Consider an infinitesimal cube in the body, as shown in Fig. 26.3B. Because of the external force applied on the body, internal forces are applied on the surface of the cube. Each internal force can be resolved into its three components and normalized by the area to give three stress components on each face. The volume of the cube can be continuously decreased such that the cube collapses to a point. The nine stress components define the second-order stress tensor and completely describe the stress state at this point. Using equilibrium conditions, we can show that the stress tensor is symmetric: that is, $\sigma_{ij} = \sigma_{ji}$; thus, the stress tensor has only six independent components. If a stress component acts in a direction perpendicular to the surface on which it acts, it is referred to as a normal stress. On the other hand, if it is parallel to the surface, it is called a shear stress. Thus, σ_{11}, σ_{22}, and σ_{33} are normal stresses, whereas $\sigma_{12,}$ σ_{23}, and σ_{31} are shear stresses. Normal stresses can change both the volume and shape of the body, whereas shear stresses induce only shape change.

The first Piola–Kirchoff stress tensor, $\mathbf{P}$, is defined as the force acting in the current configuration, $\Delta\mathbf{F}$, on an oriented area in the reference configuration, ΔA, in the limit as ΔA tends to zero. In a typical experiment, the force is constantly measured but the cross-sectional area is not. Thus, the first Piola–Kirchoff stress is an easy quantity to compute because the undeformed cross-sectional area can be measured before loading. However, when considering the balance of forces in the deformed body at equilibrium, the deformed area Δa of the surface element is required for the stress definition. The Cauchy stress, or "true" stress, is thus defined as the limit of $\sigma = \frac{\Delta\mathbf{F}}{\Delta a}$ as Δa tends to zero. Although the difference between Δa and ΔA is negligible for small deformations, the difference becomes significant for large deformations and choice of stress definition is important. A third definition, the second Piola–Kirchoff stress tensor, $\mathbf{S}$, is often used in constitutive modeling and is defined as the limit of $\mathbf{S} = \frac{\Delta\mathbf{F}'}{\Delta A}$ as ΔA tends to infinity, where $\Delta\mathbf{F}'$ is the current force, $\Delta\mathbf{F}$, mapped onto the reference configuration and therefore is defined completely in terms of the reference state. All three stress definitions can be related to one another by the deformation gradient [1].

Constitutive Relations

These definitions enable us to begin establishing a theoretical framework in which to describe the material behavior of the tissue of interest in response to mechanical forces. The material behavior will be expressed as a constitutive equation, a mathematical model that specifies the relationship between stress and strain. At this stage, assumptions must be made regarding the behavior of the material, which will dictate the framework selected. These assumptions will be tested by experimental validation of the model. The goal of constitutive modeling is to describe the important features of a tissue's material behavior in the simplest and most mathematically useful way possible. For example, the simplest constitutive equation is that for linearly elastic, homogeneous, isotropic materials, in which there is a linear, reversible relationship between stress and strain and the material properties do not vary by position or direction. For such materials, we are limited to discussion of small deformations. This gives the familiar equation, $\sigma = \mathbf{E}\,\varepsilon$, in which E is the elastic modulus and σ and ε are the engineering stress and strain, respectively. Many engineering materials (i.e., steel) can be modeled in this way; however, most biological materials are more complex.

Mechanically speaking, bone is one of the simpler tissue types and can be modeled as linear elastic, although it is highly inhomogeneous and anisotropic (the properties vary by both position and direction). This behavior can be described well using the generalized Hooke law, which can be written in indicial notation as:

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl}, \tag{26.14}$$

where C_{ijkl} is a fourth-order tensor describing the material properties and contains 81 constants. However, owing to symmetry arguments and thermodynamic constraints, the number of independent constants is reduced to 21. If the six stress and strain components are written in the form of a column matrix, the material tensor can be represented by a matrix called the stiffness matrix:

$$C = \begin{bmatrix} C_{11} & C_{12} & C_{13} & C_{14} & C_{15} & C_{16} \\ & C_{22} & C_{23} & C_{24} & C_{25} & C_{26} \\ & & C_{33} & C_{34} & C_{35} & C_{36} \\ & & & C_{44} & C_{45} & C_{46} \\ & & & & C_{55} & C_{56} \\ & & & & & C_{66} \end{bmatrix}, \tag{26.15}$$

where the other side of the diagonal is symmetric (i.e., $C_{ij} = C_{ji}$). This stiffness matrix represents a fully anisotropic linear elastic material for which 21 constants must be determined experimentally to characterize the material behavior fully. Fortunately, many tissues have some degree of material symmetry. For example, trabecular bone is frequently described using an orthotropic material model, which consists of three mutually orthogonal planes of symmetry that coincide with the chosen reference coordinate system. This reduces the numbers of independent constants to nine, which are related to the Young's moduli (E_1, E_2, and E_3) and shear moduli (G_1, G_2, and G_3) and the Poisson ratios (ν_{12}, ν_{23}, and ν_{31}) in the three planes. In the case of a fully isotropic material, which has infinite planes of symmetry, these equations reduce to the basic mechanics of materials expression of the Hooke law, with only two independent constants, E and ν.

For most biological materials (e.g., cartilage, tendon, blood vessels) the constitutive models must describe an expanding array of features. Unlike most engineering materials, most tissues are nonlinear, viscoelastic (i.e., time-dependent), inhomogeneous, and anisotropic, and experience large deformations under physiologic loads. It can be difficult to include every one of these features in a 3-D model. Fortunately, reasonable assumptions can be made to simplify the approach and yield useful information about the most important features of the tissue at hand. For example, Y.C. Fung made the observation that in many soft tissues, after several "preconditioning" cycles, the loading and unloading curves reach a steady state and the final curves lose much of their rate dependence [2]. He termed this characteristic behavior "pseudoelasticity." Thus, many tissues such as skin, tendon, and blood vessels can often be modeled as nonlinear, pseudoelastic, homogeneous, and anisotropic, with large deformations. Using these assumptions and applying the second law of thermodynamics (via the Clausius–Duhem entropy inequality), it can be shown that the second Piola–Kirchoff stress, **S**, is directly related to the derivative of the strain potential, or strain energy function, W, with respect to the Green strain, **E**:

$$S = \rho_0 \frac{\partial W}{\partial E}, \tag{26.16}$$

where ρ_0 is the mass density. Now, provided we know a proper strain energy function for a given material, we have a direct relationship between the stress and the strain. Selection of a proper functional form for W is an active area of research and can account for anisotropy, incompressibility, and nonlinearity [2,3]. One commonly used model, proposed by Fung [4,5], assumes that the exponential relationship observed in 1-D can be extended to 3-D:

$$W = \exp[Q(\mathbf{E}) - 1], \tag{26.17}$$

where $Q(\mathbf{E})$ is a polynomial function of the strain components whose functional form allows for different degrees of anisotropy.

Classically, constitutive models were phenomenological in nature and not derived from microstructure; however, many current investigators are developing multiscale models that incorporate microstructural composition, fiber–matrix interactions, and fiber orientation to predict both elastic and plastic behavior [6–8]. Such models feature

increasing complexity, and closed-form solutions are often impossible, although modern computing power allows for the solution of the incremental constitutive relations.

Many biological tissues exhibit other characteristics such as time dependence (viscoelasticity) that are essential to their function in vivo and must be incorporated to describe tissue properties accurately. Articular cartilage, for example, exhibits multiphasic behavior in which the matrix composition and interstitial fluid–matrix interactions are essential to conferring the lubricating and impact-absorbing properties of the tissue. Textbooks by Fung and Cowin provide further reading on constitutive modeling of time-dependent tissues [9,10].

Finally, validity of assumptions and predictive capabilities of constitutive models must be evaluated by experiments. Often, simple experiments (e.g., tension, compression, biaxial stretch) can be used to validate the models before application, but the capability of the models to predict essential behavior under near-physiologic conditions is critical.

Boundary Value Problems

Once the tissue properties and behavior are known, determining the actual stresses and strains experienced by cells within the extracellular matrix (ECM) requires solution of the boundary value problems defined by the physical field equations, the constitutive behavior, and the boundary conditions. Boundary conditions are simply the loads and deformations applied further up in the structural hierarchy that induce local stresses and strains at the level of interest. For classical engineering materials, the boundary value problems and admissible assumptions have been identified, and most current research focuses on their solutions; however, in the field of biomechanics, the formulation of boundary value problems, including constitutive models and boundary conditions, remains an active area of research with great promise for enhancing our understanding of biological materials [2].

UNDERSTAND THE ROLE OF MECHANICAL STIMULI

With the necessary tools established and a theoretical framework chosen, we can begin to understand how mechanical stimuli affect organs, tissues, and cells. Mechanical loads are essential for proper morphogenesis (see Chapter 24) and maintenance of normal tissue structure and function in a wide variety of tissues. In many systems, physical stimuli may also be pathogenic, inducing damage or disease, depending on the type, magnitude, and/or frequency of the stimulus. Understanding these factors is therefore important to regenerating mechanosensitive tissues.

In many tissues, subcellular components to whole tissues are coupled to adapt the structure and properties actively according to the mechanical environment. The role of mechanical stimulation has been studied and described at many hierarchical levels, linking gross tissue remodeling to mechanotransduction, the cellular and subcellular responses that convert mechanical stimuli into chemical signals.

Tissue Remodeling

We will first consider bone adaptation as an example of tissue-level remodeling to physical stresses. The mechanisms behind bone tissue remodeling were first described by Frost, who suggested that modeling and remodeling are mediated by basic multicellular units (BMU) made up of osteoblasts, osteoclasts, and osteocytes [11–14]. Osteoblasts lay down bone matrix and osteoclasts degrade it within a highly regulated and intertwining milieu of chemical signals. Osteocytes, residing within bone matrix and communicating with other cells through the lacuno-canalicular network, are thought to be the primary mechanosensors that transduce mechanical signals into chemical signals. These adaptations are stimulated by changes in the mechanical loading history.

Turner and others have studied numerous mechanical variables affecting bone adaptation [15–19] and have proposed three rules for load-induced adaptation [20]. First, bone adapts to dynamic but not static strains. Experimental observations revealed that the strain stimulus, or the strain needed to induce adaptation, was proportional to both strain magnitude and frequency:

$$E = k_1 \varepsilon f, \tag{26.18}$$

where E is the strain stimulus, k is a proportionality constant, ε is the peak-to-peak strain magnitude, and f is the loading frequency [19]. Second is the principle of diminishing returns: that is, as loading duration is increased, the bone formation response tends to level off. This effect was mathematically described by Carter and colleagues as:

$$S = k_2 \left[\sum_{j=1}^{n} N_j \sigma_j^m \right]^{\frac{1}{m}}, \tag{26.19}$$

where k_2 is a constant, N is number of loading cycles per day, σ is the effective stress, and m is a constant weighting factor, which has been estimated at 3.5–4, based on published data [20,21]. Finally, bone adaptation is error-driven such that bone cells accommodate to "normal" strain waveforms but adapt to abnormal strain changes [22]. This has been described mathematically as:

$$\frac{\partial M}{\partial t} = B\{\varphi - F\}, \tag{26.20}$$

where M is bone mass, t is time, φ is the local stress–strain state, and B and F are constants that describe the "normal" load state [23]. Thus, $\varphi - F$ represents the error function driving force for bone mass adaptation.

These rules apply to both mechanical stimulation of new bone formation and disuse-induced bone resorption. Astronauts, for example, experience significant reductions in bone mass: When the local stress–strain state, φ, becomes less than the normal earthbound state, F, because of reduced gravitational loads, the negative error function drives bone resorption. This tightly regulated system can also become pathogenic in osteoporosis, in which the communication between constituents of the BMU is disrupted and more bone is resorbed than can be replaced, leading to a decrease in bone mass and skeletal fragility.

In blood vessels, hemodynamic forces have multiple important roles in regulating vascular cells [24]. Pulsatile intramural pressures produce cyclic strain within vessel wall, and blood flows exert shear stresses on the lumen walls. These two types of physical stimuli influence the phenotype and activity of smooth muscle cells and endothelial cells within the vasculature. Tremendous research has been directed toward studying hemodynamic effects given the potential implications for preventing or treating atherosclerosis, as well as for vascular tissue engineering. Arteries are capable of remodeling their structure in response to changes in their mechanical environment. A chronic increase in systemic blood pressure induces an increase in vessel wall thickness and area, whereas reduced pressure leads to a decrease in vessel dimensions [25].

In cartilage, normal joint loading produces compressive, tensile, and shear forces that deform the cells (chondrocytes) and induce interstitial fluid flows and streaming potentials throughout the matrix [26]. These mechanical, chemical, and electric signals prominently influence the metabolism of the chondrocytes. Because articular cartilage in adults is devoid of a blood supply, mechanical deformations are critically important to facilitate the flow of nutrients and waste products into and out of the tissue. Mechanical deformations also serve to maintain the tissue's proper matrix composition, organization, and mechanical properties. It is generally accepted that static or constant compression and pressure result in loss and/or reduction of synthesis of proteoglycans and DNA in nearly a dose-dependent manner [27]. Dynamic compression has been shown to modulate proteoglycan synthesis positively, and this stimulation is heavily influenced by both the frequency and amplitude of the compressive waveform [27]. Similarly, dynamic tissue shear also has a pronounced effect on matrix components in a frequency- and amplitude-dependent manner [28].

Abnormal joint loads have been shown to induce changes in the composition, structure, and mechanical properties of articular cartilage. For example, disuse studies that employ casting or other means of immobilization have demonstrated a loss of matrix constituents such as proteoglycans and a reduction in tissue thickness and mechanical properties [29]. Conversely, moderate exercise may have beneficial effects on maintaining healthy articular cartilage [30]. Dynamic compression modulates biomarkers implicated in important disease states (e.g., osteoarthritis) such as cartilage oligomeric matrix protein [31], but high-impact loading or altered joint loading resulting from instability or injury is recognized as a significant risk factor for the development and progression of osteoarthritis [30,32]. These studies suggest that there is a range of local stresses and strains that promote healthy tissue homeostasis, but loading conditions that are abnormally high or low can trigger catabolic responses and a loss of tissue function.

Mechanotransduction

How are local mechanical signals transduced into cellular responses that affect tissue growth, repair, and remodeling? The process of mechanotransduction can be divided into four stages [33], as shown in Fig. 26.5: (1) force

transmission, (2) mechanotransduction, (3) signal propagation, and (4) cellular response. The first stage refers to the transmission of the force from the point at which it is applied to the cell surface. The second corresponds to the sensory action of the cells in sensing mechanical stimuli and transducing it into a biochemical signal, which is propagated inside the cell in the third stage. Finally, the cell responds to the intracellular signal by modulating gene expression, completing the mechanotransduction process.

In the first stage of mechanotransduction, applied forces are converted into local stimuli that may be detected by cells. Transmitted forces can cause direct cellular deformation by deforming the surrounding ECM. Applied forces may also result in local fluid flow and/or hydrostatic pressures. For example, compression of articular cartilage generates hydrostatic pressure that can regulate chondrocyte metabolism. Dynamic compression of cartilage induces fluid flow through the matrix and exposes cells to local shear stresses. The relative importance of these different types of local stimuli in vivo is not clear because of the difficulty of isolating each kind of mechanical stimulus. However, extensive research has been done to study the effects of various forms of mechanical stimuli on cells in vitro. These include tensile stretch, compression, hydrostatic pressure, and fluid flow—induced shear stress applied either statically or dynamically. These studies have allowed investigators to identify potential mechanotransduction mechanisms.

The next stage of mechanotransduction occurs at the plasma membrane of the cell, and it is here that the cell detects the external signal and converts it into an intracellular signal. The plasma membrane contains numerous receptors and ion channels that can serve as sensors of the mechanical stimuli. The key structures in this interaction are the mechanosensitive (also known as stretch-activated) ion channels, integrin receptors, and other plasma membrane receptors.

Mechanosensitive ion channels [34—36] are thought to be important to many cell types including chondrocytes [37,38], osteoblasts [39], endothelial cells [40], and cardiac myocytes [41]. Experiments involving direct perturbation of the chondrocyte membrane have implicated such ion channels in the increase in concentration of cytosolic calcium ion [42], which is a second messenger and has well-known intracellular effects [43—45].

Integrins are heterodimeric transmembrane proteins that bind to ECM proteins and cluster together leading to the assembly of focal adhesions, at which the cell contacts the ECM. Focal adhesions associate intracellularly with α-actinin [46], talin [47], tensin [48], and other cytoskeletal binding proteins as well as signaling molecules such as focal adhesion kinase [49]. Because of their associations with both structural and signaling proteins, integrins are well-placed to act as transducers of physical stimuli and have been implicated as a link between the extracellular and intracellular environments for a variety of cell types that allow transmission of inside-out and outside-in signals capable of modulating cell behavior [50—54]. Wright et al. reported that the transduction pathways involved in the hyperpolarization response of human articular chondrocytes in vitro after cyclical pressure-induced strain involve α5β1 integrin, which they suggest is an important chondrocyte mechanoreceptor [54]. Externally applied forces would cause changes in the conformations of the ECM molecules that would affect their binding to integrins and modify the force balance within focal adhesions. It is thought that increased tension within focal adhesions can trigger increased integrin clustering and focal adhesion kinase phosphorylation [55,56], which initiates a signal cascade resulting in altered gene expression.

In addition to integrins, the plasma membrane is host to other receptors for specific ECM proteins such as collagen, aggrecan, and hyaluronic acid, which may also be able to sense extracellular forces because of their interactions with their ligands. G protein—coupled receptors (GPCR) may also act as mechanotransducers or be activated as a result of other pathways, because the consequences of G protein stimulation of the phospholipase C—inositol triphosphate (IP_3) pathway have been observed in mechanically stimulated cells [40,57].

Primary cilia, microtubule-based, flagella-like extensions of the membrane, have been identified as potent mechanosensors [58]. First identified in the late 1800s and thought to be a functionless vestige, the primary cilium has been implicated as a mechanism for mechanosensation in numerous cell types including kidney [59], bone [60,61], and cartilage [62]. Jacobs and colleagues identified primary cilia in both osteocytes and osteoblasts and proposed that primary cilia sense lacuno-canalicular fluid flow caused by bone loading [61]. They demonstrated that primary cilia are required for osteocyte and osteoblast response to fluid shear stress, inducing the expression of genes (osteopontin, cyclooxygenase-2, and osteoprotegerin/receptor activator of nuclear factor κB ligand) and production of second messengers (prostaglandin E_2 [PGE_2]) associated with bone remodeling. Primary cilia have also been shown to cause intracellular Ca^{2+} release by GPCR proteolysis of polycystic kidney disease 1 to activate Runt-related transcription factor 2 (Runx2) and IP_3 production [63]. Further research is required to fully understand the mechanisms through which primary cilia respond to mechanical stimuli.

The third stage of mechanotransduction is signal propagation, in which extracellular physical stimuli propagate into the cell through cytoskeletal remodeling, calcium flux, and kinase cascade activation leading to midterm and

long-term changes in transcriptional activity [64]. A complex and incompletely understood transcription factor-mediated integration system is responsible for much cellular adaptation to physical environmental cues, regulating tissue morphogenesis. Coordinated activation and/or expression of multiple transcription factors combinatorially regulate downstream expression patterns, forming a signal integration system that interprets the cells' physical, chemical, and microenvironmental context and returns the necessary response [64].

Advances in transcriptomics have led to the identification of novel transcriptional activators whose transcriptional targets overlap with known mechanotransducers. These include nuclear factor-κB (NF-κB), serum response factor, as well as Yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding domain (TAZ) [65]. YAP and TAZ have received extensive attention because they appear to be nearly ubiquitous effectors of mechanosensation. These proteins are paralogous transcriptional coactivators that translocate to the nucleus to activate a number of transcription factors, most notably the TEA domain family (TEAD1−4) [66,67]. YAP and TAZ are localized to the nucleus on rigid substrates in response to dynamic loading, and require Rho GTPases (RHOA, CDC42, and RAC1) in addition to a number of actin processing factors [68−70]. YAP and TAZ nuclear localization is inhibited by cell−cell contact-mediated activation of hippo core kinases mammalian STE20-like protein kinase and large tumor suppressor kinase 1; subsequent serine (S127YAP/S89TAZ) phosphorylation, nuclear restriction, and degradation of YAP and TAZ [65].

Differentiation typically requires exit from a proliferative progenitor state to a functional, nonproliferative state, and can be directly controlled by both dynamic and passive mechanical cues [71]. For example, differentiation of pluripotent stem cells to motor neurons requires loss of homeobox transcription factor nanog, SRY-box 2 (SOX2), and octamer binding transcription factor 4 and induction of SOX1 and Paired box 6 and is accelerated by highly compliant substrates that promote phosphorylation and deactivation of YAP/TAZ- and mothers against decapentaplegic (Mad) and the *Caenorhabditis elegans* protein Sma (SMAD)-mediated transcription [72]. Dynamic strain also has a key role in morphogenesis; in the case of cartilage, compressive loads promote chondrocyte differentiation and matrix production in developing limb buds through cyclic adenosine monophosphate (cAMP) activation of cAMP-dependent protein kinase A and subsequent phosphorylation and association of cAMP response element binding protein and SOX9 [73]. However, context is important because, for example, cyclic stretch has been shown to have both pro- and antimyogenic capacity in C2C12 myoblasts through activation of NF-κB−mediated gene expression [74]. Finally, flow and shear force have a role in diverse cellular function. This is most evident in the cardiovascular system. Regions in the vascular tree are less susceptible to atherosclerotic lesions and inflammation as a result of atheroprotective shear flow [75]. Shear forces activate extracellular signal-regulated kinases and promote myocyte enhancer factor 2 and NF-κB nuclear localization and Krüppel-like factor 2 expression, which promote atheroprotective antiinflammatory gene expression, most notably nitric oxide synthase (NOS) [75,76]. Shear flow−generated NOS produces nitric oxide (NO), a potent vasodilator required for initial hematopoietic stem cell emergence during embryogenesis, which means that cardiovascular flow is required for hematopoiesis [77].

Similarly, the β-catenin pathway has sparked great interest as a mechanotransduction mechanism. Like YAP and TAZ, intracellular β-catenin is normally controlled by subcellular localization and proteasomal degradation in the cytosol [78]. Under mechanical stimulation, cells produce small molecules known as Wnts that bind to the membrane receptor complex of LRP5/6 and Frizzled to phosphorylate the kinase glycogen synthase kinase-3β, resulting in deactivation of the destruction complex [79,80]. This allows stabilization of intracellular β-catenin, which translocates to the nucleus to initiate gene expression, and in osteoblasts for example, it induces bone formation [81,82]. Interestingly, mechanical stimulation of osteocytes has also been demonstrated to activate the β-catenin pathway independently of Wnt signaling through NO and phosphatidyl inositol-3 kinase [83]. This pathway has the potential to provide novel targets for intervention in bone-remodeling pathologies and to manipulate the response of cells to mechanical stimuli.

Mechanotransduction is an essential component of a number of pathologic and regenerative processes: fibrosis, differentiation, and wound repair. Injury-induced transforming growth factor-β (TGF-β)-mediated SMAD signaling promotes an inflammatory response that coordinates with YAP and TAZ signaling to promote proliferation and tissue remodeling [84,85]. However, during fibrosis and cancer-associated fibroblast activation, pathologic ECM stiffening increases YAP and TAZ signaling that can overcome contact inhibition and result in an excessive wound healing response [86,87]. Likewise, bone marrow stromal cell tripotentiality is coordinated by wingless-type MMTV integration site modulation of β-catenin that is inhibited by YAP and TAZ through direct or indirect action on the β-catenin destruction complex [69,88]. Osteogenesis in particular requires rigidity-mediated nuclear localization of TAZ to enhance Runx2 activity, and YAP and TAZ together may have a long-term role in bone marrow stem cell lineage restriction [89−91].

The final stage of mechanotransduction is the altered response of the cell, which may include changes in matrix synthesis and degradation, proliferation, differentiation, apoptosis, cell alignment, and migration. The effectors of the mechanotransduction pathways are the various transcription factors, which are activated by the events discussed previously. The activated transcription factors interact with the promoter and enhancer regions of various genes to mediate transcription. This results in an increase in the expression of genes, such as in vascular cells, Cox-2, vascular endothelial growth factor, TGF-β3, and endothelial NOS (eNOS) [92], which orchestrate the cellular responses. Lee et al. demonstrated that vascular smooth muscle cells respond to mechanical strain by increasing specific proteoglycan synthesis and aggregation [93]. It is known that mechanical loading of osteocytes results in anabolic responses such as the expression of c-fos, insulin-like growth factor-I, and osteocalcin [94]. Elevations in Ca^{2+} activate a Ca^{2+}/calmodulin-dependent protein kinase that causes increased c-fos expression, which is a pro-growth transcription factor. Calcineurin, a Ca^{2+}/calmodulin-activated phosphatase, dephosphorylates and activates the nuclear factor of activated T cells (NF-AT) family of transcription factors. Different NF-ATs expressed in different cells, including those of the heart, cartilage, and bone, serve as tissue-specific activators of cell growth and differentiation [95,96].

MECHANICAL REGULATION OF VASCULARIZED TISSUE REGENERATION

Replacing tissues that serve a significant biomechanical function has proven exceptionally challenging [97]. For mechanosensitive cells and tissues, it may be possible to manipulate the mechanical environment, either in vivo or in a bioreactor, to enhance the integration, degradation, or activity of a tissue-engineered construct.

