epithelial cells [126]. The agarose component provided mechanical stability for the 3D printed structure and the Matrigel provides essential protein components for cell growth and spreading. The development of bioinks with improved mechanical properties and biocompatibility will enable additive manufacturing such as 3D printing to make tremendous opportunities for regenerative medicine [127].

Instilling peristaltic activity to the tissue engineered intestine to establish gut motility will require correctly oriented smooth muscle cell regeneration and reinnervation. Advances have been made in technologies to achieve peristalsis through the combination of autologous smooth muscle cells and biomaterials to produce patch or tubular constructs [128]. Maintaining native smooth muscle organization appears to be critical to achieving functionally contracting smooth muscle [129]. Intact smooth muscle strips retained neural and glial markers and exhibited periodic contraction whereas smooth muscle cells cultured after enzymatic digestion did not. Innervation is not only an unmet need for bioengineering gastrointestinal tissue constructs. Enteric neuropathies such as achalasia, gastroparesis, intestinal pseudoobstruction, and chronic constipation are functional gastrointestinal disorders that result from primary and secondary forms of degenerative disease that affect the nerves and muscles in the gastrointestinal tract [130]. Mouse enteric neural crest cells transplanted into aganglionic gut spread along the endogenous myenteric plexus to form functionally integrated branching networks closely associated with endogenous neural glial networks, providing evidence for the use of enteric neural stem cell therapies [131]. The appendix, a vestigial organ, might provide a potential source of autologous neural stem cells for enteric neural cell therapy [132]. Geisbauer and colleagues investigated whether a mixture of enteric cells isolated from longitudinal and circular muscle of the gut could be used as a potential source of neural crest stem cells for cell therapy. When the isolated cells were mixed in collagen containing bFGF and injected into an aganglionic segment of jejunum, ganglion-like structures were generated with elongated synapses [133]. Innervation of tissue engineered constructs is fundamental to achieving or restoring gastrointestinal transit. Colon smooth muscle cells cultured in composite chitosan scaffolds were innervated by differentiated functional neurons derived from cocultured neural progenitor cells [134]. Likewise, human smooth muscle cells and neural progenitor cells were engineered into innervated sheets of smooth muscle and wrapped around tubular chitosan scaffolds [135]. After subcutaneous implantation, the construct became vascularized and the lumenal patency was maintained.

In addition to regulating peristalsis, the enteric nervous system in the intestine controls villi activity and the modulation of secretions from gut epithelial cells. Gut endocrine cells has an important role in regulating gastrointestinal activity by releasing serotonin, secretin, cholecystokinin, gastrin, and enteroglucagon and will be an essential component of the tissue engineered intestine. Nakase and colleagues investigated the regeneration of endocrine cells and the nerve system in a canine patch model of tissue engineered small intestine using a collagen sponge scaffold loaded with autologous gastric smooth muscle cells [136]. At 24 weeks after implantation of the scaffolds into the

middle of an isolated ileal loop, the location and number of endocrine cells staining positive for chromogranin A were almost identical to those of native mucosa. Nerve fibers were present in the regenerated smooth muscle layer and villi, but the myenteric plexus of Auerbach and the submucosal plexus of Meissner were not visible. The density of smooth muscle cells implanted into the scaffolds did not affect the thickness of the regenerated smooth muscle layer, which remained approximately half that of the native smooth muscle layer, indicating that other cues will be necessary to increase its thickness. The investigators suggested that the thickness of the muscle layer might be limited by the blood supply available to the regenerating tissue, which might be increased by the delivery of angiogenic factors from the scaffold. Grikscheit and colleagues also reported that ganglion cells were distributed in the locality of the Auerbach and Meissner's plexuses in tissue engineered small intestine [90].

Regeneration of the small intestine remains at an early stage of clinical development and has yet to provide a clear demonstration of improvement in nutrient absorption that will be valuable in a clinical therapeutic setting in humans. Although no models have unequivocally demonstrated functional neointestine with peristaltic activity, they indicate that it is feasible to engineer tubular segmental replacement of small bowel that incorporates innervated smooth muscle layers. Based on these findings, it may be possible to achieve incremental steps toward tissue engineering the intestine. For example, combining existing and established surgical procedures with the principles of tissue engineering and regenerative medicine may improve existing clinical outcome measures. An example of this type of approach was demonstrated by Nakao and colleagues, who showed that the longitudinal staples used during Bianchi's procedure could be replaced with SIS graft [137]. Refinement of other existing techniques could yield further advances toward viable options for tissue engineered intestinal constructs.

COLON

The colon is an important organ for water and sodium resorption and a storage pouch for waste products. Patients who undergo total colectomy are at risk for significant morbidities [138]. The surgical creation of an ileal pouch to create a reservoir provides only a limited solution and patients may still experience inflammation of the pouch (pouchitis), malabsorption, diarrhea, cramping abdominal pain, and fever [139].

Tissue engineering approaches similar to those used for the small intestine have been applied to the colon [140]. Consequently, many of the same challenges exist. Tissue engineered colon was achieved by seeding organoid units harvested from the sigmoid colon of neonatal Lewis rats, adult rats, and tissue-engineered colon itself onto a polymer scaffold that was implanted into the omentum of syngeneic adult Lewis rats. Tissue-engineered colon was generated from each of the donor tissue sources and the resulting architecture of the neocolon was similar to that of native tissue. When anastomosed to the native bowel, there was gross evidence of fluid absorption by the tissue engineered colon.

The choice of scaffold material used for colon tissue engineering will have an impact on the viability of the neocolon. Two of the main biological scaffold materials explored in gastrointestinal tissue engineering are SIS and chitosan. Relatively few studies have made direct comparisons of these materials in terms of their biocompatibility. Denost and colleagues looked at the in vitro and in vivo properties of two bioscaffolds composed of these materials [141]. No substantial difference was observed in vitro in terms of cell attachment and proliferation, but the chitosan hydrogel facilitated improved healing of a preclinical in vivo model of colonic wall defect, including regeneration of the smooth muscle layer.

A significant drawback reported with biological scaffolds such as chitosan is their weak mechanical properties. To enhance mechanical strength, Zakhem and Bitar reported using chitosan fibers circumferentially aligned around tubular chitosan scaffolds [142]. Tensile strength and strain, burst pressure, and Young's modulus were all increased in scaffolds that contained the fibers.

ANAL CANAL

Controlled storage and timely disposal of feces relies largely on the appropriate function of sphincter muscles that constrict the anal canal and maintain fecal continence. Fecal incontinence is a common disease, particularly in aging societies in which it has a huge impact on quality of life and incurs colossal health costs. Conservative estimates indicate that approximately 2% of community-dwelling adults experience regular fecal incontinence [143]. This figure increases to 50% in the institutionalized and geriatric population [144]. Conservative treatments for fecal

incontinence are ineffective in patients with more than mild symptoms and surgical interventions produce poor long-term benefit, with frequent complications [145].

Despite holding considerable promise, cell therapy for incontinence affecting the alimentary tract remains relatively unexplored in humans [146,147]. Although the technical feasibility of injecting autologous myoblasts for treating fecal incontinence in humans has been demonstrated, these studies have been unable to demonstrate integration of cells into the damaged sphincter or a direct improvement in the functional integrity of the sphincter muscle.

A fibrin-based bioengineered in vitro model of the internal anal sphincter (IAS) was described that demonstrated physiological functionality. This type of approach is likely to offer value in studying complex physiological mechanisms underlying sphincter malfunction [148,149]. The bioengineered sphincter was surgically implanted into the subcutaneous tissues of syngeneic mice and responded to the local delivery of bFGF, resulting in improved muscle viability, vascularization, and survival of the graft [150]. This field of research has continued to advance; the first study demonstrated the feasibility of transplanting bioengineered intrinsically innervated human IAS into mice. Isolated human IAS smooth muscle cells were cocultured with immortomouse fetal enteric neurons. The construct implanted into $RAG1^{-/-}$ mice became neovascularized and the physiological function of the myogenic and neuronal components was retained. The IAS construct exhibited characteristics of IAS physiology [151]. The feasibility of implanting a bioengineered sphincter construct consisting of human IAS smooth muscle cells was explored in the perianal region of athymic rats [152]. The constructs were well-tolerated and the recipients were able to produce stool normally. For this study, vascularization was increased by delivering platelet-derived growth factor. In addition to the anal sphincter, proof-of-concept studies have demonstrated that it is feasible to bioengineer autologous bioengineered innervated pylorus constructs that consist of circumferentially aligned smooth muscle cells that exhibit tonic contractile phenotype and basal tone [153].

However, the feasibility of scaling-up this type of approach from a rodent model to humans remains uncertain. Although it is technically possible to bioengineer rings of muscle in vitro on a scale comparable to that of human sphincter muscle [154], innervation, vascularization, and cell viability in larger constructs have yet to be tested in larger-sized preclinical models.

Regenerative medicine may also offer solutions to conditions in which existing medical and surgical procedures have failed. A condition in which this affects the alimentary tract is perianal fistulas that result from a connection between the anal canal and the perianal skin surface, creating an abnormal passageway for the discharge of pus, blood, and in some cases feces, resulting in significant morbidity. The goals of fistula treatment are eradication of perineal sepsis and fistula closure while posing a minimal risk for causing sphincter muscle damage. A difficulty in treating perianal fistulas is avoiding abscess formation caused by healing of the skin before closure of the tract. To address this, collagen anal fistula plugs have been devised to treat fistulas. Although early studies reported good healing rates with little or no risk to continence, long-term follow-up has revealed variable and disappointing success rates (24–78%) [155]. Reports of the plugs failing owing to dislodgment from the tracts indicate that this approach may not provide an ideal scaffold material to promote guided tissue regeneration and closure of the tract [155]. A possible solution to this problem is the use of scaffold materials that provide both optimal conditions for rapid cell infiltration when implanted into tissue cavities and mechanical strength to maintain an open scaffold structure [156].

IN VITRO MODELS

Improved understanding of gastrointestinal developmental biology opens up new opportunities for creating 3D tissue constructs that can be used to modeling disease, understand embryonic development, and provide construct sources for therapeutic applications [157]. Principles of regenerative medicine are increasingly being used to fabricate biomimetic models of the gastrointestinal tract. Challenges that exist with developing in vitro tissue models of gastrointestinal tissue include mimicking the 3D microenvironment, interactions among different cell types, and the microbiome. New technologies are being applied to address these, including using microfluidics to create channels lined by living cells in microengineered biomimetic systems that might offer new opportunities to replace conventional animal models in preclinical toxicology testing. This approach has been applied to a variety of organs including the intestine to provide organs-on-chips that exhibit physiological properties including peristalsis-like movement [158]. Dynamic culture in a defined perfusion bioreactor has also been reported to result in tissue models that are physiologically closer to native small intestine [159]. Microfluidic cell culture devices have been designed that contain villi- and crypt-like structures that resulted in epithelial cells tightly connecting to each other and displaying absorption and paracellular transport function [160]. The incorporation of physiological parameters also

appears to be important for establishing 3D in vitro tissue models of small intestine. Bioreactors used to culture decellularized segments of porcine jejunum have been used to coculture human Caco-2 cells with human microvascular endothelial cells. Compared with routine static Caco-2 assays, culture under dynamic conditions resulted in cell morphology that more closely resembled normal primary enterocytes [161]. Recapturing essential features of the cellular microenvironment is essential if in vitro tissue engineered models are to be used for functional studies such as cell growth, differentiation, absorption, or host–microbial interactions. The inclusion of native features such as accurately sized intestinal villi has been shown to facilitate cell differentiation along the villous axis [162]. Methods used to realize such structures include 3D natural and synthetic hydrogels created using a combination of laser ablation and sacrificial molding to achieve microscale structures that mimic the density and size of human intestinal villi [163]. The microbiome of the gastrointestinal tract is increasingly being recognized as a critical component to maintaining physiological homeostasis. Biomimetic in vitro intestinal models for investigating the adhesion and invasion profile of commensal and pathogenic organisms therefore have significant value in understanding microbe-induced intestinal disorders. To explore this interaction, synthetic 3D tissue scaffolds that support coculture of epithelial cell types have been used to provide microbial niches along the crypt–villus axis for modeling the interaction of a variety of commensal and pathogenic organisms [164].

CONCLUSION

The alimentary tract is a complex organ that is essential for maintaining physiological homeostasis. Tissue engineering and regenerative medicine for hollow visceral organs have been proposed as an approach for replacing damaged or diseased tissue, as demonstrated in humans with bladder [165] and airway tissue [15]. Although these "first-in-human" studies have rightly attracted much attention, there is a long way to go until a similar approach becomes routine in the relatively complex structures of the alimentary tract.

The past few decades have delivered a series of important studies that have used the innate ability of the alimentary tract to regenerate. Further studies are needed to demonstrate whether these approaches are transferable and of clinical value to humans. Fundamental challenges such as scalability will need to be addressed to enable the results obtained in small-animal models to progress into preclinical models applicable to humans. This will require refinement of the scaffolds used and the ability to seed limited quantities of cells available in an efficient manner onto the scaffolds. These are challenges that can be overcome and will allow regenerative medicine to progress in the alimentary tract in humans.

Extracorporeal Renal Replacement

Christopher J. Pino[1], *H. David Humes*[1,2]

[1]Innovative Biotherapies, Ann Arbor, MI, United States; [2]University of Michigan, Ann Arbor, MI, United States

INTRODUCTION

The kidneys are vital organs that have critical excretory and regulatory roles in maintaining water and electrolyte homeostasis in the body while removing low−molecular weight (MW) toxins. Often overlooked, the kidneys also provide an essential endocrine function because they secrete important signaling molecules that interact with the cardiovascular, skeletal, and immune systems. The kidney was the first organ to be successfully transplanted and is one of the most common and effective transplantation surgeries performed in the world. However, global shortages of donor kidneys have proven to be a major barrier to treating kidney disease, leaving millions of chronic kidney disease patients without total functional replacement.

In the United States, 636,905 patients were listed as having end-stage renal disease (ESRD) at the end of 2012, as reported by the 2014 US Renal Data System (USRDS) database. According to the USRDS report, over 450,000 patients were receiving maintenance dialysis, 186,303 patients had a functioning kidney transplant, and 88,638 ESRD patients died during 2012 [1]. Adjusted rates of all-cause mortality are 6.1−7.8 times greater for dialysis patients than for individuals in the age-matched Medicare population [1]. The incidence rate of ESRD has plateaued and slightly decreased since 2009, with an adjusted incidence rate of 353 per million per year in 2012 [1]. The financial cost of ESRD is immense; spending for ESRD patients increased 3.2% to $28.6 billion in 2012, accounting for 5.6% of the Medicare budget [1]. A prior USRDS report estimated the cost of $54,900 per hemodialysis (HD) patient per year and $46,121 per peritoneal dialysis (PD) patient per year [2]. In contrast, transplant patients cost an average of $17,227 per patient per year [2]. The higher cost of maintenance dialysis compared with transplantation does not translate into better results; annual mortality for patients listed for transplant and awaiting a kidney is 6.3%, compared with only 3.8% for patients listed for transplant who received a kidney [2]. Although organ transplantation provides the best prognosis for survival, demand vastly outweighs the availability of donated organs. In 2014, the active waiting list was 2.8 times larger than the supply of donor kidneys [3].

Extracorporeal therapies to replace kidney function at least partially include HD, hemofiltration (HF), hemodiafiltration (HDF), and PD. These therapies replace the blood filtration function of the kidney by removing waste products and excess electrolytes via artificial or natural semipermeable membranes in extracorporeal circuits. These methodologies all address water and electrolyte balance as partial functional replacement of the kidney but are prone to various complications such as acidosis, volume overload, and uremic syndromes that accompany renal failure [4]. Conventional therapies fail to provide the lost endocrine functions of the kidney, and thus the metabolic, endocrine, and immunological roles of the functioning kidney are potential mechanisms for the difference in survival for patients who receive kidney transplants.

REQUIREMENTS OF A RENAL REPLACEMENT DEVICE

In the kidney, HF is accomplished by nephrons that generate ultrafiltrate (UF) from blood via glomeruli. Each glomerulus, a tuft of capillaries supported by a basement membrane and specialized epithelial cells called podocytes, is an efficient filter with a molecular weight cutoff (MWCO) of around 65 kDa. This allows for small molecules including small MW toxins such as urea to be removed from the bloodstream, whereas the cellular component of

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00065-5

blood and larger proteins including albumin are retained. UF is passed into the renal proximal tubule portion of the nephron, a hollow tube of cells surrounded by capillaries, which receives the filtrate from the glomerulus and accomplishes the bulk of reclamation of salt, water, glucose, small proteins, amino acids, glutathione (GSH), and other substances. A renal replacement device thus must recapitulate the filtration function of the nephron. However, in addition to its role in water−electrolyte balance, the tubule also performs metabolic functions, including excretion of acid as ammonia and hydroxylation of 25-hydroxy-vitamin-D_3 among other metabolic and regulatory functions, which are not supplemented in conventional renal replacement therapies (RRT).

The kidney is responsible for the secretion of hormones that are critical in maintaining hemodynamics (renin, angiotensin II, prostaglandins, nitric oxide, endothelin, and bradykinin), red blood cell production via erythropoietin, and bone metabolism (1,25-$[OH]_2$−vitamin D_3 or calcitriol) [5]. Free-radical scavenging and GSH-metabolizing enzymes are synthesized by the kidney, which also provide gluconeogenic and ammoniagenic capabilities [6,7]. Catabolism of low -molecular weight proteins, including multiple peptide hormones, cytokines, and growth factors, is also accomplished by the kidney [8]. The kidney also has a less-recognized immunoregulatory function. Mammalian renal proximal tubule cells (RPTC) are immunologically active. RPTCs are antigen-presenting cells [9] that have costimulatory molecules [10] that synthesize and process a variety of inflammatory cytokines [10,11]. Long overlooked, the kidney is an important immunomodulatory organ. RRT has poor patient prognosis owing to the acute tubular necrosis (ATN) that results in the loss of the kidney's immunoregulatory function. Loss of immunoregulation results in a propensity to develop systemic inflammatory response syndrome (SIRS), sepsis, multiple organ dysfunction (MOD), and a high risk for death because of systemic immunologic or inflammatory imbalance. The endocrine and immunologic roles of kidney cells are also important in maintaining kidney and other vital organs' health under stress conditions [12] and are not provided by conventional RRT.

DEVICES USED IN CONVENTIONAL RENAL REPLACEMENT THERAPY

Water and solute homeostasis function of the kidney can be practically replaced by various dialysis or filtration methods including HD, HF, HDF, and PD. In these processes, synthetic membranes are used to remove water and solutes selectively based on diffusive or convective transport. In HD, in which solute removal from the blood is driven by a concentration gradient across a membrane, the process is dominated by diffusion. However, solute transfer also occurs to a lesser extent, convectively by a process of ultrafiltration, in which water and solutes move across the membrane [13]. This process is leveraged further in HF, in which pores in semipermeable membranes allow water and solutes across the membrane independent of the concentration gradient, and predominantly on the hydraulic pressure gradient across the membrane, which mimics the filtration function of the nephron. HDF combines HD and HF processes, in which both diffusion and hydraulic pressure are used as driving forces. In PD, similar to HD, solute removal is mainly driven by diffusion across a synthetic membrane; however, instead of solutes being removed directly from blood, solutes are removed from the peritoneal fluid of the patient, which avoids complications of blood access. PD has a higher safety profile, which enables dialysis treatments at home, overnight dialysis, and continuous ambulatory dialysis.

In HD, blood exits the patient's body through a catheter, which is delivered to a dialyzer via tubing and a blood pump (Fig. 65.1A). These dialyzers are commonly filled with hollow fiber membranes formed into a bundle. Within a hollow fiber dialyzer, blood flows through the lumen, the interior of each hollow fiber. Solutes in the blood interact with the fiber's semipermeable membrane, which allows for low-MW solutes such as urea and creatinine to pass through the porous fiber wall into the extracapillary space (ECS) of the dialyzer for removal, whereas blood cells and critical large proteins such as albumin and immunoglobulin are retained in the blood. Dialysate, an aqueous solution administered during dialysis, flows opposite the blood on the other side of the semipermeable membrane in the ECS. The dialysate has various concentrations of solutes that dictate the driving force to remove, retain, or add to solute concentrations in the blood. Movement of the solute is directed from high to low concentration so that toxins are removed and critical electrolytes in the blood are maintained.

In HF, blood is filtered using a pressure difference to drive water and solutes across a semipermeable membrane and into the filtrate compartment. Like dialyzers, hemofilters are routinely filled with hollow fibers. Positive pressure can be applied to the hemofilter's blood compartment (lumen side of the hemofilter) or a negative pressure can be applied to the filtrate compartment (ECS), creating a transmembrane pressure. No dialysate solution is used in HF; rather, the filtrate is collected and discarded and ultrapure replacement solution is administered to the patient to maintain water−solute balance, as shown compared with dialysis in Fig. 65.1B.

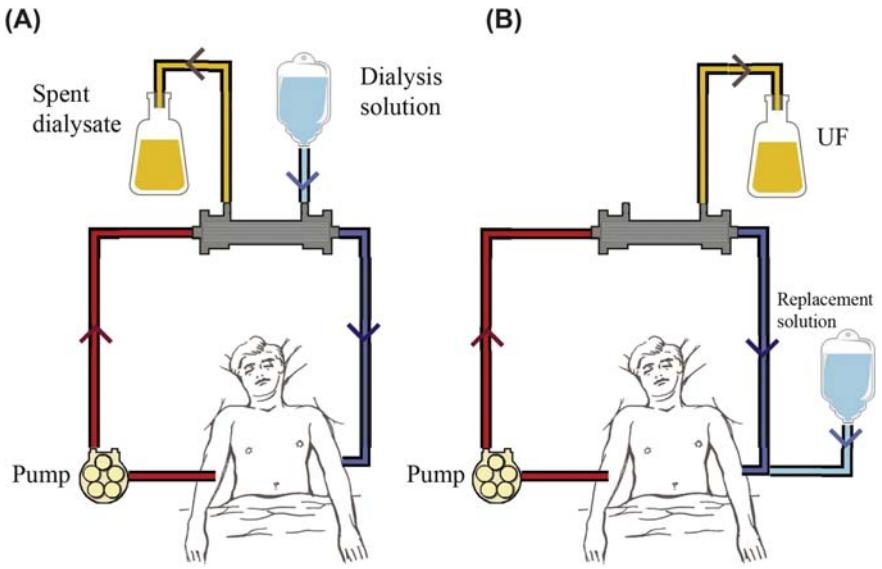

FIGURE 65.1 Diagrams of hemodialysis (A) and conventional venovenous hemofiltration (B) methods. *UF*, ultrafiltrate.

Membrane materials used in dialyzers and hemofilters are diverse, ranging from metals and ceramics to polymers. Critical to the choice of materials for dialysis membranes, biocompatibility with blood is a major concern, as are cost and manufacturing. Synthetic polymers have been the dominant membrane materials used for separation processes owing to combination of these factors. The most common polymers in the manufacturing of synthetic membranes are nondegradable ones, including cellulose derivatives such as cellulose acetate, nitrates, and esters, polysulfones, and their ether-containing derivatives polyethersulfones and polyarylethersulfone, polyacrylonitrile (PAN) derivatives, polyamides, polyimides, polyolefins such as polyethylene and polypropylene, polyvinylchloride, and fluorinated polymers such as polytetrafluoroethylene, and polyvinylidine fluoride.

ADVANCEMENTS IN CONVENTIONAL RENAL REPLACEMENT THERAPY DEVICES

Besides improvements in biocompatibility, synthetic membranes have been developed to better reproduce the physiologic process of glomerular ultrafiltration. In an attempt to recapitulate glomerular ultrafiltration and removal of "middle molecules," synthetic membranes with larger pore sizes and high water permeability have been developed. These "high-flux" membranes are commonly prepared with hydrophobic base materials, along with various hydrophilic components. These membranes can be mass produced, with wide ranges of hydraulic permeabilities for various treatments [14].

Pore size, therefore, is a critical issue in hemofilter design. Conventional polymeric membranes are typically cast or spun from polymers in solution, resulting in a heterogeneous dispersion of pore sizes and geometries within fibers or sheets, with ill-defined MWCO. New techniques using a nanoscale spinning process to control pore size, resulting in an increased uniformity of pores with desired values [15].

Based upon this technology, the main focus of recent membrane development has been to increase pore size while sharpening the MWCO of high-flux membranes to maximize removal of low MW proteins. This direction is based upon the idea that removal of a distinct class of uremic toxins, such as β2-microglobulin and myoglobin, while minimizing the loss of albumin could improve treatment outcomes of patients with ESRD. Superflux or protein-leaking membranes, provide greater clearances for low MW proteins and small protein-bound solutes, but with significantly higher loss of albumin than high-flux dialysis membranes. Other determinants of dialyzer performance may include: fiber bundle configuration, spacing, and sterilization techniques [16].

Membranes typically used today are purely artificial and are used in the form of hollow fiber modules, commonly based on cellulose or synthetic polymers, including polysulfone, PAN, and polyamide, used as such or modified with a variety of agents [17–19]. However, research in biomaterials and tissue engineering holds promise for significant future improvements. Improvements in membrane biocompatibility have reduced inflammatory reactions, but

off-the-shelf polymeric materials still induce a cascade of biochemical events leading to blood coagulation, thrombus formation, and often complement activation and inflammation. Systemic administration of anticoagulant such as heparin is required to solve these problems. However, the use of anticoagulants, may lead to additional complications such as hemorrhage, and thus researchers are trying to improve anticoagulation therapy by finding alternative antithrombotic agents such as hirudin [20] and methods of administration, such as the direct incorporation of bioactive agents onto the polymeric membrane itself [21], such as vitamin E or heparin [22].

Conventional membranes remove solutes only on the basis of molecular size, whereas the glomerulus also employs charge selectivity by the basement membrane. This nonselective nature of conventional membranes is another limitation to overcome. One possible solution to this problem is to grow cells on the hemofilter membrane to improve the selectivity of the membrane. Another approach is the design of "smart" membranes that have selective transport characteristics and contain a predetermined number and size of nonpassive nanoengineered pores that have specific interactions with solutes and solvents at the atomic level [23].

Despite improvements in membrane technologies allowing for more efficient dialysis, HF, or diafiltration therapies, all are suboptimal treatments for both acute kidney injury (AKI) and ESRD. These therapies do not meet the medical need to reduce mortality caused by AKI. Even in ESRD, the outcomes of patients receiving chronic dialysis therapy are still disappointing, with an annual mortality exceeding 25%, on average and a drastically shortened life expectancy of only 5 years [24]. Several groups have reported that the survival of critically ill patients with AKI could be improved by intensifying the dose of RRT [25–27], but the initial excitement generated by these reports has waned after studies demonstrated that the dialysis dose does not closely relate to outcomes [28–30].

RENAL ASSIST DEVICE: A MORE COMPLETE RENAL REPLACEMENT THERAPY

Complete RRT should replace metabolic and endocrine functions of the kidney not supplied by conventional RRT. One such approach, called the renal assist device (RAD), used living cells supported on synthetic scaffolds [31]. In this bioengineered device, nondegradable scaffolding materials were employed to provide physical support for renal cells grown within the device. The RAD was constructed using renal tubule progenitor cells [32,33] cultured on semipermeable polymeric hollow fiber membranes (polysulfone) on which an extracellular matrix was layered to enhance the attachment and growth of the epithelial cells [34] (Fig. 65.2A). These porous hollow-fiber synthetic membranes not only provide the architectural scaffold for these cells and allow for delivery of nutrients to support the cells, they provide immunoprotection during therapy, preventing potential immunologic reactions in patients or compromise of the cell device by the patient's immune system. With appropriate membranes, immunoprotection of cultured progenitor cells can be achieved concurrent with long-term functional performance as long as conditions support tubule cell viability [31].

In vitro experiments have tested transport and metabolic functions of the RAD using renal proximal tubule progenitor cells grown inside the lumen of hollow fiber devices with membrane surface areas of 97 cm^2 to 0.7 m^2, resulting in a device containing up to 10^8–10^9 cells [35]. The nonbiodegradability and pore size of the hollow fibers allowed the membranes to act as both scaffolds for the cells and an immunoprotective barrier. Confluent monolayer cells within the RAD exhibited morphological characteristics typical of differentiated tubule epithelia including apical microvilli, endocytic vesicles, and tight junctional complexes, as well as differentiated active transport properties, differentiated metabolic activities, and important endocrine processes [35]. RPTC cultured in the RAD were found to maintain their ability to synthesize and excrete ammonia, produce 1,25-$(OH)_2$–vitamin D_3 (the active form of vitamin D), and, through metabolic degradation, remove GSH from the perfusate. Taken together, these results suggested that the RAD had the ability to replicate the major differentiated transport, metabolic, and secretory functions performed by the healthy renal proximal tubule.

To assess the potential clinical translation of this technology, large-animal studies were undertaken using an RAD consisting of renal proximal tubule progenitor cells. In brief, dialysate from a conventional dialysis circuit can be passed into the RAD as a nutrient and oxygen source for the cells grown on the membrane. The membrane is both water- and solute-permeable, allowing for differentiated vectorial transport and metabolic and endocrine activity provided by the cells, and processed dialysate is discarded. Immunoprotection of cultured progenitor cells is achieved concurrent with long-term functional performance as long as conditions support tubule cell viability. In studies with acutely uremic dogs after bilateral nephrectomies, the RAD demonstrated replacement of filtration, transport, metabolic, and endocrine functions of the kidney [35–37]. Animals were treated with either an RAD or a sham control cartridge daily for either 7 or 9 h for 3 successive days or for 24 h continuously. Fluid and small solutes, including blood urea nitrogen (BUN), creatinine, and electrolytes, were adequately controlled in both groups, but

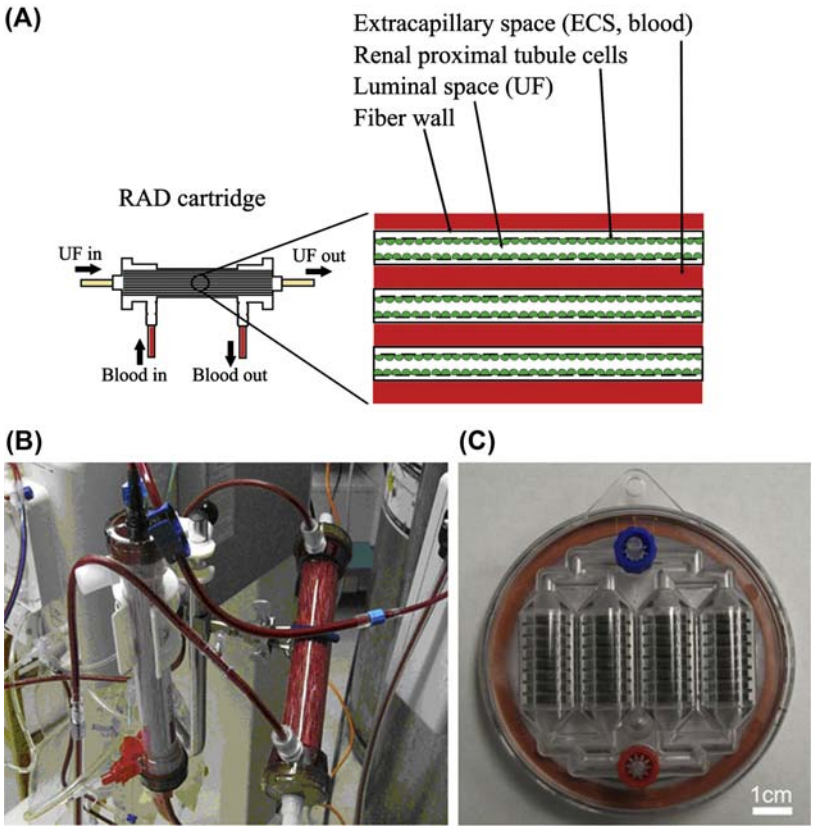

FIGURE 65.2 Depiction of renal assist device (RAD) (A), selective cytopheretic device (B), and bioartificial renal epithelial cell system (C) devices.

potassium and BUN levels were more easily controlled by RAD treatment. Furthermore, active reabsorption of K^+, HCO_3^-, and glucose and excretion of ammonia were accomplished only in RAD treatments. Glutathione reclamation from UF exceeded 50% in the RAD. Finally, uremic animals receiving cell therapy attained normal 1,25-$(OH)_2$—vitamin D_3 levels, whereas sham treatment resulted in a further decline from the already low plasma levels. Thus, these experiments clearly showed that the combination of an HF cartridge and an RAD in an extracorporeal circuit successfully replaced filtration, transport, and metabolic and endocrinological functions of the kidney in acutely uremic dogs [35—37].

Additional animal experiments in a porcine model investigated the impact of treatment with this device on the high mortality of sepsis complicated by AKI [38].

RENAL ASSIST DEVICE THERAPY OF ACUTE KIDNEY INJURY CAUSED BY SEPSIS

To examine the impact of cell therapy on the course of sepsis complicated by renal failure [38,39], a porcine model of septic shock was developed from the previous work [40,41]. Purpose-bred pigs were anesthetized and administered an intraperitoneal dose of bacteria, causing shock and renal failure. An hour later, continuous venovenous hemofiltration (CVVH) was initiated with either cell or sham RAD. Urine output and mean arterial pressure (MAP) declined within the first few hours after insult. Cell-treated animals survived 9.0 ± 0.83 h versus 5.1 ± 0.4 h ($P \leq .005$) for sham-treated animals. Serum cytokines were similar between the two groups, with the striking exception of interleukin (IL)-6 and interferon (IFN)-gamma. Treatment with the cell RAD resulted in significantly lower plasma levels of both IL-6 ($P \leq .04$) and INF-gamma ($P \leq .02$) throughout the experimental time course compared with sham RAD exposure. This controlled trial of cell therapy of renal failure in a realistic animal model of sepsis had several findings not immediately expected from a priori assumptions regarding renal function. Previously, although renal failure was strongly associated with a poor outcome in hospitalized patients, and chronic renal failure was associated with specific defects in humoral and cellular immunity, a direct immunomodulatory effect of

the kidney had not been accepted. In this trial, clear differences in survival and clear differences in a serum cytokine associated with mortality in sepsis were found between groups. The increased mortality in renal failure appears to be not attributable to inadequate solute clearance, but may arise from other bioactivity of the kidney.

Studies in both dogs and pigs have demonstrated that RAD treatment in a bioartificial kidney circuit improves cardiovascular performance associated with changes in cytokine profiles and confers a significant survival advantage in septic or endotoxin animal models [38,39,42].

CLINICAL EXPERIENCE WITH A RENAL ASSIST DEVICE TO TREAT ACUTE KIDNEY INJURY

Encouraging preclinical data led to US Food and Drug Administration (FDA) approval for an investigational new drug and Phase I/II clinical trials. The first human clinical study of the bioartificial kidney containing human cells was carried out in 10 intensive care unit (ICU) patients with AKI receiving CVVH [43]. This study demonstrated that the RAD can be used safely for up to 24 h. Cardiovascular stability was maintained and increased native renal function, as determined by elevated urine outputs, was temporally correlated with RAD treatment. All patients were critically ill with AKI and multiple organ failure (MOF), with predicted hospital mortality rates between 80% and 95%. Six of the ten treated patients survived past 30 days, with mortality reduced to 40%. The human renal tubule cells contained in the RAD demonstrated differentiated metabolic and endocrinologic activity in this ex vivo situation, including GSH degradation and endocrinologic conversion of 25-OH−vitamin D_3 to 1,25-$(OH)_2$−vitamin D_3. Plasma cytokine levels suggest that RAD therapy produces dynamic and individualized responses in patients, depending on their unique pathophysiologic conditions. For the subset of patients who had excessive proinflammatory levels, RAD treatment resulted in significant declines in granulocyte-colony stimulating factor (G-CSF), IL-6, IL-10, and especially the IL-6/IL-10 ratio, suggesting a greater decline in IL-6 relative to IL-10 levels and a less proinflammatory state. These favorable Phase I/II trial results led to a randomized, controlled, open-label Phase II trial conducted at 12 clinical sites in the United States [30]. A total of 58 patients with ARF requiring CVVH in the ICU were randomized (2:1) to receive CVVH plus RAD (n = 40) or CVVH alone (n = 18). Despite the critical nature and life-threatening illnesses of the patients enrolled in this study, the addition of the RAD to CVVH resulted in a substantial clinical impact on survival compared with the conventional CVVH treatment group. RAD treatment for up to 72 h promoted a statistically significant survival advantage over 180 d of follow-up in ICU patients with AKI and demonstrated an acceptable safety profile. Cox proportional hazards models suggested that the risk for death was approximately 50% of that observed in the CVVH-alone group.

A follow-up Phase IIb study to evaluate a commercial manufacturing process was not completed owing to difficulties with the manufacturing process and clinical study design, which identified two key missing components for successful commercialization of cell-based therapy: (1) a reliable cell source to manufacture thousands of cell devices, and (2) a cost-effective storage and distribution process for cell devices.

IMMUNOMODULATORY EFFECT OF THE RENAL ASSIST DEVICE

As described earlier, RAD treatment altered systemic circulating cytokine levels in animal and human experiments. In endotoxin-challenged and gram-negative peritonitis uremic dog models, plasma levels of IL-10 were significantly higher in RAD-treated animals [38,39]. The role of IL-10 in regulating immune response continues to be elucidated, but data suggest that IL-10 levels influence outcome in endotoxin shock and gram-negative sepsis. Several reports have demonstrated that administration of recombinant IL-10 is protective against gram-negative septic shock in murine sepsis models [44,45]. Another study in a similar model demonstrated that administration of antibodies to IL-10 was associated with higher mortality [46]. The mechanism underlying the link between proximal tubule function and IL-10 levels remains to be detailed, but preliminary data suggest that renal production of IL-6 induces liver production of IL-10 [47]. In gram-negative septic pigs without nephrectomy, RAD treatment significantly reduced plasma circulating levels of IL-6 and INF-gamma [42]. The difference in IL-6 concentrations is especially noteworthy because the plasma elevations of this proinflammatory cytokine have been directly correlated to outcome in patients with SIRS [48]. The lower concentration of plasma INF-gamma may be important owing to its central role in the inflammatory response. INF-gamma stimulates B-cell antibody production, enhances polymorpholeukocyte phagocytosis, and activates monocytes and macrophages to release proinflammatory cytokines

[49–51]. Excessive rates of INF-gamma production by natural killer cells have correlated with progression to lethal endotoxin shock in mice [52]. Further support for an immunomodulatory role of renal tubule cells has been suggested in the Phase I/II clinical trial of the RAD containing human renal tubule cells [53]. Patients treated in this study had a wide spectrum of plasma cytokine levels. The subset of patients who presented with very high plasma cytokine levels and who were treated for an adequate period showed that RAD treatment resulted in significant reductions in G-CSF, IL-6, and IL-10 levels. The greater relative reduction in the IL-6/IL-10 ratio suggests that renal tubule cell therapy may rebalance the excessive proinflammatory response with the concurrent antiinflammatory response. These results are consistent with an immunomodulatory role for the RAD in patients with ATN and MOF. To evaluate the RAD's influence further on local inflammation in tissue and distant organ dysfunction, especially in the lungs, a study compared bronchoalveolar lavage (BAL) fluid from cell-RAD–treated and noncell, sham-treated groups in a pig model with septic shock with AKI [54]. The levels of total protein in BAL were significantly higher in sham control animals than in the RAD group (143 ± 11 compared with 78 ± 10 μg/mL, respectively; $P > .05$). Proinflammatory cytokines, including IL-6 and IL-8, were markedly elevated in the control group. These results demonstrate an important role for renal epithelial cells (RECs) in ameliorating multiorgan injury in sepsis by influencing microvascular injury and the local proinflammatory response. A more promising direction to improve the outcome of AKI is to better understand and interrupt the pathophysiologic processes that are activated in AKI, resulting in distant MOD and eventually death. AKI results in a profound inflammatory response state resulting in microvascular dysfunction in distant organs [55,56]. Leukocyte activation has a central role in these acute inflammatory states. Disruption of the activation process of circulating leukocytes may limit microvascular damage and MOD [57]. The RAD appears to influence systemic leukocyte activation and the balance of inflammatory cytokines and may alter the proinflammatory state of AKI and ultimately improve morbidity and mortality.

Our group has developed a novel synthetic membrane embedded in an extracorporeal device to bind and inhibit circulating leukocytes. This selective cytopheretic device (SCD) is an acellular device that mimics many of the immunomodulatory aspects of the RAD. The SCD improved septic shock survival times in preclinical animal models [58] and improved the survival outcome of ICU patients with MOF in a prospective, single-arm, single-center study [59], a prospective, single-arm, multicenter US study [60], and a randomized, multicenter clinical trial in which SCD-therapy patients were maintained within recommended ionized calcium (riCa) range [61].

SELECTIVE CYTOPHERETIC DEVICE

SCD therapy is an acellular device-based, extracorporeal blood treatment in which a patient's blood is passed through a hemofilter followed by an SCD setup in series (Fig. 65.2B) while regional citrate anticoagulation is administered. The proprietary circuit [62] was designed to combine small solute clearance by the HF portion of the circuit, whereas the SCD portion provides immunomodulation via a low–shear stress (SS) environment for blood cells passing by the fibers within the SCD. SS encountered by blood cells within a hemofilter is greater than arterial SS in the body (>30 dyn/cm^2), whereas SS encountered within the SCD approximates capillary SS (<1 dyn/cm^2), which provides an environment for leukocyte adherence [63]. The SCD was evaluated in a porcine model of *Escherichia coli*–induced septic shock and demonstrated increased survival time for SCD-treated groups [64], along with an ability to lower neutrophil activity (serum myeloperoxidase and CD11b cell-surface expression) and diminish neutrophil tissue invasion [58].

In several clinical trials for the treatment of patients with AKI and MOD, SCD treatment affected multiple leukocyte activation parameters, lowered proinflammatory cytokines, and elevated antiinflammatory cytokines [59,60,65]. In a later Phase I/II clinical trial for the treatment of AKI, 19 patients received SCD therapy (CVVH plus SCD) and maintained a postfilter ionized calcium level in the protocol's recommended riCa range (≤0.4 mmol/L) for 90% or more of the therapy; this resulted in a 60-day mortality of 16% (3 of 19) compared with control subjects (CVVH alone) and a mortality of 41% (11 of 27) ($P = .07$) [61]. Furthermore, for patients treated with SCD within riCa, dialysis dependence was significantly lower: 0% (none of 16) compared with control patients: 25% (4 of 16) ($P = .03$) [61]. Ongoing studies are evaluating dose–response effects and full elucidation of the mechanism of action of this device.

The SCD may provide a novel approach to the immune dysregulation in ESRD. This approach may be further tested in clinical studies as an innovative intervention to ameliorate the chronic proinflammatory state of ESRD and retard accelerated atherogenesis associated with chronic renal failure [66]. A pilot trial was undertaken to explore the impact of SCD therapy in ESRD patients, with 15 ESRD patients receiving HD with C-reactive protein (CRP) levels greater than 5 mg/dL. An excellent safety profile was observed for SCD therapy with no decline in

leukocyte or platelet counts. Monocyte (MO) phenotypes in these patients was determined for peripheral blood MO using flow cytometry. SCD therapy promoted a shift in MO phenotype from predominantly CD14 expressing MO at baseline or before SCD therapy to CD14 expressing MO after SCD therapy [67]. A significant shift in MO population phenotype afforded by a single SCD therapy session was observed ($P < .013$) [67]. In a subset of patients ($n = 7$) presenting with type 2 diabetes mellitus (T2D), this persistent decline in MO CD14 expression was sustained for as long as 2 weeks after therapy [67]. These results demonstrate that SCD therapy has the potential to modulate the chronic proinflammatory state in ESRD patients.

Following up on the finding in ESRD patients with T2D, SCD therapy was evaluated in an Ossabaw miniature swine model of insulin resistance with metabolic syndrome. Treatment with the SCD in this porcine model demonstrated a decline in circulating neutrophil activation parameters and MO counts [68]. These changes were associated with improvements in insulin resistance as determined with intravenous glucose tolerance testing [68]. Improvements were also reflected in the lowering of homeostatic model assessment insulin-resistant scores for up to 2 weeks after SCD therapy [68]. These promising findings allow for the planning of clinical studies for new indications, including treatment of obese T2D patients not presenting with ESRD. Other potential indications for SCD treatment may include other disease states associated with acute or chronic inflammation, including patients receiving cardiopulmonary bypass [69].

CHALLENGE OF CELL-BASED DEVICE: ROBUST CELL SOURCE

To continue to pursue a cell-based device and move past manufacturing hurdles that hindered RAD development, a robust cell supply needed to be developed although human donor tissue is limited; focus was directed toward improving renal cell yield per human kidney. An enhanced propagation (EP) method to expand renal epithelial progenitor cells from available adult human kidney transplant discards was successfully developed and implemented to provide the biomass necessary for renal cell-based therapeutics [70]. The EP method was successful in generating renal progenitor cells using kidneys from a wide range of donors, including suboptimal health profiles consisting of long-term diabetes, hypertension, age greater than 70 years, donation after cardiac death with prolonged warm ischemia, and one donor with ESRD receiving dialysis for over 2 years. Under EP, cell yields are consistently higher than 10^{11} cells/g cortex enabling the manufacture of over 100,000 devices per donor kidney for use in acute disease indications. In addition, greater than 1.8×10^{10} progenitor cells/g cortex were isolated from the one ESRD kidney tested, which strongly supports the hypothesis that autologous therapy may be possible using cells derived from a renal sample taken early in the course of chronic renal failure. In this regard, a conservative 0.1-g renal cortex sample excised from an ESRD patient would allow the fabrication of at least 18 devices containing up to 10^8 cells/unit. Cells isolated under EP method compared favorably with respect to metabolic function and morphologic phenotype with cells used in the RAD therapy clinical trials. Cryopreservation of the EP-isolated REC, which is necessary to allow for processing of these large cell yields, has been advanced using FDA-compliant procedures. Cell death postthaw has been minimized, with therapeutic potential of progenitor-derived REC conserved as evaluated using a surrogate efficacy panel consisting of lipopolysaccharide-stimulated IL8 secretion and γGT enzyme activity.

CHALLENGE: COST-EFFECTIVE STORAGE AND DISTRIBUTION FOR CELL DEVICES, BIOARTIFICIAL RENAL EPITHELIAL CELL SYSTEM DESIGN

A major obstacle in the widespread adoption of renal cell therapy to augment RRT is the lack of an "off-the-shelf," readily available system for on-demand use. Distribution, storage, and preparation for therapeutic use at point-of-care facilities have long stood as the major impediments to tissue engineered therapies [71]. The bioartificial renal epithelial cell system (BRECS), shown in Fig. 65.2C, is the first all-in-one cell culture vessel that can be cryopreserved and function as a cryostorage device and a cell therapy delivery system [72] to overcome this critical barrier to tissue engineered products' clinical translation [71].

The BRECS was designed to achieve the support of a much greater density of cells in a much lower fill volume of the previous RAD design [72], along with the capacity to cryopreserve the full unit to facilitate distribution. The polysulfone hollow fibers used as the scaffold in the previous RAD design were limited in the cell attachment surface area and were prone to fracture during cryopreservation and thaw processes, a critical element for storage and

distribution of a cell therapy device. The cell-seeding scaffold chosen for the BRECS, niobium-coated carbon disks (Cytomatrix, Woburn, MA), was selected based on its biologically inert, nonbiodegradable, and favorable thermomechanical properties for cryopreservation. Cell culture media containing oxygen and nutrients were perfused through and around the porous disks housed within the BRECS. Growth of adequate cell numbers to achieve a therapeutic impact was possible owing to the disks' high surface area. High porosity (80–90%) allowed for sufficient, homogeneous delivery of oxygen and nutrients to the cells on the disks through a balance of convective and diffusive flows across and through the scaffold. The other BRECS components, including the polycarbonate housing and gasket materials, were carefully selected and thoroughly tested to withstand cryogenic temperatures while maintaining an uncompromised sterile internal BRECS environment.

Many different BRECS prototypes were evaluated during its development phase. In brief, prototypes were manufactured using computer numeric code machining, which allowed for initial evaluation of the combined perfusion culture and cell therapy platform. This device demonstrated uniform flow distribution during in vitro perfusion and all device components remained intact, with no indication of degradation over 6 months. Further advancements to BRECS technology had progressed through BRECS prototypes made by stereolithography toward an injection-molded design that can be mass produced [73].

In vitro cell viability and metabolic activity were confirmed in the BRECS by measuring lactate production and oxygen consumption [72]. Both metrics of metabolism were consistent throughout the duration of perfusion culture, with an interpolated total cell number of 2×10^8 cells. The average oxygen consumption rate was similar to previously reported values for metabolically active cells [31]. To determine whether RECs in BRECS maintained renal differentiated phenotypic characteristics over time in perfusion culture, human REC-seeded disks from BRECS units were processed for immunohistochemical analysis of selected renal cell differentiated markers acetylated tubulin (AT-1) and zona occludens (ZO-1). AT-1, a marker for apical central cilia of proximal tubule cells, exhibited regular staining in central regions of cells grown on disks. ZO-1, a marker for epithelial tight junctions, displayed strong expression along the surface of the cells. ZO-1–positive tight junctions and punctate AT-1–positive central cilia indicate polarized epithelium and were evident in all disks tested. Renal cell-specific catabolic function of the BRECS was confirmed by assessing GSH degradation in supplemented perfusion media [72]. GSH degradation rates in BRECS remained stable over 90-day studies, indicating long-term, sustained differentiated renal cell function in the device.

Using a cryopreservation protocol employing commercially available cryopreparative solutions (HTS-Purge, Biolife Solutions, Bothell, WA) and crypreservation (CryoStor 10, Biolife Solutions, Bothell, WA), BRECS were cryopreserved with high average cell retention and high average cell viability for human REC-seeded disks [72]. Cells after cryopreservation were shown to maintain renal cell-specific metabolic functions and retain renal cell-differentiated markers AT-1, and ZO-1, which suggested that the BRECS should provide renal cell-specific metabolic supplementation when used in conjunction with conventional RRT.

These data demonstrate that the BRECS is the first single device that can serve as a culture vessel to maintain cells, can reach cryopreservation temperatures as a full unit, and finally, can be reconstituted to provide cell therapy [72,73]. Having this storage capacity makes both emergent and acute use feasible.

Functionally, the BRECS replicates many of the metabolic replacement functions of the kidney in a way similar to that of the previous RAD. However, because of differences in materials and design, the BRECS does not replicate the molecular transport control of the RAD.

BIOARTIFICIAL RENAL EPITHELIAL CELL SYSTEM AS AN EXTRACORPOREAL THERAPY TO TREAT ACUTE KIDNEY INJURY

Following the same clinical translation path as the RAD, the BRECS was then tested in large-animal models to determine the safety profile and potential efficacy. In an acute septic shock–associated MOD porcine model, intraperitoneal administration of high-dose *E. coli* resulted in a decline in arterial blood pressure along with a reduction in vital organ perfusion. Without intervention, acellular control animal survival time was 7.6 ± 0.5 h [74]. Animals receiving BRECS therapy surviving through the predetermined study end point of 16 h were assigned a survival time value of 16 h. Average survival time for the BRECS-treated group was 13.0 ± 0.9 h ($P < .001$), which was significantly extended compared with the acellular cohort [74]. Furthermore, MAP and cardiac output (CO) declined over the septic time course for both acellular and BRECS treated groups. However, both MAP and CO were better maintained in BRECS-treated animals [74]. Hematocrit measurements demonstrated stabilization of capillary leak in BRECS-treated group whereas hematocrit increased rapidly in acellular controls. Studies show that no adverse

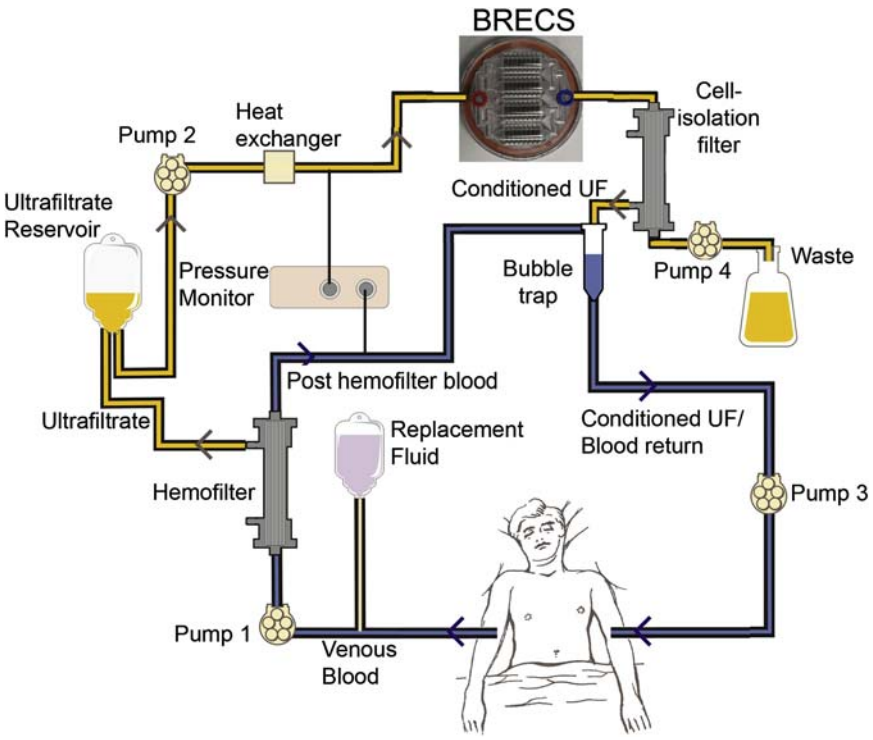

FIGURE 65.3 Diagram of bioartificial renal epithelial cell system (BRECS) extracorporeal circuit. *UF*, ultrafiltrate.

reactions attributable to the BRECS have been recorded. A schematic of a proposed BRECS therapy circuit for potential human clinical trials is depicted in Fig. 65.3.

WEARABLE BIOARTIFICIAL KIDNEY IN PRECLINICAL END-STAGE RENAL DISEASE MODEL

The development of cell therapy for treating chronic kidney disease such as ESRD has a number of technical challenges including the critical requirement of durable cell therapy and device longevity. One approach being developed is a wearable bioartificial kidney (WeBAK), which uses sorbent technology to regenerate peritoneal dialysate, which is perfused through the BRECS, to maintain cells within the cell therapy device. Similar to using UF to sustain RAD and BRECS in circuits with the patient's blood to treat AKI, dialysate is used as a nutrient and oxygen source for cells in the BRECS for the WeBAK. A large-animal ovine model was developed to evaluate BRECS supported by PD. Anephric sheep received continuous-flow PD in an extracorporeal circuit including the BRECS or acellular sham devices for up to 7 days, during which metabolic, immunologic, and endocrinologic parameters were evaluated [75]. Uremic control was achieved using continuous-flow PD. Cell viability and metabolic activity were maintained over the duration of treatment via the extracorporeal peritoneal fluid environment [75].

Although the WeBAK has not yet been evaluated in clinical studies for long-term use in ESRD, renal cell therapy paired with conventional RRT delivered from an extracorporeal circuit holds promise as a developing technology. A clinical trial failed to show survival benefit from increased doses of HD above standard care for uremic control [76], confirming that no benefit is likely to be achieved through conventional dialysis approaches to treat ESRD. Patients with ESRD display elevated levels of CRP and proinflammatory cytokines including IL-1, IL-6, and tumor necrosis factor [77–79]. All of these parameters are associated with enhanced mortality in ESRD patients. Specifically, IL-6 has been identified as a single predictive factor closely correlated with mortality in HD patients [77]. Although all ESRD patients could conceivably benefit from a bioartificial kidney, patients in the inflammatory stage who display elevated levels of chronic inflammation markers (such as IL-6 and CRP) would likely benefit most. Clinical translation will address long-term cell durability, biocompatibility, and administration protocols and additional accessory equipment required for bioartificial kidney therapy.

COMPLETE BIOARTIFICIAL KIDNEY SYSTEM FOR USE IN END-STAGE RENAL DISEASE

For the ESRD patient population, there are obvious limitations to using an extracorporeal RAD connected to an HF circuit. Ideally, a bioartificial kidney suitable for long-term use in ESRD patients would be capable of performing continuously, like the native kidney, to reduce risks from fluctuations in volume status, electrolytes, and solute concentrations and maintain acid−base and uremic toxin regulation. Such treatment requires the design and manufacture of a compact implantable or wearable dialysis apparatus and the development of miniaturized renal tubule cell devices with long service lifetimes.

Attempts have been made to develop wearable dialysis systems to improve the portability of RRT. Gura et al. published research regarding a lightweight wearable, continuous ambulatory ultrafiltration device consisting of a hollow fiber hemofilter, a battery-operated pulsatile pump, and two micropumps to control heparin administration and ultrafiltration [80]. This device regenerates dialysate with activated carbon, immobilized urease, zirconium hydroxide, and zirconium phosphate, similar to the once commercially available REDY dialysis system. Ronco and Fecondini described a wearable continuous PD system consisting of a double-lumen dialysate line with a peritoneal catheter, a miniaturized rotary pump, a circuit for dialysate regeneration, and a handheld computer as a remote control [81]. These systems still rely on inconvenient dialysate and expensive dialysis regeneration devices and/or dialyzers, but they promise to improve the convenience of dialysis.

In contrast to wearable dialysis systems, a hybrid bioartificial kidney integrates tubule cell and filtration functions. The first bioartificial kidney, consisting of a passive hemofilter and an active renal tubule cell bioreactor, has consistently demonstrated excellent safety and effectiveness in animal studies and FDA-approved human clinical trials, as described previously [16,30,42,53]. A major drawback of the current version of the bioartificial kidney is its large size, owing to the requisite extracorporeal circuit with peristaltic pumps to provide driving pressure for HF.

A new smaller and more durable RAD is being developed by Humes and colleagues. In collaboration, Fissell and colleagues are developing a nanopore membrane [82] to replace the filtration function of the glomerulus without the hemofilters and mechanical pumps of existing dialysis machines. A filtration device based on nanopore membrane technology would be implantable [83]. Further refinement of the RAD would be encouraging for ESRD patients because in principle, such a tissue-engineered device could be free of dialysate or replacement fluid while providing functions of healthy kidney that are not offered by current dialysis strategies. The combination of cell therapy and solute clearance could be a viable RRT, conferring dialysis independence to the patient.

FUTURE ADVANCEMENTS FOR WEARABLE AND AMBULATORY RENAL REPLACEMENT THERAPIES

Critical to the success of wearable and ambulatory RRT, including a wearable artificial kidney, a number of technical hurdles remain to be overcome, including creating a miniaturized, automated, safe dialysis platform to enable portability. Complex systems including multiple sensor feedback with real-time response capability would be required for combined cell therapy to augment conventional uremic toxin clearance and ensure proper cell maintenance within the cell therapy device and safe water−electrolyte balance for the patient concurrently. Real-time sensor technologies such as esophageal Doppler monitoring and peripheral waveform analysis may provide the basis for measures of central hemodynamic parameters critical to therapy. Likewise, bioimpedance and hematocrit monitoring may provide the basis for measuring changes in blood volume, because various techniques have been deployed in outpatient maintenance HD [84]. Chemical-field effect transistors offer the possibility of measuring electrolyte levels in a protein-free UF and reading out the potassium level to patients, who could then alter their diet or treat themselves with potassium-absorbing resins. Flow probes to determine the flow rate within the extracorporeal circuit and pressure sensors with safety features will be required for clinical implementation. Similar to portable or ambulatory PD systems described in literature, a WeBAK system would likely require a central processing and control unit that would receive information from sensors and determine actions for clinical management and control of the therapeutic circuit.

Other important steps toward a fully functional WeBAK include miniaturization of critical components such as pumps and power supplies or batteries. Each component of the completed system that requires power would have to be supplied by high−energy density battery packs. Technological advances in batteries and efficiency of electrical components such as pump motors and central processing units should enable a wearable dialysis system with cell therapy in the relatively near future. Although no wearable dialysis system exists, advancements in pump

miniaturization and technology to reduce the volume of regenerated dialysate during continuous portable PD are important steps to an engineered solution [85–88].

With regard to the biological component of a WeBAK, the durability of cell-based therapy suggests that the cell device itself could be maintained for at least 6 months under ideal temperature and nutrient conditions in a chronic use application without the need for replacement, which is ideal for treating ESRD with a continuous PD circuit [75].

CONCLUSION

Despite all of the advances in extracorporeal RRT, a portable, continuous, dialysate-free artificial kidney device has not yet been developed, which remains the ultimate goal of this technological progress. The enabling platform technologies discussed in this review can be seen as steps toward this overall goal from theoretical designs to prototypes evaluated on the laboratory bench, and to medical products used at the bedside. Future research requires an integrative, multidisciplinary approach to enable technologies to be brought together and tested in preparation for clinical translation. High priority must be given to sensing and regulating extracellular fluid volume, with feedback mechanisms to adjust ultrafiltration and reabsorption by the bioartificial kidney. Also, patient safety must be ensured when monitoring other critical aspects of therapy and fail-safe mechanisms to avoid acidosis or uremic syndromes.

The critical building blocks of an autonomous bioartificial kidney are advancing rapidly; revolutionary clinical trials are under way at multiple medical centers. The technologies that will enable advances to a more autonomous, dialysate-free system are under development. In addition, progress has been made in the field of cryopreservation, and thus the ability to manufacture, store, and distribute bioartificial organs is advancing. We will likely see quantum advances in renal replacement in the very near future.

List of Acronyms and Abbreviations

AKI Acute kidney injury
ARF Acute renal failure
AT-1 Acetylated tubulin-1
ATN Acute tubular necrosis
BAL Bronchoalveolar lavage
BRECS Bioartificial renal epithelial cell system
BUN Blood urea nitrogen
CA Cellulose acetate
CO Cardiac output
CRP C-reactive protein
CVVH Continuous venovenous hemofiltration
ECS Extracapillary space
EP Enhanced propagation
ESRD End-stage renal disease
FDA U.S. Food and Drug Administration
G-CSF Granulocyte-colony stimulating factor
GSH Glutathione
HD Hemodialysis
HDF Hemodiafiltration
HF Hemofiltration
ICU Intensive care unit
IFN Interferon
IL Interleukin
MAP Mean arterial pressure

WeBAK Wearable bioartificial kidney
ZO-1 Zona occludens-1

Glossary

Hemodialysis membrane A synthetic membrane used in dialysis that is employed to separate toxins from the blood through a diffusion-dominated process.
Hemofiltration membrane A synthetic membrane used in filtration of the blood to remove toxins in a process dominated by hydraulic pressure.
High-flux membrane A membrane used in hemofiltration with larger pores and higher hydraulic conductivity than conventional membranes, which allows for the removal of higher−molecular weight toxins.
Synthetic membrane A fabricated structure that enables the separation of mixtures. Conventional membranes accomplish this separation based on molecular size, because lower−molecular weight species are able to pass through pores in the membrane.

Regenerative Medicine Approaches for the Kidney

In Kap Ko, James J. Yoo, Anthony Atala

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

Kidney disease is a leading cause of death globally [1]. Among its most common forms are acute kidney injury (AKI), chronic kidney disease (CKD), and end-stage renal disease (ESRD). In AKI and CKD, the kidney loses its capacity to function and filter blood efficiently. Furthermore, AKI can often deteriorate into CKD, which affects 8–16% of the global population [2]. Medical therapies for kidney diseases such as AKI and CKD primarily involve hemodialysis or kidney transplantation. Dialysis can replace renal filtration of metabolic waste from blood, but it serves as a supportive treatment that manages symptoms and delays disease progression. In addition, dialysis cannot replace other critical kidney functions, such as synthesis of erythropoietin (EPO), which stimulates red blood cell production [3]. Consequently, treatment of renal disease should promote efficient regeneration of functional renal-specific cells or stem cells; thus, a cell-based approach that replaces or restores damaged renal cells would be a promising alternative to current treatment options.

AKI and CKD can progress to ESRD, a severe condition affecting multiple organ systems. Kidney transplantation provides the only definitive treatment for ESRD; however, the supply of transplantable donor kidneys meets less than 20% of the demand [4]. To address this issue, tissue engineering (TE) and regenerative medicine (RM) approaches have been suggested as promising solutions. Stem cell biology and cell culture technologies have enabled researchers to identify and characterize kidney-derived cells and various types of cells that could be used to treat renal diseases [5,6]. The simplest approach uses cell transplantation, in which single therapeutic cells can be administered to a patient with kidney failure to restore renal function. Because this approach is easier to administer and less invasive than other alternatives, most studies have been performed using cell therapy strategies [7,8].

Whereas various cells have been studied for potential use in cell therapy [5], engineering of renal constructs has also been attempted to facilitate renal regeneration [9,10]. In this approach, the engineered constructs contain extracellular matrix (ECM), soluble factors, and a scaffolding system to guide in vitro cultured cells. The scaffold provides support to form three-dimensional (3D) renal structures that will lead to efficient integration with the host after implantation. This approach is ideally applicable to more serious renal conditions that require replacement of diseased kidney tissues.

Compared with these two cell-based approaches, a strategy that uses endogenous cell sources is emerging as a promising alternative for renal regeneration [11]. This technique, known as in situ tissue regeneration, takes advantage of the body's natural healing processes and the ability to recruit endogenous kidney cells for kidney regeneration. For efficient renal regeneration in situ, there are two goals: (1) redesign of damaged renal tissue after injury toward appropriate microenvironments, and (2) effective infiltration of host cells containing therapeutic potential into the recreated renal niche.

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00066-7

In this chapter, cell sources that are used for cell-based therapies and associated applications to treat kidney diseases will be reviewed. In addition, several approaches to engineering renal constructs and in situ kidney regeneration will be presented.

CELL-BASED THERAPY

Cell transplantation and implantation of engineered kidney constructs have been considered as promising therapeutic methods. For both applications, establishment of a refined cell culture system is essential to obtain a sufficient number of therapeutic cells for later transplantation. To this end, various types of cell sources have been identified, characterized, and used to treat renal diseases (Table 66.1).

Cell Sources: Kidney Tissue–Derived Stem and Primary Cells

The adult kidney contains over 20 heterogeneous types of cells distributed among the various compartments, including vascular, interstitial, glomerular, and tubular structures with architectural complexity [12]. Through a

TABLE 66.1 Application of Cell Therapy for Kidney Regeneration

Cell Types and Origin	Cell Subtypes	In Vitro or In Vivo Animal Model	References
Renal progenitor cells from the Bowman capsules	Human $CD133^+$ cells from the Bowman capsule	SCID mice with glycerol-induced tubulonecrosis: homing of $CD133^+$ cells to kidney tubules	[17]
	Human $CD24^+CD133^+$ cells	SCID mice with acute renal failure: morphological and functional improvement by $CD24^+CD133^+$ cell infusion	[18]
	Human $CD133^+CD24^+PDX^-$ cells	SCID mice with acute renal failure: functional recovery such as reduced proteinuria and glomerular damage	[20]
Renal stem or progenitor cells from renal papilla	Low-cycling proliferating cells (BrdU-retaining cells)	In vitro characterization: heterogeneity of BrdU-retaining cells with epithelial, mesenchymal, and neuronal phenotypes	[22]
	$CD133/1^+nestin^+$ cells	In vitro organ culture: human $CD133/1^+$ cell integration with mouse-derived tubules for new tubule formation	[23]
Renal stem or progenitor cells from renal tubules	BrdU-retaining and $vimentin^+$ cells	I/R rat model: integration of $EGFP^+$ tubular cells with regenerating renal tubules	[27]
	$ALDH^{high}$ cells	$ALDH^{high}$ cells: cell proliferation capability and $CD133^+CD24^+$ expression	[114]
Primary renal cells	Human $CD10^+CD13^+$ cells	Pure population of human renal tubule cells	[33]
	Unpurified human primary renal cells	High percentage of proximal tubular cells (70–80%) with high proliferation capability	[34,35]
	EPO^+ cell population in human primary renal cells	I/R rat model: functional and structural improvement by amelioration of inflammation and oxidative stress	[36]

iPSC	In vitro differentiation into renal population [44,96], in vivo rat AKI: improved survival of animal through enhancement of renal functions [46], in vivo mouse AKI: human iPSCs engrafted into damaged tubules and restored renal function and structure [47]		
AFSC	In vivo renal function improvement in an AKI mouse model [50], an SCID mouse [51], an Alport syndrome mouse model [52], and a kidney autotransplantation model in pig [53]		
BM-MSC	In vivo kidney function improvement in mouse [55,56,58,61] or rat [54,57,59,60] models, clinical trials with kidney transplantation [67,68]		
ADSC	In vivo kidney function improvement in mouse [63], rat [62,64], and pig [65,66] models		

ADSC, adipose-derived stem cell; *AFSC*, amniotic fluid-derived stem cell; *AKI*, acute kidney injury; *ALDH*, aldehyde dehydrogenase; *BM-MSC*, bone marrow-derived mesenchymal stem cell; *BrdU*, 5-bromo-2′-deoxyuridine; *EGFP*, enhanced green fluorescent protein; *EPO*, erythropoietin; *ESC*, embryonic stem cell; *I/R*, ischemic/reperfusion; *iPSC*, induced pluripotent stem cell; *PDX*, podocalyxin; *SCID*, severe combined immunodeficiency.

coordinated balance, this mixed population of cells maintains homeostasis within the renal microenvironment that supports cell-to-cell interactions [13]. Disruption of renal homeostasis occurs after injury or in the case of disease, which in turn elicits the release of cellular and molecular signals to interact with cell components to facilitate regeneration and repair the damaged kidney. Extrinsic regulators within the renal niche initiate renal-specific differentiation and self-renewal of various renal cells and stem cells. Although the existence and identification of renal stem or progenitor cells in adult kidney tissues have been controversial, numerous studies indicate that renal stem and progenitor cells exist in the Bowman capsule, papilla, and tubular sections [7]. Thus, purification and expansion of these cells could be sources for cell therapy to treat renal failure.

The Bowman capsule initiates the filtration of blood and generation of urine [14]. The Bowman capsule is composed of several layers: the parietal layer, the Bowman space, the visceral layer, and a filtration barrier that contains specific kidney cell types. In early studies, a few cell surface markers were identified to isolate renal stem cells from the Bowman capsule. One such marker for cell isolation is the CD133 stem cell marker, which is expressed in hematopoietic stem cells [15] and in the kidney during embryogenesis [16]. Bussolati et al. [17] and Sagrinati et al. [18] isolated and expanded $CD133^+$ cells from normal adult kidney cortex and from kidney tissues of cancer patients obtained at nephrectomy. Although cultured $CD133^+$ cells developed into epithelial and endothelial cell phenotypes [17], $CD24^+CD133^+$ cells displayed various differentiation lineages, including mature proximal and distal tubule formation and adipogenic and osteogenic phenotypes [18]. In preclinical studies, $CD133^+$ [17] or $CD24^+CD133^+$ cells [18] facilitated therapeutic outcomes when administered into renal injury models [17,18].

Glomerular filtration for removal of waste from the blood is one of the kidney's primary functions, and podocytes within the glomerulus have a significant role in the filtration process [19]. However, because podocytes have limited ability for cellular proliferation in the injured kidney, use of stem or progenitor cells that can become more podocytes is an alternative approach for the recovery of normal kidney filtration. Ronconi et al. [20] tested this possibility using $CD24^+CD133^+$ cells. Interestingly, $CD24^+CD133^+$ cells without podocalyxin (PDX) expression ($CD24^+CD133^+PDX^-$ cells) showed tubular and podocyte differentiation, whereas $CD24^+CD133^+PDX^+$ cells contained only podocytes, which suggests that these cells behave as bipotent renal progenitors [21]. Furthermore, in an in vivo study using Adriamycin-induced nephropathy in mice, only $CD24^+CD133^+PDX^-$ cells resulted in functional recovery, including reduced proteinuria and glomerular damage, whereas injection of $CD24^+CD133^+PDX^-$ or $CD24^-CD133^-$ cells was not effective for renal repair.

Another niche for renal stem cells is the renal papilla. This is located in a central region of the kidney that contains epithelia of collecting ducts and the loops of Henle that concentrate urine [7]. In an early study [22], a renal stem-like cell population with a low cell-cycling rate was identified. To track such low-cycling cells in adult kidney, Oliver et al. [22] used a nucleotide bromodeoxyuridine (BrdU) labeling technique to demonstrate that BrdU-retaining cells existed in the papilla. In vitro and in vivo studies demonstrated that BrdU-labeled cells were heterogeneous in nature and included ZO-1–positive epithelial, α-smooth muscle actin–positive mesenchymal, and III-β-tubulin–positive neuronal phenotypes. Based on these results, the authors concluded that the renal papilla contained low-cycling cells and is a niche for adult renal stem cells.

Extending the previous conclusion that CD133-positive cells act as renal stem cells in the Bowman capsule [17], Ward et al. [23] reported that $CD133^+$ cells isolated from adult human papilla and cortex could integrate into tubular structures in their developing stages. Isolated $CD133/1^+$ papilla and cortex cells were positive for nestin, as reported previously by others [24]. A differentiation capability assay revealed that the $CD133/1^+nestin^+$ cells changed to a neurogenic and epithelial-like lineage and underwent tubulogenesis. In a metanephric organ culture, $CD133/1^+$ cells from both the papilla and cortex integrated into mouse-derived tubules during in vitro cell culture, indicating the integration capability of the renal stem cells into the formation of new kidney tubules.

The renal tubule has been considered a renal stem cell niche. It has an important role in reabsorption of electrolytes and proteins and amino acid transportation through hydrolase activity. Previously, the S3 segment of proximal tubule was identified as a renal stem niche in which a significant number of cells were observed to be mitotically active in the region, as confirmed by the expression of proliferating cell nuclear antigen [25]. To identify cellular phenotypes of tubular cells further, several studies used transgenic animals that express reporter markers [26–28]. Lin et al. used transgenic mice expressing enhanced green fluorescent protein (EGFP) protein in mature tubular epithelial cells [27]. After ischemia and reperfusion injury in mice, the investigators found that EGFP-positive tubular cells retaining BrdU labeling and vimentin expression formed regenerating renal tubules, indicating that the intrinsic cell population for renal regeneration is present in the tubule.

To use kidney tissue–derived stem cells for cell-based therapies, efficient isolation and expansion of cell populations from renal tubules are necessary. Lindgren et al. chose a stem cell marker, aldehyde dehydrogenase

(ALDH), which was used to isolate hematopoietic stem cells [29]. ALDH is an enzyme that converts retinol into retinoic acid, and its activities in various tissues [30] are closely related with stem cell proliferation and differentiation. This study reported that tubule cells with high ALDH activity ($ALDH^{high}$ cells) showed $CD133^{+}CD24^{+}$ phenotypes in the human tubule tissue and maintained better cell proliferation capability than $ALDH^{low}$ cells, indicating that $ALDH^{high}$ cells may represent renal progenitor cells from adult human tubules.

Other markers have been used to purify tubular epithelial cells. Using CD10 and CD13, epithelial cell markers [31,32], Van der Hauwaert et al. established a cell sorting method to purify proximal tubular epithelial cells from human renal tissue [33]. Although $CD10^{+}CD13^{+}$ cells comprised only about 4% of the entire cell population, once purified, they showed cell proliferation capability and maintained clear proximal tubular cell phenotypes, such as aquaporin-1 and N-cadherin. On the other hand, $CD10^{-}CD13^{-}$ cells displayed distal and collecting duct markers such as E-cadherin and MUC1; cells positive for CD10 or CD13 were heterogeneous. The investigators concluded that isolation of a pure population of human-derived renal tubule cells is possible, and the isolation method using the markers can be applied to isolate renal stem cells as well.

Our group has focused on isolating and expanding primary kidney cells that could be easily used in clinical applications [34]. After in vitro cell culture, cultivated kidney cells show efficient growth capability. Approximately 70–80% of cultured cells are composed of proximal tubular cells; the remaining cells consist of distal tubular cells, collecting duct cells, podocytes, and other types of cells. Using our established cell culture techniques, we further tested the feasibility of cell therapy using autologous cell sources. We evaluated primary renal cells from diseased kidneys to determine whether their normal phenotypic and functional characteristics are retained, and thus could be used for cell therapy [35]. Renal cells from diseased human kidneys retained characteristics similar to those of normal kidneys, which suggests that autologous cell sources may be used for cell transplantation to treat patients with renal failure [35]. In another study, we purified an EPO-enriched cell population from cultured primary kidney cells and examined the ability of EPO^{+} cells to improve renal function [36]. EPO is a hormone that produces red blood cells and functions as antiinflammatory and antioxidant molecules [37]. In an in vivo study using a rat model with CKD, we demonstrated that EPO^{+} cells ameliorated inflammation and oxidative stress, whereas unpurified cells did not. These results suggest that EPO-enriched cells within primary kidney cells may be a promising cell source for treatment of renal diseases.

Other Cell Sources: Pluripotent, Fetal, or Adult Stem Cells

Various types of cells isolated from nonrenal tissues have been considered potential cell sources, such as pluripotent cells and stem or progenitor cells from fetal and adult tissues. Among pluripotent cells, both embryonic stem (ES) cells [38] and induced pluripotent stem (iPS) cells [39] have been extensively studied in this regard. Both have self-renewable capability and multidifferentiation ability that theoretically is capable of differentiating into any type of cells. ES cells in the kidney have been studied as a potential treatment for renal failure [40–43]. However, ethical dilemmas, danger of cancer from uncontrolled growth, and immunogenic issues still need to be resolved before clinical trials can be initiated.

On the other hand, iPS cells have some advantages in terms of use as an autologous cell source for cell-based therapy compared with ES cells. iPS cells can be obtained by transducing a patient's own fibroblasts with reprogramming genes (Oct3/4, Sox2, c-Myc, and Klf4) [39]. Induction of iPS-derived kidney cells in [44,45] in vitro and some in vivo preclinical studies [46,47] demonstrated the possibility of positive therapeutic effects in treating kidney diseases. However, a sufficiently sophisticated cell culture system for mass cell culture is still needed that can maintain phenotypes and prevent teratoma formation and immunogenicity [48] in vivo.

Fetal and adult tissue-derived stem cells have lower cell growth capability than ES and iPS cells, but the use of tissue-derived cells for therapeutic applications removes the issue of possible teratoma formation. For example, amniotic fluid stem (AFS) cells have been successfully isolated from the amniotic fluid during pregnancy and expanded for therapeutic applications. Our group established a cell culture technique that allowed efficient expansion of AFS cells and demonstrated that the cultured AFS cells showed self-renewal capability and multidifferentiation ability [49]. Preclinical studies using AFS cells demonstrated beneficial outcomes in treating renal failure [50–53].

Stem cells isolated from adult tissues have been extensively studied to treat renal diseases. Mesenchymal stem cells (MSCs), one representative cell source, showed therapeutic effects in renal recovery. MSCs can be easily collected from bone marrow (BM-MSCs) and adipose tissue (ADSCs). Beneficial outcomes for both BM-MSCs and ADSCs in treating renal diseases have been reported in several preclinical models, in which the

application of BM-MSCs [54–61] and ADSC [62–66] varied from acute to chronic renal disease. A few clinical studies using MSC transplantation to improve outcomes of renal transplantation have also been published [67–69].

Engineering of Cell-Based Renal Constructs

The general strategy of engineering a renal construct for treatment of renal diseases is to fabricate functional renal structures in vitro and then implant the constructs for successful integration with host kidney tissues (Table 66.2). To engineer 3D kidney constructs, cultured renal cells are seeded onto a scaffold; the seeded cells within the scaffold are allowed to expand and mature into renal structures. Kidney tissue possesses a complex 3D tubular architecture and is composed of numerous cell types within the renal tissue; therefore, selection of the appropriate cell sources is a consideration for engineering renal constructs. Although many types of renal stem cells have been identified and characterized, use of stem cells as cell sources for engineering renal constructs is still in its infancy for practical applications [7]. Alternatively, most approaches developed for engineering kidney structures have used primary renal cells that are isolated and expanded without further purification. Primary cell culture techniques are now well-established to isolate and expand primary renal cells that demonstrate proliferation and differentiation capability during multiple passages [34].

Another important factor to consider in the in vitro fabrication of kidney structures is the efficiency of engineering the appropriate microenvironment, or niche, to allow seeded cells to form normal kidney-like structures through cell–cell/cell–matrix interactions [70]. Controlled orchestration of engineered niche components, such as the ECM and soluble factors within the scaffolds, is required for the efficient fabrication of renal constructs. Three types of scaffolding systems (natural polymers, synthetic polymers, and biologic tissue matrices) have been used for TE applications [71]. Naturally derived polymers, such as collagen, hyaluronic acid (HA), chitosan, fibrin, alginate, or agarose, provide an alternative to native tissues. Most of these natural biomaterials require biocompatible characteristics with native tissue and can support and guide cellular behaviors such as cell activation, migration, proliferation, and differentiation [72].