Mechanical Stimulation In Vivo

During development, bone formation is controlled by the spatiotemporal distribution of morphogens such as TGF-β1 and bone morphogenetic protein-2 (BMP-2). Therefore, presentation of these and other growth factors has been pursued to stimulate regeneration in challenging clinical cases such as large bone defects [98]. For further detail on this topic, please refer to Chapter 24. Notably, however, bone development is also acutely responsive to mechanical stimuli induced by fetal movement. This in utero motion functions to direct joint morphogenesis [99] and promote endochondral ossification [100]. Similarly, in natural fracture healing, the local mechanical environment determines both the course and success of healing [101]. Although it was once held that complete immobilization was needed for successful fracture healing and that the resorptive effect of disuse was necessary to release calcium for callus mineralization [102], it is now known that limited physical activity can promote tissue repair and the restoration of function [103].

Despite strong evidence that the local mechanical environment acutely influences bone healing, studies evaluating the effects of in vivo stresses on engineered tissue regeneration have emerged. Case et al. investigated the effects of controlled intermittent compressive deformation on cellular constructs using a hydraulic bone chamber device implanted into the distal femoral metaphyses of rabbits [104]. Constructs receiving 4 weeks of daily mechanical loading at 0.5 Hz were found to have ninefold more new bone formation compared with contralateral control constructs that did not receive loading. Using preclinical models of large bone defect regeneration, several groups have begun to evaluate the influence of in vivo mechanical loading on tissue-engineered bone repair [105–110]. For example, Boerckel et al. developed a rat segmental bone defect model that enables the control of ambulatory load transfer through modulation of axial fixation plate stiffness [106] (Fig. 26.4A). These studies demonstrated that bone regeneration depends on both the magnitude and timing of in vivo loading, with early loading inhibiting vascular ingrowth leading to pseudarthrosis but delayed loading enhancing bone regeneration and remodeling leading to restored functional bone properties [105–107] (Fig. 26.4B,C). Notably, this delayed loading protocol failed to induce regeneration in the presence of structural scaffolds that mimicked the properties of native bone [110], which suggests that stiff scaffolds can impede the beneficial effect of mechanical loading by stress shielding or inhibition of tissue ingrowth. Collectively, these observations suggest that the mechanical environment should be considered together with the physical and biochemical properties of engineered extracellular matrices for tissue regeneration.

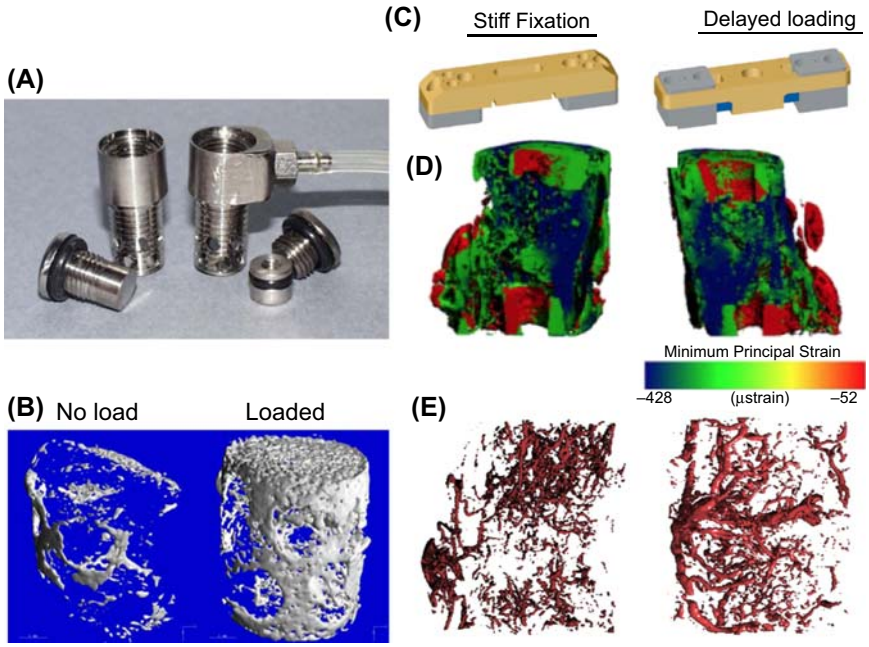

FIGURE 26.4 (A) Hydraulic bone chamber implant used to apply cyclic compressive loading to tissue engineered constructs in vivo. Implanted constructs (B) receiving the mechanical stimulus (right) had 9-fold more new bone formation than no load controls (left). (C) Stiff (top) and axially compliant (below) fixation plates. (D) Compliant fixation (right) enhanced bone formation and altered local strain disributions over stiff fixation (left). (E) Delayed loading increased vascularization compared to stiff fixation.

Mechanical Stimulation In Vitro

Many tissues bear tremendous stress and strain over repeated loading cycles in vivo while maintaining normal function. To date, no engineered construct has been developed in vitro possessing the same biomechanical properties as its in situ counterpart. One approach to addressing this challenge is to use physiologically inspired mechanical forces to transmit stimuli to developing constructs in vitro. Because these tissues normally experience a dynamic environment in vivo, the rationale is that the application of mechanical forces such as compression or shear stress will stimulate the cells of the engineered construct to secrete and organize the proper matrix proteins required to reproduce the mechanical function of the native tissue.

Perhaps the tissues of the body most subjected to mechanical forces are those of the musculoskeletal and cardiovascular origin. Consequently, orthopedic and cardiovascular tissue-engineered constructs represent the bulk of the research in which mechanical forces have been applied to developing tissues in vitro. Cartilage, bone, tendon, ligament, blood vessels, heart valves, and muscle have been cultured in vitro under the influence of mechanical forces. The remainder of this section will discuss select examples from the orthopedic and cardiovascular fields that use the in vivo environment as an inspiration to mechanically condition tissue-engineered constructs in vitro.

Cartilage Bioreactors

Cartilage bioreactors commonly apply compression and/or shear forces to modulate the construct matrix composition and mechanical properties. Although many different tissue-engineering models exist for cartilage (e.g., alginate, agarose, pellet/micromass, and scaffold and scaffold-free culture), the mechanical properties necessary to withstand the complex and demanding in vivo mechanical environment have yet to be recapitulated. For clinical success, it has been suggested that tissue-engineered constructs may need to approximate the matrix composition, organization, and biomechanical properties of native tissue to promote construct integration and load-bearing capability in vivo [111]. Bioreactor systems have produced encouraging results indicating that in vitro mechanical conditioning of tissue-engineered constructs is a promising approach to reproducing native tissue properties.

As one example, a novel dual-chambered, parallel-plate flow bioreactor system has been used to apply controlled shear stresses to the surface of cartilaginous constructs grown de novo from primary bovine articular chondrocytes without the aid of a scaffold (Fig. 26.6). The "parallel-plate" design refers to the top bioreactor surface and tissue-engineered construct face that form two parallel walls separated by a defined distance that creates a flow channel. Fluid flows through the channel, resulting in a parabolic velocity profile. Consequently, a shear stress is applied that is maximal at the upper wall and tissue surface; this is commonly referred to as Poiseuille flow [112]. One can estimate the wall shear stress (τ_w) by the following equation:

$$\tau_w = \frac{6\mu Q}{bh^2}. \tag{26.21}$$

where μ is the media viscosity, Q is the volumetric flow rate, b is the flow chamber width, and h is the fluid gap height.

Chondrocytes are seeded onto a semipermeable membrane; following a static preculture period, fluid-induced shear stress is applied to the construct. The application of flow significantly increases type II collagen compared with static (no flow) controls, as well as both Young's modulus and ultimate strength [113]. This study suggests that flow-induced shear stresses may be an effective functional tissue-engineering strategy for modulating matrix composition and mechanical properties in vitro.

Bone Bioreactors

Without a vascular blood supply in vitro, nutrient delivery to cells throughout 3-D tissue-engineered constructs grown in static culture must occur by simple diffusion alone. As a result, attempts to engineer bone greater than 1 mm thick usually result in a thin shell of viable tissue and cells localized at the periphery [114]. It has been theorized that this effect results from suboptimal mass transport conditions and a lack of mechanical stimulation in static culture. Therefore, tissue culture systems that provide dynamic media flow around or within tissue-engineered constructs have been designed to enhance nutrient and waste exchange in vitro [115]. In addition to enhancing mass transport, fluid flow applies shear stresses to the cells within the scaffolds. The effects of flow-mediated shear on cells have been studied in 2-D monolayer cultures. Continuous fluid flow applied to osteoblasts in vitro has been shown to alter bone-related gene expression and the cellular phenotype [116]. Parallel-plate flow experiments have shown that bone cells cultured in monolayer are highly responsive to flow-mediated shear stresses. Shear stresses in the range of 5–15 dyn/cm^2 affect osteoblast proliferation as well as the production of NO and PGE_2,

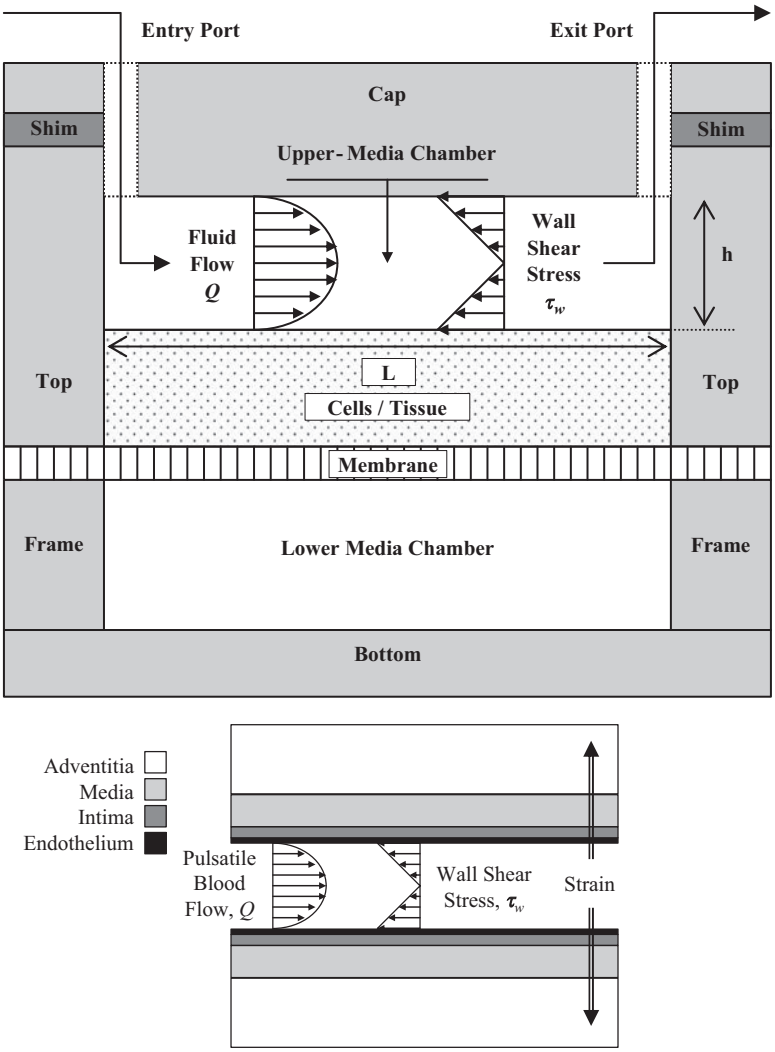

FIGURE 26.6 Dual-chambered parallel-plate bioreactor system that applies controlled shear stresses to the surface of cartilaginous construct slabs.

which suggests that shear stress is an important regulator of osteoblast function [117]. Pulsatile and oscillatory flow conditions applied to osteoblasts using in vitro parallel-plate flow chambers have also been shown to increase gene expression, intracellular calcium concentration, and the production of NO and PGE_2 compared with static controls [118,119]. Furthermore, cell responsiveness has been reported to vary with the fluid flow rate and frequency [120,121]. Proposed mechanisms for the stimulation of cells by fluid flow include increased mass transport, the generation of streaming potentials, and the application of shear stresses to the cell membranes [119,122]. Although these studies were performed using 2-D cell culture systems for short-term experiments, they suggest that variable flow conditions may also have differential effects in 3-D tissue culture systems.

Such tissue culture systems may be useful to engineer thicker, more uniform bone graft substitutes for implantation or as test bed models that simulate aspects of the in vivo environment. Whereas many different bioreactor systems have been developed, perfusion bioreactors in particular have shown significant increases in both cell viability and mineralized matrix formation on large 3-D constructs in vitro. In a study, micro—computed tomography has been used to quantify mineralized matrix production within perfused and statically cultured marrow progenitor cells seeded on large polymer scaffolds (6.35 mm in diameter and 9 mm thick) [123]. Statically cultured constructs were found to have mineralized matrix localized only to the periphery of the constructs. In contrast, perfused constructs were found to have a several-fold increase in mineralized matrix production distributed throughout the constructs (Fig. 26.7).

Blood Vessel Bioreactors

Following the same rationale for mechanical conditioning of orthopedic-engineered tissues, cardiovascular tissues can also be enhanced by in vitro mechanical stimulation. Cardiovascular tissues reside in a dynamic environment that can be mimicked in vitro using bioreactors and mechanical loading systems to deliver the physiologically inspired environmental cues.

In vivo, the pulsatile flow of blood imparts cyclic strains and shear stresses to the vessel's constituents, which respond in a variety of ways to these mechanical signals. Endothelial cells are uniquely situated in the lumen and are directly in contact with the flowing blood, which causes a shear stress to be applied to the cells. Consequently, these rapidly responding, mechanosensitive cells attain an elongated shape, aligning their long axis with the direction of flow. Sensing of the shear via cell-surface receptors, ion channels, or integrins leads to the secretion and/or activation of a number of signaling molecules such as NO, eNOS, kinases, and transcription factors [124–126]. Perhaps most important, the fluid-induced shear stress confers a protective effect on the vessel by decreasing the probability of atherosclerosis [127]. Indeed, areas of irregular blood flow (i.e., velocity, direction, and shear stress) have been implicated as sites of increased atherosclerosis [128]. Shear stress also modulates smooth muscle cell production of signaling molecules (such as NO) [129] and gene transcription levels of cell-surface receptors [130].

Tissue-engineered blood vessels (TEBVs) aim to reproduce cellular and mechanical properties of the native vessel as an effective replacement. However, similar to other engineered tissues, those cultured under static conditions fall short of native tissue properties. The concept of mechanical stimulation of TEBVs to enhance matrix organization and mechanical properties began in the mid-1990s, and it has since been an active topic of research. Historically, three types of TEBVs have received the greatest attention for application of in vitro cyclic strains. First, collagen gel-derived TEBVs were exposed to cyclic circumferential strains by Nerem and Tranquillo and colleagues. Cummings et al. demonstrated an increase in mechanical properties and altered cellular function in response to cyclic mechanical strain of smooth muscle cell–seeded collagen I matrices. Likewise, Seliktar et al. showed that 10% cyclic strain of cell-seeded collagen gels induced matrix metalloproteinase 2 (MMP-2)–mediated remodeling, yielding improved mechanical properties [131]. Gleason and colleagues presented a microstructurally motivated continuum mechanics model that combines numerous factors affecting the success of the TEBV approach, such as cell type,

matrix composition, mechanical stimulus, and their interacting effects on TEBV growth, remodeling, and mechanics [132]. Such studies point to the challenge of optimizing this approach and point to the importance of biomechanics-informed rational experimental design.

Second, the effects of cyclic stretching on biodegradable polymeric scaffolds have been investigated. Gong and Niklason reported that cyclic strain of cell-seeded constructs enhanced mesenchymal stem cell differentiation toward a smooth muscle cell phenotype and induced a more normal tissue composition [133].

Finally, Auger and colleagues presented a method of self-assembly, in which cells are cultured in two dimensions to excrete their own ECM, forming a tissue sheet, which is then rolled into a TEBV. When exposed to uniaxial stretch, the cells realign along the axis of strain and improve the contractile capacity of the resulting TEBVs [134].

Other experiments demonstrated that exposing tissue-engineered vascular grafts to fluid-induced shear stress increased endothelial cell adherence [135] and proliferation [136] and altered tissue morphology and mechanical properties [137]. Cyclic mechanical strains cause an increase in collagen (types I and III) transcription by smooth muscle cells [138], an increase in mechanical properties (strength and stiffness) that is attributed to an increase in remodeling enzymes such as MMP-2 [139] and an increase in matrix and cellular organization [136,140]. Subjecting smooth muscle cell−impregnated constructs to dynamic mechanical stress not only causes ultrastructural and orientation changes in the cell phenotype and matrix, it can also induce cells to shift from a synthetic to a contractile state [141]. Similar constructs (smooth muscle cells seeded into polyglycolic acid meshes) exposed to pulsatile radial stresses of 165 beats per minute (analogous to fetal heart rates) and 5% radial strain produces constructs with burst pressures in excess of 2000 mm Hg increased collagen deposition and desirable histological characteristics [142].

Great strides have been made in the field of tissue-engineered vascular grafts, but a completely successful graft has yet to be identified. However, as the field continues to progress and learn more about the in vivo environment, those cues can be translated to more realistic conditioning techniques for in vitro−grown constructs. This mechanical stimulation is critical to remodeling the graft to possess proper mechanical properties as well as matrix composition and organization. The same can be said for cartilage and bone. Thus, mechanical conditioning in an in vitro setting has proven to be a powerful technique to increase the similarity of tissue-engineered constructs to the native tissues they aim to replace.

EVALUATE FUNCTIONAL RESTORATION

Assessment of functional regeneration is an essential benchmark for establishing a successful tissue-engineering strategy. Often, qualitative, indirect measures of regeneration are presented without evaluating biomechanical integrity. For tissues and structures whose primary function is to bear physical loads, mechanical testing is an essential measure of repair. In cartilage regeneration, for example, many studies present only compositional and morphological assessments of healing without directly measuring mechanical function. Although composition and morphology are important measures, the true indicator of regeneration is whether the regenerated tissue recapitulates normal tissue behavior, including both the monotonic elastic and viscoelastic properties. Although it is often experimentally difficult, the establishment of standards for mechanical evaluation of engineered tissues will be a significant contribution. For tissue-engineering approaches to long bone defect healing, torsion testing is an experimentally facile and analytically simple method of determining the structural properties of the regenerated tissue and allows for direct comparison with age-matched uninjured limbs.

Other functional considerations include the assessment of long-term consequences and temporal remodeling of tissue-engineered constructs. These include the evaluation of scaffold degradation by-products, the extent of remodeling to native architecture, and the restoration of the behavior of the native material.

CONCLUSIONS

This chapter presented four steps to approaching a tissue-engineering problem successfully from the perspective of physical mechanics: (1) describe the native mechanical environment quantitatively, (2) understand the role of mechanical factors in the tissue of interest, (3) manipulate mechanical conditions to enhance function or regeneration, and (4) evaluate the degree of functional biomechanical restoration of the engineered tissue quantitatively. Although all of these considerations are active areas of research, regenerating tissues that serve a significant biomechanical function continue to prove exceptionally challenging [97]. It is clear that tissue regeneration strategies must take

into consideration the complex and demanding in vivo mechanical environment into which tissue-engineered constructs are implanted. Fortunately, a wealth of knowledge is available to tissue engineers regarding how local stresses and strains affect cell function within tissues. Integration of this knowledge into strategies for tissue replacement or regeneration will be important to achieving the goal of long-term functional restoration in patients.

INTRODUCTION

In most cases, tissue engineering in vitro or in vivo requires a scaffold to provide the optimal microenvironment for seeded cells. There is a growing trend toward using synthetic substrates to mimic natural, physiological systems for tissue engineering or regenerative medicine. Cell–substrate interactions are fundamentally important to studies geared toward designing biomimetic substrates that may replace damaged vital organs or tissues or assist in the natural healing processes of the body. This chapter reviews cell interactions with the extracellular matrix (ECM). This information is followed by sections detailing the modification of cell behavior by different aspects of a biomimetic substrate, such as its physical, chemical, and biological properties. The role of surface topography in modulating cell interactions is also discussed. Many studies have underscored the necessity of a three-dimensional (3D) environment to yield physiologically relevant data; thus, a section is dedicated to the effect of dimensionality on cell behavior. The chapter concludes with a discussion on the importance of mechanical stress in tissue development at both the cellular and tissue levels.

CELL–EXTRACELLULAR MATRIX INTERACTIONS

The principal building blocks of organs are cells. These functional units are held together to become structures such as tissues, by a hydrated gel-like material known as the ECM. The ECM provides spatial organization, anchorage, and mechanical strength for different cells within a tissue. In addition, it is also responsible for the control and regulation of cell functions such as adhesion, spreading, proliferation, migration, differentiation, and apoptosis by providing mechanical as well as biochemical stimuli.

The functions of the ECM are carried out by important components such as fibrillar and nonfibrillar glycoproteins, hydrated proteoglycans (insoluble macromolecules), and soluble molecules such as growth factors and cytokines [1]. The most important fibrous proteins that cross-link the matrix are collagen and elastin, which contribute to the tensile and contractile strength of the tissue, respectively. For instance, elastin creates the recoil after transient stretch [2] such as contraction of the heart tissue. Nonfibrous proteins include fibronectin (FN), vitronectin, and laminin, which act as anchors that initiate cell binding via cell surface adhesion receptors such as integrins. These proteins also stimulate cell signaling pathways in a bidirectional manner between the cells and the ECM. Whereas FN is ubiquitous, vitronectin has a greater role in adhesion involving endothelial cells. Laminin is a vital protein secreted by epithelial cells and forms an important constituent of the basal lamina [3].

The integrin family of cell adhesion receptors consists of heterodimeric glycoproteins (composed of α and β subunits) that show specificity for different cell adhesion proteins [4] as well as collagen. For example, $\alpha_1\beta_1$ binds collagen whereas $\alpha_5\beta_1$ and $\alpha_v\beta_3$ have affinity specifically for FN and vitronectin. The complete integrin receptor is composed of an extracellular domain that binds the ECM in a cation-dependent manner and short cytoplasmic tails that lack intrinsic kinase activity [5–10]. These proteins mediate cell adhesion via cell surface receptor–ligand

binding, leading to the clustering of the integrin receptors and formation of transient cell–ECM contacts known as focal contacts. Clustering (or mechanical force and the presence of growth factors) can bring the cytoplasmic segments of the integrins into close proximity, possibly resulting in dimerization or autophosphorylation of tyrosine kinase proteins such as focal adhesion (FA) kinase (FAK).

Focal contacts stabilize into FAs, which are molecularly complex structures containing proteins including α-actinin and talin (which connect integrins to the actin cytoskeleton), paxillin, and signaling molecules such as FAK (bound to integrins directly, but not to the cytoskeleton). Furthermore, FAs contain vital molecules such as vinculin, which link adhesion molecules to actin and other adaptor molecules. All of these molecules transmit signals for various regulatory pathways between the cell and the ECM [11]. These complexes also serve as the termination points of actin filament bundles known as stress fibers. Recruitment of Src homology 2 domain–containing proteins such as Src kinase and p130 by phosphorylated FAK to these complexes may induce their subsequent phosphorylation. In turn, the phosphorylation activates downstream pathways and alters gene expression that is ultimately translated into specific processes such as migration, proliferation, and differentiation. For instance, activation of small guanosine triphosphatase (GTPase) Rac or Erk and c-Jun N-terminal kinase pathways results in cell migration and proliferation, respectively [8].

Glycosaminoglycans such as heparan sulfate, hyaluronic acid, and chondroitin sulfate in the glycosylated proteins are also involved in cell adhesion, cell signaling, and communication. In addition, growth factors and cytokines such as interleukin-2, transforming growth factor β, and platelet-derived growth factor (PDGF), which may be either immobilized or solubilized in the ECM, are responsible for cell proliferation and differentiation. Cell interaction with the ECM has been demonstrated in the adhesion of cells to substrates coated with ECM molecules, a change of cell shape, the migration of cells along a concentration gradient of ECM ligands, and the demonstration of differentiated phenotype (development of neurites) in response to the ECM [12].

CELL–SUBSTRATE INTERACTIONS

Importance of Substrate

Although it may appear that interactions between the ECM and the cells control only cellular functions, in reality ECM–cell communication is bidirectional. The cells can regulate how much ECM is synthesized or the extent to which it is degraded by controlling the amount of ECM degrading the enzymes produced (proteases such as matrix metalloproteases, collagenase, or plasmin). This is an integral part of ECM remodeling. Furthermore, the extent and specific function of the ECM vary from tissue to tissue and are governed by the need and function of the tissue itself (e.g., connective tissue versus epithelial cells). Because the cells are constantly in close contact with the ECM, these two components exert a considerable degree of influence over each other, known as "ECM–cell dynamic reciprocity" [1]. The realm of tissue engineering ranges from basic studies elucidating the mechanisms underlying cell behavior to applications generating tissues and replacing organs. This involves the use of biomaterials that can mimic the natural environment spatially and temporally so as to facilitate cell adhesion, proliferation, or differentiation according to tissue-specific requirements. Within the context of cell–ECM interactions, important design considerations for a potential biomaterial are discussed subsequently. The influence of these design parameters on cell behavior is further illustrated with pertinent examples from the literature.

Effect of Physical Properties

Although metals and ceramics are important biomaterials, polymers are much more commonly used in tissue engineering and regenerative medicine applications because of their versatility. The focus of this chapter is therefore on biomedical polymers. Understanding cell interactions with polymers is important for designing substrata for in vitro cell culture or in vivo implantation. Because cells constantly interact with the extracellular environment, they are sensitive to changes in the surface and bulk properties. In addition, for in vivo application, the mechanical property of the substrate or scaffold may need to match the mechanical requirement of the implantation site so as not to affect the biomechanical stimulus adversely that is provided to the seeded cells in situ. Physiochemical properties such as crystallinity, morphology, and stiffness or compliance of materials affect cell attachment and cellular behavior.