Collagen and collagen-based hydrogels have been used extensively to produce scaffolds for kidney TE. Wang et al. [73] developed a renal cell isolation and culture system for engineering renal constructs in vitro (Table 66.2). Glomerular epithelial and mesangial cells isolated from renal tissues were expanded on a collagen-based membrane scaffold (collagen–vitrigel) with a stable, thin shape. The mixture of collagen with vitrigel provided an optimal environment that mimicked the native glomerular structures, which formed a reconstructed glomerular tissue when cocultured with renal cells [73]. In a similar approach, Lu et al. [74] used another collagen-based material that included a Matrigel system containing a mixed population of neonatal rat renal cells to reconstruct 3D renal tissues in vitro. Subsequently, the cells seeded within the 3D collagen hydrogel scaffold self-assembled into engineered renal tissues that contained both tubules and glomeruli-like architecture.

Using the collagen gel scaffold system, our group established a 3D renal-like construct for in vivo study. We found that primary human kidney cells can be expanded in a 3D collagen-based culture system [34], and these cells retained renal phenotypes that stained positively for proximal and distal tubules and collecting duct markers [34]. The cells formed tubule-like structures that provided renal function, such as albumin adsorption. In in vivo implantation studies, cells within the 3D kidney construct maintained their renal phenotypes and remained viable for 6 weeks after subcutaneous implantation in nude mice. These findings demonstrate that human renal cells grown under 3D culture conditions using a collagen gel system are able to generate renal tubule-like structures in vitro and may be used for kidney repair [34].

Another type of ECM contains HA, a glycosaminoglycan, which has been used as a gel-based scaffold for TE applications. HA has a vital role in mammalian development and provides appropriate mechanical properties for scaffold structures [75]. Rosines et al. used a mechanically stable HA construct as a scaffold for in vitro culture and developed a 3D cell culture method to construct renal-like tissues from fetal kidney tissues [76]. HA supported ureteric bud branching, promoted mesenchymal-to-epithelial transformation, and stimulated differentiation of the metanephric mesenchyme and ureteric buds. The authors proposed that HA might serve as an appropriate scaffolding material for kidney TE. Nevertheless, the use of hydrogel-based scaffolds such as HA and other hydrogel polymers is limited by their low mechanical characteristics and high failure rate in terms of shape retention [77].

In an attempt to address these mechanical issues, synthetic biomaterial-based scaffolds have been tested as an alternative source for TE applications. Synthetic polymers include biodegradable polymers such as poly(lactic

TABLE 66.2 Applications to Engineering Renal Constructs and In Situ Kidney Regeneration

Approach Type		Components	In Vitro or In Vivo Animal Model	References
	ECM	**Cells**		
Engineering renal constructs	Collagen/vitrigel	Glomerular epithelial and mesangial cells	In vitro testing to reconstruct renal glomerular tissue	[73]
	Collagen/Matrigel	Neonatal rat renal cells	In vitro testing to reconstruct renal tubules and glomeruli-like structures	[74]
	HA	Fetal kidney tissue	In vitro testing to reconstruct kidney-like structures for kidney development: ureteric bud, metanephric mesenchyme	[76]
	Polycarbonate	Murine kidney cells	Subcutaneous implantation (Athymic mouse), tubules and glomerular structures and functional outcomes (urine-like fluid)	[79]
	PGA	Renal segments	Subcutaneous implantation (Athymic mouse), renal structure formation in the implant	[80]
	PGA	Renal cells from bovine fibroblast using nuclear transfer technique	Subcutaneous implantation (Athymic mouse), tubules and glomerular structures and functional outcomes (urine-like fluid)	[81]
	Decellularized kidney scaffold	Renal cell and EC	Experimental orthotopic implantation using whole-kidney construct (rat)	[84]
	Decellularized kidney scaffold	EC	Experimental orthotopic implantation using whole-kidney construct (pig)	[94]
	ECM	**Bioactive factors or small molecule**		
In situ kidney regeneration	P-collagen	–	Intraperoneal injection into chronic cyclosporine nephropathy of rats, improved renal function through fibrosis reduction	[97]
	PEG-based gel	–	Injection into renal capsule pocket of rats, feasibility test of gel-based drug delivery, no renal damage and normal host cell infiltration	[98]
	Microspheres based on PLLA, PDLA, PEG	Rapamycin	Intracapsule implantation into rat I/R model, compared with subcutaneous injection, reduced fibrotic tissue in renal-injected group	[103,115]
	–	BMP-7	Systemic injection into TGF-β1–induced EMT model in mice, improved renal function	[106]
	–	Antibodies to epididymis protein (HE4)	Systemic injection to progressive renal disease model, reduced fibrosis and improved renal function	[107]
	–	BMP agonist peptide (THR-123) and ACE inhibitor (Captopril)	Intravenous injection and reduction of fibrosis in mouse renal diseases	[111]
	–	HDAC inhibitors (PTBAs analog)	Intraperitoneal injection and reduction of fibrosis in aristolochic acid–induced kidney injury	[94,112]

ACE, angiotensin-converting enzyme; *ADSC*, adipose-derived stem cells; *AFSC*, amniotic fluid-derived stem cell; *BM-MSC*, bone marrow-derived mesenchymal stem cells; *BMP*, bone morphogenetic protein; *CSF-1*, colony-stimulating factor-1; *EC*, endothelial cells; *ECM*, extracellular matrix; *EMT*, epithelial-to-mesenchymal transition; *EPC*, endothelial progenitor cells; *ESC*, embryonic stem cell; *HA*, hyaluronic acid; *HDAC*, histone deacetylase; *HE4*, human epididymis protein 4; *I/R*, ischemia/reperfusion; *iPSC*, induced pluripotent stem cells; *P-collagen*, polymerized collagen; *PDLA*, poly(D-lactic acid); *PEG*, polyethylene glycol; *PGA*, polyglycolic acid; *PLLA*, poly(L-lactic acid); *PTBAs*, phenylthiobutanoic acids; *TGF-β1*, transforming growth factor-β1.

acid), poly(glycolic acid) (PGA), and poly(lactic-*co*-glycolic acid). Owing to a well-controlled degradation profile, nontoxicity, and simple fabrication techniques, the biodegradable polymers have been used as scaffolds sources for renal TE; however, synthetic polymers are limited in terms of slow degradation in the body and may cause inflammatory responses [78].

As an initial approach to testing the feasibility of using synthetic polymers for engineering renal constructs in vitro, our group used PGA scaffolds as an artificial ECM niche to expand rabbit renal cells within the scaffold. Renal cells isolated from proximal and distal tubules and glomeruli were cultured separately and then seeded onto PGA scaffolds. Engineered kidney-like constructs were subcutaneously implanted into athymic nude mice. Nephron-like segments formed within the implant construct, and the seeded cells had proliferation capacity, as shown by BrdU staining. These results demonstrate that cultured primary rabbit renal cells could reconstitute tubular structures with a homogeneous cell type within each tubular tissue.

In another study, our group used a tubular-shaped scaffold prepared from polycarbonate material for 3D culture of murine kidney cells [79]. The tubular-shaped scaffold was connected at one end to a silicone-derived catheter that terminated in a plastic reservoir; this construct was implanted subcutaneously in athymic mice. The implanted construct retained highly organized tubular structures and formed glomerulus-like structures with extensive vascular integration. Furthermore, the tubule-like structures contained renal phenotypes of both proximal and distal tubular cells and cells of the ascending loop of Henle, as confirmed by immunohistochemistry. The newly formed structures exhibited renal function by excreting high levels of solute in a yellow urine-like fluid [79].

Using the same synthetic polymer, a similar study was performed using kidney segments. Kim et al. loaded renal segments onto 3D PGA polymer-derived scaffolds and implanted the renal-like units in vivo [80]. The 3D renal reconstructs that formed contained glomeruli and tubules, which suggested that renal structures can be reconstituted by transplanting renal segments with supporting biodegradable scaffolds.

Lanza et al. bioengineered kidney-like tissues with a nuclear transfer technique by isolating renal cells from early-stage cloned bovine fibroblasts that were then seeded onto synthetic scaffolds derived from PGA [81]. The implanted construct formed highly organized tubular- and glomerular-specific structures that exhibited secretion of urine-like fluid from the implant. Moreover, this study suggested that the ability to generate histocompatible cells using a nuclear transfer technique could address a major challenge in transplantation medicine.

The use of acellular tissue matrices as renal scaffolds is attractive because natural and synthetic polymers cannot replicate the precise spatial architecture of complex structures such as the kidney. In particular, acellular tissue scaffolds are prepared by removing cellular components from the tissues through mechanical or chemical processes to produce collagen-rich matrices [82]. These collagen-rich matrices tend to degrade slowly after implantation and are remodeled with ECM proteins secreted by ingrowing cells. Therefore, much attention has been directed toward developing renal decellularization techniques to produce acellular kidney scaffolds that can maintain native kidney structures such as ECM, bioactive factors, and vascular integrity. Several groups have developed decellularization techniques to produce acellular renal scaffolds to recreate whole-kidney constructs [83,84].

Using biologic scaffolds obtained from the decellularization process, one of the most promising approaches is to bioengineer whole-kidney constructs, in response to the shortage of transplantable kidneys. Progress in whole-organ engineering involving decellularization, followed by recellularization of the resultant collagen-rich scaffolds, has offered a promising approach to creating transplantable organ constructs [85–89]. Decellularization/recellularization techniques have enabled researchers to create bioengineered whole organs in vitro successfully, such as heart [85], lung [89], liver [86,88], and the kidney [84]. Although a few in vivo studies have been performed using small-animal models, these have been limited to short-term assessments; engineered organs function for only a few hours after implantation. An implantation study of a bioengineered rat kidney construct demonstrated the feasibility of the whole-kidney engineering technology based on decellularization/recellularization of kidney tissue [84]. In the recellularization process of acellular kidney matrices, previous studies used ES cells [90,91] and viable kidney explants [92] to recreate engineered kidney structures in vitro [84]. Although these approaches demonstrated the feasibility of using recellularization of a renal matrix to bioengineer a kidney, the field of whole-organ engineering is still in its infancy; several challenges must be addressed before clinical applications are possible.

One such challenge is long-term success in the vascular patency of bioengineered organs in vivo. Without complete and functional endothelial reseeding of vascular matrices, significant thrombosis is likely to occur within the acellular vasculature, which makes the recellularized construct nonfunctional [86,93]. To address this issue, we developed a cell seeding technique that enables efficient endothelial cell coating of the vascular walls of acellular porcine kidney matrices [94]. The acellular renal scaffold was prepared from native porcine kidneys using our previously described decellularization technique [83]. Conjugation of CD31 antibody molecules in the vascular lumen enhanced endothelial cell retention on the vasculature and improved the vascular patency of the implanted scaffold during implantation. These results suggest that endothelial cell seeding plus antibody conjugation could maintain the vascular patency of bioengineered whole kidneys in vivo. However, to make this technology amenable to clinical use, other critical challenges need to be addressed. These include fabricating acellular renal scaffolds on a clinical

scale [83,95], efficient recellularization of scaffolds using clinically relevant cell sources to recreate fully functional kidney constructs [34,44,96], and viable long-term implantation without severe thrombosis [94].

CELL-FREE APPROACH: IN SITU RENAL REGENERATION

An important issue in tissue regeneration in situ is how to fabricate a scaffolding system for efficient recruitment of host cells into the implant and reprogramming of the infiltrated cells within the scaffold. Both natural ECM and synthetic biomaterials have been used as a scaffold to promote in situ renal regeneration [97,98] (Table 66.2).

Whereas collagen-based scaffolds have been widely used as a cell seeding scaffolding system in classical renal TE, several types of collagens have been tested as a natural ECM for renal regeneration in situ. One type of collagen derivative, polymerized collagen (P-collagen), a mixture of pepsinized porcine type I collagen and polyvinylpyrrolidone, facilitated antiinflammatory and antifibrotic properties and reduced scar formation [99,100]. Generally, modulation of inflammation and fibrosis is closely associated with efficient renal regeneration. Sanchez-Pozos et al. used P-collagen to ameliorate renal pathology in a model of chronic cyclosporine A (CsA) nephropathy [97]. P-collagen partially reduced CsA-induced renal pathology and improved anatomic and functional renal properties. These effects were associated with lower levels of inflammatory markers, such as transforming growth factor-β (TGF-β) and Kim-1. In this study, P-collagen functioned as an ECM niche to improve the renal microenvironment by reducing inflammation and fibrosis, thereby improving renal function.

Controlling degradation of the ECM is necessary to maximize therapeutic effects and prevent the rapid disappearance of the added molecules [101]. Serban et al. developed a cross-linked gelatin-based microsphere with continuously tunable degradation; thus, the collagen-derived material served as an ECM scaffold [102]. An in vitro degradation profile showed that the cross-linked gelatin microspheres were resistant to enzymatic degradation. Effects of cross-linking on slow degradation were confirmed by the orthotopic injection of materials into animals. Results of this preliminary study suggested that the product of gelatin-based microbeads might be used to develop materials that catalyze kidney regeneration in the presence of renal disease.

Similarly, synthetic hydrogel systems with different degradation profiles have been developed to assess the feasibility of using them within the kidney for treatment. Dankers et al. synthesized two types of materials with different physiochemical properties based on polyethylene glycol (PEG)-based hydrogels. The hydrogels were injected into the renal capsule pocket to test the feasibility of gel-based drug delivery [98]. The injected synthetic hydrogels did not damage the renal cortex and facilitated normal host cell infiltration of macrophages and myofibroblasts. These strong, flexible, and slow-eroding chain-extended hydrogels might be suitable for the sustained intrarenal delivery of organic drugs. On the other hand, the weaker, softer, and fast-degrading bifunctional hydrogels may be more suitable for the short-term delivery of protein-based drugs to the kidney cortex. These favorable biological behaviors of supramolecular hydrogels make them excellent candidates for subcapsular drug delivery.

For the efficient delivery of such soluble factors and drugs, hydrogel systems have been developed to modulate controlled release of therapeutic drugs [101]. Zandstra et al. [103] developed a drug delivery system based on the use of synthetic monodispersing microspheres to deliver rapamycin, which is known to reduce inflammation in rodent models of kidney disease [104,105]. The microspheres were synthesized using poly(L-lactic acid), poly(D-lactic acid), and PEG, and then rapamycin was codissolved into the copolymer solutions. The rapamycin-incorporated microspheres were administered through subcapsular injection in a rat model of AKI. Therapeutic effects were then compared with subcutaneous injection to mimic systemic administration. Local intrarenal delivery of rapamycin-incorporated monospheres facilitated decreased macrophage infiltration and a significantly lower number of myofibroblasts in the kidney compared with the group with systemic administration. Local delivery of rapamycin caused a transient increase in the deposition of collagen I but not collagen III. The authors concluded that therapeutic effects might increase if rapamycin were delivered in a monosphere subcapsularly; moreover, combination with low systemic concentrations of rapamycin may lead to an effective intrarenal delivery method.

Alternatively, small proteins have been used as soluble factors to improve renal function. For example, bone morphogenic protein-7 (BMP-7), a member of the TGF-β1 family, is highly expressed in the kidney; furthermore, genetic deletion of TGF-β1 in mice results in severe impairment of kidney development. Zeisberg et al. hypothesized that administration of exogenous BMP-7 would enhance repair in severely damaged renal tubular epithelial cells. Results from this study showed that the positive effect by BMP-7 administration was closely associated with the reversal of chronic renal injury through epithelial-to-mesenchymal transition. Collectively, these results provide

evidence of cross-talk between BMP-7 and TGF-β1 in regulating epithelial-to-mesenchymal transition in healthy and diseased kidneys [106].

Similarly, in another study, fibrosis-neutralizing antibodies were administered to alter the fibrotic environment of injured kidneys [107]. Using a transgenic mouse model to track and isolate myofibroblasts, human epididymis protein 4 (HE4) was identified as the most upregulated gene in the fibrosis-associated myofibroblasts. Administration of an anti-HE4 antibody accelerated collagen type I degradation and inhibited fibrosis in three different mice models of renal disease. The authors concluded that HE4 protein is a potential biomarker of renal fibrosis and could be a new therapeutic target [107].

Despite these findings, protein-based therapy is limited by several obstacles, such as long-term pharmacologic resistance. Chemical and pharmacological studies have focused on developing small molecules for tissue regeneration [108,109]. The concept behind this approach is to stimulate the endogenous tissue niche by administering small molecules. Studies of the protein-based method showed that several treatments induced resistance, because antibodies were produced against the administered protein [110]. Thus, using small molecules may prevent this side effect and allow efficient restoration of tissue and organ function.

Several small molecules have been used to treat kidney pathology. For example, Sugimoto et al. [111] focused on the role of BMP in fibrosis formation after renal injury. They showed that THR-123, an agonist of BMP signaling, led to the repair of damaged tubular cells and improved renal function by reducing fibrosis in several renal disease models, such as nephrotoxic serum-induced nephritis, ischemic reperfusion injury, unilateral ureteral obstruction, and diabetic nephropathy [111]. THR-123 plus captopril, an angiotensin-converting enzyme inhibitor, facilitated synergistic therapeutic effects by controlling renal fibrosis. The authors suggested that a synthetic small peptide, such as a BMP-signaling agonist, could be a promising therapeutic agent to treat renal diseases via their control of fibrosis.

Other research in fibrosis reduction relevant to renal regeneration used a small molecule, histone deacetylase inhibitor, which attenuated renal injury through fibrosis reduction [112]. Novitskaya et al. reported that a phenylthiobutanoic acid analog, methyl-4-(phenylthio)butanoate, facilitated renal recovery in a mouse model of aristolochic acid—induced injury [94]. Beneficial effects of the small molecules were confirmed by decreased cell death, proliferation of proximal tubular cells, and decreased macrophage infiltration, which collectively reduced fibrotic tissue and ameliorated renal injury.

CONCLUSIONS AND FUTURE PERSPECTIVES

Developments in TE and RM have shown promising advances in repairing and restoring damage from renal failure. These approaches include cell therapy using autologous and "off-the-shelf" allogeneic cell sources, engineering cell-based renal constructs, and use of an endogenous renal cells and niche for in situ renal regeneration. Such experimental studies have tested new strategies for clinical treatments for kidney disease, and some are clinically applicable [113].

Nonetheless, several challenges need to be addressed to enhance therapeutic outcomes. Continued work is needed to understand the complex milieu of the renal microenvironment (i.e., niche) and to develop renal stem cell culture and expansion techniques to support future cell-based therapies for renal disease. In addition, future studies should address better methods to devise tissue-engineered renal constructs and their safe and effective implantation, determine novel ways to prevent immunologic side effects of cell-based therapies, and address ways to reduce thrombosis and improve innervation of the transplanted cells or engineering of renal constructs.

INTRODUCTION

Tendons and ligaments are soft connective tissues composed of closely packed, parallel collagen fiber bundles that connect bone to muscle and bone to bone, respectively. These unique tissues serve essential roles in the musculoskeletal system by transferring tensile loads to guide motion and stabilize diarthrodial joints. Injuries to tendons, such as the patellar tendon (PT) of the knee, or ligaments, such as the collateral and cruciate ligaments of the knee, upset the balance between mobility and stability of this joint. These injuries are often manifested in abnormal knee kinematics and damage to other tissues in and around the joint, such as meniscus and articular cartilage, which may lead to morbidity, pain, and osteoarthritis. With the high incidence of ligament and tendon injuries in sports and work-related activities, improvements in healing and repair of these tissues are of great interest [1].

There is dramatic variability in the propensity for healing of the medial collateral ligament (MCL) and anterior cruciate ligament (ACL) in the same knee joint. Clinical and laboratory studies have shown that injuries to the MCL could generally heal well such that nonsurgical management has become the treatment of choice and the structural properties of the femur−MCL−tibia complex (FMTC) in the functional range are restored within weeks [2−8]. However, the mechanical properties of the healed MCL (i.e., the stress−strain relationship) could not return to those of the normal MCL and the histomorphological appearance (e.g., uniform distribution of small collagen fibrils) and biochemical composition are altered (e.g., elevated type III and V collagens) [9−19]. As such, the healing MCL needed to be significantly larger (higher in quantity) to make up for the lack of quality.

For the ACL, it is well-known that a midsubstance tear would not heal and the success of nonsurgical management has been limited. Thus, surgical reconstruction of the ACL using autografts harvested from the PT or hamstring tendons as a replacement is performed to restore knee stability and function. However, there are issues affecting patient outcome from the use of bone−PT−bone (BPTB) autografts, including a persistent palpable defect in the tendon, anterior knee pain, arthrofibrosis, changes to the remaining PT, and PT adhesion to adjacent tissues (i.e., the fat pad) [20,21]. For hamstring tendon autografts, there are issues including a slower healing rate at the soft tissue to bone interphase, less long-term stability of the knee [22], significant hamstring muscle weakness [23,24], as well as an increased prevalence of bone tunnel enlargement after reconstruction [25−28].

Long-term clinical follow-up studies for patients who underwent ACL reconstruction for 10 or more years demonstrate up to 25% of unsatisfactory results that include a prevalence of osteoarthritis [29−31]. Hence, functional tissue engineering (FTE) and regenerative medicine approaches are attractive to improve the suboptimal quality of the healing MCL and issues related to ACL graft harvest and healing after reconstruction. In addition, healing of the injured ACL using FTE as an alternative to reconstruction is a subject of intense interest. These same principles could also be applied to aid the repair of other ligaments and tendons [17,32−37].

In this chapter, we will review the properties of normal and healing ligaments and tendons and discuss the current FTE methods, including the use of growth factors, gene delivery, stem cell therapy, and biological augmentation as well as mechanical augmentation, aimed at enhancing tendon and ligament healing. The goal is not only to restore

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00067-9

the normal histomorphological appearance, biochemistry, and mechanical properties of the healing ligament, but most important, to regain normal joint function. New technologies and research avenues are suggested that have the potential to enhance treatment strategies for ligament and tendon injuries.

NORMAL LIGAMENTS AND TENDONS

Biology

Ligaments and tendons are hypovascular [38–40] and hypocellular with less than 5% of the total volume occupied by cells [39,41,42]. The cells in these tissues, fibroblasts, or tenocytes, exert important functions in maintaining and remodeling the extracellular matrix (ECM) in which they reside, which consists of both fibrillar (e.g., collagen and elastin) and nonfibrillar (e.g., proteoglycans, elastin, glycolipids, and water) components. The collagen fibers are organized and well-oriented along the longitudinal direction. Normally, the cells are arranged in rows along these fibers [43,44].

Collagen fibers in normal ligaments or tendons are mainly formed by type I collagen (roughly 70–80% dry weight). When viewed histologically under unloaded conditions, these collagen fibers display a crimp pattern with a regular wavy appearance [41,42,45,46]. Under transmission electron microscopy, a bimodal distribution of collagen fibril size can be observed with one group of fibrils measuring 40–75 nm in diameter, and the other, larger fibrils 100–150 nm in diameter [47–50]. Such a bimodal distribution is functionally significant because the incorporation of a high fraction of small-diameter fibrils ensures better interfibrillar binding by virtue of their higher surface–volume ratio whereas the large-diameter fibrils meet the strength requirements. In addition, a bimodal distribution can improve fibril packing—the smaller fibrils wedge themselves in the spaces left among the larger ones [51].

Besides type I collagen, many other collagen subtypes, including III, V, X, XI, and XII, are present in much smaller amounts but still play important roles in maintaining the structure and functions of ligaments and tendons. For example, type III collagen is involved in tissue healing and remodeling [52]; type V collagen has been found to exist in association with type I collagen and serve as a regulator of collagen fibril diameter [53,54]; and type XII collagen provides lubrication between collagen fibers [55]. Interestingly, collagen types IX, X, and XI have been identified to coexist with type II collagen at the fibrocartilaginous zone of the ligament–bone and tendon–bone interfaces [56–58]. The significance of the coexistence has been related to the minimization of stress concentrations when loads are transmitted from soft tissue to bone [59,60].

The ground substance makes up only a small percentage of the total dry tissue weight of ligaments or tendons but it is nevertheless pivotal in its function because of its ability to intake water. Water and proteoglycans are crucial to the gliding function of fibers in the tissue matrix by providing lubrication and spacing of collagen fibers. Elastin, another fibrillar macromolecule in matrix, is also present in ligaments and tendons at a few percent by weight. Although its detailed significance has yet to be elucidated, elastin has been implicated in its ability to allow the tissue to return to its prestretched length and shape upon unloading. Collectively, these constituents are indispensable in the normal functioning of collagen fibers by distributing load optimally in response to mechanical stress.

Although ligaments and tendons are morphologically similar, they are different in their compositions. For example, ligaments are composed primarily of water (65–70% of wet weight) and collagen (70–80% of dry weight); type I collagen is the most abundant collagen subtype. Type III collagen (8% dry weight), type V collagen (12% dry weight), and other minor subtypes such as II, IX, X, XI, and XII, have also been found to be present [56–58,61]. Tendons, on the other hand, generally contain less water (55% wet weight) and slightly more type I collagen (85% dry weight), along with much smaller amounts of other collagen subtypes, such as III, V, XII, and XIV [49]. In addition, most ligaments are more metabolically active. They have more cellular nuclei, a higher DNA content, and greater amounts of reducible cross-links between collagen fibers [45].

Biomechanics

The major function of ligaments and tendons includes maintaining the proper anatomic alignment of the skeleton and guiding joint movements. They also transmit forces along their longitudinal axis; hence, their biomechanical properties are measured in uniaxial tension and they exhibit nonlinear behavior governed by the recruitment of collagen. These unique properties allow ligaments to maintain smooth normal joint motion that requires low loads. In response to high loads, stiffness increases dramatically to limit excessive joint displacements. Thus, when large

muscle forces are applied, the bones are well-aligned to allow them to glide smoothly on each other. Ligaments and tendons also exhibit time- and history-dependent viscoelastic behavior that could be attributed to the complex interactions of tissue constituents such as collagen, proteoglycans, water, and ground substance [62–65]. Viscoelastic properties of ligaments and tendons are important and clinically relevant. For instance, during regular activities such as walking and jogging, tissues have the ability to soften over time. This phenomenon reduces susceptibility to damage related to fatigue [63–65].

However, after injury, ligaments and tendons generally fail to recover their normal mechanical and viscoelastic properties. Thus, abnormal joint kinematics may result that can lead directly to excessive forces on surrounding tissues (e.g., articular cartilage and meniscus in the knee). This excess loading could result in further injury causing degeneration such as osteoarthritis. Because the ultimate goal is to restore the properties of ligaments and tendons, and thus the function of the injured joint, it is necessary to understand their normal mechanical behavior and how they contribute to joint function. To do this, two common mechanical tests have been designed: (1) uniaxial tensile testing, which is a test to measure the structural properties of the bone–ligament–bone complex and mechanical properties of the tissue substance; and (2) functional testing, which determines the contribution of the ligament or tendon to joint kinematics and the in situ forces in response to externally applied loading conditions.

Uniaxial Tensile Testing

Tendons are generally long and can be tested in their isolated state using sinusoidal-shape or frozen grips to limit slippage. Isolated ligaments, on the other hand, are shorter in length, which makes it difficult to clamp them independently. Hence, a uniaxial tensile test is generally conducted on the entire bone–ligament–bone complex (e.g., FMTC) with tissue insertion sites left anatomically intact. With cross-sectional area (CSA) measurements and the use of tissue markers to measure tissue strain, the structural properties of the bone–ligament–bone complex as well as mechanical properties of the ligament substance can be measured from a load to failure test [66,67].

Structural properties (Fig. 67.1) of the bone–ligament–bone complex (i.e., a load–elongation curve) are generally described by four parameters including stiffness (slope of the linear portion of the load–elongation curve), ultimate load (maximum load at which the complex fails), ultimate elongation (elongation corresponding to the maximum load), and energy absorbed at failure (area under the curve to the maximum load). These data reflect the behavior of the entire bone–ligament–bone complex, which includes tissue size, orientation of collagen fibers to applied loads, and as the contribution of the bony insertions [67].

Measuring the mechanical properties (Fig. 67.2) of the ligament substance (i.e., a stress–strain curve), on the other hand, requires knowledge of the CSA of the ligament, commonly measured using a laser micrometer system [66], and tissue strain, commonly measured using video techniques to track two or more reflective markers placed on the tissue midsubstance [8]. Stress in the tissue is obtained by dividing load by the CSA, and strain is obtained by computing change in the marker distance during the test relative to their original distance. Parameters describing the mechanical properties of the ligaments and tendons (Fig. 67.2) include the tangent modulus (slope of the linear portion of the stress–strain curve), tensile strength (stress at failure), ultimate strain (strain corresponding to the tensile strength), and strain energy density (area under the stress–strain curve until failure). These data represent the quality of the tissue, irrespective of tissue size.

The viscoelastic properties of ligaments and tendons include stress relaxation (decrease in stress over time in response to a constant elongation) and creep (increase in elongation over time in response to a constant load). In addition, they display a phenomenon called "hysteresis" in response to cyclic loading (Fig. 67.3). This results from a loss of

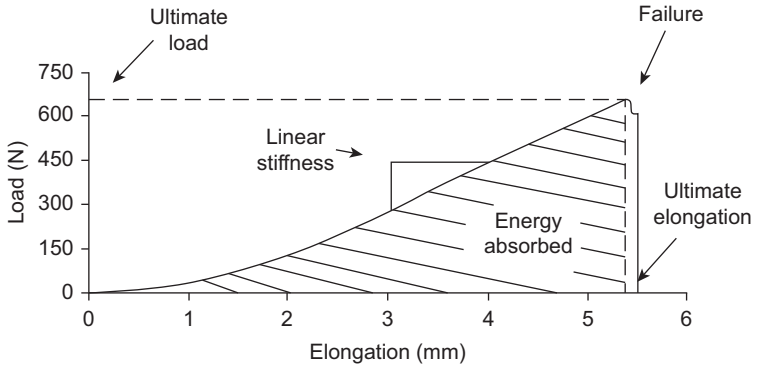

FIGURE 67.1 Typical load–elongation curve representing the structural properties of the femur–anterior medial bundle–tibia complex of the human anterior cruciate ligament.

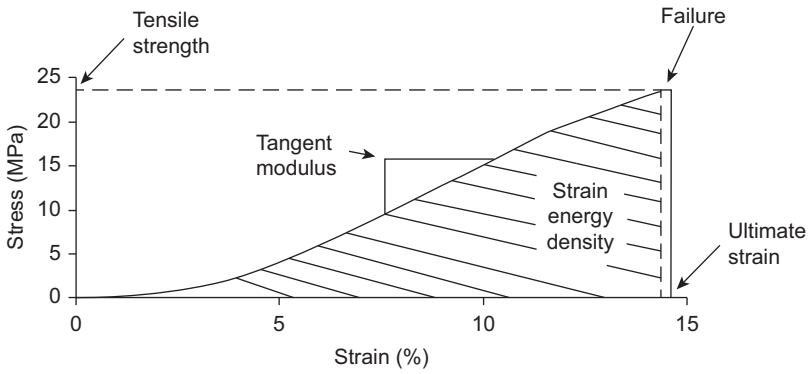

FIGURE 67.2 Atypical stress–strain curve representing the mechanical properties of the anterior medial bundle of the human anterior cruciate ligament.

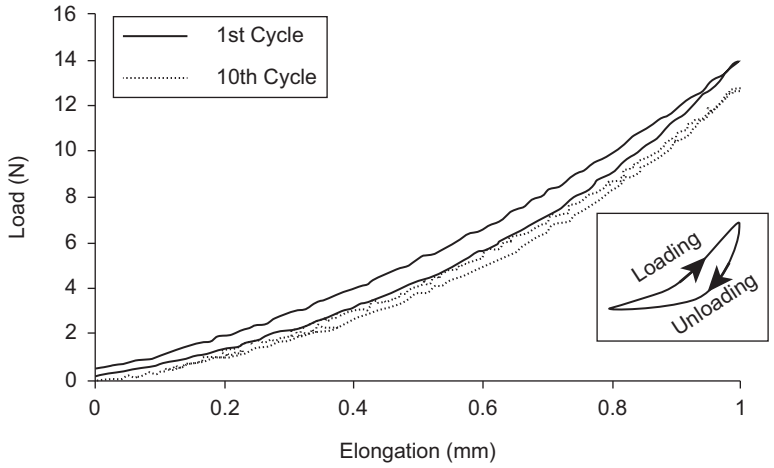

FIGURE 67.3 Hysteresis loops (first and 10th cycles) obtained from cyclic loading of the femur–anterior medial bundle–tibia complex of the human anterior cruciate ligament in uniaxial tension. The area of hysteresis (area between the loading and unloading curves) decreases with repetitive cycling, demonstrating the phenomenon of "preconditioning."

internal energy causing the loading and unloading paths to be different. The area of hysteresis reduces as the tissue undergoes several cycles of loading and unloading and the tissue is said to be "preconditioned," a state desired for a tissue before mechanical testing. Nonlinear viscoelastic models such as the quasilinear viscoelastic theory:

$$\sigma(t) = \int_{-\infty}^{t} G(t-\tau)\frac{\partial \sigma^e(\varepsilon)}{\partial \varepsilon}\frac{\partial \varepsilon}{\partial \tau}\partial\tau, \tag{67.1}$$

and single integral finite strain theory:

$$\mathrm{T} = -\mathrm{p}\boldsymbol{I} + \mathrm{C}_0\{[1+\mu \boldsymbol{I}(t)]\boldsymbol{B}(t) - \mu \mathbf{B}^2(t)\} - \mathrm{C}_0(1-\gamma) * \int_0^t \dot{\mathrm{G}}(t-s)\{[1+\mu \mathbf{I}(s)]\mathbf{B}(t) - \mu \mathbf{F}(t)\mathbf{C}(s)\mathbf{F}^T(s)\}ds, \tag{67.2}$$

have been used to model these behaviors in ligaments and tendons [62–65,68].

These basic testing methodologies described have been employed for a number of decades. In our research center, much work has been devoted to finding the most appropriate testing procedures, which include specimen orientation [69], handling, storage, and hydration [70,71]. These carefully developed methodologies have led to important findings regarding physiological changes associated with growth and development [69–71], the adaptation of ligaments and tendons to mobility [5,6,63–65,72], and the effects of injury and treatment [5,6,19].

Contribution to Joint Function

Joint motion is governed by the direction and magnitude of externally applied loads, ligament forces, contact between joint surfaces, and muscle activity. For the knee, motions include a combination of translations (proximodistal,

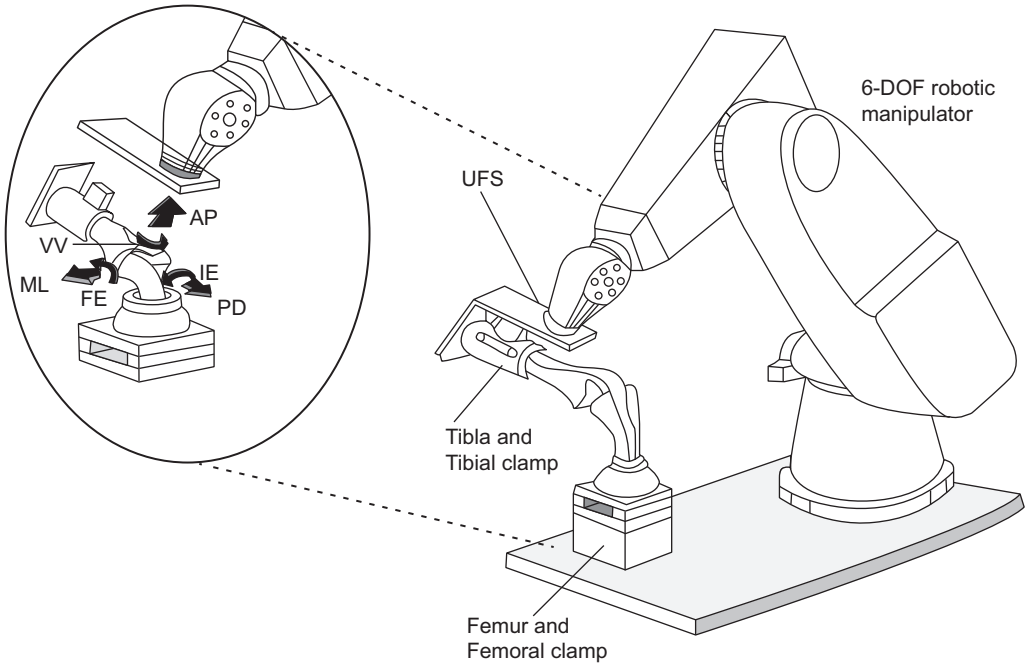

FIGURE 67.4 Schematic drawing illustrating the six degrees of freedom of motion of the human knee joint, indicating anteroposterior (AP), mediolateral (ML), and proximodistal (PD) translation as well as flexion−extension (FE), internal−external (IE), and varus−valgus (VV) rotation. *DOF*, degrees of freedom.

mediolateral, and anteroposterior) and rotations (internal−external, flexion−extension, and varus−valgus). In total, these translations and rotations describe motion in 6 degrees of freedom (DOF).

While evaluating joint function, constraining DOF of the knee can have significant impact on the results obtained [73,74]. When knee motion was allowed in all directions, sectioning the MCL resulted in only small increases in valgus laxity (21%), which suggests that the ACL has a significant role as a joint restraint to this knee motion. However, when anteroposterior translation and internal−external rotation were constrained, valgus laxity increased significantly (171%) after sectioning of the MCL. For this reason, it is important to have a testing device that allows for unconstrained knee motion.

For more than 2 decades, a robotic−universal force-moment sensor (UFS) testing system developed by our research center has been used to study knee kinematics as well as directly measure the in situ forces in the knee ligaments in response to external loading conditions (Fig. 67.4) [75,76]. This methodology has been employed to study the function of the ACL and a number of variables for ACL reconstruction, including surgical technique [77−79] and graft choice [80]. In addition, knee function after ligament injury has been studied for both the MCL and ACL [8,81−84].

HEALING OF LIGAMENTS AND TENDONS

The events of healing of ligaments and tendons can be roughly divided into four overlapping phases: hemorrhage, inflammation, repair (proliferation), and remodeling. Minutes after the ligament injury, blood collects and forms a platelet-rich fibrin clot at the injury site and the hemorrhagic and inflammatory phases occur over several days. In the hemorrhage phase, a cascade of cellular events occurs that includes release of cytokines within the clot followed by the appearance of polymononuclear leukocytes and lymphocytes. These cells respond to autocrine and paracrine signals to expand the inflammatory response and recruit other types of cells to the wound [85].

The reparative phase follows over the next couple of weeks to months. During this phase, fibroblasts recruited to the injury site start forming healing tissue. Growth factors, including transforming growth factor-β (TGF-β) and platelet-derived growth factor (PDGF) isoforms, are involved in modulating healing [86]. Meanwhile, increased neovascularization brings in circulating cells and nutrients to enhance the healing process further. The blood clot quickly turns into newly formed healing tissue that is composed of an aggregation of cells surrounded by a matrix.

However, its histomorphological appearance and biochemical composition are different from those of an uninjured ligament. Notably, there is a homogeneous distribution of smaller-diameter collagen fibrils, which is in stark contrast to the bimodal distribution of the normal ligament [12,15,50]. Biochemically, it contains elevated amounts of proteoglycans, a higher ratio of type V to type I collagen, and a decrease in the number of mature collagen cross-links.

Then the remodeling phase follows for months to years after the injury. In this phase, cellularity and levels of collagen type III are decreased, and the matrix is realigned in response to loading applied to the tissues. On the other hand, the diameter of collagen fibrils remains small, and the level of collagen type V remains elevated for years after injury [9,11,12,15,16]. Type V collagen has been shown to have a central role in regulating the lateral aggregation of smaller collagen fibrils. Thus, elevated type V collagen could be associated with the inferior mechanical properties of healing tissue [87,88].

Medial Collateral Ligament of the Knee

The healing process of the MCL follows this general healing pathway, as described earlier. Thus, it serves as a good model for studying histological, biochemical, and biomechanical changes over time. It has been shown that the process of MCL healing is greatly affected by treatment [5,6,89–92]. Laboratory and clinical studies have shown that controlled mobilization is superior to immobilization [5,6,19,93]. As a result, nonoperative repairs have a better outcome than surgical repairs. In our research center, a severe "mop-end" injury model of the rabbit MCL that tears the midsubstance while damaging the insertion sites was developed and used to compare nonoperative treatment without mobilization with surgical repair with a brief period of mobilization [19]. After 12 weeks of healing, there were no significant differences in varus–valgus knee rotation, in situ force of the MCL, or tensile properties between repaired and nonrepaired MCL [19]. Based on these studies, clinical management shifted from surgical repair with immobilization to nonoperative management (i.e., bracing) with early controlled range of motion exercises as soon as pain subsides [94,95].

The MCL heals with nonoperative treatment, and the stiffness of the healing FMTC begins to approach normal levels, but the CSA of the healed tissue continues to increase with time, measuring as much as 2.5 times its normal size by 52 weeks after injury [93]. Meanwhile, the mechanical properties of the healing MCL remain consistently low compared with those for the normal ligament and do not improve with time. In other words, the healing process involves making a larger quantity of lesser-quality ligamentous tissue. Moreover, studies show that the rate of healing of the ligament is asynchronous with the insertion sites because of its anatomical and morphological complexity.

There is also evidence that the activity level could influence the rate of healing [81–83]. A goat model was used because it has more robust activity, and it is larger than the rabbit. With this model, the stiffness and ultimate load of the healing goat FMTC are closer to control values at earlier periods than those from the rabbit model.

Anterior Cruciate Ligament of the Knee

A midsubstance tear of the ACL has limited potential to heal on its own and can lead to chronic knee instability and damage to secondary stabilizers such as the meniscus. As a result, surgical reconstruction has become the treatment of choice. With the ultimate goal of ACL reconstruction being to restore knee function, the success of these procedures depends on a number of surgical, biomechanical, and biological factors. The most popular choice is autografts from the PT, i.e., bone central (or medial) third of the BPTB, or semitendinosus plus gracilis tendons. Allografts, including the Achilles tendon, BPTB, and hamstring tendons, have seen limited use except in revision surgery or for multiple ligamentous injuries. BPTB grafts are generally considered the reference standard for ACL reconstruction because they facilitate better initial fixation for bone-to-bone healing inside bone tunnels [96–101]. However, the major drawback is that the defect after the large incision does not completely heal for months [20,102–104]. This contributes to a higher incidence of complications including donor site morbidity, patella baja, arthrofibrosis, adhesion to the fat pad, and patellofemoral pain [105–110].

Studies designed to examine the healing PT after harvest have found a deterioration of structural properties of the remaining BPTB complex with a concomitant increase in the CSA of the PT tissue [111–115]. In the rabbit model, the ultimate load of the entire BPTB complex decreased by 38% [112] whereas there was an increase in CSA of 83–108% at 12 weeks after harvest [111,115]. For the central healing tissue, its tangent modulus and ultimate tensile strength were only 15% and 18% of controls, respectively, after 26 weeks [111]. The mechanical properties of the remaining PT tissues also deteriorated compared with sham controls after 24 weeks [115].

After implantation, the autograft becomes inflamed and necrotic, leading to a decrease in graft stiffness and strength [116]. The graft undergoes revascularization and repopulation with fibroblasts followed by remodeling with restructure of the collagen fibers and proteoglycans [117]. Bone block healing within the femoral and tibial tunnels is complete by 6 weeks, whereas graft healing is incomplete, causing consistent failure to occur as the tendon is being pulled out from the tibial tunnel [118]. Over time, however, the femur−graft−tibia complex shows improvement with complete incorporation even though its structural properties fail to be restored to levels of the intact femur−ACL−tibia complex (FATC) even after 12 months [119−121]. Thus, accelerating graft incorporation and healing that lead to an earlier return to normal and sports activities has become a goal of FTE efforts. We will discuss the state of events later in this chapter.

In addition to the graft selection, a number of important surgical decisions include tunnel placement, graft tension, and fixation. A substantial amount of research has focused on these variables in both animal and human models [78,81−83,122]. All of these parameters can lead to various degrees of graft tunnel motion that may affect graft integration and graft healing. Ultimately, these factors have an impact on postoperative rehabilitation and recovery as well as when to return to normal activities and sports.

Multiple Ligamentous Injuries in the Knee

Combined ACL and MCL injuries frequently occur. The ideal treatment is still controversial. Some surgeons elect to reconstruct the ACL surgically without addressing the MCL whereas others advocate reconstruction of the ACL with repair of the MCL. Regardless of the treatment modality, clinical and basic science studies continue to show that the outcome of this injury is worse than for an isolated MCL injury but not as clear compared with an isolated ACL injury.

Our research center has elucidated the effects of ACL deficiency on the healing of the injured MCL using canine, rabbit, and goat models [81−83,92,123,124] and recommended that only ACL reconstruction be performed. Furthermore, repairing the MCL in combination with ACL reconstruction resulted in reduced valgus laxity and improved the structural properties of the FMTC but only in the very early stages. In the longer term, all positive effects diminished [123,124]. To date, surgeons prefer to perform ACL reconstruction after a combined ACL−MCL injury.

Using a larger animal model, i.e., the goat stifle joint, the function of the knee and quality of the healing MCL after a combined ACL−MCL injury treated with ACL reconstruction was examined [81−83]. It was found that the valgus rotation of the stifle joint was twice that for an isolated MCL injury. Moreover, the structural properties of the FMTC and tangent modulus of the MCL substance were substantially lower than those for the isolated MCL injury [8,81−83]. These results further demonstrate a clear need for new treatment strategies to enhance ligament healing after multiple ligament injuries.

APPLICATION OF FUNCTIONAL TISSUE ENGINEERING

FTE emphasizes the importance of biomechanical considerations in the design and development of cell and matrix-based implants for soft and hard tissue healing. Ligaments and tendons are accustomed to being mechanically challenged; therefore, tissue engineered constructs used to replace these tissues after injury or disease must meet these demands. By combining the fields of molecular biology, biochemistry, and biomechanics, novel therapeutic approaches (e.g., growth factors, gene transfer/gene therapy, cell therapy, and biological scaffolds) offer new potential for better treatment. The following is a brief review of available approaches to enhance ligament and tendon healing.

Growth Factors

The application of exogenous growth factors is based on the premise that they can promote healing that will lead to a biologically and biomechanically superior healed ligament substance. Many in vitro and in vivo studies have tried to examine their roles and determine appropriate strategies for their use.

In Vitro Studies

Cell culture or tissue explant methodologies have been the major study designs. By adding exogenous growth factors, responses including cell proliferation, synthesis of ECM proteins such as collagen, proteoglycans, tissue

remodeling enzymes, and cell migration or chemotaxis were measured and compared [125–131]. Early studies in our research center measured the effects of eight different growth factors on the MCL and ACL fibroblast culture [123,132–134]. For cell proliferation, PDGF-BB, epidermal growth factor (EGF), and basic fibroblast growth factor (bFGF) were found to have a significant effect on cell proliferation and caused greater proliferation in MCL fibroblasts versus ACL fibroblasts [134]. The proliferation of MCL and ACL fibroblasts from skeletally immature rabbits actually increased by 7.6 times in response to EGF and 5.6 times in response to bFGF [123]. In skeletally mature rabbits, the insulin-like growth factor and bFGF had significant effects on fibroblast proliferation in both cell types, but the difference was much less pronounced [134]. Other authors had shown the effect of TGF-β1 on ACL fibroblast proliferation to be dose-dependent and smaller doses could act synergistically with PDGF [135]. However, higher concentrations of TGF-β1 inhibited the stimulatory effect of PDGF. These findings suggest complex interactions of growth factors and their potential role in enhancing the proliferation of ligament fibroblasts.

In terms of protein synthesis, TGF-β1 was most effective in collagen synthesis. In MCL and ACL fibroblasts, the level of increase was 160% over controls; most of this increase was for type I collagen [133]. These data suggest that TGF-β1 may improve ligament healing by increasing matrix synthesis during the proliferative and remodeling phases and confirm what was found by other investigators [135].

In vitro models, however, are limited in the extent that they cannot reproduce the complex interplay of signals affected by growth factors in the intricate process of ligament or tendon healing where there is a highly integrated biochemical network of cell signaling events with intrinsic stimulatory and inhibitory feedback loops. Thus, in vivo studies are needed to examine the interaction of biology and biomechanics and the degree to which the healed ligament or tendon substance could restore the biomechanical properties to those for the native tissue.

In Vivo Studies

Based on in vitro studies, EGF and PDGF-BB have the greatest effect on ligament fibroblast proliferation whereas TGF-β1 better promotes ECM production. These growth factors were then applied at different dosages, in isolation and in combination, for an MCL injury in the in vivo rabbit model. It was found that only a higher dose of PDGF-BB improved the structural properties of the FMTC [75,76]. A lower dose of PDGF-BB had little effect, which demonstrated that the effects of PDGF-BB were dose-dependent. However, the mechanical properties of the ligament substance remained unchanged from untreated controls, which demonstrated that the improved structural properties resulted from the formation of a larger quantity of tissue (instead of improved tissue quality). Other investigators showed that higher doses of PDGF could improve the structural properties of the healed ligament [136]. However, administration of PDGF for more than 24 h after the injury markedly decreased its efficacy.

One possible approach to improving the in vivo application of growth factors and cytokines could be to combine it with gene transfer technology to extend their effectiveness with time. Adenoviral bone morphogenetic protein-2 (AdBMP-2) delivered to the bone–tendon interface using a gene transfer technique has been shown to improve the integration of semitendinosus tendon grafts in rabbits [137]. The stiffness (29.0 ± 7.1 versus 16.7 ± 8.3 N/mm) and ultimate load (108.8 ± 50.8 versus 45.0 ± 18.0) were also significantly increased in specimens with AdBMP-2 compared with untreated controls.

Based on these studies, an optimal therapy of introducing growth factors to injury sites is still an open question. The timing of application, mode of delivery, dosage, inclusion of scaffolds and/or cells, and interactions among these variables remain major hurdles. As an example, the delivery of stem cells transduced to express BMP-2 had adverse effects on rotator cuff repair [138]. As a result, investigations have been devoted to therapies such as platelet-rich plasma (PRP) and ECM bioscaffolds, which contain a number of bioactive factors [84,139]. In addition, it is well-recognized that stem cell delivery could modulate the healing response via trophic factors produced by the cells and not by engraftment of those cells [140]. Thus, these therapies could offer highly translational approaches to growth factor delivery.

Gene Therapy

Gene therapy offers an exciting approach to improving ligament and tendon healing. Foreign nucleic acid gene transfer can be introduced into cells to alter protein synthesis or induce the expression of therapeutic proteins. Modern gene therapy relies on mammalian viruses and cationic liposomes as delivery vectors, and both have been developed to deliver genes into host tissue via direct (in vivo injection) and indirect methods (in vitro transduction).

In our research center, we sought to determine whether genes could be transduced into MCL and ACL fibroblasts and whether ligament injury affected gene transfer and expression [141]. Both direct and indirect methods using adenovirus and BAG retrovirus, respectively, were employed. It was found that both techniques resulted in expression of the LacZ marker gene by fibroblasts from intact as well as injured ligaments. Gene expression lasted longer (6 weeks) with the direct method compared with the indirect technique (3 weeks). Fibroblasts from injured ligaments showed transduction in both the wound site and the ligament substance. There was no difference in the duration of gene expression by fibroblasts from intact and injured ligaments, which suggested that injury does not affect gene transfer or expression [141].

Antisense gene therapy that could block the transcription or translation of specific genes that are excessively expressed within healing tissue has also been studied. By binding antisense oligodeoxynucleotides (ODN) to target DNA, the efficacy of using ODNs to regulate the overproduction of collagens III and V was studied [35,142]. Normal human patellar tendon fibroblasts were transfected with antisense collagen III or V ODNs by mixing with lipofectamine. The uptake of ODNs was detected as early as 1 h and as late as 3 days after delivery. The relative expression of collagen V messenger RNA (mRNA) was reduced to $67.8\% \pm 5.1\%$ of missense levels. Also, reverse transcriptase–polymerase chain reaction results showed that the inhibitory effects of the collagen III antisense ODNs were most dominant at day 1, because the type III collagen mRNA level was $38.9\% \pm 19.6\%$ of missense controls. At days 3 and 7, differences could no longer be observed. These results suggested that antisense gene therapy can be a potential FTE approach to enhance the quality of healing ligaments and tendons.

Despite these promising results, several obstacles impede the practical implementation of gene transfer as a biological intervention for ligament healing. The immune reaction against these antigens decreases the expression of the introduced gene [143]. In addition, retroviral infection of fibroblasts often leads to shut-off of the promoter region, which adversely affects expression of the incorporated gene [144]. Thus, delivering ODNs to the appropriate target and reproducibility of the results remain great but exciting challenges.

The literature has shown other techniques such as the use of lentivirus for gene transfer. For example, bFGF was transfected into bone marrow–derived cells (BMDCs) and then implanted into the Achilles tendon [145]. However, these investigators did not observe an enhanced healing response from the injection of stem cells. Also, lentivirus–tumor necrosis factor-α (TNF-α)–RNA interference–expressing TNF-α small interfering RNA was injected in the rotator cuff tendon in a rat model [146]. Thus, the inflammatory response was attenuated by the gene therapy after a chemical insult.

Novel strategies including the search for more effective and less immunogenic vectors, modification of promoters to ensure gene expression after incorporation, and temporary and self-limiting gene expression regulation tailored to the changing environment continue to evolve in gene transfer to aid in ligament healing. Technologies such as CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats)/CRISPR-associated protein 9 could become a new strategy. As the complex steps involved in gene expression and regulation are further elucidated, the potential therapeutic efficacy of gene transfer is likely to find clinical application.

Cell Therapy

Cell therapy is another potential approach to enhancing ligament and tendon healing because the use of autogenous cells would minimize the immune response. Studies have focused mainly on the application of mesenchymal stem cells (MSCs), specifically BMDCs and synovial tissue-derived fibroblasts into the healing site [147,148]. BMDCs have been shown to have an important role in wound healing [149–151] and can be obtained in higher numbers with relative ease [152]. BMDCs combined with PRP were used to treat rabbit ACL after reconstruction, which resulted in improved structural properties after 8 weeks of healing [153]. The treated tissues with combined PRP and BMDCs had a more mature bone–ligament interface than those in the untreated controls and PRP-only group. Another study attempted transplantation of allogeneic tendon-derived stem cells to rat PT and observed improvement in healing at 16 weeks after injury [154].

Alternatively, fibroblasts, myoblasts, and bone marrow cells have been transplanted into injured ligaments after the induction of marker genes or stimulation by growth factors in vitro. However, issues remain regarding cell therapy. The number of MSCs from bone marrow are relatively low and decrease after transplantation. Thus, it is essential to develop novel in vitro techniques to expand MSCs without altering their differentiation potential. Furthermore, other methods, i.e., bioscaffolds, may be designed to prevent the loss of these cells and to sustain the positive effects.

HEALING OF LIGAMENTS AND TENDONS

The Use of Scaffolds

An empirical method to improve the healing of ligaments and tendons is to use scaffolds to augment the injured part or bridge defects. An ideal scaffold should provide a suitable biological environment for cells to migrate into it and then proliferate, an appropriate mechanical cue to guide the formation of the newly synthesized ECM, and a built-in property to degrade slowly such that the newly formed matrix could take over in bearing the mechanical loads. Both synthetic and naturally occurring biological scaffolds have been used in FTE of ligament and tendon healing [155–158]. Major advantages of using synthetic polymers as scaffolds are their ease of fabrication and reproducibility. A structure can be created that mimics the structure of a ligament or tendon, and appropriate bioactive factors (i.e., growth factors) can be incorporated into the scaffold during manufacturing. However, because the performance of synthetic grafts has been found to be less than satisfactory [159,160], the focus has been placed on the supplementary use of cells, including BMDCs and fibroblasts [161,162].

Alternatively, a number of naturally occurring biological scaffolds, e.g., bovine pericardium (Integra Life Science), human dermal collagen (Alloderm), and porcine small intestinal submucosa (SIS), have been used after proper decellularization and sterilization. Among these scaffolds, SIS products have been approved by US Food and Drug Administration and are widely used in the field. Because SIS contains a large amount of collagen (over 90%) and has a preferred collagen alignment [163], it has the potential of acting as a contact guide to promote cells to deposit new matrix in a more aligned manner [164–167]. As a result, the mechanical and viscoelastic properties of the neotissue are improved. When used, preferably as a noncross-linked biodegradable scaffold, SIS degrades gradually when implanted in vivo. The pace of the degradation not only allows gradual replacement of the scaffold with the newly synthesized host matrix, it controls the timely release of degradation products that are biologically active and beneficial to healing [167a,168,170]. Moreover, SIS entraps a certain amount of bioactive agents (growth factors, fibronectin, and so on) that can be released during degradation to enhance healing [171–173].

Medial Collateral Ligament and Patellar Tendon Healing With Extracellular Matrix (Small Intestinal Submucosa)

Multidisciplinary studies were performed to determine the effect of SIS treatment on the healing of an injured MCL (with a 6-mm gap) using a rabbit model [61,174]. Compared with the untreated group, SIS treatment resulted in improved histomorphological appearance, mechanical properties, and biochemical compositions of the healing MC; they were closer to those of normal ligament in both the short and long term (12 and 26 weeks) (Fig. 67.5). Specifically, SIS treatment further restored the heterogeneous distribution of collagen fibrils, because both large and small fibrils could be found compared with the persistently homogeneous small collagen fibrils in the untreated groups (Fig. 67.6). Accordingly, the CSA of the healing ligament in the SIS-treated group concomitantly decreased by 28%, indicating improved tissue quality. Indeed, improved mechanical properties of the healing MCL were

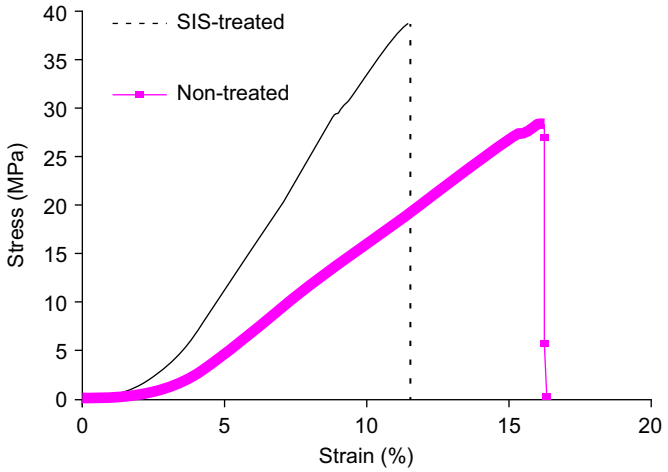

FIGURE 67.5 Typical stress–strain curves for small intestinal submucosa (SIS)-treated and untreated groups at 12 weeks after injury.

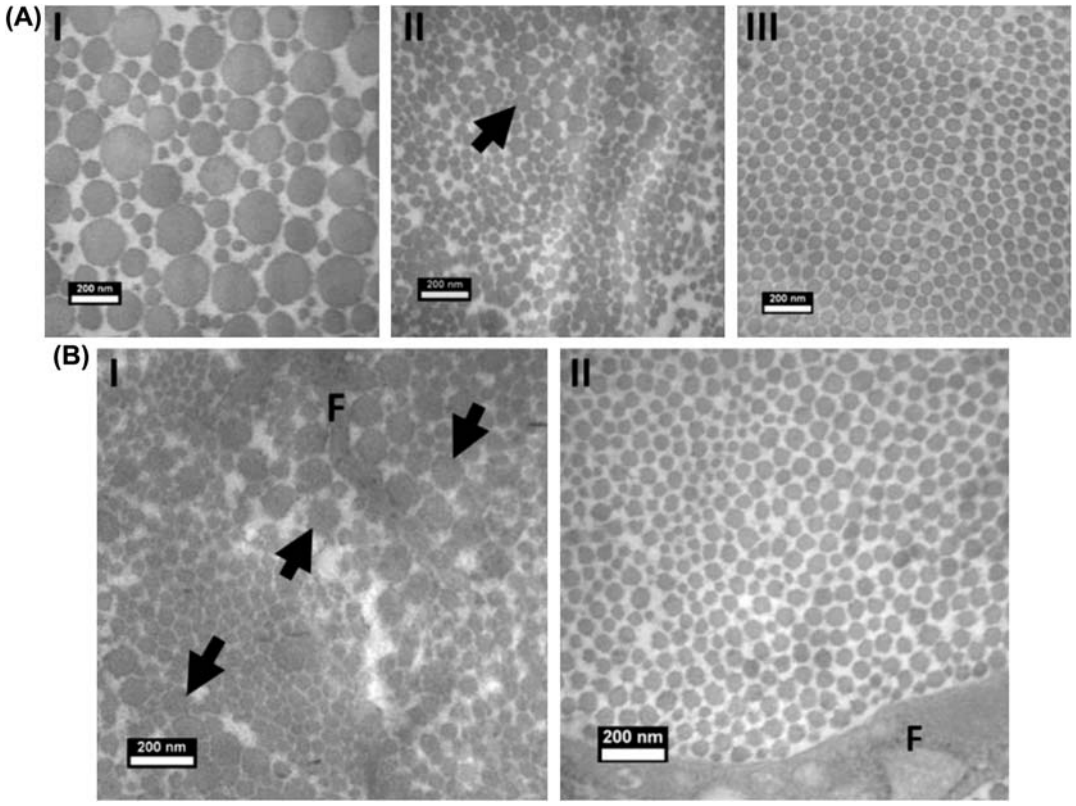

FIGURE 67.6 Transmission electron micrographs (×70,000) of collagen fibrils in (A) sham-operated medial collateral ligament (MCL) (I), small intestinal submucosa (SIS)-treated MCL (II), and untreated MCL (III) at 26 weeks after injury. *Arrow* indicates the appearance of large fibrils between cells in the SIS-treated MCL. (B) Transmission electron microscopy appearance of both large and small fibrils (heterogeneity) in the pericellular area in the SIS-treated MCL (I) and untreated MCL (II). *Arrows* indicates the large fibrils surrounding a cell process. *F*, fibroblast.

found, because the tangent modulus increased by 33% and stress at failure increased by 49% [174]. These positive findings in morphology and biomechanics were mechanistically associated with better collagen organization as well as the regulation of collagen subtypes by a number of small leucine-rich proteoglycans, decorin, lumican, and biglycan, and so on, to reduce the collagen type V−I ratio [174a].

We extended the use of SIS for PT healing. After the central third of the tendon was harvested for ACL reconstruction, an SIS scaffold was introduced to aid its healing and limit the formation of adhesion (and permit motion) between the healing PT and the underlying fat pad (Fig. 67.7). The maintenance of stress and motion of the patella−femoral joint motion would keep the homeostasis of the remaining PT [63-65,72], thus limiting problems associated with poor healing, including excessive hypertrophy of the healing PT with poor quality.

When the SIS was applied to the anterior and posterior of a central-third PT defect (3 mm wide) in rabbits, the healing defect had a more organized matrix with a large number of spindle-shaped cells at 12 weeks after surgery compared with the untreated group, which had only patches of collagen with a sparse distribution of cells [174b]. The CSA increased by 61% in the SIS-treated group; concomitantly, the BPTB complex showed 38% higher stiffness and 58% higher ultimate load. These results clearly demonstrated that SIS treatment could accelerate PT healing.

Anterior Cruciate Ligament Healing

With the advances in FTE, alternative approaches are being revisited to healing the injured ACL. Investigators have employed various biological methods such as PRP, ECM bioscaffolds, and so on to incite and accelerate ACL healing. Meanwhile, investigators also recognize that the rate of ACL healing is slow, and thus mechanical augmentation could be advantageous to maintain knee stability to facilitate the biological processes. The following overview covers both biological and mechanical augmentation for ACL healing as well as the combination of biological and mechanical strategies.

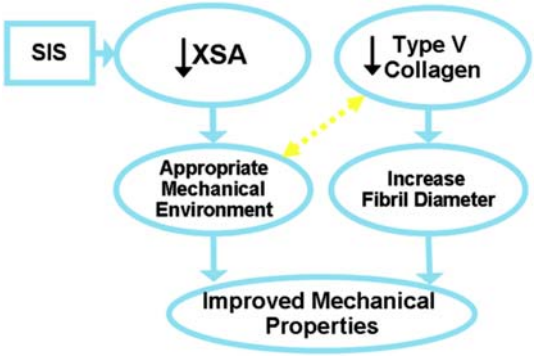

FIGURE 67.7 Schematic of possible mechanism of action of small intestinal submucosa (SIS) on medial collateral ligament healing response. *XSA*, cross-sectional area.

Biological Augmentation

There has been renewed interest in healing soft tissues with limited healing potential, such as the ACL, using biological augmentation. For example, Steadman and coworkers developed a microfracture technique that involves making very small holes in the bone at the femoral insertion site to encourage hematoma formation and provide an enriched environment for ACL healing [175,176]. This approach was used successfully to treat patients aged more than 40 years. In the laboratory, Murray and coworkers used collagen-PRP as a bioscaffold to heal a fully transected and sutured ACL in a porcine model [177,178]. At 4 weeks, the stiffness and load at yield and at failure were more than two times those of the suture-repaired control group [178].

In our research center, we used ECM bioscaffold to heal a surgically transected ACL in a goat model [84]. We combined SIS with SIS-hydrogel to heal a surgically transected ACL after primary repair. The SIS was derived from genetically modified Galα1-3Galβ−deficient pigs to reduce the potential immunological reaction in humans. The SIS sheet wrapped around the defect was used to contain the healing response at the injury site and guide tissue growth, whereas the SIS hydrogel was used to fill the defect and accelerate tissue formation by means of its desirable chemoattractant and angiogenic factors. With the new treatment, the transected ACL was found to heal with continuous neotissue by 12 weeks. Its CSA and shape were similar to those of the sham-operated intact ACL and were significantly more robust than the suture repaired (control) group. Morphologically, its collagen fibers were aligned with spindle-shaped fibroblasts. Functionally, the SIS-treated ACL had reduced anteroposterior knee instability compared with the control group whereas the in situ forces were similar to intact ACL. Furthermore, the structural properties of the FATC when tested in uniaxial tension showed that tensile stiffness was 2.5 times higher than suture repair controls and actually reached approximately 50% of the intact FATC.

A separate series of studies were performed by Nguyen and coworkers [179,180]. First attempts were made to suture the transected ACL and wrap it with SIS in a sheet form. Histologically, the collagen fibers were more dense and more compactly arranged than in the suture repair control group [180]. Afterward, an in vivo evaluation of this approach was performed and the CSA was found to be 50% of the intact ACL whereas stiffness for the SIS group was 35% higher than in the control group [179].

Studies have also shown, the feasibility of enhancing ACL graft integration after reconstruction using a triphasic scaffold using fibroblast and osteoblasts were seeded on a section of the scaffold that mimicked the native environment of the ligament insertion and bone, respectively [181,182]. Collectively these approaches demonstrate that ECM bioscaffolds have substantive potentials for improving treatment for injured ligaments and tendons.

Mechanical Augmentation

Mechanical augmentation has been shown to stabilize the knee with an injured ACL, which could aid in ACL healing. In a porcine model, Fleming and coworkers used sutures passing from bone to bone to reduce anterior joint laxity [183]. Our research center had also systematically used sutures (number 2 FiberWire sutures) for mechanical augmentation. In a goat model, we first determined the best locations of the bone tunnels for the sutures; i.e., the anterior footprint of the femoral origin and medial aspect of the tibial footprint on stifle joint stability after ACL transection [184]. In these positions, the anterior tibial translation was within 3 mm of the intact joint and the in situ force was similar to that of the intact ACL. A follow-up study showed the relative contribution of the soft tissues in resisting the anterior tibial load. Under the 67-N anterior tibial load, the ACL provided the dominant support in the intact

joint. In the case of ACL deficiency, the MCL and medial meniscus carried significant loads, reaching up to 36% and 53% of the intact ACL, respectively (at 30 degrees flexion). After suture repair of the ACL, the in situ force was 81% of the intact ACL whereas that for the augmentation sutures was 103% [185]. Thus, it could be concluded that suture augmentation provided good initial joint stability and concomitantly lowered the loads on the MCL as well as the medial meniscus.

Finally, an in vivo study was performed to examine whether suture augmentation could heal a surgically transected ACL in a goat model. After 12 weeks, the anteroposterior tibial translation of the stifle joint for the suture augmentation group was about 20% lower than that of the suture repair group (control) whereas the in situ force in the healing ACL was more than 50% higher. Morphologically, the ACL was found to heal with good neotissue formation. In terms of the structural properties of the FATC, the linear stiffness was 75% greater than that of the suture repair control. It was shown that suture augmentation had provided the needed stability to the stifle joint for intrinsic healing of the ACL to take place.

Combined Biological and Mechanical Augmentation

With evidence that biological and mechanical augmentation could individually enhance ACL healing, it begs the question whether their combination would work in synergy to enhance the ACL healing process further. It was hypothesized that mechanical augmentation would stabilize the knee immediately after surgery and enhance biological augmentation to stimulate and accelerate the ACL healing further.

For the purpose of mechanical augmentation, a novel Magnesium (Mg)-based ring was designed to bridge the two torn ends of the ACL and serve as an internal splint for mechanical augmentation (Fig. 67.8). Furthermore, the Mg ring could simultaneously load the healing ACL as well as its insertion sites to prevent disuse atrophy. The function of the Mg ring-repaired ACL was first evaluated in an in vitro study using a goat model. After the application of a Mg-based ring, the anterior tibial translation of the repaired ACL was reduced by 60−70% from the ACL-deficient state and was within approximately 3 mm of that of the intact stifle joint [186,187]. Mg-ring repair could also restore the in situ forces of the repaired ACL to within ±5 N of the levels of the intact ACL. These promising in vitro results suggest that the Mg-based ring is a good device for mechanical augmentation.

Then, the Mg-ring was used combined with ECM bioscaffolds in an in vivo animal study [186,187]. It was hypothesized that the Mg-based ring would degrade as the ACL healing progressed and its mechanical function would be replaced by the healing ACL, because Mg is biodegradable and bioresorbable [188]. After surgical transection, the Mg-based ring was sutured to connect the stumps of the ACL followed by wrapping the transection site with an ECM sheet and injection with ECM hydrogel (Fig. 67.8) [186,187]. After 6 weeks, the device had degraded 40%

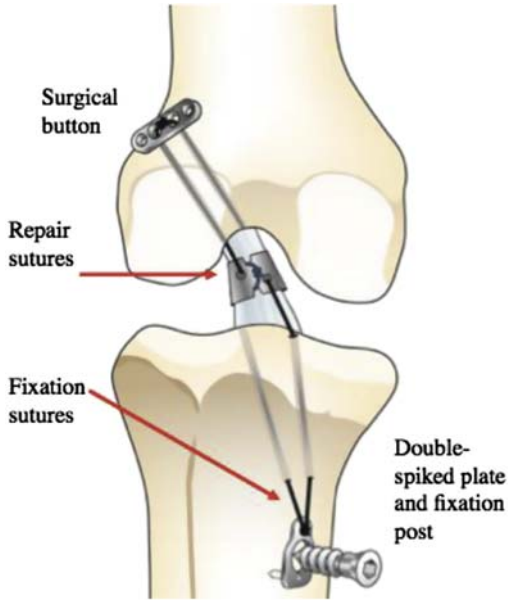

FIGURE 67.8 Schematic diagram showing the application of the Mg-based ring device to bridge the transected anterior cruciate ligament. Fixation sutures through the femoral bone tunnels are fixed using a surgical button whereas those through the tibial bone tunnels are fixed using a double-spiked plate and fixation post.

and translucent healing tissue was seen [186,187]. By 12 weeks, the function of the stifle joint was determined by the robotic–UFS testing system under 67 N anteroposterior load, the anteroposterior tibial translation of the Mg ring-repaired group was about 33% less than that of the suture repair group. The in situ forces carried by the Mg ring repair group were approximately twice those of the suture repair group. Similarly, the structural properties of the FATC (stiffness and ultimate load) for the Mg ring repair group were three times greater than the suture repair group [186,187]. These results also compared favorably to those after ACL reconstruction in the same animal model, because the stiffness was 1.5 times higher than that after ACL reconstruction in a goat model at 12 weeks [186,187,189]. Similarly, the ultimate load was 1.8 times higher. Thus, it is clear that the combined use of biological and mechanical augmentation therapy worked in synergy to accelerate ACL healing. Future work will include a long-term (26-week) study to determine whether these benefits persist.

SUMMARY AND FUTURE DIRECTIONS

In this review, biomechanical and biological problems facing repair and healing of ligament and tendon injuries were discussed. There have been tremendous improvements to clinical treatment paradigms based on studies that established a fundamental understanding of healing after ligament or tendon injury and the benefits of controlled mobilization. Nevertheless, many issues remain.

For ligaments and tendons that display healing potential after injury, major challenges are recovery of normal ultrastructural appearance, biochemical composition, and mechanical properties. Specifically, important steps to be taken are increasing the fibril diameters of healing tissues by limiting the production of type V collagen and decorin and improving the alignment of healing tissue by guiding the organization of newly produced matrix. By manipulating the healing response at the molecular and cellular levels and guiding tissue formation, the following FTE approaches may offer the potential to restore the properties of healing tissue to normal levels.

We are particularly interested in bioscaffolds such as ECM. Applied to a healing ligament or tendon in vivo, it serves as a substrate that provides contact guidance for cells to form more aligned collagen fibers with a concomitant improvement in mechanical and viscoelastic properties compared with untreated controls. Furthermore, the chemoattractant degradation products and bioactive agents of SIS could enhance the rate of healing [168], allowing better maintenance of stress and motion-dependent homeostasis. More excitingly, the SIS can be modified in vitro by seeding BMDCs on the scaffold and applying cyclic stretching to increase its alignment. Hence, when applied in vivo, the tissue engineered scaffold could serve to accelerate the initiation of the healing process by improving the production and orientation of collagen, which ultimately will help to make a better neoligament or tendon.

On the other hand, for ligaments and tendons that do not heal after injury and require surgical reconstruction using replacement grafts (e.g., ACL reconstruction), the major challenge is to promote a remodeling response so that the graft maintains sufficient stiffness and strength to provide functional stability of the joint. Most important is enhancing the rate of integration of tendon–bone interfaces during early graft incorporation, which may permit an earlier and more aggressive postoperative rehabilitation [190]. These complex issues may require a combination of approaches including gene and cell therapies as well as biologic scaffolds. Indeed, grafts treated with AdBMP-2 have shown some potential [137] in both canine and rabbit models. In addition, other biological tissues such as periosteum have been used to enhance the interface between tendon and bone, with some success [190]. All of these results suggest an exciting potential for clinical application.

Indeed, FTE has generated many exciting developments. For example, there is an exciting class of biodegradable metallic scaffolds, namely, porous magnesium or magnesium oxide, that has the advantage of initial stiffness to provide needed stability for the ligament to heal while performing its function. The degradation rate of these "smart" scaffolds could also be controlled as they are replaced by the neotissue. Furthermore, protein coating of these biodegradable metallic scaffolds could be performed for better tissue integration and controlled release of growth factors and cytokines to sustain tissue healing as well as guide tissue regeneration. In particular, Mg has been used combined with ECM bioscaffolds to heal the ACL, and it has the potential to serve as an alternative to surgical reconstruction.

To translate knowledge gained about a particular gene, protein, or cell to a clinical application will require expertise from many disciplines to work in seamlessly. One roles of biomedical engineers within this framework would be to link interactions of the functions of molecules to cells, cells to tissues, tissues to organs, and organs to body. When biologists, biomedical engineers, clinicians, and experts from other disciplines work together, this results in better therapies that lead to injured ligaments and tendons healing with properties closer to those of normal ligaments and tendons. Efforts of such a team-based approach to the new developments of FTE will bring a bright future to

the outcome of healing of ligaments and tendon injuries. With the development of precision medicine based on "big data" and cellular reprogramming on the horizon, it is easy to imagine that these FTE techniques for healing ligaments and tendons can be tailored to be patient specific to gain a more positive, long-term outcome.

INTRODUCTION

The human central nervous system (CNS), which is composed of the brain, spinal cord, and retina, is a network of more than 100 billion individual nerve cells that control our actions, sense our surroundings, and define who we are. It has several unique anatomical and physiological characteristics, including enclosure in bony structures (skull and vertebrae) that provide protection yet also hinder access; separation from systemic blood circulation by endothelial cell tight junctions, which serve as a barrier to toxins yet prevent intravenous therapeutic delivery; and a limited capacity for self-repair, notwithstanding the presence of endogenous stem cells in the brain, spinal cord, and retina.

Injuries to the CNS include stroke, traumatic brain injury (TBI), spinal cord injury (SCI), and retinal degeneration. These conditions affect millions of people worldwide and cover the entire age spectrum. CNS injury in the pediatric population includes predominantly traumatic or congenital defects, whereas in an adult population the injuries are traumatic or degenerative. Worldwide, every year approximately 15 million people experience a stroke (World Heart Federation). The incidence of traumatic SCI is 180,000 per year globally [1] whereas the prevalence in North America is approximately 1 in 1500 people [2]. Retinal degenerative conditions such as age-related macular degeneration are projected to affect 196 million people globally by 2020 [3] whereas retinitis pigmentosa (RP), which has a pediatric onset, is the leading cause of inherited retinal degeneration-associated blindness [4]. For all of these conditions, acute and chronic populations pose different treatment challenges.

Neurons, the functional units of the CNS, transmit and store information; they are extremely vulnerable to injury and degeneration. Mature neurons are postmitotic cells incapable of cell division. Thus, lost cells cannot easily be replaced and often leave a patient with a permanent functional impairment. Furthermore, a significant challenge in CNS regeneration is the complexity of the injury site. The CNS contains multiple subtypes of neurons that form an intricate system of connections with surrounding cells, such as other neurons and glia, and a complex organization that is difficult to recapitulate with current repair strategies. The anatomical location of the injury also has a significant role in the extent of trauma; a parenchymal lesion of several cubic centimeters may be clinically silent: that is, unapparent to both patient and clinician (if in the frontal cortex), severely disabling (if in the spinal cord), or fatal (if in the brain stem) [5].

Despite the complexity of the CNS anatomy, physiology, and pathobiology, tremendous progress in tissue engineering approaches have been made for treatment. This chapter focuses on tissue engineering strategies aimed at achieving functional recovery after CNS injury, including those based on drug delivery, cell delivery, and biomaterial scaffolds. Commonalities in the response to injury and barriers to regeneration are reviewed as related to the tissues of the CNS. Then various therapeutic strategies under investigation for the treatment of CNS injuries and diseases are introduced, such as drug delivery and cell therapy. The second half of the chapter covers the application of regenerative medicine to three case studies in CNS pathology: stroke, SCI, and retinal degeneration.

WOUND RESPONSE AND BARRIERS TO REGENERATION

The Blood–Brain Barrier

Under normal conditions, the CNS is considered to be immunoprivileged owing to the blood–brain barrier (BBB), which prevents entry of circulating immune cells and controls the influx of molecules into the brain. There are three main components of the BBB: (1) endothelial cells joined by tight junctions, which limit the paracellular flux of hydrophilic molecules; (2) astrocytic end feet, which tightly ensheathe the vessel walls and maintain the tight junctions; and (3) pericytes, which are important for structural integrity and tight junction formation. The BBB permits diffusion of dissolved gases such as O_2 and CO_2 along their concentration gradients. In contrast, the transport of larger molecules must be actively facilitated; nutrients (e.g., glucose) cross the BBB via transporters and endocytosis mediates the uptake of larger molecules (e.g., insulin) [6].

After injury, the BBB is damaged, leading to the initiation of an immune response cascade. Reperfusion with oxygenated blood results in the production of reactive oxygen species (ROS), which stimulate the secretion of inflammatory cytokines from ischemic cells. Activated inflammatory cells release matrix metalloproteinases (MMPs), which disrupt tight junctions between cells and the basal lamina and lead to the breakdown of the BBB. Breakdown of the BBB in turn causes leakage of plasma, red blood cells, and infiltration of immune cells such as neutrophils and other leukocytes that release proinflammatory factors [7,8]. The inflammatory response is initiated by peripherally derived immune cells such as macrophages and activated glial cells such as microglia that migrate into the injury site. Once there, macrophages and microglia release a wide range of soluble factors including cytokines, tumor necrosis factor, and interleukins (IL)-1, -6, and -10, as well as clear cellular debris by phagocytosis. The released cytokines induce the expression of secondary cytokines, chemokines, nitric oxide, and ROS, subsequently causing cell death [8a]. Pericytes of the BBB have been shown to have a role in scar formation in the spinal cord [9], which is discussed further in the following Reactive Astrocytes and the Glial Scar section.

Reactive Astrocytes and the Glial Scar

Under normal conditions, glial cells in the brain and spinal cord have a multitude of important roles, including maintenance and regulation of the extracellular microenvironment [10]. Astrocytes secrete numerous trophic factors that support neurons, regulate extracellular levels of ions and neurotransmitters, and provide an antioxidant defense for neurons [11]. They are also the main source of endogenous tissue plasminogen activator (tPA), an anticlotting agent, in the brain [12]. In the eye, the principal glial cells are the Müller glia, which support neuronal activity and integrity of the blood–retinal barrier (BRB) and protect retinal ganglion cells from glutamate and nitric oxide neurotoxicity [12a,13].