Crystallinity

The crystallinity of a polymer represents a state in which a periodic and repeating atomic arrangement is achieved by molecular chain alignment [13]. Because of their size and complexity, polymer molecules are often only partially crystalline, with crystalline regions dispersed within the amorphous regions. The degree of crystallinity of a polymer depends on the rate of cooling during solidification as well as on chain configuration. Upon cooling through the melting temperature, sufficient time must be allowed for the polymer chains to self-organize and form a crystalline region. Crystallization is favored in polymers with a chemically simple structure. Some common crystalline polymers used in biomedical applications include polyethylene, polypropylene, polytetrafluoroethylene, poly(vinyl chloride), poly(glycolide) (PGA), poly(L-lactide) (PLLA), and poly(caprolactone) (PCL). Crystalline polymers are usually stronger and more resistant to solvent penetration and softening by heat.

Crystallinity affects mechanical properties such as the strength and fatigue resistance of the polymer, but it also has an important role in determining surface physiochemical properties including surface free energy, chemical states, polarity, surface roughness, and wettability, which influence cellular response. When blood compatibility was tested on polypropylene surfaces with different crystalline states, an increase in platelet adhesiveness was observed with decreasing surface crystallinity and interlamellar spacing [14]. A decrease in interlamellar spacing resulted in enhanced albumin adsorption and diminished fibrinogen adsorption. Therefore, controlling the crystalline–amorphous microstructure at the surface layer may improve the blood compatibility of polypropylene surfaces.

When designing scaffolds for implantation, crystallinity can influence the biodegradability and cellular responses of the scaffold. The crystalline region is more resistant to water penetration and hence retards biodegradation. The adhesion, proliferation, and morphology of human articular cartilage chondrocytes were different when cultured on various degradable polymers with various crystallinity, such as PGA, PLLA, poly(D,L-lactide), different ratios of poly(D,L-lactide-*co*-glycolide)s, PCL, poly(glycolide-*co*-trimethylene carbonate) (PCTMC), and poly(dioxanone) films [15]. Significantly higher number of chondrocytes were attached to PGA and 67:33 PCTMC polymer films than on PCL and PLLA films. The total cell numbers and hence fold expansion were significantly higher than the fold expansion on tissue culture polystyrene (TCPS), although the greater fold expansion may be attributed to the lower initial cell attachment. Park and Griffith performed a study of spheroid formation by hepatocytes and proliferation of fibroblasts on PLLA substrates [16]. Their results suggested that cells proliferate more slowly on crystalline versus amorphous PLLA and faster spheroid formation on crystalline substrates. This highlights the interesting dynamics between cell–substrate and cell–cell interactions in dictating cell aggregation. Mikos et al. investigated tissue in growth through porous scaffolds composed of semicrystalline or amorphous PLLA that were implanted in rat mesentery [17]. There was a twofold reduction in percent tissue ingrowth through the crystalline scaffolds after 10 days compared with the amorphous scaffolds.

Variations in crystallinity can also lead to changes in surface roughness on nanometer-length scales [18]. MC3T3-E1 osteoblastic cells showed a higher rate of proliferation on smooth regions with a monotonic variation in rate as a function of roughness.

Morphology

The morphology of the substrate can affect cell attachment by influencing the ability of the substratum to adsorb protein and/or by altering the conformation of the adsorbed protein. ECM proteins are present in serum that is used in most cell cultures. Cell attachment to the substratum is almost always mediated by these ECM proteins adsorbed on the culture surface. Rough and porous surfaces are routinely used in clinical applications such as orthopedic, dental, and cardiovascular prostheses [19–22]. For example, numerous studies suggested that implants with a porous surface can form better tissue–implant seals to enhance tissue integration [21]. Roughness has been shown to alter the adhesiveness of platelets to hydrophobic and hydrophilic surfaces [23]. The details of surface topography and surface chemistry will be discussed in later sections.

Stiffness and Compliance

The stiffness of a material is measured by the modulus of elasticity or Young's modulus; compliance is the inverse of stiffness. Sufficient substrate stiffness is important for anchorage-dependent cells, which often rely on finite resistance to cell-generated forces to induce outside-in mechanical signals. Such signals feed back into cell tension [24], cell adhesion [25], protein expression and cytoskeletal organization [26], and cell viability [27]. Stiffness and compliance encountered during cell–cell adhesion and cell–substrate adhesion are important interactions that modulate intracellular signaling pathways and cellular events from gene expression to cell locomotion.

When Normal Rat Kidney (NRK) epithelial cells and National Institutes of Health (NIH) 3T3 fibroblasts were cultured on collagen I substrates with varying Young's modulus, they exhibited different motility and cytoskeletal organization [28]. Both cells were well-spread on rigid substrates. NRK cells became less well-spread and irregularly shaped whereas NIH 3T3 cells lost most of their stress fibers with an increase in locomotion rate when they were cultured on increasingly compliant substrates.

Cell movement can also be guided by the manipulation of flexible substrates to produce mechanical strains in polarized cells. When NIH 3T3 fibroblasts were cultured on flexible polyacrylamide sheets with type I collagen coating and transition in rigidity [29], cells approaching the transition region from the soft side could easily migrate across the boundary whereas cells migrating from the stiff side turned around or retracted as they reached the boundary. Cell also spread to a greater extent on stiff substrates compared with more compliant counterparts [30].

Contractile myocytes sense the mechanical as well as molecular microenvironment. Myoblast culture has been studied on collagen strips attached to glass or polymer gels of varying elasticity [31]. Myosin/actin striation emerges only on gels with stiffness typical of normal muscle. Adhesion strength increases monotonically with increasing substrate stiffness.

Effect of Chemical Properties

The chemical properties of a polymer have an important role in its surface functionality and consequently its cell behavior. When cells are exposed to a polymeric surface, a layer of protein adsorbs onto the surface within milliseconds. Thus, cells "see" the adsorbed protein layer rather than the actual polymer surface.

The surface chemistry of a polymer may be fine-tuned to control protein adsorption, which in turn controls cell adhesion. Depending on the desired outcome, the surface chemistry of a polymer can be modified to modulate the interactions of the adherent cells, such as morphology, migration, differentiation, proliferation, and apoptosis. In the context of biointeractions, important chemical properties of a polymeric surface may be categorized into its surface wettability and charge.

Surface Wettability

The wettability of a polymer surface is a measure of its hydrophobicity or hydrophilicity, or its surface energy. Water molecules at a polymeric surface rearrange around proteins, causing the native protein to unfold and adsorb irreversibly to the surface. Water molecules are unable to form hydrogen bonds with hydrophobic substrates. Hence, they form hydrogen bonds within themselves, leading to a more ordered structure with lower entropy. Proteins present in the serum can act as surfactants in which their hydrophobic domains interact with the substrate and their hydrophilic domains form hydrogen bonds with the water molecules. This results in release of the ordered water molecules, which is energetically favorable owing to the increase in entropy. This is known as the hydrophobic effect [32]. In general, proteins preferentially adsorb onto a hydrophobic surface, as mediated by their hydrophobic domains. The adsorbed protein monolayer is seen by the cells instead of the underlying surface, modulating adhesion to a great extent. For example, fibrinogen adsorbed onto a polymer surface greatly increases platelet adhesion.

Functionalization of polymer surfaces with poly(ethylene oxide) (PEO) creates a hydrophilic surface that easily becomes hydrated. PEO is the standard for creating a hydrated hydrophilic surface and is commonly employed to reduce uncontrolled protein adsorption or biofouling onto an implant device.

Surface Charge

The surface charge of a polymer affects protein adsorption and unfolding on its surface. Unlike surface wettability, the driving force for protein unfolding onto a charged surface is ionic interactions, not hydrophobic interactions. Protein unfolding depends on the net charge that proteins and cells encounter on the surface. For example, PEO is hydrophilic but has a net neutral charge. In contrast, NH_2 and COOH groups become ionized in solution, resulting in a net positive and negative charge, respectively. Many proteins have a net negative surface charge, which promotes their adsorption onto a positively charged surface. In addition, the glycocalyx on a cell surface (the polysaccharide mucosal layer) has a largely negative charge, adhering to positively charged surfaces via nonspecific interactions.

Cellular Response

The effect of surface chemistry on cellular behavior begins at the point of interaction. The surface chemistry influences the pattern of protein immobilization, absorptive or ionic, on the surface. For example, polymers with higher hydrophobicity are demonstrated to promote greater osteogenesis (bone regeneration) in vivo [33]. This effect has been attributed to a more favorable balance between hydrophobic and hydrophilic properties, which promotes greater protein adsorption onto its surfaces as well as enhanced cell adhesion.

Hydrophilic surfaces appear to inhibit leukocyte adhesion and the attached cells exhibit a decreased cytokine response. This results in an attenuated inflammatory reaction and decreased macrophage fusion [34]. Thus, hydrophilic polymer surfaces may offer an approach to limiting leukocyte adhesion and consequently improving the biocompatibility of an implant.

Surface chemistries also regulate the conformational changes in binding domains of FN, directing integrin binding affinity and the specificity of cell adhesion. In turn, this provides a greater degree of control over cellular behavior. For example, $\alpha_5\beta_1$ integrin was shown to bind with greatest affinity to hydrophilic, noncharged surfaces (OH functionalized end groups), intermediate affinity to hydrophilic, charged surfaces (NH_2 and COOH end groups), and least affinity to hydrophobic surfaces (CH_3 end groups). In contrast, $\alpha_V\beta_3$ integrins bind with highest affinity to COOH surfaces, intermediate affinity to NH_2, and negligible affinity to OH and CH_3 modified surfaces. These differences in binding and adhesion were reflected in the varying degrees of mineral matrix deposition and osteoblast differentiation of MC3T3-E1 cells [35].

Methods of Altering Surface Chemistry

Modifications of the surface chemistry of a biomaterial allow for the selective treatment of the superficial layer without changing its bulk property. This is achieved mainly through coating or by plasma treatment. A note of caution on oxygen plasma treatment of a polymeric substrate is that it might have an unintended effect on the physicochemical properties of the polymer. For instance, polydimethylsiloxane (PDMS) is a popular substrate for many studies of cell–substrate interactions because of the ease of fabrication and the optical transparency of the polymer. The stiffness of the substrate can also be fine-tuned by varying the cross-linking density. However, oxygen plasma treatment of PDMS can affect its surface chemistry and consequently the topography and elasticity at the nanoscale level. At low cross-linking density, it is also important to extract the unreacted cross-linkers before initiating the cellular studies [36].

Coating or deposition of a top layer includes several methods. Solvent coating or casting is a method in which a polymer is dissolved in a solvent (usually an organic solvent), which in turn is then soaked, brushed, or sprayed onto a surface. Polyelectrolyte multilayers [37] are generated by depositing alternating layers of polycationic and polyanionic monolayers onto a surface. Self-assembled monolayers (SAMs) consist of chemisorbed monolayers of closely packed alkanethiols onto surfaces such as gold, silver, or mercury. The head groups with a hydrocarbon tail may be functionalized with different end groups such as hydrophobic CH_3, hydrophilic OH, or charged COO end groups [38]. Polydopamine coating has proved effective in modifying the surface functionality of a biomaterial [39]. This versatile method applies to any base materials as well as to various conjugation chemistries. For example, Yang et al. applied polydopamine coating on 316L stainless-steel stents that demonstrated a differential response of the coating for human umbilical vein endothelial cells (HUVECs) and human umbilical artery smooth muscle cells (HUASMCs). Polydopamine-coated stents increased HUVEC adhesion, proliferation, and migration while suppressing the adhesion and proliferation of HUASMCs, thus leading to faster reendothelialization [40]. In another study, 3D tissue engineering of nanofibrous scaffolds of PCL were modified to coat the fibers with polydopamine [41]. These scaffolds allowed HUVEC cells to attach well and spread with a high cell viability. Chuah et al. conjugated the polydopamine on PDMS surface to fabricate a substrate for long-term culture of mesenchymal stem cell (MSC) adhesion and proliferation [42]. This effect was attributed to the change in the surface wettability of PDMS and the presence of hydroxyl and secondary amines on the surface compared with uncoated surfaces. Polydopamine-coated substrates have also proven to be highly efficient in supporting the reprogramming and self-renewal of human pluripotent stem cells (hPSCs) under defined conditions [43].

Another method of altering polymer chemistry is via plasma treatment of the surfaces of interest. Plasma treatment creates ionized gases such as ions, free radicals, and electrons from electron and ion impact in an electric field. These ionized particles create oxidized and groups on the polymer surface by breaking chemical

bonds. In surface etching, inert gases such as argon are employed to remove impurities and increase surface roughness. In addition, plasma etching allows the alteration of surface reactivity by cross-linking polymer chains.

Effect of Biological Properties

Although the physical and chemical properties of the biomaterial have an integral role in modulating cell behavior, biological features may be equally important if not so, because they represent the natural ECM. Thus, bioactive molecules such as adhesion ligands, growth factors, and enzymes may be physically entrapped, surface-immobilized, or covalently conjugated onto the substrate to resemble the ECM and control cell behavior.

Commonly Used Ligands

Bioactive substrates can be produced by the surface immobilization of a large variety of ECM cell adhesion proteins such as FN, vitronectin, laminin, and collagen. With the advent of molecular biology tools, the amino acid sequences of the specific cell-binding sites of these proteins have been identified, which has led to the development of short peptide ligands for the modulation of critical cellular processes. The Arg-Gly-Asp (RGD) tripeptide is a commonly occurring motif present in several cell adhesion glycoproteins; it mediates binding to specific members of the integrin family (FN and vitronectin bind via RGD to $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrins, respectively) [44]. The YGISR peptide derived from laminin binds to a family of nonintegrin cell adhesion receptors and can induce cell adhesion and motility [45]. Besides the RGD motif, substrates coated with short cell adhesion peptides are increasingly being employed to develop biomimetic substrates. Short peptides offer several advantages over entire ECM proteins. They are chemically defined and can be used in higher densities. They possess diverse functions because they can provide cell adhesion sites and matrix binding sites, promote self-assembly and growth factor binding, or a combination of all of these. Several new peptide ligands have been identified by using peptide libraries and de novo design. Overall, application of peptides instead of entire proteins eliminates immunogenic risks, facilitates conjugation without the loss of bioactivity, and improves cell adhesion and selectivity to the scaffold.

Cell surface proteoglycans have also been known to bind to proteins containing a large number of cationic amino acids. This finding has led to the generation of substrates modified with a positively charged surface.

Development of Bioactive Surfaces

Based on the naturally occurring hydrophobic effect of proteins in solution, several strategies have been developed to immobilize either naturally occurring ECM proteins or ECM-derived peptides (cell adhesion ligands) by adsorbing them directly onto a substrate. Covalent conjugates of nonadhesive bovine serum albumin (BSA) and RGD peptide adsorbed via BSA onto the surface of tissue culture plates have supported cell adhesion [46]. The disadvantage of adsorption-based methods includes easy desorption of the bioactive molecules by other proteins such as antibodies that may be routinely employed in assay procedures. More important, protein adsorption may cause the burial of the active site of the adhesion ligand, rendering it inaccessible for cell binding. Furthermore, protein adsorption may constrain the peptide in a conformation that reduces its binding affinity [47].

Challenges of bioactive surface development have been overcome by new methods of protein/peptide immobilization in which peptides are covalently grafted onto surfaces that typically do not support cell adhesion. These techniques allow the precise control and quantification of ligand density. Furthermore, the inert nature of these substrates ensures that any cell adhesion observed can be attributed solely to the covalently bound peptide. Several methods have emerged for covalent grafting of proteins or peptides onto the surfaces. Carbodiimide chemistry is a widely used method to conjugate molecules covalently containing amine groups (proteins and peptides) with carboxylic acid–containing substrates [48]. However, carbodiimide chemistry is nonspecific and cannot target a particular reactive group on the biomolecule structure and the substrate. Therefore, the binding of peptide or protein chains to the substrate can occur at multiple locations, which can prevent them from assuming the correct configuration and affect the activity of the protein or peptide.

Click chemistry-based covalent grafting is being increasingly used, because the reactions are highly efficient, region-selective, and orthogonal in nature [49]. Photoinitiated reactions can also be used to bind ligands to the substrate. This technique involves functionalizing the ligand of interest with a heterobifunctional cross-linker containing a photoreactive group, which can be subsequently conjugated with the substrate upon exposure to light [50].

Probably the most significant advantage of using phototriggered reactions is the ease with which spatial organization of the ligands can be achieved in 2D and 3D substrates.

Bioactive surfaces with immobilized ligands of varying concentrations modulate cell response differently. For instance, human foreskin fibroblasts seeded on glycophase glass-modified substrates exhibit increasingly spread-out morphologies with higher ligand concentrations. Higher ligand concentrations also generate more focal contacts and stress fibers. These findings thus established that RGD spacing of 440 and 140 nm is sufficient to promote cell spreading and cell adhesion, respectively [51]. Glycophase glass-modified substrates specific for laminin demonstrated both cell attachment and spreading of different cell types via nonintegrin cell adhesion receptors. In contrast, surfaces containing adsorbed laminin supported only cell attachment [47].

Another approach to generating nonadhesive substrates derivatized with cell-specific ligands is to employ the nonadhesive polymer poly(ethylene glycol) (PEG). Graft copolymers of RGD-modified PEG and poly-L-lysine could undergo surface immobilization onto negatively charged surfaces via electrostatic interactions. These surfaces could then support the binding and spreading of human dermal fibroblasts [52].

Alkanethiolates bind to gold and silver monolayer surfaces and form SAMs. Alkanethiolates modified terminally with the biologically inactive oligo(ethylene glycol) (OEG) have been extensively used in studying the modulation of cell behavior by substrates based on mixed SAMs. Mixed SAMs consisting of alkanethiolates modified terminally with either RGD or OEG promoted cell attachment via the cell adhesive RGD or cell repulsion by the OEG regions [53].

Finally, chemisorption is an immobilization strategy inspired by the composition of adhesive proteins in mussels [39]. The coexistence of catechol (L-dopa) and amines (lysine) in mussel pads was crucial for adhesion. Therefore, dopamine, a naturally occurring catecholamine containing both catechol and amine functional groups, was used as a bioadhesive building block for multifunctional surface coatings. To immobilize proteins or peptides, a polymerized dopamine layer is first formed on the substrate, which can then immobilize the molecule of choice.

Cell–Bioactive Surface Interactions

The property of the underlying ECM and its corresponding ligands determine cell behavior and response. Thus, the desired application (to evoke cell adhesion and proliferation versus cell migration and differentiation) may be tailored by choosing and designing the appropriate ligand, which will enable an engineered cell response. This, in turn, can affect the substrate itself, similar to the cell–ECM adaptive behavior inherent in vivo. The effects of some ligands on various aspects of cell behavior are presented next.

Cell Adhesion

Cell adhesion and its natural outcome of cell spreading are the first interactions that occur between the cell and the ECM. Cells adhere to the underlying ECM via cell–substratum bonds, which are typically receptor–ligand complexes formed between adhesion receptors (such as integrins) and their ligands (such as FN). Features of the substratum such as ligand density have been shown to affect cell adhesion and spreading via intracellular mechanisms that have not been completely delineated.

The RGD motif in the ECM proteins is an important ligand for cell adhesion. The ability of the RGD peptide to affect cellular adhesion depends on its activity, which can be modulated by the presentation of cell-binding complementary domains. Because ECM molecules exhibit multiple integrin interaction domains, spacing between these domains affects cell adhesion and migration events. For example, cells cultured on recombinant FN fragment encompassing the seventh through 10th type III repeats that presented the Pro-His-Ser-Arg-Asn (PHSRN) and RGD sequences ($FNIII_{7\text{-}10}$) in the correct structural orientation exhibited significantly higher adhesion strength and FAK activation versus surfaces modified with RGD ligand alone [54]. Interestingly, in the same study, separating the RGD and PHSRN ligands by a polyglycine linker did not improve the cellular adhesion strength compared with the $FNIII_{7\text{-}10}$ fragment, which underscores the importance of properly spacing ligands.

The immobilization strategy can also affect the integrin–ligand interaction. FN immobilization on an ammonia plasma-treated poly(tetrafluoroethylene) (PTFE) surface using glutaric anhydride promoted optimal display of the RGD motif, as opposed to a sulfosuccinimidyl-4-(*p*-maleimidophenyl)butyrate linker [55]. However, RGD peptide may not be the best choice of ligand in every case to promote cellular adhesion. In another study, the RGD, YIGSR, and IKVAV domains of the ECM protein laminin were grafted onto an aminated PCL surface [56]. The results revealed that the IKVAV sequence provided the highest cellular adhesion for human adipose–derived stem cells. Gauvreau and Laroche used their aminated PTFE surface to print different combinations of the cyclic RGD, cyclic Gly-Arg-Gly-Asp-Ser (CGRGDS), and cyclic H-Trp-Gln-Pro-Pro-Arg-Ala-Arg-Ile (CWQPPRARI) peptides,

all derived from FN [57]. They found that a combination of GRGDS and WQPPRARI were most efficient in promoting the attachment, spreading, and proliferation of HUVECs.

The length of the ligand spacer arm can also influence ligand–receptor interaction. In one study, alginate gels were modified with RGD peptides of varying spacer arm lengths. The spreading of the primary fibroblasts was directly proportional to the number of glycine units in the spacer arm of the RGD peptides, up to 12 glycine units. Increasing the spacer length from 12 to 20 glycine units did not increase the cell spreading further [58]. Similarly, the type of the spacer used affects the binding affinity of the integrin receptor to the RGD ligand–polyproline spacer (compared with an aminoethoxyacetic acid or PEG-containing spacer), resulting in ligands with higher integrin-binding affinity and improved cell adhesion properties [59].

A large number of studies have been conducted to delineate the relationships among ligand density, spatial arrangement, and their effect on cellular adhesion. Previously, the effect of ligand density on cell adhesion was studied by varying the concentration of ligand solutions in which ligands were present ubiquitously on the substrates. Hepatocytes cultured on surfaces expressing interstitial ligands (laminin or collagen type I) or basement membrane (FN or collagen type IV) demonstrated an increased rate and degree of spreading at higher ligand densities compared with lower coating densities. This direct dependence on ligand density was attributed to the increased number and density of cell adhesion receptor–ligand bonds, which may generate forces that overcome cellular traction [60]. Alternately, the formation of focal contacts could be enhanced, leading to reorganization of the cytoskeleton. Initial cell adhesion was found to occur with an increase in actin microfilament (MF) mass and a concurrent, rapid cell-spreading phase. This was later followed by a slow rate of ECM-independent spreading. It was hypothesized that the MFs may have formed focal contacts with the ECM, which may provide the force for cell spreading. The fact that only a combination of cytoskeleton-disrupting drugs (targeting actin and microtubules) could inhibit cell spreading implies cytoskeletal redundancy, which means that one structural component can compensate for the other. Furthermore, the intracellular forces generated by focal contact formation may also be transmitted to the ECM [61].

Advanced fabrication techniques have enabled researchers to gain precise control over the arrangement of ligands in microsized and nanosized islands [62]. Contact printing can be used to prepare microsized islands of ligands of approximately equal size as FAs. On the other hand, receptor-sized ligand patterns can also be designed on substrates using techniques such as self-assembled nanoparticles, block copolymer micelle lithography, and electron beam lithography (EBL) [63]. By using such techniques, it has been shown that the formation of strong adhesive protein clusters requires extracellular adhesive ligands to be spaced closer than the critical value of around 60 nm [64].

Immobilized ligand gradients on substrates allow for the testing of a large range of ligand concentrations on a single substrate. A surface-immobilized osteogenic growth peptide (OGP) concentration gradient prepared by click chemistry was used to investigate osteoblast adhesion and proliferation. The highest cell adhesion occurred on areas of low OGP concentration (40–60 pmol/cm^2), whereas cell proliferation was higher on OGP gradients at all concentrations compared with the free ligand control [65].

Cell Motility

The migration of cells is an important aspect of cell behavior, especially during embryogenesis, organ regeneration, and other repair processes such as wound healing and angiogenesis. Main requirements for initiating cell migration are the breaking of existing cell–ECM bonds and the formation of new ones in the desired direction and at the next site of attachment on the substratum.

Studies on factors affecting cell motility such as ligand concentration have shown that the migration speed of human MSCs (hMSCs) on FN or collagen IV-coated surfaces has a biphasic dependence on ligand concentration. The maximal speed is attained at intermediate ligand density. This suggests that very low densities do not provide the traction needed for movement whereas extremely high densities confer strong cell adhesiveness that deters cell detachment from the substrate. Because the shear forces for cell detachment for FN and collagen are similar, it was also concluded that the strength or adhesiveness of the initial cell–substratum bond governed cell migration speeds [66]. Studies have also shown that the high ligand density reduces the cell migration rate on 2D surfaces. In contrast, cell migration on a 1D surface was found to be independent of ligand density [67]. The study concluded that contact guidance provided by the linear topographical cue compensates for the prohibitive effect of high ligand density on cell migration. Studies have shown that contact guidance can improve the cell migration rates. Interestingly, the cell migration in the 3D fibrillar matrix was similar to the 1D matrix and both depended on the myosin II contractility.

The concentration gradient of ligands, particularly growth factors, has been studied to stimulate directed cell migration. Immobilized ligand gradients have been shown to stimulate directed keratinocyte migration [68]. In another study, a low-to-high concentration gradient of solid-phase heparin binding epidermal growth factor stimulated the migration of MSCs away from the cell source, which could potentially help in faster wound healing [69].

The initial bonds formed between the cell and ECM can also be affected by the affinity of the receptor to the ligand as well as the expression levels of the receptor itself. In one study, cell migration speed inversely depended on the expression and affinity of the integrin receptor. Maximal cell speed was achieved with intermediate ligand densities, integrin levels, and affinity. All of these parameters represent an optimal initial adhesiveness or an adequate number of cell–substratum bonds to support initial attachment followed by migration. Under conditions in which very few or too many cell–substratum bonds were formed, cells were observed to form short unstable lamellipodia or were too spread out to support movement. Interestingly, the maximal speed attained was found to be independent of ligand concentration, receptor expression levels, or affinity [70]. This suggests the involvement of other factors such as intracellular contractile force or the induction of intracellular signaling.