Injury to the CNS results in astrogliosis, the proliferation of glial cells that undergo morphological changes to become reactive astrocytes [14]. Reactive astrocytes have opposing roles in tissue repair: they are necessary for the wound response initially, yet inhibit regeneration. After stroke and SCI, reactive astrocytes and other cells produce proteoglycans such as chondroitin sulfate proteoglycans (CSPG) and myelin-associated glycoproteins (MAG) that inhibit axonal outgrowth [15]. Delivery of MMPs or chondroitinase ABC to the CNS after injury results in better cellular integration by degrading these inhibitory extracellular matrix (ECM) factors [16,17]. Despite the known detrimental effects of reactive astrocytes, it is clear that their role is more nuanced than previously thought. The ablation of reactive astrocytes after SCI exacerbates the severity of the injury [18] and has been shown to abolish axon regeneration in mice [19]. In the retina, Müller cell gliosis involves the upregulation of important intermediate filaments and the expression of neuroprotective cytokines and factors that encourage photoreceptor survival after injury [20]. Further work is needed to establish how to balance both roles of reactive astrocytes effectively to promote wound healing while facilitating axon regeneration.

Endogenous Stem Cells

Spontaneous host tissue regeneration depends on endogenous cells with the capacity to proliferate and differentiate. Although it was originally thought that repair of the CNS by endogenous mechanisms was unlikely caused by a lack of adult neurogenesis, this has been disproven. The two main regions that contribute to neurogenesis in the brain are the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone of the hippocampus [21–23]. Neural stem cells have also been found in the spinal cord, specifically in the ependymal layer of the subependymal zone of the central canal [24,25], as well as within the parenchyma after injury [25a]. After injury to the

spinal cord, these quiescent cells are stimulated to proliferate, resulting in cells positive for neural precursor markers (e.g., Sox2 and nestin) in the lesioned parenchyma [26]. Retinal stem cells have been identified in the pigmented ciliary epithelium of the eye; they proliferate in vitro and are differentiated into retinal-specific cell types in mice [27] and humans [28]. Astrocytes are another source of neurogenesis after injury; in the brain, it has been demonstrated that they are able to differentiate into functional neurons after stroke [29]. Although endogenous stem cells are stimulated by injury in the brain and spinal cord, they are not sufficient to induce recovery [30,31].

After CNS injury, a cascade of events ensues including BBB permeabilization, immune cell infiltration, and formation of a glial scar that inhibits the regeneration of tissue. Although endogenous mechanisms exist for protection (the glial scar) and repair (the proliferation of normally quiescent stem cell populations in response to injury), they are insufficient to result in significant functional repair on their own. Differences in wound response, anatomy, and cell type necessitate therapies tailored to the tissue target and pathological state, whether with biomolecule or cell-based therapeutics.

THERAPEUTIC STRATEGIES IN THE CENTRAL NERVOUS SYSTEM

Therapeutic strategies in the CNS can be classified as biomolecule or cell therapy. This section provides a broad overview of these approaches, acknowledging that the approaches are not exclusive to one another, and indeed most are typically complementary. Further detail is given in the case studies of CNS pathology (Section Case Studies in Tissue Therapy in the Central Nervous System).

Biomolecule Delivery

The use of biomolecule delivery as a protective and regenerative strategy after CNS injury has been investigated both in animal models and clinically. Molecules can be delivered systemically or injected locally. Systemic delivery is suitable only for molecules that can cross the BBB or blood–spinal cord barrier (BSCB) but the high doses required can result in undesirable side effects. Notwithstanding this limitation, many drugs acting on the CNS have been delivered systemically (for example, some small molecules such as methylprednisolone); however, molecules that do not cross the BBB, such as monoclonal antibodies, necessitate a local delivery strategy. Local injections can be performed into the epidural or intrathecal spaces of the spinal cord, into the ventricles in the brain, or directly into the tissue.

The goals of biomolecule delivery in the CNS are to limit degeneration (i.e., neuroprotection) and promote regeneration. Neuroprotection can be defined as a long-lasting maintenance of functional ability, as well as increased axonal sparing and reduced lesion volume. Neuroprotective molecules act on a variety of cellular targets, such as anti-apoptotic pathways to reduce death of certain neuronal populations or oligodendrocytes, and antiinflammatory pathways to inhibit microglial activation [32]. Growth factors previously explored for their regenerative potential have also been shown to be neuroprotective. For example, nerve growth factor (NGF), brain-derived neurotrophic growth factor (BDNF), neurotrophin-3 (NT-3), ciliary neurotrophic factor (CNTF), and glial cell-line-derived neurotrophic factor (GDNF) all promote axonal elongation and enhance the survival of sensory and/or motor neurons [33–37].

Neuroregeneration includes the growth of existing axons, sprouting of new axons from neural cell soma, remyelination, and plasticity among surviving axons, all leading to tissue repair and functional recovery. Outgrowth of motor and/or sensory neurons has been reported with the use of neurotrophic factors such as NGF [38], BDNF [39], NT-3 [38], GDNF [34], CNTF [40], and both acidic and basic fibroblast growth factor (FGF-1 and FGF-2) [41], among others. Some factors are predicted to act in synergy with one another [42] and with a second class of neuroregenerative molecules, which target growth inhibitory glycoproteins and proteoglycans by activating the Rho–Rho-associated protein kinase (ROCK) pathway. For example, MAG and NogoA are native to the CNS and bind to the Nogo (NgR) and $p75^{NTR}$ cell surface receptors, thereby triggering Rho-ROCK and growth inhibition [43]. Blocking this interaction with anti-NogoA or anti-NgR allows neurite outgrowth to resume [44]. Rho activation (and growth inhibition) can also be inhibited by increased intracellular concentrations of the nucleotide cyclic-adenosine monophosphate (cAMP) [43] or Cethrin, which showed some success in a Phase I/II clinical trial [45]. Delivery of cAMP or Rolipram, an inhibitor of cAMP degradation, has also been shown to enhance neuroregeneration in animal models [46,47] but is not yet in clinical trials. Another approach to neuroregeneration is stimulation of endogenous stem and progenitor cells in the stem cell niche. For example, specific factors (e.g., epidermal growth factor [EGF], FGF-2, cyclosporin A (CsA), and erythropoietin [EPO]) delivered to the stem cell niche stimulate neural precursor cells to proliferate and migrate, supporting the replacement of cells lost owing to injury [48,49].

Cell Therapy

The goals of cell transplantation are to replace cells lost owing to injury directly and promote the survival of endogenous cells [50,51]. Stem cells ameliorate poststroke impairments in the brain by modulating inflammation, inducing angiogenesis, and secreting neuroprotective factors into host tissue [52–54]. Theoretically, the ideal cell type would meet three requirements: (1) be from a source that is simple to harvest and does not raise ethical concerns, (2) have the ability to proliferate and generate large populations of donor cells, and (3) be from an autologous source or a one that does not require immune suppression to minimize rejection of engrafted cells.

Despite some Phase I clinical success with mesenchymal stromal cells (MSCs) in stroke and SCI [55,56] embryonic stem cell (ESC)-derived oligodendrocyte progenitor cells (OPCs) in SCI [57], and retinal pigmented epithelium (RPE) cells in retinal degeneration (e.g., NCT01344993, NCT01469832), cell transplantation is still in its infancy and is often complicated by inconsistent results. A major challenge with transplanting allogeneic or xenogeneic cells is a lack of long-term transplant survival, likely the result of the hostile microenvironment of the injury [58–60]. Limited availability of allogeneic donor cells is also an issue; even committed neural precursors isolated from fetal tissue do not proliferate to the extent necessary for widespread clinical utility. An alternative strategy involves the directed differentiation of stem cells, which have the ability for unlimited growth in culture. Several stem cell sources have emerged with the potential for therapeutic application in the CNS: ESCs, adult neural stem cells, and adult nonneural stem cells such as MSCs and adipose-derived stem cells (ADSCs). In addition, induction of pluripotent cells or transdifferentiation from adult somatic cells allows for the generation of patient-specific tissue grafts derived from the patient's own cells.

ESCs are pluripotent cells isolated from the inner cell mass of preimplantation blastocysts. The inner mass cells proliferate and differentiate to become the cells that make up the three germ layers of developing humans with the potential to become any cell in the body (pluripotent). This propagation potential can be recapitulated in culture and differentiation of these cells can be directed in a lineage-specific manner to yield terminally differentiated cells [61]. Safety is an important consideration in the clinical application of ESCs. Although there are concerns that their proliferative ability may lead to tumor and mass formation [62], none have been reported clinically. Predifferentiation of these cells is a means to diminish the implied risk of directly transplanting pluripotent cells [63]. However, in the absence of directed differentiation toward a particular cell fate, impure populations of differentiated cells can arise [64]; therefore, ESCs and their progeny should also be purified to ensure that only cells of a neural lineage are transplanted [64a]. The difficulty of translating human ESC (hESC) therapies to the clinic is highlighted through work done with hESC-derived cells for SCI by the California-based company, Geron. In early 2009, the US Food and Drug Administration (FDA) approved the first clinical trial for an hESC product, in which a suspension containing hESC-derived OPCs was injected directly into the SCI lesion site [65]. This trial was suspended twice in the first year: once because of questions regarding the purity of the cell population and then owing to microscopic cysts in the regenerating injury site in animal models. Geron halted the project completely in 2011 [66]. In 2014, the clinical trial resumed under the direction of Asterias Biotherapeutics [67], which after reviewing the preclinical safety of the OPCs [57] reported that the first eight patients showed promising results and that a further five to eight patients were to be enrolled.

Neural stem-progenitor cells (NSPCs) reside in distinct regions of both the fetal and adult CNS, namely the subventricular zone of the lateral ventricles [21,22], subgranular zone of the dentate gyrus of the hippocampus [68,69], and ependymal layer of the spinal cord central canal [24,25]. These cells undergo proliferation and maturation throughout adult life [70]. NSPCs can be isolated from embryonic or adult CNS and expanded in culture. These cells have been shown to survive, differentiate into all classes of cells in the CNS, integrate, repair tissue, and improve neurological function after transplantation into animal models of CNS disease or injury [71,72]. Adult NSPCs have lower survival than fetal NSCs after transplantation in the injured brain [73,74], and most transplanted cells differentiate into astrocytes in vivo rather than neurons or oligodendrocytes [75,76].

Nonneuronal stem cells are those derived from other tissues of the body and include MSCs, hematopoietic stem cells, and ADSCs. The majority of clinical stem cell transplantation trials to treat ischemic stroke, as listed by the National Institutes of Health clinical trial registry, use a nonneural source of cells such as autologous bone marrow–derived MSCs or hematopoietic stem cells. There are two major advantages to using these cells: (1) they are easily obtained from the body in large quantities, and (2) they can be derived from an autologous source, which eliminates immunogenicity [77]. MSC transplantation in rodents results in increased functional recovery, whereas their autologous transplantation in patients showed no adverse effects [77a,78]. It is thought that the regenerative success seen with MSCs results from their ability to secrete a variety of neuroprotective factors, such as BDNF, into the injury site to support endogenous cell survival and regeneration [79]. Work on them includes genetically engineering MSCs to overexpress certain factors that will further enhance their therapeutic effect [80].

The derivation of induced pluripotent stem (iPS) cells [81] from dermal fibroblasts has made it possible to harvest adult terminally differentiated cells and revert them to an ESC-like state [82]. Early iPS cell methods involved infection of the cells with a viral vector to induce pluripotency; current methods such as use of the *piggyBac* transposon allows the transgene to be excised once pluripotency is established, avoiding the risk of mutagenicity caused by a permanently integrated factor [83]. Exploration of this approach may eventually lead to the development of patient-specific (autologous) neural grafts grown from the patient's own cells.

The skin also contains a special type of precursor cell, termed "skips" [84,85], which has shown promise for the treatment of neurological disorders [86] such as SCI [87,88].

Transplanted cells have a high rate of cell death because of a variety of factors including proapoptotic signals, the immune response, and anoikis, that is, the lack of a scaffold for cell adhesion [58–60]. The relatively poor survival of transplanted cells suggests that a combination of cells and drug/biomolecule delivery would enhance survival and integration of the transplanted cell population. Combining delivery of neural stem or progenitor cells with chondroitinase ABC and growth factors enhanced cellular integration and functional recovery in a rat model of chronic SCI [89]. Chondroitinase ABC improves the host environment for cell engraftment by degrading the inhibitory CSPGs in the glial scar, promoting cell integration, whereas the growth factors EGF, FGF-2, and platelet-derived growth factor (PDGF)-AA enhance stem cell survival and differentiation [90–92]. To support cell survival and provide an extracellular framework for the transplanted cells, an engineered composite vehicle that can deliver both the cells and biomolecules to the therapeutic target in the CNS is desirable [93,94,94a].

CASE STUDIES IN TISSUE THERAPY IN THE CENTRAL NERVOUS SYSTEM

Stroke

Cerebrovascular disease, defined as an abnormality of the brain caused by a pathological process involving its blood supply [95], is the third leading cause of death in the United States. In terms of morbidity and mortality, it is one of the most common neurological disorders. There are two main types of stroke: hemorrhagic, caused by a ruptured cerebral blood vessel, and ischemic, caused by an occlusion in the cerebral vasculature. Approximately 87% of strokes are ischemic [96]; thus, we focus on ischemic stroke.

Pharmacological Therapy

Pharmacological treatment of stroke can be broadly classified into two categories, thrombolytic and neuroprotective. The goal of thrombolysis is to remove the blood clot that results in ischemia so that normal blood flow to the brain can be restored. However, there is an increased risk of hemorrhagic complications with this treatment and it is imperative to administer it within hours after the initial occlusion for it to be effective [97]. Thrombolysis treatment promotes the conversion of the proenzyme plasminogen in the bloodstream into the active enzyme plasmin, a protease that degrades blood plasma proteins associated with blood clotting, most notably fibrin. The only FDA-approved treatment for stroke is tPA, which activates plasminogen by catalyzing its conversion into plasmin and improves the outcome in ischemic stroke when administered up to 4.5 h after stroke [98].

In the hours and days after a stroke, there is continued cell death and impaired function in the penumbra, the area surrounding the lesion core. The penumbra contains cells that are nonfunctioning but can be rescued using therapeutic strategies [7]. Neuroprotective treatments focus on preventing further damage and preserving as much tissue as possible. Neuroprotective agents being investigated include calcium antagonists, glutamate antagonists, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid antagonists, opioid antagonists, γ-aminobutyric acid (GABA) agonists, free radical scavengers, antiinflammatory agents, and membrane stabilizers [99]. A particularly compelling example of a successfully translated neuroprotective agent is NA-1, an inhibitor of NMDA receptor-mediated neuronal death, which has been shown to reduce infarct volume in both primates [100] and humans [101] and is being tested in a US-based Phase II trial [102].

Factors for Endogenous Stem Cell Stimulation

After stroke, neural stem cells within the SVZ express elevated levels of receptors for growth factors. For example, receptors for both GDNF [103] and EGF [104] are increased. This suggests that the injured brain may be receptive to repair by its endogenous stem cell populations through growth factor delivery. In animal models of stroke, administration of EGF and EPO stimulated endogenous stem cells, resulting in regeneration of damaged tissue after pial vessel disruption [105]. Sequential administration of β-human chorionic gonadotropin (hCG) and EPO 24 h after

stroke resulted in a significant decrease in lesion volume and functional improvement in an animal model [106]. Moreover, a clinical study demonstrated that a similar sequential administration of intramuscular β-hCG and intravenous EPO 24–48 h after stroke is safe and resulted in a trend toward smaller infarct size [107]. Granulocyte-colony stimulating factor (G-CSF) has also shown promising results: Cells in the SVZ express the receptor for G-CSF and subcutaneous administration of this factor stimulated stem cell proliferation, resulting in improved functional recovery [108].

An alternative to stimulating the endogenous brain stem cells is to target bone marrow–derived stem cells, which will home to the site of injury. When G-CSF was administered intravenously to rats subjected to middle cerebral artery occlusion (MCAO), infarct volume decreased, suggesting a neuroprotective effect [109]. Moreover, a clinical study showed that subcutaneous administration of G-CSF is a safe and feasible method to mobilize bone marrow stem cells [108].

CsA, a clinically used immunosuppressant, has also been shown to stimulate neural stem cells in the SVZ [110]. CsA, encapsulated in poly(lactic-*co*-glycolic acid) (PLGA) microspheres and delivered locally to the injured cortex, demonstrated increased cell proliferation in the SVZ and a smaller infarct volume compared with untreated controls [48] (Fig. 68.1). Work has also been done to investigate the use of BDNF for stroke recovery. BDNF levels in the brain

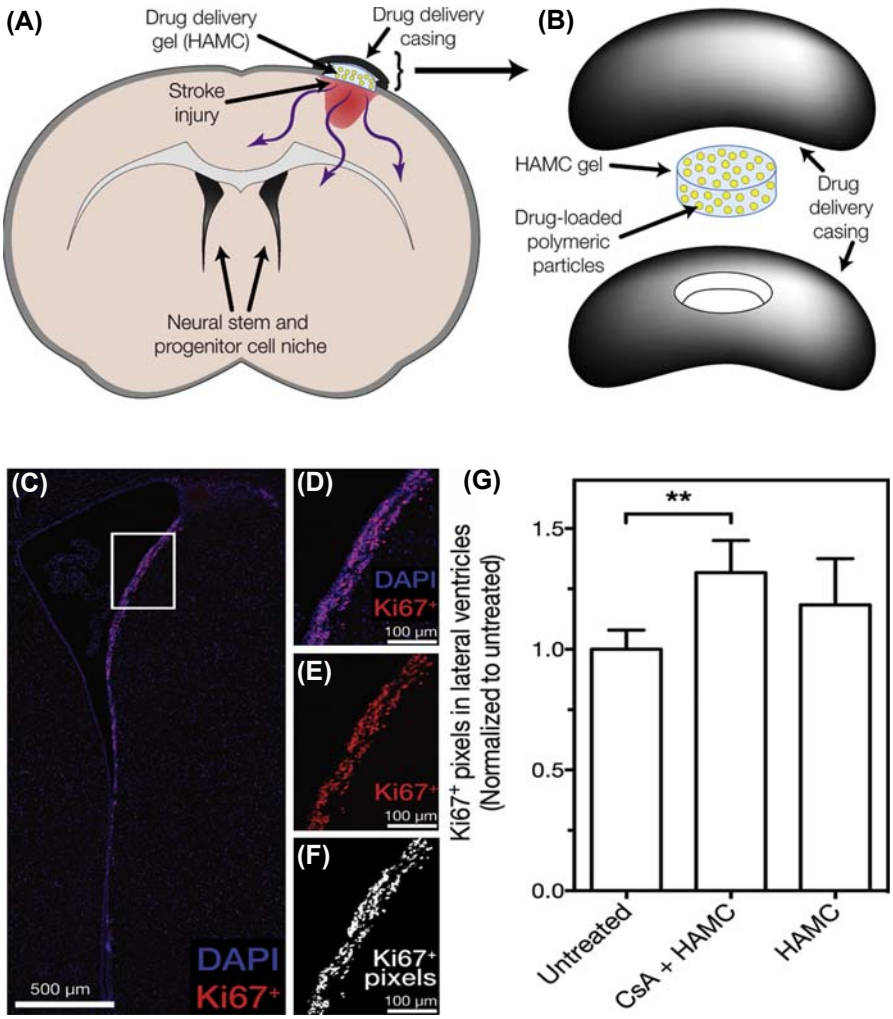

FIGURE 68.1 A localized drug delivery system for the delivery of cyclosporin A (CsA) to the stroke-injured rat brain. (A, B) A hydrogel (hyaluronan and methylcellulose [HAMC]) containing drug-loaded polymeric microspheres is injected onto the surface of the brain and contained in a polycarbonate casing. (C–G) CsA delivery to the injured brain results in a significant increase in Ki67-positive proliferative cells in the subventricular zone compared with untreated animals. *DAPI*, 4′,6-diamidino-2-phenylindole. Circumventing the blood-brain barrier: local delivery of cyclosporine A stimulates stem cells in stroke-injured rat brain. J Control Release 2015;215:1–11.*

are elevated after injury and it is important for poststroke recovery [111,112]. Delivery of BDNF, either systemically or locally, results in reduced infarct volume and improved functional recovery [113–115].

An exciting alternative to drug delivery is the delivery of viral gene vectors such as NeuroD1 to influence the direct in vivo reprogramming of reactive astrocytes of the glial scar into new neurons that can integrate into the neural circuity. A study demonstrated that this is possible in the cortex of injured and Alzheimer model mice, in which NeuroD1 was used to reprogram astrocytes successfully into glutamatergic neurons [116]. This strategy avoids the issue of immune rejection of cell transplants and may be able to generate large enough numbers of endogenous neurons while depleting the glial scar for functional recovery. Further work is needed to increase transfection efficiency and generate the neuronal subtypes needed for circuit restoration [117].

Cell Transplantation

Because of limited endogenous regeneration in the brain, exogenous cells have been transplanted as an alternative strategy. When NSPCs were administered intravenously to mice subjected to MCAO, the cells migrated to the injured side of the brain; however, only 0.09% of the injected cells were found in the brain whereas many were detected in other organs [52]. Local delivery strategies include transplantation directly into the lesion or into the surrounding penumbra, and can achieve greater numbers of cells at the injury site than systemic delivery. Directly into the lesion is favored because it is able to accommodate the injected volume without damaging healthy tissue and is adjacent to the penumbra, a region of potentially recoverable cells [93,93a]. However, despite these benefits, the hostile inflammatory environment of the lesion is not always conducive to the survival of transplants, which is limited to 1–10% of the injected population [58,118]. Because of the varying size of lesions, an injectable hydrogel that fills the irregular void is desirable (Fig. 68.2).

To support cell survival and provide an extracellular framework for cell delivery, scaffolds are being explored to promote greater cell survival and regeneration [93,94a]. Biomaterials can act as three-dimensional artificial niches to support cellular function and survival, provide physical protection from washout into the cerebrospinal fluid (CSF), and provide protection from the immune response and apoptotic signals from the ECM [58–60,60a]. Natural scaffolds such as Matrigel have been used to deliver neural progenitor cells (NPCs) into the stroke lesion and showed an increased number of cells at the transplantation site relative to delivery in artificial CSF [120]. Notwithstanding these results, Matrigel is derived from a mouse sarcoma and is inherently ill-defined, which hinders its clinical use. To elucidate whether individual components of Matrigel can improve cell survival, cells have been transplanted in collagen I [121] and a mixture of collagen I and either laminin or fibronectin [122], both of which were found to improve cell survival. Another natural polymer that has garnered much attention is hyaluronan (HA). HA constitutes a significant proportion of the CNS ECM and can be cross-linked to have a modulus similar to that of native brain tissue [60a,93]. HA is also reported to inhibit scar formation and promote angiogenesis in vivo [123,124].

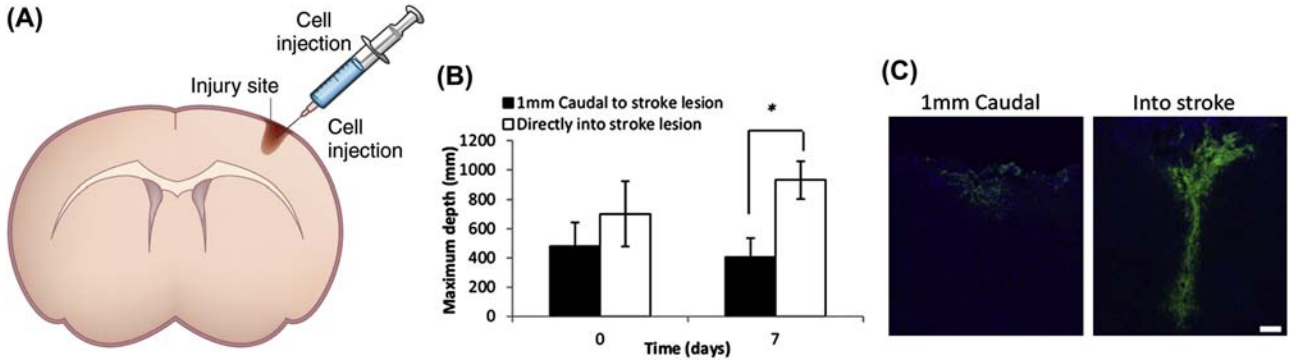

FIGURE 68.2 Injectable delivery vehicle for cell delivery to the injured brain. (A) This conceptual drawing shows injection of the space-filling vehicle into the cystic cavity formed after traumatic or stroke-induced brain damage. A craniectomy is performed to expose the injury site and a hydrogel is then injected to fill the cavity. (B, C) Comparison of injection of mouse neural stem/progenitor cells directly into the mouse stroke lesion (*white bars*) or 1 mm caudal to the lesion (*black bars*). At 7 days after injection, cells delivered directly into the lesion achieved greater depth into the brain than those delivered caudal to the lesion. Scale bar, 100μm. *(A) Reprinted with permission from Reichert W. Indwelling neural implants: strategies for contending with the in vivo environment, vol. xviii. Boca Raton: CRC Press; 2008. p. 271. A hyaluronan-based injectable hydrogel improves the survival and integration of stem cell progeny following transplantation. Stem Cell Rep 2015;4(6):1031–45.*

Combined with methylcellulose, HA methylcellulose (HAMC) hydrogels increased cell survival and motor recovery when used as a vehicle to deliver neural stem cells (NSCs) into the stroke-injured cortex of adult mice [94].

When stem cells are delivered to the site of injury, they must differentiate into the correct cell types for integration and functional recovery. It has been reported that later-stage neuronal precursors from the embryonic cortex are better able to differentiate and survive when transplanted into the stroke-injured brain compared with cells of an earlier developmental stage [73]. Similar results were observed with transplanted human iPS-derived neuronal precursors [125] and ESC-derived neuronal precursors [126]. Specific regions of the brain or different microenvironments have also been shown to drive stem cells to differentiate preferentially into glia over neurons. For example, adult NSCs from the SVG or SVZ will produce neurons only when they are transplanted in neurogenic regions; in nonneurogenic areas they differentiate primarily into glial cells [75,76,127]. An experiment comparing the transplantation of glial-restricted spinal cord progenitors and NSCs into the aging hippocampus reported that regardless of initial cell type, cells differentiated into predominantly glia, which suggests that the microenvironment of the hippocampus influences preferential differentiation of stem cells into astrocytes [128]. This phenomenon is also observed in the spinal cord, where it has been reported that if cells are not restricted to a neuronal lineage before transplantation, they will mainly differentiate into glia and exhibit lower survival [129].

A combination therapy using growth factors or peptides and stem cells has been proposed to better control and improve the efficacy of cell transplantation. For example, the combined delivery of EPO and MSCs results in increased proliferation of cells along the lateral ventricle wall and greater functional recovery than either EPO or MSC treatment alone [130]. Combining cells with peptides has a similar outcome; NSCs delivered with the adhesion peptide IKVAV, derived from the full-length laminin protein, to a TBI rat model increased neuronal cell attachment and neurite outgrowth only when IKVAV was present [131].

Rehabilitation can contribute to regeneration when combined with stem cell transplantation. To study the effects of rehabilitation, animals are housed in enriched environments (EE) where they are allowed access to a variety of objects that stimulate exploratory behavior in addition to free access to individual running wheels [132]. Combined with mouse NSPC transplantation, EE enhanced functional recovery and proliferation of endogenous progenitor cells and increased cell migration to the injury site [132]. In contrast, when rats were injected with neural precursor cells derived from human ES cells, EE had no significant effect on functional recovery [58]. The authors attributed these varying results to possible differences in the immune response and cell survival between mouse and human stem cells.

Preclinical studies demonstrate the potential of stem cell therapy to treat stroke; however, to translate this potential to the clinic, additional research is required to control cell survival, differentiation, and integration better for ultimate functional repair. Although thrombosis treatment has had the best clinical success, the short window for treatment limits its utility. Ultimately, combination strategies that both protect brain tissue from further degeneration and promote tissue regeneration will likely see the greatest success in the clinic.

Traumatic Spinal Cord Injury

Traumatic SCI results from contusion/compression or transection (laceration) of the cord. Compression injuries comprise 70% of clinical cases and partial or complete transection comprise the remaining 30% [133]. Compression of the spinal cord may be caused by dislocation of a vertebra and pinching of the cord between the anterior and posterior faces of the vertebral foramen in adjacent vertebrae. In spinal cord trauma, the level and severity of cord injury determine the extent of neurological manifestations and the prognosis. Damage to thoracic and lower vertebrae can lead to paraplegia and cervical injury may result in quadriplegia. Spinal cord injuries above the fourth cervical vertebra can also compromise respiratory function. Segmental damage to the ascending and descending white matter tracts accounts for the principal clinical deficits.

The initial primary injury causes uncontrolled necrotic cell death, inflammation, ischemia, and hypoxia. These processes persist for weeks and initiate a second wave of apoptosis in neurons and oligodendrocytes, increasing the volume of injured tissue and forming a spindle-shaped cystic cavity [134]. This secondary biochemical cascade is also evident after transection, although a cavity does not form. In both injury types, the injured tissue is isolated from the environment by reactive astrocytes through the formation of a glial scar [134]. Similar to stroke, tissue therapy after SCI is classified as neuroprotective (reducing the biochemical damage of the secondary injury) or neuroregenerative (restoring lost function through regrowth and reinnervation of axons).

Biomolecule Delivery

Classes of biomolecules used for spinal cord repair include steroidal compounds, sodium or potassium channel blockers, and growth factors. The steroid methylprednisolone, an antiinflammatory drug, is used clinically [135], but

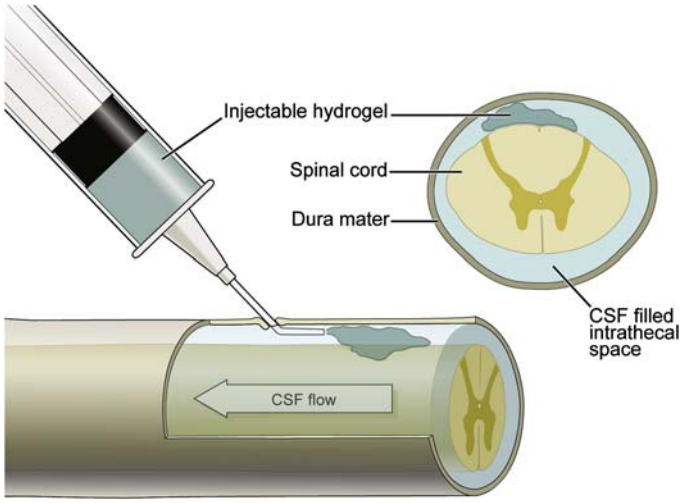

FIGURE 68.3 When injected into the intrathecal space, a hydrogel-based drug delivery system can localize and modulate biomolecule therapeutic release at the site of injury. This route is preferred over epidural delivery, in which the diffusive barrier presented by the dura mater is significant. *CSF*, cerebrospinal fluid. *Copyright (2005) by Michael Corrin, reproduced with permission of the artist.*

its beneficial effects have been questioned and it is not always administered to patients. Minocycline, a tetracycline derivative, targets the host inflammatory response and can cross the BSCB [136]. It demonstrated modest motor improvements in a Phase II trial [137], which is recruiting for a Phase III trial [138]. Riluzole, a sodium channel blocker in clinical use to treat amyotrophic lateral sclerosis, was tested in a Phase I SCI trial, which was completed in 2013; and is currently undergoing a Phase 2/3 trial (ClinicalTrials.gov identifier NCT01597518; [138a]).

Because most drugs and protein therapeutics delivered systemically cannot cross the BSCB, the most effective delivery strategies to the injured spinal cord are to the intrathecal space or directly into the cord. Local release circumvents the BSCB and enables direct tissue benefit. For example, anti-NogoA (ATI355, Novartis) was injected directly into the intrathecal space using an external pump or catheter. Although the Novartis trial results have not been published, use of the external pump caused infections in the first patients, resulting in a change of strategy to bolus injection to the intrathecal space [139]. While not circumventing the BSCB, Cethrin (Vertex) was delivered locally to the epidural space from a fibrin sealant [140]. The Cethrin trial resulted in modest improvement in cervical spinal cord–injured patients 12 months after treatment [45]. Despite these results, with epidural delivery the therapeutic molecule must cross the dura mater, arachnoid mater, and fluid-filled intrathecal space before reaching the damaged spinal cord, resulting in limited tissue penetration.

Intrathecal injection is a desirable strategy for local delivery because it bypasses the two meninges of epidural delivery and avoids both the infection associated with external pump or catheter and the tissue damage associated with the needle track of intraspinal delivery (Fig. 68.3). Continuous intrathecal infusion is most often achieved from an indwelling catheter and pump system. Implanted osmotic minipumps have been used in many preclinical in vivo studies for up to 28 days [44,141,142]. Continuous infusion provides excellent dose control, but prolonged catheterization carries with it the risk for tissue damage by catheter tips that can compress and scar the spinal cord [143]. Injectable, bioresorbable hydrogels provide an excellent alternative to the pump or catheter system. Prolonged release for up to 2 months has been demonstrated with a series of protein and drug therapeutics. For example, bolus injections of sustained release formulations, such as drug-loaded polymer particles, distribute throughout the intrathecal space [144] and hydrogels in which polymeric nanospheres are incorporated remain localized at the site of injection, achieving prolonged release. HAMC was injected into the intrathecal space in a rat model of SCI, where it remained localized for up to 7 days [145]. Drug-loaded PLGA nanoparticles were included in the HAMC formulation to sustain drug release and stabilize the hydrogel, resulting in HAMC composites that were stable for more than 50 days and sustained drug release for 28 days in vitro [146]. This formulation provided a platform for the local delivery of factors (NT-3 and anti-NogoA [90]; and cell–drug combinations such as PDGF and neural stem cells [92], or the combination of PDGF, a Gly–Arg–Asp–Gly–Ser adhesive peptide, and OPCs [91] to the injured spinal cord.

Guiding Axon Regrowth

A challenge particular to transection injuries of the spinal cord is the long-distance axon regeneration required for functional recovery. Thus, treatment strategies for transection injury use physical constructs to provide a permissive

environment and guidance cues for axonal regeneration. When the cord is completely severed, the stumps can be placed within nerve guidance channels in a strategy analogous to that pursued in peripheral nerve repair. Tube dimensions, wall thickness, porosity, and mechanical strength are all important physical factors that influence the suitability of tubes for CNS repair. Matching the mechanical properties, and specifically the modulus, of the tube to the tissue has been shown to be important to avoid necrotic tissue at the interface [147]. Considerable effort has been directed into optimizing tube fabrication methods, including polymer extrusion, casting in molds, immersion of a polymer solution-coated mandrel in a nonsolvent, and centrifugal casting of phase-separated polymerization mixtures. These techniques vary in the uniformity of the tubes produced; centrifugal casting remains the most versatile option for hydrogels and molding is the simplest [148,149]. Tubes are fabricated from a variety of both synthetic and natural materials to meet these criteria increasingly to function as platforms for drug and/or cell delivery.

One of the most popular classes of materials is hydrogels such as poly(2-hydroxyethyl methacrylate-*co*-methyl methacrylate) (P[HEMA/MMA]) [150]. P(HEMA/MMA) is biocompatible and is promising as a nerve guidance tube in the CNS and peripheral nervous system [148,149]; however, P(HEMA/MMA) is nondegradable and investigators have turned to materials such as poly(L-lactide) [151], poly(hydroxybutyrate) [152], chitosan [153,154], and collagen [155], which are degradable in vivo. Hydrogels alone have been used when the cord is partially or fully transected to fill the tissue defect and promote bridging of the gap [156,157]. The alignment of the material is also an important consideration for conduit design; it has been demonstrated that unilateral nanogrooves aligned with the direction of axon growth result in better directional guidance than less-organized topographic cues within the conduit [158].

Various cell types have been incorporated into physical constructs to enhance axon guidance and survival in the spinal cord. Schwann cells [151,152,159], astrocytes [159], and NSPCs [160,161] have been included in the inner lumen of tubes, either adherent to the inner surface or suspended in a hydrogel within the tube. Cell-adhesive hydrogels such as dilute collagen [162] and laminin-functionalized agarose [163] have shown promise in this application. One example involves rat NSPCs that were seeded in fibrin scaffolds inside chitosan channels and combined with dibutyrylcyclic adenosine monophosphate–releasing PLGA microspheres to promote recovery in the rat [163a].

Cell Transplantation

Similar to stroke, cell delivery to the injured spinal cord is challenging owing to the hostile microenvironment, glial scarring, and a lack of ECM. Nonetheless, there is significant interest in intraspinal cell delivery and investigators have used many of the cell types previously mentioned for this purpose. In acute injury models, cells have been injected into the tissue as a suspension in buffer [164,165] or polymer matrix [166] near the site of injury. One challenge unique to spinal cord regeneration is the remyelination of spared axons, thought to be an important mechanism for recovery. Predifferentiation in vitro of human ES cells to oligodendrocyte progenitors, before transplantation, has been demonstrated to increase remyelination after transplantation compared with undifferentiated cells [64a,167]. Differentiation of hESCs to oligodendrocyte progenitor cells is the basis of a clinical trial led by Asterias, as mentioned earlier. In another study, NSCs derived from either a myelinating (wild-type) or nonmyelinating (*Shiverer* mouse) cell line showed that although both cell types integrated and predominantly differentiated into oligodendrocytes, only animals that received myelinating cells showed tissue and functional benefits [168] (Fig. 68.4). The use of cells that are predifferentiated to a specific type of the *neuronal* lineage, such as GABAergic interneurons, has also shown success in restoring function and reducing neuropathic pain after SCI [169,170]. Interestingly, robust corticospinal tract regeneration in a complete transection rat model was observed after transplantation of NPCs driven toward a spinal cord identity, which suggest that the positional identity of progenitor cells is important for integration into the injury site [171].

Retinal Degeneration

In the normal eye, light reaches the neural retina, which is composed of photoreceptors (rods and cones) and is transduced into electrical impulses for the brain by various cell types (Fig. 68.5). The retinal pigment epithelium (RPE), located directly adjacent to the photoreceptors, supports photoreceptor metabolic function and has a critical role in the biochemical process of vision. Retinal disease leads to permanent loss of visual function for which there is no definitive treatment. Vision is a major factor in quality of life; in the United States, it is estimated that $4.6 billion dollars is spent on non–diabetes related retinal disorders (Prevent Blindness America). The search for cures is made more urgent by the knowledge that as populations in the developed world age, the incidence of blindness caused by

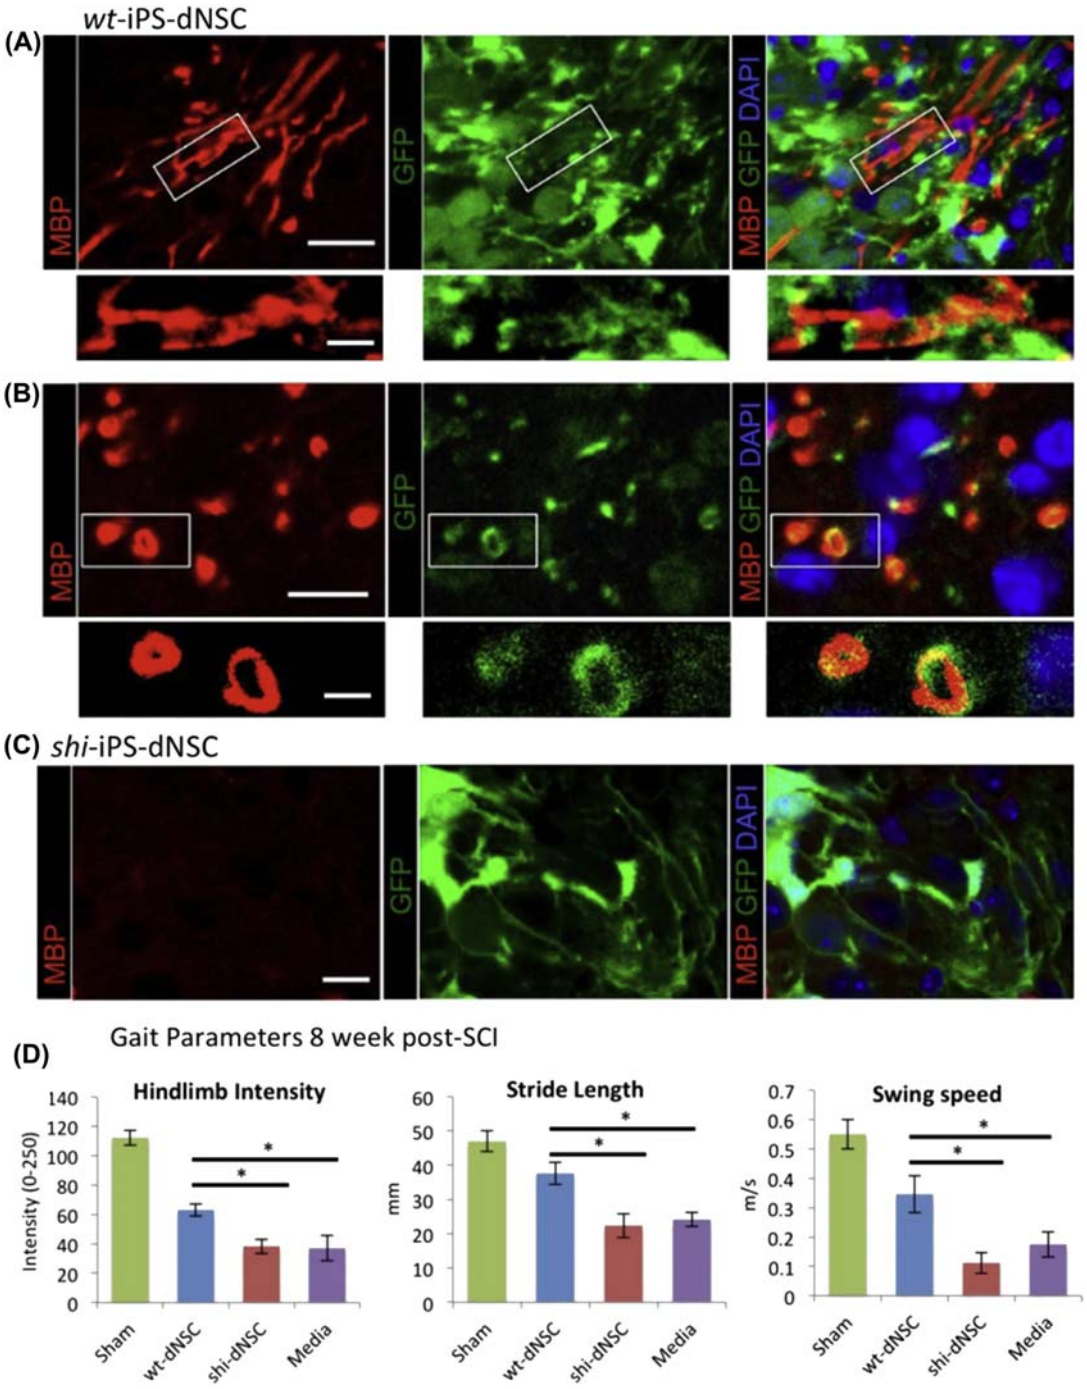

FIGURE 68.4 Remyelination is important to recovery in spinal cord injury. The delivery of induced pluripotent stem cell-derived neural stem cells (iPS-dNSC) into the injured spinal cord from wild-type (*wt*) mice (A, B) results in significant behavioral recovery attributed to increased myelination compared with iPS-dNSCs from the *shiverer* (*shi*) mutation. (C) After transplantation, the wild-type iPS-dNSCs showed remyelination myelin basic protein (MBP plus staining) of axons in both longitudinal and transverse orientations, whereas the *shiverer* iPS-dNSCs showed no myelination. (D) Gait parameters at 8 weeks after injury were significantly improved in only the wild-type dNSC group. *DAPI*, 4′,6-diamidino-2-phenylindole; *GFP*, green fluorescence protein. *Reprinted with permission from Salewski RP, Mithcell RA, Li L, Shen C, Milekovskaia M, Nagy A, Fehlings MG. Transplantation of induced pluripotent stem cell-derived neural stem cells mediate functional recovery following thoracic spinal cord injury through remyelination of axons. FIGURE 68.5 The human retina possesses a laminar structure. Photoreceptors (rods and cones) lie in the outer nuclear layer, interneurons (bipolar, horizontal, and amacrine cells) in the inner nuclear layer, and ganglion cells in the ganglion cell layer. Photoreceptors, bipolar cells, and horizontal cells make connections with each other in the outer plexiform layer. Bipolar, amacrine, and ganglion cells make connections in the inner plexiform layer. Information flows from outer lamina to inner lamina, as well as laterally via horizontal and amacrine cells. *Reprinted with permission of Delplace V, Payne SL, Shoichet MS. 2015. Delivery strategies for treatment of age-related ocular diseases: from a biological understanding to biomaterial solutions. Journal of Controlled Release. 219: 652–68.*

to retinal degeneration is expected to rise [171a,172]. Age-related macular degeneration (AMD) is the most common cause of irreversible vision loss in the United States [173]. To understand regenerative therapies for retinal degeneration, it is important to understand the pathogenesis of a typical degenerative condition such as AMD. It is commonplace to describe AMD as "dry" (atrophic) or "wet" (exudative). Dry AMD is identified by diffuse, discrete deposits in the Bruch membrane (drusen) and atrophy of the RPE, whereas wet AMD is characterized by choroidal neovascular membranes originating from the underlying choriocapillaries. These vessels are leaky and exudate can form macular scars that directly destroy both photoreceptors and the RPE. The RPE is essential for homeostatic photoreceptor outer segment phagocytosis and disruption of the RPE is associated with photoreceptor death [174,175].

Biomolecule Delivery

Retinal degeneration therapies are focused on pharmacotherapy. These therapies slow disease progression but do not restore vision loss. There have been significant advances in the treatment of wet AMD with antivascular endothelial growth factor (anti-VEGF) therapies [176,177]. Examples of available biomolecules include ranibizumab (Lucentis), bevacizumab (Avastin) [178–180], and pegaptanib (Macugen). One issue with anti-VEGF treatment for the eye is the serious off-target effects on VEGF-dependent physiological processes such as wound healing and kidney function. To address this, an anti-VEGF "sticky-trap" composed of anti-VEGF and a heparin-binding domain was designed to remain at the site of injection and thus avoid systemic effects [181]. Other experimental treatments in AMD and diabetic retinopathy focus on eliminating oxidative damage using bioactive molecules such as advanced glycosylation end-product inhibitors and antioxidants [182]. Corticosteroids and antiinflammatory drugs such as dexamethasone have been explored extensively; a number are available commercially [183,184]. An interesting example is Ozurdex, a degradable implant composed of PLGA-encapsulated

dexamethasone used to decrease macular edema in patients with diabetic retinopathy [184]. Gene therapies might also present a method for targeting defects that result from inherited retinal disorders such as Leber congenital amaurosis [185], RP [186], and ocular albinism [187].

Cell Transplantation

Cell transplantation is an alternate strategy that arguably, has seen the most clinical success in retinal degeneration compared with other tissues of the CNS. Early clinical studies conducted in patients with retinal degeneration involved retinal sheet transplants. This procedure relies on an immature retinal sheet taken from fetal tissue to extend processes and integrate with the degenerating recipient retina. The rationale is that spared inner cells of the retina require only synaptic connections with functional photoreceptors to complete the visual circuit. Various types of tissue have been allografted: fetal RPE cells in patients with AMD [188] and neural retinal cells in patients with RP [189]. These studies have shown some subjective improvement in function but also eventual rejection of the transplant [190–192]. Some of the most promising results to date were reported with the transplantation of retinal progenitor cell (RPC) sheets with intact RPE into 10 patients with RP and AMD, in which seven patients showed some improvement in visual acuity scores without cell rejection [193].

Studies suggested that stem cell transplantation shows promise for reconstituting damaged cell populations in the retina [194–196] (Fig. 68.6). Preclinical research on cell transplantation is directed toward transplanting cell suspensions into the subretinal space, and strategies involving the delivery of NPCs, healthy photoreceptors,

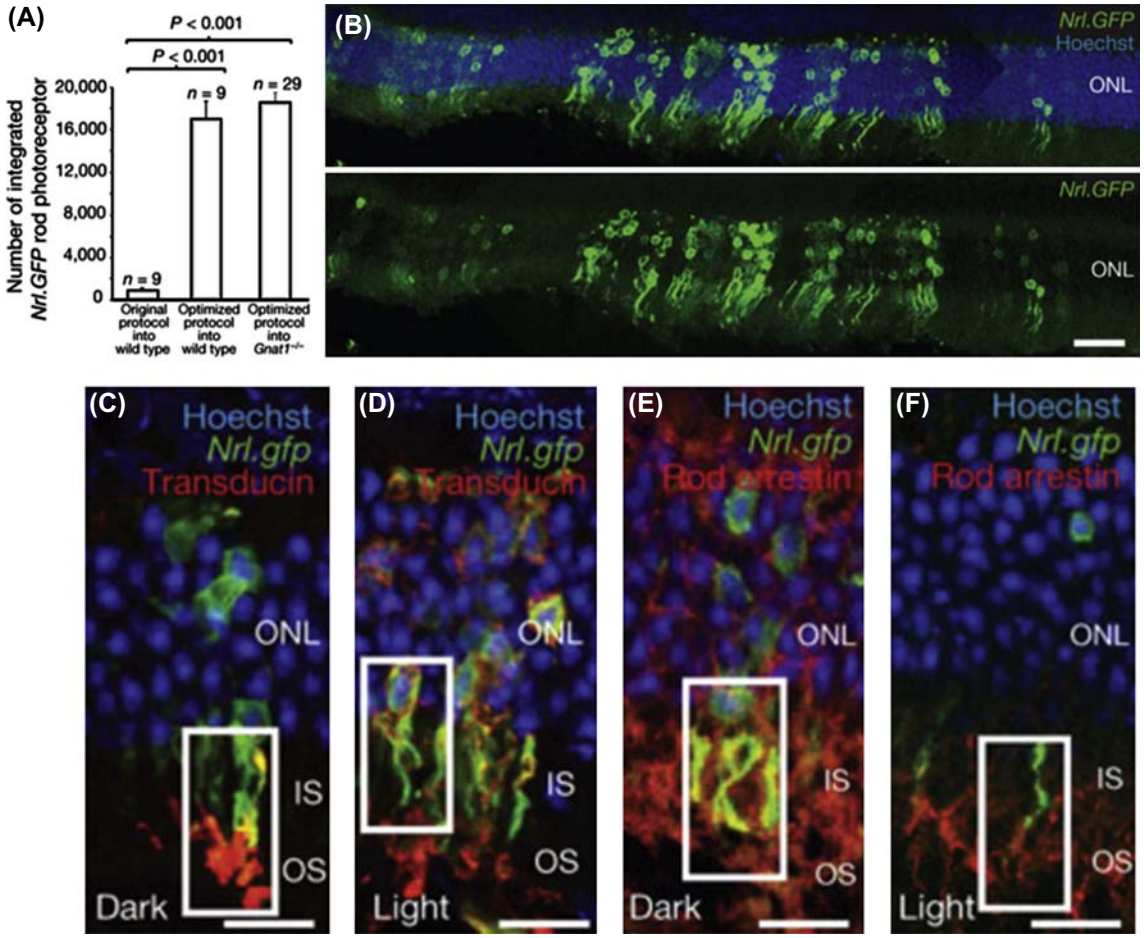

FIGURE 68.6 *Nrl*.GFP (neural retina leucine zipper gene; green fluorescent protein) rod transplantation results in integration into the adult *Gnat1*$^{-/-}$ retinal dysfunction mouse model. (A) Optimization of transplant protocol led to an increase in the number of photoreceptors present after transplantation. (B) Representative images of integrated photoreceptors (green fluorescence protein positive) in the retina with and without 4′,6-diamidino-2-phenylindole staining. Scale bar, 50μm. (C–F) Integrated photoreceptors expressed appropriate proteins (transducin and rod arrestin) at the correct location during light and dark stimulation. Scale bar, 10μm. *IS*, inner segment; *ONL*, outer nuclear layer; *OS*, outer segment. *Reproduced with permission from Pearson RA, Barber AC, Rizzi M, Hippert C, Xue T, West EL, et al. Restoration of vision after transplantation of photoreceptors. Nature 2012;485:99–103.*

photoreceptor precursors, and RPE cells are all being pursued. Immature neurons are capable of migrating and differentiating during neural development, and many studies have focused on the integration of these brain-derived neural progenitors into the retina. However, transplantation to the adult retina showed limited donor cell integration [197,198]. It was assumed that the adult retina lacks the extrinsic cues that are present during development to aid donor cell integration [199]. The inability of neural precursors to differentiate into photoreceptors suggested that a more appropriate cell source for transplantation might be neural RPCs. These cells, which are from the developing embryonic retina, are native to the retinal microenvironment and may generate photoreceptors more readily [196,200]. Morphological differentiation and integration have been observed with transplanted RPCs into the retina of adult pigs [201]. The Ali Lab demonstrated the integration of functional photoreceptors into the retina of adult mice, but only when the donor cells were postmitotic photoreceptor precursors [195,202]. These transplants showed functional synaptic activity and the ability to recover light response when transplanted into *rho*$^{-/-}$ mice, a model of selective photoreceptor loss, and *Gnat*$^{-/-}$ mice, a model lacking rod function. These studies suggest that the ontogenetic stage of the transplanted cell is likely crucial for successful integration into the outer nuclear layer of the retina and association with other photoreceptors. Interestingly, transplantation of more mature photoreceptors resulted in higher cell survival than immature RPC progeny [94,202,203]. An unexpected phenomenon, in which transplanted photoreceptors exchange intracellular material, such as green fluorescent protein, with host cells has been reported. This results in false-positive results when quantifying cell integration. This important finding may necessitate a reinterpretation of the mechanism of transplant-mediated functional recovery [204–206].

Efforts using pluripotent cell sources have focused on deriving a purified cell population for transplantation. Various protocols have been developed for enriching the proportion of ESCs that differentiate along a retinal lineage [207–209]. These cells show the ability to integrate into models of retinal degeneration [208,210] and restore some visual function in models of photoreceptor dystrophism [207]. However, the absence of a method to purify these populations means a mixed population of differentiated cells is transplanted [63]. A major challenge is in vitro amplification of adult stem cell populations to yield sufficient cell numbers for clinical utility [211]. van der Kooy reported isolation of adult retinal stem cells (RSCs) from both the mouse eye [27] and human eye [28]. These multipotent cells can differentiate to all retinal cell types and are able to survive, migrate, and integrate into the developing neural retina. A major limitation of these cells is that photoreceptors make up only a small proportion (<10%) of differentiated cells in vitro. Stable transfection of genes known to be important in determining photoreceptor fate has greatly increased the number of photoreceptors obtained under differentiation conditions and shown integration of functional photoreceptors after transplantation into developing retina [212]. In addition, the use of exogenous factors for directing the differentiation of RSCs toward rod photoreceptor fate has allowed pure populations of donor photoreceptors to be generated for transplantation without the need for gene transfection [213]. Although progress has been made in generating and transplanting stem cell-derived rod photoreceptors, little has been achieved to address cone photoreceptor loss. Given the importance of cone photoreceptors for light vision, this is an area of active research. The Wallace group has reported a protocol for cone enrichment and demonstrated that transplantation into the retina results in integration and morphological maturation of the cones [214].

Used as a transplant model, the developing mouse host eye is permissive to donor cell integration but the adult retina presents unique challenges for integration. Cell death, leakage, and migration from the transplantation site occur when cells are delivered as a suspension in saline [196]. To overcome these barriers in the adult, interdisciplinary studies including the combination of regular tissue culture with tissue engineering are being pursued. For example, retinal progenitors isolated during development are grown and transplanted on solid biomaterial scaffolds [215–217]. Although these reports are an important advancement, the scaffolds employed do not match the modulus of the retina and may lack the flexibility required for subretinal delivery [217]. More recent advances for RPE delivery include the synthesis of synthetic membranes that more closely match the physical properties of the inner collagenous layer of Bruch membrane, the location of the native RPE [218,219]. These membranes improved the survival of human RPE in the rabbit retina after transplantation [220]. Materials such as synthetic polymers and collagen have been explored for this application with successes in animal models of AMD [220,221]. An alternative to implantable scaffolds is injectable vehicles such as an in situ gelling, bioresorbable hydrogel-based cell delivery vehicle for transplanting the adult RSCs into the subretinal space of adult mice [94,222]. This hydrogel allowed for normal RSC survival and proliferation and for greater continuous integration of RSCs into the RPE versus saline vehicle controls [94]. Hyaluronan-based hydrogel scaffolds were also shown to promote the survival of primary photoreceptors in vitro [223]. This cell delivery strategy may be useful for treating advanced maculopathy, in which large areas of RPE are destroyed [215]. These advances in solid and injectable scaffolds bring a new dimension to the treatment of retinal disease in which the scaffold itself can provide a prosurvival and prointegration environment for transplanted cells based on its composition. Translation to the clinic will depend on further increasing cell survival and host tissue integration to restore visual function.

CONCLUSIONS AND OUTLOOK

Regenerative therapy in the treatment of CNS injury is at the forefront of techniques that address the source of functional deficits. Important advances have been made in many disorders including stroke, SCI, and retinal degeneration. The combination of drug delivery, cell delivery, and biomaterials scaffolds is a promising approach to create a permissive environment populated with cells primed for regeneration. For this reason, future efforts will continue to see a merging of strategies of cells and biological factors with biomaterials-based scaffolds important for cell survival and integration, two key limitations of cell transplantation today. Continued innovation is required in the field of scaffold design to provide the optimal microenvironment for cell survival, differentiation, and integration. The biochemical and mechanical properties of the scaffold, in addition to cell−cell interactions, are active areas of research in biomimetic scaffold design.

Cell delivery requires determining the optimum population for transplantation that produces significant integration with existing neuronal circuitry and functional recovery. Optogenetics, a tool that allows for the precise control of the action potential of a transplanted neuron using light, can elucidate the mechanisms behind functional recovery after cell transplantation. Controlling the firing of transplanted cells after delivery and integration into tissue may provide direct evidence of whether cells are truly integrating into the host circuitry or relying on the secretion of factors, and which mechanism is more important for functional recovery [224,225].

For endogenous stem cell stimulation, advances in drug delivery technology will allow temporal and spatial control of released factors; yet, more work is needed to determine which factors to release and when. Moreover, for local release, new delivery strategies will be required that are minimally invasive and ensure diffusion through CNS tissue, thus encouraging local stimulation of stem cells. Because many cells have common receptors, uniquely stimulating the endogenous stem cells among other resident cells in a tissue may be difficult. The complexity of the CNS and its numerous protective barriers has made the intricacies of its function difficult to understand and repair. Notwithstanding these challenges, the promise of regenerative medicine in the CNS can build on successes in other tissues and advance treatments to the clinic.

Peripheral Nerve Regeneration

Mahesh C. Dodla, Melissa Alvarado-Velez, Vivek J. Mukhatyar, Ravi V. Bellamkonda

Duke University, Durham, NC, United States

PROBLEMS AND CHALLENGES WITH PERIPHERAL NERVE INJURIES

Injuries to the peripheral nervous system (PNS) occur frequently and are a major source of disabilities. PNS injuries impair the ability to move muscles, feel normal sensations, and can lead to painful neuropathies. PNS injuries are classified as being traumatic, nontraumatic, or surgical in nature. Traumatic nerve injuries result from collisions, motor vehicle accidents, gunshot wounds, fractures, lacerations, or other forms of penetrating trauma. Each year around 360,000 patients experienced traumatic peripheral nerve injuries in the United States. Only 15% of the patients had PNS injuries that could be treated, and around 50% of them showed no measurable signs of recovery or had drastically reduced muscle strength. Nontraumatic peripheral nerve injuries are mostly attributed to nerve compression and adhesion. It is estimated that approximately 400,000 repair procedures are performed in the United States each year to correct carpal tunnel syndrome, a nontraumatic nerve injury [1]. Although treatments for nontraumatic nerve injuries have higher efficacy than do traumatic nerve injuries, patients still face pain, loss of muscle strength, and reduced dexterity for several weeks to months. Surgical nerve injuries result from medical procedures such as prostatectomy. Prostatectomy procedures most often require sacrificing one or both cavernosal nerves, which adversely affects erectile function and bladder control. In this chapter, we review several techniques used to repair peripheral nerve injuries and discuss current limitations that need to be overcome in order to enhance functional recovery after nerve injury.

HISTORICAL BACKGROUND

The simplest technique for nerve repair in the case of nerve transection injuries is coaptation of the two ends of the nerve using sutures or fibrin glue. However, in many cases there might be a loss of nerve segment owing to injury or there might be a time lag between the injury and surgical repair during which the nerve ends might retract, resulting in a nerve gap. In such cases, end-to-end nerve suturing cannot be done without creating tension in the nerve segment, resulting in a poor regeneration outcome [2]. To overcome this problem, the two nerve ends are approximated using grafts, such as nerve autografts or allografts, muscle grafts, vein grafts, muscle–vein grafts, and synthetic nerve guidance conduits or nerve guidance channels (NGCs).

Historically, during the 19th and early 20th centuries, various materials were used to promote nerve repair, such as bone, metal tubes, blood vessels, and fat sheaths [3–6]. The use of autologous nerve grafts was also first reported during this time [7]. However, because of improper surgical techniques, anatomical repair rarely led to an appreciable return of function. During World War II, surges in numbers of nerve injuries led to advances in microsurgical techniques and instrumentation. Further refinements in microsurgical techniques and drug therapies have had beneficial effects [8]. Significant advances in surgical techniques have since been achieved and biological factors rather than surgical techniques limit improvements in nerve regeneration. Further advances may come from a greater understanding of the molecular mechanisms of nerve regeneration. Advances in multiple areas such as

nerve cell culture, biomaterials design, and genetic techniques may lead us to develop NGCs that can successfully repair injured nerves.

CURRENT STRATEGIES FOR PERIPHERAL NERVE REGENERATION

Nerve autografts are considered the reference standard for bridging nerve gaps in the PNS [9]. Autologous tissue grafts possess several advantages such as low immunogenicity and a structural support that promotes cell adhesion and migration [10]. However, there are several disadvantages to this technique. Obtaining a natural graft could lead to loss of function and potential neuroma formation at the donor site, multiple small grafts may be needed in case of a long nerve gap, and there could be a size mismatch between the donor nerve graft and the injured nerve. More important, complete functional recovery is seldom obtained with autografts [11]. Therefore, there is interest in developing treatments and biomaterials that match or exceed the functional performance of autografts.

Natural or synthetic scaffolds, known as NGCs, for peripheral nerve regeneration consist of a tubular structure that serves as a "guidance channel" to direct nerve regeneration from the proximal to the distal end. In addition, scaffolds contain multiple properties or elements inside the tubular structure that promote and guide nerve regeneration, reduce scar tissue formation, and reduce inflammation, among others. In general, scaffolds for nerve repair should support axonal proliferation, have low antigenicity, support vascularization, be porous for oxygen diffusion, and avoid long-term compression. The use of NGCs reduces tension at the suture line, protects regenerating axons from the infiltrating scar tissue, and directs the sprouting axons toward their distal targets. The luminal space of NGCs can be filled with growth-promoting matrix, growth factors, and/or appropriate cells. In some cases of nerve repair, NGCs have been used to leave a small gap intentionally between the injured nerve ends to allow the accumulation of cytokines, growth factors, and cells [12]. Also, the NGCs can be used as an excellent experimental tool to control the distance precisely between the nerve stumps, test the fluid and tissue entering the channel, and vary the properties of the channel. Overall, NGCs can be thought of as having four central components that contribute to peripheral nerve regeneration: (1) scaffold/substrate, (2) growth factors, (3) extracellular matrix (ECM) molecules, and (4) cells. A nerve graft may have a combination of these components or all four of them. In this analytical framework, the presence of these components and their spatiotemporal distribution determine the efficacy of the graft (Fig. 69.1). In this chapter, the grafts are classified as isotropic or anisotropic based on the distribution of these four central components. In isotropic grafts, the components are distributed uniformly within the graft with no directional cues. In anisotropic grafts, one or more of these components is distributed nonuniformly to create a gradient that may provide a directional cue, usually to direct the axonal growth toward the distal target.

ISOTROPIC SCAFFOLDS FOR NERVE REGENERATION

Natural Scaffolds

Isotropic natural materials used as scaffolds include veins, skeletal muscle fibers, and collagen. Although these materials support nerve regeneration, they do not provide directional cues to the axons. Autologous vein grafts have been shown to provide a good environment for axonal regeneration in short nerve gaps [13,14]. However, the use of vein grafts for long nerve gaps has been less successful because of the collapse of veins caused by their thin walls and constriction owing to the surrounding scar tissue [15]. To prevent vein grafts from collapsing and improve their performance, intraluminal space fillers such as autologous Schwann cells (SCs), collagen, and muscle fibers have been used. Collagen-filled vein grafts were found to promote better axonal growth than empty vein grafts for a 15-mm nerve gap in rabbits [16,17]. Similarly, SC-seeded venous grafts supported axonal growth and performed better than did unseeded grafts to repair 40- and 60-mm nerve gaps in rabbits [18,19]. The principal drawback of this approach is that it requires the availability of the relevant amount of live autologous SCs (up to 8 million cells/mL), which are difficult to obtain. Muscle–vein combined grafts, in which the muscle fibers are inserted in veins, were used in 10-mm-long nerve gaps in rats and were found to promote axonal regeneration comparable to that of syngeneic nerve grafts [20]. Although the muscle–vein grafts were able to promote nerve regeneration in 55-mm-long nerve defects in rabbits, they were not comparable to nerve autografts [20]. Autologous muscle–vein combined grafts have been used clinically in humans to bridge nerve gaps ranging from 5 to 60 mm. The results were scored as "poor," "satisfactory," "good," and "very good," based on the recovery of sensory and motor functions. Of the 21 lesions repaired (in 20 patients), 10 were of the sensory nerves and 11 were mixed nerve lesions. All lesions in

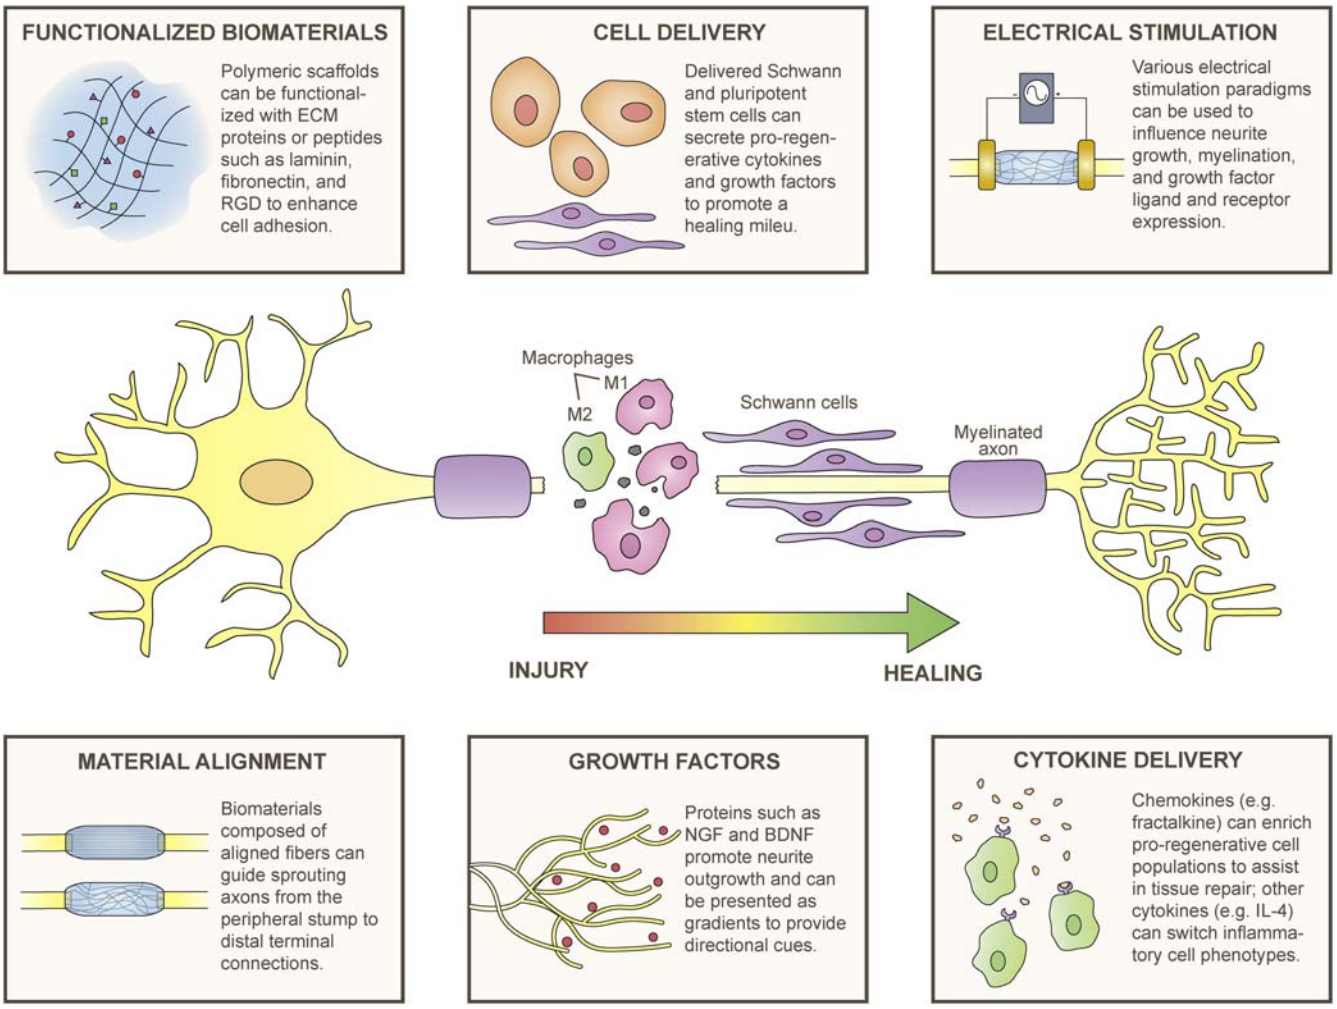

FIGURE 69.1 **Strategies for peripheral nerve regeneration.** Research in this field has encompassed multiple strategies, each targeting a unique aspect of the healing process after nerve injury. Future iterations in the design of scaffolds could combine these strategies and possibly evoke a synergistic response in nerve repair and regeneration. *BDNF*, brain-derived neurotrophic factor; *ECM*, extracellular matrix; *IL-4*, interleukin 4; *M*, macrophage; *NGF*, nerve growth factor; *RGD*, Arg-Gly-Asp. *Image courtesy of Dr. Syed Faaiz Enam, Duke University.*

the sensory nerves except one greater than 30 mm showed "good" to "very good" recovery. All lesions in the mixed nerves showed "satisfactory" to "good" recovery of motor and sensory functions [21]. Although autogenous/natural materials have shown encouraging results when used for nerve repair, they have certain drawbacks. In the case of autogenous grafts, drawbacks include the need for a second surgery, loss of function at the donor site, and neuropathic pain at the donor site. Allografts have problems related to preservation and immune rejection. To circumvent these problems, researchers have developed artificial or synthetic scaffolds for peripheral nerve.

Synthetic Scaffolds for Nerve Repair

Unlike natural scaffolds, synthetic scaffolds can be tailored to augment nerve regeneration in terms of their mechanical, chemical, and structural properties (Fig. 69.1). Nerve regeneration in silicone NGCs has been studied in detail [22]. Within a few hours of nerve repair using an NGC, the tube fills with serum exuded by the cut blood vessels in the nerve ends. This fluid contains neurotrophic factors as well as several cytokines and inflammatory cells such as macrophages. The macrophages remove the myelin and axonal debris formed as a result of injury. The fluid also contains the clot-forming protein fibrin. Within days, the fibrin coalesces and forms a longitudinally oriented fibrin cable bridging the two nerve ends. Without the formation of the fibrin cable, axonal regeneration cannot occur, which makes the fibrin cable formation a critical step. The fibrin cable is then invaded by cells migrating from the proximal and distal nerve stumps, including fibroblasts, macrophages, SCs, and endothelial cells (which form

capillaries and larger vessels). Axons from the proximal end grow into the fibrin matrix and are engulfed in the cytoplasm of SCs. Some of these axons then reach the distal nerve end and become myelinated. In inert silicone tubes of 10 mm or shorter, these processes occur spontaneously. However, it is generally accepted that impermeable, inert NGCs such as silicone do not support regeneration across defects larger than 10 mm without the presence of exogenous growth factors. The regeneration process can be improved by various approaches such as changing properties of the tube (permeability, porosity, texture, and electric charge characteristics) adding matrices, neurotrophic factors, ECM molecules, and cells [23]. These strategies augment nerve regeneration by affecting the sequence of events that lead to bridging of the nerve gap.

Synthetic NGCs can be classified as impermeable, semipermeable, and resorbable based on the porosity and/or degradability of the material used. Silicone tubes are an example of an impermeable NGC because they do not permit the movement of molecules across tube walls. Porosity affects the movement of soluble factors, oxygen, and waste products into and out of the NGCs, which is vital for nerve regeneration. Examples of semipermeable tubes are polysulfone and polyacrylonitrile/polyvinylchloride (PAN/PVC). Nerves regenerated in semipermeable tubes featured more myelinated axons and less connective tissue [24,25]. PAN/PVC channels with a molecular weight cutoff of 50 kDa support regeneration even in the absence of a distal nerve stump [24]. Examples of bioresorbable tubes are polylactic acid (PLA), polyglycolic acid (PGA), poly(L-lactide-*co*-glycolide) (PLGA), poly(lactide-*co*-caprolactone), and poly(3-hydroxybutyrate). The use of bioresorbable tubes negates the need for a second surgery to remove the implant and prevents long-term compression of the nerve. However, it is critical that degradation of the tube not allow fibroblasts to invade the lumen space before regeneration occurs, because this may prevent axons from regenerating.

Hydrogel Scaffolds for Nerve Repair

NGCs can be filled with gels to support axonal elongation. Here we briefly describe some of the isotropic gels used for nerve regeneration. Agarose is a polysaccharide derived from red agar and is widely used in gel electrophoresis and gel chromatography. SeaPrep agarose hydrogel has been shown to support neurite extension from a variety of neurons in a nonimmunogenic manner [26–28]. Agarose gels also allow molecules to be covalently linked to the gels through functional groups on their polysaccharide chains. For example, laminin protein or fragments of laminin can be covalently coupled to SeaPrep agarose gels to enhance their ability to support neurite extension [29]. Although agarose gels support neurite growth on their own, the coupling of molecules such as laminin significantly enhances the gels' ability to promote neurite extension.

Collagen is another gel commonly used to promote PNS regeneration. Collagen can be used to fill the intraluminal space of a vein graft to prevent it from collapsing and improve its nerve repair efficiency. In collagen-filled vein grafts, the number and diameter of myelinated axons were significantly increased compared with vein grafts without collagen gel [16,17]. Nerve repair with silicone tubes has also been significantly improved by filling them with collagen gel. Additionally, Collagen tubes filled with collagen gel have promoted more rapid nerve sprouting and better morphology than saline-filled collagen tubes [30]. However, in some cases, collagen gels have hindered regeneration [31]. This negative effect, which presumably results from gel remnants blocking diffusion and axonal elongation, might be overcome by reducing the concentration of the collagen gel [32].

Hyaluronic acid, an ECM component, is associated with decreased scarring and improved fibrin matrix formation. It is hypothesized that during the fibrin matrix phase of regeneration hyaluronic acid organizes the ECM into a hydrated open lattice, thereby facilitating migration of the regenerated axons [33]. Hyaluronan-based tubular conduits, which are used for peripheral nerve regeneration, resulted in more myelinated axons and higher nerve conduction velocities than silicone tubes filled with saline with little cytotoxicity upon degradation [34,35]. Other gels used in vivo to promote nerve regeneration include Matrigel, alginate gels, fibrin gels, and heparin sulfate gels (Tables 69.1 and 69.2) [36–38].

Extracellular Matrix Molecules for Nerve Regeneration

Insoluble ECM molecules such as laminin, fibronectin, and forms of collagen promote axonal extension, and thus are excellent candidates for incorporation into the lumen of NGCs. Agarose gels cross-linked with laminin showed enhanced neurite extension from chick dorsal root ganglia (DRG) in vitro [29]. Agarose gels cross-linked with laminin and soluble nerve growth factor (NGF) showed nerve regeneration comparable to autografts over a 10-mm gap in rats [39]. However, axonal extension in the laminin gels depends on concentrations of laminin, and high

TABLE 69.1 Classification of Nerve Grafts: Examples and References

1. Isotropic grafts: have uniform distribution of one or more of the four components

concentrations of laminin hinder regeneration [32]. Matrigel (a gel containing collagen type IV, laminin, and glycosaminoglycans) supports some degree of regeneration over a long nerve gap in rats when introduced into the lumen of NGCs [37]. Similarly, a gel mixture containing laminin, collagen, and fibronectin significantly improved nerve regeneration compared with saline-filled silicone channels [40]. Another approach to incorporating ECM signals into nerve conduits is the use of the RGD peptide, which is an amino acid sequence found in multiple ECM proteins [41]. Various research groups found that attachment of Arg-Gly-Asp (RGD) to collagen or poly([lactic acid]-*co*-[(glycolic acid)-alt-(L-lysine)]) conduits improved peripheral nerve regeneration [41,42]. Therefore, peptides and proteins that facilitate cell adhesion and migration within the scaffolds have an important role in cell−scaffold interactions and could be used to enhance nerve regeneration.

Neurotrophic Factors and Cytokine Delivery for Nerve Regeneration

Neurotrophic factors are produced in the target organs and by SCs in response to injury. These neurotrophic factors maintain the target organ−nerve synapse. A nerve injury usually results in disruption of communication between the target organs and the neuronal cell body and leads to Wallerian degeneration (the breakdown of myelin sheath and axons). The cytokines released during Wallerian degeneration activate SCs that produce neurotrophins such as NGF

and brain-derived neurotrophic factor (BDNF). Studies have shown that NGF production in target organs of sensory and sympathetic nerves in the PNS promote the survival of sensory ganglia and nerves, including spinal sensory nerves and sciatic nerves [43,44]. Also, it has been shown that BDNF expression is upregulated in injured peripheral nerves that promote the survival and outgrowth of sensory and sympathetic nerves as well as motor nerves [45]. Many other trophic factors, including insulin-like growth factor, fibroblast growth factor, and ciliary neurotrophic factor (CNTF), have been shown to be involved in the promotion of nerve regeneration [46,47].

Neurotrophic factors are likely an important part of future clinical therapies for peripheral nerve injuries and diseases. In diseases in which the functions of SCs are severely suppressed (multiple sclerosis, for example) or when acellular grafts (containing no viable SCs) are used, application of neurotrophic factors could be highly effective in facilitating nerve regeneration. Various studies have developed scaffolds for the sustained delivery of neurotrophic factors to enhance nerve regeneration. Hubble and Sakiyama-Elbert developed a fibrin matrix that immobilizes heparin molecules by electrostatic interactions, which in turn immobilizes heparin-binding growth factors. When implanted in vivo, the fibrin matrix releases the bound growth factor as a result of fibrin degradation [48]. This system was used to deliver NGF for peripheral nerve regeneration in vivo and basic fibroblast growth factor (bFGF) for neurite extension from chick DRG in vitro [45,48]. Fibrin−heparin−NGF matrix was observed to promote nerve regeneration comparable to syngeneic nerve grafts over a 13-mm nerve gap in rats. Fibrin matrix that released bFGF in vitro enhanced neurite extension from DRG by 100% compared with unmodified fibrin matrix. The use of PLGA microparticles for drug delivery has also facilitated the sustained delivery of neurotrophic factors such as glial cell line−derived neurotrophic factor (GDNF) and other cytokines such as erythropoietin (EPO) [49,50]. In a rat common peroneal nerve defect, sustained delivery of GDNF for 2 and 4 weeks using PLGA microparticles increased the axon counts and promoted larger fiber diameters comparable to autograft [49]. Another group found that delivering EPO using PLGA microparticles enhanced the functional recovery of a rat sciatic nerve defect by increasing the motor nerve conduction velocities [50]. Successful recovery using fibrin−heparin matrices and PLGA microparticles shows the importance of the temporal and spatial controlled delivery of neurotrophic factors and cytokines or nerve repair. Future research in this field may focus on developing biomaterials for the sequential delivery of neurotrophic factor and cytokines after peripheral nerve injury.