Because integrins have been shown to cluster and mediate downstream cytoplasmic signaling, the spatial arrangement of the ligand also influences motility. Murine fibroblasts were grown on surfaces that presented the YGRGD ligand either singly or in clusters while maintaining the same average ligand density for the entire surface. Cells showed higher adhesion strength and migration speeds when the ligand was presented in increasing cluster numbers compared with single ligands. Furthermore, the maximum speed attained by the clustered ligands was achieved with lower overall ligand densities compared with the higher ligand densities required when ligands were expressed singly. Finally, the presence of stress fibers and distinct FAs in cells exposed to the clustered ligand confirmed the importance of the orientation of the ligands in cell adhesion and motility [71]. Well-designed surfaces with precise control of ligand presentation and interligand distance allow for a mechanistic understanding of ligand–receptor interaction and its effect on cell migration. With the invention of nanotechnology tools, significant progress has been made in the design and fabrication of surfaces with precise and controlled ligand presentation. In a study, gold RGD-immobilized nanodots were prepared with 58 or 108 nm interligand spacing [72]. Fibroblasts formed stable FAs on the 58-nm spacing surface, which resulted in stationary cells. On the 108-nm spacing surface, however, the cells had higher migration rates, which were associated with the high turnover of FAs. Furthermore, the molecular properties of FAs were dissimilar on differently spaced ligands: e.g., the presence of zyxin, an FA protein, was significantly lower in FAs formed on the 108-nm spacing surface [72]. Another study showed that cells can sense ligand spacing variations as low as 1 nm and use this information to induce cell polarization and cell migration [73].

Integrin-mediated cell migration is the universal mechanism employed by cells with the exception of leukocytes. Leukocyte migration in 3D environments occurs independently of integrin-mediated migration. Instead, these cells migrate by the sole force of actin-network expansion, which promotes protrusive flowing of the leading edge. Integrin-mediated adhesion and migration are necessary only when cells need to overcome tissue barriers such as the endothelial barrier [74].

Cell Proliferation, Self-renewal, and Differentiation

Cell–ECM interactions can also modulate cell function, although the underlying mechanism remains unclear. Identification of critical parameters such as cell–cell contacts, key proteins, and intracellular tension will allow their incorporation into an artificial ECM that can stimulate desired cell function when necessary.

Because stem cell phenotype and fate are influenced by the interaction of cells with the niche, many studies have focused on investigating the effect of ECM ligand type, density, and spatial arrangement, which provide stimuli for directing the differentiation of stem cells into specific lineages. Similarly, self-renewal of stem cells is regulated by several ECM molecules. A study showed that although FN has a vital role in the proliferation and self-renewal of mouse embryonic stem cells (mES), excessive FN levels could result in cell spreading and differentiation [75]. Laminin-511 is another important ECM ligand that supports mES attachment, proliferation, and pluripotency [76]. Interestingly, this study showed that other forms of laminin, such as -332, -111, or -411, were not effective in maintaining cell adhesion and self-renewal [76]. Subsequent studies showed that recombinant laminin-511 supports attachment and proliferation and maintains the pluripotency of human embryonic stem cells (hESCs) as well as induced pluripotent stem cells (iPSCs) by binding to $\alpha_6\beta_1$, an integrin that is frequently expressed by these cells [77]. Other integrins that can maintain the pluripotency of iPSCs include $\alpha_V\beta_5$ integrin via vitronectin binding [78].

Stem cell differentiation is also affected by the type of ligand, density, and presentation. Studies have shown that a combination of ligands could modulate the differentiation of stem cells, which was not achieved with the use of a

single ligand molecule. For example, cell culture substrates functionalized with peptide ligands for $\alpha_5\beta_1$ and $\alpha_6\beta_1$ integrin efficiently supported the early mesodermal differentiation of hESCs. Cellular differentiation, however, could not be induced in the same cell culture medium with the use of either ligand alone [79]. The spatial presentation of ligands is another factor that could regulate cell differentiation. Increased lateral spacing of adhesion peptide induced the increased adipogenic differentiation of MSCs whereas the smaller spacing of ligands resulted in the osteogenesis of MSCs [80]. These results established the strong effect of nanometer-scale changes in ligand arrangement on stem cell differentiation.

Cell shape has been long proved to be a vital regulator of cell function. Bioactive surfaces can be tailored to modulate cell shape by controlling the ligand density or arrangement (to create patterns) on the surface. Hepatocytes cultured at very low initial densities (to minimize cell–cell interactions) on substrates coated with different densities of FN, collagen type I, laminin, or collagen type IV would exhibit a density-dependent alteration of cell shape. The lowest densities were sufficient to support cell attachment but not promote cell spreading, as evident from the rounded cell morphology. In contrast, higher densities mediated a shift to extensive cell spreading. These changes in cell shape were accompanied by corresponding changes in cell function. Rounded cells observed on low-density surfaces exhibited a lower degree of proliferation and bore signs of differentiation, such as the increased production of liver-specific proteins such as albumin. On the other hand, highly spread-out cells on high-density surfaces tended toward proliferation rather than differentiation [81]. The density of ligands influences the number of cell–ECM bonds formed and consequently cell shape. This, in turn, may regulate the switch between proliferation and differentiation via several possible mechanisms such as the clustering of the integrin receptors leading to cytoskeletal reorganization, upregulation of downstream signaling pathways, or the distribution of intracellular forces.

The effect of cell shape on function was also convincingly demonstrated when hepatocytes were grown on laminin-coated adhesive islands (2–80 μm) surrounded by nonadhesive PEG areas. Primary rat hepatocytes were restricted to these adhesive islands and adopted the underlying square or rectangular island morphology, as opposed to cells showing pleiomorphic forms when grown on nonpatterned adhesive surfaces. This confinement of cell shape led to increased cell differentiation (albumin secretion) with a concomitant reduction in growth. Because the ligand density was maintained over the various islands, this regulation of cell function could not be attributed to a lack of cell–ECM contacts but primarily to cell shape, and consequently triggered molecular pathways [22].

Effect of Topography

Cells in tissues or organs respond to organized spatiotemporal stimuli. During the development of an embryo, the surrounding ECM provides a hierarchical organization of topography that ranges from meso to molecular scales. Topography, coupled with biochemical and physical cues, regulates cellular functions such as migration, adhesion, morphogenesis, differentiation, and apoptosis in a developing embryo [82]. Defined topographical cues allow the systematic study of cell–substrate interactions (termed contact guidance) and can also modulate cellular orientation and morphology that may in turn be extended to modify other cellular responses.

Fabrication Techniques

To study the effect of topography on cellular behavior, patterning techniques have been developed to create defined substrate topography at the micron scale. With further advancements in patterning techniques, topographical structures may be fabricated at the nanometer scale over larger areas and with greater ease [83]. Fabrication at nanometer dimensions is highly relevant because most in vivo structures are found at the nanometer scale, such as the 40- to 120-nm collagen fibrils of the basement membrane.

Several reviews have been published on common techniques used to generate topographically modified surfaces to study cellular behavior [84,84a]. Many techniques have been developed from photolithography. One of the first studies using photolithography to fabricate patterned structures involves coating a resist onto a surface and subsequently exposing it to UV light through a patterned mask [85]. Thus, a photochemical reaction occurs only at the exposed areas of the resist. These reacted areas of the resist are either retained or dissolved away when soaked in a developer solvent, depending on whether a positive or negative resist is used. Photolithography allows the facile fabrication of submicron-sized topography with great reproducibility over large areas. However, the size of the feature achieved is curtailed by the wavelength of light diffraction. This limitation may be overcome by EBL to fabricate fine features at the submicron level. However, this method is both expensive and time-intensive.

TABLE 27.1 Commonly Used Two-Dimensional Substrate Patterning Techniques for Tissue Engineering and Regenerative Medicine Applications

Technique	Materials That Can Be Patterned	Advantages	Disadvantages
Nanoimprinting	Thermoplastic polymers, polymer resists	One step patterning of thermoplastics Very high resolution (<50 nm) High throughput Cost-effective	Requires a master mold Requires etching step to transfer patterns for substrates other than thermoplastics
Photolithography	UV-sensitive prepolymers	Does not require a master mold Well-suited for low-resolution, UV–cross-linked hydrogel patterning	Low-resolution (micron range) Limited to hydrogel patterning unless combined with etching step or soft lithography
Hot-embossing	Thermoplastic polymers	One-step patterning of thermoplastics Cost effective	Requires a master mold
Injection molding	Thermoplastic polymers	Rapid and low-cost operation High throughput	Higher capital cost Limited to micron resolution Requires electroformed master dies [89]
Electron beam lithography (EBL)	Spin coated EBL resists such as poly(methyl methacrylate)	Excellent resolution (<10 nm) Master mold is not required High-nanoscale reproducibility	High capital cost Slow patterning Requires etching and embossing step to transfer patterns to cell culture substrate
Soft lithography (molding)	Polydimethylsiloxane, hydrogels, protein solutions	Simple process, cost-effective Applicable to wide range of materials	Requires a master mold Challenging to obtain nanoscale resolution

Patterns obtained by photolithography may be transferred to elastomeric molds such as PDMS. This technique, known as soft lithography, allows structures as small as 30–50 nm to be fabricated [83]. Soft lithography can also be used to "stamp" patterns onto a surface; this is known as microcontact printing [86].

Polymer demixing, which is based on phase separation, can also generate nanoscale structures. For instance, polystyrene and poly(4-bromostyrene) were shown to demix spontaneously, producing islands that varied from 13 to 95 nm in height, depending on the ratio of polymer to solvent mixture [87]. Although this technique is simple and inexpensive, its main disadvantage is a compromise in precision.

Electrospinning [88] has emerged as a simple, efficient method to produce polymer fibers as scaffolds for cell and tissue engineering. Briefly, electrospinning uses a high-voltage field to overcome the surface tension of a polymer solution, to form fibers that are deposited onto a grounded surface. Electrospinning yields a nonwoven mesh that, if collected over a longer time, can form a nonwoven 3D scaffold. Alignment of the fibers can be accomplished by spinning the grounded surface at the same speed as the rate of fiber deposition (Table 27.1).

Cellular Responses to Topographical Cues

The complex cross-talk among cell adhesion molecules and the ECM, intracellular and ECM-generated mechanical forces, and biochemical signaling molecules, elucidates a correlation between cell shape and function [90]. Control of cell morphology dictates cell behavior such as growth, differentiation, and survival. Topographical cues can induce changes in cell morphology, affecting cellular responses such as proliferation, gene expression, cytokine production, and cellular function. These responses vary depending on the cell type and the geometry and size of the topographical features; they are reviewed elsewhere [91,92]. It has been suggested that all cell types will attain a spherical morphology with a less-organized cytoskeleton when exposed to isotropic features 5 μm or smaller in dimension [93].

Disordered topographies on poly(methyl methacrylate) (PMMA) substrates have an important role in cell differentiation and aggregation. Varying the degree of randomness in nanopit spacing was shown to affect cell adhesion and increase the expression of bone-specific ECM [94]. Interestingly, a range of semirandomness of the nanopits was shown to provide optimal enhancement in cell adhesion and promote bone-specific ECM.

The importance of the feature size was illustrated when smooth muscle cells were cultured on PDMS and PMMA surfaces presenting a range of different-sized grooves. Cells exhibited superior alignment along the grooves of surfaces with the smallest topographical features. Epithelial cells aligned on uniform grooves and ridges showed greater adhesion strength when the groove size was reduced from 4000 to 400 nm by exposure to fluid shear stress [95]. Illustrating the effect of feature size on cellular behavior, it was shown that cells grown on adhesive, patterned islands of varying sizes and shapes conformed to the underlying substrate geometry.

At the nanometer scale, uroepithelial cells cultured on hemispherical pillars or step edges demonstrated a stellate morphology compared with the spread-out morphology adopted when grown on smooth surfaces. The less-spread morphology also correlated with a decrease in cytokine production. Interestingly, uroepithelial cells cultured on parallel grooves and ridges showed only differences in morphology while cytokine production remained unaffected [96]. Furthermore, smooth muscle cells showed a decreased rate of proliferation when cultured on nanoimprinted gratings compared with those cultured on nonpatterned surfaces [97], which demonstrated the effect of nanotopography on cell morphology, proliferation, and migration. Muhammad et al. also showed that nanograting topography on titanium oxide substrate suppressed the proliferation of human coronary artery smooth muscle cells [98]. In another study, gratings with line widths of 350 nm and 1 and 10 μm on PDMS were used to study the differentiation of hMSCs into neuronal lineage, with or without retinoic acid induction. The expression of microtubule-associated protein 2 (MAP2) was most significantly upregulated on 350-nm gratings compared with the 1- and 10-μm gratings. A synergistic effect of nanotopography and retinoic acid was also observed on the upregulation of neuronal marker, compared with the induction of retinoic acid or of topographical alone [99]. These studies further illustrate the significance of topographical feature size on cellular responses.

Neuronal cells present a unique response to topography. Unlike other cell types, neurons have certain distinctive cell shape features. A typical neuron is a polarized cell with soma and dendrites on one end and axons on the other. Neurite alignment or outgrowth was shown to increase with increasing groove depth from 0.2 to 4 μm. With isotropic pillars, hippocampal neurons could expand from pillar to pillar in a highly ordered manner when interpillar spacing was less than 40 μm [100].

Multipotent neural stem cells (NSCs) are highly interesting to regenerative medicine and neuroscience studies because they are present in both developing and adult central nervous system. The NSCs are capable of self-renewal and differentiation into astrocytes, oligodendrocyte, and neurons whereas the neural progenitors (NPCs) are lineage restricted and capable of fewer divisions. The major types of progenitors found in the adult human brain are ventricular zone NPCs, hippocampal neuronal progenitor cells, and white matter glial progenitors [101–108]. Many studies have expressed the significant influence of topography on NSC and NPC differentiation, proliferation, morphology, and even regional specification. Christopherson et al. demonstrated the application of electrospun polyethersulfone fiber mesh coated with poly-L-ornithine and laminin for the maintenance of rat hippocampus-derived adult NSC [109]. That study showed that as the diameter of the fiber mesh decreased from 1452 to 283 nm, the proliferation and spreading of the NSCs increased and exhibited lower aggregation. Furthermore, the fibers were more efficient at promoting differentiation when the NSCs were cultured under differentiation conditions. Moe et al. studied the influence of different geometries and sizes in neural differentiation of primary murine NPCs (mNPCs) using a microarray of various topographical structures as a Multi-ARChitecture chip [110]. The customizable microarray contains distinct topographies of various architectural complexities, from nanometer to micrometer dimensions, with different aspect ratios and hierarchical structures on a single chip. They showed that anisotropic gratings significantly promoted differentiation of the stem cells into neurons. In contrast, glial differentiation was enhanced on isotropic holes and pillars. Interestingly, a similar trend of neuronal differentiation of hESCs was shown by Ankam et al. [111]. In their study, the anisotropic nano- and microgratings enhanced neuronal differentiation and maturation of hESCs. These studies showed that the geometry and size of a topographical structure can influence the lineage commitment of the stem cells, even when the cells were cultured under the same condition. Tan and Tann et al. took one step further to investigate whether topography affects regional specification in the derivation of midbrain dopaminergic neurons [112]. The gratings and hierarchical gratings, which were composed of a secondary set of nanogratings imprinted on top of microgratings, showed the most significant enhancement in the midbrain dopaminergic neuron derivation.

The aspect ratio of the height and width of topographical features is also an important parameter in guiding neurites. Different depths of grooved substrates have been studied systematically and have been shown to have an effect on cell morphology [113] and neuronal differentiation [114]. Neurons differentiated from mNPC on groove substrates of different depths (0.35, 0.8, 2, and 4 μm) revealed that an aspect ratio of height to width > 1 would enhance neurite growth. With a height to depth aspect radio < 1, neurite alignment parallel to the grooves decreased. A model was proposed to hypothesize that the depth-sensing ability of the neurites is involved with the interplay

between filopodia adhesion and neurite bending. Thus, the size of topographical features, ranging from nanoscale to microscale, has been shown to have a role in directing neural differentiation and neurite guidance.

In addition to stem cell differentiation, neurite guidance, and morphological changes, topographies affect and regulate other cellular responses. Cells stretched by the underlying substrate were observed to switch from an apoptotic mode to growth [115]. The geometry of the underlying substrate was also found to affect fibroblast attachment, in which the greatest adhesion occurred at ridges but diminished on nanosized pits and columns [116]. Differences in proliferation and adhesion can lead to differential endocytotic activities of cells on topographies. Human fibroblasts attempted to endocytose nanocolumns 100 nm in diameter fabricated using colloidal lithography [117]. Another work demonstrated that the topographical effects influence endocytosis, and in turn the efficiency of drug and gene delivery in hMSCs and fibroblasts [118]. The enhanced cellular endocytosis exhibited by the cells on micro- and nanopillars promoted the internalization of fluorescently labeled dextran, as well as the nonviral gene transfection of green-fluorescent protein encoding plasmid with lipofectamine. By optimization and careful design, various topographies can be applied to regulate drug and gene delivery and cell proliferation.

Corneal endothelial cells generally have low in vitro proliferation rates and are nonproliferative in vivo. However, studies demonstrate that appropriate surface topographical cues can induce higher proliferation rates in corneal endothelial cells [119] as well as in primary human corneal endothelial cells [120]. Furthermore, topographical cues increased the expression of the tight junction protein zona occludens 1 (ZO1) and promoted in vivo cell-like morphology [120]. The study also demonstrated that the donor-derived human corneal endothelial cells were able to memorize the topographical cues such that even after passaging, the cells could consistently express increased ZO1 and improve cell morphology.

Pathological changes to the microstructure of basement membranes can occur under pathological conditions. Fuchs endothelial dystrophy (FED) is one such disease that is characterized by the development of microdomes and pillars-like structures known as corneal guttata on the corneal endothelial basement membrane. Rizwan et al. characterized the guttata dimensions at various stages of FED disease and then developed synthetic guttata substrates as an in vitro disease model. This model was subsequently used to study the monolayer formation and migration of primary corneal endothelial cells on guttata-like microtopography [121]. This study is an example of how in vitro disease models can be used to mimic basement membrane microstructural changes and consequently to study the mechanisms underlying cell behavior in pathological settings.

Whereas many studies have demonstrated the significant influence of substrate topography on cellular responses, researchers have also been actively investigating the mechanisms underlying the topographical regulation of cell behavior. It has long been demonstrated that genetic expression can be influenced by surface topography. Human gingival fibroblasts aligned along 60-, 30-, and 15-μm grooves 5 and 10 μm deep on titanium-coated silicon demonstrated increased production of both cellular and plasma FN compared with nonaligned controls. The narrower grooves favored plasma FN whereas the wider grooves favored cellular FN [122].

How does topography affect gene expression? One working hypothesis is changes of integrin expression and/or clustering that subsequently affect FA signaling. The changes in hMSC integrin expression were studied using 350-nm patterned or unpatterned substrates [123]. A reduced expression of integrin subunits α_2, α_V, β_2, β_3, and β_4 was observed on nanopatterned substrates compared with unpatterned substrates. In addition, integrin expression was generally higher on TCPS than on PDMS substrates, which suggests that the substrate surface chemistry and stiffness were also contributing factors to integrin expression in hMSCs. Teo et al. showed that integrin-activated FAK is an early sensor and regulator of topography-induced hMSC differentiation [124]. FAK phosphorylation was required for topography-induced hMSC differentiation whereas FAK overexpression overruled the topographical cues in cell lineage bias. This work indicated a direct effect of FAK activity on topography-induced gene expression, explaining how hMSCs can sense and transduce topographical signals via FAK and cytoskeletal contractility to induce cell differentiation.

Actomyosin contractility could be another intracellular mechanism involved in topography-induced differentiation. Ankam et al. showed that high actomyosin contractility induced by a nanograting topography is crucial for neuronal maturation of hESCs during neuronal differentiation. Treatment of cells with the myosin II inhibitor (blebbistatin) and myosin light chain kinase inhibitor (ML-7) greatly reduces the expression level of MAP2 [125]. The mechanical signals are transduced through FAs via a mechanism involving vinculin, and into the contractile actomyosin cytoskeleton.

Another study identified zyxin as one of the molecular players involved in the topography-mediated modulation of cellular response [126]. When hMSCs were cultured on PDMS with 350-nm grating topography, downregulated zyxin expression led to smaller and more dynamic FAs. Because the association of zyxin with FAs depends on force, smaller zyxin-positive adhesions as well as their higher turnover rate suggest that the traction force in FAs on 350-nm topography is decreased. These changes led to faster and more directional migration on 350-nm gratings.

It also suggests that the 350-nm grating topography decreases intracellular tension. Interestingly, a higher turnover rate of zyxin was observed when cells were cultured on more compliant substrates [127]. Therefore, phenomenologically, the initial molecular response of a cell to nanotopography appears to mirror that of a compliant substrate.

Another crucial part of the mechanistic understanding of topography-induced differentiation is the effect on the stem cell differentiation efficiency and speed, and the crucial time period for applying topography to enhance stem cell differentiation. Chan et al. quantified the effect of topography on the neural differentiation of hPSCs during 21-day differentiation, and showed that gratings increased the rate of neural differentiation [128]. The group also compared the significance of a priming period in which the stem cells were cultured on the topography in maintenance media, with the actual contact of topography during the differentiation period. The hPSCs with both topography priming and topography contact during differentiation showed faster progress in differentiation compared with the culture with only the priming or topography contact during differentiation. The study demonstrated that topography contact is significant for topography-induced differentiation, and the effect of topography priming and topography contact is additive in enhancing differentiation.

In addition to stem cell–directed differentiation, a study showed that topography at the microscale can promote the direct conversion of fibroblasts into neurons [129]. When neuronal transcription factors Ascl1, Brn2, and Myt1l were overexpressed in murine fibroblasts, the fibroblasts could be transdifferentiated into functional neurons, the subtype of which depended on the topography of the PDMS substrate. The purity and conversion efficiency of the induced neurons (iN) were increased on micrograting substrates, whereas neurite branching was increased on microposts and decreased on micrograting. Compared with the reprogramming conducted on planar PDMS, the iNs reprogrammed on 5-μm micrograting showed upregulation of vasoactive intestinal polypeptide and downregulation of thymus cell antigen 1 and bone morphogenetic protein 5, and coupled with microarray DNA analysis, reflected a more gamma-aminobutyric acid-ergic rather than glutamatergic phenotype [129].

Although that study sheds light on the impact of topography at the cytoplasmic level, another study linked extracellular physical cues to changes in the nucleus [130]. When the same hMSCs were cultured on PDMS with 350-nm grating topography, 2D gel electrophoresis and western blotting showed that A-type lamins and retinoblastoma protein were downregulated compared with hMSCs cultured on planar PDMS. The differentiation potential of the hMSCs was also altered. When the hMSCs were cultured in mixed media containing adipogenic and osteogenic cues, the adipogenic markers peroxisome proliferator activator receptor γ and low-density lipoprotein in hMSCs cultured on 350-nm topography were downregulated whereas the osteogenic markers osteocalcin and Runt-related transcription factor 2 (Runx2) were upregulated compared with planar controls.

Electrically Conductive Substrate

Bioelectricity is the electrical currents and electrical potentials generated by or occurring within living cells, tissues, and organisms. For example, neurons conduct signals by using electrical fields. Similarly, cardiac tissue is composed of aligned cells and cardiomyocytes, which conduct the electrical current that provides signals for cardiac contraction and blood flow. The heart consists of Purkinje fibers, which are electrically conductive and essential for the conduction system of the heart. Because electrical current is an indispensable part of cell and tissue function, electrically conductive substrates and scaffolds for tissue engineering applications can be designed to facilitate better cellular cross-talk and tissue regeneration. Commonly used naturally occurring biopolymers or synthetic polymer scaffolds are not electrically conductive. These materials can be rendered electrically active by combination with conductive components such as carbon nanotubes (CNTs), carbon nanofibers, and gold nanowires. Shin et al. showed that the addition of CNTs into gelatin hydrogels improved cardiac cell adhesion and maturation, and promoted cell–cell electrical coupling [131]. The cardiac cells also showed synchronous beating on these CNT-incorporated hydrogels. These effects depended on the CNT concentration in the hydrogel, which indicated that the appropriate amount of electrical conductivity in a scaffold is an important parameter. Limitations of these electrically conductive scaffolds components are that they are nonbiodegradable and their long-term in vivo effects are largely unknown, which could present challenges for in vivo transplantation. This limitation may be addressed to an extent by blending conductive polymers such as polyaniline and polypyrrole with the scaffold material solution before processing. Polypyrrole has been shown to degrade in aqueous conditions [132] and polyaniline, although nonbiodegradable, can be used to synthesize biodegradable copolymers [133].

Besides endogenous electrical signals, externally applied electrical stimuli have long been known to modulate cellular functions and tissue healing. In the 1960s, Bassett et al. demonstrated that the mechanism of bone formation in adult dogs could be altered by applying direct electrical currents of varying intensities [134]. Since then, a

multitude of studies have confirmed the effect of external electrical fields on the cellular function of several tissues including heart, lungs, skin, and vascular and neuronal tissue. Schmidt et al. showed that neurite outgrowth could be enhanced by applying exogenous electrical fields on cells cultured on electrically conductive substrates [135]. In their study, cells exposed to either a constant potential or a constant current applied through polypyrrole film exhibited significant and uniform improvements in neurite extension with no directional bias. In another study, Rowlands and Cooper-White showed that proper exogenous electrical stimulation could enhance the proliferation rate of smooth muscle cells but also lead to increased contractile protein expression [136]. Conducting polymer substrates (polypyrrole) doped with hyaluronic acid and coated with collagen IV and Matrigel were used to mimic the basement membrane of smooth muscle cells.