In addition to neurotrophic factors, other cytokines can be delivered to modulate aspects of the regenerative process after peripheral nerve injury. Scientists have focused on the effect of inflammatory and immune responses in the healing mechanisms of multiple tissues. In the context of peripheral nerve injury, scientists have found that macrophage polarization has an important role in nerve regeneration [51]. Macrophages can be classified across a spectrum in which the two ends represent inflammatory (M1) and antiinflammatory macrophages (M2). It is believed that macrophage phenotype, M1 or M2, could influence SC infiltration within the NGC and affect the healing process. The delivery of interleukin-4, a cytokine that switches macrophage population toward an M2 phenotype, from agarose scaffolds resulted in an increase in SC infiltration within the scaffolds and faster axonal growth in the rat sciatic nerve gap [51]. Another approach to creating an antiinflammatory environment within the injury site is the selective recruitment of M2 macrophages. M2 macrophages express high levels of fractalkine (CX3CR1); therefore, the delivery of CX3CL1 can be used for their selective recruitment. It has been shown that CX3CR1 delivery increased the infiltration of M2 macrophages and the number of regenerated axons at the distal end of the scaffold [52]. These results suggest that modulating inflammatory or immune responses may be a successful strategy to enhance NGC performance and promote successful nerve regeneration.

Seeding Neuronal Support Cells for Nerve Regeneration

In the PNS, SCs are support cells that wrap around the axons. SCs form a multilamellar sheath of myelin, a phospholipid-containing substance, around axons that serve as an insulator and increase nerve conduction velocity. In NGCs used for nerve regeneration, the formation of a fibrin cable, migration of SCs, and longitudinal arrangement of SCs (known as bands of Büngner) are necessary processes for axonal regeneration. For nerve gaps less than a critical length (10 mm), these processes occur spontaneously, leading to axonal regeneration. However, for nerve gaps greater than 10 mm, spontaneous nerve regeneration does not occur, because a fibrin cable and bands of Büngner fail to form [9]. SCs of uninjured nerves are quiescent. After nerve axotomy, the SCs become “reactive” and produce a number of neurotrophic factors, including NGF, BDNF, and CNTF [44,53]. They also synthesize and secrete ECM molecules such as laminin, which is known to modulate neurite outgrowth and express a variety of other cell adhesion molecules. All of these components have been suggested to have roles in supporting neuronal survival and axonal regeneration.

Using SCs in NGCs bypasses the fibrin cable formation step, accelerates the formation of bands of Büngner, and introduces a persistent source of neurotrophic factors, leading to more efficient nerve repair. This could decrease the time required by the axons to reconnect to the target organ and may increase the distance over which regeneration occurs. SCs isolated from the peripheral nerve of a patient and expanded in vitro could be used to treat the patient's nerve injuries. The addition of SCs has been shown to improve the performance of various scaffolds significantly, such as empty NGCs, collagen gels, venous nerve grafts, and muscle grafts, compared with control scaffolds without SC [18,54,55]. The ability of SC-seeded NGCs to promote regeneration was found to depend on the SCs' seeding density and immunocompatibility between donors and host [56]. For syngeneic SCs, it was observed that increasing the seeding density improves the nerve regeneration outcome. Heterologous SCs elicited a strong immune reaction, impeding nerve regeneration [56]. The performance of SC-seeded NGCs was further improved by designing longitudinally aligned channels in the tube to resemble acellular nerve grafts (see discussion on anisotropic scaffolds).

As an alternative to SCs, other cells could be used, as such or genetically modified, to produce desired levels of neurotrophic factors or to express specific ECM molecules. Fibroblasts, genetically modified to produce NGF, BDNF, neurotrophin-3 (NT-3), and bFGF, showed promising results in central nervous system (CNS) regeneration [57]. Olfactory ensheathing cells have been shown to promote the regeneration of cut nerves in the adult rat spinal cord [58]. Although these are examples of CNS regeneration, these genetically modified cells can be used for PNS regeneration as well. The addition of bone marrow stromal cells to NGCs has shown improved peripheral nerve regeneration over empty NGCs [16,17]. Similarly, pluripotent stem cells derived from hair follicles have shown improvements in rats [59]. However, the difficulties of isolating and culturing these cells from the patient before surgery could limit this approach for some surgical procedures.

Electroconductive Scaffolds for Nerve Regeneration

Electrical stimulation is another technique that has been used to promote nerve regeneration. Previous work showed that electrical stimulation of the soleus nerve of rabbits after a crush injury promoted twitch force, tetanic tension, and muscle action potential in soleus muscle, indicating enhanced nerve growth [60]. To elucidate how electrical stimulation accelerated nerve growth, various groups evaluated its effects on growth factors expression as well as other cellular responses. Electrical stimulation increased the expression of BDNF and tropomyosin receptor kinase B receptors on regenerating motor neurons [61]. Another group observed increased neurotrophin expression after electrical stimulation following nerve repair using a nerve allograft [62]. In addition to an increase in growth factor expression, it was found that stimulating motor neurons at 20 Hz for 1 h accelerated the sprouting of axons after nerve injury [61,63]. These results have motivated research groups to develop electroconductive scaffolds that create an electrical environment within large nerve gaps [64].

Electroconductive scaffolds can improve peripheral nerve injuries significantly. Polypyrrole (PPY) is an electroconductive polymer that has shown great potential as a nerve scaffold owing to its cell compatibility [65]. Various research groups have shown that scaffolds containing PPY increase the percentage of neurite-bearing cells and median neurite length [65,66]. Scaffolds made of PPY and poly(D,L-lactic acid) were able to repair a rat sciatic nerve injury in a way similar to autologous graft [65]. Another study found that conductive PPY—chitosan improved not only axonal regeneration but also remyelination. The researchers also found an improvement in the animals' motor and sensory functions [64]. The mechanism by which electrical stimulation enhances peripheral nerve regeneration still needs to be fully elucidated. However, future strategies could combine electrical stimulation with other scaffold components discussed throughout this chapter to accelerate successful nerve repair after a peripheral nerve injury.

ANISOTROPIC SCAFFOLDS FOR NERVE REGENERATION

The four essential elements of nerve scaffolds, neurotrophic factors, ECM molecules, and cells can be presented in an aligned fashion so as to orient the regenerating axons toward their distal targets. Several anisotropic scaffolds have been fabricated to affect neuronal behavior. Neuronal as well as glial cells respond to the underlying topographical cues in a particular manner. Distinct cellular processes, including migration, polarization, and gene expression, have been shown to be affected by the isotropy of tissue engineered scaffolds [67]. Although the exact mechanisms of how topographical cues affect cell behavior have yet to be elucidated, they have been hypothesized to affect protein attachment, orient cell cytoskeleton, and affect downstream gene regulation [68,69]. In this section, studies involving nerve grafts that provide directional guidance are discussed.

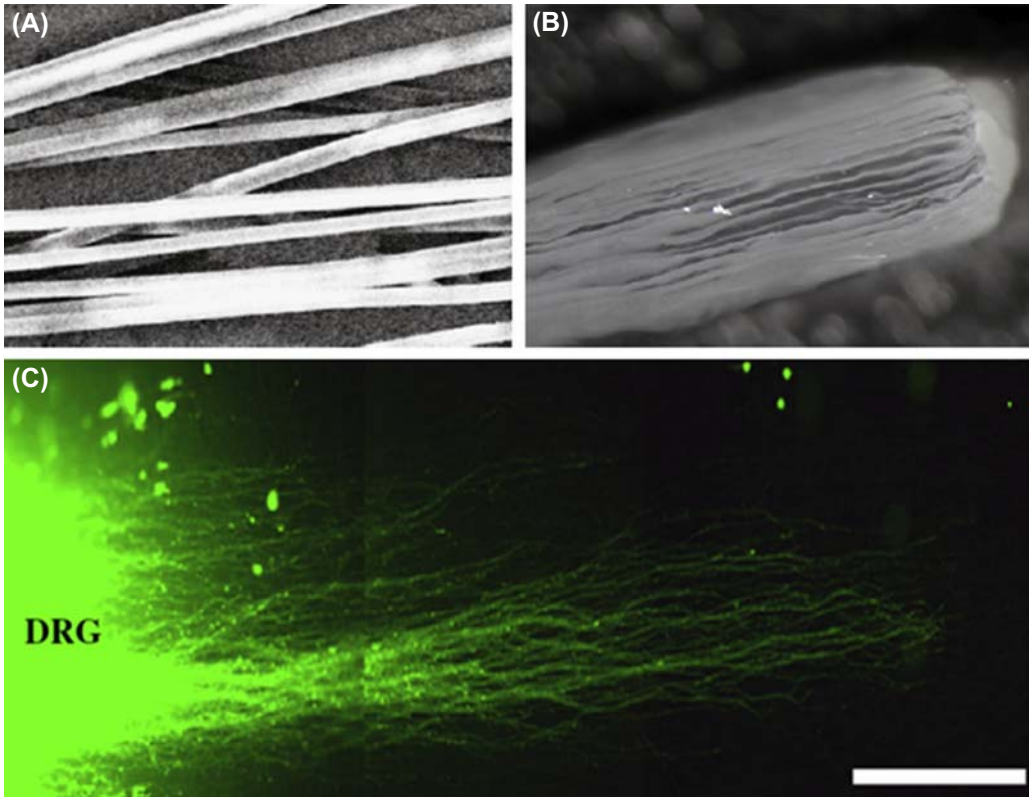

FIGURE 69.2 **Nanofilaments for contact guidance-mediated growth.** (A) Scanning electron microcopy image of PAN-MA nanofilaments with a diameter of 400–700 nm. (B) Three-dimensional nanofilament-based scaffold, along with agarose gel, embedded in a polysulfone nerve guidance channel can be used to direct neurite growth in vitro or axonal growth in vivo. (C) Chick dorsal root ganglia (DRG) extending neurites along horizontally oriented PAN-MA filaments, in vitro (scale bar = ¼ 1 mm. *PAN-MA*, poly(acrylonitrile-*co*-methylacrylate). *Images courtesy of Dr. Young-tae Kim, Georgia Institute of Technology.*

Aligned Anisotropic Scaffolds

We hypothesize that the superior performance of autologous nerve grafts is the result of its cellular components and its longitudinally aligned structure. The longitudinally aligned structure of the degenerating nerves in the autografts provides contact guidance and direction to the regenerating nerves. In an attempt to mimic autografts, longitudinally patterned or oriented gels and filaments to guide and accelerate the regenerating axons have been designed (Fig. 69.2). It has been shown that a poly(acrylonitrile-*co*-methylacrylate) nanofilament-based scaffold alone can facilitate regeneration across a 17-mm nerve gap in rats [70]. Many other combinations of materials have been used, such as collagen filaments embedded in collagen tubes, laminin-coated collagen fibers in collagen tubes, laminin-fibronectin double-coated collagen fibers in collagen tubes, poly(L-lactide) filaments in silicone tubes and PLA tubes, and PGA fibers in chitosan tubes [71–75]. All have been found to improve regeneration significantly compared with saline-filled tubes. In addition to synthetic filaments, magnetically aligned fibrin and collagen type I gels have been used to provide directional guidance to neurites in vitro and axons in vivo [36,76,77].

Neurotrophic Factors

Neurotrophic factors have been delivered mostly in an isotropic manner in vivo. However, in vitro studies suggested that gradients of neurotrophic factors can direct growth cones toward the source of neurotrophic factor [78]. Insoluble and soluble gradients of NGF, NT-3, and BDNF have been shown to direct the growth of neurites from PC12 cells toward increasing concentrations of neurotrophic factors [79,80]. In vivo, poly(ε-caprolactone-co-lactide) (PCLA) scaffolds with NGF gradients have been shown to improve nerve regeneration significantly better than isotropic NGF scaffolds [81]. Therefore, anisotropic scaffolds with gradients of neurotrophic factors, along with other components, might be an important tool for PNS regeneration.

Extracellular Matrix Molecules

Gels containing ECM molecules, such as laminin, collagen, fibronectin, and glycosaminoglycans, have been widely used to make isotropic scaffolds for nerve regeneration. ECM molecules promote axonal growth by the mechanism of differential adhesion, in which axons preferentially grow on substrates of ECM molecules owing to the presence of specific cell surface receptors. In vitro experiments with spatial patterns of whole ECM molecules or their peptide derivates have been used to direct the growth of neurites as well as enhance neurite extension [82,83]. Studies have demonstrated that gradients of ECM proteins could orient and enhance neurite outgrowth toward increasing concentrations of ECM molecules in vitro [82–85].

In vivo, ECM protein-coated fibers have been used to enhance nerve regeneration, in which the fibers provide contact guidance for regenerating axons and the ECM protein provides the adhesive substrate [71,73]. Also, anisotropic scaffolds created by gradients of laminin coupled to agarose along with sustained delivery of NGF from lipid microtubes matched autograft performance in terms of axonal diameter distribution after a peripheral nerve injury [86,87].

Cell-Seeded, Longitudinally Aligned Nerve Guidance Conduits and Channels

Neuronal-growth supporting cells can be incorporated with longitudinally aligned filaments and gels in NGCs to enhance nerve regeneration. Because support cells synthesize ECM proteins and neurotrophic factors, aligned cells often result in directionally aligned ECM. Biodegradable conduits of a copolymer of lactic and glycolic acids (PLGA) with longitudinally aligned channels have been used for nerve regeneration [88]. With the lumen coated with laminin and seeded with SCs, the channels showed regeneration comparable to nerve autografts over a 7-mm nerve gap in rats. PLA tubes with a micropatterned inner lumen and seeded with SCs, showed better nerve regeneration compared with unpatterned tubes with SCs [89]. However, disadvantages of cell-seeded NGCs include the need for prolonged isolation and cell culture to prepare cells for implantation, a high cell yield, and high cellular morbidity.

NATURAL NERVE GRAFTS

A common source of nerve grafts is the sural nerve, which is easy to obtain, has the appropriate diameter for most grafting needs, and is relatively indispensable. Other graft sources include the anterior branch of the medial antebrachial cutaneous nerve, the lateral femoral cutaneous nerve, and the superficial radial sensory nerve [90]. However, a motor nerve has a preference for a motor pathway (i.e., motor nerve graft) and shows inferior regeneration if a sensory nerve graft such as sural nerve is used. Similarly, a mixed nerve shows superior regeneration with either a mixed nerve or a motor nerve graft compared with a sensory nerve graft [91]. Therefore, clinical outcomes might be improved by using alternatives to sensory nerve grafts in reconstructing a mixed nerve. However, there are relatively few expendable motor or mixed nerves in the human body that could be used as graft materials. Therefore, a more feasible alternative would be to use nerve allografts or biosynthetic graft materials. Cadavers are an abundant source of graft materials and avoid the complications of harvesting autografts. However, cadaveric nerve allografts require maintenance and can be used only with immunosuppressive therapy. Withdrawal of the immunosuppressant leads to profound loss of axons in the allografts. The axonal loss is most profound in mixed nerve allografts compared with motor nerve allografts, followed by sensory nerve allografts [92].

Allografts, cold-preserved and/or freeze-thawed to prevent immune rejection by the host body, perform better than fresh allografts in terms of axon density, fiber diameter, and nerve conduction velocity [93]. Using natural materials (nerve grafts) for regeneration is ideal. However, it has been shown that if autografts or allografts are preserved for too long, their ability to support regeneration supporting is compromised [94]. Also, the pretreated allografts do not perform as well as autografts [93].

Although nerve autografts are used as the reference standard, the lack of functional recovery even with autografts remains an important clinical problem. Techniques employed to improve the performance of the nerve autografts include treatments to either remove the inhibitory molecules, such as chondroitin sulfate proteoglycans (CSPGs), or provide factors for axonal growth, such as NT-4/5 or BDNF. CSPG molecules have a core protein structure with glycosaminoglycan (GAG) side chains composed of chondroitin sulfate. Because of their large size and negative charge, the GAGs of CSPGs are thought to hinder neurite access to growth-promoting matrix molecules and repel the axons, inhibiting their growth [95]. It has been shown that CSPGs are upregulated almost sevenfold in the distal segment of peripheral nerve after transection nerve injury [96]. The upregulated CSPGs contribute significantly to

the inhibition of neurite sprouting and, consequently, growth into the distal nerve segment. Treatment of the injury site with chondroitinase ABC, which digests away the inhibitory CSPGs, increased the neurite ingrowth into the distal nerve segment several-fold compared with controls with no chondroitinase ABC treatment [97]. Treatment with chondroitinase ABC, however, did not improve neurite ingrowth in a crush injury model, which suggests that CSPGs are not upregulated in a crush injury.

Syngenic nerve grafts treated with chondroitinase ABC, heparinase I, heparinase III, or keratanase enzymes have shown significantly improved axonal ingrowth from the proximal nerve end into the nerve graft compared with untreated controls [98]. Autografts treated with a combination of all four enzymes showed the most significant neurite growth into the graft. However, combination treatment was not significantly different from the arithmetic sum of the individual treatments. This suggests that molecules such as heparan sulfate proteoglycan and keratan sulfate proteoglycan also contribute to the inhibition of neurite growth apart from CSPGs, and the pathways or mechanisms of inhibition for each of these molecules might be independent of each other. In another study, the exogenous supply of BDNF and NT-4/5 increased the number of axons regenerating into the nerve graft compared with untreated nerve grafts [99]. These techniques, used in clinical applications, could lead to better results with autografts or allografts.

Acellular grafts have been developed to address the problem of host response to allografts as well as the shortage of autografts. Cadaveric nerves are decellularized while keeping the ECM structure intact in order to promote nerve growth. It has been show that acellular cadaveric nerves from rats are able to bridge a 10-mm nerve injury [100]. In the same study, acellular grafts treated with NGF and vascular endothelial growth factor (VGEF) showed increased axonal diameter and neurovascularization at 1 month. Other studies have also shown that incorporating VGEF and NGF in acellular grafts promoted SC migration, increased the number of axons, and improved neovascularization compared with control [101]. In longer gaps (40 mm in Rhesus monkeys), acellular allogenic grafts seeded with autologous SCs enhanced nerve density and fiber counts [102]. Functionality of acellular grafts depends on the structural integrity of the graft after it has been processed for the removal of cells and immunogenic components. For this reason, several laboratories have developed chemical processing techniques that focus on preserving the integrity of the ECM structure. Studies with optimized acellular grafts created by Schmidt's group suggested that axon density after 84 days depended on graft structure and content [103]. In another study, processed acellular grafts held their laminin structure and promoted better functional results compared with nerve conduits in bridging nerve gaps [104].

ANIMAL MODELS

Traditionally, nerve regeneration studies involved the use of various animal models such as mice, rats, swine, canines, sheep, and nonhuman primates. Rat or mouse models are used initially to determine the efficacy of various treatments. If the results are encouraging, they are followed by experiments with larger animal models. For PNS regeneration studies, the most commonly studied nerve models are the sciatic nerve and its branches, the tibial and peroneal nerves. Other models include the cavernosal and facial nerves. The most common nerve injury model is the single-anastomosis model, in which the injury and repair are performed on one sciatic nerve and the contralateral sciatic nerve is used as a control. This model is useful when the nerve gap is not more than 20 mm. The second version is the cross (double) anastomosis model, in which both contralateral sciatic nerves are transected; the proximal end of the right sciatic nerve is then sutured to one end of an implanted tube and the distal end of the left sciatic nerve is inserted into the other end of the tube [105]. This model allows the study of gaps in excess of 25 mm. Although convenient, the rodent models have a serious drawback in that they present only short nerve gaps for regeneration studies. For a regeneration technique to be applied successfully in clinical trials, the nerve gap model has to be more than 40 mm long. To create a long nerve gap model, rabbits, cats, dogs, sheep, and nonhuman primates have been used [20,38,71,106,107]. The large-animal models are an important intermediary step before clinical application of experimental therapeutic approaches.

CONCLUSION

Despite significant advances in research into the development of synthetic NGCs, nerve autografts are still considered the first-choice strategy for nerve repair, especially in the case of long nerve gaps. However, performance of autografts themselves has been unsatisfactory. Use of autografts usually results in the good recovery of sensory functions but poor return of motor functions. Hence, there will be continued interest in ideas to enhance the

performance of autografts further by various treatments such as chondroitinase ABC, NT-4/5, and BDNF. However, the shortage of autografts and allografts is a major hindrance to their use. This shortage can be overcome by developing synthetic alternatives that can be tailored to enhance nerve growth. Modulating the spatiotemporal distribution of the four components of grafts can potentially improve the potential therapeutic outcomes of synthetic grafts. Ongoing rapid advances in cell biology, cell culture techniques, genetic engineering, and biomaterials research are likely to provide new tools to improve regeneration using synthetic grafts, and the day may be near when an engineered construct performs as well as autografts [1].

Regenerative Medicine for the Female Reproductive System

Renata S. Magalhaes, Anthony Atala

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

Normal embryonic development of the female reproductive system results from the presence of two X chromosomes, the absence of SRY gene expression (sex-determining region on the Y chromosome), and a complex network of gene interactions that determine the differentiation of the bipotential genital ridge into ovaries by 6–8 weeks of gestation [1,2]. In the genital ridge, primordial germ cells proliferate and enter meiosis to become oocytes [3]. Subsequently, internal genital development follows the female pathway in which a pair of Müllerian ducts (alternatively known as paramesonephric ducts) derived from invagination of the coelomic epithelium within the intermediate mesoderm is retained. The Müllerian ducts grow caudomedially to reach the urogenital sinus around the 10th week and its fusion and differentiation forms the fallopian tubes, uterus, cervix, and upper two-thirds of the vagina in the midline pelvis. At birth, the development of reproductive structures proceeds and complete maturation is achieved only at puberty when a cascade of hormone-regulated events results in adult physical characteristic and the capacity to reproduce.

Environmental or genetic factors may compromise organogenesis, resulting in a range of anatomical Müllerian duct malformations classified according to the developmental stage affected (duct formation, fusion, and septal reabsorption), with an estimated prevalence of 0.1–5% of the general female population [4–7]. Severe genital malformation such as Mayer–Rokitansky–Küster–Hauser syndrome (MRKHS) (abnormal or absent uterus, cervix, and upper part of the vagina) occurs in approximately 1 of 4000 newborn girls and can be associated with upper urinary tract and skeletal disorders [8–10].

Congenital and acquired diseases may adversely affect a woman's reproductive potential, leading to social and psychological problems [11–13]. Despite advancements in reproductive medicine and reconstructive surgery over the past decades, there is an increased demand for therapies that have the potential to restore function and/or compensate for the anatomical absence of female genital tissues and organs. Regenerative medicine has emerged as an attractive alternative to overcome limitations of current therapeutic approaches by integrating various technologies that range from tissue engineering to gene editing.

This chapter highlights progress in regenerative medicine and tissue engineering applications in the female reproductive system.

PRINCIPLES OF TISSUE ENGINEERING

Tissue engineering combines cell biology, materials science, biomedical engineering, and an appropriate environment to develop implantable biological substitutes that can restore and maintain normal organ function [14,15]. The development of a bioengineered tissue is a multistep process. As illustrated in Fig. 70.1, the first step is finding a viable immunocompatible cell source for the tissue of interest, preferably autologous, that can be isolated and expanded while maintaining the desired phenotype. When primary or progenitor autologous human cells cannot

be obtained from a particular organ, pluripotent human stem cells may be an alternative source given their potential to differentiate into a specialized cells type. Alternatively, multiples studies have shown that adult stem cells derived from the bone marrow, amniotic fluid, cord blood, or placenta have a great potential for regenerative therapies [16]. The next step in the process involves identifying a biocompatible material (scaffold) that supports cell growth in vitro and facilitates the complex process of tissue regeneration in vivo, withstanding the physiological and mechanical properties demanded by the organ [17]. In select circumstances, biomaterials alone or loaded with growth factors may be sufficient to replace native tissues. The constructs (scaffold plus cells) are usually incubated and/or preconditioned in vitro using a bioreactor system or directly implanted into the patient for in vivo tissue maturation.

THE VAGINA

The vagina is a distensible organ that extends from the vestibule of the vulva to the uterine cervix, which allows for sexual intercourse and serves as a channel for menstrual bleeding and childbirth. The vaginal canal is lined by a mucosa of nonkeratinized stratified squamous epithelium that has an important role as a barrier against harmful pathogens and harbors a dynamic microbiota that is shaped by ovarian hormone changes throughout a woman's lifetime [18]. The muscular layers consist of highly vascularized fibromuscular tissues and a network of nerves that are associated with pleasurable sensation during sexual activity [19].

Acquired vaginal pathologies or congenital anomalies, including MRKHS, cloacal exstrophy, and complete androgen insensitivity syndrome, can adversely affect the vagina's anatomy, resulting in devastating psychosexual issues [20]. Nonsurgical vaginal dilation has been recommended as a first-line therapy but it is time-consuming, distressing, and unfavorable for severe conditions [21]. Another option is vaginal surgical reconstruction, which involves the creation of a canal (neovagina) between the bladder and rectum. A variety of vaginoplasty techniques have been described and a wide range of materials to line the surgically created cavity have been proposed including skin grafts, allogeneic tissue (amniotic membrane and epidermal sheets), peritoneum, artificial grafts, autologous buccal mucosa, and autologous in vitro cultured vaginal tissue [22].

Although no consensus has been established regarding what material should be used for reconstructive surgery, the application of nonvaginal tissue has been associated with complications such as graft rejection, chronic stenosis, and poor mechanical strength. The lack of materials that adequately mimic the vaginal tissue structure has led researchers to apply tissue engineering techniques to fabricate autologous vaginal tissue grafts [23].

Engineering of Functional Vaginal Tissue

Preclinical studies demonstrated the feasibility of engineering functional vaginal tissue using preconfigured scaffolds seeded with autologous vaginal epithelial and smooth muscle cells in a rabbit model [24,25]. We applied a similar strategy on a pilot cohort study to assess the use of autologous cell-engineered vaginal constructs in four patients aged 13–18 years with MRKHS [26]. Primary epithelial and muscle cells were isolated from 1 × 1-cm vulvar biopsies from each patient and expanded separately. Vaginal-shaped scaffolds made of decellularized porcine smallintestinal submucosa (SIS), a matrix rich in collagen and growth factors, were seeded with autologous cells at a density of 1×10^7 cells/cm^2 (for each cell type) and incubated for a week before surgery. The constructs initially measuring 7 × 10 cm were customized for each patient based on their pelvic cavity morphometric analyses. A vaginal reconstruction surgery was carried out for the autologous engineered vaginal construct implantation and a vaginal stent was put in place after surgery and kept for 2 weeks. Subjects were followed up for 8 years, and annual tissue biopsies, serial imaging, and clinical examinations confirmed vaginal tissue-like structures and long-term vaginal cavity patency (Fig. 70.2). In addition, all patients were sexually active and had functional variables for arousal, lubrication, orgasm, satisfaction, and painless intercourse within the normal range.

In another study, Panici et al. [27] reported the creation of an autologous in vitro cultured vaginal tissue for vaginoplasty in a 28-year-old woman with MRKHS. A 1-cm^2, full-thickness mucosal biopsy from the vaginal vestibule was taken and cells were expanded onto collagen IV–coated plates for 2 weeks. When autologous in vitro cultured cells reached 314 cm^2, they were mounted on hyaluronic acid–embedded gauze, maintaining the epithelial cell layer away from the gauze, and used to cover the surface of a surgically created vaginal canal. The gauze was kept in place by a vaginal mold. Thirty days after the procedure, the canal appeared normal in length and depth and a neovagina wall biopsy revealed epithelization resembling native vaginal tissue. The same group

Tissue-engineered autologous vaginal organs in patients: a pilot cohort study. Lancet July 26, 2014;384(9940):329–36. PubMed PMID: 24726478. Epub 2014/04/15. eng, with permission from Elsevier.*

reported a 12-month follow-up study in 23 women with MRKHS who underwent neovaginoplasty using the same approach [28]. At 3 months after surgery, neovaginal biopsies showed vaginal-like tissue, and at 12 months, all patients had satisfactory sexual quality of life.

Although the clinical experience to date is promising and provides a compelling demonstration of safety and feasibility, the technology for creating human functional autologous engineered vaginas is not yet ready for wide application and this procedure is still considered experimental.

THE UTERUS

The uterus is the largest organ of the female reproductive system. It has an inverted pear shape and is anatomically divided into the uterine body or fundus (upper part) connected on each side to the fallopian tubes and the lower segment where the cervix opens into the vaginal cavity. The average dimensions of the normally developed adult uterus are approximately 8 cm long, 5 cm wide (upper part), and 3 cm thick. Its histological elements include the inner layer called endometrium composed of luminal and glandular epithelium surrounded by stroma; the myometrium, consisting of oriented layers of smooth muscle cells; and the perimetrium, the serosa that envelops the organ.

The uterus has complex vascular, contractile, and immune systems that together, in response to cyclic ovarian hormonal cues, support sperm migration, embryo implantation, fetal nourishment throughout gestation, and intense contractions during childbirth [29]. The endometrium undergoes approximately 400 cycles of controlled cellular proliferation, differentiation, angiogenesis, breakdown, and shedding of the basal layer throughout a woman's reproductive life [30]. In addition, a dramatic process of uterine cell differentiation, hypertrophy, and hyperplasia occurs during pregnancy, increasing the uterus weight up to 10 times; and by 4–5 weeks postpartum it returns to nongravid weight [31]. Based on this dynamic tissue remodeling, evidence for the existence of adult progenitor/stem cells in the human uterus has been reported [32,33]. Abnormal endometrial progenitor/stem cell function and disruption of their surrounding niche may be associated with proliferative diseases such as endometriosis and endometrial cancer as well as inappropriate tissue remodeling, which can potentially affect embryo implantation and fetal development [34].

Despite the advancement in minimally invasive surgical procedures, hormonal therapies, and assisted reproductive technologies, congenital and acquired uterine disorders remain a contributor to infertility in approximately 2–8% of woman of reproductive age [12,35].

Gestational surrogacy is an available option to achieve genetic motherhood; however, it involves complex legal issues and is still not approved in many countries [36–38]. Human allogeneic uterus transplantation has been proposed, and it proves to be feasible and successful in terms of pregnancy. However, this approach raises concerns regarding donor shortage and adverse effects of immunosuppression [39,40].

The development of regenerative medicine strategies aims to restore, enhance, and maintain normal uterine function.

Uterine Tissue Regeneration

Initial experiments using synthetic polymer-based grafts to regenerate a section of a rat uterus showed that 6 weeks after implantation, nonabsorbable polytetrafluoroethylene (Teflon) elicits an intense local inflammatory response, leading to severe adhesions, obstruction, and poor tissue ingrowth; whereas endometrium-like tissue ingrowth was observed within biodegradable polyetherurethane/poly-L-lactide grafts, but they failed to provide luminal patency [41].

We investigated the possibility of engineering autologous uterine tissue using a biodegradable synthetic polymer seeded with primary cells [42,43]. Endometrium and myometrium cells were isolated from rabbit uterine horns and expanded in vitro separately. These cells were seeded in a stepwise fashion on the surface and lumen of preconfigured uterine-shape scaffolds formed from polyglycolic acid coated with poly-DL-lactide-*co*-glycolide (PLGA) in chloroform (5% w/v), which were then used to replace a sub-total excised horn (mesometrium was retained) in animals from which the cells derived. Six months after cell-seeded construct implantation, the neouterine tissue showed organized cellular and anatomical structures as well as expression of specific markers for epithelial, stroma, and smooth muscle cells. Breeding studies to assess in vivo functional responses of the engineered uterine tissue are being conducted.

In another study, Campbell et al. [44] used the peritoneal cavity as an in vivo bioreactor to produce an autologous graft. Tubular boiled blood clot templates of 2.5 × 0.5 cm were implanted into the peritoneal cavity of rats. After 2 weeks, the encapsulated myofibroblast-rich tissue resulting from foreign body response was harvested and used to replace approximately one-third of one uterine horn of the host animal. At 12 weeks, the grafted tissue developed organized morphology with luminal and glandular epithelium, and two distinct layers of smooth muscle bundles interspersed with collagen, resembling native tissue. The researchers reported that grafted uterine horns supported embryo implantation and fetal development to the late stages of gestation, with reproductive outcomes comparable to normal controls.

Allogeneic extracellular matrices have also been tested as biological scaffolds alone, cell-seeded scaffolds, or growth factor delivery vehicle. Ansari et al. [45] replaced a segment of the rabbit uterine horn with a specially prepared human umbilical vein. At 6 months after implantation, there was no evidence of host rejection; the luminal surface of the graft showed epithelial reorganization but there was minimal myometrial ingrowth. In another study, Taveau et al. [46] tested the ability of different lengths (0.5−2 cm) of porcine SIS membranes to regenerate a segment of a rabbit uterine horn. Approximately 8 weeks after surgery, histological analysis showed tissue ingrowth of all layers within SIS grafts but disorganized myometrium architecture. The authors examined tissue functionality by naturally mating animals 28 days after the surgical procedure. They reported that the ability to maintain luminal patency and support pregnancy was limited to the size of the grafts. Longer grafts did not provide enough mechanical strength and collapsed.

In another study, bovine skin-derived collagen membranes loaded with collagen-binding human basic fibroblast growth factor (bFGF) were used as scaffolds in a rat model [47]. A section of the uterine horn was removed (approximately 1.5 cm in length and up to two-thirds in circumference) and replaced by 1.5 × 0.5 cm collagen membranes. At 90 days after surgical implantation, the bFGF delivery system enhanced vascularization, improved tissue ingrowth, with luminal and glandular epithelium development and partially organized muscle bundles, and supported pregnancy.

Ding et al. [50] investigated the effects of collagen membranes loaded with donor rat bone marrow−derived mesenchymal stem cells (BM-MSCs) in a murine model of severe uterine injury. They used isolated $CD29^+$, $CD44^+$, $CD90^+$, $CD34^-$, and $CD45^-$ BM-MSCs that displayed multilineage mesodermal differentiation. Collagen scaffolds (1.5 × 0.5 cm) were seeded with labeled BM-MSC suspension (5×10^5 cells/cm^2 scaffold) and incubated for 1−3 h before being engrafted in a partially removed uterine horn. At 4 weeks after surgery, BM-MSCs were mostly located at the basal layer of the remodeled endometrium and the perigraft tissue expressed higher levels of bFGF, insulin-like growth factor-1, vascular endothelial growth factor (VEGF), and transforming growth factor-β1 compared with the collagen membrane-only group. At 90 days, neotissue showed increased blood vessel density and organized endometrium and myometrium structures, and supported embryo implantation and viable offspring with comparable size and weight to those from normal uterine tissue.

The application of decellularization techniques has been explored to create naturally-derived matrices for uterine tissue reconstruction. As an initial step, Santoso et al. [48] described different protocols to decellularize rat uterine tissue patches using sodium dodecyl sulfate (SDS), high hydrostatic pressure (HHP), or Triton-X at optimized conditions; and examined matrices' effects on in vivo uterine tissue regeneration. Histological results indicated efficiency upon cell removal and minimal changes in the overall matrix structure using SDS and HHP protocols whereas at the conditions used, Triton-X severely reduced collagen and elastin content within the matrix. At 30 days after the transplantation of 15 × 5-mm decellularized scaffolds into rat uteri, all uterine tissue layers were observed within the grafts, which were able to support pregnancy in both SDS and HHP groups.

Vascular perfusion technique using Triton X-100, dimethyl sulfoxide, and sodium deoxycholate has also been applied to create whole uterus scaffolds for tissue regeneration [49]. Miyazaki et al. [51] attempted to repopulate a whole rat decellularized uterine matrix injecting 5.1×10^7 neonatal uterine cells, 2.7×10^7 adult uterine cells, and 1.0×10^6 rat BM-MSCs in the uterine wall. After 3 days of incubation in a perfusion system, an endometrium-like tissue formation was observed, although cells were not evenly distributed within the matrix. When recellularized grafts measuring 1.5 × 0.5 cm were implanted in a partially excised rat uterine horn, uterine tissue ingrowth was noticed within the grafts and pregnancy outcomes were reported to be nearly comparable to animals with an intact uterus.

In another study, Hellström et al. [52] isolated and expanded donor primary heterogeneous uterine cells and mixed them with rat green fluorescent protein (GFP)-labeled MSCs to recellularize whole-rat uterus matrices. Patches of 2 × 0.5 cm were seeded through multiple injections of a cell mix (one primary uterine cell per 150

GFP-MSCs) and incubated for 72 h. In vitro analysis of recellularized scaffolds revealed limited cell distribution mainly restricted to the matrices' external surface. Recellularized patches of 5×10 mm were grafted in full-thickness excised uterine horns and animals were mated 6 weeks later. Uterine-like tissue ingrowth was described within the grafts, mainly from host cells (labeled GFP-MSCs could not be found in the transplanted construct), and remodeled uterine horns supported pregnancy and fetal development, although embryo implantation did not occur directly over the patches.

Autologous stem cell therapies targeting endometrial disorders such as severe intrauterine adhesions (Asherman syndrome) have been proposed and ultimately investigated in patients [53–55]. Santamaria et al. [55] conducted a pilot study in 16 women (aged 30–45 years) with refractory Asherman syndrome and endometrial atrophy. Patients received granulocyte–colony-stimulating factor infusion to mobilize BM-MSCs, and then CD 133^{+} cells (endothelial progenitor cell markers) were isolated from the peripheral blood. These freshly isolated cells were delivered (an average of 124.39 million cells) into the spiral arterioles via intrauterine arterial catheterization. After autologous BM-MSC injection, patients received hormonal therapy and endometrium functionality was assessed. The authors reported increased endometrial vascularization and menses intensity and duration in the first 3 months after treatment. Pregnancies were achieved spontaneously and through in vitro fertilization, with two live births of healthy babies at term after cell therapy.

Uterine Cervix Tissue Engineering

The cervix has important mechanical and protective roles during pregnancy and undergoes significant remodeling during parturition. An impaired uterine cervix can result in preterm birth, which is associated with significant perinatal complications. House et al. [56] demonstrated that tissue engineering strategies can be applied to create three-dimensional (3D) cervical-like tissue constructs by seeding human cervical cells on silk sponge scaffolds. Stromal cells were isolated from premenopausal women's cervical canal biopsies, seeded on a collagen-coated porous silk protein scaffold, and cultured under either static or dynamic conditions. After 8 weeks, cervical cells proliferated on a silk-based scaffold and synthesized an extracellular matrix with biochemical constituents and morphology that resembled native tissue. The dynamic culture condition was associated with significantly increased collagen deposition, glycosaminoglycan synthesis, and mechanical stiffness. These results suggest that human tissue engineered cervical-like constructs could be applied as an in vitro system to investigate cervical remodeling.

THE OVARIES

The ovaries lie on each side of the lateral pelvic wall and are connected to the uterus by the fallopian tubes [57]. The ovarian follicle is the functional unit of the ovary and is composed of an oocyte (germ cell) surrounded by layers of somatic follicular cells (granulosa and theca cells) and a basement membrane. At birth, the ovarian cortex contains a pool of primordial follicles formed during embryonic life that determines a finite reproductive life span [58]. Between puberty and menopause, hormonal signals recruit dormant primordial follicles, initiating a highly regulated process called folliculogenesis. Activated follicles increase in size over a period of weeks regulated by both endocrine and intraovarian mechanisms [59]. During folliculogenesis, granulosa cells proliferate and differentiate in several layers around the oocyte, theca cells differentiate into theca interna (androgen-secreting cells) and externa (connective tissue), and a fluid-filled cavity (antrum) is formed. At this stage, follicle growth and development rely on pituitary gonadotropins (follicle-stimulating hormone and luteinizing hormone). Gap junctions are formed between cells, facilitating communication between granulosa cells and the enclosed oocyte, which is essential for the maturation and release of an egg capable of fertilization.

At each reproductive cycle, ovarian follicles synthesize hormones (sex steroids and peptides) and a subset of dominant follicles that reach maturation and ovulation will undergo terminal differentiation and form the corpus luteum, which secretes progesterone, a hormone necessary to maintain pregnancy.

Systemically, ovarian hormones have a fundamental role in preparing the uterus for embryo implantation, mammary gland development, sexual function, skeletal growth, and bone homeostasis [60].

At the onset of menopause, a natural and permanent cessation of ovulation occurs, and the suppression of sex steroid hormones production may lead to vasomotor symptoms, sleep disturbances, urogenital problems, osteoporosis, and sexual dysfunction. Pathological loss of ovarian function may occur due to surgical resection, early

menopause, or ovarian failure in cancer-treated patients, impairing fertility and leading to an increased risk for cardiovascular diseases and osteoporosis.

In the attempt to restore ovarian physiological roles as a gonad and endocrine gland, several approaches applying regenerative medicine principles have been explored.

Tissue Engineered Ovarian Follicles

Human ovarian tissue banking has been proposed as an alternative to preserve fertility and future endocrine function in young women undergoing sterilizing chemotherapy or radiation [61]. Immature follicles have the greatest potential to be preserved and recovered from the freeze-thawing process [62]. However, after cryopreserved ovarian tissue transplantation, the onset of revascularization can take up to 5 days, and ischemia-reperfusion damage may induce graft follicle depletion [63]. Shikanov et al. [64] developed a delivery system combining hydrogels and angiogenic factors to enhance ovarian graft survival in mice. The ovarian cortical tissue was cryopreserved, thawed, and encapsulated in fibrin hydrogel modified with heparin-binding peptide (to provide a controlled release of heparin binding growth factors) loaded with VEGF. The encapsulated tissue was then transplanted into the ovarian bursal cavity. Results indicated that the delivery strategy enhanced graft vascularization, improved survival of primordial follicles, and enabled natural conception and live births.

When autologous transplantation of cryopreserved ovarian tissue carries the risk for reintroducing malignant cells into the patient, strategies for in vitro maturation of early-stage follicle have the potential to provide an additional option to preserve and restore fertility. Several in vitro culture methods for the follicle-enclosed oocyte maturation have been successfully investigated in mice and large animal species. However, the translation into human follicles has been challenged by their greater diametric sizes, creating the need for extended culture time [65,66]. Culture of early-stage human ovarian follicles in 2D systems has been associated with spatial disruption of cells, because the portion of the follicle that is in contact with the culture substrate attaches to the surface and granulosa cells migrate away from the oocyte, leading to flattened follicles [67–70]. To address 2D-related limitations, 3D culture systems have been developed to recapitulate the biological architecture of ovarian follicles and provide an environment that supports follicle growth and maturation [71,72]. Pangas et al. [73] pioneered the use of alginate as a hydrogel for in vitro culturing individual immature ovarian follicles in a mice model. Alginate is a naturally occurring polysaccharide, typically extracted from brown algae, and one of the most commonly used biomaterials for encapsulation owing to its biocompatibility, low toxicity, low cost, biomechanical properties, and ability to form gel in the presence of calcium ions [74,75]. Studies using alginate-based encapsulation techniques have demonstrated a preserved in vivo-like spherical follicle morphology and communication between the somatic and germ cells, creating a microenvironment that favors normal folliculogenesis and proper steroidogenesis [72,76–79]. Xiao et al. [80] described a two-step follicle culture method that supports human oocyte maturation. In the first step, secondary follicles were mechanically isolated from the patients' ovaries and encapsulated individually in 0.5% alginate hydrogels. The beads were cultured in 96-well plates; once the follicles reached the antral stage (400–500 μm), they were released and transferred to low-attachment plates and then cultured for up to 30–40 days. This two-step strategy aimed to recapitulate the dynamics of in vivo ovarian folliculogenesis, in which immature follicles gradually move from the rigid cortex zone to the less dense perimedullary region. The authors reported the development of fertilizable metaphase II oocytes using this in vitro maturation approach.

In another study, Krotz et al. [81] created a self-assembled artificial human ovary to mature early antral oocytes. Theca cells isolated from antral follicles of reproductive-aged women were seeded into agarose molds to form a honeycomb structure. Granulosa cell spheroids or cumulus–oophorus complexes (COC) were then placed in the honeycomb openings and the constructs were cocultured for up to 7 days. At 72 h, theca cells surrounded the COC, resulting in self-assembled microtissues that supported oocyte maturation.

Cell encapsulation techniques have also been investigated as a potential cell-based hormone therapy for menopausal symptoms. This delivery system aims to reduce unwanted side effects of hormone replacement therapy by providing an endogenous pulsatile hormone release regulated by the hypothalamus–pituitary–gonad axis. Ideally, the microcapsules should be biocompatible, provide a barrier between the allogeneic ovarian cells and the recipient to prevent immune rejection, and promote long-term cell survival. Sittadjody et al. [82] developed an engineered multilayer ovarian tissue that secretes ovarian hormones in vitro in response to follicle-stimulating hormone and luteinizing hormone (Fig. 70.3). Ovarian cells were isolated from immature rats and encapsulated in alginate hydrogel as a multilayer construct that recapitulates native follicular architecture. Using a microfluidic device, poly-L-ornithine–coated microcapsules containing granulosa cells were mixed with theca cells and

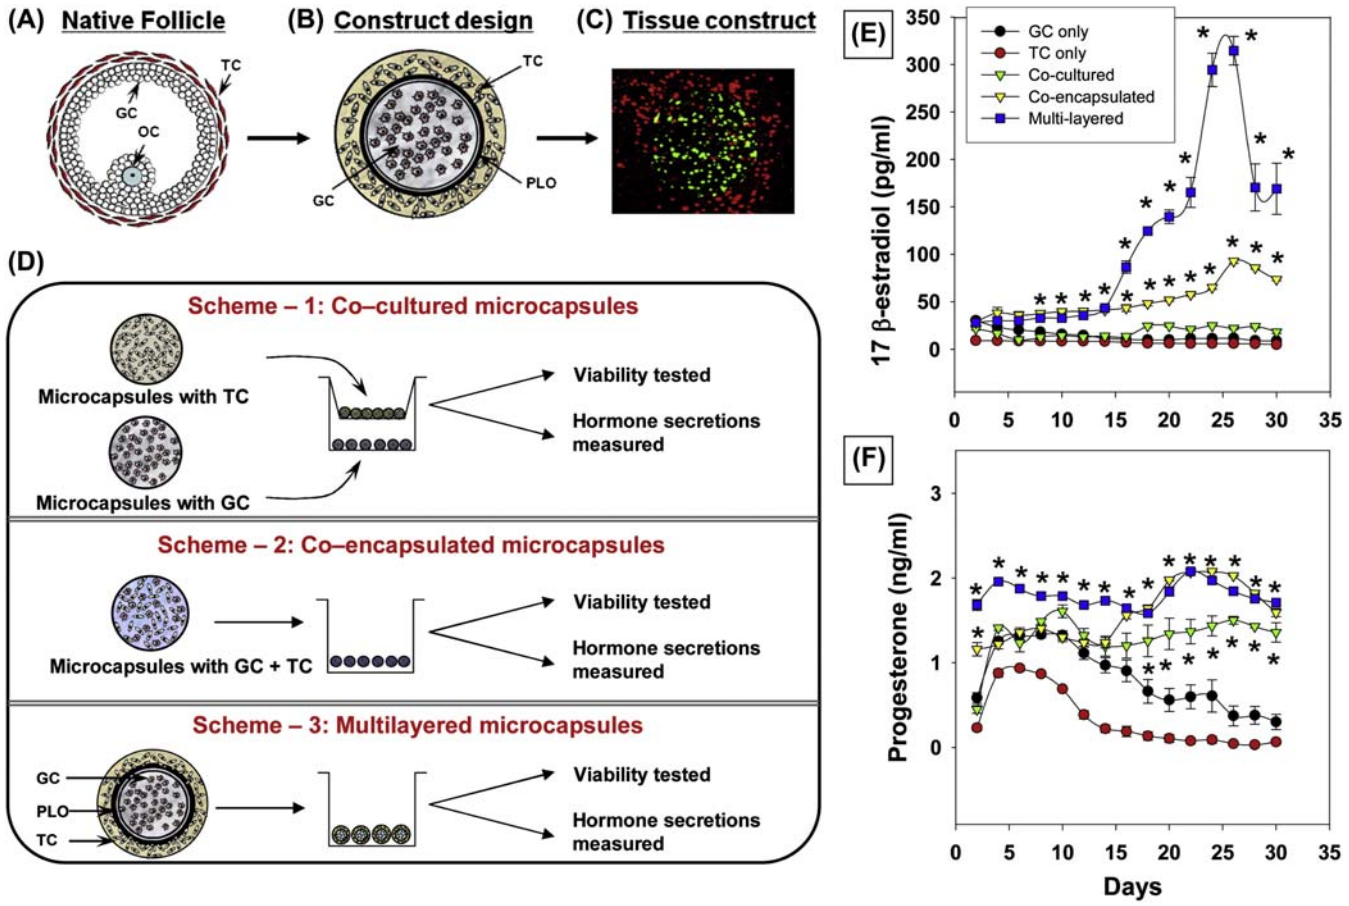

FIGURE 70.3 Encapsulation approach for reconstructing ovarian endocrine tissue: (A) Schematic diagram of a native ovarian follicle. (B) Multilayered alginate microcapsule design to mimic native follicular structure. (C) Three-dimensional (3D) confocal image of microcapsules demonstrating compartmentalization of different cells and distribution of CellTracker green-labeled cells (granulosa) in the inner layer and CellTracker orange-labeled cells (theca) in the outer layer. (D) Outline of the study demonstrating the cocultured/coencapsulated/multilayer microcapsules as the three approaches used. (E) Sustained E_2 and (F) P_4 secretion by granulosa and theca cells encapsulated using three different schemes. In contrast to 2D cultures, E_2 levels are maintained or increased with time and the presence of both GC and TC (through Schemes 1 and 2, or 3) led to increased levels of E_2 production compared with GC or TC alone. Multilayer cultures led to significantly increased levels of E_2 production. Each data point represents the mean ± standard error of the mean of six values (three wells per group assayed in duplicates). *Denotes statistical significance at $P < .05$ compared with granulosa and/or theca cells alone. The figures represent data from one of two separate experiments. *E_2*, 17β-estradiol; *GC*, granulosa cells; *OC*, oocyte; *PLO*, poly-L-ornithine; *P_4*, progesterone; *TC*, theca cells. *Adapted from Yalcinkaya et al. Yalcinkaya TM, Sittadjody S, Opara EC. Scientific principles of regenerative medicine and their application in the female reproductive system. Maturitas January 2014;77(1):12–9. suspended in 1.5% alginate to be encapsulated. Multilayered constructs were cultured in the presence of gonadotropins and showed sustained secretion of sex steroids and peptide hormones over 30 days.

Microencapsulated ovarian cells have been reported to secret steroid hormones in vivo. Gou et al. [84] implanted approximately 2×10^6 microencapsulated allogeneic ovarian cells in the abdominal cavity of ovariectomized mice. Ninety days after transplantation, cells within the microcapsules survived and maintained the balance of bone absorption and formation by secreting estrogen continuously. Similarly, Liu et al. [85] co-microencapsulated granulosa and theca cells in alginate–chitosan–alginate and transplanted them into ovariectomized rats. Animals exhibited normal serum levels of estradiol and progesterone for 60 days and most of the retrieved microcapsules remained intact.

Regenerating Ovarian Tissue From Stem Cells

Studies in reproductive biology have challenged the belief that most female mammals are born with a finite number of oocytes that are incapable of postnatal renewal. The existence of germline stem cells (GSCs) in the juvenile

and adult mouse ovary was first postulated by Johnson et al. [86]. During an investigation of follicular atresia, a series of experiments revealed that based on the oocyte degeneration and clearance rates, proliferative germ cells are needed to support the animals' reproductive life span. The researchers identified a group of large ovoid cells in the surface epithelium of the ovary that immunostained positive for the specific germline marker mouse Vasa homolog (MVH) and incorporated 5-bromodeoxyuridine, thus confirming their proliferative potential. Furthermore, the MVH-positive cells expressed genes involved in the initiation of meiosis (synaptonemal complex protein 3). Finally, ovarian tissue from wild-type mice grafted into ovaries of mice with ubiquitous expression of GFP, contained GFP-positive germ cells surrounded by wild-type granulosa cells, indicating that proliferative germ cells sustain oocyte and follicle production in the postnatal mammalian ovary [86].

A study conducted by Zou et al. [87] made a major breakthrough claiming that postnatal mouse ovaries retain the capacity for oogenesis. Using a cell-sorting approach, GSCs, also referred as oogonial stem cells (OSCs), were isolated from the cortical layer of neonatal and adult mouse ovaries and cultured for long term. After being infected with GFP virus, these cells were transplanted into ovaries of infertile mice; and results indicated they underwent oogenesis and produced live GFP-positive offspring. In a subsequent study, White et al. [88] refined a fluorescence-activated cell-sorting protocol to isolate OSCs from mice ovaries and applied the same strategy into cryopreserved ovarian tissue from reproductive-aged women. Using an antibody against DEAD-box polypeptide 4 (the human ortholog gene of MVH), rare mitotically active cells were purified from human ovarian cortical tissue. These cells showed primitive germline profile, in vitro growth properties, and were able to generate oocytes in vitro and in vivo after xenotransplantation into immunodeficient female mice.

Nevertheless, the potential clinical relevance of the human equivalent of mouse OSC findings should be further explored because the incidence of OSCs in young adult mice ovaries is estimated to be extremely low, approximately 0.014% of all ovarian cells [88].

Extraovarian sources have been used to obtain germ-like cells including the bone marrow [89], fetal and newborn skin [90,91], mesenchymal cells [92], embryonic stem cells (ESCs), and induced pluripotent stem cells (iPSCs) [93,94].

Hayashi's group achieved major progress in reproductive biology, reprogramming murine ESCs and iPSCs into fully functional oocytes in vitro [94]. Previously, Hayashi et al. [93] reported the ability to differentiate murine ESCs and iPSCs into primordial germ cell-like cells (PGCLCs) that can develop into functional oocytes when transplanted into immunocompromised female mice. After in vitro maturation and fertilization, these PGCLCs-derived oocytes contributed to fertile offspring [93]. In addition, a stepwise culture system was used to reconstitute in vitro the entire cycle of the mouse female germ line [94]. Starting with either ESCs or iPSCs, the expression of several genes was induced to create PGCLCs, which were then mixed with female gonadal somatic cells obtained from embryos to support germ cell in vitro development into mature oocytes. An in vitro fertilization protocol was used to test the oocytes' functionality, and the resulting embryos were transferred into surrogate females. The authors reported that only 3.5% of two-cell embryos derived from laboratory-grown oocytes resulted in viable offspring, which was much lower than that from in vivo−generated oocytes (61.7%), and the pups were healthy and grew into fertile adults. This culture technique may provide a platform to study molecular and cellular mechanisms of oogenesis of other mammalian species, including humans.

OTHER TISSUE ENGINEERING APPLICATIONS IN THE FEMALE REPRODUCTIVE SYSTEM

Pelvic Organ Prolapse

Pelvic organ prolapse (POP) is the abnormal descent of organs such as the uterus, bladder, urethra, intestine, and vagina that occurs when the pelvic floor supporting ligaments and muscles weakens. The estimated prevalence is approximately 30−40% of all women; pregnancy, aging, obesity, and genetic predisposition are the main risk factors. Commonly, these women experience symptoms of bladder, bowel, and sexual dysfunction that negatively affect their quality of life [95]. Surgical treatment options for POP involve reconstructive procedures with native tissue and/or the use of synthetic meshes to support the pelvic structural defect. However, mesh-related complications such as infection, mesh exposure, perforation, chronic inflammation, mesh shrinkage [96], and the lifetime risk for repeated surgeries [97] has led scientists to develop engineered grafts to enhance pelvic floor support and provide a more durable treatment. Hung et al. [98] engineered a fascia equivalent from isolated human vaginal fibroblasts. Full-thickness vaginal biopsies were taken from symptomatic POP patients and cells with high collagen I/III ratios were used for in vivo experiments, because they expressed greater proliferation potential. Vaginal fibroblasts were labeled with dialkylcarbocyanine fluorescent solution, suspended in collagen gel, and seeded

into biodegradable PLGA scaffolds. Fascia constructs were incubated in vitro for 5 days and implanted into immunodeficient mice subcutaneously. At 12 weeks after the surgical procedure, histological analysis of the grafts revealed the presence of labeled cells within a well-organized tissue formation, with an abundant collagen component, whereas poor tissue ingrowth was observed in the nonseeded collagen gel-coated PLGA grafts.

The use of cells derived from prolapsed vaginal tissues may not be ideal though; as they have shown altered in vitro characteristics including delayed fibroblast-mediated collagen contraction and lower production of collagen synthesizing enzymes compared with nonprolapsed tissue [99].

As an alternative autologous cell source, human endometrial mesenchymal stem cells (eMSCs) have been investigated in tissue engineering approaches for POP repair. Previously, human endometrial eMSCs were identified in a perivascular location in the human endometrium; characterized as multipotent, highly proliferative, and self-renewing stromal stem cells; and isolated using CD146, platelet-derived growth factor receptor-β, and sushi domain containing-2 (SUSD2) markers [33]. Using a xenogeneic model, Ulrich et al. [100] investigated the in vivo tissue responses and mechanical behavior of a novel nondegradable scaffold seeded with human eMSCs. In that study, SUSD2-enriched human eMSCs were labeled and seeded into a 10 × 25-mm polyamide mesh coated with 12% porcine gelatin at a density of 250,000 cells/mesh. According to the authors, polyamide mesh has biomechanical properties comparable to those of vaginal tissue. After 48 h of incubation, the constructs were implanted into the dorsum of immunodeficient rats and assessed at different time points up to 90 days. The cell-seeded mesh showed enhanced vascularization at day 7 after implantation; and at 90 days, results reveled a mild chronic inflammatory response, improved tissue organization, and minimal fibrosis around the seeded graft, which provided higher extensibility compared with nonseeded meshes. In addition, the organized collagen deposition was identified as being of rat origin, not human, which suggested that eMSCs exert a paracrine effect over the long term.

Future preclinical studies using clinically relevant models that represent a woman's pelvic tissue environment would be necessary to evaluate the efficacy and adverse effects of tissue engineered grafts for pelvic reconstructive surgery [101].

CONCLUSIONS AND FUTURE TRENDS

A successful pilot study of autologous engineered vaginal organs, with up to 8 years' follow-up, supports the potential of regenerative medicine technologies for treating female genital organs disorders. However, clinical trials involving a large number of patients are required to ensure that the most innovative therapies are as safe and effective as possible.

Advances have been made with engineering uterine tissue in preclinical models, but additional studies of biomaterials that produce adequately vascularized uterine tissue should be performed in systems that mimic the complex architecture and plasticity of the human uterus. In addition, important findings regarding the identification of human eMSCs with capabilities similar to those of BM-MSCs make the uterus an attractive source of stem cells that should be further explored for autologous cells therapy and tissue engineering applications.

Regenerative medicine principles have also been used to reconstitute the entire process of oogenesis in vitro and to engineer functional ovarian follicles, which represents a major achievement in reproductive biology. Nevertheless, challenges remain regarding the optimization of these in vitro culture systems for human gonadal cells.

Finally, the future of regenerative medicine applications for the human female reproductive system will rely on better understanding organogenesis and the complex physiological mechanisms of these organs to achieve the ultimate potential of these technologies.

Regenerative Medicine for the Male Reproductive System

Hooman Sadri-Ardekani, Anthony Atala

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

The science of male reproductive function and dysfunction has experienced significant progress in recent years. In particular, clinical applications of molecular medicine to male infertility and hypogonadism [1], the "invention" of intracytoplasmic sperm injection (ICSI) as a treatment of male infertility [2], and the introduction of effective oral medication for erectile dysfunction (ED) [3,4] can be considered major breakthroughs. Infertility affects around 15% of couples who wish to have children, and half of these cases are associated with male-related factors [5]. ED is defined as a consistent or transient disorder; inadequate erection affects at least half of men aged 40–70 years, whereas chronic ED affects about 5% of men in their forties and up to 25% of men by age 65 years [6,7]. Hormonal and surgical approaches have been used to treat patients with reproductive system disorders. Regenerative medicine has become a promising concept in the development of new therapies for all fields of medicine, including reproduction [8]. The field of tissue engineering and regenerative medicine covers different areas of biomedical technology, including biomaterials, tissue engineering, and stem cell therapy. Three main strategies have been employed: (1) using extracellular matrices (ECM) without cells, allowing the natural ability of the body to generate new tissue, (2) using ECM seeded with cells for implantation, and (3) directly injecting cells with or without carriers such as hydrogels. ECMs used for tissue engineering may be either synthetic or derived from natural sources [9,10]. Different cell types may also be used, including (1) tissue-specific stem cells; (2) mesenchymal stem cells (MSCs); and (3) pluripotent stem cells such as embryonic stem cells, induced pluripotent stem cells, or amniotic and placental-derived stem cells. These cells can be either autologous or allogeneic. Autologous cells derived from a small biopsy are the preferred source because of immune compatibility. The biopsy is obtained from the patient and the cells isolated from this biopsy tissue are expanded in vitro. However, for some patients this is not an option because there is not enough functional tissue to obtain a biopsy. Therefore, other sources of cells, such as stem cells (either autologous or allogeneic), might be used for these patients [9,10]. The ultimate goal of regenerative medicine strategies to treat reproductive system disorders is to restore normal sexual function and preserve fertility.

TESTES

The hypothalamus, pituitary, and testes form an integrated system responsible for adequate secretion of male hormones and normal spermatogenesis. The general anatomy of the testis consists of the seminiferous tubules and, among them, the interstitial space [11]. The seminiferous tubules, which contain germ cells at different maturation levels, depend on age. The pool of germ cells is supported by spermatogonial stem cells (SSCs), which are covered by a layer of Sertoli cells embedded in lamina propria [12]. The lamina propria consists of the basal membrane covered by peritubular cells. Differentiated germ cells including spermatocytes and spermatids are located

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00071-0

across the tubule toward its center. The main component of the interstitial space is the Leydig cell population, which produces testosterone; the interstitial space also contains macrophages, lymphocytes, loose connective tissue, and neurovascular bundles [13].

Spermatogonial Stem Cell Technology

Etiologies of nonobstructive azoospermia include endocrinopathy, testicular failure, genetic anomaly, and idiopathic factors. On average, every day in the United States, about five men become azoospermic owing to the adverse effect of cancer treatments [14]. In sexually mature boys and men with cancer, who are at risk for infertility, sperm cryopreservation is the simplest and most effective method to preserve fertility [15]. However, less than 25% of these patients apply for sperm banking [16]. Lack of knowledge about semen cryopreservation is a major reason for the low percentage of sperm storage [16]. However, because the production of sperm has not yet started in prepubescent boys [17], sperm banking is not an option for prepubertal cancer patients. On average, more than 14 boys aged less than 15 years are diagnosed with cancer every day and more than 80% of them will be cured [18]. Therefore, long-term infertility will be a critical issue for many of these childhood cancer survivors who have no option for sperm banking. SSCs are present in the testis of most mammalian species, including nonhuman primates and humans [19]. Spermatogonia are cells located in the basement membrane of seminiferous tubules in the testis (Fig. 71.1); a small subpopulation of them are SSCs that have a primary role in spermatogenesis [19]. Normally, SSCs are able to divide and differentiate into haploid germ cells (sperm) and maintain fertility in men during life [19].

In 1994, the feasibility of isolating and transplanting SSCs to restore fertility in mouse testes was established [20]. Since then, several groups have been successful in transplanting SSCs in other species including nonhuman primates [21]. This has given great hope for finding an effective alternative to preserving fertility in adult males and may also be a solution for restoring fertility in prepubescent boys after cancer treatment. In addition to cancer survivors, patients who may benefit from SSC implantation include but are not limited to those with cryptorchidism (at risk for infertility because of undescended testes at birth) and Klinefelter syndrome (47XXY; at risk for testis fibrosis) [19].

In 2002, Nagano and colleagues [22] isolated human SSCs from six infertile men and transplanted the cells to busulfan-treated nude mice. It was shown that human SSCs migrated into the base membrane of mouse seminiferous tubules of testis, but their numbers decreased significantly 1 month after transplantation. However, some SSCs remained in the mouse testis for up to 6 months with no evidence of differentiation [22]. A xenotransplantation study of prepubescent human SSCs showed results similar to those of the previous study on adult human SSCs [23]. The feasibility of SSC transplantation in a nonhuman primate model was demonstrated by Hermann and colleagues [21]. In that study, ejaculatory lentiviral positive sperm was found in the testes of more than 75% of adult (9 of 12) and 60% of matured prepubescent (two of five) recipient macaques monkeys for up to 63 weeks (average of 40.1 $\pm$ 4.9 weeks) after lentivirus-marked SSC transplantation. Autologous transplantation was twice as successful (70.5%; 12 of 17) than allotransplantation (33.3%; two of six) in terms of the presence of sperm in the ejaculate [21]. The ability of these sperm to fertilize eggs and develop preimplantation embryos was confirmed by performing ICSI. However, full pregnancies and live births were not observed in that study [21]. These results suggest that this

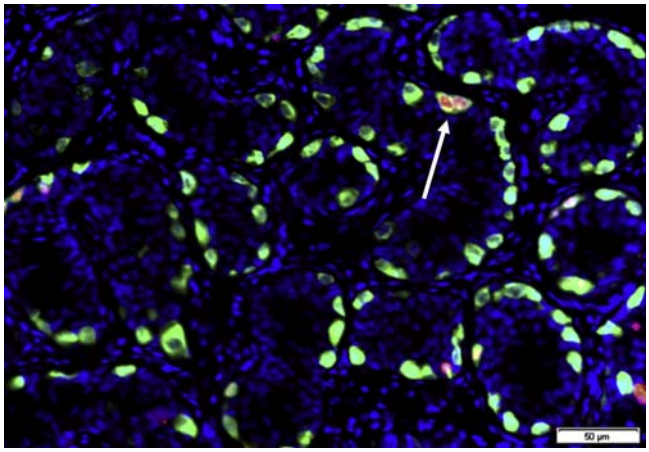

FIGURE 71.1 Spermatogonia cells (green fluorescent) in the base membrane of seminiferous tubules of a 5-year-old boy. The cells were stained by melanoma-associated antigen A4 antibody as a spermatogonia marker. Some of the spermatogonia cells have already started proliferating (*white arrow*; stained by Ki67 antibody). 4′,6-diamidino-2-phenylindole (*blue*) identified the nuclei of the cells. Scale bar = 50 µm.

technique could be translated to a clinical application in humans. In that study, an average of 88 ± 17.1 and 45.8 ± 14.5 million viable cells were used for transplantation to adult and juvenile testes, respectively [21]. It is well-known that increasing the number of cells corresponds linearly with the SSC transplantation success rate [24]. The number of SSCs in testis is low (0.03% of germ cells and 1.25% of spermatogonial cells in mice; unknown in humans) [25,26], and the size of testicular biopsy from premature boys undergoing cancer treatment is also small (around 100 mm^3; containing 30,000/mm^3 spermatogonia) [19,27]. Although human SSC autotransplantation has not yet been tried, it is expected that successful human SSC autotransplantation requires in vitro expansion of these cells before transplantation. This culture method had been developed in animal models [26,28–30]. In a study involving the isolation and culture of human testicular cells from six adult men who underwent orchiectomy as part of prostate cancer treatment, we were able to maintain and propagate human SSCs in vitro for longer than 20 weeks [31]. The number of SSC increased more than 18,000-fold over 64 days of in vitro culture. In a follow-up study using testicular tissue from two boys aged 6.5 and 8 years, who were diagnosed with Hodgkin lymphoma, isolated SSCs were able to propagate in vitro for at least 15.5–20 weeks [32]. Other groups have been successful in culturing human SSCs [33–36]; however, this culture system should be optimized under Good Manufacturing Practice regulations.

Before the first clinical trial of SSC autotransplantation in human, several safety issues must be addressed. First, especially in nonsolid cancer survivors such as hematopoietic malignancies, transplanted cells should be free of malignant cell contamination that may reintroduce the cancer to the recipient. In a study on culturing acute lymphoblastic leukemia (ALL) cells combined with testicular cells from three patients, ALL cells were undetectable beyond 26 days of culture even at an extremely high initial concentration (40% ALL cells) [37]. However, it will be beneficial to test more cell lines from different types of leukemia to ensure complete purging of malignant cells. Second, the genetic integrity of stored, isolated, and propagated SSCs is important because it can influence the next generation of offspring. It has been demonstrated that in vitro expanded mouse SSCs showed normal karyotype and stable androgenetic imprinting over 24 months [38]. Our work confirmed the genetic stability of in vitro propagated human SSCs; however, we found some changes in the epigenetic status of human SSCs during culture [39].

Although it is ideal to try for natural conception after SSC autotransplantation, in vitro spermatogenesis followed by ICSI is another option to preserve fertility in many patients. In vitro spermatogenesis models have moved forward from initially conserving anatomical structure of the testis in culture to complete meiosis from testicular mouse germ cells [40]. We developed a three-dimensional (3D) testis organoid system from adult human testicular cells (human testis organoid [HTO]) [47]. These HTOs consist of SSCs, Sertoli, Leydig, and peritubular cells (Fig. 71.2A). Each

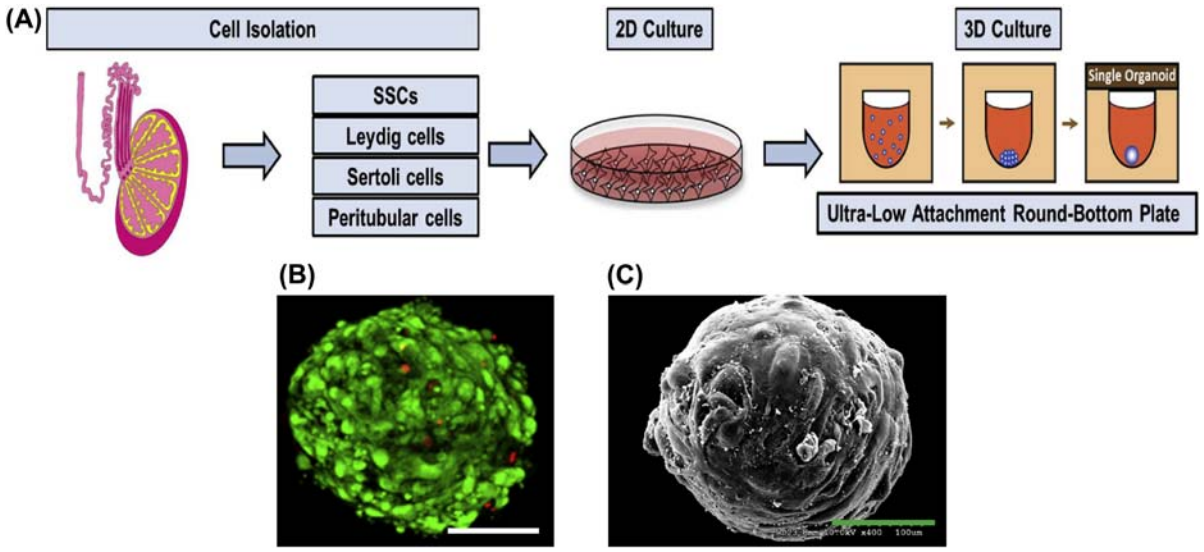

FIGURE 71.2 Human three-dimensional (3D) testis organoid system (HTO). (A) Testicular cells, including spermatogonial stem cells (SSCs), Leydig cells, Sertoli cells, and peritubular cells, are isolated and propagated in 2D culture and then seeded into ultralow attachment round-bottom plates for the 3D formation of organoids. The HTO formation takes 48–72 h. (B) Live/dead staining of organoid revealed maintenance of viability throughout the culture period. Green and red fluorescents represent alive and dead cells, respectively. (C) Ultrastructural analysis of multicellular human testicular organoids using scanning electron microscopy to show exterior morphology. Scale bars = 100 μm.

organoid is approximately 300 μM in diameter and remains viable for at least 3 weeks (Fig. 71.2B and C) in an enriched medium with testicular ECM. This organoid system mimics in vivo spermatogenesis by supporting the differentiation of SSC to postmeiotic germ cells, albeit at a low frequency of approximately 0.2% [41]. The feasibility of using this system should be tested on prepubertal human testicular cells, and then the fertilization potential of the differentiated haploid cells should be analyzed.

Androgen Replacement Therapy

Testosterone is the primary male sex hormone that has multiple roles in the body. It has important roles in developing male reproductive tissues such as testes and prostate as well as promoting secondary sexual characteristics such as increased muscle and bone mass and the growth of body hair [42]. Patients with testicular dysfunction and hypogonadal disorders may need androgen replacement therapy to restore and maintain physiological levels of serum testosterone and its metabolites. Therefore, testosterone therapy can increase muscle strength, stabilize bone density, improve osteoporosis, and restore secondary sexual characteristics, including libido and erectile function [43]. However, long-term exogenous testosterone therapy is not optimal and can cause multiple problems, including excessive erythropoiesis, bone density changes, and even infertility [44]. To address these problems, researchers are looking for an effective method to provide sufficient endogenous testosterone. In an animal model, isolated Leydig cells from rats that were cultured and stimulated with human chorionic gonadotropin (hCG) showed a high level of testosterone production [45]. In that study, engineered alginate-poly-L-lysine–encapsulated Leydig cell microspheres (with an average diameter of 0.7 $\pm$ 0.06 mm) were injected into castrated rats. Approximately 10% of a normal adult rat Leydig cell population was injected into each castrated animal. Serum testosterone levels increased and were maintained up to 40% of normal for a maximum of 43 days with no hCG stimulation [45]. Bilateral testicular agenesis or atrophy often requires placing testicular prostheses and androgen supplementation [46]. In this regard, the possibility of creating hormone-releasing testicular prostheses was investigated [47]. To form testicular prosthesis, isolated chondrocytes from bovine articular cartilage were seeded on testicular-shaped polymer scaffolds. Implanted engineered testis prostheses loaded with 100 μg testosterone enanthate were able to maintain physiologic levels of testosterone in vivo for at least 16 weeks in recipient mice [47]. For a better outcome, combinations of Leydig cell technology and engineered testicular prosthesis need to be explored further.

As mentioned, we developed a 3D testis organoid system from adult HTOs [41]. This HTO system consists of SSCs, Sertoli, Leydig, and peritubular cells. The Leydig cells in this multicellular structure could produce androgen with and without hCG stimulation [41] (Fig. 71.3).

Future work should focus on the feasibility of implanting adequate numbers of these HTOs to castrated animal models as a potential novel androgen replacement therapy.

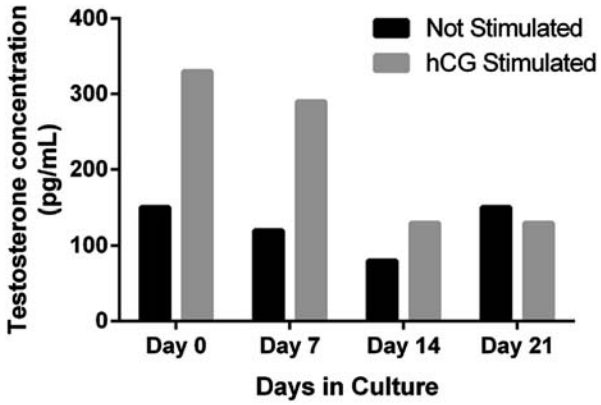

FIGURE 71.3 Androgen production by human three-dimensional testis organoid system. Testosterone concentration in organoid culture media was measured over 3 weeks. Organoids were treated with human chorionic gonadotropin (hCG) to stimulate testosterone production. Media from organoids treated with hCG were compared with control media from organoids with no hCG treatment. On days 0, 7, and 14, organoids produced more testosterone when stimulated with hCG. However, on day 21, organoids did not produce more testosterone when stimulated with hCG. The lack of increase in testosterone production on day 21 in response to hCG stimulation could have resulted from organoids becoming desensitized to hCG (at each time point, secreted hormones from a group of 16 organoids were pooled; n = 16).

EJACULATORY SYSTEM

Ejaculation is the process of transporting sperm through the urethra and expelling semen from the urethral meatus. The organs involved in the ejaculatory process are the epididymis, vas deferens, prostate, seminal vesicles, bladder neck, external urethral sphincter, and bulbourethral glands. In normal ejaculation, anatomic structures are precisely coordinated via neural centers to allow normal ejaculation to take place [48,49].

Engineering Vas Deferens

Congenital bilateral absence of the vas deferens (CBAVD) causes obstructive azoospermia, which is common in about 1% of infertile men [50]. Because CBAVD men have normal spermatogenesis, they are able to achieve biological fatherhood with the help of assisted reproduction techniques, i.e., surgical sperm extraction and in vitro fertilization (IVF) [51]. In addition, conception requires the female partner of men with CBAVD to undergo ovarian stimulation for an IVF/ICSI procedure. A solution to this problem would be to replace the vas deferens. A novel approach for the tissue engineering of vas deferens was tried in a rabbit model [52]. Polyethylene tubes (0.86 mm in diameter and 6 cm long) were implanted into the peritoneal cavities (as an in vivo bioreactor) of 16 rabbits [52]. After 2–3 weeks, the tubes were removed and the encapsulating myofibroblast-rich tissue that resulted from the foreign body response to the biomaterial was harvested for grafting as vas deferens in the rabbits [52]. At 2, 4, 6, and 8 months after implantation, morphological and immunohistochemical evaluations showed that the structure of engineered vas deferens was similar to that of native vas deferens tissue [52]. In addition, the presence of sperm in the ejaculate indicated normal function of the engineered vas deferens. However, more research on large-animal models is required before this approach can be used in humans.

Urethra Reconstruction

The male urethra is a narrow fibromuscular tube that conducts urine and semen from the bladder and ejaculatory ducts, respectively, to the exterior of the body. Many surgical procedures, such as grafting to replace damaged areas of the male urethra, may eventually fail. Various strategies have been proposed over the years to regenerate urethral tissue in several animal models, including woven meshes of synthetic polymers such as polyglycolic acid (PGA) without cells [53,54] and with cells [55], naturally derived collagen-based materials such as decellularized bladder submucosa [56], and acellular urethral submucosa [57]. The effectiveness of using collagen-based inert matrix was confirmed clinically in a series of four patients with a history of failed hypospadias reconstruction. Twenty-two months' follow-up showed successful repair of urethral defects with human bladder acellular collagen matrix in three of four patients [58]. In another study of 30 patients with recurrent stricture disease, human demineralized bone matrix obtained from cadaveric donors was processed and prepared for use as an off-the-shelf material [59]. Up to 36 months' follow-up showed that a healthy urethra bed (two or fewer prior urethral surgeries) was needed for successful urethral reconstruction using the acellular collagen-based grafts. In an advanced study with more than 10 years' follow-up [60], human clinical trials with a collagen-coated PGA tubularized scaffold seeded with autologous cells were conducted in a pilot series of five patients. The scaffolds were seeded with autologous cells derived from bladder biopsies taken from each patient. The cell-seeded scaffolds were then matured in an incubator and used to repair the urethral defects present owing to trauma. Long-term follow-up evaluation showed normal-range urinary flow rates and voiding cystourethrograms indicated that these patients maintained wide urethral calibers. Yearly biopsies showed that the grafts had a histological architecture consistent with normal urethral tissue (Fig. 71.4).