A combination of electrical stimulation and a unique extracellular microenvironment can also be used to modulate cellular differentiation, regenerate tissues, and achieve faster wound healing. Cells can sense electrical stimuli as well as the characteristics of the physical microenvironment such as topography and stiffness. Therefore, electrically conductive scaffolds can be used in conjunction with physical cues to take advantage of the beneficial synergistic effects of physical and electrical cues and thus obtain greater control of cellular fate.

Carbon Nanotube and Graphene Surfaces

Carbon coatings have been established as a new biocompatible material that has no biochemically adverse effects on cells in culture [137]. Since this discovery, several studies on CNTs, graphene, and graphene oxide (GO) have been investigated, which have demonstrated a high potential for modulating cellular functions. Each of these materials provides an intrinsic set of physical, electronic, chemical, and mechanical properties and provides nanoscale dimensionality, cues, and texture [93].

The effects of CNTs are controversial because some studies have shown cytotoxic effects whereas others have shown increased cell adhesion and proliferation. It has been postulated that the line between adverse and augmented effects is based on the CNT length, degree of dispersion, and purity [138]. Multiwalled CNT (MWCNT)-soaked collagen was shown to improve initial cell attachment and proliferation of 3T3 mouse fibroblasts greatly. Increased adhesion was attributed to enhanced filopodia that wrapped around the CNTs. Because alkaline phosphatase activities were similar between cells that adhered to MWCNT-covered collagen and bare collagen controls, no significant effect on cell differentiation was expected [139].

Single-walled CNT (swCNT) coatings on surfaces have proved to increase cell adhesion and cell spreading of MSCs. MSCs preferentially adhered to swCNTs; after 1 week of culturing, they began to cross over to neighboring swCNTs. This favorable adhesion demonstrates nanostructure-directed growth that can be applied to neuronal culturing [140]. Furthermore, it has been demonstrated that mES can differentiate into neurons, astrocytes, and oligodendrocytes on a multilayered swCNT surface, which raises the possibility of a new potential surface for neural interfaces [141].

Graphene and GO surfaces have demonstrated accelerated osteogenic stem cell differentiation of hMSCs. The effect of a graphene coating does not appear to change cell adhesion or morphology on SiO_2 [142]; however, a comparison between bare PDMS and pure graphene and GO showed increased hMSC adhesion and proliferation on the carbon surfaces [143]. The accelerated osteogenic differentiation can be attributed to the special $\pi-\pi$ interactions, which allow for increased mineralization and an ability to preconcentrate osteogenic inducers such as dexamethasone and β-glycerol-phosphate [143]. GO has also demonstrated an increased capacity for absorbing serum proteins owing to its surface roughness and surface oxygen content [144].

A comparison of MWCNT, MWCNT/GO, single and multilayer GO, and reduced GO (rGO) on glass cover slips was performed using NIH 3T3 mouse fibroblast cells. The rGO and rGO/MWCNT had slightly increased cell adhesion after 48 h of incubation; however, the surfaces with MWCNTs had a larger cell area. The carbon-based materials exhibited an elevated amount of FAs, which implied a higher affinity for carbon versus the glass coverslip [145].

EFFECT OF DIMENSIONALITY

Research aimed at gaining a fundamental understanding of tissue development or designing a new biomaterial has always employed substrates that mimic the ECM as closely as possible. However, one aspect that has been more difficult to imitate is the 3D nature of the tissue. In the in vivo microenvironment, cells are not only surrounded by other cells, they are encompassed by the ECM (between the cells or as a basement membrane) and its various components (growth factors and proteins).

Importance of Three Dimensions

Culturing cells in a 3D environment promotes normal cell polarity, as opposed to a 2D culture in which cells are exposed to different upper and lower microenvironments, which results in an artificial cell polarity [26]. Growth on 3D substrates is not curtailed to a single plane. Hence the surface area over which cells can adhere and cell–cell communication can take place is enhanced. Because of the proximity of the cells to the ECM, the local concentration of important cytokines and enzymes may be greater than that distributed over a cell monolayer. Moreover, the presentation of ECM ligands to spatially oriented cells may afford the simultaneous stimulation of several signal transduction pathways [146], leading to greater control over cell behavior and function. Thus, 3D systems provide spatial regulation of the cells and also affect cellular responses to the physical and biochemical cues provided [147]. This may also lead to the remodeling of the ECM itself, thus modulating the dynamic reciprocity of the cell–ECM system more effectively. The significance of 3D culture versus 2D has been highlighted in many studies [148,149].

Substrates for Three-Dimensional Culture

It has been demonstrated that experiments carried out on a planar, rigid substrate elicit results that may not be comparable to those obtained under in vivo conditions [146]. To obtain a more biomimicking in vitro microenvironment, sufficiently porous substrates are increasingly being developed that provide spatial freedom to allow the movement of cells as well as the transport of nutrients. In addition, cell adhesion ligands and growth factors are being incorporated to bestow adhesive and proliferative properties to these substrates to recreate the natural environment. Substrates that serve as 3D environments include polymer scaffolds, hydrogels, porous cellulose beads, electrospun scaffolds [150], 3D printed scaffolds [151] and decellularized tissue [152].

Polymers for Three-Dimensional Scaffolds

Several types of synthetic polymers and naturally occurring biopolymers have been used to grow 3D tissues. Commonly used synthetic polymers include PEG, PLLA, poly(acrylic acid), and poly(lactic-*co*-glycolic acid) (PLGA). Synthetic polymers offer several advantages over naturally occurring biopolymers: they can be chemically defined and they are highly reproducible and xeno-free. They also offer opportunities for versatile chemical modifications and the tailoring of functional groups to facilitate the conjugation of different molecules of interest to the polymer backbone. However, synthetic materials have limited biodegradability and do not support the adhesion of all cell types. Short sequences of self-assembling peptides have been synthesized to mimic ECM proteins [153]. Naturally occurring biopolymers can also be used to fabricate scaffolds for 3D cell culture. Traditionally, collagen is the mostly commonly used 3D culture scaffold among biopolymer materials because it offers easy cell encapsulation and forms a hydrogel at 37°C in a gentle environment that does not damage the encapsulated cells. Alginate, gelatin, chitosan, gellan gum, and hyaluronic acid are among other naturally derived materials that have been used successfully for 3D cell culture [154].

These materials can be fabricated into 3D cell culture scaffolds by employing a variety of methods, depending on the requirements of specific tissue growth. Commonly used 3D scaffold fabrication methods are discussed next.

Preparation of Three-Dimensional Scaffolds

Hydrogel Scaffolds

Hydrogels are among the most commonly used material-processing techniques for 3D scaffold preparation and consist of a network of cross-linked hydrophilic polymer chains that can absorb water. Both synthetic and natural biopolymer materials can be fabricated into hydrogels that bear close resemblance to the tissues in terms of mechanical properties and water content [155]. Three important properties of hydrogels that influence 3D cell growth include the porosity, biodegradability, and source of the material. High porosity leads to more efficient cell infiltration and nutrient delivery to the inner sections of the 3D scaffold. If the hydrogel is biodegradable, it allows cells to remodel their microenvironment, which ultimately improves tissue growth. In general, bioactive materials (e.g., gelatin, collagen, and silk) promote cell adhesion, proliferation, and tissue growth versus synthetic material hydrogels (e.g., PEG hydrogel). However, they are poorly defined and inherent batch-to-batch variability confounds the

effects of the scaffold on cell functions. Hydrogels prepared with short, biodegradable, synthetic peptides that mimic extracellular proteins are increasingly being studied as fully defined 3D scaffolds [156].

Three-Dimensional Printed Scaffolds

3D printing involves the laying down of successive layers of material in additive manufacturing to form 3D shapes, which enables better control of pore morphology, size, and matrix porosity compared with other fabrication methods. With the help of computer-aided design and by using patient medical imaging data, 3D-printed scaffolds can be developed with an intricate design that are patient-specific. However, only a limited number of materials can be processed in 3D printers. Traditionally, 3D printing has been used to print molten materials such as metals, ceramics, and plastics. To fabricate scaffolds for tissue engineering, processes have been modified to print commonly used tissue engineering scaffold materials such as PCL, PLGA, and PEG. The ink for 3D printing can be used in two different forms: with or without cells. Once the material is deposited, it can be cross-linked by different methods such as heat, UV light, or binder [157]. 3D printing with inks containing cell suspensions is particularly interesting owing to its ability to fabricate cell-seeded scaffolds in a single step. The material needs to meet a number of requirements to be suitable for the 3D printing of scaffolds. It should possess suitable rheological properties to enable the deposition of strands of various thicknesses. Second, after deposition, the material should be mechanically strong enough to hold its shape until cured. Finally, the swelling of the material should be known so as to accommodate changes in the size of the printed strands. Schuurman et al. studied the concentration of gelatin methacrylate (GelMA) precursor, UV dose, and the incorporation of viscosity-enhancer to determine the parameters for the successful fabrication of 3D-printed scaffolds of gelatin strands [151]. 3D bioprinting also permits the fabrication of tissues with multiple cell types. Duan et al. printed mechanically robust, living trileaflet heart valves that contained aortic valve leaflet interstitial cells as well as aortic root sinus smooth muscle cells using alginate/gelatin bioinks [158].

Electrospun/Nanofibrous Scaffold

Electrospinning has evolved as a promising technique for fabricating fibrous scaffolds for 3D culture. This method produces nonwoven materials with fiber diameters ranging from a few nanometers to over 1 μm. In a typical electrospinning process, a polymer solution or melt is forced through a needle by using an electrostatic field, resulting in the formation of a jet that breaks up to produce fibers of adjustable diameter. The fibers are collected on a grounded substrate. Electrospun nanofibers are similar to native ECM in terms of morphology, which has led to their popularity as tissue engineering scaffolds [150]. A wide range of scaffold materials can be processed into scaffolds by electrospinning. A few limitations associated with electrospinning include poor cell infiltration and migration as a result of the close packing of scaffold fibers, the toxicity of the residual solvent, and the low mechanical strength of the scaffolds for load-bearing applications. Several strategies have been used to produce electrospun scaffolds with large pore sizes. These include the fine-tuning of electrospinning parameters [159] using sacrificial materials as porogens [160] and electrospinning in wet media [161].

Decellularized Tissue

Synthetic 3D scaffolds are an improvement over 2D scaffolds because they provide an in vivo–like microenvironment for promoting cell functions and tissue growth. However, they are lacking in two important aspects. First, synthetic scaffolds do not recapitulate the complete ECM protein composition and ultrastructure of the microenvironment. Second, they do not contain blood vessels, which are essential for large organs such as the heart and liver. Without the presence of vasculature in large synthetic scaffolds, the delivery of nutrients to cells farther from the surface of scaffolds becomes difficult when the scaffold size approaches that of organs such as heart or liver. These limitations of synthetic scaffolds pioneered the use of decellularized tissues and organs as scaffolds for 3D cell culture.

The cell-free organ is actually a combination of blood vessels and ECM secreted and remodeled by the native cells. By using the decellularized tissue or organ as a scaffold, the benefit of nature's own platform can be manipulated to engineer a new organ. However, it is essential that the methods employed for cell removal preserve the delicate structure of the ECM while ensuring complete cell removal from the organ or tissue. The choice of chemical agent to be perfused into the tissue or organ for decellularization depends on several factors such as tissue or organ density (e.g., dermis versus adipose tissue), the number of cells in the tissue or organ (e.g., liver versus tendon), the lipid content (e.g., brain versus urinary bladder), and the thickness (e.g., dermis versus pericardium) [162]. Every cell removal agent and technique will alter the ECM composition and cause some degree of ultrastructure disruption; however, efforts must be taken to minimize these undesirable effects. For example, detergents are effective agents

for cell removal because they solubilize cell membranes; however, they can also dissociate proteins in the ECM. Another challenge is the complete removal of the cell removal agent from the decellularized organ, because residual traces can damage the seeded cells [152]. Decellularization using physical forces has also been studied. The freeze–thaw process is a promising strategy for lysing cells without the loss of ECM proteins. However, postprocessing is required to remove the lysed cells from the tissue or organ. Furthermore, freeze–thawing can produce minor alterations in the ultrastructure of ECM [163]. Flynn et al. used the freeze–thaw process successfully to provide an inductive microenvironment for the adipogenic differentiation of human adipose-derived stem cells [164].

Development of Three-Dimensional Culture and Materials

New Materials

Numerous smart materials have been designed that incorporate unique material properties that benefit the 2D as well as 3D cell culture. These materials include stimuli-responsive materials that respond to external stimuli such as temperature, light, or pH, bioresponsive materials, shape memory polymers, double-network or interpenetrating network hydrogels, self-assembled materials such as peptide hydrogels, and photodegradable materials with spatiotemporal control of material degradation (Table 27.2). pH-sensitive materials are polyelectrolytes that contain weak acidic or basic groups, which either accept or release protons in response to changes in pH. In one study, pH-sensitive hydrogel scaffolds improved cell function, which was attributed to their ability to swell or contract in response to pH changes that modulated oxygen transport and cell infiltration [165]. Lei et al. fabricated a fully synthetic thermoresponsive hydrogel for the 3D culture of hPSCs [166]. These thermoresponsive scaffolds made of poly(*N*-isopropylacrylamide)-*co*-poly(ethylene glycol) could support the long-term and serial expansion of multiple human pluripotent stem cell lines with a high expansion rate. Moreover, the same hydrogel scaffolds supported the directed differentiation of stem cells. In another study, magnetic field–responsive hydrogels were fabricated by impregnating alginate scaffolds with magnetic particles; these scaffolds were seeded with aortic endothelial cells [167]. The cells were able to reorganize into cellular vessel-like structures in magnetically stimulated scaffolds without supplementing growth factors. In contrast, the cells formed sheets or aggregates in the nonstimulated (control) scaffolds. Hybrid cross-linking can also impart new properties to materials. GelMA is a commonly used photocurable hydrogel that has shown promising results in numerous tissue engineering applications [168]. However, it lacks mechanical strength and has limited control over the biodegradation rate. Gelatin is known to gel physically at low temperatures. In a study, this property of gelatin was exploited and GelMA precursor solution was UV–cross-linked after it had gelled at a low temperature. This new material with hybrid cross-linking (termed GelMA+) showed more than eightfold improvement in material strength and greater control over the enzymatic biodegradation rate (Table 27.2) [169].

New Technology Development

Advances in 3D cell culture have been made possible by the concurrent development of technologies that aided several aspects of 3D tissue engineering, such as control of the 3D microenvironment, fabrication of scaffolds for 3D culture, imaging of cellular interactions with the 3D microenvironment, and the large-scale manufacture of cells [179]. For example, technologies such as 3D printing, electrospinning, polymer demixing, microencapsulation, and microfluidic 3D cell culture have enabled the development of 3D scaffolds with an ECM-mimetic microenvironment and a controlled pore size. 3D printing technology has made feasible the fabrication of vasculature within the scaffolds by using 3D-printed sacrificial sugar templates in the hydrogel scaffold [180].

Characterizing cellular interactions with the 3D environment remains challenging because high-resolution 3D imaging is more complicated than 2D imaging. New techniques are required to comprehend the complex cellular interactions fully in 3D. CLARITY is a technique that transforms 3D tissue into a 3D nanoporous hydrogel-hybridized form that is optically transparent and macromolecule-permeable [181]. Superresolved fluorescence microscopy is a set of imaging techniques that offer nanoscale resolution by bypassing the diffraction limit of light, which is not achievable with conventional light fluorescence microscopy. This technique can also be used to image the 3D morphology of nanoscopic cellular structures [182].

Microfluidic platforms have given rise to the rapid generation of cell-laden microspheres for 3D culture. Toh et al. used a microfluidic platform to culture hepatocytes in a 3D environment. This system was used to test dose-dependent drug toxicity in vitro and predict in vivo hepatotoxicity [183]. Headon et al. generated size-controlled, biofunctionalized microgels for cell encapsulation using a microfluidic platform with precise control over the sphere size [184]. Alginates can be cross-linked in a salt bath in an environment that is gentle to cells. Therefore, alginates

have commonly been used to microencapsulate cells for 3D cell culture. The cells can be mixed with alginate precursor and dispensed into the aqueous salt solution using needles or droplet microfluidic platforms [185]. 3D culture has been applied to the field of stem cell technology as well. Pluripotent stem cells can be differentiated into different cell types within a 3D cell culture scaffold [186]. In addition, stem cells can self-organize into 3D tissues that can self-renew and differentiate when appropriate media, cell culture substrates, and biochemical cues are employed. These are called organoids and mimic some of the functions of real organs with applications as model organs for drug testing and other uses [187].

Finally, bioreactors are increasingly being developed for large-scale 3D cell culture. Bioreactors can have several designs, such as rotating wall vessels, direct-perfusion systems, hollow fibers, and spinner flask bioreactors [188]. At the core of a bioreactor is usually a small cylindrical chamber composed of a polymer scaffold that supports cell adhesion and growth as well as nutrient delivery. The bioreactor needs to maintain high levels of humidity and oxygen for optimum cell growth. An overview of the 3D technology development for cell culture and tissue engineering is provided in Fig. 27.1.

Cellular Responses to Three-Dimensional Substrates

Most cells in the in vivo environment are surrounded by other cells and the ECM in the third dimension. 3D substrates provide a more physiologically relevant environment for cell growth and tissue development. Although 2D cell culture methods have been well-established for many cellular studies, 2D culture methods cannot fully recapitulate the natural 3D environment. Therefore, in vitro 3D cell culture tests have been proposed to provide more predictable and reliable analysis with more relevance to the corresponding in vivo responses [189,190].

Researchers have discovered striking differences in cell responses, such as cell adhesion and cell migration, between 2D and 3D microenvironments [148]. Studies of cell–substrate interactions in the 3D environment become increasingly important for tissue engineering and the development of in vitro drug-testing models [179].

Cell Adhesion

Cell morphology is one of the major differences observed when comparing cells in 2D and 3D substrates [148,191]. On 2D substrates, cells are flat as either individual cells or a monolayer. The cells can adhere and spread in the horizontal x–y plane but they cannot spread in the vertical z dimension. Similar to cells on the basement membrane in vivo, the cells cultured on 2D surfaces can adapt an apicobasal polarity. The polarity and 2D cell morphology are relevant for some cell types, such as epithelial cells and endothelial cells. However, most mesenchymal cells assume a stellate morphology and polarize only during migration [192]. The geometries of 2D or 3D substrates also determined if integrin-mediated adhesions to the ECM form on only one side of the cell or on multiple planes around the cell surface. The difference in cellular responses with 2D substrates compared with 3D culture could arise from these variations in the spatial distribution of integrin–ECM adhesions [148]. Variations in matrix stiffness, structural diversity, and topography of the extracellular environment could affect the recruitment of proteins to adhesion sites, leading to the variations observed in different 3D contexts [193,194]. Although imaging FAs in 3D contexts is challenging because of the decreased size or intensity of adhesions, advances in imaging methods have enabled FA imaging in 3D matrices [195,196]. Thus, quantitative studies and models can be developed to provide insight into the mechanism of cell adhesion in 3D matrices.

Cell Migration

Advances in materials science, scaffold fabrication, biological tools, high-resolution imaging, and force traction measurement [197,198] have facilitated groundbreaking research in studying cell migration on 3D substrates. Studies on cell migration on 3D cell culture systems and in vivo conditions have revealed several differences compared with cell migration in 2D, including their morphology and mechanical and signaling control [148,199].

Using microphotopatterning lines, Doyle et al. showed that cell migration in both 1D and 3D is rapid and uniaxial, and the cell migration is independent of ECM ligand density but dependent on myosin II contractility and microtubules. The 1D and 3D migration were also characterized by an anterior microtubule bundle with a posterior centrosome [67]. Other researchers also illustrated the existence of multiple modes of 3D migration, including lamellipodial, lobopodial, and amoeboid migration, in which cells use different types of cell protrusions [200,201] and collective cell migration [202]. Another study showed that the classic polarized patterns of signaling, such as Rac and Cdc42, which guide migration in 2D models, are not essential for efficient 3D migration [199,202]. In contrast to lamellipodia-based migration on 2D, polarization signal molecules at the leading edge of 2D motile cells are not present in 3D lobopodia cell migration. Meanwhile, various studies showed that physical properties of the ECM such as stiffness, cross-linking, and pore size affect 3D migration [203,204]. Cells can also detect the porosity and the elasticity, linearity, or nonlinearity of the matrix, and adjust their migration mode accordingly [201].

Cell–Extracellular Matrix Reciprocity

3D culture also governs dynamic cell–ECM reciprocity, as seen in the response of cells to mechanical stress during matrix remodeling. In the case of fibroblasts grown on collagen matrices, this involves an increased density of collagen fibrils. As the fibroblasts exert a mechanical force on the underlying matrix, these collagen fibrils are either aligned or randomly oriented, depending on whether the matrix is restrained to the dish (scenario mimicking 2D culture) or free-floating, respectively. Alignment of the fibrils consequently affects cell morphology as stimulation with PDGF yields fibroblasts with a stellate morphology and isometric tension. In contrast, fibroblasts grown on the floating matrices (lack of tension in the matrix) adopt neuronal extensions and a dendritic network [204a].

The intrinsic state of the cell can also influence ECM adhesion by regulating integrin gene expression [205]. A study used a small interfering RNA-based screen of over 300 chromatin modifiers to identify functional interactions among different proteins that regulate differentiation of human epidermal stem cells [206]. One network of genetically interacting factors was found to affect distinct but functionally related genes, including those encoding α_6 and β_1 integrins and other proteins involved in mediating interactions with the ECM. The study showed that the chromatin modifiers that regulate differentiation are also involved by affecting genes encoding α_6 and β_1 integrins and other ECM-interacting protein, thus influencing stem cell interactions with the ECM. The study showed that epigenetic strategies are employed by the epidermal stem cells to protect from differentiation by adjusting cell–ECM adhesion.

Effect of Externally Applied Mechanical Stimuli

Cells reside in a dynamic environment in the body and are sensitive to changes in the microenvironment. Mechanical forces applied on the cell–polymer construct will often modify the cellular response, which renders cell–polymer interactions in the presence of mechanical stimuli an important area of study (Fig. 27.2).

Mechanical stimuli are particularly important in tissue engineering and regeneration, such as cardiovascular grafts, bone, cartilage, and tendon/ligament engineering, because different types of dynamic or static mechanical stresses are experienced by various tissues. The polymer substrate should possess physical properties that match the mechanical properties of the implant site. It should also have the ability to support the mechanical force exerted on the implanted graft at the site, such as pulsating blood flow through arteries and weight-bearing bone grafts.

In vitro systems have been developed to model the effect of mechanical stimuli in mechanical conditioning of the engineered tissues to enhance tissue functions. The biomimetic mechanical stimuli applied could be in the form of compressive, tensile, or shear force [207] (e.g., compressive stress on chondrocytes [208] or fluid shear stress on endothelial cells [209]). One type of experimental setup involves seeding cells on a flexible substrate such as an elastic membrane and applying a defined, stepwise, or cyclic strain to the substrate [210–212]. Bioreactors have also been designed to apply mechanical stimuli to induce functional maturation of the engineered tissue for tissue regeneration [213]. With the advancement of lab-on-chip technologies, microfluidic platforms have also been used to study how dynamic mechanical forces can affect cell–substrate interactions. Microfluidic chips have been designed to study various aspects of cell responses and to manipulate and analyze cells [214–216], cell migration [217], stem cell differentiation [218], and in vivo modeling [219].

The application of mechanical forces could trigger intracellular signaling via mechanosensors such as the actomyosin cytoskeleton and mechanosensitive ion channels [220,221]. The applied mechanical stimuli can also transduce signals to cells and hence direct stem cell differentiation via mechanosensing pathways such as RhoA signaling. For

example, when fluid flow is applied to C3H10T1/2 murine MSCs, RhoA and Rho kinase (ROCK)II are activated, which enhances Runx2 expression for commitment to osteogenesis [222].

Mechanotransduction

When a force is applied to cells growing on substrates, the cells sense the changes in the physical environment and transduce the mechanical signals to intracellular biochemical signals by a mechanism called mechanotransduction [223,224]. Mechanotransduction involves a series of complex and dynamic interactions between different cellular organelles and components [225] such as integrins, FAs, and the cytoskeleton, which collectively have important roles in biophysically induced cellular behaviors [225–227]. Various indirect and physicochemical mechanisms such as calcium signaling [228] and mechanosensitive ion channels [229] also contribute to mechanotransduction [92,207,230].

The class of integrin adhesion receptors is one of the cellular mechanosensors for mechanotransduction [231], as discussed previously. FAs are one of the most important integrin-mediated cell–matrix adhesions involved in mechanotransduction [225,232]. They are composed of a large complex network of adhesion molecules [233], including talin, vinculin, and FAK. FAs link the actin cytoskeleton to transmembrane integrins [11,234]; hence, the formation and maturation of FA are driven by cross-talk between both components [225].

FA mechanosensing has been shown to be crucial for mechanotransduction and force-mediated stem cell differentiation. FA maturation and actin polymerization of MSC were promoted in response to micropillar substrates [235]. The phosphorylation of FAK was also essential for topography-induced differentiation [124]. By inhibiting FAK activity, topography-induced differentiation was abolished. Various independent studies collectively demonstrated that FAK activity and cytoskeletal contractility have an essential role in topography-induced differentiation.

Force generation in the cytoskeleton is required for cell adhesion to ECM. The contractile cytoskeleton consists of actin, myosin, microtubules, and intermediate filaments. Increasing evidence has demonstrated the significance of the cytoskeleton in stem cell differentiation [123,125,236,237].

Contractile forces in nonmuscle cells are generated by nonmuscle myosin II. Cells use actomyosin contractility for a two-way interaction with the ECM. Engler et al. showed that matrices of different elasticity could regulate the differentiation of MSCs into different lineages [236]. The specific nonmuscle myosin II inhibitor blebbistatin blocked all elasticity-directed lineage specification without significantly affecting cell function and shape, thus providing evidence of cytoskeletal force generation in ECM sensing. This tension-mediated signaling is reflected by the reorganization of actin MFs or stress fibers to reflect surface features, such as their observed alignment to nanogratings [99,125,226,238]. This cellular force sensing also modulates Rho GTPase levels and MAP kinase activity for downstream stem cell gene regulation.

Rho GTPases are molecular switches that control various signal transduction pathways in cells [239] including the regulation of the actin cytoskeleton. Rho, Rac, and Cdc42 are the three best-characterized members of the Rho GTPase family. Many studies illustrate the importance of Rho in regulating the actin cytoskeleton in mechanotransduction. Increasing ECM stiffness or force application activates Rho [240], which, through a series of reactions, eventually promotes actomyosin stress fiber assembly [241], significantly changing the mechanical properties of the cell [242].

Using micropatterned islands of FN to control cell spreading, it appears that cell shape controls the osteogenic-adipogenic lineage commitment of MSCs through RhoA-dependent actomyosin contractility [237]. Adipogenesis is induced in MSCs confined to small ECM islands, whereas osteogenesis is induced in MSCs cells, with extensive spreading and higher cytoskeletal tension on large ECM islands. Inhibition of actin polymerization and tension by cytochalasin D or inhibition of ROCK activity mimics the phenotype of poorly spread cells, resulting in adipogenesis.

The intricate physical network described earlier sets the framework for the physical continuity spanning from the ECM to the nucleus. Mechanical signals such as topographical perturbations from the ECM can be transduced by structural alterations in the network to elicit differential gene expression in stem cells [243–245].

Whereas the actin MFs are anchored to the ECM through the integrins, they are also physically connected to the nuclear membrane in a coherent actomyosin cytoskeleton. Nesprins are a class of large outer-nuclear membrane proteins that bind actin MFs through their Klarsicht, ANC-1, Syne homology (KASH) domains [246,247], which are physically connected to the Sad1p, UNC-84 (SUN) domain protein of the inner nuclear membrane, forming a KASH–SUN complex to mechanically bridge the actin stress fibers to the nuclear membrane lamins. The nuclear lamina has an important role in mechanotransduction [248] and consists of a meshwork of intermediate filaments and lamin proteins that are physically associated with both the KASH–SUN complex [249,250] and the chromatin [245,251]. The linker of nucleoskeleton and cytoskeleton (LINC) complex, which includes the nuclear lamin and SUN binding to KASH domain of the actin-associated Nesprins, was shown to link both the nucleoskeleton and cytoskeleton. The presence of the LINC complex demonstrates that the mechanical forces arising owing to cell-substrate interactions and the substrate rigidity can physically affect the structural organization of the nucleus [246,252], potentially resulting in changes in gene expression. Forces that are transmitted to the nuclear scaffolds via the LINC complex may regulate critical DNA enzymes or factors. Indeed, the direct physical connection between the cell nucleus and cell–substrate interactions was illustrated in an earlier study [253]; the disruption of intermediate filaments leads to the mechanical decoupling of the integrins and nuclei.

Cellular Responses in Modifying Extracellular Matrix

The ECM forms the underlying substrate for cell adhesion, growth, differentiation, and mechanical support. It is known that connective tissue cells adapt their ECM to changes in mechanical load, such as in bone remodeling, or wound healing. In turn, changes in the ECM content can influence the performance of the tissue, such as the stiffness of heart and vasculature and the strength of bone and cartilage. Experimental evidence confirms that specific ECM proteins are regulated by mechanical stimuli in vivo. For example, tenascin-C and collagen XII are two ECM components associated with fibrillar collagen in tissues bearing high tensile stress such as tendons, ligament, periosteum, arterial smooth muscle, and heart valves [254–256].

In cardiac tissue, fibroblasts are the principal cell type responsible for secreting components of the ECM. In vitro studies using rat cardiac fibroblasts have shown long-term ECM component changes in response to variations in mechanical load. In response to both cyclic and static uniaxial stretch, an increase was obtained in both collagen I

and collagen II messenger RNA expression [257]. When the rat cardiac fibroblasts were cyclically stretched for various durations, mitogen-activated protein kinase was most rapidly activated and collagen I expression became most abundant [258].

CONCLUSION

Cell–substrate interactions are centrally important to many biological processes and have been investigated extensively from various angles. Discussed in the context of tissue engineering and regenerative medicine, this chapter covers the basics and general principles of this tremendously complex phenomenon. The examples cited here reiterate the importance and relevance of elucidating the interactions of cells with substrates (Fig. 27.3). The aim of this review is to provide a starting point for readers to design optimal substrates for specific tissue development. Despite advanced developments in fabrication and analytical technologies, many challenges remain for a deeper understanding of the cell–substrate phenomenon. The heterogeneous nature of the cell population in any tissue remains a challenge. Technologies for single-cell analysis and high-throughput assays have provided much knowledge. As the quality and quantity of the data improve with new characterization techniques, automated image analysis, efficient data analysis, and data mining of the massive data generated from high-throughput assays and computational modeling may become possible for developing a meaningful theoretical framework to describe and predict these cell–substrate interaction phenomena. The ability to fabricate a biomimicking environment to analyze cell–substrate interactions at the single-cell level in situ will also provide important insight: for instance, in uncoupling the effects of cell–cell communication from cell–substrate interactions. Finally, as the field of regenerative medicine continues to be fueled by advances in stem cell biology, studies of cell–substrate interactions, particularly with stem cells, transdifferentiation, and iPSCs, will be more important and rewarding in understanding tissue regeneration and disease development.

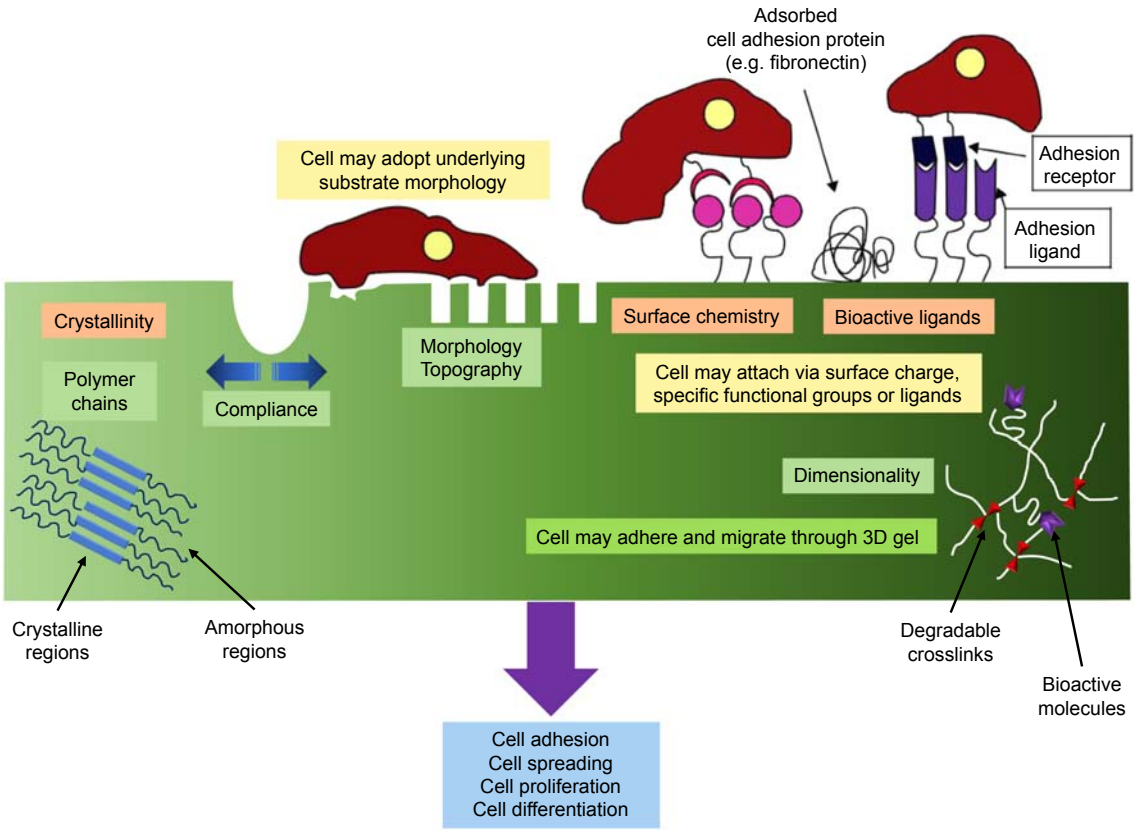

FIGURE 27.3 Schematic depicting the different properties of a substrate that influence cellular behavior. *3D*, three-dimensional.

Intelligent Surfaces for Cell Sheet Engineering

Hironobu Takahashi, Tatsuya Shimizu, Teruo Okano

Institute of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University, Tokyo, Japan

INTRODUCTION

Cell- and tissue-based therapy has become a promising approach to curing a number of diseases and disorders. To obtain sufficient therapeutic effects, transplanted cell populations need to survive and then function appropriately in the transplanted site. The conventional method delivers cells directly by injecting suspended cells to the target site in the body; however, poor cell retention and survival at the target site are severe problems that prevent significant therapeutic effects on the damaged tissues. Tissue engineering, which was first proposed in the 1980s by R. Langer and J. P. Vacanti, promises to overcome this limitation in the field of cell-based therapy [1–3]. Delivery of cultured cells to damaged tissue in patients requires supporting materials for the primary cells that provide specific environments for cell growth in vitro while maintaining their structure during delivery. Advances in tissue engineering have produced scaffolds of various kinds of natural and synthetic polymeric materials to provide cells with a three-dimensional (3D) environment for adhesion, proliferation, and differentiation into a specific cell phenotype [4–6]. This technology is able to organize and arrange cells 3D in vitro. For example, collagen, fibrin, and alginate have often been used as a scaffold [7,8]. However, the implantation of naturally derived polymers may trigger an immune rejection in some patients, which has led to the wide use of synthetic polymers for tissue construction. For example, poly(lactic-*co*-glycolic acid) and its derivatives are commonly used for scaffold fabrication because their physical properties and degradation rates can be custom designed [9,10]. On the other hand, regardless of the scaffold materials used, most still have limitations such as insufficient cell migration into the scaffold and poor permeability to permit the ingress of cells and nutrients. In addition, the degradation of the scaffold can decrease the in vivo stability of scaffold-based tissues after implantation. Furthermore, in many cases, 3D scaffolds occupy some space within the constructed tissues that prevents cell–cell interaction. To overcome these limitations, a scaffold-free tissue generation system was needed for a new class of regenerative medicine technology. Intelligent thermoresponsive cell culture substrates can be used as powerful tools to establish a unique type of tissue engineering called "cell sheet engineering."

THE INTELLIGENCE OF THERMORESPONSIVE POLYMERS FOR CELL SHEET ENGINEERING

Thermoresponsive Polymer for Biomedical Applications

A number of stimulus-responsive polymers have been used as functional biomaterials in the fields of diagnostics, drug delivery system, and tissue engineering [11–14]. The physical properties of these materials change depending on the temperature or pH. In some other cases, light irradiation or exposure to an electrical and magnetic field can be used as a trigger to change their properties. Thermoresponsive poly(*N*-isopropylacrylamide) (PIPAAm) is well-known as a functional polymer for such uses as thermally induced drug release and thermally regulated separation systems [15–18]. The physical properties of PIPAAm change across its lower critical solution temperature (LCST) of

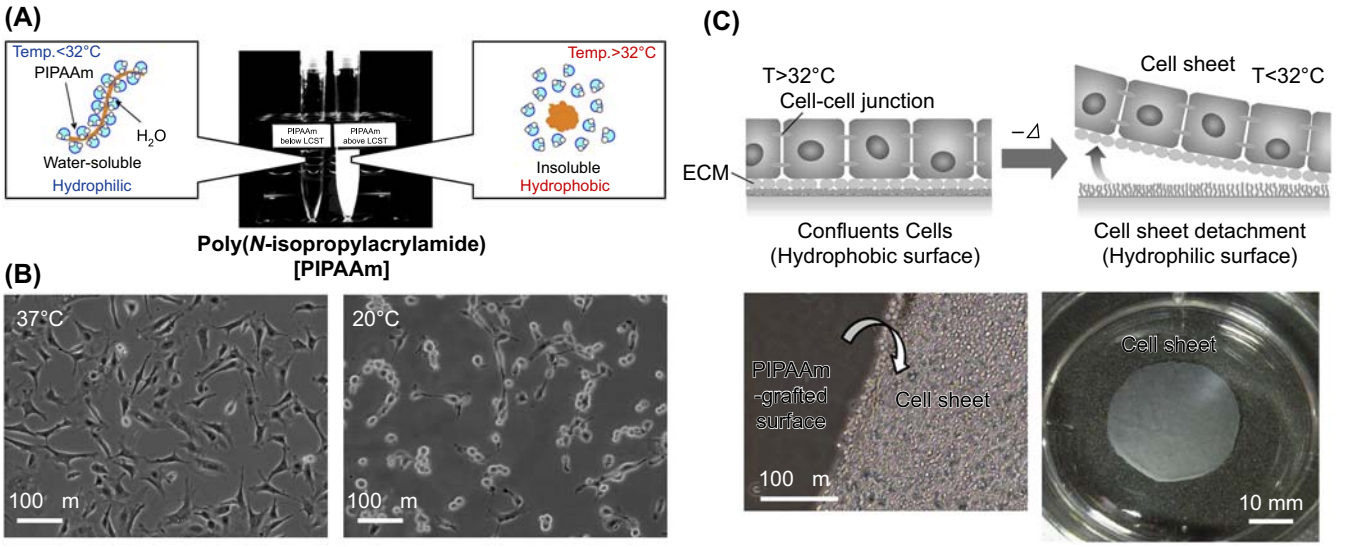

FIGURE 28.1 (A) Temperature-dependent change of hydrophilicity/hydrophobicity of poly(*N*-isopropylacrylamide) (PIPAAm) in solution. (B) Detachment of adhering cells on a thermoresponsive surface by lowering the culture temperature to 20°C. (C) Harvesting a cell sheet with preserved cell−cell junctions and associated extracellular matrix (ECM) without the use of enzymatic treatment. Photograph shows that the cell sheet shrinks two-dimensionally by detaching from the surface. *Adapted with permission from Takahashi H, Nakayama M, Yamato M, Okano T. Controlled chain length and graft density of thermoresponsive polymer brushes for optimizing cell sheet harvest. Biomacromolecules 2010;11:1991−99.*

32°C in aqueous media. Specifically, it has a hydrophilic property owing to the hydration of the polymer chain below the LCST, and then the chain conformation changes to a compact globule state above the LCST and the polymer becomes hydrophobic (Fig. 28.1A) [19]. This temperature-dependent switching behavior has been widely used in the field of drug delivery and allows us to design stimuli-induced release systems for various kinds of drugs (e.g., hydrophobic small molecules, biopharmaceuticals).

Thermoresponsive Surface for Regulating Cell Adhesion and Detachment

The thermoresponsive property of PIPAAm has been used to provide intelligence to a tissue culture substrate. PIPAAm-grafted surfaces behave as a cell adhesive surface at the normal culture temperature (37°C), whereas the surface becomes hydrophilic and they behave as a nonadhesive surface below the LCST. As a result, various kinds of cells adhering to the surface at 37°C detach spontaneously from the surface when the temperature is lowered below the LCST (for example, 20°C) (Fig. 28.1B) [20−22]. This thermally regulated cell detachment allows the adhered cells to be collected from the culture surface without an enzymatic treatment such as trypsinization. Importantly, when cells are confluent on the intelligent surface, a cellular monolayer can be harvested as a single continuous cell sheet by lowering the culture temperature (Fig. 28.1C). In conventional studies, naturally derived materials are widely used as scaffolds to provide an appropriate environment for transplanted cells and manipulate the therapeutic cells. On the other hand, the thermoresponsive surface is able to release a single cell sheet with only the associated extracellular matrix (ECM) (Fig. 28.1C). Moreover, because the cell sheet is harvested without enzymatic treatment, important membrane proteins and cell−cell junctions within the cell monolayer remain intact when it is transplanted. This unique tissue construction method is called "cell sheet engineering" and is applied to tissue engineering and regenerative medicine [23].

Controlled Grafting of Thermoresponsive Polymer on Culture Substrates

To achieve the regulation of cell adhesion and detachment, PIPAAm needs to be grafted precisely at a nanoscale. The amount grafted and its thickness are key factors to provide the appropriate hydrophobicity for cell adhesion at normal culture temperature; the surface is allowed to become nonadhesive by lowering the temperature across the LCST (approximately 30°C in culture medium). The PIPAAm is grafted by electron beam (EB) irradiation to an

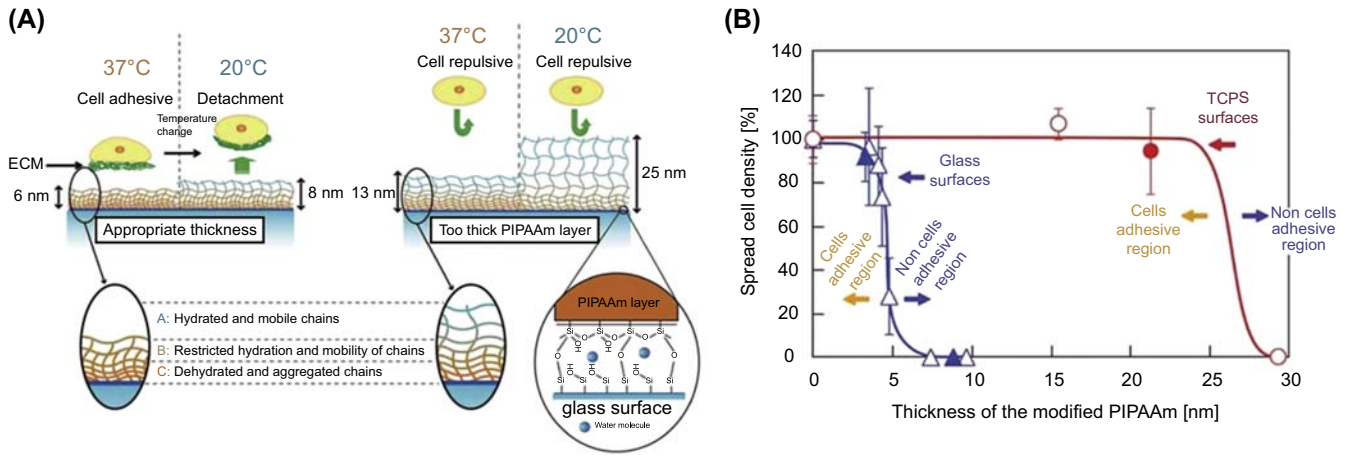

FIGURE 28.2 (A) Schematic illustration of molecular motion of poly(*N*-isopropylacrylamide) (PIPAAm) chains and cell adhesion and detachment behaviors on PIPAAm-grafted surfaces at different graft thicknesses. A PIPAAm layer at an appropriate thickness allows both cell adhesion at 37°C and cell detachment at 20°C. On the other hand, when the amount of PIPAAm is increased by changing electron beam irradiation, the surface is nonadhesive for cells regardless of the culture temperature. (B) Correlation of cell adhesion and thickness of the PIPAAm layer on a glass substrate and tissue culture polystyrene (TCPS) substrate. The range of the appropriate thickness is different between glass and TCPS substrates. *Adapted with permission from Fukumori K, Akiyama Y, Kumashiro Y, Kobayashi J, Yamato M, Sakai K, Okano T. Characterization of ultrathin temperature-responsive polymer layer and its polymer thickness dependency on cell attachment/detachment properties. Macromol Biosci 2010;10: 1117–29.*

N-isopropylacrylamide solution on a tissue culture polystyrene (TCPS) dish. As a result, PIPAAm can be grafted covalently and the amount grafted can be controlled at a nanoscale. The polymer thickness can be optimized by changing the monomer concentration and EB irradiation conditions. A previous study demonstrated that a PIPAAm layer approximately 20 nm thick is appropriate to achieve both cell adhesion and detachment by changing the temperature [25]. A thicker layer of PIPAAm makes the surface too hydrophilic for most types of cells, so they are unable to adhere in significant numbers on the surface even at a normal culture temperature (Fig. 28.2A). In addition, the appropriate thickness of the PIPAAm layer depends on culture substrates. For example, when PIPAAm is grafted on a glass substrate, a smaller amount of PIPAAm is optimal for regulating cell adhesion and detachment behavior owing to the difference in surface properties between TCPS and the glass surface (Fig. 28.2B) [26,27]. Therefore, to prepare a thermoresponsive surface for cell sheet engineering, precise control of the polymer grafting is required. Thermoresponsive culture dishes prepared using EB-irradiation methods are commercially available.

Variety of Fabrication Techniques of Thermoresponsive Cell Culture Substrate

Several kinds of polymer grafting techniques have been developed to produce thermoresponsive surfaces for cell sheet engineering. Surface-initiated living radical polymerization (LRP) processes can provide polymer brush–type thermoresponsive surfaces. Because the LRP processes are widely used to synthesize polymers at precisely controlled molecular weights, this polymer grafting is advantageous to fabricate well-defined thermoresponsive polymer brushes. Atom transfer radical polymerization and reversible addition-fragmentation chain transfer (RAFT) polymerization have been successfully used for PIPAAm brush grafting onto cell culture surfaces [24,28,29]. For example, because surface-initiated RAFT approaches allow the fabrication of polymer brushes with a uniform chain length, the grafted conditions can be precisely adjusted by controlling both the chain length and the graft density of the polymer (Fig. 28.3) [24]. On the other hand, a block copolymer of PIPAAm domain and a hydrophobic polymer domain can be used to achieve a simple coating on a culture surface by spin-coating the free polymer in solution [30]. In this approach, unlike the LRP process, PIPAAm can be synthesized as a free polymer, and then the culture surface can simply be coated with the polymers. To fabricate any kind of cell sheet, a suitable thermoresponsive surface needs to be selected according to the features of the cell sheet such as the cell type. This approach has promoted the development of a wide variety of thermoresponsive surfaces that have been used effectively to fabricate unique cell sheets.

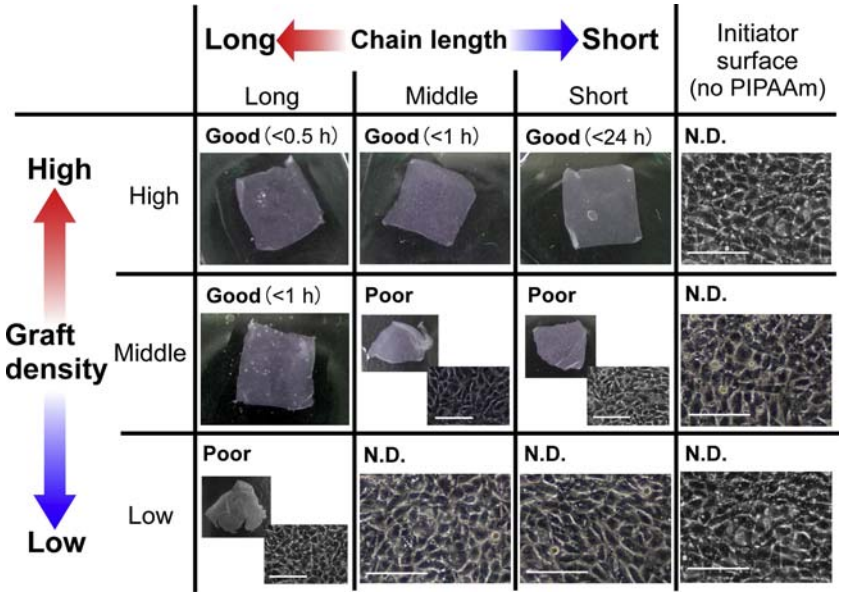

FIGURE 28.3 Performance of cell sheet harvesting using various kinds of poly(*N*-isopropylacrylamide) (PIPAAm) brush surfaces with different polymer chain lengths and graft densities. "Good" and "not detached" ("N.D.") in the photographs indicate complete cell sheet harvest by reducing the temperature (20°C) and no cell sheet detachment within 24 h by reducing the temperature, respectively. "Poor" indicates that some cell sheets showed complete harvest within 24 h but some did not. By changing the chain length and density of the PIPAAm brush (three different densities and chain length in the figure), thermoresponsive properties could be precisely controlled. Scale bar: 100 μm. *Adapted with permission from Takahashi H, Nakayama M, Yamato M, Okano T. Controlled chain length and graft density of thermoresponsive polymer brushes for optimizing cell sheet harvest. Biomacromolecules 2010;11:1991−99.*

CLINICAL APPLICATIONS FOR CELL SHEET ENGINEERING

The advantages of cell sheet engineering have been shown in a number of experimental studies as well as in human clinical studies of cell transplantation. The use of intelligent surfaces allows us to harvest therapeutic cells with complete preservation of cell−cell junctions and the associated ECM [31,32]. Therefore, a cell sheet can be manipulated simply without an artificial scaffold and transplanted just by placement onto a target site. Because the preserved ECM layer acts as a glue to adhere cell sheets tightly to the host tissue, this cell transplantation can be completed without additional treatments such as suturing. With these advantages, human clinical studies are ongoing targeting the regeneration of cornea, esophagus, heart, periodontal ligament, and cartilage.