Spinal Ejaculation Generator

The incidence of anejaculation in the population is small, but when it is present, it represents a formidable challenge to the infertile couple and the treating physician [61]. Spinal cord injury (SCI) is the most common cause of anejaculation encountered in clinical practice [62]. The incidence of traumatic SCI is estimated at 16 individuals per million per year in Western Europe and 39 individuals per million per year in North America, with a prevalence of 300 and 853 individuals per million, respectively [63]. In the United States, mean age at occurrence of SCI is 37.1 years and 77.1% of SCI patients are male [64]. Ejaculation can be physiologically defined as the rhythmic, forceful expulsion of semen at the urethral meatus. Ejaculation is composed of two successive phases, emission and expulsion, each involving different pelvic-perineal anatomical structures [65]. Emission is controlled by autonomic

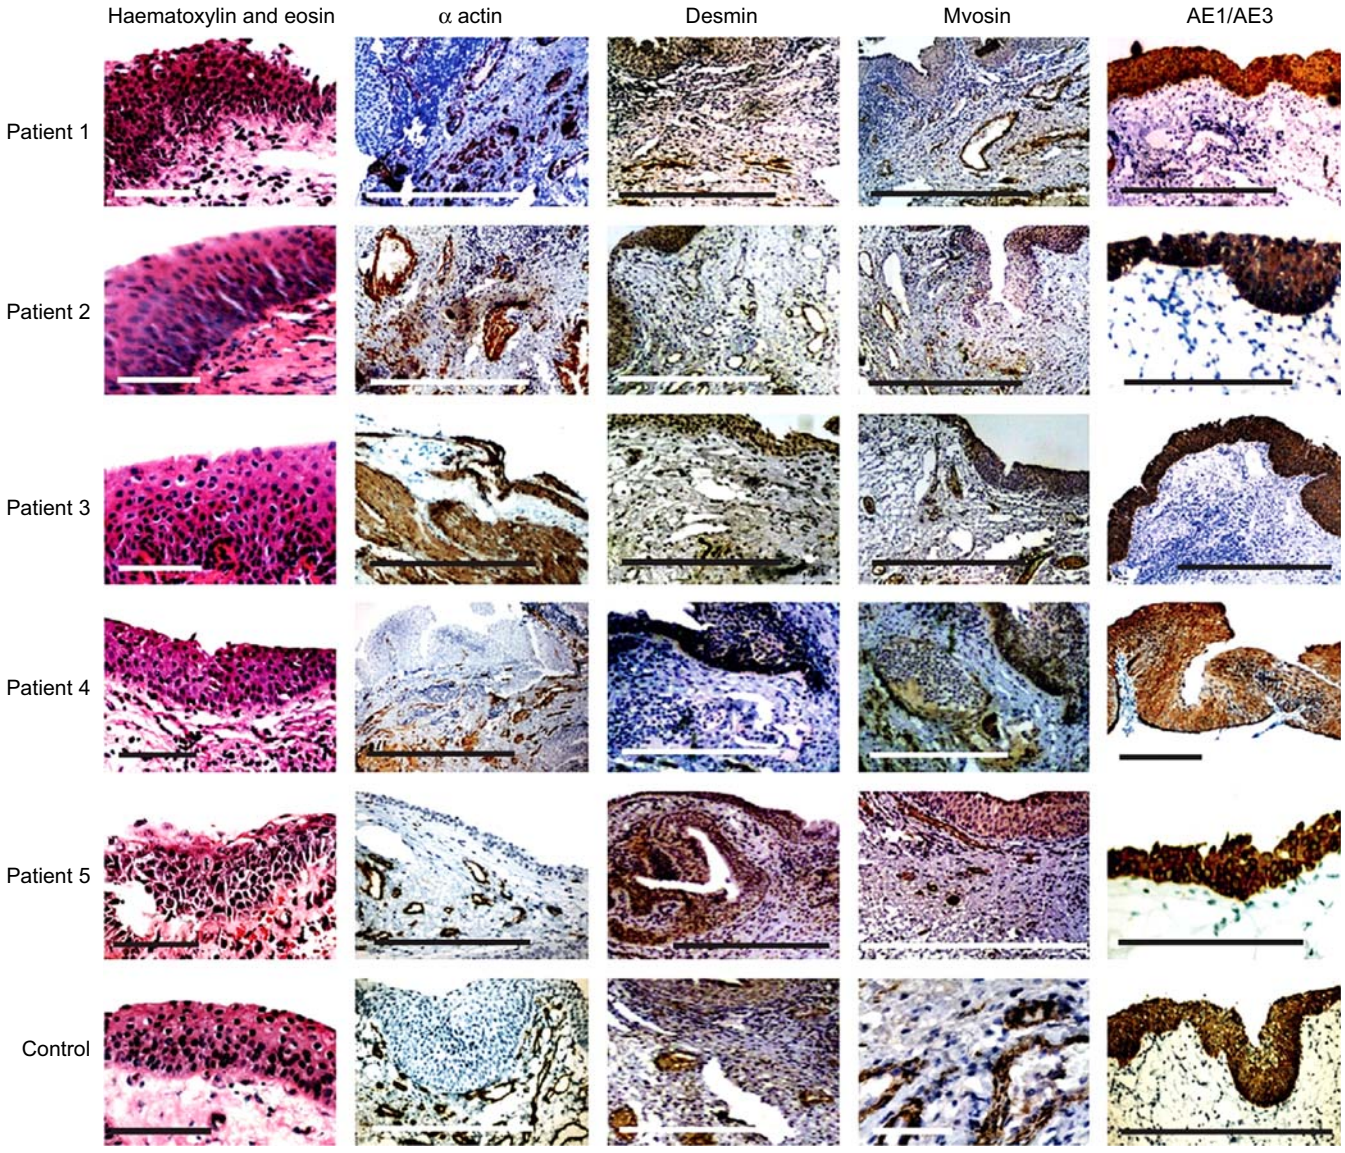

FIGURE 71.4 Histological and immunocytochemical analyses of implanted engineered urethra. Results of urethral biopsies of engineered segments from every patient at 1 year after surgery and from a control sample of healthy urethral tissue. *AE1/AE3,* Anti-pan Cytokeratin antibody. All scale bars = 25 μm.

(sympathetic and parasympathetic) spinal centers, and expulsion is controlled by somatic spinal centers. These centers act in synchrony for antegrade ejaculation to occur. In rats, such synchronization has been reported to be led by a group of lumbar spinothalamic neurons forming the spinal generator of ejaculation (SGE). The critical role of the SGE and its organization have been described in functional and neuroanatomical studies [65–69]. Penile vibratory stimulation (PVS) is a procedure that uses external vibration to stimulate the sensory nerves on the penis, with resultant reflex ejaculation (Fig. 71.5A). Electroejaculation is an option for men with SCI who have lower motor neuron lesions and for those who have failed PVS, but it is more invasive. This technique uses electricity delivered via a rectal probe to recruit the ejaculatory reflex. The Seager Electroejaculator (Dalzell Medical Systems, The Plains, VA) remains the only US Food and Drug Administration–approved device for this procedure (Fig. 71.5B).

Numerous studies have focused on therapeutic approaches of SCI in animal models. Significant progress on functional remyelination [70], direct injection of biological agents [71], formation of neuronal relays [72], biomaterial approaches to enhancing neurorestoration [73], and neural stem cells transplantation [74,75] has been made. These studies promise translation to more clinical trials on SCI and neuronal regeneration. Although the main aim of these studies is to correct motor and sensory deficits, it will be interesting to evaluate improvement in ejaculation function of these patients, as well.

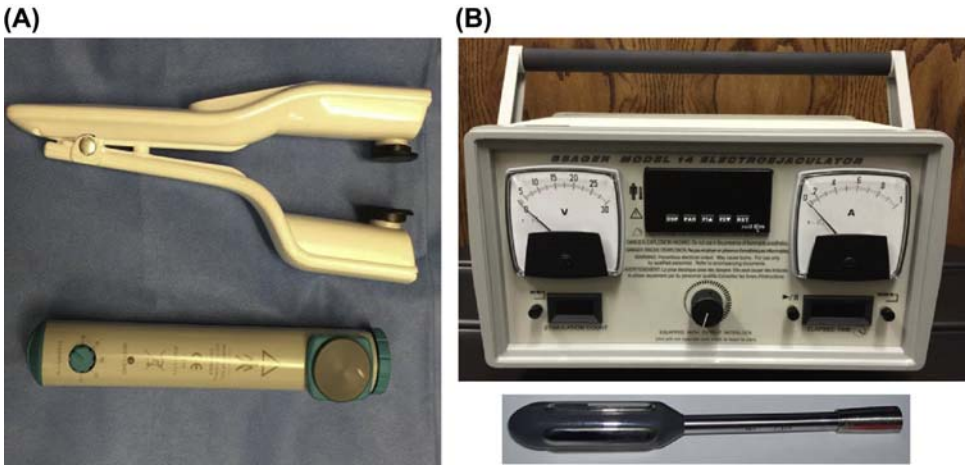

FIGURE 71.5 Instruments to collect semen from patients with spinal cord injury. (A) Penile vibratory stimulators including FertiCare (bottom device) and Viberect X3 (top device). These devices can be placed on the dorsum or frenulum of the penis, or both. (B). Seager Electroejaculator and its transrectal probe. The probe is used to deliver electrical current directly to the prostate and seminal vesicles, resulting in ejaculation. The harvested sperm can be used for either intrauterine insemination or in vitro fertilization.

PENIS

Penile Reconstruction

Congenital and acquired genitourinary tract anomalies of the penis require surgical reconstruction. Lack of sufficient normal autologous tissue is the major limitation in many surgical procedures for different conditions such as ambiguous genitalia, epispadias, hypospadias, micropenis, aphallia, severe chordee, impotence, female to male genital reassignment, and traumatic or iatrogenic penile defects [76–78]. The possibility of developing tissue composed of corporal cells in vivo has also been investigated [79]. Human corporal smooth muscle cells (SMC) and endothelial cells (ECs) were seeded on biodegradable polymer scaffolds at concentrations of 20×10^6 and 10×10^6 cells/cm^3, respectively. These constructs were then implanted in the subcutaneous space of nude mice [79]. Histological evaluation showed the formation of vascularized corpus cavernosum composed of these two cell types 28 and 42 days after implantation [79]. To achieve a 3D corporal structure, naturally derived polymer scaffold from rabbit corporal tissue was used combined with primary human cavernosal SMC and ECs [80]. Engineered corporal tissues were maintained in culture for up to 4 weeks and then implanted into nude mice [80]. The matrices showed stable collagen concentration 8 weeks after implantation [80]. Immunocytochemical studies using α-actin and factor VIII antibodies confirmed the presence of corporal SMC and EC in vivo [80]. Organ bath studies also showed that the cell-seeded corporal tissue matrices responded to electrical field stimulation [80]. In a follow-up study, structural parameters were evaluated up to 6 months after implantation in a rabbit penile defect model [81], in which the engineered corporal bodies showed structural integrity on cavernosography. The presence of sperm after copulation was confirmed in rabbits with the engineered corpora [81]. In all of these studies, it was shown that a short segment of the penile corporal body (approximately one-third of the penile corpora) can be replaced using naturally derived collagen matrices with autologous cells [79–81]. To improve the results of previous studies, engineering of the entire length of both penile corpora was attempted [82]. In another study, the matrices were seeded with the autologous corporal SMC and EC, using a novel multistep cell seeding protocol [83], and the cell seeded matrices were used to replace the entire pendular penile corpora in 12 male rabbits [82]. At 1, 3, and 6 months after implantation of the engineered corpora, the rate of sperm presentation on vaginal swabs and pregnancy rates of mated female rabbits was 83% and 30%, respectively. Untreated rabbits showed no evidence of intravaginal sperm and no pregnancies occurred [82]. These studies demonstrate that penile corpora cavernosa tissue can be engineered and transplanted to restore function.

Penile Transplantation

As an option for penile reconstruction, penile transplantation has been considered, especially after near-complete penile loss. So far, three allogenic penile transplantations have been performed worldwide. The first was performed

successfully in China in 2006; however, it was removed after 2 weeks because of the recipient and his wife experienced severe psychological problems [84,85]. The second case was described in 2014 and was performed in South Africa. The surgery was complicated by a reintervention after 4 days to remove a thrombus from the anastomosis and another reintervention for hematoma drainage. However, the patient reported normal sexual and urinary function 3.5 months after transplantation [86]. The third case was the first US-based penile transplantation and was performed in a patient with penile cancer [87]. The requirement of lifelong multidrug immunosuppression with the risk for serious side effects remains a limiting factor for the widespread clinical application of penile transplantation [88].

Stem Cell Therapy for Erectile Dysfunction

ED is defined as the consistent or recurrent inability to achieve or maintain an erection sufficient for sexual activity [89]. Interest is increasing in recruiting endogenous or exogenous stem cells to treat ED [90]. It is generally believed that tissue-specific stem cells exist in most postnatal tissues. Two types of foreskin stem cells have been isolated , including skin-derived progenitors [91] and MSCs [92]. In a rat study using 5-ethynyl-2′-deoxyuridine labeling, the presence of stem and progenitor cells was shown. These cells, mainly distributed within the subtunic and perisinusoidal space of penis, are defined as subtunic penile progenitor cells and perisinusoidal penile progenitor cells. These cells expressed c-kit, A2B5, and proliferating cell nuclear antigen [93]. It is expected that reactivation of endogenous stem cell potential might rejuvenate damaged erectile function [94]. Human MSCs have been isolated from a large number of adult tissues (bone marrow, adipose tissue, skeletal muscle, etc.). Adipose tissue, which is a rich and easily obtainable source of MSC, has been of particular interest in treating ED [95]. MSCs express low levels of major histocompatibility complex (MHC) class I and do not express MHC class II molecules; thus, they are minimally immunogenic. Therefore, they can be used from either autologous or allogenic sources [96]. Isolated MSCs from rat paratesticular fat tissues were injected in a bilateral cavernous nerve injury model. One month after injection, measurement of intracavernous pressure revealed significant improvement in ED [97]. All of these observations demonstrate how stem cell treatment is a promising tool to restore normal erectile function, but these applications need further development for future clinical trials.

CONCLUSION

Regenerative medicine is a branch of translational research in tissue engineering and molecular biology that deals with the process of replacing, engineering, or regenerating human cells, tissues, or organs to restore or establish the normal function of tissues and organs. Most of the effort toward engineering male reproductive tissues has occurred in animal models. The safety of engineered reproductive tissues is usually more critical than other organs because in many cases, more than just recipients are involved. The health of offspring as well as the patient's partner should be considered in any future clinical trials. Regenerative medicine has opened new avenues to treat disorders of male reproductive system affecting fertility and sexual life.

Regenerative Medicine of the Bladder

Yuanyuan Zhang, Anthony Atala

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

The urinary bladder is a hollow muscular organ lined with urothelium or transitional epithelium. The main source of force, the detrusor muscle, is a layer of the urinary bladder wall made of smooth muscle fibers that is arranged in spiral, longitudinal, and circular bundles. The smooth muscle tissues can be extended to store the urine and then completely empty the bladder. As a passive barrier, the urothelium does not generate mucus. This internal lining of the bladder wall, which is composed of urothelial tissue and lamina propria, is believed to regulate some aspects of overall bladder physiology in response to stimuli such as distension during filling [1].

The urinary bladder functions as a storage vessel for urine to delay the frequency of urination. It is one of the most elastic organs of the body and can increase its volume greatly to accommodate up to 800 mL of urine at maximum capacity in adults. Transitional epithelium, elastic fibers, and visceral muscle tissue in the walls of the urinary bladder contribute to its distensibility and elasticity, allowing it to extend easily and return to its original size several times each day.

Congenital disorders, cancer, trauma, inflammation, and other conditions of the bladder can damage its histologic structure or cause complete loss of function. Both situations usually necessitate eventual reconstruction or replacement of the damaged tissue. Although patients with diseased or injured organs can be treated with transplanted organs, there is a severe shortage of donor organs that worsens yearly as the population ages and new cases of organ failure increase. Lower urinary tract reconstruction has been performed with autogenic nonurologic tissues such as gastrointestinal segments, mucosa from multiple body sites, homologous tissues from a donor (cadaver or living donor kidney), and heterologous tissues or substances (e.g., bovine collagen) [2]. All of these materials may cause a series of complications after surgery because the implanted tissue is rejected or inherently different functional parameters may cause a mismatch in the system. For example, replacement of bladder tissue with gastrointestinal segments can be problematic because the urothelium normally excretes proteins [3] whereas gastrointestinal tissue generally absorbs them. This mismatched state can lead to metabolic complications in addition to infection and other issues [4]. Therefore, replacement of lost or deficient urologic tissues with functionally equivalent ones would improve the outcome of reconstructive surgery in the genitourinary system. This goal may soon be achievable with the use of tissue engineering techniques.

Tissue regeneration uses the principles of cell biology, biomaterials science, bioactive factors, and biomedical engineering to develop biologic substitutes that can restore and maintain the normal function of damaged or lost tissues and organs. Tissue engineering involves using natural or synthetic matrices, often termed scaffolds, that encourage the body's natural ability to repair itself and assist in determining the orientation and direction of new tissue growth. Often, tissue engineering uses a combination of these techniques. For example, matrices seeded with cells can be implanted into the body to encourage the growth or regeneration of functional tissue. These cells, materials, and bioactive factors all could be called "biomaterials."

Scientists have attempted to grow native and stem cells, engineer tissues, and design treatment modalities using regenerative medicine techniques for the urinary tract system. This article reviews progress in bladder reconstruction using tissue engineering technology.

CELL SOURCES

Bladder and Ureter Cells

Although implanted tissue can be heterologous, allogeneic, or autologous in experimental animal models, only autologous cells are used in the clinic setting [5] to avoid graft rejection and the long-term use of immunosuppressive medications after allogeneic transplantation. Autologous somatic cells obtained from the bladder or ureters [6] are often used for tissue engineered bladders. The donor tissue is dissociated into individual urothelial and smooth muscle cells (SMCs), which are expanded in culture, attached to a support matrix, and then implanted back into the host. Ideally, this approach allows lost bladder tissue function to be restored or replaced with limited complications [7–10]. However, suitable bladder cells from the patient for this purpose are sometimes limited or unobtainable because of bladder exstrophy, malignancy, or other reasons.

Stem Cell Sources

Adult stem cells could be a suitable alternative to bladder cells. They are an appealing cell source for tissue regeneration, in part because of their self-renewal, long-term expansion in vitro, and differentiation potential. Three types of cell sources have been used for bladder regeneration in experiment models: autologous cells (i.e., urothelial cells (UCs) and smooth muscle cells (SMCs), urothelial progenitor cells [11,12], bone marrow-derived stromal cells (BMSCs) [13,14], adipose stem cells (ASCs) [15,16], urine-derived stem cells (USCs) [17–20], hair follicle stem cells [21,22]); allogeneic cells: (such as UC+SMC [23], and MSCs); xenogenous cells: (such as amniotic fluid-derived cells (AFCs) [24], dental pulp stem cells [25], hBMSCs+HSPCs [14], and genetically modified hBMSCs [26]). Different types of stem cells used for urinary bladder reconstruction are listed in (Table 72.1)

Adult stem cells avoid some ethical issues associated with embryonic stem cells (ESCs) or induced pluripotent stem cells (iPSCs). They do not transdifferentiate into a malignant phenotype; thus, there is a diminished risk for teratoma formation or immunogenicity after the cells are implanted in vivo. In addition, these cells possess paracrine effects and immunomodulatory properties, are immune-privileged (i.e., tolerate the introduction of antigens without eliciting an inflammatory immune response), and have a low immunogenic potential [27]. Adult stem cells, especially mesenchymal stem cells (MSCs) and hematopoietic stem cells, are well-investigated cell types in stem cell biology [28]. Adult stem cell research remains an area of intense study, because their potential for therapy may be applicable to various degenerative disorders. Many other types of adult stem cells have been identified in organs all over the body and are thought to serve as primary repair entities for their corresponding organs. The discovery of such tissue-specific progenitors has opened up new avenues for research. Adult stem cell populations have been found in many adult tissues other than the bone marrow, skin [29] and adipose tissue [30], including those traditionally considered a postmitotic organ, such as brain [31], heart [32,33], and urine [34].

ESCs or iPSCs exhibit two remarkable properties: the ability to proliferate in an undifferentiated but still pluripotent state (self-renewal) and the ability to differentiate into different specialized cell types [35]. These cells have been maintained in the undifferentiated state for at least 80 passages and 200 population doublings in vitro when grown using published protocols [36,37]. In addition, human ESCs differentiate into cells from all three embryonic germ layers in vitro. However, these cells are banned for many clinical applications because of risks for immunogenicity and teratoma in addition to ethical dilemmas associated with manipulating embryos in culture.

Although the entire urinary tract system is responsible for excreting ions, metabolic products, and toxic wastes from the body, it is a closed system with a germ-free environment, unlike the digestive system, which is open and does not have sterile conditions. Some living cells in urine can survive for a few hours within the sterile urinary system. Stem cells exist in human voided urine and urine drained from the upper urinary tract. These cells, termed USCs [34], possess stem cell characteristics with clonogenicity, cell growth pattern, robust proliferative potential, and multipotential differentiation. These cells can be obtained using simple, safe, noninvasive, and low-cost procedures, which avoids the adverse events associated with obtaining cells from other sources. A single USC can expand to a large population with 60–70 population doublings [38,39]. When seeded onto a scaffold and subcutaneously implanted into nude mice, multilayered tissue-like structures formed consisting of urothelium and smooth muscle. In addition, USCs differentiated into endothelial, osteogenic, chondrogenic, adipogenic, skeletal myogenic, and neurogenic lineages. However, within the 3 months of study, they did not form teratomas despite telomerase activity. USCs have been used in cell-based therapies and urogenital tissue engineering applications, including urethral tissue [39,40], bladder reconstruction [20], kidney and urethral sphincter [41,42], vesicoureteral reflux [41], and erectile dysfunction [43,44].

TABLE 72.1 Different Sources of Stem Cells for Bladder Regeneration

	MSCs	Primitive Stem Cells	USCs	ESCs/iPSCs	Somatic Cells
Cell types	BMSCs [13,14], adipose stem cells [15,16], Urothelial progenitor cells [11,12], Hair follicle stem cells [21,22] Dental pulp stem cells [25], hBMSCs plus hematopoietic stem and progenitor cells [14] Genetically modified human BMSCs [26]	Amniotic fluid-derived cells [24,48] or placenta-derived stem cells	USCs [17–20],		UC plus SMC [23]
Self-renewal and expanded capability	Limited, PD ~30	High, PD	High, PD 60–70	Very high, PD >200	Limited, PD <30
Multilineage differentiation capability	Multipotent but mainly limited within mesodermal cell lineages	Yes	Multipotent differentiation potential	Pluripotent (can form all lineages)	No
Urothelial, endothelial, or myogenic differentiation capability	Very low	High	High	Low	No
TA/Telomere length	Cannot be detected	Yes	≤75% USC clones possess TA and relative long telomere	Possess TA and long telomere	No
Harvest approach	Invasive, relatively hard to harvest BMSCs at senior level	Aspirate from amniotic fluid	Noninvasive, simple, cost-low, safe	Invasive for iPSCs	Invasive
Pure stem cell isolation	Hard to isolate pure stem cells	Easy	Very easy	Easy	No
Number of stem cells harvested	1 MSC/10^4 BMSCs at newborn baby, 1 MSC/10^6		100–140 USC clones/ 24 h urine in adult		No
Rejection after implanted in vivo	Autogenous or allogeneic	Allogeneic	No rejection	Likely to be rejected if donor is unmatched	No rejection if autogenous cells are used
Oncogenic potential	No reported	No reported	No reported	Yes, harbors disease-causing genes of donor	No reported

AFCs, amniotic fluid-derived cells; *BMSCs*, bone marrow stromal cells; *ESCs*, ethical issues associated with embryonic cells; *iPSCs*, induced pluripotent stem cells; *MSCs*, mesenchymal stem cells; *PD*, population doubling; *SMC*, smooth muscle cell; *TA*, telomerase activity; *USCs*, urine-derived stem cells; *UCs*, urothelial cells.

In chronic bladder diseases, USCs might be a good cell source for bladder tissue regeneration because cells from the upper urinary tract are normal. In treatment of end-stage bladder diseases or muscle-invasive bladder cancer, using engineered bladder tissue with USCs would be superior to bladder reconstruction using intestinal segments. Intestinal segments used for bladder reconstruction appear to be at increased risk for malignancy, particularly adenocarcinoma, because of histologic changes in the intestinal mucosa after long-term exposure to urine. Studies showed that all children with neurogenic bladder disease are at increased risk for bladder cancer regardless of exposure to intestine [45]. Bowel tissue also increases the risk for complications such as stone formation and excess mucous secretion [46]. Harvesting USCs from patients who already have a nephrostomy tube in place would be a simple, noninvasive, and low-cost approach to obtaining cells for engineering bladder tissue.

Alternate sources of stem cells are the amniotic fluid and placenta. These contain multiple partially differentiated cell types derived from the developing fetus [47,48]. Stem cell populations have been isolated from these sources and express embryonic and adult stem cell markers, but they do not form teratomas. The cells are multipotent and can differentiate into cells from all three germ layers. In addition, such cells have high replicative potential and could be stored for future self-use without the risks for rejection and without ethical concerns.

Mechanism of Cell Therapy

Cell Expansion

Fetal stem cells, such as amniotic fluid and primitive stem cells (such as placenta-derived stem cells), showed promise for future clinical applications [47,48]. These cells can develop into cells from the endoderm, mesoderm, and ectoderm and can be maintained for over 250 population doubling (PD). Long telomeres are retained and a normal karyotype without tumorigenicity is observed in vivo [49]. Adult stem cells have been successfully isolated from various types of tissues. These cells usually reach a PD rate of 20–40 in 10 passages [19].

USCs can generate large numbers of cells in a single clone [20,39]. Around 100–140 USC clones can be formed from 24-h urine collection from one individual [50]. Up to 75% of these cells are highly proliferative owing to their relatively higher telomerase activity (USC-TA^{+}) and longer telomeres compared with BMSCs [20]. USCs are reported to have a PD rate of 60–70 for up to 20 passages, whereas other USCs without telomerase activity can be maintained for 8–10 passages with 34 population doublings. Based on this ratio of cells and urine volume, two urine samples containing 20–30 USC clones could potentially yield at least 1.5×10^9 USCs at the end of passage 4 within 4–5 weeks [5,38].

Isolation of USCs is a separation- and digestion-free procedure. Urine samples are simply centrifuged and cells are seeded in mixed media composed of keratinocyte serum-free medium and embryonic fibroblast medium at a 1:1 ratio [34]. Expanded USCs are a relatively homogeneous population and require only 2–5% serum to be maintained in vitro; by contrast, most MSCs require 10–20% serum [20]. When cells collected from voided urine are cultured in USC culture media, only USCs tend to attach to the culture container and continuously expand in culture [9]. This quick, easy, and economical process for USC isolation may also facilitate their large-scale expansion for potential clinical trials.

Multipotentiality

During tissue repair, stem cells accelerate tissue repair and regeneration in various ways (Table 72.2). Although ESCs and iPSCs are pluripotent and can differentiate into multiple specialized cell types [35], their differentiation capability into urologic-specific cell types is relatively low [19]. Under appropriate conditions, BMSCs can be successfully induced into cells with bladder SMC characteristics, both in vitro and in multiple animal models [51–53]. Induced BMSCs proliferate at a rate similar to bladder SMCs and possess a similar histologic appearance and contractile phenotype. However, only 5–10% of cells in BMSCs can be induced into urothelial-like cells with specific lineage marker expression [53–58]. One reason for this could be their relative scarcity; only an estimated 1 in $1–1.5 \times 10^4$ cells in bone marrow are BMSCs [59].

Although the effects of aging on MSCs remain controversial, some studies show an age-related decline in stromal vascular fraction number, proliferation rate, longevity, differentiation potential, and MSC immunophenotype expression in BMSCs from older compared with younger donors [60–64]. This question becomes greatly important because the aging population is increasing, and thus the prevalence of urologic diseases is also increasing. Considering the large quantity of MSCs required for clinical applications (up to 10^9), especially for bladder reconstruction, it is critical to find a stable cell source with potent MSCs [5].

TABLE 72.2 Multiple Modes of Action Assigned to Adult Stem Cells

Multiple Functions of Stem Cells	Outcomes and Potential Applications	References
Multipotent differentiation	Osteocytes, chondrocytes, adipocytes, myocytes, epithelial and endothelial cells for cell replacement	Bharadwaj et al. [20,38]
Secretion of trophic factors	Recruitment resident cells to tissue repair	Liu et al. [119]
Secretion of extracellular matrix	Prompt cell proliferation, rejuvenation, and differentiation of bone marrow-derived stem cells	Pei et al. [120]
Immunomodulatory and antiinflammatory	Inhibited T- and B-cell proliferation to decrease fibrosis	Wu et al. [70]
Gene delivery via angiogenic growth factor gene transfection	Soluble factor gene therapy to accelerate tissue regeneration at site of chronic injury with extensive scarring	Liu et al. and Ouyan et al. [43,121,122].

Unlike many other cell lineages, USCs can efficiently differentiate into urologic tissue-specific cell lineages, including UCs, SMCs, and ECs. They have higher differentiation frequency into UCs than BMSCs. Under the same induction conditions for 7 days, up to 60−70% USCs are induced into a uroepithelial lineage, compared with only 5% for BMSCs [20,65]. When induction extended to 14 days, up to 90% USCs were differentiated. Cells develop a cobblestone-like morphology and express both urothelial-specific cell markers (uroplakin-III and uroplakin-Ia) and generic epithelial cell markers (CK7 and AE1/AE3). Differentiated USCs also present tight junction markers (ZO-1, E-cadherin, and cingulin) in a dose-dependent and time-dependent manner [20]. Those cells display enhanced barrier function with at least a 60% decrease in leakage compared with noninduced cells [20].

Urothelially differentiated USCs were seeded on a porcine small intestinal submucosal (SIS) scaffold and cultured in vitro for 14 days before implantation into nude mice. Constructs generated stratified layers in vivo and neotissue expressed urothelial-specific cell markers (uroplakin-III and uroplakin-Ia). USCs have differentiation potency into SMCs comparable to that of BMSCs [53]. Up to 80% of induced USCs express early smooth muscle differentiation markers (α-smooth muscle actin and calponin), contractile SMC markers (desmin and myosin), and smooth muscle-specific marker (smoothelin) after 14 days' induction with smooth muscle differentiation media in vitro [20]. Cells exhibit rapid lattice contraction as mature SMCs. When implanted in vivo on a porcine SIS scaffold, those cells formed multiple layers of SMCs beneath UC layers and presented SMC markers (desmin, myosin, and α-smooth muscle actin). USCs are also capable of endothelial differentiation with barrier function. EC-induced USCs display vessel-like structures on a solidified Matrigel surface after in vitro induction. Those cells express EC-specific genes (von Willebrand factor [vWF], and CD31), proteins (CD31, vWF, kinase insert domain receptor, fms-like tyrosine kinase-1, and endothelial nitric oxide synthase), and tight endothelial junction marker (VE-cadherin). When implanted subcutaneously into athymic mice, EC-induced USCs effectively form neovessel structures [66].

Paracrine Effects and Immunomodulatory Properties

Stem cells have two important roles in tissue regeneration. First, they can directly replace diseased cells by engrafting, cell fusion, and differentiating into the required host cell type (for example, bone marrow transplant and cell therapy for myocardial ischemia). Second, grafted cells stimulate the host's cells to repair the injured tissue without the donor cells contributing directly to form the new tissue. This happens because the grafted cells secrete factors that signal the host's cells to change their biological behavior and the microenvironment. This signaling from one cell to another is called a paracrine effect.

Adult stem cells also can invoke a paracrine response [67]. The implanted stem cells secrete factors that promote angiogenesis and protect against apoptosis, fibrosis, and inflammation [13,68,69], which prompts the host's cells to repair the tissue themselves. Humans and most mammals have a wound repair mechanism that on its own can only

deal with small wounds, but not for large wounds. Large wound is often remodeled by scar tissue. However, human tissue still possesses regenerative potential once it receives the appropriate signals to initiate internal tissue regeneration and repair provided by paracrine effects of the grafted stem cells.

Although stem cells have a short life span (1−3 weeks) after implantation, they have long-term effects on tissue repair. For example, they appear to be important for initiating tissue regeneration but are expendable once the patient's cells are activated. Paracrine effects are amplified once the grafted cells are attracted to injured tissues. Cells within the damaged tissues often secrete cytokines, regulatory factors that act as mediators to generate an immune response that attracts grafted cells. Sequentially, the grafted cells secrete their own cocktail of proteins that stimulate the host's stem cells and inhabit inflammation and oxidative stress, protect against fibrosis, promote resident cell proliferation, and increase vascularization and blood flow into the injured areas.

In addition, paracrine effects of adult stem cells can reduce immune response and possess immunoregulatory properties. For example, regulatory T cells have an important role in inducing peripheral tolerance, inhibiting proinflammatory immune responses, and decreasing immune reactions. To test the immunomodulatory effects of USCs, our studies demonstrated that USCs can inhibit the proliferation of peripheral blood mononuclear cells (PBMNCs) (T and B cells), and secretion of interleukin (IL)-6 and IL-8 [70]. In the specific experiment, the mononuclear cells usually proliferate when mixed with other somatic cells owing to immune stimulation. In contrast, PBMNC concentrations in USC wells are much lower than in somatic cells, even BMSC culture wells [70]. Colorimetric enzyme-linked immunosorbent assays showed less 5-bromo-2′-deoxyuridine labeled in the USC PBMNC-mixed culture wells and more in BMSC culture wells. As costimulatory molecules, CD80 and CD86 initiate and modulate T-cell immune response. Both CD80 and CD86 expressed on the surface of antigen-presenting cells interact with cytotoxic T-lymphocyte antigen-4 expressed on activated T cells and mediate critical T-cell inhibitory signals. About 3% of the BMSCs were positive for CD80 (versus 1.05% of USCs) and 1.3% of the BMSCs were positive for CD86 (versus 0.55% of USCs). Human cytokine release arrays showed that IL-6 and IL-8 concentrations were elevated after stimulation by PBMNCs in USC supernatant, higher than BMSC supernatant. Thus, it indicates that IL-6 and IL-8 might be the main immunomodulatory cytokines to target in future studies aimed at preventing and treating bladder abnormalities that accompany diabetes, other immune system disorders, or rejection of transplanted organs.

BIODEGRADABLE BIOMATERIALS

A biological scaffold tailored to stem cells is central to mimicking the function of the extracellular matrix (ECM) in tissue engineering. The ECM provides structural support and a physical environment so that cells can attach, proliferate, migrate, differentiate, and function [71]. It confers mechanical properties to tissues and delivers bioactive cues for regulating activities of residing cells; it also provides a dynamic environment for vascularization and new tissue formation. Scaffolds can be designed to stimulate and direct tissue formation to replace portions of tissues or whole tissue structures. The material would possess appropriate porosity and microporosity (interconnectivity between pores) to expedite cell attachment, migration, penetration, differentiation, tissue growth, and integration. The ideal type of cell replacement should be composed of materials with similar physical and mechanical properties as the native tissue and should degrade at the same rate as the new tissue is generated. Porosity should allow nutrient transfer and cell adhesion without compromising mechanical strength. Two categories of scaffolds designed to carry cells include synthetic scaffolds and natural collagen matrix for bladder regeneration (Table 72.3).

Synthetic Scaffolds

Various porous structures composed of natural or synthetic biodegradable and biocompatible materials have been used as scaffold carriers. Some biomaterials have been approved by the US Food and Drug Administration (FDA) for use in medical devices in humans. These include polyesters of naturally occurring α-hydroxy acids such as polyglycolic acid (PGA), polylactic acid, poly(lactic-*co*-glycolic acid), and polycaprolactone. Metabolites formed after degradation of these materials have been confirmed to be nontoxic and are eventually eliminated from the body as carbon dioxide and water [72]. Because these polymers are thermoplastics, they can easily be formed into a three-dimensional (3D) scaffold with the desired microstructure, gross shape, and dimensions by various techniques, including molding, extrusion [73], solvent casting [74], phase separation techniques, and gas foaming techniques [75]. In addition, synthetic polymers can be manufactured on a large scale using various

TABLE 72.3 Summary of Advantages and Limitations of Biodegradable Materials for Bladder Regeneration

	Advantages	Limitations
SYNTHETIC SCAFFOLDS		
• PGA/PLGA • PLLA • Collagen-fibrin hybrid scaffold with IGF1 [123] • Acellular collagen-heparin scaffolds with growth factors [124] • VEGF-loaded nanoparticle-modified BAMAs [125] • PGA with PGA–chitosan "sandwich" graft [126]	• Renewable, sustainable, biodegradable • Safe for use, nontoxic, free-immunogenic, free-carcinogenic, free-thrombogenic • Ease of manufacturability • Reasonable cost • Durable and storage stability • Process ability: fine complex architectures such as porosity rate, pore size can be generated; highly controllable • Consistent products	• Take time to be degraded • Poor biocompatibility • potential toxic degradation of by-products • Lacks specific integrin-binding site
BIOLOGICAL SCAFFOLDS		
Silk fibroin [23,127,128], or BAMG-SF matrix [128] SIS [129–131], BSM BAMG [15,24,132] or UBM [133] Decellularized colon matrix [134] Matrix with hydrogel (such as HA-PLGA-modified SIS [135])	• Unlimited source biomaterials • Easy to produce • Most allogenic or xenogeneic antigen contents can be removed after decellularization • Native architecture is preserved • Growth factors and cytokines bound with matrix remain • Integrin-binding sites are retained • Easy to suture to bladder tissue	• Variability depending on the source of biomaterial • Antigenicity • Weak biomechanical properties • Not suitable for subtotal cytoplasty • Take time to produce in the laboratory

BAMA-SF, bladder acellular matrix graft-silk fibroin; *BAMG*, bladder acellular matrix grafts; *BSM*, bladder submucosa membrane; *HA-PLGA*, hydroxyapatite-poly(lactide-*co*-glycolide). *IGF*1, insulin-like growth factor 1; *PGA/PLGA*, polyglycolic acid/polylactic-*co*-glycolic acid; *PLLA*, poly-L-lactic acid; *SIS*, small intestine submucosa; *UBM*, urinary bladder matrix; *VEGF*, vascular endothelial growth factor.

techniques including electrospinning [76], phase separation, gas foaming, particulate leaching, inkjet printing, and chemical cross-linking. Strength, degradation rate, and microstructure may be adjusted during manufacturing. Scaffolds can be made in different shapes and porosity to facilitate cell engraftment, or they can be further modified by incorporation, surface adsorption, or chemical attachment of bioactive factors. However, a drawback of synthetic polymers is the lack of biologic recognition. To incorporate cell recognition domains into these materials, copolymers with amino acids have been synthesized [77]. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(orthoesters), can be used to fabricate scaffolds with controlled properties [78].

Biodegradable Properties

Biodegradable biomaterials in tissues of the urinary tract system function as an artificial ECM to replace biologic and mechanical functions of native ECM. These biomaterials facilitate localization and delivery of cells or bioactive factors (e.g., cell adhesion peptides, growth factors) to desired sites in the body and define a 3D space for the formation of new tissues with appropriate structures. They are also a guide for the development of new tissues with appropriate function. Direct injection of cell suspensions without such matrices has been used in some cases [79]. However, without this scaffold function, localization of transplanted cells is difficult to control.

For cell-based tissue engineering, expanded cells are seeded onto a scaffold synthesized with the appropriate material. Because most mammalian cell types are anchorage-dependent and will die if no cell adhesion substrate is available, biomaterials provide such a substrate capable of delivering cells to specific sites with high loading efficiency. Biomaterials can also provide mechanical support against in vivo forces, maintaining the predefined 3D structure during tissue development. Furthermore, bioactive signals such as cell-adhesion peptides and growth factors, can be loaded to regulate cellular function. Generally, two classes of biomaterials are used for engineering of genitourinary tissues: synthetic polymers and acellular tissue matrices. Although synthetic polymers can be produced on a large scale with controlled properties of strength, degradation rate, and microstructure, naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition, which can lessen host-versus-graft reactions.

Limitations of nutrient and gas exchange restrict tissue engineered implants to a volume of approximately 3 mm^3. Therefore, to engineer large complex tissues and organs, vascularization of the regenerating tissue is essential. Three approaches have been used to encourage the vascularization of bioengineered tissue. First, incorporating angiogenic factors into bioengineered tissue can attract host capillaries and enhance neovascularization. Second, some studies have investigated the effects of seeding endothelial cells with other cell types in the bioengineered tissue [69]. Finally, vascularizing the matrix before cell seeding has been attempted. There are many obstacles to overcome before large tissue engineered solid organs are produced, but developments may provide important knowledge and essential materials to accomplish this goal.

Porosity

Recellularization of biological materials (scaffold) with cell-seeded technology provides a promising option in tissue regeneration. The scaffold needs to have a 3D structure with high porosity but also maintain normal tensile strength. A 3D scaffold with higher porosity and relative larger pore size (50−200 μm) promotes cell proliferation, migration, and infiltration into the matrix and appears to allow abundant cell loading onto the scaffold, thereby promoting in vivo tissue regeneration [80−82]. Treatment with 5% peracetic acid led to high porosity on the surface of the matrix with less cellular material retained; about 75% of normal tensile strength remained. Cells penetrated deeper into the lamina propria of the matrix compared with untreated matrix [83].

Natural Collagen Matrix

Naturally occurring matrix materials may also function as 3D scaffolds in tissue engineering and regenerative medicine, including both decellularized natural matrix and matrix produced from naturally extracted polymers. Natural materials are widely used in tissue regeneration such as bladder submucosa (BSM) and SIS, and naturally derived materials such as collagen, silk fibroin (SF), and alginate. As the most abundant structural protein in the body, collagen is an FDA-approved biocompatible material for various medical uses. Natural decellularized ECM retains tissue-specific architecture and provides various biological and physical material properties specified by the nature of the original tissue. Such matrix materials also share highly conserved matrix proteins among species, such as collagen, laminin, and fibronectins, which suggests that they could be nonimmunogenic and attractive for the purposes of recellularization and tissue integration.

Under certain circumstances, UCs and SMCs differentiated from adult stem cells can form multiple uniform layers on porcine decellularized SIS scaffold in vitro and in vivo, which shows the potential of this 3D cell/matrix to develop into a multilayer mucosal structure similar to native urinary tract tissue [40]. When seeded with USCs, bacterial cellulose scaffolds represent a promising material for urinary conduits with a multilayered urothelium and cell/matrix infiltration in vitro and in vivo [39]. However, in the context of future clinical applications, decellularized matrix could be contaminated by xenogeneic factors. There is also a risk for incomplete decellularization and residual cell bodies and altered tissue properties owing to complete decellularization and deproteinization [84,85].

Acellular Tissue Matrices

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues, often by mechanical and chemical manipulation of a segment of bladder tissue and small intestine [40,86]. Matrices slowly degrade after implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrowing cells. Acellular tissue matrices support cell ingrowth and regeneration of genitourinary tissues, including urethra and bladder, with no evidence of immunogenic rejection [86]. Because protein structures (e.g., collagen and elastin) in acellular matrices are well-conserved and normally arranged, the mechanical properties of acellular matrices are not significantly different from those of native BSM [87].

Collagen

Collagen is the most abundant and ubiquitous structural protein in the body and is readily purified from both animal and human tissues through enzyme treatment and salt/acid extraction. Collagen exhibits minimal inflammatory and antigenic responses and is approved by the FDA for many types of medical applications, including wound dressings and artificial skin [88]. This material can be processed into various structures such as sponges, fibers, and films [89].

Silk

SF is a protein obtained from *Bombyx mori* cocoons and may have potential uses in low urinary tract reconstruction. SF contains up to 90% of the amino acids glycine, alanine, and serine found in other natural biomaterials. SF has excellent biocompatibility and low inflammatory properties and can be fully degraded by naturally occurring proteolytic enzymes [90]. SF has used as an effective biomaterial for bones [91], cartilage [92], blood vessels [93], peripheral nerves [94], cornea [95], bladder [96], and urethra [97], among other tissues. Silk processing methods enable the construction of films [98], foams [99], hydrogels [100], gel-spun matrices [96], and woven or nonwoven meshes [101]. Electrospinning may also be an appropriate technique for urethral reconstruction with SF because it can create a 3D and highly porous scaffold in a conformation that mimics ECM structure in vivo [76].

Matrix Binding With Growth Factors

Tissue engineering approaches should mimic the in vivo setting by providing a biocompatible scaffold, a cell source of appropriate progeny or type, nutrients and other environmental conditions, and appropriate bioactive factors. Localized delivery of bioactive factors is understood to be effective and necessary in mimicking the natural microenvironment of cells within specific tissues. Delivering biomolecular cues, especially growth factors, in solution is difficult because of their rapid diffusion to extracellular fluids, and growth factors always have a limited half-life in vivo. However, sustained delivery of growth factors is important for clinical applications of tissue engineering.

Vascular endothelial growth factor (VEGF) is an important active protein for inducing angiogenesis in tissue engineering, but it requires a delivery system targeted to a given site. There are several ways in which matrix could binding with growth factors. Native human VEGF fused with a collagen-binding domain (CBD-VEGF) can bind to collagen specifically to exert angiogenesis effects that promote regeneration. CBD-VEGF was constructed by linking a sequence that encodes the collagen-binding domain (TKKTLRT) with VEGF complementary DNA. CBD-VEGF was inserted into one plasmid (pET-28a). The plasmid was transformed into the BL21 strain of *Escherichia coli*. CBD-VEGF could be purified from the protein made from *E. coli*. When collagen was used as a scaffold in tissue engineering to which CBD-VEGF can bind in vitro and in vivo, VEGF could maintain activity [102].

PRECLINICAL MODELS

Tissue Regeneration Models

Two in vivo experimental models have been used for bladder regeneration, including hemi-cystoplasty (in which 40−50% of bladder tissues are removed) and subtotal cystoplasty (in which >75% bladder tissue is removed or trigone-sparing cystectomy is performed) (Table 72.4). Cell-seeded or cell-free seeded scaffolds are capable of increasing bladder volume in small animals after hemi-cystectomy, whereas cell-seeded scaffolds are often designed to replace diseased bladder in a larger animal model after subtotal cystectomy. A rodent model such as rat is often used to test new cell sources or new biomaterials and study histologic changes in the regenerative bladder. Larger animal models are used to evaluate further the alterations in bladder function and volume, and anatomic and histologic structures (Table 72.5), in preparation for clinical applications. Beagles or minipigs are most commonly used larger animal models for these purposes.

Fibrotic Bladder Model

Most in vivo experiment models of tissue engineered bladders are performed in the normal bladder after cystectomy. However, in clinical situations, patients have diseased bladders with fibrosis or chronic inflammation or lack a good blood supply. Thus, a model is needed that mimics disease conditions to test the potential of tissue engineering technology. Several approaches have been used to create a neurogenic bladder dysfunction model [103] or fibrotic bladder model induced by bladder atrophy owing to urinary diversion [104], bladder ischemia [105], or chemical agents [106].

To generate a bladder atrophy model, urinary diversion is performed to cause a rapid decrease in contractile function in adult or fetal animal bladders. Liu et al. [104] developed a urinary diversion model in the rat. Female Sprague-Dawley rats were distributed into age matched control, sham urinary diversion and urinary diversion groups. Each group was subsequently evaluated 1 or 8 weeks after urinary diversion or sham operation. Diversion was done by surgical disconnection of the ureters from the bladder and implantation into the uterine cervix. The results demonstrated that bladder weight decreased in the diversion group. The urinary diversion group had decreased

TABLE 72.4 Experimental Animal Models for Bladder Reconstruction

	Advantages	Challenges
SURGICAL PROCEDURES		
Hemi-cystoplasty	• Evaluation of cell-seeded or nonseeded tissue engineered technology for bladder augmentation • Neobladder often retains contractile function because of original bladder plus regenerated bladder • Histologically, fully regenerated urothelium; partial muscle regeneration and innervation	Stone formation, graft shrinkage
Subtotal cystoplasty	• Assessment of cell-seeded tissue engineering technology for bladder replacement • Acts as urinary reservoir • Regenerated urothelium • Bladder capacity increases at early stages	• High risk of graft collapse or shrinkage and bladder stone formation • Limited innervation, myogenesis and blood supply at center of graft • Bladder volume may decrease over time
ANIMAL MODELS		
Large animals		
Canine [24,132,135,136]; Porcine, i.e., juvenile Yorkshire swine [27,127]; rabbit [23]; sheep [124]; nonhuman primates [13]	• Physiology, anatomy, and histology similar to humans; • Autograft models; • Easy development of subtotal cystoplasty model • Test both synthetic or thicker nature-based collagen scaffold with cells • Easy to perform urodynamic studies • Enough tissue regenerated to perform contractility studies of muscle strips in organ bath	• High cost to purchase and maintain large animals • Not easy to fix urethral catheter after surgery in pigs and nonhuman primates
Small animals		
Athymic rodent [26] and Rat [15,123,128,134]	• Easy to maintain • Well-known histology • Allogeneic and xenogeneic-grafted stem cells not rejected by the host • Economical • Commonly used for hemi-cystoplasty • Dynamically observe bladder regenerative processes at the different time points • Allogeneic or even xenograft models	• Subtotal cystoplasty model not possible • Require thinner scaffold • High risk of stone formation • Requires special fine devices for urodynamic study and images • Cannot observe immune reaction within graft in immunodeficient rodents

intercontractile intervals and voided volumes compared with the control and sham-operated groups. Compliance was decreased in bladders of rats with urinary diversion. Smooth muscle and urothelium were decreased as a proportion of the total bladder cross-sectional area. Collagen increased in rats with either 1 or 8 weeks of urinary diversion versus controls. Urinary diversion caused decreased expression of muscarinic 3 and ligand-gated purinergic 1 receptor but no change in muscarinic 2 or ligand gated purinergic 2 receptors. Urinary diversion causes dysfunctional and abnormal morphometric alterations in the bladder in this model.

In a study by Matsumoto et al. [107], urinary diversion was performed on fetal sheep after 90 days of gestation (term = 147 days) and bladder tissue was obtained 2 weeks later. Bladders from fetal sheep subjected to urinary diversion weighed significantly less than control fetal bladders. Marked reorganization of smooth muscle elements was observed in those with diversion. Carbachol stimulated a tonic contraction whereas field stimulation administered during tonic contraction elicited a phasic relaxation or a biphasic response consisting of an initial relaxation

TABLE 72.5 Criteria for Tissue Engineering Techniques for Bladder Regeneration

PREIMPLANTATION	
Cells	• Characterize cell proliferation capacity, phenotypes, paracrine effects of stem cells, urothelially and myogenically differentiated stem cells or cultured urothelial and smooth muscle cells with immunocytochemical staining; label to monitor fate of grafted cells if needed.
Scaffold	• Determine biocompatible, biodegradable and mechanical properties, porosity, pore size, and bioactive proteins within scaffold (for natural collagen-based extracellular matrix biomaterials)
Cell–biomaterial interaction	• Demonstrate interactions for cell adhesion and infiltration into scaffold using histologic techniques
POSTIMPLANTATION	
Gross examination	• Graft size and hardness, tissue adhesion around organs • Signs of graft contraction, stones, or calcification on bladder lumen side
Bladder function tests	• Bladder volume, pressure, and contraction style with urodynamics • Contractility of regenerated bladder strips assessed with organ bath
Histologic structure	• Cell survival rate • Distribution and life span of labeled graft cells • Entirety of urothelial layers and thickness of muscle layers • Ratio of collagen and muscle in regenerated bladder tissue • Angiogenesis or revascularization and innervation

and then a phasic contraction in control and diverted bladders. Contractile responses of defunctionalized strips to carbachol were significantly less than those of control bladder strips. In brief, urinary diversion in normal fetal sheep resulted in marked bladder atrophy, reduced muscle mass, and decreased bladder contractility.

Both indwelling urethral catheterization and suprapubic catheterization are types of urinary diversion. The former is associated with a risk for urolithiasis, urethral trauma, urethral erosions and/or strictures, bladder fibrosis, epididymitis, orchitis, and bladder cancer. Therefore, in most clinical cases, indwelling urethral catheters are inappropriate for long-term treatment and suprapubic catheters are a better option. However, clinical data [108] showed that long-term indwelling urinary catheterization has similar rates of upper tract damage, vesicoureteral reflux, renal or bladder calculi, and symptomatic urinary tract infections compared with suprapubic catheters. The catheter was changed every 2 weeks, which can prevent the complications of indwelling urethral catheterization. Although a bladder dystrophy model is closer to diseased conditions, it is time-consuming to create such a model. A novel bladder fibrotic model is needed for bladder tissue regeneration studies.

CLINICAL TRIALS

Clinical Translation

Human urothelial and muscle cells can be expanded in vitro, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells. The cell–polymer scaffold can then be implanted in vivo. Histologic analysis indicated that viable cells were able to self-assemble back into their respective tissue types and would retain their native phenotype [109]. These experiments demonstrated for the first time that composite layered tissue engineered structures could be created de novo. Before this study, only nonlayered structures had been created in the field of regenerative medicine.

To determine the effects of implanting engineered tissues in continuity with the urinary tract, animal models of bladder augmentation were used [110]. Partial cystectomies were performed in dogs. The animals were divided into two experimental groups. One group had the bladder augmented with a nonseeded bladder-derived collagen matrix; the second group had the bladder augmented with a cell-seeded construct. The bladders augmented with matrices seeded with cells showed a 100% increase in capacity compared with bladders augmented with cell-free matrices, which showed only a 30% increase in capacity.

Most of the free grafts (without cells) used for bladder replacement in the past were able to show adequate histology in terms of a well-developed urothelial layer, but they were associated with an abnormal muscular layer that varied in terms of its full development. It has been well-established for decades that the bladder is able to regenerate generously over free grafts. Urothelium is associated with a high reparative capacity. Bladder muscle tissue is less

likely to regenerate in a normal fashion. Both urothelial and muscle ingrowth are believed to be initiated from the edges of the normal bladder toward the region of the free graft [111]. Usually, however, contracture or resorption of the graft has been evident. The inflammatory response toward the matrix may contribute to the resorption of the free graft. It was hypothesized that building 3D structure constructs in vitro before implantation would facilitate the eventual terminal differentiation of the cells after implantation in vivo and minimize the inflammatory response toward the matrix, thus avoiding graft contracture and shrinkage. The dog study demonstrated a major difference between matrices used with autologous cells (tissue engineered matrices) and those used without cells [110]. Matrices implanted with cells for bladder augmentation retained most of their implanted diameter, as opposed to matrices implanted without cells for bladder augmentation, in which graft contraction and shrinkage occurred. The histomorphology demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in matrices implanted without cells. Epithelial mesenchymal signaling is important for the differentiation of bladder smooth muscle [112]. The results of initial studies showed that the creation of artificial bladders may be achieved in vivo; however, it could not be determined whether the functional parameters noted were caused by the augmented segment or the intact native bladder tissue. To address the functional parameters of tissue engineered bladders better, an animal model was designed that required a subtotal cystectomy with subsequent replacement with a tissue engineered organ [113].

Cystectomy-only and nonseeded controls maintained average capacities of 22% and 46%, respectively, of preoperative values. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue engineered bladder replacements. These findings were confirmed radiographically. The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% total compliance, respectively). The compliance of the cell-seeded tissue engineered bladders showed almost no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal UCs with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue engineered bladders showed a normal cellular organization consisting of a trilayer of urothelium, submucosa, and muscle. Immunocytochemical analyses confirmed the muscle and urothelial phenotype. S-100 staining indicated the presence of neural structures [113]. These studies, which were performed with PGA-based scaffolds, have been repeated by other investigators and showed similar results in large numbers of animals over the long term [114]. The strategy of using biodegradable scaffolds with cells can be pursued without concerns regarding local or systemic toxicity [115]. However, not all scaffolds perform well if a large portion of the bladder needs replacement. In a study using SIS for subtotal bladder replacement in dogs, both the unseeded and cell-seeded experimental groups showed graft shrinkage and poor results [116]. The type of scaffold used is critical to the success of these technologies. The use of bioreactors, in which mechanical stimulation is started at the time of organ production, has also been proposed as an important parameter for success [117,118].

To evaluate the effect of cell-seeded tissue engineering technology in the bladder regeneration compared with scaffold alone, a group of experimental dogs underwent a trigone-sparing cystectomy and were randomly assigned to one of three groups. One group underwent closure of the trigone without a reconstructive procedure, another underwent reconstruction with a nonseeded bladder-shaped biodegradable scaffold, and the last underwent reconstruction using a bladder-shaped biodegradable scaffold that was seeded with autologous urothelial and SMCs [113]. The cystectomy-only and nonseeded controls maintained average capacities of 22% and 46%, respectively, of preoperative values. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue engineered bladder replacements; however, the subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42%, respectively, of total compliance). The compliance of the cell-seeded tissue engineered bladders was almost no different from preoperative values (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal UCs with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue engineered bladders showed normal cellular organization consisting of a trilayer of urothelium, submucosa, and muscle [113], indicating the benefit of cell-seeded tissue engineering technology in the bladder reconstruction, compared with the nonseeded tissue engineered bladder.

Clinical Studies

Clinical experience involving engineered bladder tissue for cystoplasty reconstruction started in 1998. A small pilot study of seven patients was reported [5] using a collagen scaffold seeded with cells with or without omentum

coverage or a combined PGA−collagen scaffold seeded with cells and omental coverage. Patients reconstructed with the engineered bladder tissue created with the PGA−collagen cell seeded scaffolds showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods over time [5]. It is clear from this experience that the engineered bladders continued to improve with time, mirroring their continued development. Although this report was promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional bladders. This was a limited clinical experience; the technology is not yet ready for wide dissemination because further experimental and clinical studies are required. FDA phase II studies have been completed.

CONCLUSION

We reviewed experimental and clinical data related to bladder regeneration, highlighting the use of different stem cell types and various biomaterials. Progress suggests that engineered urologic tissues may have wide use for clinical applicability. Assessments of the histologic structure and physiologic function of the urinary bladder can better elucidate mechanisms responsible for functional tissue engineered bladders. Well-established in vitro and in vivo models are available for experimental evaluations of the regenerated bladder, providing invaluable data to predict clinical efficacy.

Standard cell culture studies can define the biological and molecular cues of urothelial, smooth muscle, and endothelial cells or differentiated stem cells. Novel and noninvasive cell sources are needed to improve the regenerative efficacy of urinary bladder further. In addition, 3D construction remains critical to recapitulate the epithelial-stromal microenvironment in bladder regeneration studies. The development and optimization of reliable and reproducible scaffolds with the necessary porosity, biodegradability, flexibility, and firmness are vital for assessing the in vitro and in vivo efficacy of tissue engineered bladders. Biomaterials coated with growth factors are promising tools for bladder regeneration. Therapeutic investigations should be continued with the development of new biomaterials and optimized cell source to improve treatment outcomes for bladder diseases through tissue engineering technology.

Therapeutic Applications: Tissue Engineering of Skin

Fiona M. Wood

University of Western Australia, Perth, Australia

INTRODUCTION

There has been an explosion of activity in the field of skin tissue engineering (TE) specifically focused on skin repair and regeneration. A simple online search of the key words "tissue engineering" and "skin," 2007–17, reveals 51,842 publications, 41,780 of which are peer reviewed. Progress has been made in the areas of biomaterials for scaffold generation, the reliable source of cells, and novel approaches to assembly such as three-dimensional (3D) printing. However, skin is much more than a two-layered waterproof construct that provides microbiological protection. Comprehensive skin functioning involves maintaining homeostasis with intimate connectivity with the immune neuroendocrine systems. There is an intimate relationship with the underlying fat of the hypodermis and skin adnexal structures are functionally active [1]. Therefore, a fully integrated vascular and neural network is essential for cellular and neural signaling and driving cutaneous responses to changes in both the host and external environments [2]. The skin adnexal structures remain elusive to large-scale replication although our body of knowledge is building. Furthermore, the challenges of developing a vascularized construct integrating small vessels are such that the rapid or immediate restoration of skin function remains an ambitious goal [3].

Each of us is a self-organizing mass of multiple cell types. From fertilization of the embryo onward, our tissue structures develop until an adult morphology is achieved. At that point, our capacity for self-organization is directed to maintaining that morphology in the face of daily insults and the processes of aging. When a given insult overwhelms our capacity to repair by regeneration, the result is scar repair [4].

We know that tissues retain the variable ability to heal by regeneration [5]. With respect to the skin, in all but trivial injuries the capacity for regeneration is exceeded, triggering cellular mechanisms that result in scar formation. The mechanism of pathology or injury also has an impact on the outcome; for example, burn injury is notorious for developing aggressive scars that compromise the individual functionally, cosmetically, and psychologically [6].

It has been well-described that to heal a wound, we need a source of cells capable of differentiating into the given tissue type and an extracellular matrix (ECM) capable of supporting cell migration, proliferation, and differentiation [7]. We and others have spent considerable resources researching these areas to improve the speed and quality of wound healing to reduce the scar [8]. The question we ask is: "How can we harness the technology of TE of skin to provide a controlled repair to restore the original morphology?"

TE was initially coined by Vacanti in 1990 and can be defined as the application of engineering principles to biological systems [9]. The healing of skin has been the subject of writings as far back as ancient times with the attempts to stimulate healing, protect the surface while healing, and even replace the skin surface [10]. Explorations into using TE principles in skin repair are based on a significant history. With the increasing knowledge and understanding of the skin structure and function along with the developing TE techniques, the question remains, can we provide a regenerative repair avoiding scar?

We know that the skin provides the barrier to the external environment as a dynamic, complex, 3D structure made of cells from all embryological layers. Integral to its functions are the vessels and nerves within the tissue construct. Furthermore, skin is specialized over different body sites, adapting to local functional needs demonstrated by the

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00073-4

macroscopic differences seen between areas, e.g., the eyelid compared with the palm of the hand. Notable body site differences are seen in the distribution and character of the hypodermis and adipose tissue with an influence on the function and repair potential. The varying capacity of skin to respond to injury is seen with the greater scar potential of sternal and deltoid areas [11].

Thus, as we go forward in developing TE solutions to skin, it is timely to take stock of the skin's functions and interactions. How will skin's changes over the different body sites influence TE needs? Collaboration with specialists in bioinformatics will be essential to understanding the implications of changes in genes, genetic expression, and epigenetics with the resulting phenotypic expression we need to guide the cells and matrix interactions into the tissue constructs [12].

In the therapeutic use of TE, an understanding of the etiology of the skin defect and pathophysiology of the patient will identify what needs to be replicated, rebuilt, and replaced.

Implementation into clinical practice hinges on the TE being problem-driven, providing a practical, timely, cost-effective solution to the clinical problem [13]. TE technologies have been used to produce skin constructs used to test a range of topical preparations and explore toxicology. However, from a clinical viewpoint, TE of skin has developed in response to the clinical need for, e.g., skin repair in major burns [14], chronic ulcers [15], and giant nevi [16]. It is clear that the current reference standard of skin loss, skin grafting, will always leave a scar [17]. The development of TE creates the opportunity to tailor the repair to the defect with the understanding that one solution will not fit all. TE offers innovative solutions providing a spectrum of clinical solutions including:

- strategies to facilitate wound healing in situ by introducing bioactive agents ranging from biomaterials to cell-based therapies, and
- the development of laboratory-based, multilayered tissue constructs including multiple cell types tailored to a specific skin defect.

The development of TE of skin is intimately linked to the vision of facilitating scar-free healing. It has broad implications for after trauma or surgery and in fibrosing pathologies in which the common outcome is a functional compromise owing to the distortion of normal tissue architecture. In the developed world, it is estimated that 100 million patients acquire scars each year as a result of 55 million elective operations and 25 million operations after trauma. Within this number, it is estimated that there are approximately 11 million keloid scars and four million burn scars, 70% of which occur in children [18]. There is a clear opportunity to affect survival and quality of life by engaging in TE solutions.

We are living in a time when science and technology are advancing at an exponential rate. Harnessing the power of that science and technology into clinical practice presents an ever-increasing challenge. We are all aware of the latest breakthroughs holding promise to improve the quality of life, such as genetic engineering facilitating DNA manipulation to improve health. However, the growth of knowledge is possible in controlled systems in which experiments can be designed to investigate a single variable; here lies the greatest challenge: for example, in burn injury research. The design of clinical trials is dogged by the complexities of assessing the extent of injury, the individual's response, and the availability of validated outcome measures.

Clinical practice is a fusion of experience and knowledge with the development of medical subspecialization directed toward a targeted problem-solving approach and has facilitated great advances in clinical care. However, this should not be at the expense of broad general knowledge gaining insight into potential links and facilitating cross-fertilization. It is essential to link the tissue engineer with the clinical specialist to ensure that the opportunities, risks, and benefits of TE skin are understood, to facilitate appropriate clinical trials. By collaboration among disciplines, there are real opportunities for improvements in clinical care translating to improved outcomes for patients [19].

The road from the bench to the bedside is long and navigates the areas of regulation, commercialization, reimbursement, and clinical trial design, to name a few. Also, translational research itself is an area in need of research and audit. The investigation of drivers and barriers to the implementation of TE skin solutions is an area of increasing effort. It is vital to learn from history and understand the current situation to continue developing innovative TE solutions but also innovative solutions within health systems, to move timely translation into clinical practice.

To put the challenges and opportunities into context, this chapter will:

- explore the functions of the skin and injury responses we need to understand to harness the TE technology effectively,
- identify the needs that could be supplied by TE strategies,

- discuss available technologies,
- demonstrate TE skin solutions in clinical practice, and
- look to future challenges in areas with a need for further development.

DEVELOPMENT, ANATOMY, AND FUNCTION OF SKIN

Skin is commonly described as a multilayered physical barrier composed chiefly of the surface cellular epidermis and relatively acellular dermis. Exploring the development, anatomy, and functions of skin demonstrates its complexity and will guide our TE endeavors.

> There is no magician's mantle to compare with the skin in its diverse roles of waterproof, overcoat, sunshade, suit of armour and refrigerator. Sensitive to the touch of a feather, to temperature and pain, withstanding the wear and tear of three score years and ten and executing its own running repairs. *[20]*

During development the initial covering of the embryo is the periderm, which is thought to have a barrier function expressing tight junctions; it interacts with the amniotic fluid, which has surface microvilli. Periderm cells express keratins, which are also associated with migratory epidermal cells seen in wound healing. During the first 6 weeks, the epidermis becomes two-layered, with the outer periderm and the inner developing epidermis. During this time there is no dermis, but a subepidermal cellular layer with deposition of basement membrane type IV collagen and laminin is seen by 5 weeks. By 8 weeks, there is evidence of vascular development. During the embryonic fetal transition stage at 9–10 weeks, several changes are seen:

- epidermal cells express keratins 1 and 10, which are associated with differentiation;
- maturation of the basement membrane occurs with the development of cell adhesion and expression of integrins a6 and b4;
- rapid deposition of dermal matrix takes place;
- migration of melanocytes begins from the neural crest;
- Langerhans' cells are detected originating in the fetal thymus and bone marrow; and
- Merkel cells are seen initially in the epidermis and subsequently in the dermis.

The early fetal period from 11 to 14 weeks sees the development of the hair follicles within the skin. The skin adnexal structures continue to develop and mature into the midfetal period at 15–20 weeks. As the fetus grows in the late period, 20–40 weeks, acceleration of stratum corneum can be identified in specific regions, including the palms, soles, face, and scalp. There is a close association between keratinization and hair follicle development, with the stratum corneum developing initially in the perifollicular regions. The mature stratum corneum is a structure that develops in the late fetal period: a combination of the terminally differentiated keratinocytes forming a cornified envelope and lipid extrusion from the abundant lamellar bodies of the granular layer keratinocytes.

Embryologically, the neural tissue and the epidermis are derived from ectoderm. By the end of the fourth week of embryonic development, the neural ectoderm has separated from the surface ectoderm, forming the neural tube. Under normal conditions, the nerve endings will never be exposed to the external environment. The skin forms the interface and has developed as the interactive responsive surface. In the following weeks, mesoblastic cells from the neural crest migrate into the skin as melanoblasts and the early nerve fibers develop as the vasculature migrates into mesodermal elements destined to become dermis. A close association is seen in development with the skin, developing as a tactile organ providing feedback information from the surface to the developing central nervous system (CNS). An understanding of neural plasticity of the CNS and the peripheral nerve field underpins the self-organization principle. The co-development is put forward as an explanation of the coevolution of the human CNS and the skin as an adaptive dynamic interface.

In the fully developed skin, there are cells from all three embryological layers in a complex framework of ECM. There are functions common to all skin areas, but there has also been adaptation to the specific functions of given body sites that are seen even at the early fetal stages.

The mature epidermis is composed primarily of keratinocytes arising from a layer of basal cells situated on the basement membrane. As the keratinocytes differentiate, they form a stratified squamous epithelium. As the cells undergo terminal differentiation, they lose their nuclei and form a highly cross-linked protein-based layer of keratin. The basal cells are in intimate contact with terminal dendrites: synapse-like structures have been described between nerve endings and keratinocytes. The melanocytes are situated in the basal layer with the melanosomes being

transferred to the differentiating keratinocytes giving the color of the skin owing to pigment load. The cells linking to the immune system, Langerhans' giant cells and dendritic cells, are also present in the epidermis. The epidermis is specialized to the body sites, most noticeably with the thickened cornified layer of the sole and palm [21].

The dermis is attached to the epidermis at the dermal epidermal junction by the basement membrane morphologically arranged as the rete pegs, which are exaggerated in the glabrous skin areas. The dermis is mainly connective tissue, predominantly collagen, with elastin seen in the superficial papillary dermis. The fibroblast is the cell that produces the ECM, which is specialized over differing body sites; areas such as the groin and axilla are thin and more elastic than the thicker, more rigid dermis of the back. Cells of hematopoietic origin such as lymphocytes and macrophages migrate into the dermis as the vascular bed becomes established and are involved in immune surveillance. The neural and vascular networks maintain the skin and facilitate the functions of the dynamic interactive skin interface [22].

The investigation of wound healing, in parallel with an understanding of skin development and functions, gives us the opportunity to develop innovative methods further to apply to TE. The skin has developed specifically in relation to the multiple functions it performs. As an active organ, it is responsive to changes in the external and internal environment, pivotal in maintaining the body's homeostasis. Our knowledge of skin functions is still growing and includes:

- a semipermeable barrier, overcoat, and suit of armor;
- thermoregulation and refrigerator;
- antibacterial and waterproof;
- UV protection and sunshade;
- sensory receptor that is sensitive to the touch of a feather, temperature, and pain;
- self-regenerating, withstanding the wear and tear of a lifetime;
- capable of rapid repair, executing its own running repairs;
- immune modulation;
- psychological interaction; and
- vitamin production.

The loss of skin integrity can result in severe morbidity and even mortality. The body needs a barrier against the atmosphere to maintain homeostasis. The production of the stratum corneum can be mimicked in tissue culture by exposing a sheet of keratinocytes in culture to an air–liquid interface [23], but it requires maturation in situ to develop the "smart material" of the enucleated cell bodies fully and the extracellular lipoproteins moisturized by vitamin E–producing sebum.

The keratinocytes produce surface proteins that are antimicrobial in the first line of defense against colonizing bacteria on the skin surface [24]. The expression of these proteins changes as the keratinocyte is stressed, as in wounding or culturing, such that protection from microbial invasion is highlighted.

The multiple and specific sensory inputs to the skin are pivotal in regulating the body's temperature and immune responses and psychological responses via neural and neuroendocrine control systems. Animal studies have highlighted the sensory role of the skin in normal development; touch is associated with growth potential of the internal solid organs [21].

The skin is also profoundly influenced by the pathophysiology of the individual, with cutaneous changes in anatomy and physiology being linked to many disease processes.

With this expanding body of knowledge with respect to the skin, we engage the fields of TE to provide solutions to repair and replace skin defects to maintain function and avoid scarring. To do so, we also need a working knowledge of the skin response to injury and tissue loss: the processes of wound healing [25].

Briefly, wound healing in skin is a complex series of cascading events that has been described in three overlapping stages from the initial inflammation to tissue formation and subsequent tissue remodeling [26].

The initial response is clot formation to achieve hemostasis. The activation of platelets releases the contents of their α-granules, resulting in activation of the clotting cascade and the release of adhesive proteins forming the matrix of the clot, e.g., fibrin and chemotactic factors and growth factors into the wounded area. The coagulation pathway links to activation of the complement pathway's facilitation of the recruitment of neutrophils needed to facilitate the inflammatory response by removing cellular debris and microorganisms.

The ingrowth of new vessels as granulation tissue is initiated and the keratinocytes at the wound edge mobilize to commence reepithelialization. Macrophages migrate to the wound, releasing multiple protein growth factors as the wound response progresses to the repair phase. Both hemopoietic and mesenchymal stem cells (MSCs) from the

circulation are attracted into the wound with fibroblasts producing ECM, some as myofibroblasts associated with wound contraction.

There is an increased interest in the interactions between the keratinocytes and underlying fibroblasts as the matrix is remodeled and the new basement membrane develops. As the keratinocyte is exposed to collagen, it secretes collagenase and as the basement membrane integrity is restored, the cells revert to their normal phenotype in the situation in which healing is achieved without scarring. Molecular cues after inflammation are associated with positional information and assist in driving the cell−ECM interactions.

In situations of more extensive tissue damage, the fibroblast transforms to a scar phenotype with the production of disordered collagen, resulting in an ECM framework that differs chemically, architecturally, and mechanically from the native skin construct. The interactions between the ECM and the fibroblasts respond to the changes as healing progresses from tissue repair to remodeling. The initial migratory fibroblast transitions to the profibrotic phenotype, producing ECM proteins. In the remodeling phase, the cell number within the dermis or scar reduces as the cells undergo apoptosis. The construct is dynamic and responsive to cellular, chemical, and mechanical cues.

Knowledge of the wound-healing progression over time allows the TE skin solution to be clinically integrated into the process and may be directed toward a number of target strategies: the control of cells in growth, the genetic manipulation of cells to express a given phenotype, seeding of the retained dermis with cells from the dermal epidermal junction, removal of the full thickness of the area of compromised skin, and replacement with a specifically tailored TE construct.

POTENTIAL PREREQUISITE REQUIREMENTS FOR TISSUE ENGINEERED SKIN SOLUTIONS

The skin matures from the softness of the newborn to the skin in old age with the loss of elasticity and reduced potential for repair [27]. We believe that the young heal rapidly but scar aggressively, in contrast to the elderly, who heal more slowly and scar less [28]. Regeneration of the skin without functional or aesthetic deficit, rather than enhanced repair, remains the ultimate goal of wound-healing therapies [29]. However, the degree of scarring and the quality of the repair depend highly on the time taken to heal, with faster healing correlating to improved outcome [8]. The availability of the TE skin for timely use is a key factor balancing the issues of allograft to autograft and biological to nonbiological solutions. The differences in wound-healing responses with age, the condition of the patient, and the etiology of the defect will have implications when harvesting donor tissue for TE and will potentially influence the choice of TE technique [30].

The skin surface is continually replaced under normal conditions and the morphology is retained over the years with changes seen as a result of injury, pathology, and aging. The capacity to regenerate and self-organize becomes overwhelmed in all but trivial injuries such that the repair forms a scar that all too often is debilitating, both physically and psychologically. The traditional approach to reducing the time to healing a skin defect has been to graft skin. Full-thickness skin grafts (FTSG) will give the best scar result but appropriate donor sites to match with recipient sites can lead to skin mismatch with retention of the donor site characteristics, as seen when an FTSG from the groin is used to release a contracture on the palm of the hand. The donor site availability for split-thickness skin grafting (SSG) may be limited in size when large body surface areas are compromised as in burn injury or giant nevi. The area of cover of a given donor site can be increased by meshing or expanding, as in the Meek technique [31]. The expansion of the SSG is associated with small areas of wound healing by secondary intention and a poorer scar outcome. It is the desire to eliminate or at least reduce the scar by reducing donor site morbidity that has driven TE of skin over the past several decades.

Essential factors to achieving healing are:

- a source of cell's capable of differentiating into the tissue and
- an ECM capable of supporting the cells.

With an increased understanding of the skin physiology and interactions with the internal and external environment, we need to also consider:

- the 3D spacial information of the area under repair and
- feedback from the surface to facilitate self-organization.

The ideal needs for a TE skin replacement continue to be debated and are related to the clinical indications for use. Variations in skin with body site and age dictate that a tailored solution is required. Furthermore, the mechanism of

skin loss has a profound impact on the local and systemic response; when comparing surgical excision with a burn injury, it is seen that the burn is associated with an extreme inflammatory response [32]. The interventions and timing of the interventions are important considerations when preparing the wound for the TE construct. In our group, in treating acute burn injury and scarring, we have been guided by the following basic requirements [33]:

- rapidly available
- autologous
- site-matched
- reliable wound adherence
- minimal donor site morbidity
- clinically manageable
- improved quality of scar
- affordable

The list could be debated and expanded according to clinical needs and opportunities such as the use of allograft MSCs with their demonstrated immune privilege [34]. However, the improvement of outcome by clinically manageable affordable solutions affords a solid benchmark.

For TE to be successful it is clear that an in-depth working knowledge of the biology of the tissue is essential. There are a number of cell types within the skin, each with specific and often interrelated functions, some established within the construct, and others transitory from the circulation; their origin and maintenance of clonal capacity remain elusive. It is fundamental to the success of TE to have an understanding of essential information about how the cells relate to the other cells and the ECM of the skin to develop into a mature tissue construct [35].

The ECM scaffold is integral to tissue integrity. We know that the physical shape, mechanical properties, and chemical composition of the environment of a cell influence its phenotype. The predominate dermal cell responsible for ECM production, the fibroblast, changes its phenotype after injury and repair, as demonstrated in the epigenetic modification. The stiffness of the ECM is linked to the fibroblast phenotype, and an understanding of the mechanobiology is an opportunity to guide appropriate tissue regeneration. With the complexity of multiple factors at play, hierarchical mathematics will be useful such that the field of bioinformatics may assist in refining design in the future [36].

In designing of the TE solution, an understanding of this relationship will lead to increased clinical success guiding phenotypic expression. From an engineering perspective, there are technologies that will facilitate innovative clinical solutions such as the advanced modeling and fabrication for scaffold manufacture. Bioprinting has demonstrated the capacity to use the advancing knowledge of biomaterials, natural and synthetic, combined with the cells to produce scaffold cell constructs of increasing complexity. The materials for use need to [37]:

- be biocompatible;
- have properties compatible with mechanical aspects of bioprinting, such as extrusion;
- facilitate appropriate tissue-specific cell viability and function;
- maintain structural integrity and mechanical properties after printing;
- be responsive to chemical and cellular signaling; and
- integrate into the host tissue environment with vascular and neural connectivity.

The development of bioreactors to maintain viability and expand cell numbers associated with scaling up in an appropriately regulated laboratory is essential for cell culture–based techniques [23]. With the advent of bioprinting, it is essential to consider cell capabilities that ideally [37]:

- have the capacity for cell proliferation generating adequate cell numbers in a timely fashion, depending on the pathology being treated;
- are nonimmunogenic or autologous;
- are multipotential;
- are responsive to the environment; and
- have a capacity to integrate without fibrosis.

The increased use of MSCs as immune-privileged cells in a range of pathologies has led to the exploration of them as a source of cells in the TE field meeting these criteria [34]. The increasingly reliable generation of patient-specific induced pluripotential stem cells (iPSCs) provides an alternative source of cells with the capacity to be plastic down a range of lineages, affording potential for future differentiation into specialized cells of the skin adnexal structures [38]. As a source of cells for genetic engineering, treatment of cutaneous pathology becomes a possibility. Cells from

a range of sources can be guided by the introduction of signaling molecules to facilitate activity such as migration, proliferation, and differentiation, bringing us back to having an in-depth working knowledge and even expanding that knowledge base from embryology to wound healing to introduce the appropriate triggers. The cells can also be manipulated by physical changes such as hypoxia to stimulate responses or be guided by introducing magnetic nanoparticles to allow manipulation by external forces such as a magnetic field [39]. Putting the ECM and cells into proximity of a 3D structure is the beginning of the process that needs to be guided either in the laboratory or in situ in the wound to develop into the tissue construct.

It is clear from the experiences of the past several decades that many of the proposed TE skin solutions are disruptive technologies. It is essential that the TE skin not be designed for only a clinical problem and that it should be reproducible and reliable, but also that it should be linked to an education and training program so that its full clinical potential is realized [19].

CURRENT TISSUE ENGINEERING SKIN TECHNOLOGIES

Engineering principles have been applied to skin for many years with the development of medical devices to harvest SSG accurately and mesh the skin to allow expansion. The practice of tissue expansion is a well-established surgical tool for the development of skin by subcutaneous insertion of inflatable devices in vivo, which can be serially enlarged with the resulting development of the skin as demonstrated by cell proliferation [40]. The tissue-expanded skin has all layers and the complete characteristics of the donor site, including retention of adnexal structures and functional innervation [41].

There is increasing interest in the concept of tissue expansion in vitro with a full-thickness skin biopsy put under tension in a bioreactor system to maintain its viability and facilitate cell replication resulting in tissue growth [42]. However, these solutions are limited by time, area, and in some cases, donor site and scar outcome. The need remains to provide both rapid large surface area cover and complex site-specific specialized skin repair, with the ultimate goal of healing by regeneration, not scar repair.

The initial approach to TE skin was to separate the layers and consider the epidermis and dermis to be separate problems.

Work by Green in 1970 focused on the culture of keratinocytes into cell sheets suitable for grafting [43]. The solution to large surface area skin repair was to harvest cells from an uninjured donor site and to undertake laboratory-based tissue expansion. The resulting sheets of cells could be used to close the wound as would a traditional SSG. However, there were problems with the time taken to culture in the laboratory, fragility, adherence to the wound surface, and durability over time, because only the epidermis was replaced; in addition, cost was problematic [44]. In trying to solve some of these problems, there has been a development in the area of subconfluent cell transfer on a number of cell culture surfaces [45] in addition to the delivery of cells in suspension as an aerosol [46]. Subconfluent cells have more reliable adherence and are available in a shorter time frame, from 3 weeks for sheets to 5 days for subconfluent cultures [47]. The process of harvesting cells from the dermal epidermal junction by enzymatic and physical dissociation has been used for immediate delivery of a noncultured cell population to the wound [48]. The cells are a mixed cell population in the same ratio as that seen in the normal skin construct, because there has been no selection of cell populations seen when culturing. The maintenance of the melanocytes enables the development of appropriate pigmentation [49]. The cells adhere, migrate, and proliferate across the wound surface and then differentiate and self-organize into a mature epidermis. The scar outcome is intimately linked to the underlying wound bed, which will be discussed in a later section.

The development of a suitable dermal scaffold is also the focus of the TE field [50]. Topographical features are known to influence cell behavior through a phenomenon known as “contact guidance,” and alteration in the size of the surface detail can elicit different cell responses [51]. Running parallel to studies on the epidermal cell culture was work by Yannas and Burke on dermal replacement, which culminated in the first commercially available product, Integra [52]. The concept of tissue-guided regeneration within an architectural framework is in clinical practice [53]. Underpinning research on the composition and construction demonstrated the importance of considering both aspects: a combination of bovine collagen coated with glycosaminoglycan but with a pore size of less than 60 mm or greater than 100 mm, resulting in disordered granulation tissue, with the optimal pore size resulting in the migrating cells expressing a reticular dermal fibroblast phenotype. The main drawback with Integra is that it addresses only the dermal aspect, with the outer layer on silicone acting as a pseud-epidermis for the period of vascularization, usually 3 weeks before a second surgical procedure is needed to repair the epidermis [54]. The epidermal repair is with a thin SSG, which may be meshed to cover a larger area than the donor site with epidermal cells to speed the time to

healing and reduce the mesh scar pattern [55]. The two-stage problem has been addressed by trying to reduce the time to vascularization or by developing constructs that can be used with an SSG at the same procedure. Apligraft, Matriderm, and Pelnec are dermal templates marketed to provide appropriate topography and matrix properties to promote cell migration into the wound, improve healing, and reduce scarring as a one-stage procedure with SSG [56]. An alternative is to use our knowledge of healing as we see cells migrating from areas of the skin adnexal structures in the dermis to form the new epidermal layer. Introduced cells harvested from the dermal epidermal junction seeded into Integra will migrate and organize into a new epidermis with an established dermal epidermal junction within 3 weeks [57]. The use of Integra is a clear demonstration of the potential of tissue-guided regeneration with the expression of a cell phenotype guided by the morphology and chemistry of the matrix [58].

It is well-established that cells change their phenotype in response to changes in their environment [59]. The development of suitable technologies to generate an optimal environment for wound healing is important to enhancing cell response to tissue injury, reducing the time to heal and improving the outcome. Our knowledge of ECM−cell interactions is increasing with the recognition of the cell signaling by nanoscale structures on cell surfaces with roles in attachment and cell migration [60]. Developments in nanotechnology have opened up possibilities in TE to improve scaffold design, but relatively little is known about how changes in topography at the nanoscale affect cell behavior [61]. The scaffolds can be manufactured to address specific skin functions: to protect against injury from loss of fluid and proteins, enable the removal of exudates, inhibit exogenous microorganism invasion, and improve the aesthetic appearance of the wound site [62]. Scaffolds are generally matrices of synthetic and/or natural polymers fabricated by various techniques including solvent-casting, gas foaming, electrospinning, phase separation, freeze-drying, melt molding, and solid free-form fabrication [63]. Critical to their performance is reproducibility, with control over pore size and the distribution of pores, removal of residual toxic organic solvents, and the control of the inflammatory and immune responses owing to polymer degradation and the associated by-products [64]. The printing technology could conceivably be used directly in wound bed preparation, providing initial protection and a blueprint for cell migration and guided tissue regeneration [65].

Our group has explored anodic aluminium oxide (AAO) as a potential scaffold or template in TE [66]. Self-organized oxide growth under controlled conditions generates a densely packed hexagonal array of uniform-size nanopores aligned perpendicular to the surface of the AAO film. The size of the pores can be nanoengineered by manipulating the anodization time and voltage, the anodizing electrolyte, and/or the time of postchemical etching. Aluminum oxide is well-known for its biocompatibility in the human body; it is inert, stable, and nonreactive, which makes it suitable for TE applications. Engineering of surfaces to manipulate healing is a rapidly expanding area; interactive dressing systems is in widespread clinical use. With the realization of the impact of surface topography and chemistry on cell expression and developing nanoengineering techniques such as electrospinning and electrospraying, there is increasing interest in smart surface technology skin healing [67]. Biocompatible polymeric self-assembling nanofiber constructs have the advantage of a large surface area that can be linked to bioactive compounds. The release of the bioactive compounds can be controlled by intrinsic factors such as in a hydrogel, release kinetics, or extrinsic release triggers [67]. Exciting advances have been made in the area of nanocubes, nanocages, and nanorods as primary candidates to be studied for the phototherapeutic release of bioactive agents [68]. Clinically, the results of single cytokine applications have been disappointing and study of natural healing processes is a result of complex cascade interactions over time [68]. It is unsurprising that we cannot achieve with a single cytokine administration what is the result of complex cell−ECM interactions. The aim of advancing technology is to mimic the structure and function of the ECM with the ability to adapt over time to the changing environment of the healing wound [69].

TE technologies are also used to test the potential impact of agents on the skin, such as in the cosmetic industry. The degree of complexity of laboratory-based testing systems vary from 3D-printed constructs at an air−liquid interface to produce a differentiated epidermal layer to techniques such as the “scar in a jar” system for testing biological activity of drugs targeting specific pathways in fibrosis [70].

Bringing together the scaffold and cellular components has been successful with the development of multilayered constructs seeded with multiple cell types [71]. Clinical series have been presented demonstrating a soft supple skin but with the persistent problem of poor color match [72]. An understanding of the interdependence of the cells of the dermal epidermal junction may well be important to the development of skin constructs with the appropriate melanocyte function [73]. The main drawback in the clinical use of complex laboratory-based constructs is the time taken in the laboratory [74]. However, the potential to use such a technology in timed reconstructive surgery as opposed to acute trauma is beneficial with the ability to tailor the skin construct to the planned defect. The 3D distribution of cells within the wound has been addressed by the innovative use of “inkjet printing” technology, with the cells “printed,” controlled by the shape and depth of the defect [75]. The cell type within the system can be

changed with the fibroblasts being laid down before the keratinocytes [76]. ECM and other proteins can also be introduced into the system, such as hair-based keratins, chemical-processing substrates from biological origins to develop innovative scaffold solutions to enhance cell performance within the constructs.

The source of the cells and the guidance along a path of differentiation are critical elements for a functional skin construct. The use of iPSCs offers the potential for differentiation into multiple cell types, including fibroblasts, keratinocytes, and melanocytes [77]. Guidance of cell differentiation and ECM production may hold the answer to replicating the adnexal structures. The iPSCs also have potential in gene-based therapies in treating skin disorders such as epidermolysis bullosa [78]. The use of the cells as therapeutic delivery agents may broaden therapeutic opportunities.

The time to availability of a TE technique is a key driver to their clinical employment. The use of allograft materials allows an "off-the-shelf" approach, whereas autograft material may take time in the expansion phase [79]. The use of scaffolds alone can provide an advanced wound management system to facilitate healing and can replace a tissue defect guiding repair as it is replaced or provide a permanent solution. The use of cells alone can also provide a surface epithelium that can modulate the underlying healing, form a mosaic of cells of intrinsic and extrinsic origin guiding repair, or provide a permanent surface [80].

The combination of the two elements can provide an advanced skin repair solution, but because the differentiation of the construct is more advanced, the time taken in the processes is prolonged. Consideration of the time taken has led to an investigation of the construct being used in the immature form differentiating in situ. It is clear that TE provides a range of innovative solutions that are useful for many wound and skin replacement areas. Effective use of the technology hinges on the clinician understanding the wound preparation and the aim of the repair. The wound assessment drives the initial clinical decisions directing management in terms of resuscitation, tissue salvage, and infection control, and then planning the repair. An understanding of the range of TE solutions is essential to appropriate clinical implementation.

Consideration of the hypodermis in the resulting functional unit adds a further degree of complexity and opportunity to advance the quality of the tissue construct [81]. Fat grafting to improve the contour of the hypodermis has been shown to be associated with modulation of the cutaneous scarring. The cellular mechanism of the interaction is of interest when considering the opportunity for systemic, regional, or local solutions for a given clinical problem.

TISSUE ENGINEERING SKIN SOLUTIONS IN CLINICAL PRACTICE

The following clinical case of an extensive 65% total body surface area burn injury associated with multiple fractures and pneumothorax is used to demonstrate the decision making and options available in current practice. The initial stabilization and resuscitation is life-saving, along with attention to infection control using Acticoat, a nanocrystalline silver dressing. Once stable, surgical debridement is planned to excise the areas of skin that cannot be salvaged. Although the timing of debridement is vigorously debated with respect to controlling ongoing inflammation and improving outcome potential, an important element in decision making is what is available to cover the debrided wounds, either as a temporary measure or as a permanent replacement. A full-thickness wound requires dermal and epidermal repair for the optimal outcome. In large−surface area wounds, standard SSG is not possible in one procedure owing to restricted donor sites; the SSG can be meshed to achieve healing in a larger area but healing of the interstices by secondary intention often leaves an unsightly meshed pattern scar. Cadaver allograft has been widely used but provides only a temporary solution and will require serial cover as the donor sites heal. A combination of allograft dermis and sheet cultured epithelial autograft (CEA) has been reported to result in a composite repair with retention of the dermal elements. The CEA sheets may take 21 days to culture, or more timely availability can be achieved using preconfluent cultures on carriers or delivered as suspension. The dermis can be replaced with a number of off-the-shelf products such as Matriderm, Pelnec, or Apligraft. The TE technique most widely reported to date remains Integra. The use of composite TE skin could be considered to augment the second stage of the repair with Integra, because it takes time in laboratory preparation.

In this case, Integra was used to reconstruct the dermis in the areas of full-thickness excision, as seen in Fig. 73.1, in which the Integra is held in place with a combination of staples and dressings to facilitate vascularization and integration of the construct. In areas where dermis could be salvaged, cells were harvested from the dermal epidermal junction of uninjured skin using a ReCell kit with Biobrane as a dressing. The main drawback with Integra is the period of vascularization of 3 weeks before proceeding to repair of the epidermis. The epidermis was repaired using a thin meshed SSG 1−3 combined with a noncultured cell suspension from the ReCell kit to reduce the meshed pattern scar. The healing is seen in Fig. 73.2 with the mash pattern fading well in the upper compared with the lower

FIGURE 73.1 Postsurgical debridement of full-thickness burn over 65% of the total body surface area (TBSA) and replacement with Integra dermal scaffold held in place with elastic netting; area of a partial-thickness burn on the abdomen treated with autologous cells under a protective dressing; and uninjured skin donor site on the left flank.

FIGURE 73.2 Post-second procedure to repair the epidermal layer using a combination of meshed split-thickness graft with a noncultured autologous cell spray.

abdomen. At the time of scar maturity in Fig. 73.3, the scar situation demonstrates the issues faced by the patients [82]:

- contour deflect caused by the removed subcutaneous fat layer,
- persistent mesh pattern in the lower scar,
- mismatch of pigmentation,
- contracture bands distorting the anatomy, and
- the repair resulting in a scar.

There has clearly been progress; the development of TE techniques is intimately linked to the advancing survival and quality of scar in patients with major burn injuries. However, there is a clear need to continue to develop TE with the aim of total 3D soft tissue and skin replacement [83].

THE FUTURE

The vision of scarless healing has led to the exploration of regeneration and the interplay among genes, cells, and tissues [84]. Pluripotential stem cells are present within each individual; the drivers of the cells down a regenerative path are an as yet unknown but exciting area of research with promise for the future [85]. The introduction of

FIGURE 73.3 Two years after injury, before planned reconstructive surgery.

allograft stem cells such as MSCs may provide an alternative source of cell regeneration [86]. Understanding that every intervention from the time of injury influences the scar worn for life has pushed research in a multitude of directions. TE of skin is an exciting area that already has made a significant clinical impact [87]. However, we are far from the routine provision of technologies and strategies to provide site-matched, fully functional skin [88]. Great progress has been made in the areas of dermal templates and cell-based therapies and bringing the two elements together in skin constructs. The clinical implementation of TE skin solutions, along with the use of interactive surface dressing systems, has improved outcomes.

The task is far from completed:

- Skin adnexal structures are elusive [89].
- Timely availability of TE skin remains problematic [3].

In addition, more work is needed in:

- harnessing the explosion in smart material technology [90];
- developing vascular constructs, the small vessel problem [91];
- understanding the drivers of tissue-guided regeneration [92];
- understanding the concept of self-organization and the bioinformatics behind morphology [93];
- investigating the impact of both reinnervation and neural plasticity and its role in scarless healing [94];
- understanding the barriers to clinical translation [95]; and
- developing regulatory pathways for novel solutions to ensure safe but timely availability [96].

At the high-tech end of the spectrum, we may consider bringing together laser surface imaging linked to fabrication to build bioreactors with the shape of the defect, with the "smart" cytokine-loaded scaffold materials tailored to the correct 3D shape. Cells of the appropriate body site could then be introduced into the scaffold by cell-printing methods in the individualized bioreactor and the flow of tissue culture medium used to induce small-vessel formation. At the time of transplant, the application of external techniques such as infrared could control the release of biologically active molecules from the "smart" scaffold surface to ensure, for instance, reinnervation and restoration of function with the capacity to integrate into the body. Understanding of linking local tissue replacement with systemic integration is essential to facilitate the linking partially cellular constructs with a 3D framework architecture facilitating secondary cell migration and ingrowth. An alternative to the individualized bioreactor could be the wound itself, prepared by "smart" surfaces and directly seeded with cells. With the understanding of the drivers to self-organization, they could be used to enhance in situ tissue-guided regeneration.

CONCLUSION

Over the past several decades, the concept of TE has been an area of active research, investigating innovative solutions. Multiple combinations of 3D engineered scaffolds exist with a functional cell load to produce tissue over time, which is the fourth dimension of skin repair fundamental to the clinical selection of technique.

The elements required for tissue repair are:

- a source of cells capable of differentiation into the lost tissue,
- an architectural framework for cells to migrate into and express the appropriate phenotype,
- 3D spatial information of the damaged tissue and the relationship to the surrounding viable uninjured tissue interface, and
- a feedback mechanism to guide self-organization.

In Jul. 2005, the *Medical Journal of Australia* published a vision of clinical care in a number of disciplines in 50 years' time:

> Assessment is key in understanding the extent of injury. Debridement is focused on tissue salvage.
>
> Reconstruction balances repair with regeneration. Investigation of multimodality, multiscale characterisation, including confocal microscopy and synchrotron technology will quantify assessment.
>
> Debridement using autolytic inflammatory control techniques with image guided physical methods will ensure the vital tissue frameworks are retained. Tissue guided regeneration afforded by self-assembly nano-particles will provide the framework to guide cells to express the appropriate phenotype in reconstruction.
>
> To solve the clinical problem a multi-disciplinary scientific approach is needed to ensure the quality of the scar is worth the pain of survival.

Many of the technologies highlighted are available, but the significant need for clinical translation remains to move along the innovation pathway to ensure safe implementation into health care systems. Progress requires collaboration at all stages from basic science to clinical trial design and health economics, driven by improved clinical outcomes. Translation of new technologies into health systems requires the rigor of a research framework to identify and measure the impact of innovation in communication and education. Close working relationships between basic research and clinical service delivery are essential. Furthermore, the scientific and clinical advances need to be in line with regulation programs and linked to commercial interest to ensure their widespread availability.

If the solution to the problem is scarless healing by a regenerative repair process and the aim is to improve the outcome from injury by restoring function, the future must blend the long-term vision with incremental short-term improvements.

There has been great progress in TE of skin, and it is an exciting area that offers tangible clinical solutions with an enormous potential for further improvement. The range of potential solutions that have developed is clear recognition of the complexity of the problem and the unique requirements relating to body site, patient, and pathology and the extent of the skin needing to be replaced, repaired, or regenerated. The challenge we face is to capitalize on that tradition and link to the opportunities afforded by unprecedented growth in science and technology, to ensure the quality of the scar outcome is worth the pain of survival.

Regenerative Medicine Approaches for Engineering a Human Hair Follicle

Gail K. Naughton

Histogen, Inc., San Diego, CA, United States

INTRODUCTION

The hair shaft consists of terminally differentiated keratinocytes, which are tightly compacted to form the hair shaft. Hair shafts are made by the hair follicle, a complex miniorgan that is formed primarily during fetal and perinatal skin development [1–3]. Hair follicle formation involves tightly coordinated interactions between the ectoderm and mesoderm with ectodermal stem cells giving rise to all epithelial components of mesoderm cells forming the follicular dermal papilla, as well as the connective tissue sheath [4]. It is composed of an outer root sheath (ORS), inner root sheath, and hair shaft. Under normal homeostasis the hair follicle undergoes a cycling, which is characterized by the formation of a new hair and shedding of an old hair through the growth cycle (anagen), apoptotic regression (catagen), and a resting phase (telogen) (Fig. 74.1). A very unique characteristic of the mammalian hair follicle is its lifelong recapitulation of its molecular embryogenesis each time it enters into anagen. Dermal papilla cells (DPs) are located at the base of the follicle and are surrounded by epithelial matrix cells. DPs support the proliferation as well as the differentiation of epithelial matrix cells and activate bulge stem cells during the transition from telogen to anagen. The bulge is part of the ORS that is close to the sebaceous gland and the interfollicular epidermis. Bulge cells give rise to all of the epithelial cell types during anagen, as well as the sebaceous gland and overlying epidermis. In anagen, cells at the base of the hair follicle proliferate and migrate up the follicle to form a new hair. Simultaneously, the bulge cells give rise to progeny. Robust activity during anagen requires an increase in nutrients and the phase is therefore also associated with new blood vessel formation to facilitate a more rapid supply of these nutrients.

Much has been learned about the regeneration of skin and skin appendages through wound-healing studies and cell- and tissue-based treatments. Some of the earliest approved products in regenerative medicine were cell-based three-dimensional engineered tissues for the treatment of acute and chronic wounds [5]. These products taught us the importance of naturally secreted growth factors and matrix proteins in inducing healthy granulation tissue, angiogenesis, and reepithelialization. Unfortunately, none of the products induced the formation of critical skin appendages, including hair follicles and sweat glands. Anecdotal evidence in wound care reported cases with badly debrided skin healed with the formation of new hairs. [5a] It had been previously thought that mammalian hair follicles only form during fetal development [6] and that the loss of hair after birth was permanent. Reports that hair follicles could be developed de novo after wounding were published decades ago in mice [7], rabbits [8], and humans [9] but these were not accepted due to the lack of evidence of follicular neogenesis. In 2007 a pivotal paper was published showing that hair follicles formed de novo after wounding in genetically normal adult mice [10]. Evidence was presented that nascent follicles arose from epithelial cells outside of the stem cell niche and suggested that wound epidermal cells can assume a hair follicle stem cell phenotype. Overexpression of the Wnt ligand in the epidermis increased the number of new follicles, while inhibition of Wnt signaling completely stopped the folliculogenesis. The regenerated follicles produced new hairs and cycled up to three times during the 90 days following wounding, supporting the presence of functional stem cells in the newly formed follicle. The de novo formation of hair follicles in the adult mammal mimics embryogenesis at the molecular level and raises the possibility

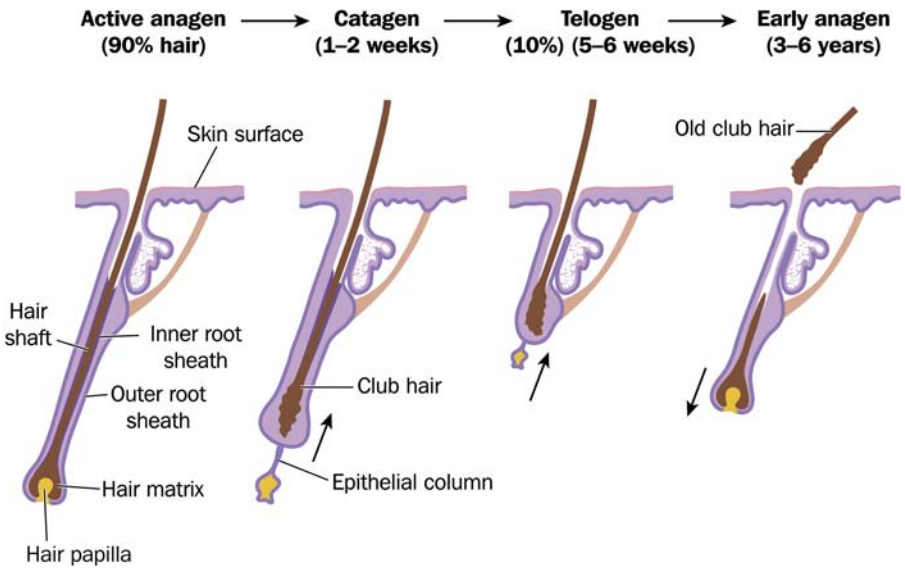

FIGURE 74.1 The normal hair follicle cycle.

of forming new follicles from preexisting hair follicle stem cells in the scalp or from controlled wounding when used in combination with Wnts and other cell stimulatory molecules. A number of preclinical and clinical studies have been performed using cells and cell- and tissue-derived materials to induce stem cell proliferation in the dying follicle or create new follicles in the scalp.

The onset of hair loss is characterized by a much shorter than normal anagen (growth phase) and a reduction in hair density [4]. Given this mechanism, the development of a successful hair loss treatment needs to address two key processes: the transformation of vellus hairs into terminal hairs by stimulating and extending the length of the anagen phase, and the induction and maintenance of the anagen across the entire area effected by miniaturized follicles that result in increased hair density. The number of patients with alopecia has been on the rise and has been attributable to hormones and genetic factors [11], as well as autoimmune diseases, chemical and heat stress, medicines, and psychological stresses [12,13]. Androgenetic alopecia (AGA) is the most common form of hair loss in men during which terminal hairs turn into vellus hairs under the influence of dihydrotestosterone (DHT). Hair follicular miniaturization occurs as a consequence of progressively shorter anagen phases. To date the treatments of alopecia have focused on either blocking the DHT or inducing greater blood flow to help support anagen. These treatments need to be used daily, and within 2 weeks of stopping treatment there is a mass shedding of hair. What is needed is a treatment that will reactivate the miniaturized follicle and cause normal and sustained anagen. Research suggests that dormant hair follicles in human scalp affected by alopecia have a largely intact bulge stem cell population and a significantly reduced population of hair germ progenitors [14]. The hair germ progenitors become activated at the very onset of anagen, while the bulge stem cells become activated shortly after the actual initiation of anagen [15]. It is therefore conceivable that the reactivation of anagen in alopecia-affected telogen (resting) hair follicles may occur by the delivery of threshold levels of growth factors to induce bulge cells as opposed to triggering hair germ cells. The use of such a growth factor therapy has been studied through a variety of approaches, including autologous platelet-derived growth factors (PDGFs), growth factors from adipose cells grown under hypoxic conditions, growth factors from hypoxia-induced multipotent stem cells (HIMSCs), and the use of autologous stem cells to act as growth factor delivery units.

USE OF AUTOLOGOUS GROWTH FACTORS IN HAIR FOLLICLE REGENERATION

Autologous growth factors have been associated with the promotion of tissue regeneration in a number of medical applications. Early work with platelet-rich plasma (PRP) showed excellent generation of granulation tissue and subsequent reepithelialization of hard-to-heal diabetic ulcers. Autologous PRP is derived from centrifuging whole blood to collect a pellet of platelets. Alpha granules in activated platelets release numerous growth factors, including epidermal growth factor (EGF), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF-BB), transforming growth factor beta 1 (TGF-B1), and vascular endothelial growth factor (VEGF). Although initial studies

with PRP focused on the treatment of diabetic ulcers, PRP is routinely injected into the skin for wrinkle indications, it is injected into joints to reduce pain and inflammation, and some findings suggest that PRP may also significantly support hair follicle restoration. One such study involved the treatment of 19AGA patients with plasma rich in growth factors (PRGFs) [16]. Five PRGF injections were administered into the mid-dermal region and phototrichograms were performed at baseline and at 1 year following the last set of injections to assess follicle density/diameter and the terminal/vellus hair ratio. After PRGF therapy, mean hair density/diameter increased as did the terminal/vellus hair ratio. An improvement was also noted in epidermal thickness, perifollicular neoangiogenesis, terminal/miniaturized hair ratio, and cell proliferation. Although this was an uncontrolled clinical trial, the data do support a potential therapeutic effect of the autologous growth factors on hair follicle regeneration. Currently, a number of practitioners are looking at factors that can affect the ability of PRGFs to induce terminal hairs, including the age of the patient, vitamin D deficiencies, and general health.

USE OF ADIPOSE-DERIVED STEM CELLS AND THEIR CONDITIONED MEDIUM FOR HAIR GROWTH

Adipose-derived stem cells (ADSCs) are mesenchymal stem cells (MSCs) found within the stromal−vascular fraction of subcutaneous adipose tissue [17]. ADSCs self-renew, display a multilineage developmental plasticity, and have been used in a variety of tissue repair and regeneration clinical studies. It has been reported that ADSC transplantation promotes hair growth in animal experiments [18]. This is not surprising since hair regeneration depends on cell−cell interactions, as well as external signals surrounding the follicle. Communication between adipose tissue and the hair follicles is key and adipose cells play an important role in the progression of the hair cycle [19]. Canine ADSCs were isolated and cell differentiation into dermal papilla-like tissues (DPLTs) was induced by culturing them in a dermal papilla-forming medium. The trichogenicity (hair forming potential) of the differentiated cells (DPLTs) was assessed and athymic mice were treated either with control or the differentiated cells. DPLTs were seen to have a compact aggregated structure and they secreted a complex extracellular matrix component, as well as versican and alkaline phosphatase, two dermal papilla-specific proteins. New hair fibers were seen 15−20 days postinjection, with the greatest number of hairs seen in the treatment group. Regenerated hairs in the control group were predominantly found in the periphery of the wound and were characteristically short and thin. By contrast, the DPLTs-treated mice had new hairs throughout the treatment area, as well as a significantly higher amount of sebaceous glands at days 10 and 20 and increased vascularization. These data suggest that engineered canine DPLTs demonstrate characteristics of dermal papillae and have a positive effect on hair regeneration. A phase 1/2 trial is currently under way in the United States to test the ability of autologous ADSCs to promote hair growth in men with male pattern baldness.

A critical function of ADSCs is the secretion of growth factors that activate neighboring cells and mediate diverse skin-regenerative effects, including wound healing, antioxidant protection, and antiwrinkling [20]. ADSCs also secrete regenerative growth factors that participate in hair morphogenesis and regeneration. The hair growth promoting effect of ADSC-conditioned media (ADSC-CM) was studied by subcutaneous injection of the CM into C3H/NeH mice [21]. The CM contains a variety of growth factors, including VEGF, hepatocyte growth factor (HGF), insulin-like growth factor (IGF), and PDGF. The researchers discovered that culturing ADSCs under hypoxic conditions significantly improved their proliferative and self-renewal capacity and enhanced their growth factor secretion. The hypoxia-derived CM (HCM) induced the enhanced proliferation of human keratinocytes, as well as human follicle dermal papilla cells in vitro as compared to the CM from ADSCs grown under normoxic conditions (NCM). Based on these data, the induction of hair growth in 7-week-old C3H/HeN female mice ($n = 21$) treated with HCM was assessed. Mice received three subcutaneous injections of 100 μL NCM or HCM. Injections were given at days 0, 3, and 6 and skin darkening as an early indicator for hair follicle formation was monitored for a 12-week period of time. After 8 weeks, dark spots and hair regeneration were seen in the areas of injection with complete hair growth seen by 12 weeks in the HCM-treated animals. Dark spots and hair regrowth were not seen in the NCM-treated mice. Clinical pilot studies have been performed to study the hair growth effect of ADSC-CM on both male and female patients [22]. In women with female pattern hair loss, ADSC-CM was applied to the scalp after microneedling, the use of ultrafine needles to interrupt the skin barrier. After 12 weeks there was a significant increase in both hair thickness and hair density, and no adverse reactions were reported. The researchers also studied the effect of intradermal injections in both men and women with hair loss. Twenty-two patients received six sets of injections every 3−5 weeks and this treatment regimen resulted in an increase in hair numbers after week 12. No large, controlled, double-blinded clinical studies have been conducted to date and research is being done to enhance the hair regeneration potential of ADSC-CM.

TISSUE-DERIVED MATERIALS FOR HAIR REGENERATION

Human placental extract (*Hominis placenta* [HP]) has been used for decades in China and Korea as a therapeutic agent for liver regeneration and endocrine abnormalities. HP extract has been shown to have antiinflammatory, wound-healing, and antioxidant effects in the clinical setting [23]. Initial studies with cow placenta showed an increase in hair density in the mouse model [24] and this led to an investigation into whether HP treatment could influence hair growth in mice. Fifteen 7-week-old male C57BL/6 mice were divided into control, minoxidil, or HP-treated groups. Animals were depilated to synchronize hair follicle growth to the anagen phase. Animals received topical treatment of the controls or treatment once daily for 15 days, after which time measurements were taken for hair growth and thickness by dermoscopy. Immunohistochemistry was also performed on skin sections from all animals to assess BrdU incorporation and DNA synthesis. Results demonstrated an increase in hair number, hair shaft diameter, and density in the HP-treated animals as compared to the control animals. In addition, high levels of BrdU incorporation were observed in the dermal papilla, ORS, and connective tissue of the HP-treated animals. Proliferating cell nuclear antigen was highly expressed in the lower regions of the hair matrix, indicating induced DNA synthesis in the treatment group. Fibroblast growth factor 7 (FGF-7), a critical growth factor in the stimulation of anagen, was seen to have an increased expression in the outer layer of the hair shaft and surface epithelium in the HP-treated group. Placenta extracts have been utilized in a variety of clinical indications, including wound healing where the growth factors, amino acids, and angiogenic-promoting agents have proven to be beneficial. Hair follicle cycling has a great deal in common with the processes involved in wound healing and HP continues to be assessed as an anagen-promoting stimulus.

ADDITIONAL STUDIES ON SECRETED GROWTH FACTORS AND HAIR GROWTH

Additional preclinical studies have been performed to build on the research showing the importance of Wnt proteins and other growth factors in the stimulation of follicular stem cells to induce sustainable anagen. In one such study, MSCs were engineered to overexpress Wnt1a [25]. Wnt-CM was injected into the murine model discussed earlier and resulted in accelerated hair follicle progression from telogen to anagen and enhanced alkaline phosphatase expression in the DP region. Of great significance is the fact that hair induction-related genes were upregulated even when they had been first selectively downregulated by treatment with DHT. This study clearly demonstrated that MSC-produced Wnt1a promoted the ability of the DP cells to induce hair cycling and regeneration in a physiological manner in a model simulating male pattern baldness. In another study, neural stem cell (NSC) extract was used to stimulate the hair follicle niche to induce hair growth in the mouse model. Expression levels of multiple growth factors and signaling factors were studied and it was reported that NSC extract enhanced hair growth by activating hair follicle niches via the coregulation of TGF-B and bone morphogenetic protein (BMP) signaling pathways in the telogen phase. The activation and differentiation of intrafollicular hair follicle stem cells, extrafollicular DPCs, and matrix cells was also seen both in vitro and in vivo. Key growth factors, including HGF, IGF-1, keratinocyte growth factor (KGF), and VEGF, were also increased to enhance hair growth stimulation. This study clearly demonstrated the ability of NSC extract to promote hair growth through the direct regulation of hair follicle niches via the TGF-B and BMP signaling pathways, as well as the induction of critical growth factors [26].

SIMULATING THE EMBRYONIC ENVIRONMENT

In the mid-1990s it was reported that scarless healing occurs in the embryonic/fetal environment even after extensive surgery [27]. The embryonic environment is known to be characterized by rapid cell growth and cell differentiation, and embryonic tissue develops under low oxygen (hypoxic) conditions, and, unlike adult tissue, it contains predominantly collagens III and V and low levels of TGF-B and bFGF. Ezashi et al. [28] have shown that mimicking the embryonic condition of hypoxia enhances the growth of human embryonic stem cells (hESCs) and both hESCs and adult stem cells show improved maintenance of their undifferentiated state under low oxygen conditions [28–30]. To assess the effect of embryonic conditions on normal cells, neonatal fibroblasts were seeded onto dextran beads and grown in suspension in controlled closed bioreactors under 5% oxygen. Under these cell culture conditions, over 5000 genes were differentially expressed as compared to identical growth conditions with normal oxygen. A large number of the upregulated genes were associated with multipotent stem cells, including SOX 2, Oct4,

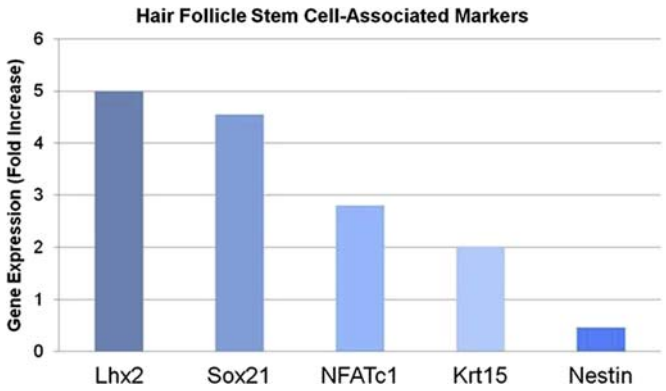

FIGURE 74.2 Expression of hair follicle-related stem cell markers in neonatal cells grown under simulated embryonic conditions.

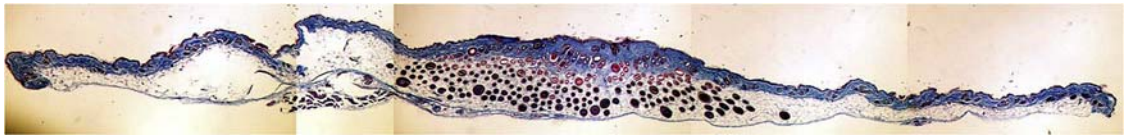

FIGURE 74.3 Injection of hypoxia-induced multipotent stem cell (HIMSC)-conditioned media subcutaneously into the C-57bl/6 mouse model induced an increased density of hair follicles at the site of injections.

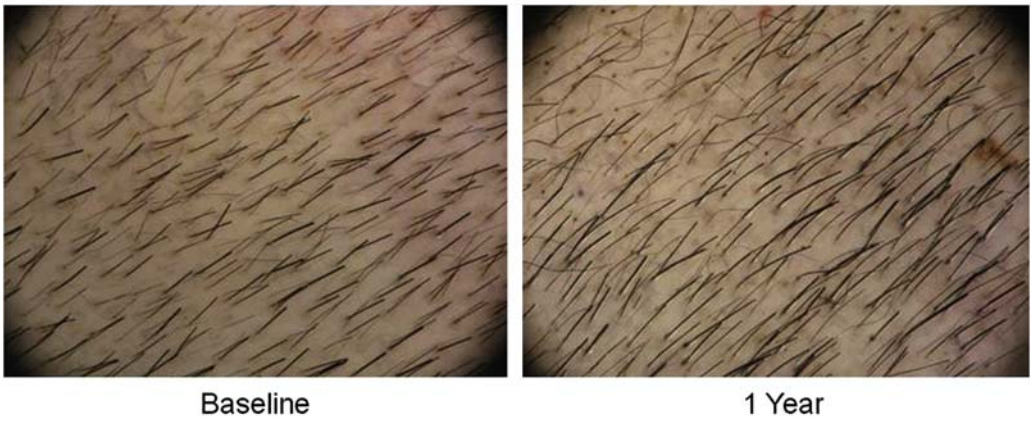
NANOG, and KLF4 genes [31]. The expression of stem cell-associated proteins, including Nodal, Brachyury, Nestin, and Oct4, was also seen. It was also noted that genes were upregulated and surface markers were expressed, which are normally associated with follicular stem cells, including Lhx2, SOX 21, Nestin, NFATc1, and Krt 15 (Fig. 74.2).

Because of this finding, CM from the HIMSCs was utilized to study whether the composition could induce hair growth in the C57Bl/6 mouse model. Intradermal injections of the CM induced new hair growth in the treated mice and an increased number of hair follicles and hair follicle stem cells were noted in the treatment area (Fig. 74.3). No such hair induction was seen in the unconditioned media controls.

The CM was analyzed and shown to contain high levels of growth factors associated with the induction and increased endurance of anagen, including HGF, FGF-7 or KGF, VEGF-A, follistatin, angiogenin, and placental growth factor (PlGF-1 or PlGF). Given this composition, a proof-of-concept clinical study was performed to assess the ability of the HIMSC-CM, called hair-stimulating complex (HSC), to induce hair growth in men with male pattern baldness [32]. The clinical study was a double-blind, placebo-controlled, randomized, single site trial and was designed to evaluate safety of the HSC product and assess efficacy in stimulating hair growth. All 26 subjects tolerated the single, intradermal injection of HSC procedures well, and no signs of an adverse reaction were reported. Histopathological evaluation of the treatment site biopsies taken at 22 and 52 weeks posttreatment revealed no abnormal morphology, hamartomas, or other pathological responses. Treatment and control regions received temporary tattoos so that photographs at each follow-up time point could be taken in exactly the same region. Trichoscan image analysis of HSC-treated sites at 12 and 52 weeks showed significant improvements in hair growth over the placebo. At the initial 12-week evaluation period, HSC-treated sites demonstrated an increase in hair shaft thickness (6.3% $\pm$ 2.5% vs. $-$0.63% $\pm$ 2.1%; $P = .046$), thickness density (12.8% $\pm$ 4.5% vs. $-$0.2% $\pm$ 2.9%; $P = .028$), and terminal hair density (20.6 $\pm$ 4.9% vs. 4.4 $\pm$ 4.9%; $P = .029$). At the 1-year time point a statistically significant increase in total hair count ($P = .032$) continued to be seen. The fact that hair counts continued to increase over the 1-year period even after only one injection at day 0 supported the hypothesis that HSC stimulated a prolonged and sustainable anagen, a result that had not been reported in previous clinical hair growth studies. An example of such growth is seen in Fig. 74.4 where trichoscan data demonstrated a 123% increase in terminal hairs over the 52-week period.

To assess the efficacy and safety of an increased number of injections and a second dosing at week 6, a phase 1/2 study was conducted in Manila with Investigational New Drug (IND) approval by the Food and Drug Administration Philippines. The clinical study was a double-blind, randomized, two center trial in 56 subjects. All subjects tolerated the eight 0.1 cc intradermal injections at baseline and 6 weeks well, and no signs of an adverse reaction were reported. Blood and urine samples taken before and after each injection set showed no liver, kidney, or bone marrow toxicity. Trichoscan image analyses of treated and control sites were taken at baseline, 12, 24, 36, and 48 weeks. At the



Hair Count:	Baseline	12 week	1 year
HSC	214.5	224.5	324.5

FIGURE 74.4 One-time injection of hair stimulating complex (HSC) yielded significant new terminal hair growth in treated areas at 12 weeks and 1 year.

12-week time point, significant improvements in total ($P = .0013$), terminal ($P = .0135$), and vellus ($P = .033$) hair growth over baseline were seen, as was an increase in cumulative thickness density ($P = 026$). The primary efficacy endpoint of increased terminal hair at 12 weeks was met, with a 19.5% increase seen, a 49.5% increase over the same endpoint in our proof-of-concept trial. In addition, unlike currently approved products, HSC induced hair growth in the temporal recession, as well as vertex and mid-scalp regions, and was highly effective in men over 40 years of age, as well as in men in their 20s and 30s. At the 48-week time point there continued to be a significant increase in total hairs over baseline ($P = .028$). These results clearly demonstrate the safety and efficacy of intradermal injections of HSC in subjects with AGA and the benefit of a second treatment at 6 weeks to capture preanagen follicles that were too early in the cycle at week 0.

An additional clinical study was conducted on five men and five women in the United States under a physician IND. This "safe passage" study involved 20 (0.1 cc) injections at baseline, 20 at week 6, and 40 injections at week 12 and week 40. The injections were well tolerated and no serious adverse effects were reported. Some subjects reported an itching at the injection sites, which was resolved within 30 min. An increase in hair growth, as demonstrated by global photography, was seen in all patients, which included men with male pattern baldness, as well as women with hair loss associated with stress, chemical damage, and perimenopausal hormonal changes. Fig. 74.5A and B show results in two of the 10 patients treated.

To be able to do phase 2 dosing studies in men and to remove nongrowth factor-related impurities from the CM, HSC production was modified to include capture of the growth factors by a heparin sepharose column and the use of various filters to remove DNA. The six key growth factors in HSC that are associated with hair growth are measured by enzyme-linked immunosorbent assay before product release and sterility, bioburden, and a series of viral testing are performed. Cell potency assays are performed to assess the activity of follistatin, FGF-7/KGF, and the angiogenic factors in the product. The following is a summary of the proposed mechanism of action of HSC in the induction of hair growth.

A number of growth factors work synergistically to induce and maintain angiogenesis in the hair follicle. The hair follicle undergoes cyclic expansion and regression, which requires changing demands for vascular support, with perifollicular vascularization being seen during anagen and decreased vascularization associated with catagen and telogen. VEGF helps to mediate the induction of angiogenesis to provide the increased nutritional needs of hair follicles during rapid cell division in anagen [33]. In addition to increasing vascularization, VEGF induces the division of DPCs, which is a key step in the induction of hair follicle formation. Angiogenin is a soluble factor normally secreted by DP cells [34]. Angiogenin is a potent angiogenic factor that also promotes the stimulation of DP and ORS keratinocytes and the subsequent elongation of the hair follicle.

HGF is a multifunctional polypeptide that acts as a mitogen, motogen, and morphogen. In addition to promoting angiogenesis, it has been shown to stimulate follicle growth of human hair and follicle elongation by stimulating DP

FIGURE 74.5 (A) Escalating doses of hair-stimulating complex (HSC) every 6 weeks induced cosmetically relevant new hair formation in a subject with male pattern baldness. (B) HSC induced new vellus hair formation within 18 weeks in the temporal recession region of a 38-year-old female with stress-induced alopecia.

cells and hair bulb-derived keratinocytes [35,36]. PlGF is a member of the VEGF subfamily and is important in promoting angiogenesis and vasculogenesis, particularly during embryonic development. PlGF has been shown to play a role in the promotion of hair growth by accelerating the growth of hair follicle cells and prolonging anagen hair growth [37]. The mechanism of action involves preventing hair follicle cell death by increasing levels of phosphorylated extracellular signal-related kinase and cyclin D1.

FGF-7/KGF is synthesized by skin fibroblasts and DP cells and has a mitogenic effect on skin keratinocytes. It is thought to be the most potent growth factor reported to date [38]. The KGF receptor is found on ORS cells and addition of KGF to these cells in organ cultures has significantly increased hair follicle cell proliferation [39]. In vivo the FGF-7/KGF secreted by DP cells causes both rapid proliferation of ORS cells and the resulting keratinocytes to migrate into the hair follicle shaft and form a new vellus hair or convert vellus hairs to terminal hairs [40].

Follistatin is found in all human tissues and organs and has the primary function of binding and bioneutralizing members of the TGF superfamily, with particular affinity for activin. It is an antagonist to both activin and BMP, both of which are involved in maintaining a slow cycle of stem cell proliferation in resting hair follicles [41,42]. Follistatin has been shown to be an important regulator of cell proliferation, differentiation, and apoptosis in hair follicle initiation and hair cycling. In AGA, androgens induce TGF-B1, which inhibits growth of the dermal papilla cells and keratinocytes [43]. Adding follistatin to dermal papilla cells helps to reverse this blockage, further strengthening the role of this activin antagonist in hair growth [44].

Naturally occurring growth factors work synergistically to promote proliferation, differentiation, and angiogenesis. The composition of growth factors in HSC works together to induce angiogenesis of the hair follicle for adequate nutrient support, as well as stimulating DP cells and ORS cells to proliferate to induce hair follicle elongation, cell migration into the hair shaft, and subsequent hair growth.

Given the early clinical results with HSC, a study was performed in Japan to see if it could be effective as a holding solution for follicular units implanted in hair transplant procedures [45]. Saline is the most common solution used to

preserve hair follicles for the period of time between removal and implantation. Surgeons have come to accept a large degree of hair loss, known as effluvium, from the transplants, and patients need to be patient for the months it takes to allow the transplanted hair to recover from shock and enter into the anagen cycle. As expected in the weeks following transplant, the investigator reported that transplanted hairs held in saline were lost to effluvium at the 6-week follow-up. Of the hairs held in the human cell conditioned media (hCCM) solution, however, most remained intact at this follow-up time point, reflecting not only the more hospitable environment created by the hCCM but potentially also the increased wound-healing capabilities of the material. Fifty-five percent of the follicles soaked in saline for up to 2 h during the transplant procedure showed hair loss, whereas only 10% of the follicles soaked in hCCM resulted in showing the effluvium response.

BIOENGINEERING A HUMAN HAIR FOLLICLE

A major challenge facing stem cell biologists is the bioengineering of an entire functional organ.

Since the hair follicle is a miniorgan it is an ideal candidate to utilize as a goal to be the first organ to be engineered. Formation of such a follicle would require simulating the series of molecular and cellular events that will recreate follicle morphogenesis. The steps will progress from the formation of dermal condensations, to epithelial invagination, to DP formation at the base of the follicle, to the arrangement of the various cell types and their morphogenesis, to the differentiation of hair shaft components, and then to actually demonstrate the creation of a hair. Creation of a functional hair follicle would not only be a major milestone in regenerative medicine, it would allow the creation of tissue-engineered skin for burn patients that would provide the critical functions of skin appendages in addition to providing a novel therapy for people with alopecia.

Early work studying how hair follicles are formed during early development resulted in the reconstitution of pelage hair follicles when a mixture of prepared cell suspensions from embryonic or neonatal mice was grafted onto the dorsal surface within a silicon chamber [46]. Zheng et al. [47] demonstrated that dissociated neonatal mouse epidermal and dermal cells could be reconstituted to form hair follicles. The de novo follicles formed in a sequence similar to that seen in embryonic development, showed follicular layering, formed a bulge region, as well as a sebaceous gland, and demonstrated appropriate biochemical differentiation markers and cycling. Isolated K15 enhanced green fluorescent protein-positive bulge cells showed stem cell properties and created new follicles. An additional important finding was that the ratio of epithelial and dermal cells injected affected the efficiency of the hair formation. The study showed that 5000 dermal cells and 2500 epidermal cells were necessary to produce a single follicle.

Ebama et al. [1] used a similar technique to attempt to create a functional human follicle. Cografting of neonatal foreskin human keratinocytes with murine DP-enriched cells produced structures resembling hair follicles with multiple epidermal cell layers and a well-keratinized inner region. The follicular structures expressed hair keratin markers, as well as markers associated with developmental stages, but lacked normal hair. These results were also repeated with adult keratinocytes. Neither the enriched DP population nor the epidermal fraction alone formed any follicles, further elucidating the importance of the epithelial−mesenchymal interactions in hair follicle regeneration.

Building on the research with the mouse and human-dissociated cells to form new follicles, Sriwirlyanont and colleagues worked to produce functional follicles in engineered skin [48]. To date the growth of hair appendages in tissue-engineered skin substitutes has not been accomplished in a reproducible manner predominantly due to the lack of trichogenicity in postnatal cells. In this study a chimera of human neonatal-cultured keratinocytes and murine-cultured DP cells was grafted orthotopically to full thickness wounds on athymic mice. Noncultured dissociated murine skin cells were used as the positive control and human cultured keratinocytes and fibroblasts without DP cells were the negative control. Neonatal murine-only skin substitutes produced external hairs with sebaceous glands, while chimeric skin substitutes formed hairs without the gland. The latter was associated with the upregulation of the LEF-1 hair-related gene and the downregulation of stearoyl-CoA desaturase, a sebaceous gland marker. No visible hairs or glands were formed with human-only skin substitutes. Results of this study illustrated that sebaceous gland formation is not a prerequisite for hair growth in tissue-engineered skin substitutes.

The regeneration of a human hair using epidermal and dermal components in ex vivo or mouse models has not been demonstrated to date.

Research by Rahmani et al. [49] has resulted in identifying a cell type that has furthered progress in human hair regeneration and may lead to generating new hair in the human scalp. To assess how DP cells are maintained in healthy follicles an in vivo fate mapping of adult hair follicle dermal sheath (DS) cells was performed. It was seen that a subset of DS cells is retained following each hair cycle and that these cells exhibit a self-renewal characteristic and are key in repopulating the DS and DP with new cells. Hair regrowth was retarded when the DS cells

were ablated and hair type specification was altered, supporting the hypothesis that the DS cells function to modulate normal DP function. This work identified a bipotent stem cell within the adult hair follicle mesenchyme and supported the approach of using the DS cells in the clinical setting.

A phase 1/2a study utilizing an autologous cell-based treatment for AGA has been completed by RepliCel Life Sciences and has demonstrated safety and effectiveness. Subjects with mild-to-moderate AGA as characterized by the Ludwig scale (female subjects) or Norwood Hamilton scale (male subjects) were enrolled in the study. After blood sample testing substantiated their general health, scalp biopsies were taken and sent to a cyclic guanosine monophosphate-compliant facility. Biopsies were dissociated and treated to isolate dermal sheath cup (DSC) cells, which were then expanded in culture. The 19 subjects returned to the clinic after the DSC cells were grown to numbers sufficient for transplantation. The process for creating and implanting the DSCs is shown in Fig. 74.6. Subjects were their own control and received medium alone (placebo) or replicated DSC cells in medium into areas of their scalp that were randomized by a predetermined blind. The primary protocol of the study was to assess local treatment sites for any abnormalities at the 6-month time point. The secondary endpoints at 6 and 24 months assessed both safety and efficacy. At the 6-month interim point the data collected showed no serious adverse reactions in any of the subjects. Thirty percent of the subjects experienced a burning sensation at the site of treatment, which was resolved within 24–48 h. At 6 months, several efficacy endpoints were successfully met as well. Significantly more patients demonstrated a greater than 5% increase in hair density at the DSC-treated areas, with density increases ranging from 5% to 19.6%. Increases were seen in total hair density, as well as vellus and terminal hair density. Additional clinical studies are currently under way in Japan and are being conducted by Shiseido Company, a world leader in aesthetic products. The clinical data to date support the importance of DS cells in hair growth, particularly with the cosmetically relevant increase in hair density.

Similar autologous cell-based studies have been performed with a combination of epithelial and dermal cells or dermal cells alone by both Intercytex Group plc and Aderans Research. Trials have consistently shown safety in all patients and signals of efficacy in a number of treated subjects.

In autologous cell-based trials a number of questions still remain to be answered. These include the mechanism of action and whether the injected cells actually develop a new follicle, become part of an existing follicle, or stimulate hair growth by releasing growth factors and exosomes that then increase growth in the targeted hair follicle. The

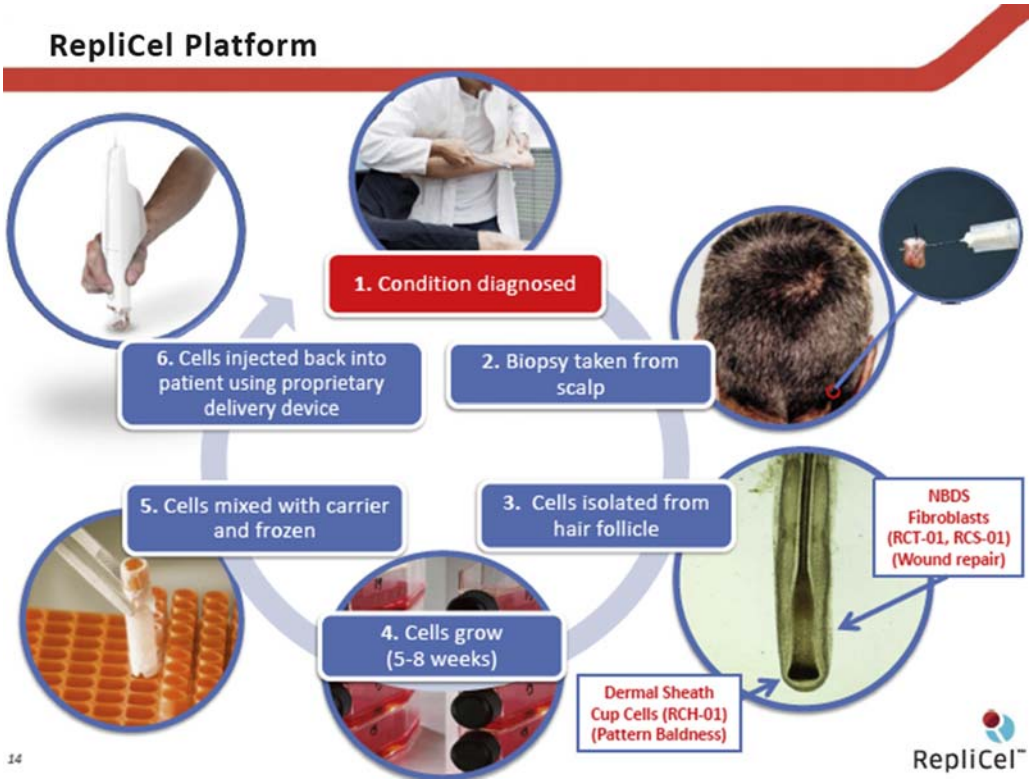


FIGURE 74.6 Collecting and processing dermal sheath fibroblasts for implantation for hair regrowth.

number of cells necessary to be utilized to stimulate hair growth is key, since the ratio of new hair follicles to donor follicles must be great enough to produce a commercially feasible product. Being able to measure and retain trichogenicity of the implanted cells is essential, as well as being able to understand whether a regenerating system in vivo has the ability to attract other cells from the body, as is seen with the recruitment of bone marrow cells in the process of normal wound healing, which should offer a real benefit in new organ formation.

SUMMARY

The ultimate goal in organ replacement regenerative medicine is the ability to create fully functional organs that have been damaged or destroyed by injury, aging, or disease. The hair follicle is an ideal miniorgan, which has been targeted to achieve this goal since it reforms itself throughout life through key interactions between epithelial cells and inductive cells from the mesenchyme. Whether success will be achieved by creating the follicle in vitro in complex three-dimensional culture systems or injecting a combination of cells and growth factors into the scalp for remodeling in vivo is still unknown. Studying follicular neogenesis in the embryonic environment has led to tremendous advances in understanding the complex signaling pathways and epithelial−mesenchymal interactions necessary to stimulate human hair growth. Research by several laboratories has underscored the powerful inductive ability of the follicular dermal cells. Although current cellular implant approaches have focused on autologous dissociated cells from the scalp, the potential of an allogeneic approach is very feasible. Dermal hair follicle tissue has successfully been transplanted between individuals without any sign of rejection [50]. In addition, it is believed that the hair follicle is an immune privileged location that does not express the major histocompatibility complex class 1 antigen that is associated with the rejection process [51]. To make progress in either autologous or allogeneic expanded cells for transplantation we must make progress with developing solutions for maintaining trichogenicity of the cells in culture. A very intriguing proposition is the utilization of iPS cells or other stem cells in bioengineering a human hair follicle. A number of stem cell types, including neural [52] and bone marrow-derived MSCs [53], have shown the capacity to form skin and hair when injected into a blastocyst. A product designed to engineer new hair follicles, consisting of inductive dermal cells and competent epithelial cells, is likely to be the first organ system to be successful in the clinic.

CHAPTER

75

US Stem Cell Research Policy

Josephine Johnston, Rachel L. Zacharias

The Hastings Center, Garrison, NY, United States

INTRODUCTION

Since James A. Thomson and colleagues reported the isolation of pluripotent stem cells from human embryos in 1998 [1], stem cell research has received considerable public and policy attention. Because the isolation of embryonic stem cells involves destroying human embryos, some groups and individuals have opposed, or raised concerns about, some or all of the research on moral grounds. The opposition and concern have influenced a number of policies and laws at state, federal, and international levels. From 2001 until 2009, much embryonic stem cell research was ineligible for federal funding in the United States. In 2009, federal rules were relaxed somewhat, although federal funds still may not be used to create embryonic stem cells or to support research on cells taken from embryos created for research purposes, including by cloning. Despite these restrictions, embryonic stem cell research progressed into the 21st century in the United States using monies supplied by individual donors, charitable organizations, and states. After briefly discussing ethical and policy issues in adult and fetal stem cell research, this chapter will survey the current policy issues in embryonic and induced pluripotent stem cell (iPSc) research, beginning with federal and state funding policies, which will be compared to regulation strategies adopted in other nations active in the research, before considering oversight, commercialization, and ethical issues that arise as the research and technology move forward.

SOURCES OF STEM CELLS

Stem cells are special kinds of cells that can regenerate themselves and make new, more specialized cells. For the purposes of an ethics and policy discussion, stem cells can be divided into four kinds based on the source of the cells: adult stem cells, fetal stem cells, iPScs, and embryonic stem cells. In terms of ethics, politics, policy, and law, much depends on the source of the cells.

Adult Cells

"Adult" stem cells are derived from the somatic cells of adults and children (frequently taken from an umbilical cord). Although obtaining adult stem cells can raise some ethical issues, they are similar to those raised in other kinds of research involving human subjects, the most important of which is the requirement for free and informed consent [2]. Because the ability of competent adults to consent to research enjoys wide acceptance, somatic stem cell research has not been a major focus of ethical or political debate. It does, however, enter public consciousness as a less controversial, proposed alternative to embryonic stem cell research. Opponents of embryonic stem cell research cite clinical success of adult stem cells as evidence that research using embryonic cells is unnecessary [3,4]. However, many adult stem cell scientists insist on the importance of pursuing research on stem cells from both sources [5,6].

Fetal Cells

Pluripotent stem cells have also been extracted from the primordial reproductive tissue of aborted fetuses [7]. Any source of stem cells that relies on women undergoing elective terminations is likely to be controversial in the United

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00075-8

States simply because of the ongoing debate over the morality and legality of abortion. Nevertheless, researchers have used tissue from aborted fetuses since as early as the 1930s and federal funds are currently available for this kind of stem cell research.

Although research involving human fetuses has been regulated in the United States since allegations of experiments on in and ex utero fetuses emerged in the early 1970s [8] (and around the same time as the Supreme Court's famous 1973 decision on the legality of abortion in *Roe v. Wade* [9]), it seems that these regulations do not apply to most stem cell research using fetal cells. Human subject regulations, promulgated in 1975, require extra protections where federally funded research involves pregnant women, fetuses, and human in vitro fertilization (IVF). Among other things, these regulations forbid researchers from having any involvement in a woman's decision to terminate her pregnancy or from offering gestational carriers financial inducements [10]. Although it has always been clear that these regulations applied to in utero fetal research, there has been some uncertainty as to whether the regulations apply also to research that, like stem cell research, uses cadaveric fetal tissue [11]. In March 2002, the Office for Human Research Protections issued a guidance for research involving fetal stem cells in which it states that the research will only be subject to federal human subject protections where it involves "a living individual," which would exclude fetal stem cell research unless the formerly pregnant woman is involved in the research [11].

Likewise, the 1993 federal legislation on fetal tissue transplantation research likely does not apply to stem cell research using fetal cells unless the research also involves transplanting the cells into humans. Similar to the restrictions imposed by the federal human subject regulations, this legislation stipulates that no alteration in the timing, method, or procedures used to terminate the pregnancy should be made solely for the purposes of obtaining the tissue, nor can tissue be paid for or taken without the consent of the gestational carrier [12]. This legislation reappeared in public discourse in 2015, when the reproductive health care provider Planned Parenthood was accused of illegally profiting from fetal tissue donated to research [13]. Under the 1993 law, centers such as the accused California clinic can be reimbursed for the cost of obtaining, storing, and processing fetal tissue, but cannot be paid for the donation itself. Although 12 state inquiries found no evidence of illegal activity on behalf of Planned Parenthood, the organization stopped obtaining reimbursements for fetal tissue in October 2015 [14].

Even though both the federal regulations and the fetal tissue transplantation legislation likely do not apply to most fetal stem cell research, practices similar to those required by these laws (and lessons learned from cases that arise from their interpretation) will likely be considered by Institutional Review Boards (IRBs) reviewing fetal stem cell research.

Various states also have laws affecting fetal stem cell research, which will apply to all researchers in those states regardless of their funding source. For example, five states ban research involving aborted fetuses and 12 states ban paying for fetal remains [15]. Despite fetal stem cell research's intimate connections with fetal tissue research and the controversial practice of induced abortion, this kind of stem cell research has seldom been the subject of public debate.

Embryos

Instead, debate has consistently focused on research that uses stem cells extracted from 4- to 7-day-old human embryos, referred to broadly as human embryonic stem cells (hESCs). Because any single cell in the very early human embryo can develop into a whole fetus, it is thought that embryonic stem cells have the potential to develop into almost any cell type and repair damaged or diseased parts of the human body. The therapeutic potential of embryonic stem cells therefore is thought to be enormous, but so is the moral peril because extracting these stem cells generally necessitates destroying the embryo. For this reason, the research has been vigorously opposed by many individuals and groups, including (but not limited to) those who consider the early embryo to be a person or, if not a full person, an entity of such sufficient moral significance that it should not be created for, or destroyed in, research.

Embryonic stem cells can be derived from embryos created by two mechanisms: IVF or cloning. IVF embryos are created through the combination of an egg and sperm cell in a lab. Embryos produced through IVF may have been produced for reproductive uses but then determined no longer to be clinically necessary (so-called "spare" or "surplus" embryos), or they may have been produced specifically for research use. This difference in the reasons for creating the embryos is worth understanding. Creating embryos for research use is often opposed on the grounds that it is wrong to create human life for the purposes of destroying it [16]. Research use of spare embryos, on the other hand, has received more support on the ground that the embryos would be destroyed anyway.

Whether the intention of the original creator of the embryos is sufficient reason for permitting research on spare embryos but not on embryos created for research use has been questioned [17,18]. Even if this moral issue can be

resolved, spare embryos may not be satisfactory as the sole source of embryos for stem cell research because there may not be sufficient numbers available to meet demand. A 2003 survey of US fertility clinics reports that of the more than 400,000 embryos in frozen storage in the United States, only 2.8% have been donated to research [19]. Other researchers have argued that these frozen embryos will not be genetically diverse enough for therapeutic purposes [20]. Whether for these reasons or others, the US National Academies, which issued guidelines for embryonic stem cell research in 2004 (discussed in more detail later), proceeded on the basis that researchers could use spare embryos and embryos created for research use, including by cloning.

The arguments against creating life purely for research use are also used to argue against using cloning techniques to generate human embryos. Currently, cloned embryos are created through a technology called somatic cell nuclear transfer (SCNT) (SCNT was used in the cloning of Dolly the Sheep in 1997 [21]). In ethics and policy discussions, cloning is usually broken down into two types based on the end goal of the cloning: therapeutic or research cloning and reproductive cloning. Therapeutic cloning uses SCNT to create cloned cells that will only be used in vitro, including embryos or somatic cells from which hESCs or iPScs can be derived, respectively. In therapeutic cloning, cloned embryos are not implanted for reproduction, and are discarded after stem cells have been derived [22]. Reproductive cloning is the creation of a cloned embryo through SCNT with the goal of creating a new living person. While therapeutic cloning destroys embryos, reproductive cloning would, if successful, result in the birth of a cloned human. Therapeutic and reproductive cloning are treated differently in policy in the United States and internationally.

Induced Pluripotent Stem Cells

In 2002, Catherine Verfaillie and colleagues announced that they had isolated multipotent adult progenitor cells from bone marrow [23]. Then, in 2006, scientists in Japan and the United States announced the creation of pluripotent stem cells from adult skin cells [24,25]. These iPScs are human somatic cells reprogrammed to develop into nearly every human cell type, and are believed to be functionally very similar or identical to embryonic stem cells. Many consider these somatic cell-based lines to be an ethically simpler alternative to embryonic stem cells that could satisfy the same scientific and clinical needs. In the past decade, iPSc technologies have contributed considerably to research on human diseases, drug screening, and, with the introduction of gene editing, offer a virtually unlimited supply of human cell lines to research efforts [26].

Debates continue regarding the scientific differences between hESc and iPSc lines, and the significance (if any) of the ways in which they vary [27,28]. Due to the self-renewing quality of both cell types, hESc and iPSc may introduce a risk of neoplasm and tumor formation if the cells are not engineered properly. As such, hEScs were only approved in clinical trials in 2009, and iPScs have yet to be used clinically [29,30]. While embryonic stem cells frequently garner ethical attention surrounding the destruction of embryos, pluripotent stem cells have raised separate ethical considerations, mainly stemming from their creation by human cloning technologies.

At the time of writing, research remains active in both the embryonic stem cell and iPSc domains. While future developments could shift research toward exclusive use of iPScs, past and current state, federal, and international policies have centered primarily on embryonic stem cell research.

UNITED STATES FEDERAL AND STATE STEM CELL POLICY

History of US Stem Cell Law and Policy

Federal policies affecting human stem cell research include those targeted specifically at the research, or aspects of it, and more general policy that has implications for stem cell research. In both cases, most of these policies affect hESc research.

An example of policy that predates the derivation of hEScs is federal regulation of research involving human embryos, which began in the 1970s. Following the 1973 decision of the Supreme Court in *Roe v. Wade*, the United States Department of Health, Education and Welfare (DHEW) (a predecessor to the Department of Health and Human Services [HHS]) placed a moratorium on research with living human embryos. In 1974 Congress followed suit, creating their own moratorium on federal funding for research on embryos and embryonic tissue. While the DHEW moratorium was lifted in 1975, a de facto Congressional ban remained, and was translated into legislation in 1995 with the passage of the Dickey–Wicker Amendment [31,32]. The amendment specifies that no HHS (which includes the National Institutes of Health [NIH]) funds can be used for the creation or destruction of a human embryo for research

purposes. Since 1996, this policy has appeared as a rider to the annual appropriation acts for the Departments of Labor, Education, and Health and Human Services. Since then, no research on human embryos themselves, including the derivation of stem cells and the creation of human embryos through cloning, has been supported with federal funds. Instead, funds from states and private sources have been used to create embryonic stem cell lines. Once those lines have been created, federal funding has been available for research on them (see later). While the terms of this funding have varied by administration, Presidents Clinton, Bush, and Obama formulated policies to allow for federal funding of research on hEScs, within the bounds of the Dickey–Wicker Amendment. Unless Congress removes this provision from HHS appropriations, or until embryonic stem cells (or their equivalent) can be extracted without destroying or harming human embryos [33], federal funding cannot be made available for the critical derivation step in the research.

Following the announcement of derivation of hEScs in 1998, President Clinton developed a policy to permit use of federal funds to study embryonic stem cells without contravening the Dickey–Wicker Amendment [2]. Under the policy, federal funds could be used for research on embryonic stem cells *after* they had been extracted from the embryo, but the funds could not be used for the crucial extraction step in the process. In opposing President Clinton's policy, some members of Congress complained that although it did not pay for embryo destruction, it nevertheless encouraged research that required the destruction of human embryos [2]. The basic reasoning in President Clinton's policy—that extraction of stem cells from embryos is a separate step from research on those cells once extracted—has persisted in the policies of Presidents Bush and Obama since, and was tested in a federal court in 2010. However, President Clinton's policy itself was not able to be implemented before his presidency ended, and the federal policy was altered dramatically in 2001, when President George W. Bush announced that he would limit federal funding to the study of embryonic stem cells that were already in existence at the time that his policy was announced (9 p.m. Eastern Standard Time on August 9, 2001). Research on newly derived cell lines would not be permitted with federal money. Other conditions included that the cells must have been extracted from "spare" embryos that were donated with the informed consent of the donors, to whom no financial inducements may have been offered [34]. To facilitate research on existing embryonic stem cells that met these criteria, the NIH set up a stem cell registry shortly after the policy was announced listing embryonic stem cell lines eligible for use in federally funded research and available for shipping. In his 2001 address, President Bush stated that more than 60 embryonic stem cell lines met his criteria, but for a variety of reasons only 22 lines were consistently listed in the registry as available for shipping.

In explaining his policy, President Bush explicitly referred both to scientists' beliefs in the enormous therapeutic potential of embryonic stem cell research and to his own belief in the value of embryonic life. Of embryonic stem cell research, he noted: "At its core, this issue forces us to confront fundamental questions about the beginnings of life and the ends of science. It lies at a difficult moral intersection, juxtaposing the need to protect life in all its phases with the prospect of saving and improving life in all its stages." He called himself "a strong supporter of science and technology" but also noted that he believes "that human life is a sacred gift from our Creator" [35].

If President Bush intended his policy as a compromise between the value of scientific research and the value of embryonic life, it was one that left many scientists, disease groups, and others unsatisfied. Substantial criticism was directed at the 2001 policy. Those who oppose any research in which human embryos are destroyed argued that the federal funding restrictions needed to be supplemented with a nationwide ban on creating embryos for use in research, including by cloning [2,36]. A more vocal opposition called the 2001 policy overly restrictive. Their arguments included that the President overvalued embryonic life (that it is not more important than research aimed at treating disease) [2], that the policy was arbitrary and inconsistent [2], that the cell lines in the NIH registry were of poor quality and inappropriate for long-term use [37], and that the policy harmed American science by encouraging scientists to focus on research for which federal funding is available or to move to other countries to conduct their research [2].

During the Bush presidency, stem cell research was an important and in many cases partisan political issue. Federal policy was debated during the 2004 presidential campaign [38] and was a major issue at the Democratic National Convention, where Ronald Regan Jr., son of former Republican President Ronald Regan, gave a speech calling for greater government support of embryonic stem cell research. State policies to fund hESc research ineligible for federal support (described later in the chapter) were in some cases motivated by disagreement with President Bush's 2001 policy.

Other political activity, however, was bipartisan, including two 2004 letters—one signed by over 200 congressional representatives and the other signed by nearly 60 senators—asking President Bush to relax federal funding restrictions on embryonic stem cell research. Similar bipartisan support was expressed for the Stem Cell Research Enhancement Act, introduced in 2005 and 2007, which would have provided federal support for hESc research using embryos created for IVF, no longer clinically necessary and donated with informed consent [39–41]. Both attempts

were passed by the House and Senate, but vetoed by President Bush (an override was unsuccessful in 2005 and not attempted in 2007). Republican politicians who supported changes in federal policy included Senator Orrin Hatch, who mixed opposition to abortion with support for embryonic stem cell research provided it used only spare embryos [42]. Although the Stem Cell Research Enhancement Act was never passed, its language and motivations contributed to a shift in federal policy at the commencement of the Obama administration.

Current US Stem Cell Research Policy

Federal Policy

At the time of writing, US policy for embryonic stem cell research is contained in President Obama's March 9, 2009 Executive Order [43], the NIH Guidelines on Human Stem Cell Research [44], and any applicable state laws [45]. The 2009 Executive Order and NIH guidelines establish the criteria for embryonic stem cell research that uses federal funds. They do not apply to research conducted using nonfederal monies, such as might be supplied by an individual donor, a company, a charitable organization, or a state government. Nevertheless, because much basic biomedical research is traditionally funded by the federal government, the federal funding policies have a significant impact on embryonic stem cell research in the United States.

Executive Order 13505 does little more than revoke the policy announced in 2001 by President George W. Bush, state that the NIH may fund research using embryonic stem cells, and request that they issue new guidance for such research. The particulars of the new federal funding policy are to be found in the NIH Guidelines on Human Stem Cell Research, released in 2009. Under these guidelines, federal funding may be used to study embryonic stem cells derived from embryos "that were created using in vitro fertilization for reproductive purposes and were no longer needed for this purpose" (sometimes referred to as spare, surplus, or leftover embryos) and that were donated by the individuals who sought reproductive treatment. The donors must have given their voluntary written consent for the embryos to be used in research, and documentation must be available to show, among other things, that the donors received no cash or in-kind payment in exchange for making the donation and that there was a clear separation between the decision to create the embryos for reproductive purposes and the decision to donate. The guidelines also establish a registry of cell lines that meet federal funding criteria and describe procedures for establishing eligibility for funding of lines that are not already on the NIH registry. Because of the continued applicability of the Dickey–Wicker Amendment, federal funding is not available for the derivation of stem cells from embryos or research on cells taken from embryos that were created for research purposes, including by cloning [44].

Although considerably less controversial, President Obama's Executive Order and the NIH guidelines that followed have also been criticized for being too permissive by those opposed to embryonic stem cell research and too restrictive by those who believe federal funding should be available for research on stem cell-extracted embryos created for research purposes, including by cloning [46].

Overall, stem cell policy under President Obama has received little political attention. The most notable opposition came by way of the courts, just months after the announcement of Obama's executive action. A suit was brought against the Obama administration (specifically, HHS Secretary Kathleen Sebelius) by two adult stem cell researchers, James Sherley and Theresa Deisher, who argued that federal policy violated the spirit of the Dickey–Wicker Amendment by funding research that relies on the destruction of human embryos. The case succeeded initially in the federal district court for the District of Columbia [47]. But after a series of appeals, the US Court of Appeals for the District of Columbia Circuit overturned the decision in 2012, citing no wrongdoing or violation of Dickey–Wicker in the NIH's interpretation of the guidelines [42]. In 2013, the Supreme Court refused to hear the case, decidedly upholding NIH's 2009 guidelines and the limited federal funding of hESc research [48] (Figs. 75.1 and 75.2).

State Policy and Private Funding

In response to President Bush's 2001 hESc research funding policy, advocates lobbied both state governments and private parties to provide funds for the research. The funding helped propel the research forward. Harvard University's Douglas Melton and colleagues announced in 2004 that they had derived 17 new embryonic stem cell lines with support provided by the Juvenile Diabetes Research Foundation, the Howard Hughes Medical Institute, and Harvard University [49]. According to a 2005 special report in *Scientific American*, about $200 million of private money was spent on US stem cell research annually during the Bush administration [50]. We could find no reports of whether or how private funding of hESc research has changed since 2009. However, private foundations continue to contribute heavily to hESc research despite the increased federal funding under the Obama administration [51].

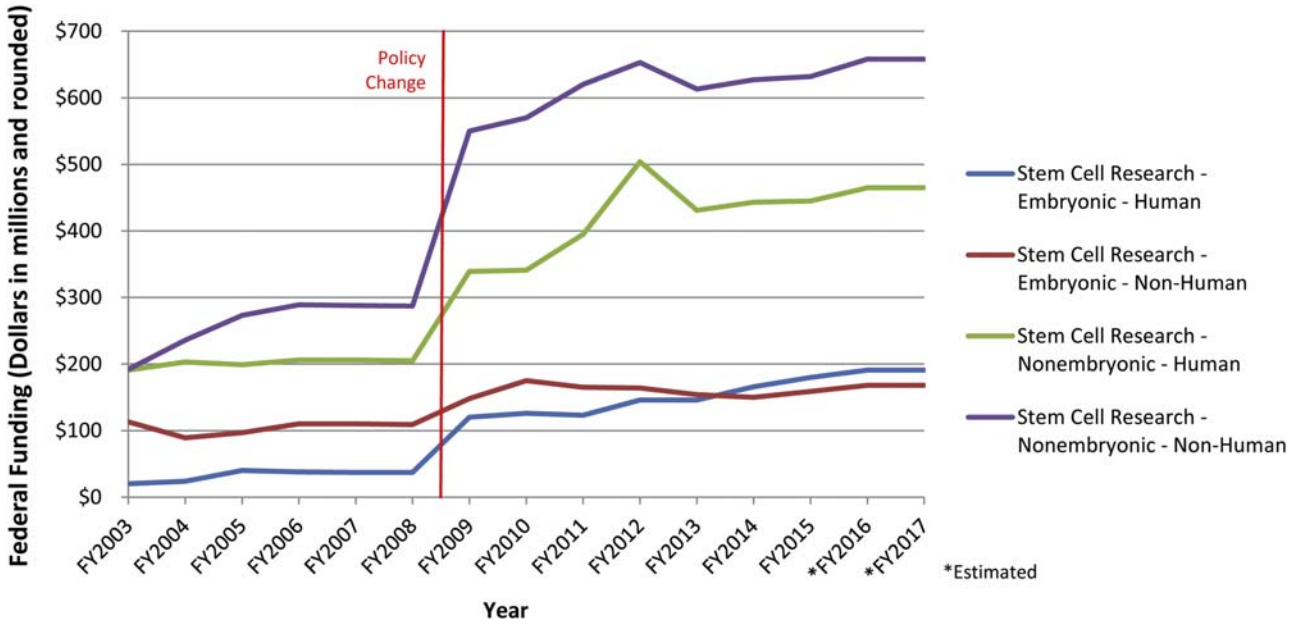

FIGURE 75.1 **Federal funding for embryonic versus nonembryonic stem cell research (FY2003–FY2017).** Changes in federal funding for embryonic and nonembryonic human and nonhuman stem cell research between the years 2003 and 2017. The *red line* denotes the shift from the Bush administration to the Obama administration, at which time US federal stem cell research and funding policies changed significantly.

Estimates of funding for various research, condition, and disease categories (RCDC); February 10, 2016. https://report.nih.gov/categorical_spending.aspx.*

In response to President Bush's hESc research policy, states also moved to fund stem cell research, as outlined in Table 75.1. In 2004, New Jersey became the first state to announce funding for local stem cell researchers, creating the Stem Cell Institute of New Jersey and the New Jersey Stem Cell Research Grant Program [52]. This program, as well as one in Illinois, has since ended, but funding continues to be available in other states, including New York, Connecticut, Maryland, Massachusetts, and Wisconsin [53].

Continued

TABLE 75.1 Human Embryonic Stem Cell Research Laws and Funding by State—cont'd

State Specific Notes:

[a] *Amendments both allocating and prohibiting state funding for stem cell research have been introduced in Florida, neither have passed into law.*

[b] *Minnesota law prohibits use of living human conceptus (any human organism from fertilization through the first 265 days thereafter) for any type of scientific, laboratory research or other experimentation. It is unclear whether embryonic stem cells fall under this definition: while the publically funded University of Minnesota Stem Cell Institute is permitted to use embryonic stem cell lines (from embryos created for IVF and not necessary for reproduction), no grants for hESc research have been issued in the state.*

[c] *Nebraska limits embryonic stem cell research with state funds; restrictions apply to state healthcare funds provided by tobacco settlement dollars. No state facilities or funds can be used to destroy or create an embryo for the purpose of research (no derivation of stem cells or SCNT). Thus, derivation of hESc and use of SCNT can be conducted with public funds only with cell lines developed elsewhere. Both hESc derivation and SCNT are permitted using private funds.*

[d] *A 2005 veto indirectly allows Nevada state funds to be used for research on human embryonic stem cell lines that existed before August 2001 (in accordance with the Bush Policy).*

[e] *In 2015, the Oklahoma House passed a bill criminalizing embryonic stem cell research. The bill did not progress through the Senate and was not passed into law. State funding is allocated only to non-embryonic stem cell research, but funding is not explicitly forbidden by law.*

[f] *Like Minnesota, Pennsylvania law prohibits "knowingly performing nontherapeutic experimentation upon any unborn child […from fertilization until birth]." However, it does not explicitly ban embryonic stem cell research, which has been conducted at the University of Pennsylvania.*

Thus far, however, the largest state initiative has been in California [54]. In November 2004, voters in California supported a proposition to allocate $3 billion over 10 years to embryonic stem cell research. The initiative, known as Proposition 71, authorized the state of California to sell $3 billion in general obligation bonds to provide funding for stem cell research and research facilities in California. Under the proposition, the funds have been distributed as grants and loans to California-based institutions by the Californian Institute for Regenerative Medicine (CIRM, established 2006), which also established regulatory standards for the research [55]. Critics of the initiative called it fiscally irresponsible given the state's economy and other health and research needs, and argued that the institute as structured lacked accountability [55]. Nevertheless, 59% of voters approved the measure. In 2015, California launched CIRM 2.0, described as a "radical overhaul" of the agency's operations, systems, and programs with an emphasis on speed, partnerships, and patient preference. In 2015, the state provided $135 million to 47 grants and 252 programs supporting stem cell research [56].

STEM CELL RESEARCH GUIDELINES

The National Academies of Science

The very limited federally funded hESc research program combined with increased interest in hESc research by states and private funders created a situation in which research was being funded by a variety of funders around the United States without the benefit of national rules or guidelines. In 2004, issues surrounding creation, use, and donation of hEScs were taken up by a panel convened by the US National Academies of Science (NAS), a private, nonprofit organization whose mission is to advise the nation on issues in science, engineering, and medicine. While they do not carry the force of the law, in general the National Academies' reports and recommendations are very influential and its *Guidelines for Human Embryonic Stem Cell Research* [57] received significant media attention when they were first released in April 2005. The 2005 guidelines (and their 2007 and 2008 revisions) were instrumental templates for state legislatures and institutions as they developed their own funding and research policies.

They were adopted, at least in part, by most major US research institutions [58]. While the guidelines are not the first document to speak to the conduct of embryonic stem cell research in the United States, at the time they were formulated it was not clear whether any of the previous guidance applied to contemporary hESc research because previous guidance was formulated under President Clinton but never implemented and effectively revoked by President Bush, or was simply too restrictive to meaningfully guide institutions and researchers that had made the decision to move forward with the research [59]. The guidelines were therefore received as filling a policy vacuum.

President Obama's 2009 Executive Order and the subsequent guidelines released by the NIH overrode the NAS guidelines to a certain extent. In 2010, the National Academies released a significantly amended set of guidelines, intended to be interpreted in tandem with the NIH's regulations [58]. The committee noted that non-NIH guidelines (such as its own) would continue to be important in the areas not eligible for federal funding, and thus not governed by the NIH. Some of these areas include the derivation of stem cell lines (ineligible for federal funding under Dickey−Wicker), research on hESc lines that were derived from embryos produced from some source other than IVF for reproductive purposes (including IVF for research purposes and SCNT cloning methods), and the wider range of experiments on chimeras. In the areas in which the NIH guidelines do overlap, NAS recommended that the NIH guidelines supersede its own. Where research falls outside of the scope of the federal guidelines, NAS generally recommends that the research is "permissible only after additional review and approval." This research includes generation of hEScs by whatever means and research involving the introduction of hEScs into animals other than humans and primates at any stage of development. NAS continued to recommend that research involving in vitro culture of any intact human embryo for longer than 14 days, and the introduction of hEScs into nonhuman primate blastocysts or non-hEScs into human blastocysts should not be permitted at this time.