Cornea Reconstruction

The unique cell sheet features mean that cell sheet engineering can be applied to treat epithelial tissues effectively. In fact, oral mucosal epithelial cell sheets have been exploited for corneal reconstruction. Severe trauma or eye diseases such as Stevens−Johnson syndrome can cause the complete loss of corneal epithelial stem cells and may result in corneal opacification with severe visual loss; to date no effective therapy has been established without limbal allograft transplantation. Cultured epithelial cell sheets derived from oral mucosal tissue have been successfully fabricated on the intelligent surface and are transplantable simply by handling with the support of a poly(vinylidene fluoride) membrane and placing the sheet onto the patient's corneal stroma without a scaffold [33]. The transplanted cell sheets adhere rapidly to the host corneal surface without suturing. A preclinical study using a rabbit model demonstrated that this cell sheet retained the corneal epithelium-like structure. After transplantation, it was confirmed that vascularization and inflammation were inhibited in the transplanted tissue and the corneal clarity and smoothness recovered significantly (Fig. 28.4). Clinical studies demonstrated that by transplanting the autologous epithelial cell sheet to human patients, this treatment with cell sheets provided good tolerability and efficacy after grafting.

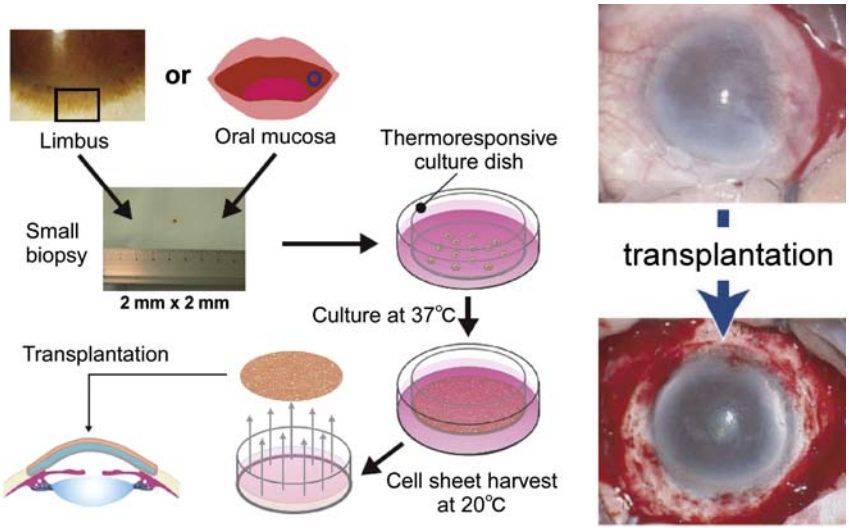

FIGURE 28.4 Schematic illustration of the preparation method for an oral mucosal epithelial cell sheet using the intelligent surface, and photograph of a transplanted cell sheet onto a diseased eye.

Esophagus Reconstruction After Endoscopic Submucosal Dissection Treatment

Mucosal epithelial cell sheets can be transplanted to an ulcer wound bed after endoscopic submucosal dissection (ESD). ESD is a commonly used operative procedure to resect superficial early-stage cancers in the gastrointestinal tract with low invasiveness compared with open surgery. However, postoperative inflammation and stenosis are still major complications observed in the resected area. Severe esophageal stricture after endoscopic treatment often requires repeated endoscopic balloon dilations or a temporary stent. Transplantation of autologous oral mucosal epithelial cell sheets promotes epithelialization of the resected area and prevents postoperative complications including esophageal stenosis [34–37]. These transplantable epithelial cell sheets retain all of the cell membrane proteins and ECM deposited during culture. Therefore, these cell sheets can easily adhere to and integrate into the transplanted tissue sites within a short period. In addition, the placement of cell sheets into the mucosal defect does not require sutures or other adhesives. Furthermore, an autologous epidermal cell sheet is useful for preventing esophageal stenosis after ESD. More autologous cell sheets can be fabricated than ones originating from oral mucosal tissue. Based on these animal studies, human autologous oral mucosal epithelial cell sheets are fabricated using an intelligent surface. Preliminary results showed early reepithelialization of the ulcer site; results suggest its efficacy for preventing stricture in cases of circumferential ESD. A further randomized study is being prepared to fully assess the potential benefits of using cultured autologous cell sheets therapies in regenerative medicine.

Myocardium Regeneration

Cell-based therapy is also predicted to be an important treatment for patients with severe heart failure including dilated cardiomyopathy (DCM) and ischemic heart disease. Skeletal myoblasts have been widely used in the clinical application of cell transplantation because of possible advantages including their autologous origin, high obtainability, high proliferative potential in vitro, and strong resistance to hypoxia followed by ischemia [38,39]. However, because of the poor retention of suspended cells to the target cardiac tissue, in many cases multiple injections are required to deliver high numbers of cells. In addition, the needle injection itself is highly invasive and induces cell death at the injected area, resulting in a risk for myocardial infarction [40]. To overcome these issues, the skeletal myoblast sheet derived from medial vastus muscle has been developed as a patch for myocardial regeneration. Sawa and coworkers demonstrated that autologous skeletal myoblast sheets harvested from the intelligent surface could be used to treat severe DCM [41,42]. Using this effective cell delivery approach, large numbers of myoblasts can be transplanted onto a damaged site. The myoblast sheets potentially release therapeutic cytokines including stromal-derived factor-1, hepatocyte growth factor, and vascular endothelial growth factor (VEGF) and deliver them to a damaged tissue effectively [43]. Although conventional scaffold-based cell transplantation also allows delivery of therapeutic myoblasts, it is unable to form the kind of cell-dense microenvironment found in a cell sheet construct.

In addition, its inflexible bulky properties are unable to withstand the dynamic pulsation of the host myocardial tissue. Studies demonstrated that this scaffold-free tissue delivery system has been also used to deliver other cell types (e.g., cardiac stem cell, adipocyte) in cell sheets to treat myocardial infarction in mice [44,45]. These strategies also have the potential to become a novel drug delivery system for myocardial treatment. In a case report, autologous myoblast sheets were transplanted into the heart of a patient with DCM. This cell sheet transplantation dramatically improved cardiac functions, resulting in no symptoms attributable to heart failure, left ventricular assist device weaning, and eventual hospital discharge.

Periodontal Ligament Regeneration

Periodontitis is an inflammatory disease characterized by periodontal tissue destruction. It predominates as the main cause of tooth loss in adults. It is well-known that periodontal ligament (PDL) tissues include stem cell populations and possibly differentiate into alveolar bone and cementum. A clinical study using autologous PDL cell sheets was carried out and achieved periodontal regeneration [46,47]. To fabricate PDL cell sheets in this human clinical study, PDL tissue was obtained from an unnecessary tooth such as a wisdom tooth. To deliver a large number of cells, triple-layered cell sheets were generally implanted in the proximity of the infrabony defect. No adverse events were found in nine patients and the safety and efficacy of the cell sheet approach were confirmed [48].

Cartilage Regeneration

Regenerative products for articular cartilage are available for patients with osteochondral defects but repeated abrasion of an articulated surface causes symptoms of immovable joints and pain. This radical treatment for osteoarthritis has not yet been established; current treatments such as nonsteroidal antiinflammatory drugs and injection of hyaluronic acid are usually conducted to retard disease progression. Triple-layer chondrocyte sheets might be applicable as a curative treatment for this partial-thickness defect of articular cartilage [49]. A clinical study is ongoing in which autologous chondrocyte sheets are transplanted onto the lesion of early middle-stage osteoarthritis. This scaffold-free cell transplantation is anticipated to be effective in patients with full-thickness cartilage defects as well as those with partial thickness defects.

CELL SHEET ENGINEERING PRODUCES SCAFFOLD-FREE, THREE-DIMENSIONAL TISSUE CONSTRUCTS

Cell Sheet Layering Technique

Progress in induced pluripotent stem cell (iPS) technology worldwide has opened up an entirely new era of life science research [50–52]. In the field of tissue engineering and regenerative medicine, iPS technology provides an important key to achieving cell-based therapies with the patient's own cells. In addition, it is expected that human cell-based tissue models will be developed for drug discovery and biological studies because patient-specific cells can be used to produce a customized tissue model for a specific disease. To exploit this excellent source of cells for medical applications, more integrated tissue engineering technology is required. 3D scaffolds from natural and synthetic polymers have commonly been used to provide a 3D environment for cell adhesion, proliferation, and differentiation into specific cell phenotypes. On the other hand, cell sheet engineering allows the creation of scaffold-free 3D tissues by layering multiple cell sheets. By placing one cell sheet onto another, the layered cell sheets bond tightly because of the preserved ECM underneath each individual cell sheet (Fig. 28.5) [53,54]. The cells can communicate with each other both physically and biologically [55–58]. The combination of these characteristics in the cell sheet layering process allows us to engineer functional 3D tissues. For example, cardiomyocytes cultured on the intelligent surface can be harvested as a single continuous cell sheet and each cardiomyocyte sheet exhibits synchronized beating within the cells of the sheet. Furthermore, when multiple beating cardiomyocyte sheets are layered, beatings at different rates are further synchronized throughout the entire 3D myocardial tissue construct [55,56]. This indicates that just by layering each cell sheet atop each other, they can interact electrochemically

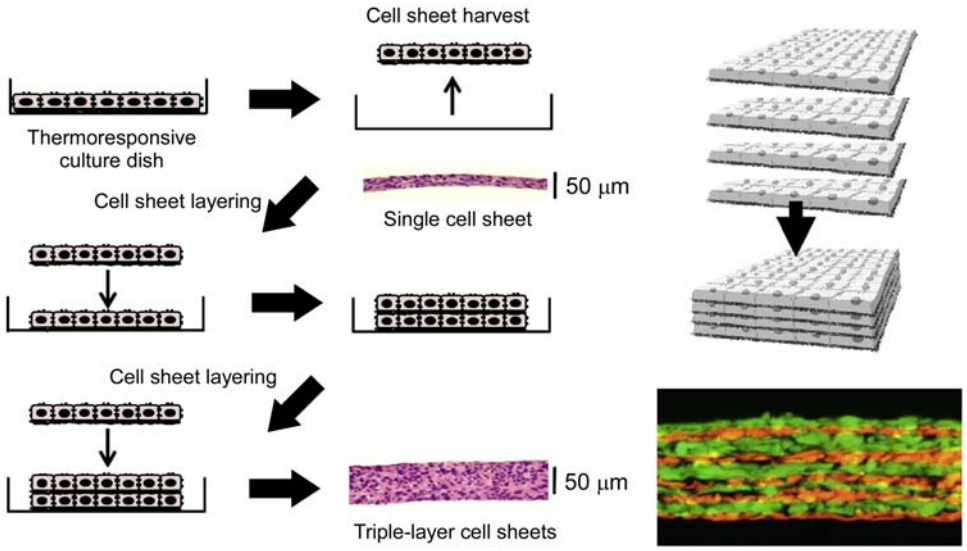

FIGURE 28.5 Cell sheet layering process for the production of a multilayer cell sheet construct without the use of scaffold. Because of the preserved extracellular matrix proteins, multiple cell sheets can be stacked tightly simply by layering them. *Adapted with permission from Haraguchi Y, Shimizu T, Sasagawa T, Sekine H, Sakaguchi K, Kikuchi T, et al. Fabrication of functional three-dimensional tissues by stacking cell sheets in vitro. Nat Protoc 2012;7: 850–8.*

between each cell layer. Therefore, this technique offers the potential for constructing large-scale 3D tissues without the use of a 3D scaffold.

Three-Dimensional Coculture System Based on Cell Sheet Layering

Cell sheet layering technology can be used to produce unique 3D cocultured tissue constructs. In the field of liver tissue engineering, because it is difficult to preserve hepatocyte-specific functions in vitro, several culture methods have been proposed, including coculture with other types of cells [59]. In particular, coculture methods with endothelial cells (ECs) significantly contributed to maintaining hepatic functions compared with conventional monolayer cultures [60,61]. However, the structural configuration of hepatocytes is considerably different from that of the natural liver. Cell sheet engineering can be applied to harvest a rat hepatocyte sheet from the intelligent surface and then sandwich it between two endothelial cell sheets (Fig. 28.6A) [62,63]. Within this 3D hepatic tissue construct, in vivo–like hepatocyte polarization was organized (Fig. 28.6B). This morphological similarity between the engineered rat hepatic tissues and native liver is advantageous for preparing bioartificial liver devices that require a highly effective delivery system for blood components to the hepatocytes. In addition, hepatocyte-specific functions, including albumin secretion, ammonia removal, and the induction of cytochrome P450, were highly preserved (Fig. 28.6C) [62]. The technology for layering multiple cell sheets is a simple operation and successfully reproduced both heterotypic/homotypic cell–cell and cell–matrix interactions with the native hepatocyte configurations. Because the 3D hepatic constructs closely mimic the in vivo environment, it could be valuable as a tissue model for drug screening, as an implantable tissue for cell-based therapies, and as an efficient culture platform for bioartificial liver devices [64].

Vascularization in Cell Sheets for Large-scale Tissue Construction

Although cell sheet layering is useful for producing large-scale tissues, most engineered tissues including multilayer cell sheets require vascularization to supply sufficient oxygen and nutrients inside the tissues [65–67]. As described earlier, synchronously pulsatile myocardial tissues have been successfully fabricated by stacking multiple cardiomyocyte sheets [55,56]. However, in a long-term in vitro culture, severe necrosis can be found within the

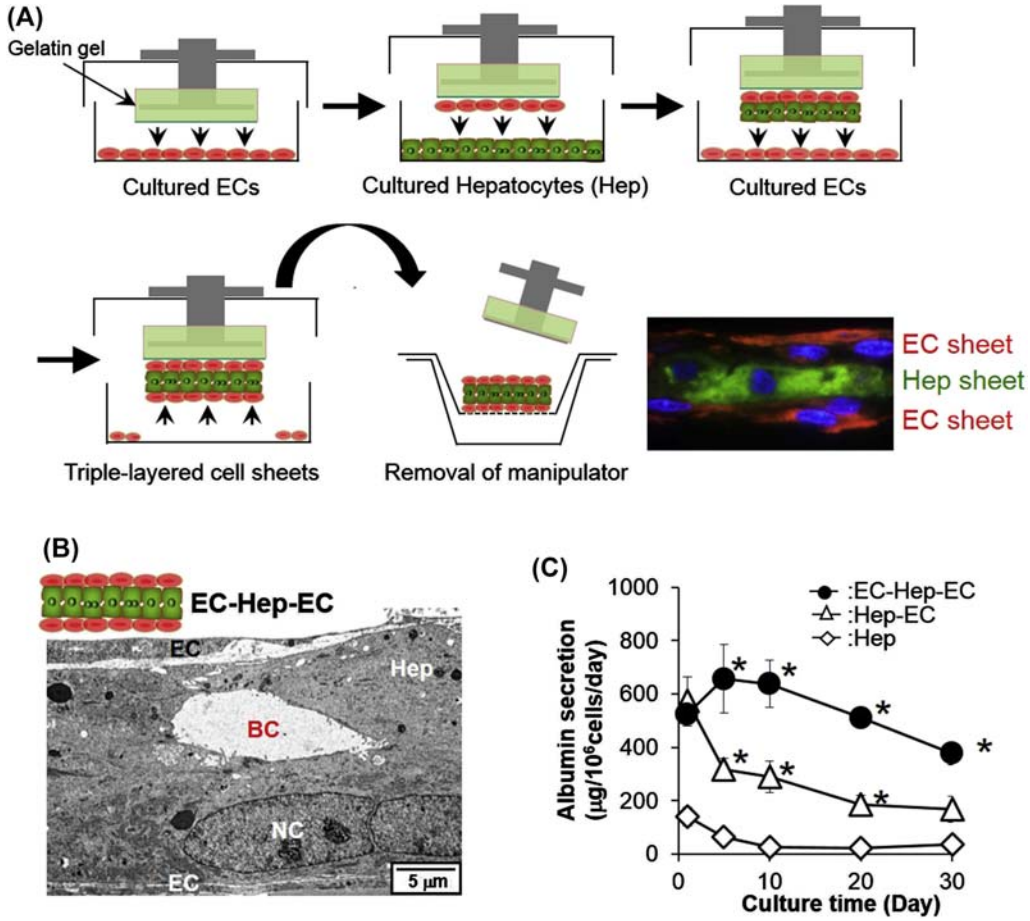

FIGURE 28.6 (A) Preparation of multilayer cell sheets composed of rat hepatocytes (Hep) and endothelial cell (ECs). (B) The formation of bile canaliculus (BC) can be observed only in multilayer cell sheets in which a hepatocyte sheet is sandwiched between two EC sheets (EC-Hep-EC). (C) Albumin secretion is maintained in the long term by sandwiching a hepatocyte sheet between two EC sheets, compared with double-layered hepatocyte and EC sheets and a single hepatocyte sheet. *NC*, nucleus. *Adapted with permission from Kim K, Utoh R, Ohashi K, Kikuchi T, Okano T. Fabrication of functional 3D hepatic tissues with polarized hepatocytes by stacking endothelial cell sheets in vitro. J Tissue Eng Regen Med 2017; 11: 2071–2080.*

engineered myocardial tissue [68]. This has been a limitation of producing thicker multilayer cell sheet constructs. Typically, in tissue transplantation, host-originated blood vessels invade the transplanted tissue, providing a supply of oxygen and nutrients within the tissue. However, thick tissues often become necrotic before sufficient neovascularization is established in the tissue. Moreover, neovascularization in engineered tissue cultured in vitro has not been achieved successfully. Coculture with EC is a promising approach to promoting vascular formation within engineered tissue. Through the cell sheet layering process, ECs can be incorporated simply by being sandwiched between two other cell sheets. Interestingly, the ECs form vascular-like branching networks in the layer cell sheets, which promote vascularization and connections to the host vasculatures after transplantation [69,70]. However, in an in vitro culture, maturation of the prevascularized networks is limited and perfusable tubular structures can rarely be found within the layered cell sheet construct. To overcome this problem and produce a thicker tissue, a technique for the in vitro formation of mature blood vessels was developed. To mimic in vivo conditions, layered cardiomyocyte sheets cocultured with ECs are transferred onto a vascular bed using a resected section of femoral tissue containing a connectable artery and vein [71,72]. For example, when a triple-layered cell sheet construct is placed on the vascular bed in the bioreactor system, the preserved ECM allows the cell sheets to adhere tightly onto the vascular bed; consequently, branching endothelial cell networks connect to the blood vessels originating from the vascular bed. After the formation of functional tubular blood vessels in the tissue construct, the cell sheets can survive owing to the newly formed vasculatures. This enables other triple-layered sheets construct to be layered onto the first cell sheet construct without causing necrosis, resulting in the production of six-layer cell sheets. Based

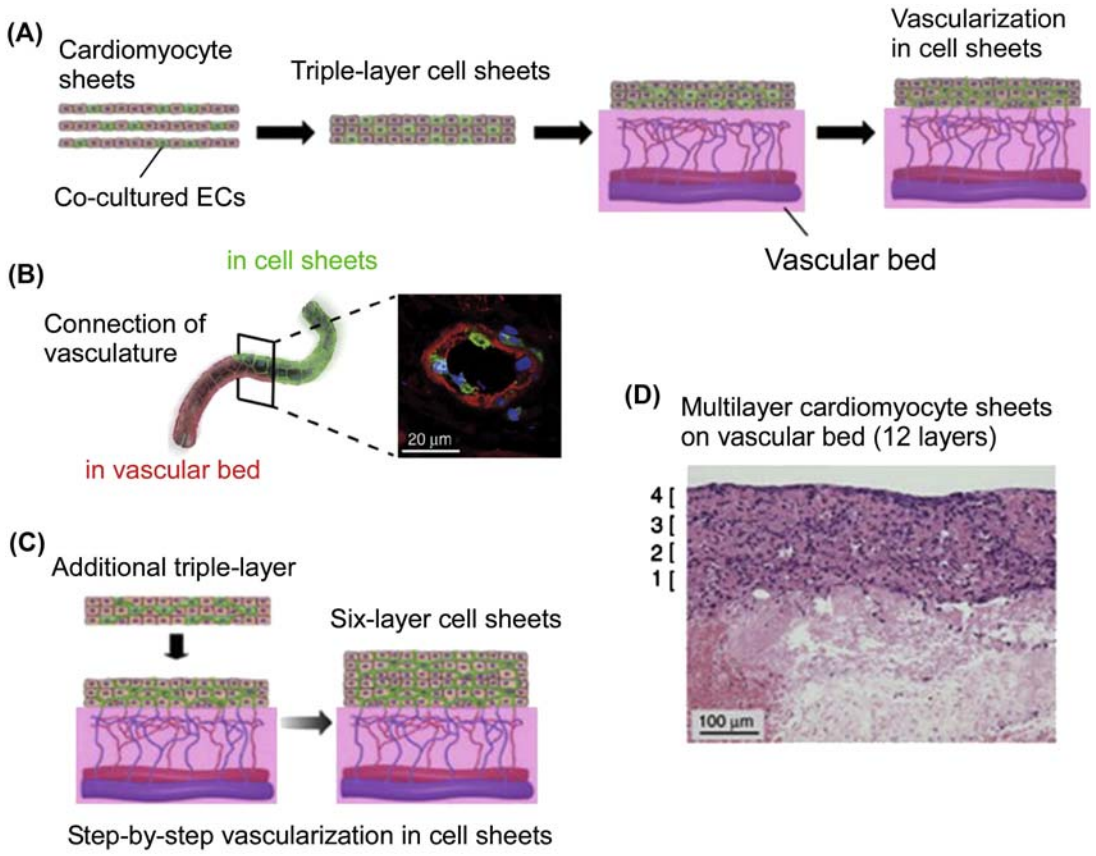

FIGURE 28.7 (A) Production of vascularized cell sheet constructs using a vascular bed. Endothelial cell (ECs) cocultured with cardiomyocyte sheets form a vascular-like branching network. (B) The EC network can connect to the vasculature in the vascular bed and oxygen and nutrients are supplied to the multilayer cell sheets through the newly formed vasculature. (C) After vascularization, step-by-step layering of additional triple-layer cell sheets produce thicker cell sheet constructs complete with new vasculature formations. (D) A previous study demonstrated that a 12-layer cardiomyocyte sheet construct could be produced using this vascular bed system without severe necrosis inside the construct. *Adapted with permission from Sekine H, Shimizu T, Sakaguchi K, Dobashi I, Wada M, Yamato M, et al. In vitro fabrication of functional three-dimensional tissues with perfusable blood vessels. Nat Commun 2013;4:1399.*

on this repeated cell sheet layering, the in vitro cell-dense tissues can be scaled up as desired. This technique may be applied to many other tissue types needed to generate thick vascularized tissues (Fig. 28.7).

COMBINATION OF CELL SHEET ENGINEERING AND SCAFFOLD-BASED ENGINEERING

Whereas cell sheet technology established scaffold-free tissue engineering, the unique properties of cell sheets could also be used jointly with scaffold-based tissue engineering. In the field of vascular tissue engineering, the basic strategy is to mimic a native blood vessel by combining vascular cells, mostly ECs and smooth muscle cells (SMCs), with a tubular scaffold under suitable culture conditions. Electrospinning is one of the most useful techniques for producing a tubular scaffold of synthetic polymers [73,74]. By seeding ECs onto a tubular scaffold composites of synthetic polycaprolactones and type I collagen, an engineered vascular tissue was produced and maintained structural integrity after implantation in a rabbit aortoiliac bypass model [75]. To produce mature blood vessels, SMCs have an important role because they contribute to the contractility and mechanical stability of mature vasculatures, and so they are often used as another cell source of vascular grafts [76,77]. However, because of the tubular-shaped geometry of the vascular scaffolds, cell seeding onto the exterior surface of the scaffold fails to achieve efficient cell penetration into the vascular scaffolds. In a cell sheet engineering approach, SMC sheets can be produced using a thermoresponsive substrate and the vascular graft can be effectively wrapped with the sheet

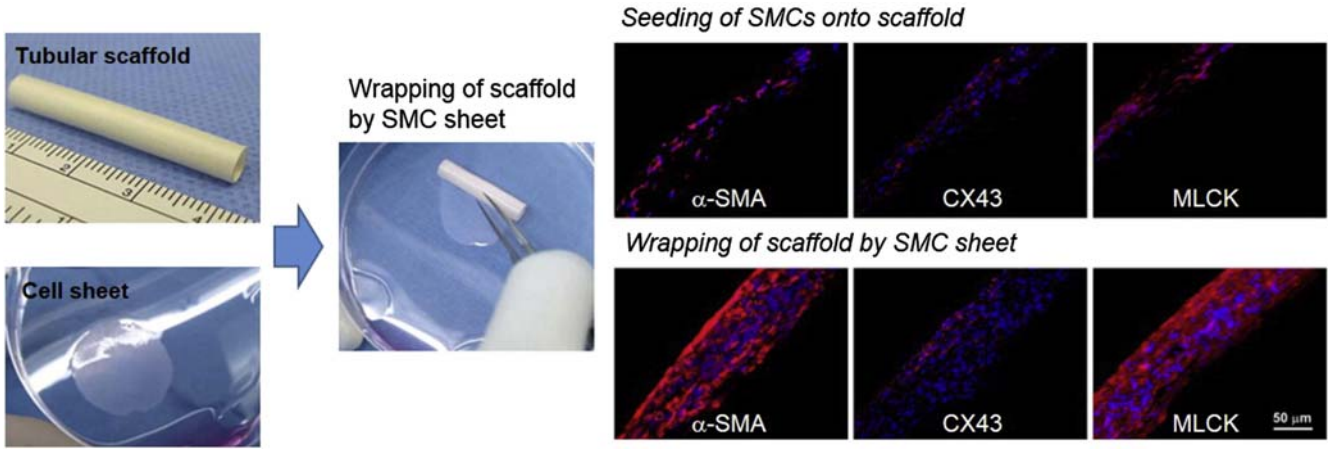

FIGURE 28.8 Fabrication of smooth muscle cell (SMC) layers on a vascular scaffold based on cell sheet engineering. By wrapping a tubular scaffold composed of polycaprolactone/collagen with SMC sheets, a mature smooth muscle layer can be efficiently produced, compared with one simply fabricated by seeding SMCs onto a scaffold. *α-SMA*, α-smooth muscle actin; *CX43*, connexin43; *MLCK*, myosin light chain kinase. *Adapted with permission from Ahn H, Ju YM, Takahashi H, Williams DF, Yoo JJ, Lee SJ, et al. Engineered small diameter vascular grafts by combining cell sheet engineering and electrospinning technology. Acta Biomater 2015;16:14–22.*

(Fig. 28.8) [78]. Cell sheet technology can produce a mature smooth muscle layer before it is applied to the vascular graft. Unlike simply seeding SMCs, the cells forming a cell sheet retain the all-important cell–cell junctions and express contractile proteins when they are applied onto the vascular scaffold. In addition, the secondary harvested cell sheet can be subsequently layered onto the first cell sheet and the graft can continue to be wrapped with multiple cell sheets. In a previous study, triple-layer SMC sheets were fabricated around a tubular scaffold. On the other hand, cell necrosis within the multilayer cell sheets needs to be addressed. In the previous study, a pulsatile perfusion bioreactor system was used to improve the nutrition supply and gas exchange. In addition, the pulsatile flow and pressure to the cell sheet–vascular scaffold led to tissue maturity that could withstand the level of blood flow from the native artery.