The committee that drafted the original NAS guidelines was asked to consider the use and derivation of stem cells from embryos originally created during fertility treatment, embryos created using donated eggs and sperm, and cloned embryos. It therefore did not engage in the debate over whether it is morally permissible to destroy human embryos in research, as is required for derivation of embryonic stem cells. It also did not consider whether there is a moral difference between research that uses spare embryos and research that uses embryos created specifically for research purposes, including by cloning. The acceptability of these sources of stem cells was assumed.

Overall, the NAS committee recommended banning very little scientific activity. Instead, it recommended institutional review of protocols, oversight of the involvement of egg, sperm, and embryo donors, establishment of stem cell banks, and documentation of research activity. Two recommendations were particularly significant. First, the committee recommended that much embryonic stem cell research be subject to a mixture of local and national oversight. Local oversight would occur at each institution engaged in embryonic stem cell research, which would establish an Embryonic Stem Cell Research Oversight (ESCRO) committee to oversee all issues related to the derivation and use of embryonic stem cells, review all proposals for scientific merit, maintain records of research that takes place at the institution, including registries of new cell lines, and educate investigators. As noted by the 2010 amendment, many stem cell institutions created ESCRO committees. While the 2009 NIH guidelines did not require such a board, the National Academies maintains the importance of ESCRO committees in consulting and training roles at all institutions conducting stem cell research. ESCRO committees remain especially important at centers conducting nonfederally funded hESc research, which is not subject to the same federal oversight or regulation. In many cases, local IRBs provide additional oversight. Even though much embryonic stem cell research does not strictly speaking need to go before an IRB, the NAS committee recommended that the procurement of egg, sperm, and embryos should always be reviewed by an IRB, regardless of the applicability of federal regulations, and that IRBs never waive the requirement for informed consent from a person donating cells, eggs, sperm, or embryos to research, even where the federal human subject research regulations provide for such a waiver.

The other significant set of recommendations in the 2005 NAS guidelines addressed the involvement of egg, sperm, and embryo donors. In line with much guidance, law, and regulation around the world, the NAS guidelines recommended requiring consent from embryo donors for research use of those embryos. They went beyond previous US guidance, however, by extending this requirement to egg and sperm donors, including when the embryo was originally created for fertility purposes. At the time of the recommendation, gamete donors were asked to consent to reproductive use of their gametes, but were not generally asked to consent also to subsequent research use of any embryos their gametes were used to produce [60]. This NAS committee noted that this requirement might rule out the use of some embryos already created for fertility purposes that are now in frozen storage. The most recent iteration of the guidelines specifies that "written agreement at the time of gamete donation that one potential use of the blastocysts and/or morulae is embryo research will constitute sufficient consent," meaning that consent specifically to hESc research is not needed [58].

On the issue of compensating egg, sperm, and embryo donors, the NAS guidelines noted the arguments in favor of compensation: paying egg and sperm donors is routine in the US fertility context, and many Americans

participating in other kinds of research are offered financial inducements to secure their participation. They acknowledged that arguments for compensating egg donors are particularly strong: "the invasiveness and risks of the procedure suggest that financial remuneration is most deserved, but at the same time there is a greater likelihood of enticing potential donors to do something that poses some risk to themselves" [58]. These arguments notwithstanding, the National Academies committee followed previous US guidelines and guidelines and laws from many other nations in recommending that egg donors be reimbursed only for "direct expenses," and that no payment whatsoever be offered to sperm or embryo donors. They did allow, however, for reimbursement of fertility clinics for costs, including professional services, associated with obtaining consent and collecting eggs, sperm, or embryos.

In addition to cash payment, the NAS guidelines recommended against compensation in kind. Donors are not to receive any benefit from their donation, including "personal medical benefit" (excepting autologous transplantation, where the donor receives stem cells derived from his or her donation). This rule would prevent a kind of egg- or embryo-sharing arrangement whereby women or couples receive cheaper or free fertility treatment in exchange for donating a portion of their eggs or embryos to stem cell research. Similar arrangements exist in the fertility context, where women or couples receive a discount if they donate some of their eggs to others undergoing fertility treatment. This arrangement would help make fertility treatment available at a lower cost, but it would also more quickly exhaust the woman's or couple's supply of eggs or embryos, thereby possibly reducing their chances of achieving pregnancy [61]. In 2008, NAS's Human Embryonic Stem Cell Research Advisory Committee revisited the issue of donor compensation. The committee retained its prohibition on compensating embryo donors and discussed the arguments for and against compensating gamete donors. The guidelines were amended to make explicit that "actual lost wages" qualify as direct expenses for which gamete donors may be compensated, but additional payments are still not permitted [62].

International Society for Stem Cell Research

In 2006, the International Society for Stem Cell Research (ISSCR) released its first set of guidelines for embryonic stem cell research [63]. ISSCR is the world's largest professional organization for stem cell scientists, and is not tied to specific countries or national policy agendas. The guidelines were revised and expanded in 2016 [64].

As can be seen in Tables 75.2 and 75.3, in many ways the updated ISSCR guidelines are very similar to those of the National Academies. Like NAS's recommendation to form institutional oversight committees, ISSCR recommends formation of Embryo Research Oversight committees. However, under the ISSCR guidelines, these committees could operate at not only an institutional level, but could also provide local, regional, national, and international oversight. The ISSCR guidelines recommend similar standards for informed consent and the reimbursement and payment for embryos and other biological materials, and, notably, agree with the NAS that informed consent must be collected from all gamete donors. The scope of technologies and research uses covered by the ISSCR guidelines is, like in the NAS guidelines, quite broad. Both sets of guidelines address (and by extension apply to) many more kinds of research than are covered by the NIH guidelines, including derivation of cells from research embryos. Nonetheless, ISSCR takes at times a more conservative approach to novel technologies, research types, and sources of embryonic stem cell lines than the NAS guidelines. For instance, their guidelines propose a more robust review for the derivation of new stem cell lines and for the use of cells derived from research embryos [64].

Likely because they are at the time of writing the most recently published set of guidelines, the ISSCR's recommendations address the broadest scope of technologies, including gene editing of nuclear genomes of human sperm, eggs, or embryos, mitochondrial replacement therapy, and the creation and use of human totipotent cells [64]. The potential of these technologies has expanded considerably in the years since the publication of the NIH guidelines and NAS's final 2010 report. While not specific to the American policy context, the ISSCR's recommendations provide critical insights into many developing uses of embryos and embryonic stem cell lines.

INTERNATIONAL COMPARISONS

Biomedical research is an international undertaking and stem cell research is no exception. The governments of nations active in embryonic stem cell research employ a variety of regulation strategies, most of which include some restrictions on and oversight of the research while still allowing it to move forward. No single regulatory approach has prevailed internationally, although some patterns have emerged. For instance, many nations use national legislation to regulate stem cell research, often requiring oversight by a national stem cell research committee

TABLE 75.2 Federal and Professional Guidelines: Scope of Guideline Application

	NIH[1]	NAS	ISSCR
Research Using Previously Derived hESCs:			
Created using IVF for reproduction; no longer clinically necessary*			
Created by Somatic Cell Nuclear Transfer (SCNT)			
Created by parthenogenesis			
Created using IVF specifically for research purposes			
Generation and Derivation of new hES cell lines			
Use of hESCs or induced pluripotent stem cells to create chimeras:			
The introduction of hES or iPS cells into non-human primates at any stage of embryonic, fetal or postnatal development	[2]		
The introduction of hES or iPS cells into animals other than humans or primates at any stage of embryonic, fetal or postnatal development	[2]		
The introduction of hES or iPS cells into non-human primate blastocysts or of any embryonic stem cells into human blastocysts			
Allowing any animal to breed that has hES or iPS cells that could contribute to the germ line			
Research using SNCT for reproductive cloning			
Research involving human totipotent cells			
Research involving *in vitro* culture of any intact human embryo for longer than fourteen days			

* Eligible for federal funding.

hESCs, *Human embryonic stem cells;* iPScs, *induced pluripotent stem cells;* ISSCR, *International Society for Stem Cell Research;* IVF, *in vitro fertilization;* NAS, *National Academies of Science;* NIH, *National Institutes of Health.*

Key:

Green: Permitted after currently mandated reviews; all research under this designation must follow all accompanying guidelines pertaining to consent, reimbursement, banking, etc.

Yellow: Permitted only after additional review and approval.

Red: Not permitted by guidelines at this time. In the case of NIH, research pertaining to these areas is not eligible for federal funding. The other two guidelines are not legally binding, but institutions, states, and private funders are advised to consider guidelines when considering which projects to fund and approve.

Gray: Not considered by guidance.

Notes:

[a] *The NIH guidelines speak and apply to only that research which is federally funded. Thus areas of stem cell research that are not addressed in the NIH guidelines are neither eligible for federal funding nor controlled by the NIH's guidance.*

[b] *The NIH 2009 guidelines prohibited funding on the creation of human–animal chimeras in which human stem cells are introduced into nonhuman primate blastocysts. In 2015, the NIH created a moratorium on funding for the integration of human stem cells in all nonhuman vertebrate animals' pregastrulation-stage embryos. The NIH issued a call for comments in 2016 to consider ending the moratorium and consider extending the scope of chimera research. For more, see the "Animal–Human Chimeras" section at the end of this chapter.*

TABLE 75.3 Federal and Professional Guidelines: Research Guidelines

	NIH	NAS	ISSCR
INFORMED CONSENT			
Donors must understand all options for embryos no longer needed for reproductive purposes	x		
Decisions related to creation of human embryos for reproductive purposes must have been made free from influence of researchers proposing to derive or utilize hESCs in research	x	x	x
Donors must provide consent for embryo donation to research at the time of donation	x	x	x
Donors must provide consent for tissue and cell donation if at any time these materials are to be used for research involving the creation of human embryos			x
All gamete donors must provide consent for embryo donation		x	x
During the consent process, donors must be informed: **1.** That embryos would be used to derive hESCs and may be kept for many years **2.** What would happen to embryos in the derivation of stem cells for research **3.** That the research is not intended to provide direct medical benefit to the donor **4.** That the results of research may have commercial potential, and the donor(s) would not receive financial or other benefits **5.** Whether information that could identify the donor(s) would be available to researchers	x	x	

Continued

TABLE 75.3 Federal and Professional Guidelines: Research Guidelines—cont'd

	NIH	NAS	ISSCR
During the consent process, donors must be given: **1.** The information that hESCs or iPSCs may be used for research on transplantation, genetic manipulation, or the mixing of human and nonhuman cells in animal models **2.** A summary of the risks involved to the donor **3.** A statement as to whether donors wish to be contacted in the future to receive information obtained through studies of the cell lines, if identities are to be retained		x	
Donors must be informed that they can withdraw consent at any time until stem cells are derived	x		
Donors must be informed of institutional policies on return of incidental findings			x
REIMBURSEMENT AND PAYMENT			
No payments, cash or in kind, can be offered for donated embryos	x	x	x
Research oversight bodies must authorize proposals to reimburse or compensate donors			x
Compensation for egg donors should cover "direct costs" of time, effort, and inconvenience only		x	x
OVERSIGHT			
Mechanisms should exist on institutional, regional, and/or national level(s) to oversee and approve novel technologies, methods, or cell types		x	x
IRBs should review the procurement of all gametes, morulae, blastocysts, or somatic cells for the purpose of generating new hESc or iPSc lines		x	
IRBs should approve any processes pertaining to banking of hESc lines		x	
DERIVATION, BANKING, AND DISTRIBUTION			
Institutions engaged in obtaining and storing hESc lines should develop standards for: **1.** Committee review and oversight of banking and withdrawals **2.** Documentation requirements (donor consent and IRB approval forms, medical, clinical, and diagnostic information, infectious disease screening, culture conditions, and cell line characterization) **3.** A secure system for privacy of donors, especially with identifiable information		x	
National and international repositories should accept deposits of newly derived stem cell lines and distribute them on an international scale			x

or licensing authority. Substantively, bans on creating embryos by cloning are common, although not universal, as are bans on creating embryos by fertilization except as part of fertility treatment, which means that research in many, although certainly not all, nations is limited to surplus or spare embryos. The US approach of regulating federally funded research but leaving nonfederally funded research unregulated is highly unusual by international standards [65].

In the United Kingdom, comprehensive legislation governing all research and medical use of human gametes and human embryos has existed since 1990 [66]. A major feature of the legislation is that it institutes few bans, but requires that all collection and use of embryos and gametes be licensed and overseen by an independent body called the Human Fertilisation and Embryology Authority (HFEA). The existence of this legislation and the HFEA before hESCs were first isolated meant that the research already had a regulatory system into which it could immediately be slotted, obviating the need for significant new legislative action by the UK government in response to the research (although regulations were promulgated in 2001 to add three new purposes for which research on embryos is permitted, including increasing knowledge about serious disease) [67]. Some scholars have urged the United States to adopt a similar regulatory system, under which very few activities are banned outright but instead require a license and are subject to oversight [68].

In neighboring Canada, national funding guidelines similar to the policy formulated by President Clinton were released in 2002 by the Canadian Institutes of Health Research (CIHR) [69]. Significant terms of these guidelines include that all research using CIHR funds is subject to national oversight by the Stem Cell Oversight Committee, that all embryonic stem cell lines generated using CIHR funding must be recorded in a national electronic registry and made available to other Canadian academic researchers at a cost, and that stem cells can only be extracted from

spare embryos (embryos cannot be created for research purposes, including by cloning). In 2014, the CIHR guidelines were integrated into the 2nd Edition of Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans in December 2014 [70].

The CIHR guidelines were followed in 2004 by the Assisted Human Reproduction Act, which, like the legislation in the United Kingdom, regulates much more than just embryonic stem cell research [71]. Several provisions of the Act, however, directly impact embryonic stem cell research. In particular, the Act prohibits creating a cloned embryo and creating an embryo for "any purpose other than creating a human being or improving or providing instruction in assisted reproduction procedures," thereby limiting embryonic stem cell research in Canada to embryos originally created in the course of fertility treatment (although the legislation does not specify that such embryos be surplus to the fertility needs of the donors) [72].

The distinction that many policies draw between stem cell research involving embryos created for use in research (including by cloning) and research involving embryos originally created for use in fertility treatment also appears in Australia's Research Involving Human Embryo's Act 2002 and the Prohibition of Human Cloning Act 2002. Both Acts limit research to "excess ART embryos," defined as embryos created for use in the assisted reproductive technology treatment that are now excess to the needs of the woman or couple for whom they were created [73]. The Prohibition of Human Cloning for Reproduction and the Regulation of Human Embryo Research Amendment Bill 2006 retained these conditions, but further specified laws on cloning, allowing for SCNT while prohibiting reproductive cloning [74]. Similar conditions are attached to research in other nations, including France, Denmark, Finland, Greece, the Netherlands, and Japan (a full breakdown of country policies can be seen in Table 75.4).

South Korea, a country active in stem cell research, is in the unusual position of permitting the creation of cloned embryos for research into rare or incurable diseases, but prohibiting the creation of embryos for research by IVF. Under a 2004 law, revised in 2008, IVF may only be used to create embryos for reproductive purposes, which can later be donated to research if not used. Cloned embryos may only be created for use in research into the treatment of rare or incurable diseases [75]. In early 2006, cloning research led by Woo-Suk Hwang of Seoul National University was found to have included a number of questionable practices, including that some egg donors were members of the research team, some egg donors were paid to donate, and researchers accompanied some egg donors as they underwent the extraction procedure [76]. Following charges of embezzlement and falsifying results against the prominent stem cell researcher, the South Korean government halted approvals and funding for stem cell research until early 2009. Embryonic stem cell projects have been approved again, and since 2012 South Korea has reemerged as a leader in stem cell research, due both to a federal funding boost and considerable regulatory freedom [77]. In Israel, another country active in stem cell research, no legislation regulates the field, although there is a law against implanting a cloned embryo [78]. Therefore derivation of stem cells from embryos created for research use, including by cloning, is allowed (although to date there are no reports of Israeli scientists creating cloned embryos) [79]. Under Singapore's 2004 legislation, research is permitted on spare embryos and embryos created for research, including by cloning [80]. With over 40 active stem cell research groups in the country limited by very few regulations, the country has been called "Asia's Stem Cell Center." In 2012, Singapore established a Bioethics Advisory Committee to oversee research, but provides very few legal or regulatory barriers [81].

SELECTED ETHICAL, LEGAL, SOCIAL, AND POLICY QUESTIONS OF STEM CELL RESEARCH

As embryonic stem cell research moves forward in the United States, various ethical and policy questions arise, some of which have already been discussed. For example, should researchers create embryos in the laboratory by fertilization or cloning or should they only use spare embryos? Either way, they will need to interact with fertility clinics or with egg, sperm, or embryo donors, raising questions about how those interactions should be conducted. Should researches pay fertility clinics for procuring gametes and embryos for stem cell research? How should gamete and embryo donors be approached to donate, precisely whose consent should be required, and should the donors be compensated? Once researchers extract cell lines, are they obliged to make those lines available to other researchers? Should researchers patent new cell lines or new stem cell-related processes? If they do obtain patents, what practices should they follow in licensing those lines or processes? Should researchers be allowed to mix human cells and animal cells in the creation of chimeras or hybrids, and what could happen if they do so? Here we address several of these issues in some detail.

Key:

Green: Permitted by Law or Guidance (some uses may be limited by rules or regulations)

Red: Prohibited by Law (some uses may be exceptions, and allowed under specific conditions)

Grey: Not considered in law — implicitly permissible, not governed by regulations or guidance

TABLE 75.4 Human Embryonic Stem Cell Research Laws and Funding in Countries With Applicable Policies—cont'd

** The country doesn't explicitly regulate stem cells, but one of the country's laws allows surplus IVF embryos to be used for research purposes, suggesting that hESC research is implicitly permissible.*
+ Banned unless medically, scientifically, and therapeutically vital, in particular for the specific embryo involved.
~ The country has no legislation on stem cell research, but the creation of embryonic stem cell lines and research on such lines is de facto *prohibited.*
^Researchers must provide explicit justification for research or use of embryos/ESCs and establish that creation / use of embryos is essential for research.
Country Specific Notes:
[a] In Austria, ESC research is de facto *prohibited because embryos and gametes cannot be donated for purposes other than assisted reproduction with heterosexual couples. However, the use of imported hEScs was not addressed explicitly by law and thus is implicitly permissible. While the derivation of embryonic stem cells from human embryos is currently prohibited, the Austrian Bioethics Commission has advocated for hESC derivation of surplus embryos.*
[b] The law in Chile is unspecific. A 2006 law defends the "protection of human life from the moment of conception," and states that no human embryos can be destroyed to obtain stem cells, and that ES cell lines only can be used for "therapeutic diagnosis or scientific research".
[c] The creation of and research with hES cell lines is banned in Germany as a "matter of principle." In 2008, Germany eliminated a past law that made it a criminal offence to use hES cells in research conducted outside German's borders. Research on imported hES cell lines is allowed, but hES cells cannot be derived in Germany, and must have been imported before May 1, 2007.
[d] ESC research has been permitted in Iran since 2002, when Supreme Leader Ayatollah Khamenei issued a 'stem cell fatwa*' that declared that human embryo research was consistent with Shia tradition. Iranian scientists and bioethicists have since developed ethics guidelines for hES cell research.*
[e] Ireland has no legislation on embryo or stem cell research, but the Irish Medical Council has banned medical practitioners from creating embryos specifically for research.
[f] Lithuania limits hESC and embryo research to non-interventional clinical observations only.
[g] Mexico is currently debating an amendment that would ban all research on human embryos, thereby halting the creation of and any research on hESC lines.
[h] In New Zealand, research can only be conducted on non-viable embryos (in contrast with viable excess IVF embryos, permitted by other countries).
[i] Stem cell research is only allowed in Romania under official approvals. There is no regulation of IVF, research on embryos, or hESCs.
[j] Embryonic stem cell research is permitted in Singapore under recommendations from the Bioethics Advisory Committee, which are adhered to by the scientific community. The creation of embryos through SCNT is permitted on a case-by-case basis to derive patient-specific cells.
[k] South Korea permits SCNT as a source for hESCs (in addition to excess IVF embryos) despite the ban on production of non-reproduction embryos; SCNT can be used "for the purpose of conducting research aimed at curing rare or currently incurable diseases."
[l] Sweden permits therapeutic cloning if hereditary genetic traits remain unchanged.
[m] Turkey allows for non-embryonic stem cell research when officially approved, no hESC research is permitted.
[n] United States law and guidelines allow for SCNT and the derivation of hESCs at large, but neither are permitted as part of federally funded research. Some individual US states have laws addressing SCNT and hESC research.

Compensating Egg Donors

The South Korean stem cell controversy over the procuring of eggs in South Korea for use in cloning research brought additional attention to egg donation. Findings related to the donation process raised concerns about whether the women who donated eggs to Hwang's research did so completely voluntarily. Voluntariness is a core commitment of modern research ethics [82], which generally translates into requirements that no one is pressured to participate in research and that each participant is able to withdraw from the research at any time without endangering ongoing medical care [82]. Researchers usually avoid enrolling family members and employees because they might reasonably feel significant pressure to participate. The commitment to voluntary participation, and specifically the derived right to withdraw from the research at any time, could also be under threat if researchers physically accompany volunteers through procedures as Hwang and his colleagues apparently did.

Concern to protect voluntariness is also a major factor motivating bans on compensating egg donors, the argument being that the need for money could compel participation, especially, though not exclusively, among the poor. Nevertheless, it is unclear whether the concern is sufficient to justify a complete ban on compensation, particularly in a US context. As the National Academies committee noted, many other research participants in the United States receive compensation in exchange for their involvement in research [57]. Such payment, particularly where modest, is said to be not only a necessary incentive, but also fair treatment of research subjects (after all, the researchers and their staff will be paid for the time and resources they contribute toward the research). The concern about voluntariness in the hESc context is likely heightened because egg donation is time-consuming, painful, and involves some risk. Egg donors are injected with drugs over weeks so that they superovulate (produce many eggs). The eggs are then removed from the woman by either inserting a hollow needle through her vagina or by laparoscopic surgery. Risks of the stimulation and egg-collection process include hot flashes, headaches, sleeplessness, mood alteration, ovarian hyperstimulation syndrome, nausea, vomiting, pain, bleeding, and infection. There is even a controversy over a possible danger of ovarian cancer from the medications and ovarian stimulation for IVF [83,84]. Could payment encourage some women to donate eggs even though donation might be painful and pose a risk to their health? The answer is yes. However, whether the risk and pain are unacceptable is another issue. In theory at least, if an IRB approves research involving egg donation, it has decided that the risk to donors is reasonable in relation to the importance of the knowledge that may reasonably be expected to result [85]. Compensation is not supposed to be offered to research participants to seduce them to take an unacceptable risk.

But voluntariness may not be the only concern about paying egg donors in stem cell research. There is also some opposition to paying anyone for providing bodily materials (rather than solely for their time and effort), for example, as expressed in a federal law prohibiting payment for organ donation (although that law expressly does not apply to blood, sperm, or human eggs) [86]. The stance against the sale of bodily materials is well defended in scholarly circles. Bioethicist Thomas Murray argued nearly 30 years ago that all donations of body parts, whether for research or for clinical treatment, should be gifts and not sales [87]. Others, however, including law professor Lori Andrews, writing around the same time, countered that individuals "have the autonomy to treat their own (body) parts as property," particularly those parts of the body that they can regenerate [88].

The debate about compensating egg, sperm, and embryo donors continues today. Beyond clarifying their definition of "direct reimbursable expenses" as "costs associated with travel, housing, child care, medical care, health insurance, and actual lost wages," the NAS guidelines included a note on autonomous choice:

> To facilitate autonomous choice, decisions related to the creation of embryos for infertility treatment should be free of the influence of investigators who propose to derive or use hES cells in research. Whenever it is practicable, the attending physician responsible for the infertility treatment and the investigator deriving or proposing to use hES cells should not be the same person.

Although included in the final iteration of the guidelines, the recommendations leave the issue open for interpretation by researchers, and further questioning by the scientific and policy communities at large [58]. The only state that provides for compensation of egg donors is New York, which in 2009 announced that its funds could be used to offer women up to $10,000 for donation of eggs to hESc research.[1]

Commercialization and Access to Treatments

Another argument against paid donation is that it adds to the costs of conducting research and thereby the price of eventual treatments. But this argument works best if the same spirit is adopted by the scientists, institutions, and companies involved in the research and in any eventual treatment. Indeed, a commitment to scientific progress and widely available treatments in stem cell research might entail a commitment by all those involved to, for example, banking and widely distributing new cell lines, participating in international collaboration, and adopting patenting and licensing practices designed to facilitate access (including possibly not patenting some discoveries at all) [89]. These concerns about secrecy, privacy, access, and commercialization in stem cell research mirror a larger debate in biomedical research in general [90].

[1] The legal status of compensation limits like that announced by New York's Empire State Stem Cell Board is currently unclear in light of a recent class action lawsuit filed by egg donors in opposition to fertility industry caps on payments (*Kamakahi et al. v. American Society for Reproductive Medicine et al.*, Case No. 3:11-cv-01781-JCS, in the US District Court for the Northern District of California).

In terms of access, particular emphasis is often put on patenting and licensing practices, which can have an enormous impact on progress made by other researchers, as well as on the availability of eventual treatments [91]. Indeed, a number of patents already attach to embryonic stem cell research [92], including a long-standing patent claiming a purified preparation of primate (including human) embryonic stem cells and a method for isolating them [93]. To establish its 2001 registry, the NIH negotiated with patent holders to issue licenses to noncommercial entities royalty free so that research could move forward. The NIH-negotiated licenses, however, explicitly cover only research and do not extend to commercial activities [94]. It is not yet known whether these same terms apply to research using lines in the new NIH Human Embryonic Stem Cell Registry.

As a general matter, patents in biomedical research can restrict other researchers from using a specific method or material, creating monopoly-like conditions, and hampering the progress of research. These conditions could significantly raise prices and reduce equitable access to treatments. Access for research and treatment was among the issues motivating the lawsuit over gene patents held by Myriad Genetics that was resolved in the Supreme Court in 2013. While the reasoning in the *Myriad* case refers specifically to the ineligibility of DNA sequences for patents, some have predicted that the case's vague precedent for "natural" biologic materials could impact stem cell patents [95,96]. If it does not, the patentability of stem cell research methods and future treatments could raise treatment prices and create significant disparities in treatment access. At the time of writing, the future of the Affordable Care Act and other insurance and drug pricing regulations is uncertain in the United States. Without suitable insurance and treatment cost protections, disparities in access to stem cell treatments may be even more pronounced.

Patenting and licensing issues were to some extent anticipated in California's Proposition 71, which included a provision requiring the establishment of standards in all grants and loans allowing the state to financially benefit from licenses, patents, and royalties and resulting from the research activities funded under the measure [55]. Regulations implementing these standards require that a portion of profits be returned to the state [97].

Animal–Human Chimeras

To develop and test possible human clinical uses, human stem cells are being implanted into nonhuman animals at various stages of development. "Human–animal chimeras" are created by introducing human genetic material into nonhuman animal embryos. Human stem cells can be inserted into animal embryos, fetuses or postnatally, and will grow and develop into various organs and systems within the animal. The ethical and legal questions surrounding chimera animals depend on where and when human stem cells are introduced into the animal system: is the animal a primate or vertebrate that is genetically similar to humans; are stem cells inserted into the blastocyst, embryo, or later stage in the animal's development; will the human cells impact an animal's nervous system or enter its germ line for reproduction; and will the animal be brought to term or allowed to reproduce?

Although guidelines vary as to how they address the creation of animal–human chimera (refer to Tables 75.2 and 75.3), they are all attentive to several similar factors. First, whether or not the animal into which the human cells are introduced is a close genetic relative of humans is considered to be important both clinically and ethically. From the perspective of clinical validity, a primate or other vertebrate animal is a more useful test model than an animal with dramatically different genetic and biological structures from humans. However, from an ethical perspective, some commentators have raised concerns about the "humanization" of animals. If an animal species is a close genetic neighbor to humans, it is thought that human stem cells introduced early in development could be sufficiently integrated into the animal in ways that could be "morally humanizing"—that is, that move the animal's moral status toward human beings thereby creating a novel creature with a novel, and unclear, moral status [98].

This concern about moral status is also behind two other important issues about animal–human chimeras: the location and number of the human cells within the nonhuman animal, and the stage of development during which stem cells are introduced in animals. If stem cells are introduced in a postnatal animal, they are unlikely to become integrated into systems beyond the organ or tissues at which they were targeted [98]. However, if human stem cells are transplanted into animal embryos (single celled) or blastocysts (between 50 and 100 cells), they are considerably more likely to become integrated into many if not all of the animal's biological systems, including the animal's central nervous or reproductive systems. Could human stem cells in the brain of a pig, for instance, "humanize" it [98]? Could human cells enter the animal's reproductive system causing it to produce human sperm or eggs? In response to the latter concern, prohibition on breeding of any animals into which human stem cells have been transplanted is widespread [44,54,64].

The NIH 2009 guidelines specifically stated that research introducing embryonic or iPScs into any animals at any stage of development could not be covered by federal funding [44]. In 2015, the NIH extended the federal funding ban on chimera research, announcing a moratorium on funding for research introducing human pluripotent cells into all nonhuman vertebrate animal pregastrulation embryos [99]. After a public comment and workshop period, NIH released a call for public comments in September 2016 [100] on a proposal to expand the prohibition on introducing hEScs or iPScs into nonhuman primate embryos to include preblastocyst-stage in addition, to blastocyst-stage embryos. Within its proposed changes, the NIH proposed to potentially permit (as decided by the steering committee) funding for research integrating human stem cells into nonhuman vertebrate embryos up through the end of the gastrulation stage (lifting the 2015 moratorium), as well as research in which human stem cells are introduced into postgastrulation, nonhuman, nonrodent mammals, which may present a "substantial functional modification to the animal brain by human cells" [98]. This final provision, if supported by federal funding, could result in researchers being able to create animals that present the aforementioned risk of "humanization." Such a concern has raised several questions. For instance, what addition of human materials, if anything, would constitute an "elevation of moral status" in a research animal such that it could no longer be used for research? Furthermore, a concern about humanization begs a more fundamental question about our own humanness, moral status, and consciousness. Some have argued that the interactions and impact of human material in chimeras will not reach a point at which these questions truly become necessary, and that instead, issues surrounding animal welfare and the potential harms that we may have on research animals are more important at present [98] (Currently, many research centers mandate that Institutional Animal Care and Use Committees oversee animal–human chimera research and other stem cell transplants occurring in nonhuman animals.) Nonetheless, as stem cell technologies and research move forward, questions about research that blurs the line between humans and nonhuman animals will likely remain at the forefront of ethical and policy decision-making.

CONCLUSION

As this brief overview shows, stem cell research, and in particular hESc research, has led to the development of numerous policies. In the United States, as well as in some other nations, these policies have responded to the controversial nature of research involving the destruction of human embryos. The US federal funding policy of 2001, which limited the use of federal funds in embryonic stem cell research, generated a lot of attention, including significant criticism. In response to the 2001 policy's limits, funds for embryonic stem cell research were provided by private donors, charitable organizations, and some states. In 2009, President Obama repealed the 2001 policy. Nevertheless, federal funding, while now more widely available, is still limited to research on cells derived from spare embryos and cannot be used to derive new cell lines.

As research on embryonic stem cells taken from a variety of sources moves forward in the United States and internationally, some of it without funding or guidelines, a range of policies are developing that respond to a number of important issues, including local and national oversight, the role of donors in the research, the consequences of commercial interests, the creation of animal–human chimeras, and the extension of stem cell research technology using new technologies such as gene editing. At the time of writing, it is still unclear if and how the Trump administration will approach the ethical issues associated with embryonic stem cell research and funding. Simultaneously, stem cell and greater bioscience technologies are developing into increasingly complex arenas, including involving advances in gene editing. It will be important to continue to observe how stem cell research remains intertwined with ethical, legal, and policy questions on domestic and international fronts.

List of Acronyms and Abbreviations

CIHR Canadian Institutes of Health Research
CIRM California Institute for Regenerative Medicine
hESc Human embryonic stem cell
HFEA Human Fertilisation and Embryology Authority (United Kingdom)
HHS Department of Health and Human Services, once was DHEW: Department of Health, Education and Welfare
iPSc Induced pluripotent stem cell
IRB Institutional Review Board
ISSCR International Society for Stem Cell Research

IVF In vitro fertilization
NAS National Academy of Science
NIH National Institutes of Health
SCNT Somatic cell nuclear transfer

CHAPTER

76

Ethical Considerations*

Ronald M. Green

Dartmouth College, Hanover, NH, United States

INTRODUCTION

Since the first development of human embryonic stem cells (hESCs) in 1998 [2,3] there has been a consensus in the scientific community that pluripotent cells hold great promise for developing new treatments for a variety of serious and currently untreatable disease conditions [4,5]. Although clinical successes in this area have been slow in coming, research is ongoing and novel therapies are beginning to show promise in clinical trials [6,7].

Nevertheless, because hESC research involves the manipulation and destruction of human embryos, the field has also been a focus of ethical controversy and opposition. In the course of these debates, many challenging ethical questions have been raised. Scientists, clinicians, or patients using hESCs or therapies must formulate their own answers to these questions. Society, too, must address them to determine the extent to which hESC research may require oversight and regulation. This chapter presents the most pressing of these questions, and critically examines some of the answers that have been proposed to them.

IS IT NECESSARY TO USE HUMAN EMBRYOS?

Whether it is permissible to destroy human embryos to create hESC lines is a leading question, to which we turn in question 2 later. However, in late 2007, teams led by Yamanaka in Japan and Thomson in the United States announced success in the use of gene transfer technology to produce induced pluripotent stem cell (iPSC) lines [8,9]. Some have argued that this development obviates the need to develop or use hESC lines [10]. They assume that if we can directly manipulate somatic cells and perhaps even produce patient-specific (autologous) stem cells there is no reason to destroy human embryos or use hESCs derived from such destruction. However, there are both scientific and ethical reasons for questioning this assumption.

Scientifically, there is a question of whether iPSCs will prove suitable for use in human transplant and cell regeneration therapies. Early iPSCs exhibited high rates of tumorigenicity in mice, possibly a result of the use of retroviral vectors to carry pluripotency-inducing transcription factors, including the cancer-related factor c-Myc [11,12]. Reports suggest that the genomic reprogramming process in iPSCs may be less complete than that which takes place in the fertilized egg, causing the resulting cells to exhibit abnormal expansion and early senescence [13]. There is also a concern that because iPSCs are produced from somatic cells that have been exposed to aging and toxins, they may exhibit harmful mutations when used in clinical therapies. Because of these concerns and the possible costs of patient-specific therapies, some argue that banks of tissue-matched hESCs offer better prospects for therapies. In a review of these issues, Hug and Hermerén conclude that "if we consider all the aspects of safety, it is hardly possible to determine which therapy based on which type of cells would be safer according to the present state of knowledge" [14].

Research to answer these questions is ongoing (for example, [15,16]), but doing so will require a better understanding of the reprogramming process in embryonic cells. For this reason alone, the use of human embryos is likely

*This chapter is a substantial revision and updating of the chapter "Ethical Considerations" that appeared in Atala et al. [1].

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00076-X

to continue to be an important feature of stem cell research [17]. At this time, there exist many useful hESC lines created from donated human embryos. There are also currently hundreds of thousands of frozen embryos remaining from infertility procedures that will likely be destroyed and that could be used for research [18]. If stem cell research involving embryos were halted, this vast resource would go to waste. Many people feel that it is unwise to foreclose any of the available paths to developing pluripotent cells for regenerative medicine research. The view of the National Research Council remains in force: "The application of stem cell research to therapies for human disease will require much more knowledge about the biological properties of all types of stem cells" [4].

Ethically, it can also be asked whether the production and use of iPSCs is free of concerns. It is widely assumed that iPSCs avoid ethical controversy because they are produced from somatic cells, which unlike early embryos have no inherent potentiality of developing into a human being. But the work of Nagy and others shows that embryonic stem cells, when inserted into tetraploid embryos, are able to develop the placental material needed for further development [19–24]. This possibility raises complex ethical questions. Is potentiality morally relevant if it is accompanied by such intensive technical interventions? Embryos produced by in vitro fertilization (IVF) or nuclear transfer (cloning) also require intensive technical interventions, and opponents of hESC research normally condemn the use of these as sources for hESCs. If it is acknowledged that the potentiality for full human development, however assisted, confers moral status on an entity, then iPSC research may not be the ethical panacea that many of its proponents believe it to be. As Giuseppe Testa [25] observes:

> The point is not that one can no longer use the potentiality argument because fibroblasts might now be considered as potential persons in a more concrete way than ever before… That is, there is no longer, if there ever was, any ready-made grid of boundaries that biology can let us see as if they were simply out there and that can serve as neutral justification for political choices.

Finally, it might be asked whether, even within the framework of hESC research, we must destroy embryos. In 2005, the Bush administration's President's Council on Bioethics issued a White Paper encouraging research in alternate methods of hESC derivation, including the use of arrested or developmentally nonviable embryos [26]. Several of these proposals, such as the deliberate genetic manipulation of embryos to prevent their normal development, are not free of ethical controversy [27,28]. A method involving single-cell blastomere biopsy has also been developed and implemented that could obviate the need to destroy the embryo to develop an hESC line [29]. While this approach raises questions of risk to the manipulated embryos, it can be justified in the context of preimplantation genetic diagnosis (PGD), where cells are routinely removed as a diagnostic procedure.

Reviewing all these considerations, we can say that considered scientifically and ethically there is no easy route around the destruction and use of human embryos in pluripotent stem cell research.

IS IT MORALLY PERMISSIBLE TO DESTROY A HUMAN EMBRYO?

hESC lines are usually made by chemically and physically disaggregating an early, blastocyst-stage embryo, and removing its inner cell mass. At this stage the embryo is composed of approximately 200 cells, including an outer layer of differentiated placental material, and the undifferentiated (pluripotent) cells of the inner cell mass. The embryo dies as a result of this procedure. New methods that permit the development of pluripotent cell lines without destroying an embryo have not yet replaced this standard method for developing hESCs, and most existing hESC lines were created this way. Hence the question remains: may we intentionally kill a developing human being to expand scientific knowledge and potentially provide medical benefits?

At one end of the spectrum of answers are those who believe that, in moral terms, human life begins at conception when a new, self-developing genome comes into being. For many of those holding this view, the early embryo is not morally different from a child or an adult human being. It cannot be used in research that is not to its benefit, and it cannot be used without its consent [30–32]. Furthermore, proxy consent by parents in such cases is inadmissible, since it is an accepted rule of pediatric research that parents may not volunteer a child for risky studies that are not to its benefit. Many Roman Catholics, evangelical Protestants, and some Orthodox Jews take the position that life (morally) begins at conception, and they oppose hESC research.

At the other end of the spectrum are those who believe that the embryo is not yet fully a human being in a moral sense. They hold a "developmental" or "gradualist" view of life's beginning [33–37]. They do not deny that the early embryo is alive and has the biological potential to become a person, but they believe that other features are needed for the full and equal protection we normally accord children and adults and that these features only develop gradually across the full term of gestation. These features include such things as bodily form and the ability to feel or

think. Since the early embryo lacks organs, it cannot have these features or abilities. They also note that the very early embryo lacks human individuality, since it can still undergo twinning at this early stage, and two separate embryos with distinct genomes can fuse to become a single individual [38]. Some dismiss this argument, maintaining that the possibility of twinning or fusion does not reduce the genetic uniqueness or moral status of the earliest developing cells [39], but it is hard to see how the claim that "a person begins at conception" can easily withstand these biological facts. Finally, the very high mortality rate of such embryos (most never implant) reduces the force of the argument from potentiality [40,41]. Those who hold this developmental view do not agree on the classes of research that warrant the destruction of embryos, but most support some form of hESC research. Their reasoning is that, although the early embryo merits some respect as a nascent form of human life, the lives and health of children and adults outweigh whatever claim it possesses [42].

Each individual faced with involvement in hESC research must arrive at his or her own answer to the question of the status of the early human embryo and when, if ever, it may be destroyed. Legislators and others must also wrestle with these issues. On March 9, 2009, President Barack Obama issued an executive order authorizing federal funding for research involving the use, but not the derivation, of hESC lines. Whether this position will be sustained by the Trump administration remains to be seen.

MAY ONE BENEFIT FROM OTHERS' DESTRUCTION OF EMBRYOS?

If, as some maintain, the human embryo is a morally protectable entity that cannot be intentionally destroyed, can researchers, clinicians, or patients justify the downstream use of a cell line produced from its destruction? This raises the more basic question of whether we can ever benefit from deeds with which we morally disagree or regard as wrong [43,44]. It is also the question of when a connection with wrongdoing becomes complicit with it [45].

Why is it morally wrong to benefit from others' misconduct? One answer is that by doing so we may encourage similar deeds in the future. This is most apparent in cases where our conduct directly instigates wrongdoing, such as when we authorize theft or receive stolen goods [45]. However, it seems less objectionable to benefit from others' wrongdoing when their deeds are independently undertaken and not in any way prompted or encouraged by us. For example, few would object to using the organs from a young victim of a gang killing to save the life of another dying child. The use of organs benefits one person and in no way encourages teen violence. Can similar logic apply to stem cell research using spare embryos remaining from infertility procedures?

It helps to remember that most embryos used to produce hESC lines are left over from infertility procedures. Couples using IVF routinely create more embryos than can safely be implanted. There are already hundreds of thousands of these embryos in cryogenic freezers in the United States and around the world [18]. Despite strenuous efforts, including some supported by the US government, few frozen embryos are adopted [46,47]. Most of these supernumerary embryos will be destroyed. In 1996, British law mandated the destruction of 3600 such embryos [48]. Does using hESC lines made from surplus embryos encourage either the creation or destruction of embryos?

Although a downstream researcher, clinician, or patient may abhor the deeds that led to the existence of an hESC line, including the creation and destruction of excess human embryos in infertility medicine, nothing that a recipient of an hESC line chooses to do is likely to alter, prevent, or discourage the continuing creation or destruction of human embryos, or make the existing lines go away. Those who use such embryos may also believe that if they refuse to use an hESC line, they would forgo great therapeutic benefit. People in this position will struggle with the question of whether it is worthwhile to uphold a moral ideal or engage in a symbolic act when doing so has no practical effect, and when it threatens to expose others to harm.

It is noteworthy that in an August 2001 address to the nation, President George W. Bush adopted a version of the position that allows one to benefit from acts one morally opposes. Stating his belief that it is morally wrong to kill a human embryo for others' benefit, the President nevertheless permitted the use of existing stem cell lines on the grounds that the deaths of the embryos had already occurred [49]. Similarly, Germany permits the importing and use of hESC lines created before January 1, 2002, the date on which the Bundestag passed a law governing such matters (this date was later moved to May 2007). These initiatives reflect the belief that it does not encourage further destruction of embryos to permit the use of previously generated cell lines. President Bush did not go so far as to permit the use of lines that could in the future be derived from embryos certainly slated for destruction because their progenitors choose never to use them. However, in July 2009, the National Institutes of Health (NIH) implemented an executive order issued in March 2009 by President Obama that authorized funding for the use, but not the derivation, of new hESC lines from embryos remaining from infertility procedures [50]. Opponents of hESC research have criticized this derivation-versus-use distinction as morally problematical, but apart from the moral issues,

this distinction is legally necessary because the Dickey–Wicker Amendment prohibits federal funding for research in which a human embryo is destroyed [51].

In summary, the downstream use of stem cells derived from embryos remains a source of moral controversy and disagreement. Each researcher or clinician who opposes embryo destruction will have to examine his or her own conscience in the light of the foregoing considerations to determine how much they wish to associate themselves with the use of hESC lines created in ways to which they morally object.

MAY WE CREATE AN EMBRYO TO DESTROY IT?

Is it ever morally permissible to create an embryo deliberately to produce a stem cell line? This was done in the summer of 2002 at the Jones Institute in Norfolk, Virginia [52]. Those in favor of this research defend it on two grounds. First, they say that in the future, if we seek to develop stem cell lines with special properties, such as closer genetic matches to tissue recipients or properties introduced by gene editing (see question 7 later), it may be necessary to produce stem cell lines to order using donor sperm and eggs. Second, they argue that it is ethically better to use an hESC line created from embryos that have been produced for just this purpose, with the full and informed consent of their donor progenitors, than to use cell lines from embryos originally created for a reproductive purpose.

Those who believe the early embryo is our moral equal oppose the deliberate creation of embryos for research or clinical use. They are joined by some who do not share this view of the embryo's status, but who believe that it is morally repellant to deliberately create a potential human being only to destroy it [53]. They argue that this research opens the way to the "instrumentalization" of all human life and the use of children or adult human beings as commodities. Some ask whether such research does not violate the Kantian principle that we should never use others as "a means only" [54].

On the other side of this debate are those who believe that the lesser moral status of the early embryo permits its creation and destruction for lifesaving research and therapies [55,56]. The proponents of this research direction ask why it is morally permissible to create supernumerary embryos in IVF procedures to help couples have children, but morally wrong to do the same thing to save a child's life. They are not persuaded by the reply that the status of the embryo is affected by its progenitors' intent, and that it is therefore permissible to create excess embryos for a "good" (reproductive) purpose, but not for a "bad" (research) purpose. They point out that the embryo is the same entity, and its status should not depend on its progenitors' intentions. We do not ordinarily believe that a child's rights are dependent on its parents' intent or degree of concern [57]. They conclude that it is not parental intent that warrants the creation of excess of embryos in such cases, but the embryo's lesser moral status and the likelihood of significant human benefit from its use. These same considerations, they believe, justify deliberately creating embryos for stem cell research.

MAY WE CLONE HUMAN EMBRYOS?

This question arises in connection with the patient-specific stem cell technology known as "human therapeutic cloning." It involves the deliberate creation of an embryo using somatic cell nuclear transfer (cloning) technology to produce an immunologically compatible (isogenic) hESC line [58].

Immune rejection could occur if the embryo used to prepare a line of hESCs for transplant does not share the same genome as the recipient. This would be the case whether the cell line was created from a spare embryo or from one made to order. Therapeutic cloning offers a way around this problem. In the case of a diabetic child, for example, the mother could donate an egg whose nucleus would then be removed. A cell would be taken from the child's body and its nucleus inserted into the egg cytoplasm. With stimulation, the reconstructed cell would divide, just like a fertilized egg. If the resulting embryo were transferred back to a womb, it could go on to birth and become a new individual—a clone of the child. But in therapeutic cloning, the blastocyst would be dissected and an hESC line prepared. Growth factors could be administered to induce the cells to become replacement pancreatic cells for the child. Because these cells contain the child's own DNA, and even the same maternal mitochondrial DNA, they would not be subject to rejection. Research has also shown that the small amount of alien DNA from the mitochondria of a donor egg would probably not provoke an immune response [59].

Although this is a promising technology, it raises a host of novel ethical questions. One is whether the embryonic organism produced in this way should be regarded as a "human embryo" in the accepted sense of that term [60]. Those who believe that "life begins at conception" tend to answer this question affirmatively, even though cloned

"embryos" are not the result of sexual fertilization [61]. They believe that it is no more permissible to create and destroy a cloned embryo than to do so with one produced by sexual fertilization. They base their view on the biological similarities between cloned and sexually produced embryos and on the argument that both have the potential to become a human being. However, as we have seen, if the embryo's status rests on its potential, some degree of potentiality attaches today to all bodily cells, which no one would argue should be withheld from use in biomedical research or therapy.

Therapeutic cloning implies the availability of human oocytes and raises the special question of ovulation induction. This is an invasive medical procedure, with both known and undetermined risks [62,63]. Not only must egg donors be informed of these risks, but steps also must be taken to preserve the voluntary nature of their consent. This includes avoiding financial incentives that create an "undue influence" on donors' judgment. It also includes preventing them from being pressured into producing excess eggs or embryos for research in return for discounts on infertility services [64].

Fears about coercion and the exploitation of poorer women or women of color have led some to oppose paid egg donation for research [65,66]. Several states, including California and Massachusetts, have passed laws prohibiting this practice. Nevertheless, experience has shown that women will not donate eggs for either reproductive or research purposes without adequate compensation [67]. In the face of these problems, New York State reversed the legal trend and approved payment for research egg donation.

Those who defend payment for oocytes point out that payment to research subjects involved in risky research is a common practice. They also ask why it is permissible to pay reproductive but not research egg donors [68]. The Ethics Committee of the American Society for Reproductive Medicine has supported payment for research egg donors. It conceptualizes this in terms of appropriate compensation for a donor's time, inconvenience, and discomfort, but not for the eggs themselves [69,70].

Finally, there is a moral question specific to cloning itself. The more scientists are able to perfect therapeutic cloning, the more likely it is that they will sharpen the skills needed to accomplish reproductive cloning, which aims at the birth of a cloned child. There is a broad consensus in the scientific and bioethics communities that, for the foreseeable future, cloning technology poses serious health risks to any child born as a result of it [71]. There are also serious, unresolved questions about the psychological welfare of such a child [72]. Finally, there is the possibility that embryos created for therapeutic cloning research might be diverted to reproductive cloning attempts. All these concerns raise the question: do we really want to develop cloning technology for the production of isogenic stem cells if doing so hastens the advent of reproductive cloning [73]?

The advent of iPSCs and the prospect of efficiently producing patient-specific stem cell lines have weakened the arguments for therapeutic cloning with its many associated controversies.

MAY WE USE HUMAN STEM CELLS TO CREATE CHIMERAS?

In stem cell research, human-to-animal chimera experiments involve the transfer of pluripotent or multipotent human stem cells into animals at embryonic, fetal, or postnatal stages of development to study stem cell behavior [74]. Some forms of chimera research are common and widely acceptable. For example, hESCs are routinely used to form teratomas in immunodeficient mice to assess stem cell quality and developmental potential. The creation of humanized antibody systems in mice is also central to cancer immunotherapy research.

Researchers have expressed interest in creating humanized organs or tissues in larger animals for disease modeling, drug testing, and perhaps eventual organ transplant [75]. Animal models with human cells in the brain can be used to study many human brain diseases, including Parkinson's, Alzheimer's, and schizophrenia, and may be useful models for testing new drugs [76]. However, these proposals raise many ethical questions because hESCs or human islet-derived precursor cells (hiPCs) inserted into an animal embryo prior to gastrulation can incorporate themselves into neural or reproductive tissues. Modifying neural tissues risks the creation of an animal with significantly increased potential for human sentience and self-awareness, a concern that is greatly increased in the case of nonhuman primates whose brain architecture might reasonably support human-like cognition and feelings. Humanizing reproductive tissues risks the inadvertent mating of two animals with such tissue in their gonads and a resulting pregnancy or birth of a human child from an animal womb. Some have argued that either prospect is ethically unacceptable because it represents a threat to human dignity [77,78], although what constitutes human dignity or its violation is difficult to assess [74]. Nevertheless, in terms of recognized human subject protections and animal welfare considerations, few would disagree that it is wrong to create animals with significantly humanized brains or to bring about a human pregnancy in an animal uterus.

Part of the difficulty in coming to terms with these questions are the many variables involved. Research and therapeutic benefits that are often speculative must be weighed against risks, which depend in part on the nature of the animals being used, the times at which pluripotent cells are inserted into the developing organism, the likelihood of these cells integrating themselves into various animal tissues and organ niches, and whether the organism will be allowed to come to term. Compounding this complexity is the "irreducible degree of uncertainty about the cognitive nature of the new chimeric animal, and how it would manifest distress, anxiety, or other factors relevant to one's assessment of animal welfare" [74].

These complexities counsel case-by-case assessment of research directions, protocols based upon careful monitoring of outcomes, and the best evolving information about risks and benefits [66,79–81]. The International Society for Stem Cell Research (ISSCR) summarizes this position when it calls for "specialized oversight" of such research utilizing "baseline animal data grounded in rigorous scientific knowledge or reasonable inferences" and involving "a diligent application of animal welfare principles" [82]. In August 2015, the NIH imposed a moratorium on its funding of human-to-animal chimera research pending public comment on revised guidelines. These guidelines include the creation of a high-level internal NIH steering committee to provide broad policy oversight for this research. In addition, the guidelines include specific prohibitions on (1) inserting hESCs or hiPSCs into nonhuman primate blastocyst-stage embryos, and (2) breeding of animals where the introduction of hESCs or hiPCs may contribute to a germ line (i.e., make human eggs or sperm) [76]. A 2011 report by the British Academy of Medicine also recommends a prohibition on "substantial functional modification of the NHP [normal pressure hydrocephalus] brain, such as to engender 'human-like' behavior," though it offers somewhat more lenient permission, with oversight, for "substantial modification of an animal's brain that may make the brain function potentially more 'human-like,' particularly in large animals" [83]. Despite disagreements by national bioethics bodies at the margins of research possibilities, there is a consensus that chimera research involving the humanization of animal brains and any research that risks a human birth requires ongoing, case-by-case, specialist scrutiny of the scientific and ethical issues involved.

MAY WE GENETICALLY MODIFY HUMAN EMBRYOS?

Gene editing has recently been given new precision and applicability by development of CRISPR-Cas9 technology. It is now possible to target specific gene sequences in somatic cells, stem cells, gametes, or embryos for deletion or modification. This raises the prospect of human genetic engineering for the purpose of disease prevention and treatment and for genetic enhancement. For example, it might be possible to use genetically modified cells or stem cells to provide therapies for HIV AIDS or sickle cell anemia. Pathologies that begin at early uterine development might be prevented by the modification of parental gametes or the early embryo itself. Germline interventions like these have the added advantage of preventing future transmission of the disease-causing mutations. In many cases it is true, the same goal can be accomplished without gene editing by use of PGD and embryo selection, but gene editing permits the introduction of novel gene sequences not available in the parental lineage. It can also facilitate genetic enhancement, the creation of human beings who are "better than well" [27,28].

Despite its capabilities, CRISPR-Cas9 has deficiencies. It can alter and disrupt DNA at locations other than the intended ones ("off-target results"); it can change the DNA in some but not all, resulting in a mosaic of altered and unaltered cells, and can generate immune responses if introduced into the body. Although the CRISPR-Cas9 system is still undergoing development to reach the level of safety where it could be used in clinical applications, there is broad consensus that it would be premature and ethically questionable to attempt germline gene editing at this time, even for serious genetic diseases. In December 2015, leading scientists and bioethicists convened an international summit on human gene editing that concluded:

> It would be irresponsible to proceed with any clinical use of germline editing unless and until (i) the relevant safety and efficacy issues have been resolved, based on appropriate understanding and balancing of risks, potential benefits, and alternatives, and (ii) there is broad societal consensus about the appropriateness of the proposed application.

The report continues:

> At present, these criteria have not been met for any proposed clinical use: the safety issues have not yet been adequately explored; the cases of most compelling benefit are limited; and many nations have legislative or regulatory bans on germline modification. However, as scientific knowledge advances and societal views evolve, the clinical use of germline editing should be revisited on a regular basis.[84].

ARE THERE SPECIAL CONSIDERATIONS GOVERNING THE USE OF STEM CELLS IN CLINICAL RESEARCH AND CLINICAL APPLICATIONS?

Like all research or clinical translation involving the use of animal or human subjects, stem cell research is governed by a set of fundamental ethical principles that have been embodied in national and international codes and laws. As enunciated by the ISSCR, these principles include (1) research integrity; (2) primacy of patient welfare; (3) respect for research subjects; (4) transparency; and (5) social justice [82].

Some commentators have warned against "stem cell exceptionalism"—the singling out of stem cell research for unwarranted special attention [74]. Thus it may be asked whether the use of stem cells in research or clinical treatments raises any novel ethical questions. Given the controversial and moral status of hESCs and the long-lasting but still uncharted powers of stem cells themselves, it seems wise to add special provisions to the guidelines governing research and clinical applications when hESCs and hiPSCs are involved. Such guidelines have been developed by the Chief Medical Officer's Expert Group in Great Britain [85,86], by private ethics boards at the Geron Corporation [87] and Advanced Cell Technology [88] in the United States, by committees of the National Research Council and Institute of Medicine [66,80,81], by the NIH [50,89], and by the ISSCR [82,90,91]. These various guidelines tend to share several features.

Stem Cell Research Oversight/Embryo Research Oversight Committee Review

There is agreement that, in addition to the usual review of research proposals by an Institutional Review Board (IRB), it is appropriate that there be another layer of review provided by a stem cell research oversight (SCRO) committee, or, as it has more recently been termed, an embryo research oversight (EMRO) committee. The name change reflects the advent of hiPCs, the use of which, except for those having "organismal potential," raises fewer issues than the use of hESCs. In its most recent guidelines, the ISSCR recommends EMRO review for research involving human embryos, embryo-derived cells or that which entails "the production of human gametes in vitro when such gametes are tested by fertilization or used for the creation of embryos," and research on human totipotent cells that have the potential to sustain embryonic or fetal development [82]. In contrast, use of iPSCs requires human subjects review but does not require specialized EMRO review so long as the research does not generate human embryos or totipotent cells [82]. The ISSCR also exempts from EMRO review research with established hESC lines that are confined to cell culture or involve routine and standard research practice, such as assays of in vitro differentiation or teratoma formation in immune-deficient mice.

EMROs can operate at institutional or higher levels, and should include as members scientists and/or physicians not directly engaged in the research under consideration but with relevant expertise, ethicists, "members or advisors familiar with relevant local legal statutes governing the research," and "community members, unaffiliated with the institution through employment or other remunerative relationships, who are impartial and reasonably familiar with the views and needs of research subjects, patients and patient communities who could be benefited by stem cell research, and community standards" [82].

Donor and Procurement Issues

Because hESC and therapeutic cloning research require a supply of human gametes and embryos, any of which raise sensitive issues of moral status and familial relationships, steps must be taken to elicit the informed consent of donors, to protect their privacy, and to minimize any risks to which they might be subject. Because hiPCs are derived from human somatic material, existing IRB regulations concerning review and informed consent cover their derivation, and no EMRO committee review is needed. Nevertheless, the possibility of the use of such cells in chimeric animals and special transplantation issues recommend EMRO review in some cases. To aid researchers, the ISSCR has offered the outlines of a sample consent document for these purposes [82].

In general, explicit and contemporaneous informed consent (consent given at the time of procurement) is required when donors are asked to provide biomaterials for the creation of embryos, hESCs, or immortalized hiPC lines. Contemporaneous consent is not necessary if researchers procure somatic cells from a tissue bank, but in such cases the tissue bank's consent documents must evidence that donors consented to the use of their biomaterials for gamete creation or for stem cell research. There is wide consensus that donors of cells, sperm, or embryos should not be compensated, although it is regarded as permissible to provide compensation for the time, inconvenience, and discomfort associated with the donation of oocytes for research so long as payment does not vary according to the planned use of the oocytes, the number or quality of oocytes retrieved, the number or outcome of prior donation

cycles, or the donor's ethnic or other personal characteristics [70]. Payment levels should not be so high as to constitute an "undue influence" on a woman's decision-making.

Informed consent requires that donors fully understand the nature of the research being undertaken (for example, that it may require the destruction of an embryo), and that they explicitly consent to it. Whenever possible, donors should be given the option of agreeing to some forms of hESC research but not others (e.g., the creation of stem cells but not cloned embryos). It is morally impermissible to elicit somatic cells, sperm, eggs, or embryos for the production of stem cell lines without informing donors that an immortalized, pluripotent cell line might result that could be widely used in research or therapeutic applications. If there are likely to be commercial benefits flowing from the research, donors must also be informed of this, and their rights (if any) in such benefits should be clearly specified. If the research involves therapeutic cloning, both egg and somatic cell donors must be informed that a cloned embryo and a cell line with the egg donor's mitochondrial genetic material and the somatic cell donor's nuclear DNA will result. iPSC somatic cell donors should also be informed about the developmental and commercial possibilities of their cellular materials. Special questions also arise about the use of somatic cells, embryos, or sperm whose provenance is uncertain, including embryos created with sperm whose donor is unknown [92].

An emergent problem given the possible widespread use of hESCs and iPSCs is the discovery of incidental genetic findings in the course of downstream research that might be of health importance to donors. ISSCR and other bodies recommend the development of a policy on whether and how incidental findings will be returned to donors and the communication of this policy to donors at the time of the informed consent process. Successful implementation of this policy depends on the traceability of cell lines and strict compliance with material transfer agreements [82].

In conducting research, efforts should be made to preserve donor privacy by removing identifying information from gametes, embryos, and cell lines, and keeping this information apart in a secure location. In view of the controversy surrounding much of this research, donors can be subjected to harassment or embarrassment if their association with the research is revealed without their consent. In an era where it is increasingly possible to identify donors from the DNA of the resulting stem cells, donors should be warned of possible risks to their privacy and that of their family members.

Finally, there is a question about the use of hESC lines previously produced (or produced abroad) under less comprehensive guidelines. The NIH faced this question in its effort to develop guidelines following President Obama's executive order permitting funding for hESC research. Many hESCs available for use had not been developed in precise conformity to the newly developed guidelines. The NIH met this problem by forming a Working Group of the Advisory Committee to the Director to consider exceptions that conform to the spirit of the guidelines. Rather than "grandfathering" preexisting hESCs, the Working Group is empowered to judge hESC lines "derived in a responsible manner" to be eligible for use in NIH-funded research [50].

Research Conduct

Guidelines also apply to the overall conduct of research. These include the requirement that no embryo used in hESC or therapeutic cloning research be allowed to develop beyond 14 days. This internationally recognized limit is based on the substantial changes that occur at gastrulation, which marks the beginning of individualization and organogenesis [93]. At this time, ISSCR guidelines also prohibit reproductive cloning research; research in which human embryos (or organized cellular structures that might manifest human organismal potential) are gestated ex utero or in any nonhuman animal uterus, or have undergone modification of their nuclear genome and are implanted into or gestated in a human or animal uterus; and research in which animal chimeras incorporating human cells with the potential to form human gametes are bred to each other [82]. Supervision and accountability of all staff and scientists involved in this research to prevent any diversion of gametes or embryos to reproductive purposes is required.

Clinical Translation

Stem cell-based treatments have been the clinical standard of care for some conditions, such as hematopoietic stem cell transplants for leukemia, but research on stem cell-based therapies has greatly expanded in recent years. Investigational New Drug applications have been filed for several therapies, and clinical trials are under way. As might be expected, problems have already developed. In late 2009, the Food and Drug Administration (FDA) asked the Geron Corporation to halt its trial on a groundbreaking stem cell therapy for spinal cord injury when a review revealed the formation of cysts in some (animal) trial subjects [94].

All tissue transplantation involves risks for the recipient, but for several reasons these risks are magnified in the case of stem cell transplants:

- Stem cells are novel therapeutic agents whose development and manufacture require innovative procedures for ensuring purity and homogeneity. Additional risks derive from the fact that cells are likely to be expanded in culture and/or exposed to xenoculture materials, viruses, or other infectious agents before transplantation. The likely use of these cells by large populations increases the need for careful oversight in cells' development and manufacture.
- Cell types may differ in their ability to proliferate and safely implant in the body. Their use poses risks of infusional toxicity, severe immune responses, and tumorigenesis. An additional problem is ectopic or off-target insertion.
- Animal models may not accurately reflect toxicity in humans.

In response to these challenges, in 2008 a multidisciplinary, international task force of the ISSCR proposed ethical guidelines for clinical translational research. The task force issued 39 recommendations, most of which fall into five broad categories: (1) cell processing and manufacture, (2) preclinical studies, (3) clinical research, (4) stem cell-based medical innovation, and (5) considerations of social justice [91].

With regard to cell processing and manufacture, the task force recommended that these be conducted under "scrupulous, expert, and independent review and oversight." As a rule, minimally manipulated products (cells maintained in culture under nonproliferating conditions for short periods of time) require less oversight than those subjected to extensive manipulations, such as genetic alterations. The same is true of autologous versus allogenic use and use for homologous versus nonhomologous functions (Recommendations 8 and 9). Good manufacturing practice must be applied to manipulated products and those destined for allogeneic use. Donors of cells should be screened for infectious diseases and the donor should give written informed consent that covers the likely storage, future manipulations, analyses, uses of their cells, commercial potential, and possible risks to the donor's privacy, including exposure of genetic information (Recommendation 3).

Preclinical studies are meant to provide evidence of product safety and proof-of-principle of therapeutic effect. This normally requires sufficient studies in animal models, including larger animals where structural tissue needs to be tested in a load-bearing model (Recommendations 11 and 14). Researchers must develop and implement a clear plan to assess the risks of tumorigenicity for any cell product (Recommendation 18). Cell cultures and animal models should be used to test the interaction of cells with drugs to which recipients will be exposed, including the immunosuppressants planned for recipients (Recommendation 19).

Clinical trials of stem cell research must conform to internationally accepted principles governing the protection of human subjects, including regulatory oversight, peer review by an expert panel independent of the investigators and sponsors, fair subject selection, informed consent, and patient monitoring. In addition, there are special issues raised by stem cell research. Because of their undetermined risks stem cell-based therapies, as a rule, must aim at being clinically competitive or superior to existing therapies. Where there are already efficacious therapies for a disease condition, the stem cell-based intervention must be of low risk and offer a potential advantage (such as better functional outcome; single procedure vs. lifelong drug therapy). Greater risks are permissible where there is no efficacious therapy and where the disease condition is severely disabling and life threatening (Recommendation 25). Patients need to be informed that cell-derived products have never been tested before in humans, that researchers do not know whether they will work as hoped, and that, unlike many pharmacological products or even many implantable devices, stem cells may stay in the body and generate adverse effects for the lifetime of the patient. To respect their values, and because some subjects may have moral objections to the use of embryo-derived cells, subjects should be informed about the source of the cells (Recommendation 28). To determine the consequences of cellular implantation, and with consideration of cultural and familial sensitivities, subjects should be asked for autopsy in the event of death (Recommendation 31).

Considerations of social justice apply to all research involving human subjects but receive special importance in view of public involvement in this emergent research area. Among the recommendations of the task force are public engagement in the policy making of governmental agencies (Recommendation 37), fair allocation of benefits and risks, and the need to develop alternative models of intellectual property, licensing, product development, and public funding to promote fair and broad access to the new diagnostics and therapies (Recommendation 38). One justice consideration especially pertinent to stem cell research is the establishment of stem cell collections with genetically diverse sources of cell lines (Recommendation 38). The task force concludes its recommendations with an aspirational goal that companies, subject to their financial capability, should offer affordable therapeutic interventions to persons living in resource-poor countries who would not otherwise have access to these therapies.

Universities and other institutions are asked to incorporate this requirement in their intellectual property licenses (Recommendation 39).

Clinical Application

Recommendations for the ethical introduction of stem cell therapies take place against a background marked by the presence of many clinical programs offering "stem cell therapies" outside the boundaries of proper clinical trials and ethical or legal oversight [95]. These unsupervised stem programs exploit a loophole in the FDA regulation of biologics that permits the use of cells that have been subject to "minimal manipulation" [96]. In some cases desperate patients have suffered serious illnesses, including growths caused by proliferating and ectopic transplanted stem cells [97]. In its 2016 report, the ISSCR issues a stern rebuke to such programs.

> The ISSCR condemns the administration of unproven stem cell-based interventions outside of the context of clinical research or medical innovation compliant with the guidelines in this document and relevant laws, particularly when it is performed as a business activity. Scientists and clinicians should not participate in such activities as a matter of professional ethics. For the vast majority of medical conditions for which putative "stem cell therapies" are currently being marketed, there is insufficient evidence of safety and efficacy to justify routine or commercial use [82].

The ISSCR guidelines do not altogether prohibit innovative clinical therapies. They affirm that "unproven stem cell-based interventions" can be provided to at most a very small number of patients outside the context of a formal clinical trial but in accordance with a set of "very restrictive conditions." These include the existence of a written plan outlining the scientific rationale and justification of the procedure, why it has a reasonable chance of success, and why it should be attempted compared to existing treatments. This plan should offer a full characterization of the types of cells being transplanted, how they will be administered, and a commitment to clinical follow-up and data collection to assess the procedure's effectiveness and adverse effects. The plan should be peer reviewed by independent experts, and have the full support and accountability of the health care institution where it is based. Patients must provide voluntary informed consent and understand that the intervention is unproven. There should be an action plan for adverse events, including insurance coverage for patients. Finally, the conduct of innovative treatments requires a commitment by clinician-scientists to use their experience with individual patients to contribute to generalizable knowledge. This includes communication of all outcomes to the scientific community in professional meetings and journals, and timely movement to formal clinical trials [82].

CONCLUSION

Fully answering all of the questions this chapter has raised would require an ethical treatise. However, in my view, the moral claims of the very early embryo do not outweigh those of children and adults that can be helped by hESC and therapeutic cloning technologies. While iPSC research is promising, reliance on it should not replace the use of hESC lines produced through proven techniques, and that are currently available. As we move forward to clinical translational research, care should be taken that there is proper oversight for these novel and potentially harmful therapies. Some may disagree with these conclusions. Continuing dialog about these questions and clearer scientific research results will bring us closer to a consensus on these issues.

INTRODUCTION AND CHAPTER OVERVIEW

The field of regenerative medicine encompasses a breathtaking array of interdisciplinary scientific approaches that address a broad spectrum of clinical needs. Ongoing advances in scientific knowledge related to cell biology, gene transfer therapy, biomaterials, immunology, engineering principles, and technology applicable to biological systems foster innovation of regenerative medicine products. This places the regenerative medicine community in a position to address a number of challenging and critical health needs including the treatment of disease conditions resulting from pancreas, liver, and kidney failure; structural cardiac valve repair; skin and wound repair; and orthopedic applications, among others. Scientific challenges confronting this field include expanding the knowledge base in each discipline as well as developing an interdisciplinary approach for identifying and resolving key questions. The US Food and Drug Administration's (FDA's) regulatory review process mirrors the scientific challenges with regard to the development of review paradigms that cross scientific disciplines.

This chapter will provide a brief historical review of the FDA and its organizational structure and discuss topics pertaining to the regulation of regenerative medicine products including possible regulatory pathways for combination products and relevant jurisdictional issues. Sources of information concerning FDA regulatory policies important to regenerative medicine product developers will also be discussed. It is essential for individuals, institutions, and companies responsible for the clinical trials of regenerative medicine products to be aware of FDA regulatory policies and how to obtain the necessary information. These entities are collectively referred to in FDA regulations as Sponsors (the term "Sponsor" for drugs and biologics is defined in 21 Code of Federal Regulations [CFR] 312.3[b] whereas "Sponsor" is similarly defined in 812.3[n] for devices). Suggestions will also be provided regarding how to engage FDA effectively during the development of a novel regenerative medicine product.

BRIEF LEGISLATIVE HISTORY OF UNITED STATES FOOD AND DRUG ADMINISTRATION

Medical products regulated by the FDA include human and animal drugs, medical devices, and biological products such as vaccines, cellular and gene therapies, and blood products. Among the therapeutic agents of biological origin regulated by the FDA are cellular therapies, including products derived in whole or part from human tissue, and xenotransplants. In addition to medical products for human use, the FDA regulates food other than most meat and poultry; radiation-emitting products for consumer, medical, and occupational use; cosmetics; medical products

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00077-1

for veterinary use; and animal feed. The FDA's role in medical product regulation extends throughout the entirety of the product life cycle. Depending on the product category, this may mean oversight, including review and inspection, of clinical trials, of the premarket product approval/clearance process, of manufacturing controls, controls over labeling, and registration and listing requirements. After a product is marketed, the FDA also continues its oversight in a variety of ways, including inspections, mandatory and voluntary postapproval (e.g., Phase IV) studies, and surveillance of adverse events reported to the FDA.

FDA laws and regulations have developed over time, partly in response to serious medical adverse events or by other public health and safety concerns. Early regulation of biological products was prompted in part by the death of 13 children in 1901 after the administration of diphtheria antitoxin prepared from a source contaminated with tetanus. In response, Congress passed the Biologics Control Act in 1902. This act provided for regulation of viruses, serums, toxins, and analogous products; required licensing of manufacturing establishments and manufacturers; and provided the government with inspectional authority. The Act focused on requiring control of manufacturing processes for producing biological products, reflecting the extent to which the starting source material and the manufacturing process defined the final product.

In 1906, Congress passed the Federal Food and Drugs Act, proposed in part in reaction to the meat-packing industry conditions described in Upton Sinclair's book, *The Jungle*. Although the primary focus of the Act was on food safety, the law also required that drugs be provided in accordance with standards of strength, quality, and purity unless otherwise specified in the label. Premarket review of new drugs was not required until the passage of the 1938 Food, Drug, and Cosmetic Act (FD&C Act), which repealed the earlier 1906 Federal Food and Drugs Act. In 1937, the sulfa drug Elixir Sulfanilamide, previously available only in tablet or powder form to treat streptococcal infections, was marketed as a liquid using diethylene glycol, an analog of antifreeze, as a formulating solvent. This change in formulation, which was made without the requirement for premarket review, resulted in over 100 deaths, many of whom were children, and prompted the passage of the 1938 FD&C Act. The 1938 Act also put medical devices and cosmetics under FDA authority and authorized factory inspections.

The Public Health Service Act (PHS Act), passed in 1944, incorporated the 1902 Biologics Control Act and is the current legal basis for the licensing of biological products. Because most biological products also meet the definition of "drugs" under the FD&C Act, they are also subject to regulation under that Act.

The requirement for premarket demonstration of efficacy and the authority for FDA oversight of clinical trials were provided by the Kefauver–Harris amendments to the FD&C Act in 1962. These amendments were prompted in part by the tragic adverse events resulting from use of thalidomide as a nonaddictive prescription sedative. This drug, which was not approved as a sedative in the United States, resulted in thousands of birth defects in children born outside this country when taken by pregnant women during the first trimester.

The Medical Device Amendments to the FD&C Act were passed in 1976, after reports of safety issues with respect to the Dalkon Shield intrauterine device. The Medical Devices Amendments included risk-based requirements for premarket notification or approval of medical devices. Before 1976, FDA authority was limited to taking action against marketed devices found to be unsafe or ineffective.

LAWS, REGULATIONS, AND GUIDANCE

The previous section summarized the history of laws that form the underpinning of FDA medical product regulation. This section provides a brief description of how laws are made and implemented, the procedures for promulgating regulations, and a description of how the FDA develops and uses guidance documents.

Laws are created as an outcome of legislative activity conducted in the US Senate and House of Representatives resulting in passage of a bill. Once Congress passes a bill, it becomes law if it is signed by the president. If the president vetoes the bill, it becomes law if two-thirds of the Senate and House of Representatives vote in favor of the bill. A federal law also is denoted as a public law and may contain a name, such as the FD&C or PHS Acts. These laws are then incorporated into the US Code (USC), which is updated every 6 years, with supplements published regularly to incorporate changes to statutes between updates. Drug, biologic, and device laws can be found in the USC at:

- Drugs and Devices: Title 21 Chapter 9, and
- Biologics: Title 42 Chapter 6A.

When laws are passed, government agencies such as the FDA often implement them by promulgating regulations. Sometimes an agency may elect to promulgate regulations on its own, whereas other laws may explicitly require an agency to issue regulation. The process for making regulations must be performed in accordance to the Administrative Procedures Act (Title 5, USC, Chapter 5). This Act generally requires agencies such as the FDA to provide public notice and opportunity for comment as part of the rule-making process.

FDA regulations are contained in the CFR. Regulations for drugs, biologics, devices, tissues, and combination products, along with related regulations, may be found in various parts of Title 21 of the CFR. The following is a list of key regulatory provisions:

- Drugs: 21 CFR Parts 200–299, 300–369;
- Biologics: 21 CFR Parts 600–680;
- Devices: 21 CFR Parts 800–898;
- Human Cells, Tissues, and Cellular and Tissue-based Products (HCT/P): 21 CFR Parts 1270/1271;
- Combination Products: 21 CFR Parts 3 and 4;
- Recalls: 21 CFR Part 7;
- Informed Consent/Institutional Review Boards (IRBs): 21 CFR Parts 50/56;
- Financial Disclosure by Clinical Investigators: 21 CFR Part 54;
- Good Laboratory Practice for Nonclinical Laboratory Studies: 21 CFR Part 58; and
- Good Guidance Practices: 21 CFR Part 10.115;

Guidance documents are nonbinding publications that describe the FDA's interpretation of policy pertaining to a regulatory issue or set of issues related to:

- the design, production, labeling, promotion, manufacturing, and testing of regulated products;
- the processing, content, and evaluation or approval of submissions; and
- inspection and enforcement policies.

Guidance documents, which are developed in accordance with Good Guidance Practices found at 21 CFR 10.115, are intended to clarify the FDA's current thinking related to regulatory issues and procedures. Unlike regulations and laws, guidance documents are not enforceable. Therefore, Sponsors may elect to choose alternate approaches that still comply with existing laws and regulatory requirements. In most cases, guidance documents are issued in draft form for public comment before implementation. In cases in which prior public participation is not feasible or appropriate, the FDA may issue a guidance document for immediate implementation without first seeking public comment. The publication of guidance documents reflects the FDA's efforts to convey up-to-date information on general and cross-cutting topics to those involved in the developing field of regenerative medicine.

When considering developing a guidance document, the FDA may freely discuss related issues with the public. In fact, the FDA may hold a public meeting, advisory committee meeting, or workshop to obtain input on scientific issues. Finally, after receiving public input, the FDA will evaluate submitted comments and finalize the document. Guidance documents are a useful way for the FDA to communicate current thinking to the public. Within the arena of regenerative medicine, it is valuable to be aware of both product-specific and cross-cutting guidance documents. Some of the more pertinent guidance documents to this field, such as those related to preclinical testing, manufacturing practices, and clinical trial design, are discussed in this chapter. In addition to guidance documents, the FDA may refer to guidelines published by the International Council for Harmonization of Technical Requirements for Pharmaceuticals for Human Use (ICH). ICH is an international effort to harmonize regulatory requirements. ICH guidelines, similar to FDA guidance documents, are nonbinding.

FOOD AND DRUG ADMINISTRATION ORGANIZATION AND JURISDICTIONAL ISSUES

Scientific development of regenerative medicine products involves extensive testing and planning before marketing authorization. It can be helpful for individuals and organizations involved in product development to engage in early dialog with the appropriate FDA review unit to receive and consider the FDA's comments on the design of the preclinical and clinical development plan. This section describes the FDA's organizational structure and provides basic information regarding jurisdictional decisions made to determine the appropriate regulatory pathway for a broad range of products.

The FDA is an agency within the Department of Health and Human Services (DHHS) consisting of seven centers and the Office of the Commissioner. Three of the centers are responsible for regulating medical products for humans. The Center for Biologics Evaluation and Research (CBER) has jurisdiction over a variety of biological products, including blood and blood products, vaccines and allergenic products, and cellular, tissue, and gene therapies, as well as some related devices. The Center for Devices and Radiological Health (CDRH) has jurisdiction over diagnostic and therapeutic medical devices, administration of the Mammography Quality Standards Act program, and ensuring the safety of radiation-emitting products. The Center for Drug Evaluation and Research (CDER) has jurisdiction over a variety of drug products, including small molecule drugs and well-characterized biotechnology-derived therapeutic biological products that include monoclonal antibodies and cytokines.

For many medical-use products, it is clear which center within the FDA should have primary jurisdiction for the premarket review. For other products, including some technologically novel products under development, determining which center has jurisdiction for review may be unclear. Important starting points for determining product jurisdiction are the formal regulatory definitions of biological products, drugs, devices, and combination products. The formal definitions are as follows:

- Biological Product (42 USC 262[i](1)): A virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, protein (except any chemically synthesized polypeptide) or analogous product, or arsphenamine or derivative of arsphenamine (or any other trivalent organic arsenic compound), applicable to the prevention, treatment, or cure of a disease or condition of human beings.
- Drug (21 USC 321[g] [1]): (A) Articles recognized in the official US Pharmacopeia, official Homeopathic Pharmacopeia of the United States, or official National Formulary, or any supplement to any of them; and (B) articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals; and (C) articles (other than food) intended to affect the structure or any function of the body of man or other animals; and (D) articles intended for use as a component of any articles specified in clause (A), (B), or (C).
- Device (21 USC 321[h]): An instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent, or other similar or related article, including any component, part, or accessory, which is: (1) recognized in the official National Formulary, or the US Pharmacopeia, or any supplement to them, (2) intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in man or other animals, or (3) intended to affect the structure or any function of the body of man or other animals, and which does not achieve its primary intended purposes through chemical action within or on the body of man or other animals and which is not depend on being metabolized for the achievement of its primary intended purposes.
- Combination Product (21 CFR 3.2[e]): (1) A product composed of two or more regulated components, that is, drug–device, biologic–device, drug–biologic, or drug–device–biologic, that are physically, chemically, or otherwise combined or mixed and produced as a single entity; (2) two or more separate products packaged together in a single package or as a unit and composed of drug and device products, device and biological products, or biological and drug products; (3) a drug, device, or biological product packaged separately that according to its investigational plan or proposed labeling is intended for use only with an approved individually specified drug, device, or biological product where both are required to achieve the intended use, indication, or effect and where upon approval of the proposed product the labeling of the approved product would need to be changed, for example, to reflect a change in intended use, dosage form, strength, route of administration, or significant change in dose; or (4) any investigational drug, device, or biological product packaged separately that according to its proposed labeling is for use only with another individually specified investigational drug, device, or biological product where both are required to achieve the intended use, indication, or effect.

The FDA's Office of Combination Products (OCPs), located in the Office of the Commissioner, has broad administrative overview responsibilities covering the regulatory life cycle of drug–device, drug–biologic, device–biologic, and drug–biologic–device combination products. When jurisdiction is uncertain, Sponsors may contact the OCP for assignment of primary regulatory review responsibility for combination and other medical products. Jurisdictional determinations are made after a formal submission process called a Request for Designation. The appropriate FDA center jurisdiction is determined by considering the primary mode of action of the product.

APPROVAL MECHANISMS AND CLINICAL STUDIES

There are several premarket approval pathways for medical products, depending on whether the product is a drug, biological product, or device. Approval pathways, explained in more detail subsequently, include the New Drug Application (NDA) for drugs and the Biologics License Application (BLA) for biologics. The Premarket Approval Application (PMA), Humanitarian Device Exemption (HDE), 510(k) clearance mechanism, and De Novo classification process are various regulatory pathways used for medical devices. Clarification regarding the type of application needed for a particular regenerative medicine product may be helpful to the Sponsor early in development to enable the Sponsor to discuss the data needed for a marketing application during the planning stage.

NDAs and BLAs are applications for licensure under the safety and effectiveness requirements of the FD&C Act. Biologics are further subject to the approval standards set forth in the PHS Act that requires demonstration that the product is safe, pure, and potent. Further information concerning the licensure of drugs and biological products is

provided in "Guidance for Industry: Providing Clinical Evidence of Effectiveness for Human Drugs and Biological Products" [1]. For a medical device, the appropriate regulatory pathway and classification depend heavily on the associated risks; Class I includes devices with the lowest risk and Class III includes devices with the highest risk. A PMA is an application for approval for most Class III medical devices; the Sponsor must show reasonable assurance of safety and effectiveness [2]. The premarket notification, or 510(k), clearance process applies to products that are "substantially equivalent" to a Class I or II (or in a few cases, a Class III) medical device already on the market [3]. The De Novo process provides a pathway to Class I or Class II classification for medical devices for which there is no legally marketed device to enable a demonstration of "substantial equivalence" but for which regulatory controls provide a reasonable assurance of safety and effectiveness [4]. Under medical device regulation, a product can also gain approval through an HDE, which is a marketing approval for certain devices for rare conditions and is exempt from the effectiveness requirements of a PMA but requires demonstration of safety and probable benefit [5]. To qualify for this type of application, a Sponsor would first need to receive a designation from the FDA Office of Orphan Products Development that the medical device is a Humanitarian Use Device intended for treatment or diagnosis of a disease or condition that affects or is manifested in not more than 8000 individuals per year in the United States.

Many but not all combination products are approved or cleared under a single marketing application. For example, depending on the specific facts, including the primary mode of action of the product, a combination biological device could be licensed under the biologics authorities or approved under the medical device authorities. After approval of a marketing application, there are also postmarketing requirements such as reporting [6].[1,2] In addition, modifications to the product or labeling may require prior approval. The FDA has published regulations and guidance documents that address submission and approval processes for modifications to marketed products [3,6].[3,4,5] Compliance with manufacturing requirements is also an ongoing Sponsor obligation. The FDA has issued a guidance document entitled "Guidance for Industry and FDA Staff: Current Good Manufacturing Practice Requirements for Combination Products," which provides direction regarding applicable manufacturing requirements for combination products [7]. Owing to the relatively new nature of regenerative medicine and its developmental status, postapproval topics will not be further discussed in this chapter.

When clinical investigation is needed to evaluate the safety and efficacy of an investigational product before marketing approval, an Investigational New Drug (IND) application is required for drugs and biologics and an Investigational Device Exemption (IDE) is generally required for devices [8,9]. For both types of applications, the Sponsor needs to submit a description of the product and manufacturing process, preclinical studies, a clinical protocol, information on any other prior investigations such as human clinical studies, and a rationale for the study design. An IRB review and informed consent are also required. The FDA has 30 days to review the application to determine whether the study may proceed. The contents are specifically laid out in FDA regulations for each type of application. Requirements for the content of an IND can be found at 21 CFR 312.23, and for an IDE at 21 CFR 812.20.

For some products, there may be applicable guidance with respect to the manufacturing information and the preclinical data needed to support the study. For example, "Guidance for FDA Reviewers and Sponsors: Content and Review of Chemistry, Manufacturing, and Control (CMC) Information for Human Somatic Cell Therapy Investigational New Drug Applications (INDs)" provides information on characterization and manufacturing of a cellular product to be submitted in an IND [10]. Information on a general preclinical study design for regenerative medicine products using cellular or gene therapies can be found in the "Guidance for Industry: Preclinical Assessment of Investigational Cellular and Gene Therapy Products" [11]. For medical devices, "Guidance for Industry and FDA Staff, Investigational Device Exemptions (IDEs) for Early Feasibility Medical Device Clinical Studies, Including Certain First in Human (FIH) Studies" [12] provides information on early feasibility study IDEs that allow for early clinical evaluation of significant risk devices. Early feasibility study IDEs may be appropriate early in device development when clinical experience is necessary because nonclinical testing methods are not available or adequate to provide the information needed to advance the developmental process. Applicable regulations and guidance should

[1] Reporting for Biological Products: 21 CFR 314.80 and 21 CFR 314.81, 21 CFR 600.14, 21 CFR 600.80, 21 CFR 600.81, 21 CFR 601.28, 21 CFR 601.70, and 21 CFR 601.93.

[2] Postmarketing Reports for Applications for FDA Approval to Market a New Drug (NDA): 21 CFR 314.80 and 314.81.

[3] PMA supplements: 21 CFR 814.39. (2007).

[4] Supplements and Changes to an Approved NDA: 21 CFR 314.70, 314.71, 314.72. (2007).

[5] BLA 21 CFR 814.39, 21 CFR 314.70, 21 CFR 314.71, 21 CFR 314.72.

be further consulted for information on adverse event reporting, labeling, study conduct and monitoring, and other topics related to requirements for conducting an IND [8] and IDE [13–15]. For information on general clinical study design and conduct issues, the FDA has many guidance documents that may be helpful [16,17]. For some indications there may be guidance documents that apply across technologies, such as the "Guidance for Industry: Chronic Cutaneous Ulcer and Burn Wounds—Developing Products for Treatment" [18] and "Guidance for Industry: Cellular Therapy for Cardiac Disease" [19]. In addition, guidance documents not directly applicable for a specific product, indication, or technology may be worth consulting, because the documents may provide some insights into general clinical issues, such as assessment parameters that may be valuable.

MEETINGS WITH INDUSTRY, PROFESSIONAL GROUPS, AND SPONSORS

Although the terminology and procedures may vary, all three FDA centers performing medical product review encourage meetings with Sponsors to address questions before a regulatory submission and at specific developmental milestones. When requesting a formal or informal meeting with the FDA, it is helpful to provide background information as well as specific discussion questions. Further information about formal meetings, such as what to include in a meeting request and what type of information to include in the briefing package submitted before the meeting, is provided in "Guidance for Industry: Formal Meetings Between the FDA and Sponsors or Applicants" [20] and "Guidance for Industry and FDA Staff, Requests for Feedback on Medical Device Submissions: The Pre-Submission Program and Meetings with Food and Drug Administration Staff" [21]. Early-stage device meetings are addressed in "Early Collaboration Meetings Under FDA Modernization Act (FDAMA): Final Guidance for Industry and CDRH Staff" [22].

The FDA also interacts with organizations representing a group of interested parties (e.g., the International Society for Cellular Therapy, the American Association for Blood Banks, the Biotechnology Industry Organization, and Pharmaceutical Research and Manufacturers of America), which provides an opportunity to discuss topics of interest to the FDA and the organization. These interactions can be valuable for the FDA and stakeholders because they are a way to understand general issues of concern better, as opposed to product-specific discussions with individual firms. In addition to such interactions and meetings with individual sponsors, the FDA has various advisory committees that review available data and information and make recommendations related to a variety of issues, many of which are pertinent to the field of regenerative medicine. Advisory committees will be discussed further in the Advisory Committee Meetings section.

REGULATIONS AND GUIDANCE OF SPECIAL INTEREST FOR REGENERATIVE MEDICINE

The topics discussed thus far have been of general applicability to medical product regulation: marketing pathways, clinical trial regulation, meetings, guidance development, and related topics. This section will review a few topics of particular interest to the scientific community engaged in developing regenerative medicine products: FDA regulations of human tissue products, product characterization for cellular products, FDA policy and guidance on xenotransplantation, and gene therapy.

Regulation of Human Cells and Tissues Intended for Transplantation

An understanding of the regulations applicable to cells and tissues is important for developers of regenerative medicine products because human cells or tissues comprise the whole of many products or are a key component of them.

In 1997, noting the fragmented approach to the regulation of human cellular and tissue-based products, the FDA issued the "Proposed Approach to the Regulation of Cellular and Tissue-Based Products" [23]. This document proposed a tiered risk-based approach to regulating these products. According to the proposed approach, products posing a lesser degree of risk would be subject to the rules designed to minimize communicable disease risks and additional regulatory requirements would be imposed on products posing an additional risk. The proposed approach to regulating human tissues was implemented in three parts, collectively referred to as the "tissue rules": Establishment Registration and Listing, Donor Eligibility, and Current Good Tissue Practice (CGTP). The complete

set of rules went into effect on May 25, 2005 and is codified in 21 CFR Part 1271. The tissue rules derive from the statutory authority of section 361 of the PHS Act, which addresses the control of spread of communicable diseases. Because the tissue rules apply to all human cellular and tissue-based products, it is important for Sponsors of regenerative medicine products to be aware of these rules, as well as the specific additional requirements for biologics or devices that may apply, depending on the particular regulatory pathway for their products.

With some exceptions that are noted in the tissue rules, human cells or tissue intended for implantation, transplantation, infusion, or transfer into a human recipient are regulated as an HCT/P. Examples of HCT/Ps are musculoskeletal tissue, skin, ocular tissue, heart valves, dura mater, reproductive tissue, gestational tissue such as umbilical cord tissue and amniotic membrane, and hematopoietic stem/progenitor cells. Specifically excluded are vascularized organs, minimally manipulated bone marrow, blood products, xenografts, secreted or extracted products such as human milk and collagen, ancillary products, and in vitro diagnostic products.

Tissue rules require HCT/P establishments to do the following:

- register and list their HCT/Ps with FDA (21 CFR 1271 Subparts A and B);
- evaluate donors through screening and testing to reduce risk for transmission of infectious diseases through transplantation (21 CFR 1271 Subpart C); and
- follow CGTP to prevent the spread of communicable disease (21 CFR 1271 Subpart D).

Additional requirements for reporting, labeling, inspections, importation, and enforcement are described in 21 CFR 1271 Subparts E and F; these provisions apply only to HCT/Ps regulated solely under Section 361 of the PHS Act, and therefore would not apply to most regenerative medicine products.

The Establishment Registration rule defines the circumstances under which a product would be subject to the HCT/P rules only (21 CFR 1271.10), and when there would be additional regulatory oversight such that a BLA, PMA, or other marketing application would be required (21 CFR 1271.20). Products that meet all of the following conditions are regulated by the FDA solely under the HCT/P rules: (1) the HCT/P is not more than minimally manipulated, (2) the HCT/P is intended for homologous use, (3) the HCT/P is not combined with a drug or device (with certain exceptions), and (4) the HCT/P does not have a systemic effect and is not dependent upon the metabolic activity of living cells for its primary function (except for autologous use or allogeneic use in a first or second degree blood relative, or reproductive use). If any of these four conditions are not met, a marketing application is required. The Tissue Reference Group handles various inquiries from stakeholders concerning application of the HCT/P rules including generating recommendations for consideration for CBER, CDRH, and OCP regarding whether specific HCT/Ps meet the criteria specified in 21 CFR 1271.10 for regulation solely under Section 361 of the PHS Act. Additional information and documents regarding these rules, as well as electronic forms for registration and listing, can be found on the FDA's website for Tissue and Tissue Products [24].

A joint FDA—Centers for Disease Control and Prevention (CDC) workshop held in 2007 on the Processing of Orthopedic, Cardiovascular, and Skin Allografts is relevant to the regenerative medicine field. The workshop discussed pertinent information regarding current clinical practices, experiences, expectations, and assumptions of safety when using tissue allografts; the challenges of processing allografts with a focus on disinfection and sterilization methods; and the usefulness, reliability, and validation of tissue culturing methods. Some manufacturing topics discussed at the workshop are addressed in "Guidance for Industry: Current Good Tissue Practice (CGTP) and Additional Requirements for Manufacturers of HCT/Ps" [25].

The FDA issued "Guidance for Industry: Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/Ps)" to assist establishments in making donor eligibility determinations with compliance to the Donor Eligibility rule (21 CFR 1271 Subpart C) [26]. Since 2007, multiple guidance documents have been published to provide updated or new recommendations for HCT/P donor screening and donor testing as well as guidance involving regulatory considerations for HCT/Ps from adipose tissue, to meet minimal manipulation criterion, interpret and apply homologous use, and interpret the scope of the same surgical procedure exception under 21 CFR 1271.15(b) [27].

Human Cellular Therapies

Although therapeutic products composed of or containing cells vary greatly in the specific details of their application, cell or tissue source, manufacturing process, and characteristics, there are regulatory considerations that apply to all cellular preparations being developed as investigational regenerative medicine products intended for early-phase clinical studies. Control of the source material, demonstrated control of the manufacturing process,

and characterizations of the cellular product that results from the manufacturing process are three such safety and quality considerations and will be discussed briefly next.

The cell source will vary for different products and may be autologous or allogeneic, undifferentiated stem or progenitor cells, or terminally differentiated cells. Ensuring the safety of source cellular materials used during manufacture of an investigational regenerative medicine product begins by determining the eligibility of the donors selected to provide the source material through screening and testing. This screening and testing are part of the tissue rules described earlier in this chapter. Autologous products are not required to comply with the donor screening and testing requirements in the tissue rules but they carry labeling requirements to communicate risks for infectious substances. However, if autologous tissue either is positive for specific pathogens or has not been screened or tested, it is recommended that manufacturers document whether tissue culture methods could propagate or spread viruses or other adventitious agents to persons other than the recipient [10]. Donor eligibility determination is required for all allogeneic donors of cells and tissues.

There are other aspects of the cell source may raise substantial concerns. In addition to screening and testing donors for communicable disease agents, according to the "ICH Guidance on Quality of Biotechnological/Biological Products: Derivation and Characterization of Cell Substrates Used for Production of Biotechnological/Biological Products," the FDA has suggested that Sponsors consider the importance of evaluating donor medical history information and the relevance of conducting specified molecular genetic testing as part of an overall comprehensive assessment program to establish the suitability of a specific cellular preparation for use in manufacturing a regenerative medicine somatic cellular product [28]. The rationale for and feasibility of collecting additional information about molecular genetic testing were discussed in a public meeting of the FDA Biological Response Modifiers Advisory Committee (now known as the Cellular, Tissue, and Gene Therapies Advisory Committee [CTGTAC]) convened on Jul. 13–14, 2000, on the topic of "Human Stem Cells as Cellular Replacement Therapies for Neurological Disorders" [29]. A description of the physiological source of the cellular material, including the tissue of origin and phenotype such as hematopoietic, neuronal, fetal, or embryonic, conveys important information about the cells and their critical attributes.

Control of the manufacturing process provides assurance about the consistent, reproducible production of the cellular component. Often, manufacturing will involve a multistep process that must be performed using aseptic techniques to prevent introduction of microbial contamination [30]. In addition to these precautionary techniques, the final product resulting from the manufacturing process should be demonstrated to be free of viable contaminating organisms. For manufacturing processes that involve in vitro cell culture, the cell product should also be tested for mycoplasma contamination, which may be introduced by manufacturing reagents or the culture facility environment [31]. A final rule became effective on Jun. 4, 2012, which amended the sterility regulations in part to provide manufacturers of biological products with greater flexibility, as appropriate, and encourage use of scientific and technological advances in sterility test methods as they become available.[6]

Many types of reagents may be used to manufacture the cellular component of a product, including those that promote cellular replication or induce differentiation, and those used to select targeted cell populations, specifically serum, culture medium, peptides, cytokines, and monoclonal antibodies. It is possible that the manufacturing process uses reagents that are FDA approved or cleared, clinical grade, or research grade. Depending on the grade of a particular reagent, additional documentation may be needed to verify the source, safety, and performance of the reagent. For example, some materials, such as serum, may be human- or animal-derived products, which have an increased risk for containing adventitious agents and therefore require further documentation of the safety testing performed on each lot of material. It is essential that reagents be properly qualified [10,31–33]. Demonstration of manufacturing control is evidenced by strict adherence to standard operating procedures and quality control assessment of manufacturing intermediates, as well as testing of the final cellular preparation.

Because of inherent biological complexity, it is unlikely that a unique biomarker or other single analytical test will be sufficient to permit full characterization of a cellular product. Accordingly, as recommended in "Guidance for Industry: Guidance for Human Somatic Cell Therapy and Gene Therapy," the FDA asks Sponsors to provide documentation that their testing paradigm developed for the final cell product encompasses a multiparametric approach that may involve biological, biochemical/biophysical, and/or functional characterization [10,33,34]. Therefore, in addition to microbiological testing, tests developed to demonstrate the following should be conceived to determine the degree to which the characteristics of the manufactured cell preparation conform to desired and specified criteria [10,33,34]:

[6] Amendments to Sterility Test Requirements for Biological Products (77 FR 26162).

- identity of the cell product (physical and chemical characteristics identifying the product as being what is designated on the label and distinguishing the product from other products manufactured in the same facility);
- purity (freedom from contaminants including endotoxin, residual reagents, and unintended cell populations); and
- potency/biological activity (the specific ability of the cells, as indicated by appropriate laboratory tests, to effect a given result relevant to the specific indication for use).

This process can be challenging for a number of reasons. For example, the mechanism of action associated with a cell product may be incompletely understood, which may constrain the ability to develop a specific potency assay. Direct assessment of potency for a cellular preparation may not be possible owing to a lack of appropriate in vitro or in vivo assay systems. On Feb. 9–10, 2006, FDA CTGTAC discussed this challenging topic and obtained input on alternative approaches for performing potency assessments of cellular therapy products [29]. A guidance document was issued in Jan. 2011, to provide manufacturers of cellular and gene therapy products with recommendations for developing tests to measure potency [35]. Because process and product development are iterative and will continue throughout the life cycle of the cellular product, continued multiparametric characterization of the cellular product throughout the manufacturing process may aid in identifying critical process steps, establishing relevant specifications and acceptance criteria, and demonstrating comparability after manufacturing changes.

Ensuring the safety of cell products that in and of themselves constitute a regenerative medicine product or that constitute a component of a product requires demonstrated control over each facet of the manufacturing process. This assurance begins with acquisition of the source material and is carried forward through manufacturing and characterization of the final cellular preparation using specified analytical tests based in large measure on the intrinsic biological properties of the cell product.

Xenotransplantation

The success of allogeneic organ transplantation has increased the demand for human cells, tissues, and organs. Scientific advances in the areas of immunology and molecular biology, coupled with the growing worldwide shortage of transplantable organs, have led to increased interest in xenotransplantation. In addition to the potential use of xenotransplantation to address the shortage of human organs for transplantation, there are increasing efforts to use other xenotransplantation products in treating disease. An example of this is the investigational use of encapsulated porcine pancreatic islet cells to treat type 1 diabetes. Along with the promise of xenotransplantation are a number of challenges, including the potential risk for transmission of infectious agents from source animals to patients and the spread of any zoonotic disease to the general public [36]. In addition, the potential exists for recombination or reassortment of source animal infectious agents, such as viruses, with nonpathogenic or endogenous human infectious agents, to form new pathogenic entities. These considerations demonstrate the need to proceed with caution in this area.

The US Public Health Service (PHS) Agencies, including the FDA, the National Institutes of Health (NIH), the CDC, and the Health Resources and Services Administration, have worked together to address the risk of infectious disease transmission, publishing the "PHS Guideline on Infectious Disease Issues in Xenotransplantation" [37]. This Guideline discusses xenotransplantation protocols, animal source, clinical issues, and public health issues. After publication of the PHS Guideline, the FDA published a guidance document entitled "Guidance for Industry: Source Animal, Product, Preclinical and Clinical Issues Concerning the Use of Xenotransplantation Products in Humans" to build on concepts in the PHS Guideline and provide more specific advice regarding xenotransplantation product development and production, and xenotransplantation clinical trials [38].

Xenotransplantation is defined in the PHS Guideline and FDA Guidance as any procedure that involves the transplantation, implantation, or infusion into a human recipient of live cells, tissues, or organs from a nonhuman animal source or human body fluids, cells, tissues, or organs that have had ex vivo contact with live nonhuman animal cells, tissues, or organs.

Examples of investigational xenotransplantation products are:

- transplantation of xenogeneic hearts, kidneys, or pancreatic tissue to treat organ failure, or implantation of neural cells to ameliorate neurological degenerative diseases;
- administration of human cells previously cultured ex vivo with live nonhuman animal, antigen-presenting, or feeder cells; and
- extracorporeal perfusion of a patient's blood or blood component through an intact animal organ or isolated cells contained in a device to treat liver failure.

The use of genetically modified source animals has the potential to overcome physiological and immunologic barriers to successful xenotransplantation as demonstrated in pig to nonhuman primate animal models [39].

When using genetically engineered (GE) animals for xenotransplantation, consultation with the Center for Veterinary Medicine (CVM) before initiating a clinical trial is recommended. GE animals are regulated by CVM under the New Animal Drug provisions of the FD&C Act and its enabling regulations (21 CFR 511 and 514). The requirements and recommendations for producers and developers of GE animals and their products are further clarified in "Guidance for Industry 187: Regulation of Genetically Engineered Animals Containing Heritable Recombinant DNA Constructs." Review teams for xenotransplantation products consist of experts from CBER, CVM, and, when applicable, CDRH.

Medical products that do not contain living cells are not considered to be xenotransplantation products by this definition. Therefore, products that include some common animal-derived components such as collagen, small intestinal submucosa, and heart valves do not automatically fall under this category. When a product does meet the definition, xenotransplantation guidelines are applied as appropriate to the specific product. The FDA encourages any potential sponsor of a xenotransplantation product to familiarize themselves with available documents that can be found on the FDA's website [40].

Gene Therapy

Human gene therapy seeks to modify or manipulate the expression of a gene or to alter the biological properties of living cells for therapeutic use. Products that mediate their effects by transcription or translation of transferred genetic material, or by specifically altering host (human) genetic sequences, are considered gene therapies. Gene therapy products are diverse and include genetically modified viruses (viral vectors), genetically modified microorganisms (e.g., bacteria, fungi), genome-edited/editing products, and ex vivo genetically modified human cells. The FDA regulates human gene therapy products as biological products. The field of gene therapy holds great promise for treating a wide array of illnesses, from genetically inherited diseases such as cystic fibrosis or hemophilia to heart disease, acquired immune deficiency syndrome, graft versus host disease, and cancer. The use of gene therapy in the areas of wound healing, tissue repair, and tissue engineering is also being investigated.

Many of the same regulatory concerns already discussed for human cellular therapies apply to gene therapies, including appropriate qualification of source materials, proper control of the manufacturing process, and sufficient characterization of the final product. There are a number of safety issues associated with gene therapy, however, which are unique to this area. Safety issues specific to gene therapy trials may include generation of replication-competent virus (when using replication-incompetent vectors), vector and/or transgene-associated immune responses, toxicity associated with transgene overexpression, and inadvertent germline transmission of vector. These risks are exemplified by (1) the death of a study subject in 1999 owing to toxicity after administration of high-dose adenovirus vector [41], and (2) genomic integration of retroviral vectors, which has been shown to result in genotoxicity. In the latter case, five children developed leukemia and one died as the direct result of altered gene expression owing to retroviral vector integration [42,43] Detailed recommendations from the FDA regarding what type of CMC information to submit in an early-phase study of gene therapy products are available in the "Guidance for FDA Reviewers and Sponsors: Content and Review of Chemistry, Manufacturing, and Control (CMC) Information for Human Gene Therapy Investigational New Drug Applications (INDs)" [33]. This guidance covers product manufacturing and characterization information (from component qualifications to final formulation procedures), product characterization and release testing (including microbiological testing, identity, purity, potency, as well as other testing), and product stability, giving specifics in these areas that are pertinent to gene therapy.

Special considerations should also be made when conducting preclinical assessment of gene therapy products. For instance, preclinical testing for gene therapy products includes tests designed to determine the biodistribution (i.e., localization and persistence) of the vector in various tissues, as well as assess transgene expression. Additional information on the evaluation of biodistribution in preclinical studies can be found in Section IV.B of the "Guidance for Industry: Preclinical Assessment of Investigational Cellular and Gene Therapy Products" [44]. Clinical trials evaluating gene therapy products may also differ in design from clinical trials for other types of pharmaceutical products because of the distinctive features of these products as well as the target patient populations, outcome measures, and risks involved. Therefore, the FDA has also published advice regarding clinical trial design in the "Guidance for Industry: Considerations for the Design of Early-Phase Clinical Trials of Cellular and Gene Therapy Products" [45].

Gene therapies may differ from conventional drugs in that vector and transgene expression may persist for the lifetime of the subject. In these cases, there is a risk for delayed adverse effects. Indeed, the previously mentioned leukemias in a clinical study of gene therapy for the treatment of X-linked severe combined immunodeficiency did not occur until approximately 3–15 years after exposure to the retroviral vector. These events highlight the need for long-term assessment of study subjects receiving gene therapies. The FDA has discussed these issues, noting that the assessment of risk is based on the persistence of vector sequences, the potential for integration into the host genome, and transgene-specific effects. The FDA has published "Guidance for Industry: Gene Therapy Clinical Trials—Observing Subjects for Delayed Adverse Events," which addresses the duration and types of observations to be performed based on the patient population and the risks presented by the gene therapy product [44].

Although regulatory authority for gene therapy clinical investigations rests with FDA, the NIH serves an important complementary role. In addition to funding a number of gene therapy research studies, the NIH provides an important forum for open public deliberation on the scientific, ethical, and legal issues raised by novel FIH gene therapy clinical research applications. This is accomplished through the Recombinant DNA Advisory Committee (RAC), an expert advisory committee to the NIH director [46]. Clinical studies discussed in this forum include studies funded by the NIH, as well as industry-funded studies conducted at clinical sites receiving NIH funding for recombinant DNA research. Also, since the 2013 report by the National Academy of Science and Medicine (previously known as the US Institute of Medicine), NIH-supported clinical investigators have needed to register gene transfer protocols with the NIH Office of Science Policy [47]. In consultation with appropriate regulatory and/or oversight authorities including, IRBs and Institutional Biosafety Committees, the RAC may also identify protocols for public review based on criteria outlined in the 2013 report.

Cell–Scaffold Combination Products

Cell–scaffold combination products often face unique product development challenges because of their inherent complexity. These products often combine metabolically active cells and extracellular matrix or other scaffold components into complex three-dimensional structures, which makes the manufacture, characterization, and study of these products a challenge. Such a complex product that is derived from chemically or physically combining multiple entities cannot be defined solely by the characteristics of the individual components alone. Other factors such as product assembly and the resulting cell–scaffold interactions have critical roles in determining final product characteristics. Furthermore, depending on the intended therapeutic function, these products may be designed to remodel or degrade in vitro during processing in bioreactors and/or in vivo after transplantation during clinical use, thereby precluding complete functionality testing at the time of product release. Packaging, shipping, and shelf life for these dynamic cell–scaffold products are also nontrivial considerations.

As with other products, product safety and efficacy of cell–scaffold products need to be supported by a combination of appropriate in vitro and in vivo preclinical testing. The FDA draws on its extensive experience in regulating mammalian cell products and other tissue-derived products in evaluating product safety and efficacy. Many of the important tests needed for the individual components, such as sterility, mycoplasma, pyrogenicity/endotoxin, scaffold characteristics, adventitious agent testing, cellular viability, identity, and purity, are applicable for the combined product as well. Demonstration of product potency and/or performance is also necessary. The complexity of these products, however, presents challenges for product characterization. Animal models are often used to characterize safety and performance of cell–scaffold products. However, these models have limitations that are confounded by anatomical as well as physiological differences between the animals and humans. Therefore, characterization of these products may require the development of new scientific techniques and assays [48]. In vitro analyses of cell scaffold products may have a critical role in product characterization and evaluation for safety, efficacy, and potency. Nondestructive product testing and rapid characterization tests may also aid in product development. The goals, challenges, and methods of in vitro analyses of cell–scaffold products were discussed at an FDA–National Institute of Standards and Technology (NIST) cosponsored workshop [49]. Challenges and approaches of correlating product characteristics with clinical performance of absorbable medical devices, similar to materials that may be used as cell scaffolds, were discussed at an ASTM International–FDA cosponsored workshop [50].

A critical consideration for developers of cell–scaffold combination products is determining which tests need to be conducted on individual components before assembly and which are most relevant after product assembly. For

example, if undifferentiated cells are directed to differentiate during culture after combination with the scaffold, the individual cellular component will have a phenotype different from that of the cellular component in the final product.

In addition, biocompatibility testing to determine the potential for an unacceptable adverse biological response to the scaffold component is generally most appropriately conducted on the scaffold before combination with the cellular component to prevent convolution of the results. The biocompatibility tests that need to be performed will depend on the type and duration of contact the scaffold will have with the body. Regarding biocompatibility, the FDA issued a guidance document on Jun. 16, 2016 to provide further clarification and updated information regarding the use of International Standard Organization (ISO) 10993-1, "Biological evaluation of medical devices—Part 1: Evaluation and testing within a risk management process" to support applications to the FDA [51].

For many innovative products, such as cell−scaffold combinations used for regenerative medicine, the final product and instructions for use can be expected to undergo iterative modifications over time. Consequently, refinement of the product by the Sponsor and review of product modifications by the FDA will be an ongoing process. It is critical for the Sponsor to have a good understanding of the product and key scientific and/or clinical issues that can affect the safety and efficacy of the product, including the establishment of appropriate manufacturing controls to ensure product quality and consistency. When changes are made in the composition or manufacture of the cell and/or scaffold component of the combination product, it is essential that the Sponsor fully evaluate the impact of such changes to the final product's quality and function.

PRECLINICAL DEVELOPMENT PLAN

The primary goals of the preclinical development program for an investigational device or pharmaceutical product is to establish a scientific rationale for the use of the product in a specific clinical investigation and to demonstrate an acceptable product safety profile. Thus, the conduct of pharmacology and toxicology animal studies is important to identify and characterize possible local and systemic adverse effects. These studies also serve to determine potential safe dose levels in humans and to guide selection of a dose escalation scheme (if applicable) and a clinical monitoring paradigm. For cellular therapy, gene therapy, and cell−scaffold combination products there are frequently additional product-specific safety questions that might need to be addressed before initiation of a clinical trial. For example, for cell−scaffold constructs, there may be safety concerns related to the cells (e.g., inappropriate cell proliferation or differentiation, potential for cell migration from the scaffold) as well as the scaffold (e.g., its ability to perform a specific function at the anatomic site of implantation, degradation properties, structural integrity). These safety concerns may be independent of, or interdependent on, each component of the construct.

As a result of their increasing complexity, many of these products do not have an established paradigm for preclinical evaluation. Sponsors are therefore encouraged to approach the FDA early in their preclinical development program to discuss the scope and design of the preclinical studies that will support the use of their investigational product in a clinical population.

The FDA has held public discussions at Advisory Committee meetings and published Guidance documents that focus on appropriate preclinical testing of cellular therapy, gene therapy, and cell−scaffold combination products. These discussions and publications provide valuable recommendations and considerations for Sponsors as they prepare their preclinical development plan. In addition to various FDA Guidance documents that are referenced throughout this chapter, a list of relevant Advisory Committee meetings can be found in the Advisory Committee Meetings section.

CLINICAL DEVELOPMENT PLAN

The goal of the clinical development program is to establish a product's relative safety and efficacy under specific directions for use in particular diseases or conditions. In the field of regenerative medicine, variability in the product poses unique challenges in clinical trial design and conduct. An additional challenge is the need, with many of these products, to observe their integration into the host over a prolonged period. To facilitate the development of cellular therapy and gene therapy products, the FDA published the "Guidance for Industry: Considerations for the Design of Early-Phase Clinical Trials of Cellular and Gene Therapy Products" [45]. This guidance provides recommendations regarding selected aspects of the design of early-phase clinical trials of cellular therapy and gene therapy products.

However, because of the wide variety of regenerative medicine products and their potential applications, a case-by-case assessment is warranted for the design of each clinical trial. The FDA encourages sponsors to communicate with the FDA throughout product development. Such communications can include formal meetings (e.g., presubmission meeting; end of Phase 2 meeting) and requests (e.g., request for Special Protocol Assessment for products regulated as a biologic, or an Agreement Meeting for products regulated as a device) and informal interactions [20,22,52]. In addition, the FDA encourages IND sponsors to plan ahead by developing and submitting a Target Product Profile (TPP) early in product development. The TPP is an evolving draft of the product labeling and should be revised as clinical development proceeds. Submission of the TPP can facilitate communications between the FDA and the sponsor and enable the FDA to provide more comprehensive advice regarding the overall development program [53].

Food and Drug Administration's Standards Development Program

Since its inception, the development and use of standards have been critical to the mission of the FDA. The use of standards in FDA medical product regulation began with the 1906 Federal Food and Drugs Act. As defined in accordance with the standards of strength, quality, and purity in the US Pharmacopeia and the National Formulary, drugs could not be sold in any other condition unless the specific variations from the applicable standards were plainly stated on the label (Federal Food and Drugs Act, 1906). In current times, federal government agencies, including the FDA, are encouraged when practical to use voluntary consensus standards, whether domestic or international, when performing regulatory activities in lieu of government-unique standards that are developed by the government for its own uses. Standard-setting activities include the development of performance characteristics, testing methodology, manufacturing practices, product standards, scientific protocols, compliance criteria, ingredient specifications, labeling, or other technical or policy criteria.

As with guidance document development, in which Good Guidance Practices describe the FDA's procedures for developing and using guidance documents, specific regulations describe FDA participation in outside standard-setting activities. Regulations governing this participation can be found in 21 CFR 10.95. In addition, the FDA's Staff Manual Guide 9100.1 establishes agency-wide policies and procedures related to standards management activities to ensure a unified approach to standards within the FDA. Constructive FDA participation in organizations responsible for developing standards applicable to the products regulated by the agency is considered essential.

The FDAMA of 1997 provides for the recognition of national and international standards in medical device reviews for IDEs, HDEs, PMAs, and 510(k)s [54]. A "recognized consensus standard" is a consensus standard that the FDA has evaluated and recognized, in full or in part, for use in satisfying a regulatory requirement and that the FDA has published in a Federal Register notice. A "consensus standard" is a standard developed by a private sector standards body using an open and transparent consensus process. Conformance with recognized consensus standards is strictly voluntary for a medical device manufacturer, who may choose either to conform to applicable recognized standards or to address relevant issues in another manner. Standards may also be used in support of non-device applications when appropriate and not in conflict with an FDA regulation or Guidance. Lists of recognized standards, Guidance Documents, and Standard Operating Policies and Procedures can be found on the FDA's website.

The scientific and manufacturing novelty of many regenerative medicine products presents unique challenges for meeting regulatory requirements with respect to product testing, developing performance characteristics, testing methodologies, scientific protocols, product standards, ingredient specifications, and compliance criteria. Increased development and use of standardized analytical methods and metrics have the potential to facilitate product characterization and reduce time to market by leveraging industry and government efforts. CDRH and CBER actively engage with Standards Development Organizations (SDOs) such as ASTM International and the ISO. CDRH and CBER staff attend standards meetings and workshops and participate in developing the standards and formally voting on the publication of standards. ASTM Committee F04 on Medical and Surgical Materials and Devices Division IV is actively engaged in developing standards for tissue engineered medical products (TEMPs). F04 Division IV consists of six subcommittees: (1) Classification and Terminology, (2) Biomaterials and Biomolecules, (3) Cells and Tissue Engineered Constructs, (4) Assessment, (5) Adventitious Agent Safety, and (6) Cell Signaling. The ASTM TEMPs group has developed more than 25 published standards, including standard guides, standard practices, and test methods, and has approximately 30 draft standards under preparation. The first of these standards were developed for substrates, biomaterials, natural materials such as collagen, alginate, and chitosan, terminology, cells and cell processing, bone morphogenetic protein, assessment of adventitious agents, and test methods for

characterizing biomaterials. These standards are reviewed on a regular basis by the appropriate ASTM subcommittee (SC) to ensure that the standards reflect current scientific knowledge. The FDA liaisons elected to represent the Agency on each of the six subcommittees review the standards to ensure that standards developed do not conflict with current FDA regulatory practices. Some examples of approved standards with which the TEMPs group was involved include standards for characterizing and testing biomaterial scaffolds, quantifying cell viability within biomaterial scaffolds, and repairing articular cartilage in vivo.

Another SDO with which FDA is involved is ISO, a nongovernmental international organization that develops consensus standards in collaboration with both the private and public sector. Standards for regenerative medicine/tissue engineering products are developed in Technical Committee (TC) 150 SC 7, Tissue Engineered Medical Devices, and in TC 194, Biological Evaluation of Medical Devices. Within TC 150, SC 7 are two active Working Groups (WGs): WG 1 Management of Risk, and WG 3 Tissue-engineered medical products for skeletal tissues. TC 194 SC 01 is responsible for Tissue Product Safety, and within SC 01 are four WGs: WG 01 Risk Assessment, Terminology, and Global Aspects, WG 02 Sourcing Controls, Collection, and Handling, WG 03 Elimination and/or Activation of Viruses and Transmissible Spongiform Encephalitis (TSE) Agents, and WG 04 TSE Elimination. ISO standards of particular interest to regenerative medicine products are those in the 10993 series (10993-1−20). Additional ISO standards-setting activities for regenerative medicine/tissue engineering products take place in TC 276, Biotechnology, WG 01 Terminology, WG 02 biobanks and bioresources, WG 03 analytical methods, WG 04 bioprocessing, and WG 05 data processing and integration. Standards are available through ISO's website: http://www.iso.org.

There are many benefits to standards development, adoption, and use. Participation in standards development activities benefits the regenerative medicine community in that these activities can facilitate the development and maintenance of guidance for industry, address issues not addressed in FDA Guidance documents, facilitate product design, and lead to international harmonization. From a business perspective, participation in standards development activities can provide a competitive advantage by influencing technical contents, reduce the cost of production by improving factory flexibility and supply chain management, foster innovation and support research and development, and increase trade by shortening the time between concept and global availability. Standards can be used by developers of regenerative medicine products to meet regulatory expectations. In turn, the benefit to the regenerative medicine community helps the public by providing products that are more thoroughly characterized with a greater understanding of the conditions of use of the products. Thus, the FDA has a critical role in providing support for standards development activities.

ADVISORY COMMITTEE MEETINGS

As mentioned in the Meetings With Industry, Professional Groups, and Sponsors section, because of the diversity of innovative technology evaluated by FDA review staff, the FDA makes use of scientific Advisory Committees or Panels (for medical devices) to complement its internal review process. These advisors provide independent, professional expertise and technical assistance to contribute to scientific regulatory decision-making processes. Outside experts can be asked to review data or make recommendations about study designs across a product or clinical area; outside advisors can also be helpful at earlier stages of product development. Expertise on the advisory committee often includes scientific, statistical, and clinical experts, as well as consumer representation, patient advocates, and industry participation. Most meetings are public, and there is an opportunity for public participation in the form of public comment.

There are 34 Advisory Committees as well as a number of SCs and one DHHS Committee administered by CBER. The areas of responsibility for the Panels and committees are divided along medical specialty areas. The Advisory Committee for cellular, tissue, and gene therapy products, as mentioned earlier, is the CTGTAC. This committee has discussed a number of topics that are of potential interest to product developers in the regenerative medicine area, including:

- Hematopoietic stem cells for hematopoietic reconstitution (Feb. 2003),
- Allogeneic islet cell therapy for diabetes (Oct. 2003),
- Somatic cell cardiac therapies (Mar. 2004),
- Cellular products for joint surface repair (Mar. 2005),
- Potency measures for cell, tissue, and gene therapies (Feb. 2006),

- Cellular therapies derived from human embryonic stem cells—considerations for preclinical safety testing and patient monitoring (Apr. 2008),
- Animal models for porcine xenotransplantation products intended to treat type 1 diabetes or acute liver failure (May 2009),
- Clinical issues related to FDA draft guidance "Preparation of IDEs and INDs for Products Intended to Repair or Replace Knee Cartilage" (May, 2009),
- Testing of replication competent retrovirus/lentivirus in retroviral and lentiviral vector-based gene therapy products (Nov. 2010),
- Cellular and gene therapy products for the treatment of retinal disorders (Jun. 2011), and
- Oocyte modification in assisted reproduction for the prevention of transmission of mitochondrial disease or treatment of infertility (Feb. 2014).

The presentations for each topic, as well as transcripts of each discussion, are available on the FDA's website referenced at the end of this chapter [29].

The Medical Devices Advisory Committee consists of 18 Panels that cover the medical specialty areas. Panel meetings are held regularly to discuss specific products. A few examples of past Panel meetings are:

- General and Plastic Surgery Panel regarding dermal fillers (Nov. 2008),
- Orthopaedic and Rehabilitation Devices Panel regarding a bone putty (Mar. 2009),
- Ophthalmic Devices Panel regarding a visual prosthetic device (Mar. 2009),
- Neurological Devices Panel regarding a spinal surgery sealant (May 2009),
- Ear, Nose, and Throat Devices Panel regarding an implantable hearing system (Dec. 2009),
- Orthopedic and Rehabilitation Devices Panel regarding metal-on-metal hip arthroplasty systems (Jun. 2012),
- Circulatory Systems Devices Panel regarding an atrial appendage device (Oct. 2014), and
- General and Plastic Surgery Devices Panel regarding wound care products combined with antimicrobials or other drugs (Sep. 2016).

A complete list of upcoming Medical Devices Advisory Committee Panel meetings and searchable archive of past meetings with agendas and materials can be found on the FDA's website [55].

FOOD AND DRUG ADMINISTRATION RESEARCH AND CRITICAL PATH SCIENCE

The FDA recognizes the complexity of the scientific issues related to regenerative medicine products. FDA research laboratories have an important role in ensuring that the agency stays abreast of the rapid changes and developments affecting the entire field as well as addressing specific regulatory science questions. In 1992, CBER researchers began systematic efforts to uncover mechanisms that control the behavior of cells subjected to various environmental stimuli, particularly those encountered during normal wound healing, regeneration, and prenatal development. Those studies led to the discovery of several growth factors and feedback mechanisms that control these pathways [56–63]. Other research addressed interactions between hematopoietic and mesenchymal cell lineages both in vitro and in vivo [64,65]. The success of those efforts led to the recruitment of additional investigators in these areas. In 2004, the FDA introduced the Critical Path Initiative to identify and support research priorities that are expected to advance innovation in medical products. The Critical Path Opportunities List "presents specific opportunities that, if implemented, can help speed the development and approval of medical products" [66]; it is available on the FDA's website. A number of the research topics on the Critical Path Opportunities List have applications to regenerative medicine, such as developing characterization tools for cell therapy and tissue engineering, biomarkers for cardiovascular disease, and advanced imaging technologies. FDA laboratories are actively engaged in these and other research questions that will facilitate the advancement of the field of regenerative medicine.

A priority of the Critical Path Initiative is updating and modernizing techniques, to ensure that the agency and the research community have the tools necessary to bring safe and effective products to market. Efforts include promoting collaborations spanning multiple centers and regulatory jurisdictions across the FDA as well as among the FDA and other relevant organizations (e.g., other agencies, academic organizations, regulated industry). Developing research collaborations and the requisite infrastructure to support those and other efforts will facilitate review of combination products, which are often seen in regenerative medicine.

An example of collaborative work across FDA laboratories is a multiinvestigator project at CBER using a battery of state-of-the-art analytic techniques chosen to provide complementary data on cell state and seeking to develop

new biomarkers for cell therapies. The project aims to characterize mesenchymal stromal cells from a number of perspectives, including genetic stability, proteomic and phosphoproteomic analysis, microRNA analysis, messenger RNA profiling by microarray and quantitative polymerase chain reaction analysis, chromatin immunoprecipitation, and examination of the potential for cells to mature and contribute to the formation of organs and tissues. Furthermore, the study will look for molecular differences between cells from early versus late passage numbers. Importantly, the same cells that go through this panel of tests will be implanted in a mouse model of hind-limb ischemia, allowing for the correlation of product characterization data with the in vivo outcome with regard to localization, differentiation, and functionality. This FDA research project may yield information that will be useful for product characterization, in-process testing, lot release criteria, developing comparability and stability protocols, and predicting cell fate and function after receiving a cell therapy.

A major issue associated with the clinical use of cellular therapies is predicting what happens to the cells after administration. Another FDA Critical Path research study at CBER will advance cell therapy by developing methods for in vivo tracking and imaging of neural stem cells (NSCs) after transplantation. NSCs from adult, fetal, and embryonic sources have been proposed as treatments for degenerative conditions such as Parkinson disease and for the repair of tissues damaged by stroke and spinal cord injury. Magnetic resonance imaging and single photon emission computed tomography are being used to determine cellular location and the persistence of engraftment qualitatively and quantitatively. The goal of this project is to develop methods for evaluating biomarkers that may be predictive of NSC function.

The FDA's research projects often involve collaborations with other federal and academic partners to employ new technologies to address regulatory science questions. For example, a collaboration between FDA and the NIST is using automated microscopy to characterize the differentiation of mesenchymal stem cells (MSCs). The goal is to improve the safety of MSC products by developing robust assays that can be used for in-process and lot release testing.

FDA Critical Path research also addresses some of the challenges faced in both product development and product evaluation. For example, after the observation of unexpected toxicity of adenoviral vector gene therapy in a clinical trial, CBER research provided insight into how adenovirus vectors cause toxicity and developed an animal model for gene therapy in the context of preexisting liver disease [67]. CBER researchers and regulators also worked with a consortium from industry and academia to develop reference material for adenoviral vector particles [68]. FDA research is ongoing to understand the nature of toxicity of systemically delivered adenovirus and mechanisms for vector clearance to improve the safety of gene therapy trials [69].

Some FDA laboratories are engaged in research projects related to tissue. CDRH scientists are studying the effects of mechanical and electrical stimulation on cardiac cell cultures and how the parameters modulate cellular physiology. A CBER–CDRH collaboration is examining the relationship between encapsulation of chondrocytes in a scaffold material, with and without mechanical stress, on the status of several signaling pathways. Another intercenter collaborative research project between CDRH and CDER conducts a comprehensive translational assessment of human induced pluripotent stem cell-derived cardiomyocytes to evaluate drug-induced arrhythmias [70] and to predict individual patient response to drugs by using patient-specific stem cells collected in an FDA-sponsored clinical trial [71]. A Critical Path collaborative research project with partnerships outside the US government involves CDRH, CBER, the University of Maryland, the University of Akron, and Tufts University, and evaluates the accuracy and reproducibility of three-dimensional (3D) printed scaffolds containing cells. This project assesses the material and biological properties of the printed scaffolds in the presence or absence of cells on printing accuracy.

The FDA's interest in 3D printing, also known as additive manufacturing, is in part because it is driving the innovation of medical products, including in the area of biological and tissue engineered products for regenerative medicine purposes. 3D printing involves the layer-by-layer deposition of material to produce a 3D part from a digital design file. With the increase in use of 3D printing and the uncertainty of how the technology can affect the safety and effectiveness of the products, interest in 3D printing has increased at the FDA and led to the formation of the Additive Manufacturing Working Group. The WG held a public workshop on Oct. 8–9, 2014, to obtain input from stakeholders, entitled "Additive Manufacturing of Medical Devices: An Interactive Discussion on the Technical Considerations of 3D Printing" [72]. The workshop aimed to bring together experts in the field to discuss with the FDA the current state of the art of 3D printing, and included discussions on 3D printing of medical devices, biologics, and pharmaceuticals. Some of the considerations discussed during the public workshop are presented in FDA web content and documents on 3D printed devices [73] and a technical review [74] These documents primarily focus on medical devices, with important considerations for evaluating 3D printed devices including the following: the effect of build orientation and location on final device performance, including mechanical and physical

properties; process validation of the 3D printing systems to ensure consistency between print jobs; sterilization and removal of residual materials; and characterization of material properties before and after printing.

In the case of printing biological products, also known as bioprinting, applications may include printing tissue scaffolds, constructs containing living cells [75], and even small tissue [76] and organ structures [77]. 3D printing may offer an approach to make a medical product with a complex architecture, such as porous structures or internal lattice structures. In addition, cells and biomaterials could potentially be printed simultaneously with more precise spatial control to produce constructs with desired properties. Although the FDA has experience regulating 3D printed medical products [74] no FDA-approved or cleared biological products incorporate 3D printing. These types of products will typically be regulated along the same pathways as non-3D printed products. However, because of the complexity of 3D printed biologics, there may be some additional technical considerations for sponsors to take into account and evaluate compared with non−3D printed products. Some of these considerations may include, but are not limited to, the printing parameters and consistency, material selection, finishing steps, biocompatibility, mechanical and physicochemical properties, and the biological function of the finished product. Known applications of bioprinting technology used for research purposes include skin [76], cartilage [78], bone [79], nerve [80], and blood vessels [81].

With accelerating advancement in this area, the FDA continues to communicate with the public regarding considerations for 3D printed medical products. Through ongoing research collaborations, and discussions with stakeholders, the FDA is committed to fostering safe and effective innovation in the area of 3D printed medical products.

With support through the Critical Path Initiative, FDA research laboratories provide an important source of in-house expertise in regenerative medicine and other cutting-edge technologies and research areas. Although by no means exhaustive, the examples provided here demonstrate the diverse range of topics under investigation at the FDA. Especially in consideration of the rapid change and development of the regenerative medicine field, Critical Path research efforts ensure that the FDA stays abreast of current innovations. The FDA's research programs provide an important source of the latest science to inform the regulatory process and bring safe regenerative medicine products to market.

OTHER COORDINATION EFFORTS

Because of the highly interdisciplinary nature of regenerative medicine, the FDA recognizes the need to build collaborative efforts to review products successfully in this area. The FDA is therefore a partner in the Multi-Agency Tissue Engineering Science (MATES) Interagency Working Group. This partnership, which spans more than a dozen federal agencies, is designed to provide a forum to facilitate communication and coordination across the government regarding activities in tissue engineering and regenerative medicine. The full strategic plan can be found at the MATES website [82].

In another example of interagency interaction, collaboration, and coordination, the FDA has established Memoranda of Understanding (MOU) agreements with two different NIH institutes that involve FDA scientific review staff and NIH extramural research program officers. The MOUs cosigned by the National Institute of Neurological Disorders and Stroke and the National Heart, Lung and Blood Institute incorporate safeguards to protect from disclosure shared, nonpublic information such as trade secrets and confidential commercial information, identities of study participants and other personal information, privileged and/or predecisional agency information, research proposals, progress reports, and/or unpublished data or information protected for national security reasons. Under the MOU agreements, participants are able to hold unfettered discussions and exchange information that enables the respective agencies to maintain currency with respect to ongoing scientific activities that could affect regenerative medicine from both the laboratory and clinical research perspectives. Interagency MOU interactions identify gaps in knowledge related to the state of available scientific information and familiarity with FDA regulatory expectations. This, in turn, contributes to identification of promising basic research with the potential for clinical translation.

There are also efforts to promote collaboration within the agency. For example, the FDA Commissioner's Fellowship Program (CFP) is facilitating a collaboration related to the regulation of regenerative medicine across the FDA's product jurisdictions. The CFP was established in 2008 to attract new talent to the agency while providing an opportunity for those to learn about FDA regulatory science for future careers outside the agency. Within its annual cohort of fellows, a regenerative medicine fellowship program has been established. Because many regenerative medicine products involve combining biologics and device technology, regenerative medicine fellows work across both CBER and CDRH to facilitate cross-agency collaboration and conduct research projects related to the regulation of regenerative medicine products.

Interaction between the FDA and the scientific and regulated communities is an important area of collaboration. Workshops are one such example, including the previously mentioned FDA-NIST cosponsored session regarding cell–scaffold products. Workshops provide valuable opportunities for the agency to receive input from outside scientific experts and other stakeholders. An additional common example of this type of activity is the liaison meeting, in which the FDA directly engages in dialog with professional societies (e.g., International Society for Stem Cell Research, American Association of Blood Banks, American Association of Tissue Banks, International Society for Cellular Therapy) regarding scientific or regulatory issues related to a certain research area. The FDA is a founding member of the National Academy of Medicine (NAM) Forum on Regenerative Medicine. This forum, which is similar in structure and function to NAM's longstanding Drug Forum, provides a neutral convening mechanism for interested parties from academia, industry, government, patient/provider organizations, regulators, foundations, and others to discuss difficult issues facing the application of, and opportunities for, regenerative medicine. The Kidney Health Initiative, an existing public–private partnership that includes the FDA, has begun a roadmapping project to develop renal replacement therapies. CBER and CDRH have a leading role in this effort. All of these activities ensure that the FDA receives continuous input on the latest scientific discoveries to inform the regulation of safe products.

CONCLUSION

The field of regenerative medicine is exciting, with scientific advances leading to the promise of future therapies for current unmet medical needs for patients. The FDA regulatory approach to the evaluation of medical products includes an ongoing assessment of how the science of those products informs regulatory policy. To meet the needs of the challenging array of products that are on the horizon, the FDA intends to continue the current dialog with the scientific community and product Sponsors as part of its mission to develop science-based regulatory review policies that are robust and predictable.

Regenerative Medicine Manufacturing—Challenges and Opportunities

Paul Cohen[1], *Joshua G. Hunsberger*[2], *Anthony Atala*[2]

[1]North Carolina State University, Raleigh, NC, United States; [2]Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

WHY REGENERATIVE MEDICINE MANUFACTURING?

Why regenerative medicine manufacturing? The answer is simple. For regenerative medicine-based technologies and products to become the next standard of care, advances are needed in manufacturing processes. This chapter will highlight the current challenges facing regenerative medicine and list what the primary challenges are that are hindering widespread adoption. We will then consider some of the challenges in lack of standards and lack of definition of quality, as well as some of the technical challenges. After highlighting these challenges, we will delve into the opportunities that exist in regenerative medicine manufacturing. These opportunities exist in areas of regulatory and standard setting and we will cover some of work currently being done in these areas. There are also opportunities for new technologies and we will cover some of the advances being made for scale-up, reducing costs, quality control systems, automation, modular plug and play systems, and bioprinting. Next we will consider regenerative medicine manufacturing systems of the future. While these systems do not currently exist in full form today we believe these systems will be part of every major clinical regenerative medicine program in the next 20 years. We will conclude this chapter by reviewing the global landscape focusing on technical societies and domestic and international efforts.

CURRENT CHALLENGES AND OPPORTUNITIES IN REGENERATIVE MEDICINE MANUFACTURING

Primary Challenges for Widespread Adoption

The primary challenges for widespread adoption of regenerative medicine-based technologies have been reviewed extensively [1–7]. Table 78.1 highlights some of these challenges. While the science of regenerative medicine continues to progress, for widespread adoption we must solve several roadblocks related to the manufacturing aspect of these treatments. Currently, high cost, quality, and logistics issues threaten the promise of bringing regenerative medicine therapies to those in need. The lack of efficient, controllable manufacturing processes makes cost and quality difficult to achieve. Moreover, Food and Drug Administration (FDA) approval procedures make continuous improvement far more difficult and costly.

More efficient, cost-effective manufacturing will require advances in automation and control to remove human work and reduce variability where possible, because differences in procedures induce increased variability. Improved biosensors will also be needed to control quality and consistency, which will also drive down cost.

Cell expansion is an example of an area, common to all therapies, in need of cost-effective scale-up. Progress is being made in the development of scalable suspension cultures that can generate billions of human cells using

Principles of Regenerative Medicine, Third Edition

TABLE 78.1 Current Challenges in Regenerative Medicine Manufacturing

Need for scale-up (e.g., expand to billions of cells)
High costs of manufacturing regenerative medicine product
Lack of sufficient quality control systems for in-line sensing
Lack of automation
Lack of closed and modular systems
Lack of standards for regenerative medicine

single-use bioreactors [8,9]. This necessitates advances in bioreactor design, as well as sensors to meet the large quantities of cells for a given product. Additionally, it should reduce cost and make these therapies more widely available [10].

Lack of Standards

Regenerative medicine covers a broad range of therapies as it manipulates genes, cells, and tissues to repair or replace diseased, damaged, or missing organs. This may include bone, skin, as well as other cells and tissues. The transition from laboratory to clinic has been slow due to the inherent complexity of the treatments and a lack of standards and standardization that complicates manufacturing thereby increasing cost. Many traditional measurements of efficacy, potency, purity, and quality that work with traditional pharmaceutical manufacturing may not be sufficient for regenerative medicine treatments.

The National Institute of Standards and Technology (NIST) has developed a regenerative medicine and advanced therapies laboratory program that advances cell therapy, gene therapy, and tissue engineering by developing measurement infrastructure, including enabling tools, reference materials, methods and protocols, and bioinformatics and modeling tools [11]. NIST also has a regenerative medicine biomanufacturing program that is seeking to develop measurement solutions, serve as a neutral ground for the discussion of underpinning measurements and other manufacturing needs, and also lead and contribute to the development of standards [12]. NIST has also entered into a memorandum of understanding with the Standards Coordinating Body for Gene, Cell, and Regenerative Medicines and Cell-Based Drug Discovery to advance the field by developing consensus standards.

ASTM International and the International Organization for Standardization (ISO) have a partnership in additive manufacturing where they have jointly released the Additive Manufacturing Standards Development Structure [13]. This provides a framework for meeting the needs for new standards in areas including regenerative medicine. ASTM also has many technical committees that serve as working groups to develop new standards in areas such as additive manufacturing (Committee F42) and medical and surgical materials and devices (Committee F04). ISO is another standard setting organization that brings together technical experts from around the world to develop international standards. For instance, there are ISO standards currently available for tissue-engineered medical products (ISO 19090:2018) and quality management systems (ISO 90001:2015 and ISO 13485:2016).

For cell therapies, standards for imaging tools and protocols for cell characterization (identification, quantity, and function) are needed, as well as reference materials for fluorescence imaging and flow cytometry. For tissue engineering standards for scaffold design, structure and properties are needed as are standards for the computational models required. FDA has released guidance for additive manufactured devices that are implanted [14]. While these are not yet approved and some may not apply to scaffolds, they illustrate the complexity of standards development for future manufacturing systems and the need to incorporate them into process design. These are summarized in Table 78.2. In addition to standards, the manufacture of regenerative medicine products needs standardization of procedures and protocols to minimize variability, thereby increasing quality and decreasing costs.

Logistics

Currently, cells are preserved and stored at cryogenic temperatures. This impacts handling procedures, cost, efficacy, safety, equipment requirements, retrieval, and effects on the regenerative medicine product. In addition, the ability to distribute product to point-of-use locations is constrained by the number of cryogenic containers.

TABLE 78.2 Summary of Recent Food and Drug Administration (FDA) Guidelines for Additive Manufactured Devices

Area	Components
Overall device design	Comparison of desired feature sizes and tolerances to process
Patient-matched device design	Effects of imaging, software interacting with design models, complex design file conversion, cybersecurity and personally identifiable information
Software workflow	File format conversions, digital device design to physical device, build volume placement, addition of support material, slicing, build paths, machine parameters and environmental conditions, automated software validation
Material controls	Starting material, material reuse
Postprocessing	Full documentation
Process validation and acceptance activities	Process validation, revalidation, acceptance procedures, test coupons
Quality data	Analysis of sources of quality data to identify existing and potential causes of nonconforming product
Device testing	Description, mechanical testing, material characterization, residue removal and sterilization
Labeling	Recommended for Additive Manufactured (AM) devices that are patient matched, may include patient identifier, use, final design iteration or version used to produce the device

Sensors and Quality Control Systems

There are significant challenges with the development of sensors and quality control systems for regenerative medicine manufacturing, although they differ between cell expansion, tissue, and organs. Product loss or slow growth for cell-based therapy batches may slow testing or attainment of full expansion. For cells, tissue and organ sensors or sensor suites are needed to properly control processes and assure quality.

Bioprinting

While there a many bioprinters on the market, none meet the proposed FDA guidelines and can be used for human patients. As summarized in Table 78.2, there are many issues covered in the FDA proposed guidelines and no currently marketed bioprinter meets these. It is important to note that issues involving hardware design, software, material control, and validation will make this challenging.

Scale-Up and Automation

Benchtop research does not easily scale up for production for a number of reasons. Since there is little standardization of processes causing poor reproducibility the translation to production is difficult. Also, it is time consuming and expensive to change protocols once approved by the FDA. Standardized protocols, whether for manual or automated manufacturing, will help reduce variability and enable scale-up. However, the human element adds uncertainty and cost. Therefore automation for autologous products is crucial for widespread adoption. Currently, there is no marketed, fully integrated, modular manufacturing system.

Collectively, we have highlighted some of the opportunities in regenerative medicine manufacturing and listed them in Table 78.3. We mention that there can be technologies developed that can assist with scaling-up processes such as using single-use technologies [15]. There is also an opportunity for developing solutions for reducing costs, which could include multiple solutions discussed further in this perspective article [10]. Other opportunities exist with developing in-line sensing systems, automating processes through integration of robotics and artificial intelligence, and developing plug and play infrastructures to accommodate different manufacturing processes. A final set of opportunities exists in the development of standards and ensuring seamless integration of these new regenerative medicine-based products with regulatory pathways. The FDA has published two new draft guidance documents that are intended to assist with bringing innovative, safe, and effective products to patients as efficiently as possible. The first guidance document is called "Expedited Programs for Regenerative Medicine Therapies for Serious Conditions." The second document is called "Evaluation of Devices Used with Regenerative Medicine Advanced

TABLE 78.3 Current Opportunities in Regenerative Medicine Manufacturing

Develop technologies for scale-up (e.g., single-use technologies)
Develop solutions for reducing cost (e.g., defined media)
Develop solutions for quality control systems (e.g., microfabricated biosensor technologies for in-line sensing)
Develop technologies that can automate processes (e.g., integration of robotics and artificial intelligence into manufacturing processes)
Develop solutions for modular systems (e.g., plug and play infrastructure to accommodate different modules)
Current ASTM and ISO efforts for developing standards (e.g., ISO 19090:2018 for tissue-engineered medical products)
FDA guidance documents for advancing regenerative medicine-based products (e.g., Technical Considerations for Additive Manufactured Medical Devices)

Therapies." The first guidance document describes the Fast Track designation and breakthrough Therapy designation, which are available for regenerative medicine therapies. It also describes requirements for the new Regenerative Medicine Advanced Therapy (RMAT) designation program, which was created by the 21st Century Cures Act. The second draft guidance document on devices provides the FDA's current thoughts on evaluating devices used in the recovery, isolation, and delivery of RMATs.

ENVISIONED REGENERATIVE MEDICINE MANUFACTURING SYSTEMS OF THE FUTURE

Envisioned regenerative medicine manufacturing systems of the future will enable these technologies, therapies, and products to be commercialized and made widely available. Table 78.4 illustrates some of these envisioned system areas, their system attributes, and companies of interest that have some of the capabilities needed to build these systems. Fig. 78.1 captures some of the envisioned manufacturing systems of the future that could bioengineer new tissues and organs by integrating a clinical-grade 3D bioprinting approach into the manufacturing process. Next we will cover some of the system attributes we believe will be critical for these advanced regenerative medicine manufacturing systems.

Standardization will be critical for future regenerative manufacturing systems due to the inherent variability and need to make procedures more consistent within and between manufacturing sites. Both manual and automated manufacture will rely on adherence to standards and standardization. NIST is working to establish standards for cell measurement, live cell imaging, quantitative flow cytometry, and bioprinting. One concern is that measurements of efficacy, potency, purity, and quality that are used for pharmaceuticals may be insufficient for regenerative medicine. Moreover, standardized procedures for cell expansion, size of biopsies, and other critical operations are needed for manual and automated manufacture.

Fully integrated, modular, and automated manufacturing systems are critical and this will help to drive standardization since automation will depend, to a certain extent, on this. Such a system would utilize closed pods or cassettes for all processing to remove the possibility of contamination. This "plug and play" design philosophy would also lend flexibility to these manufacturing systems allowing them to produce a wide array of regenerative medicine products for individuals. An integrated modular robotic system with closed pods could have the ability to exploit standard processes, including cell harvesting, cell processing, nutrient addition, tissue digestion, incubation, imaging and characterization, tissue banking, quality control, and preservation prior to use or shipping.

The collection of data, scheduling, and control of such a system will be complex and require new sensors and smart controls. The use of machine learning to sense quality characteristics and remove human visual perceptions (and biases) will be needed. Control for processes that can be highly variable may take weeks and must be done in a way that gets needed cells, tissue, and organs to critically ill patients reliably. Smart manufacturing refers to

TABLE 78.4 Envisioned Manufacturing Systems of the Future

Future System Areas	System Attributes
Fully integrated/modular/closed/sterile/automated manufacturing systems	• Closed, integrated purification, formulation and vial fill • Seamless media to bioreactor/cell culture vessel transition • Cell concentration standard method to maintain viability/potency • Customizable modules for expansion and cell retrieval • Automated cell handling in a fully controlled aseptic environment. Scale-up for mass production • Passaging and layering multiple types of cells in a closed system • Automatic monitoring of glucose utilization/lactose production to adjust nutrient supply for continuous feed • Off-the-shelf closed systems that can be easily upscaled
Xeno-free defined media systems	• Synthetic serum for human immune cells and mesenchymal stem cells first. Following its success it can be extended to other tissue sources in the human body • Universal "basal" media • Synthetic, defined serum substitute "panel"
Supply chain and logistic systems	• Platform technologies for shipping human stem cells and mesenchymal stem cells should be initially tested • Further development of formulations and methods for extending liquid storage stability • Further development and optimization of formulations and methods for freeze drying
Biosensing systems	• 3D printer for engineered tissues • Microfabrication of biosensors • Better oxygen and glucose monitoring sensors • Improved material for adherent cells to maximize cell seeding and harvesting
Nondestructive quality control systems	• One area is lactate and ammonia management • In-line measurement of cell density • Real-time cell "state"/phenotype monitoring • Data capture and mining/correlation • Microscope with software for recognizing and quantifying cellular structures • Disposable sensors or built-in sensors for growth factor levels in addition to pH, osmolarity, O_2, and CO_2. Glucose, ammonia, and K^+ would be great as well • There will not be a path to a universal solution—too divergent. Pick either most universal quality control specification/parameter (most therapy agnostic) or highest impact upcoming therapy—propose and prototype a solution
Automated and closed patient-specific systems	• Integrated, standardized disposables for product types • Processes that are patient specific and would involve modeling the patient's anatomy • Easily adaptable semiuniversal automated system • Semiuniversal disposables • Automated injector with detailed process control • Novel single-use sensors/sensing approaches for noninvasive monitor/control of process parameters and detection of microbial contamination • Disposable single-use bioreactors that will support all steps from seeding through harvest • Instrumentation that can provide CO_2 and temperature control without traditional incubators
Cell and tissue expansion systems	• Determine if same system could be scaled to fit both small- and large-scale needs • In-line cell "state"/phenotype monitoring • Scalable bioreactor technology • Novel single-use format for high-density cell culture (adaptable adherent or suspension, or tissue constructs) • Design for scale-out strategy for autologous therapies

FIGURE 78.1 Envisioned future manufacturing systems: illustrated here is an envisioned future manufacturing system where 3D bioprinting will be incorporated into an end-to-end modular manufacturing system that can produce at scale bioengineered tissues and organs.

"fully-integrated, collaborative manufacturing systems that respond in real time to meet changing demands and conditions" [16]. It has the potential to use data and models to control such complex systems. Another aspect of an integrated automated manufacturing system is the ability to share information. Blockchains, a computer science construct that uses a distributed recording and storage of transaction records in a manner that safeguards patient confidential information, can be used to link information through the process to understand cause and effect and better control production.

Xeno-free defined media systems will be able to support a large panel of clinically relevant cell types that will be needed for cell and gene therapies, as well as tissue engineering applications. These systems will greatly accelerate product development times, as well as reduce costs and variability by removing serums and recombinant proteins and replacing them with defined biochemical substitutes. The RegenMed Development Organization is currently using a consortium-based model to develop a platform technology that seeks to build a universal media system similar to the one we envision here to support clinical cell manufacturing. Efforts like these will greatly accelerate the field.

Biosensing systems will be integrated into regenerative medicine manufacturing processes to monitor the viability, phenotypic characteristics, biomechanical characteristics, and physiologic responses of cells, scaffolds, organoids, organoid systems (e.g., body-on-a-chip personalized medicine systems), tissues, and bioengineered organs. These biosensing systems will be microfabricated and allow improved monitoring of oxygen, glucose, metabolites, pH, temperature, and many additional attributes that can be customized based on the cellular and tissue-specific systems being engineered and manufactured. These biosensing systems can also be integrated into 3D bioprinting systems to ensure the integrity of starting materials (e.g., cells, biomaterials, bioinks, etc.) and confirm the viability, phenotypic characteristics, biomechanical characteristics, and physiological responses from 3D bioprinted organoids, tissues, and organs.

Nondestructive quality control systems will provide in-line measurement of specific quality control attributes needed in regenerative medicine manufacturing processes of the future. One area of need will be improved monitoring of lactate and ammonia management, as well as other biochemical markers that provide important information to maintain the viability of cellular and tissue systems. These in-line measurements will capture data in real time and have artificial intelligence systems to make correlations and predictions on safety and quality attributes of the current and final clinical product that will also save time and money by only advancing products with a high probability of possessing final safety and quality attributes needed for the manufactured clinical product.

Cell and tissue expansion systems will be adaptable to both small- and large-scale needs. The miniaturized systems will enable autologous patient-specific therapies at the bedside, while the large-scale systems will provide a pathway for allogeneic therapies to be manufactured at industrialized scale for widespread use. Within these two systems, in-line cell "state" or phenotype monitoring will be critical to ensure safety and quality attributes are maintained throughout the manufacturing process. There will also be opportunities for novel single-use formats for high-density cell cultures.

Supply chain and logistic systems must be used carefully when considering the expansion of regenerative medicine therapies. Current technologies are expensive as companies must buy and maintain an appropriate number of cryogenic storage containers for shipment. Otherwise, timely shipment and product quality cannot be guaranteed.

Current thinking and research seeks novel cell preservation technologies for regenerative medicine. This may include the development of advanced tissue and organ preservation technologies and processes for cell banking, such as specimen harvest, cell retrieval, selection and expansion, tissue typing, storage, and distribution. Promising paths include the development of new and more stable dimethyl sulfoxide-free stabilizer formulation compositions, lyophilization formulations, and characterization of the effects on the product (cellular function) both pre- and post-thaw identification of reagents that serve to preserve cellular function upon freeze drying. Additionally, novel drying technologies that optimize formulations for reconstitution are needed. Specialized packaging for cells, tissues, and organs is needed, as well as training to properly employ their technologies, as well as appropriate infrastructure at point-of-care facilities.

Solutions may utilize short-term cryostorage coupled with new techniques for distribution. Such hybrid storage would enable initial cryogenic storage followed by noncryogenic distribution for high-quality products. Customized designs for closed preservation systems coupled with sensors may also be employed to monitor quality and enable longer preservation time.

GLOBAL LANDSCAPE FOR REGENERATIVE MEDICINE MANUFACTURING

The global landscape for regenerative medicine manufacturing is exciting and filled with tremendous potential. Next we will highlight some of the technical societies that are forming in this area, as well as the numerous manufacturing-focused initiatives that are being launched around the world. Table 78.5 lists the initiatives, focus areas, and websites where you can obtain additional information.

Technical Societies

There is a new technical society recently formed called the Regenerative Medicine Manufacturing Society (RMMS). RMMS is a new organization that has a vision of enabling the adoption of manufacturing platform technologies into standards, regulatory pathways, and commercial products by assembling a diverse network of stakeholders. These stakeholders fall into these major categories: (1) industry, (2) academia (basic and clinical research), (3) regulatory agencies, (4) nonprofit organizations, and (5) investment and funding agencies. RMMS has a strategic goal to bring these stakeholders together to achieve a number of regenerative medicine manufacturing aims, including the following: (1) enabling the development of scale-up tools and reagents; (2) enabling the development of standards; and (3) seamless integration of platform technologies with regulatory pathways. Additional information on this new technical society can be found at http://regenmedmanufacturing.org/. The first RMMS conference

was held in Miami, Florida, in January 2018 in concert with the World Stem Cell Summit and brought together leaders from industry, academia, and government.

Domestic Efforts

Efforts currently under way in the United States to advance regenerative medicine manufacturing are growing every day.

21st Century Cure's Act, also known as the Cures Act, was signed into law on December 13, 2016, with the intention of assisting the acceleration of medical product development and bringing new advances to patients in a faster, more streamlined manner. The Cures Act seeks to incorporate the perspectives of patients into the development of drugs, biological products, and devices in the US FDA's regulatory process. The Cures Act has the intention of speeding up the development and review of novel medical products (including medical countermeasures) and gives new authority to assist the FDA in building and retaining scientific, technical, and professional experts by establishing new product development programs such as (1) RMAT, a new expedited option for eligible biologics, and (2) the Breakthrough Devices Program to accelerate the review of innovative medical devices. The Cures Act also charges the FDA with improving the regulation of combination products by creating one or more intercenter institutes to coordinate activities in major disease areas between the drug, biologics, and device centers. In total, the Cures Act provides $500 million over 9 years to assist the FDA in implementing this law to accelerate the discovery, development, and delivery of 21st century cures. Currently, the FDA has submitted a work plan to Congress that lays out a budget for advancing seven strategic areas of activity: (1) patient-focused drug development, (2) advancing new drug therapies, (3) modern trial design and evidence development, (4) patient access to therapies and information, (5) antimicrobial innovation and stewardship, (6) medical device innovations, and (7) improving scientific expertise and outreach at the FDA.

The National Network for Manufacturing Innovation (e.g., Manufacturing USA) has funded two institutes dedicated to advance regenerative medicine manufacturing through public/private partnerships. These institutes join 12 others, each focusing on a technology or industry group by bringing together industry, academia, and government to increase competitiveness through applied research, outreach, and workforce development.

The National Institute for Innovation in Manufacturing Biopharmaceuticals (NIIMBL) has a mission "to accelerate biopharmaceutical manufacturing innovation, support the development of standards that enable more efficient and rapid manufacturing capabilities, and educate and train a world-leading biopharmaceutical manufacturing workforce, fundamentally advancing U.S. competitiveness in this industry" [17]. NIIMBL will initially seek to understand biomarkers for potency, develop sensors for these biomarkers, and use this knowledge and developments for cost-effective scale-up for mesenchymal stem cells, T-cells, and induced pluripotent stem cells.

The Advanced Regenerative Medicine Institute "will make practical the large-scale manufacturing of engineered tissues and tissue-related technologies, to benefit existing industries and grow new ones" [18]. The institute seeks to develop innovations across five thrust areas: (1) cell selection, culture, and scale-up; (2) biomaterial selection and scale-up; (3) tissue process automation and monitoring; (4) tissue maturing technologies; and (5) tissue preservation and transport.

The Medical Technology Enterprise Consortium (MTEC) is a nonprofit biomedical technology consortium that collaborates with multiple government agencies under a 10-year renewable Other Transaction Agreement with the US Army Medical Research and Material Command. MTEC fosters integrated research partnerships to provide solutions to military, veterans, and the civilian population. Consortium thrust areas include: (1) prevention, diagnosis, and treatment of infectious diseases, (2) care of combat casualties, (3) clinical and rehabilitative medicine, (4) military operational medicine, (5) medical simulation and information sciences, and (6) advanced medical technologies. Significant emphasis is placed on aspects of regenerative medicine that will facilitate manufacturing scale-up.

International Efforts

There are also many regenerative medicine international efforts and three specific efforts that we will focus on here include: (1) the Centre for Commercialization of Regenerative Medicine (CCRM), (2) Catapult, and (3) Japan.

CCRM is a nonprofit, public/private consortium whose mission is to generate sustainable health and economic benefits through global collaboration in cell and gene therapy, as well as regenerative medicine. CCRM has recognized there is an unmet need in advancing cell, gene, and regenerative medicine-based treatments to the clinic. This

Canadian-based effort uses stem cells, bioengineering, and biomaterials combined with their consortium and infrastructure to coordinate product development and commercialization.

The Cell and Gene Therapy Catapult is a network of centers in the United Kingdom designed for innovation in specific strategic areas to promote future economic growth. Each Catapult center specializes in a different area of technology, including areas such as cell and gene therapy, high-value manufacturing, transport systems, medicines discovery, and others. This Catapult network provides access to technical capabilities, equipment, and additional resources to develop new products and services on a commercial scale.

Japan is advancing regenerative medicine by enabling early commercialization and early reimbursement. This effort is in response to half the population of Japan, which is over age 50, and regenerative medicine-based therapies have been limited in the past because of the difficulty in progressing through Japan's Pharmaceuticals and Medical Devices Agency. Prime Minister Shinzō Abe has launched an economic revitalization plan that includes ¥110 billion ($1 billion) in funding for stem cell research. In addition, two new regenerative medicine laws were enacted. Law No. 84/2013 provides an amendment for the Pharmaceutical Affairs Act, renamed the Pharmaceutical and Medical Device Act, and provides conditional marketing authorization. This new regulation provides revenue for regenerative medicine products as soon as this conditional approval is granted, which could be achieved after a small patient number phase 1 safety trial. Law 85/2013 is part of the Safety of Regenerative Medicine Act, and is for clinical and physician-led research. This Act focuses on the cells and allows them to be processed outside hospitals at accredited cell-processing centers to enable manufacturing processes that are more robust with the intention of promoting a safer product through a tier-based risk-dependent analysis.

SUMMARY AND CONCLUSIONS

This chapter on regenerative medicine manufacturing presented a comprehensive overview of current challenges and opportunities that currently exist in this space. We have also provided a perspective on envisioned regenerative medicine manufacturing systems of the future with focus on specific attributes that we believe will be critical for widespread adoption of regenerative medicine-based technologies and products. Moreover, we briefly described the global landscape for regenerative medicine manufacturing and highlighted some of the technical societies and efforts currently under way.

PRINCIPLES OF REGENERATIVE MEDICINE
THIRD EDITION

Edited by Anthony Atala, Robert Lanza, Antonios G. Mikos, and Robert M. Nerem

Research and clinical applications in the expansive field of regenerative medicine incorporate therapies associated with any disease that results from malfunctioning, damaged, or failing tissues. From cell treatments to engineering damaged blood vessels, corneas, and organs for transplantation into human patients, regenerative medicine is changing the face of health care and expanding the possibilities for the translation of therapies. Now in its third edition, *Principles of Regenerative Medicine* remains the most comprehensive book in the field. This new edition in the expansive field of regenerative medicine has been fully updated and details the technologies and advances applied in recent years to strategies for healing and generating tissues. Contributions from a stellar cast of researchers, clinicians, and industry and government representatives cover the biological, molecular, cellular, and biomaterial bases of regenerative medicine, highlighting stem cells and wound healing, cell and tissue development, and a variety of enabling technologies such as three-dimensional printing. Advances in cell and tissue therapies, including the restoration of tissues and organs damaged by disease such as diabetes, heart disease, liver disease, and renal failure, are incorporated to provide a view to the future and a framework for additional studies. Topics such as regulatory and commercial parameters, including biomanufacturing, are also covered, providing an in-depth look at the field of regenerative medicine from the basic sciences to clinical translation and commercialization. This textbook would be beneficial to students, researchers, clinicians, industry and government representatives, and members of the public at large who are interested in the topic.

- Comprehensively covers the interdisciplinary field of regenerative medicine with contributions from leaders in stem cell biology, tissue engineering, cell and developmental biology, biomaterials sciences, nanotechnology, physics, chemistry, gene editing, bioengineering, and surgery
- Includes a large number of new chapters devoted to the most recent advances in the field of regenerative medicine by the scientists who made the breakthroughs
- Edited by a world-renowned team to present a complete story of the development, progress, and promise of regenerative medicine