MICROFABRICATED INTELLIGENT SURFACE FOR ENGINEERING COMPLEX TISSUE CONSTRUCTS

Copatterning to Create a Cellular Microenvironment

Progress in cell sheet engineering technology has led to cell sheets being applied to the construction of various kinds of tissues and organs [79–82]. It has been confirmed that many different types of cells can be applied to fabricate cell sheets using a thermoresponsive surface. On the other hand, living tissues are composed of multiple cell types in which cell-to-cell interactions influence and maintain the development of characteristic physiological functions and activities. As described earlier, for example, ECs can provide the appropriate environment for hepatic cells under normal culture conditions [60,61]. In previous studies, it was demonstrated that when hepatic cells and ECs were copatterned on micropatterned surfaces, the patterned hepatocytes effectively maintained their functions even in 2D culture by optimizing the size of the hepatic cell patterns [83]. These results demonstrate that copatterned cell sheets of hepatocytes and ECs are one option for producing functional hepatic tissues. Micropatterning on a thermoresponsive surface supports the fabrication of copatterned cell sheets [84,85]. EB irradiation using photomasks onto a PIPAAm surface allows poly(*n*-butyl methacrylate) (PBMA) to be grafted spatio-selectively onto the surface (Fig. 28.9A). Because the LCST of the polymer-grafted regions is decreased by the presence of PBMA patterns, the regions become adhesive only at 27°C, whereas the nonirradiated regions show a cell-repellent property at the same temperature. Therefore, rat primary hepatocytes can be patterned on the PBMA regions at 27°C and then secondary seeded ECs can be patterned on the PIPAAm homopolymer regions at the normal culture temperature, resulting in the copatterning of hepatocytes and endothelial cells on the thermoresponsive surface (Fig. 28.9B–D). Because the copatterned hepatocytes, which can be harvested as a cell sheet (Fig. 28.9E), maintain the functions to synthesize albumin and urea, this type of functional hepatocyte assembly is expected to be useful for liver tissue engineering.

Regulating Cell Orientation in Cell Sheet Engineering

Intelligent Surfaces for Regulating Cell Orientation

Native tissues often form specific structures that are well-known important factors for producing an appropriate functionality [86–89]. Ideally, engineered tissues should be produced in an environment that closely mimics the microstructure of native tissue. In particular, some kinds of native tissues, such as muscle tissues, have well-organized orientations of cells and/or ECM, and their tissue anisotropy are a critical factor in providing biomimetic functions to engineered tissues. For example, in native skeletal muscle, the bundle structure of highly oriented myofibers is essential for generating mechanical functions. Micropatterning approaches can be used to regulate the cell orientation on culture substrates [90]. Although a variety of microfabricated substrates have been reported, conventional substrates have limitations to releasing the well-organized cell monolayer from the culture surface. Because the intelligent surface allows the harvest of aligned cells as a single-cell sheet, cell sheet engineering overcomes these limitations to facilitate the design of 3D cell orientation within a densely packed cell environment. To achieve this, several kinds of micropatterned thermoresponsive substrates have been developed [91,92]. Using these substrates, cell orientation is first regulated 2D and then the aligned cells are stacked as cell sheets layer by layer. Microgrooved polydimethylsiloxane substrates are widely used to control cell alignment, and the same method can be applied to produce aligned cells on the thermoresponsive surface [93]. First, a microgrooved TCPS substrate is prepared and then PIPAAm is grafted over the whole surface. As a result, the surface functions to regulate cell orientation and release the cell sheet. The LRP process is also effective for producing micropatterns on a thermoresponsive polymer layer. Through two-step polymerization, hydrophilic poly(*N*-acryloylmorpholine) (PAcMo) can be grafted site-specifically on a PIPAAm layer, resulting in block polymer, PIPAAm-*b*-PAcMo domains and PIPAAm domains (Fig. 28.10A) [94,95]. The width of the patterns is a key factor in the regulation of cell orientation, and the previous study demonstrated that a 50 × 50-μm striped pattern was appropriate for producing a cell sheet composed of aligned cells. Because of the difference in the cell-to-surface affinity on the surfaces, cells are aligned parallel to the stripe patterns simply by cell seeding. For example, human dermal fibroblasts proliferate and reach confluency while maintaining alignment on the patterned surfaces (Fig. 28.10B) [92,95]. Harvested cell sheets typically shrink 2D and maintain the original aspect of the cell monolayer, whereas here the aligned actin fibers in the cell monolayer induced two distinctive shrinking rates in the vertical and parallel sides of the cell alignment (Fig. 28.10C). This suggests that the cell orientation influences the physical properties of cell sheets. In addition, the cell alignment induces a change in the biological properties of cell sheets. A previous study demonstrated that VEGF secretion from a normal human dermal fibroblast sheet was increased by organizing the alignment of fibroblasts [95]. As described

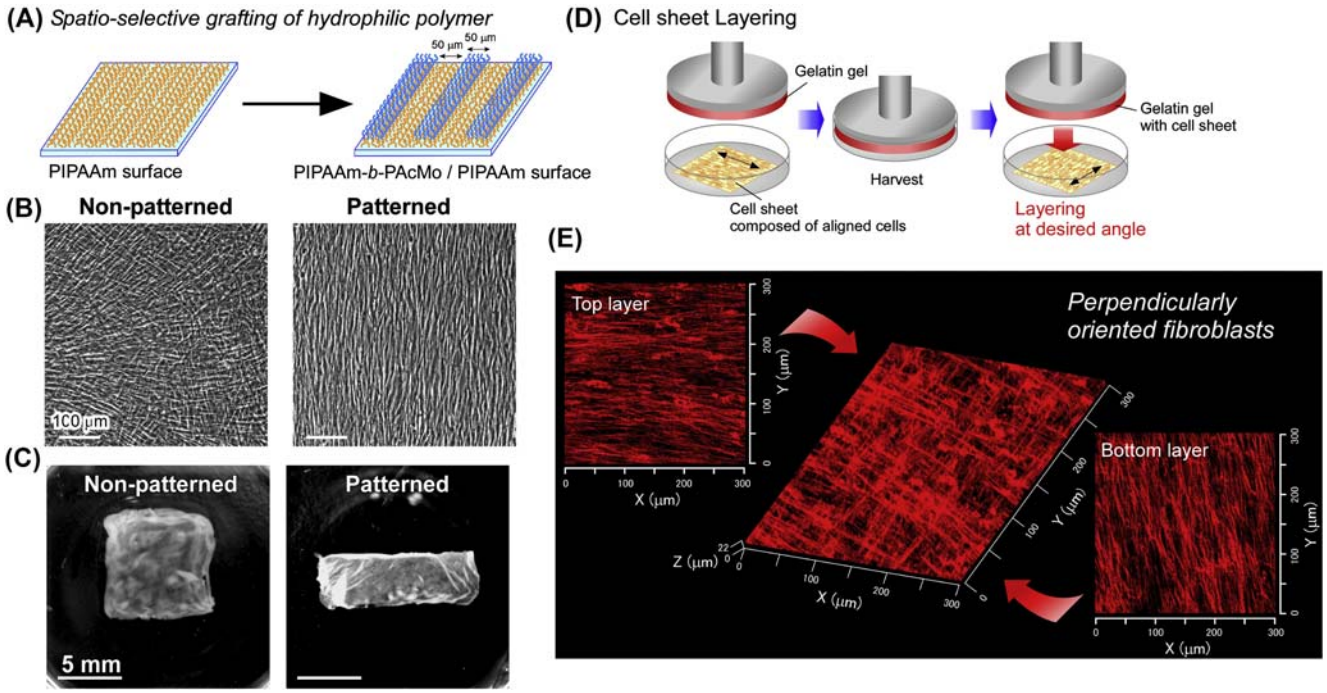

FIGURE 28.10 (A) Fabrication of micropatterned thermoresponsive surface composed of poly(*N*-isopropylacrylamide) (PIPAAm) regions and PIPAAm-*b*-poly(*N*-acryloylmorpholine) (PAcMo) regions through spatio-selective grafting of PAcMo on a PIPAAm-grafted surface. (B) Microscopic images of fibroblast sheets prepared using normal (nonpatterned) and patterned thermoresponsive surfaces. (C) Photographs of cell sheets harvested from normal (nonpatterned) and patterned thermoresponsive surfaces by lowering culture temperature. (D) Schematic illustration of layering process of cell sheets composed of aligned cells using a gelatin gel-coated manipulator. (E) Fluorescence image of perpendicularly layered fibroblast sheets produced by cell sheet layering. Actin fibers of cell sheets are stained red. *Adapted with permission from Takahashi H, Nakayama M, Shimizu T, Yamato M, Okano T. Anisotropic cell sheets for constructing three-dimensional tissue with well-organized cell orientation. Biomaterials 2011;32:8830–8.*

earlier, vascularization is one of the main issues to constructing large-scale tissue successfully [71,72] and angiogenic growth factors such as VEGF are important mediators to promoting vascularization in tissues. Therefore, this could potentially enhance vascularization in multilayered cell sheets. These patterned substrates are also able to regulate the orientation of osteoblasts, SMCs, and mesenchymal stem cells [91].

Arrangement of Three-Dimensional Orientation Using Cell Sheet Layering Techniques

Because cell sheets can be manipulated using a gelatin gel-coated plunger [53], cell sheets composed of aligned cells can be layered while maintaining the designed orientation. In some native tissues, tissue anisotropy is organized 3D and the orientation of their structures is essential for specific mechanical and biological functions. For example, native myocardial tissue consists of multiple layers of aligned cardiomyocytes that are oriented in various directions throughout the whole tissue [88,89,96]. This well-organized 3D oriented structure is important for generating the anisotropic electrical propagation found in the native myocardium. However, it remains difficult to arrange different cell orientations vertically using conventional biomaterial scaffolds. Employing the cell sheet layering technique, cell sheets composed of aligned cells can be layered upon each other to achieve the desired directions (Fig. 28.10D). For example, 3D perpendicularly oriented fibroblast sheet constructs can be created without using a 3D scaffold (Fig. 28.10E) [95]. This strategy is simple and flexible for creating a variety of tissue architectures. As described earlier, the cell-dense tissue structure is important for multiple cell sheets to communicate with each other within the layered cell sheet construct. Therefore, this technique of arranging cell orientation within engineered tissues is expected to be useful for producing biomimetic myocardial tissues.

Skeletal Muscle Tissue Engineering

Because native skeletal muscle tissue is made of highly oriented myofibers, the orientation of muscle cells needs to be regulated to produce biomimetic muscle tissue constructs [97–99]. Using the micropatterned intelligent surface, it is possible to align human skeletal muscle myoblasts in a direction parallel to the striped patterns (Fig. 28.11A) [57,58].

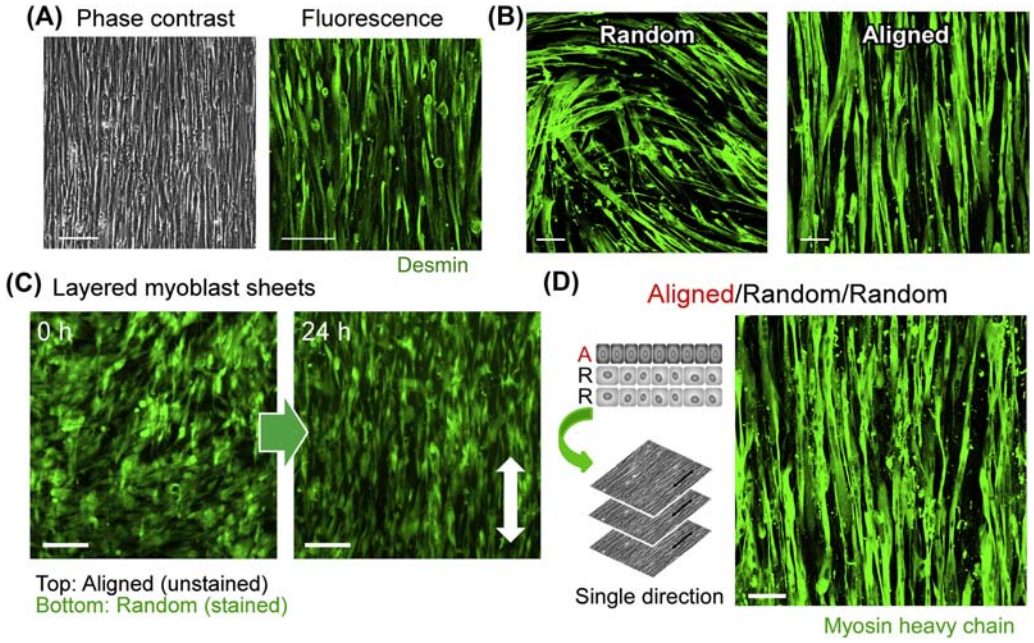

FIGURE 28.11 (A) Myoblast sheet prepared using a micropatterned thermoresponsive surface. (B) Myotubes differentiated from random and aligned myoblasts fabricated on normal and patterned surfaces. (C) Rearrangement of cell orientation of random myoblasts (bottom cells: fluorescently stained) by layering a cell sheet composed of aligned myoblasts (top cells: unstained). (D) Myotube construct produced through the differentiation of three myoblast sheets (top layer: aligned myoblasts; middle and bottom layers: random myoblasts). The random myoblasts self-organize their orientation with the top cell sheet's alignment after they are layered. *Adapted with permission from Takahashi H, Shimizu T, Nakayama M, Yamato M, Okano T. The use of anisotropic cell sheets to control orientation during the self-organization of 3D muscle tissue. Biomaterials 2013;34: 7372–80.*

After reaching confluence, the aligned myoblasts can be harvested as a single continuous cell sheet by lowering the culture temperature to 20°C. Then, after culturing the aligned myoblasts in differentiation media (e.g., 2% horse serum–containing media), they differentiate into myotubes while maintaining their aligned orientation (Fig. 28.11B). In addition, regulating the aligned orientation stimulates the formation of longer myotubes, compared with randomly oriented myoblasts. This aligned structure will be important for producing biomimetic muscle tissue [100]. Moreover, because the aligned myotubes can be layered with cell sheet technology, this combination supports the production of 3D aligned muscle tissues, which is required for scaling up skeletal muscle tissues. On the other hand, previous study found a unique behavior of myoblasts [57]. When a single cell sheet composed of aligned myoblasts was layered onto a normal cell sheet composed of randomly oriented myoblasts, the bottom myoblasts rearranged their orientation in the same direction as the top aligned cells (Fig. 28.11C). Consequently, all myoblasts became aligned within the layered cell sheet construct. Although the mechanism has not yet been elucidated, this self-organization process possibly shows an important factor for regulating cell–ECM orientation in native muscle tissues. Furthermore, this self-organizing behavior allows us simply to produce 3D myotube constructs with a single orientation. Because the top cell layer stimulates random cells to become aligned, three cell sheets of aligned myoblasts are not necessary to produce a triple-layer myotube construct with a single common direction. Myoblasts in the tissue construct are able to self-adjust their 3D orientation precisely. After self-organization is completed, the 3D tissue construct forms an aligned structure of myotubes (Fig. 28.11D). This cell sheet–based technology provides a new potential for constructing complex tissues composed of natively oriented cell assemblies, particularly for skeletal muscle tissue [58].

CONCLUSIONS

Progress in tissue engineering enables cells to be cultured 3D on polymeric scaffolds and then transplanted at desired sites for tissue regeneration. Scaffold-based tissue engineering continues to develop, but cell sheet engineering has also expanded its unique features and advantages to create a new field in regenerative medicine. Intelligent surfaces allowing us to use cell sheets have been applied to human clinical studies that deliver therapeutic cells to

damaged sites. Moreover, the cell sheet transplantation approach will probably be applied to other tissue regeneration applications in the near future. Moreover, new cell sheet technologies including polymer grafting, cell patterning, and cell sheet layering promise to advance the production of sophisticated 3D tissues with complex structures. To develop an integrated tissue model for future drug discovery, we need to develop techniques to construct more complex tissues. To meet this challenge, a new level of cell sheet engineering must be developed to be able to construct any complex tissue with well-organized structures. The combination of microfabricated and thermoresponsive substrates will provide anisotropy within the cell sheets and allow us to use them as "anisotropic tissue units" to produce flexible tissue constructs with multiple 3D orientations. Progress in cell sheet engineering has shown the potential to produce scaffold-free 3D oriented tissue constructs with complex microstructures mimicking native tissues.

INTRODUCTION

Regenerative medicine aims to develop methods to regrow, repair, or replace damaged or diseased cells, tissues, or organs [1] based on integrated strategies from tissue engineering, molecular biology, biomaterials, and stem cell biology. Tissue regeneration can be achieved by stimulating the repair mechanisms of the body, particularly by the delivery of stem cells that can perform biological functions and materials that can function as scaffolds to promote cell proliferation. Because human tissues have a nanoscale structure (Fig. 29.1), progress in nanotechnology has accelerated advances in regenerative medicine with the ability to mimic the composition and structure of human tissues and organs at the nanoscale [4,5] (Fig. 29.2). In addition, many functional nanomaterials have been used to deliver drugs, proteins, and genes for tissue regeneration [4].

Since Richard Feynman first proposed the idea of developing technology at the atomic scale in 1959, nanotechnology has been rapidly developed and actively investigated in many biomedical research fields. According to the US National Nanotechnology Initiative, nanotechnology is defined as "the understanding and control of matter at dimensions of roughly 1−100 nm, where unique phenomena enable novel applications." Nanotechnologies have been incorporated into multiple research areas related to regenerative medicine, including drug delivery, stem cell therapy, and scaffolds for tissue engineering [6−9]. For example, thermoresponsive liposome (TSL) nanoparticles can release their cargo at the liposome transition temperature [10]. When doxorubicin (DOX) was loaded into TSL nanoparticles, only a small amount of leakage was monitored at 37°C. As the temperature was raised to 42°C, almost 100% of DOX was released from TSL nanoparticles. In this respect, TSL nanoparticles have the potential to be applied to target a tumor site where the temperature is higher (~40−42°C) compared with normal tissues (~37°C) [10].

In this chapter, we will present the unique physicochemical properties of nanomaterials for applications in regenerative medicine. In addition, we will discuss nanotechnology-based strategies in regenerative medicine for treating multiple types of tissues, including bone, muscle, blood vessels, and neural tissues. We will also introduce nanotechnology-based stem cell therapy, particularly for controlling stem cell fate and function.

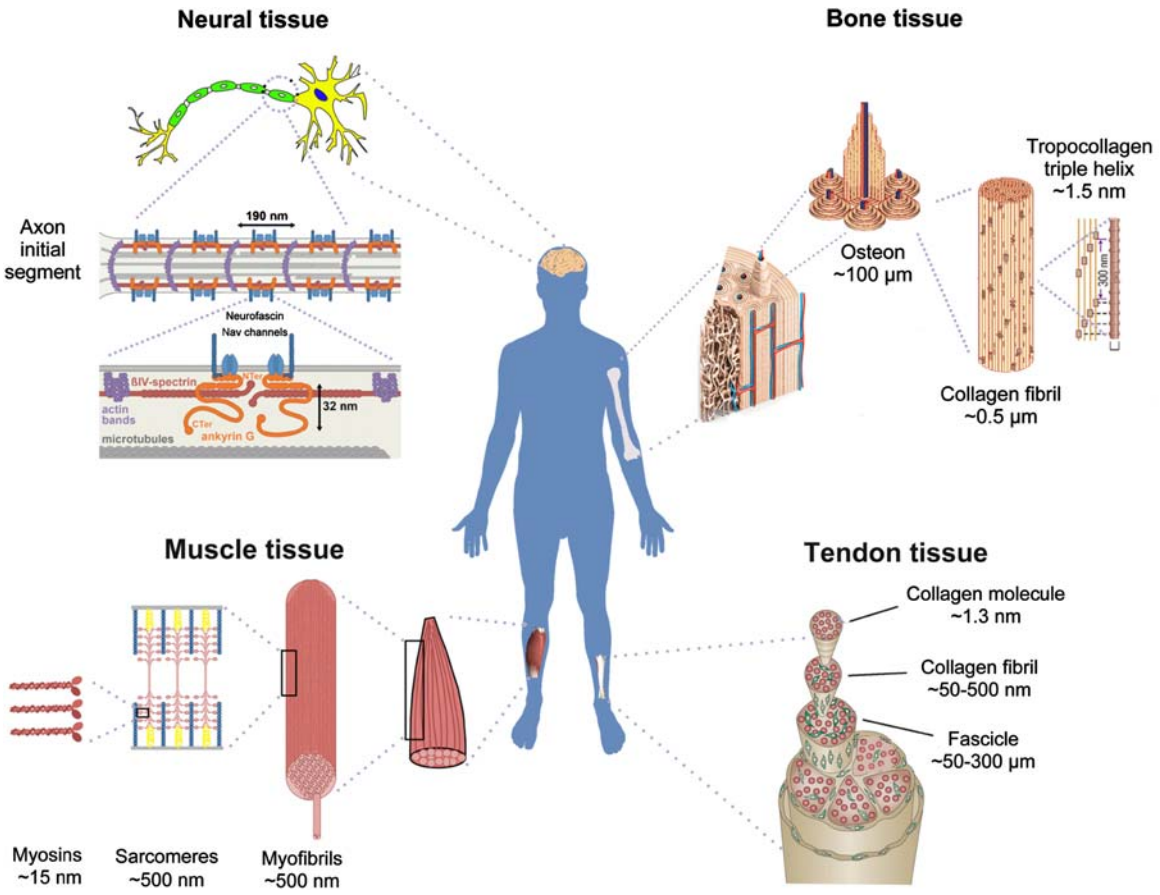

FIGURE 29.1 **Nanoscale features of human tissues.** In neural tissue, the axon initial segment is responsible for generating action potentials in neurons and is organized at the nanoscale. This structure is organized periodically in a longitudinal direction and is layered radially. This nanoscale architecture is crucial for neuronal function. (Adapted from Leterrier et al. [2].) The compact bone tissue consists of osteons (100 μm), which are composed of reinforced fibers formed by aggregated type I collagen and calcium phosphate nanoparticles (Adapted from Wegst et al. [3].) In muscle tissue, myofibrils are aligned in parallel and are composed of sarcomeres. The sarcomeres consist of protein filaments composed of actin and are arranged in a direction parallel to thick filaments composed of aggregates of myosin. Myofibrils, sarcomeres, and myosin can have nanoscale dimensions. In tendon tissue, a tendon fiber is composed of a hierarchical structure of tendon fibers, fascicle, and nanoscale collagen fibrils (50–500 nm), which are further composed of collagen molecules (~1.3 nm). *Adapted from Nourissat G, Berenbaum F, Duprez D. Tendon injury: from biology to tendon repair. Nat Rev Rheumatol 2015;11:223–33.*

PROPERTIES OF NANOMATERIALS

One aim of regenerative medicine is to embed cells in synthetic or natural scaffolds to produce functional tissues or organs. In the body, cells interact closely with the nanostructured extracellular matrix (ECM), where these nanoscale topographical features can direct cellular growth, adhesion, motility, and differentiation [5]. Cells also adhere to proteins located in the nanofibrous ECM, such as laminin and fibronectin, by their nanoscale receptors such as integrins and cadherins [11]. To fabricate biomimetic scaffolds that can be used to improve tissue regeneration, nanomaterials such as nanoparticles, nanofibers, and nanofilms have been developed to mimic the composition and structure of tissues at the nanoscale [4,5]. These nanomaterials possess distinguished physicochemical, optical, magnetic, and electrical properties compared with their bulk-level counterparts [12] (Fig. 29.3). Next, we will discuss these unique properties of nanomaterials that have enabled novel applications to develop functional tissues, targeted delivery, and in vivo stem cell imaging for tissue regeneration.

Physical Properties

The physical properties of natural systems, such as their size, shape, and surface topography, are directly related to their function. For example, the discoidal shape of erythrocytes promotes its mechanical flexibility and

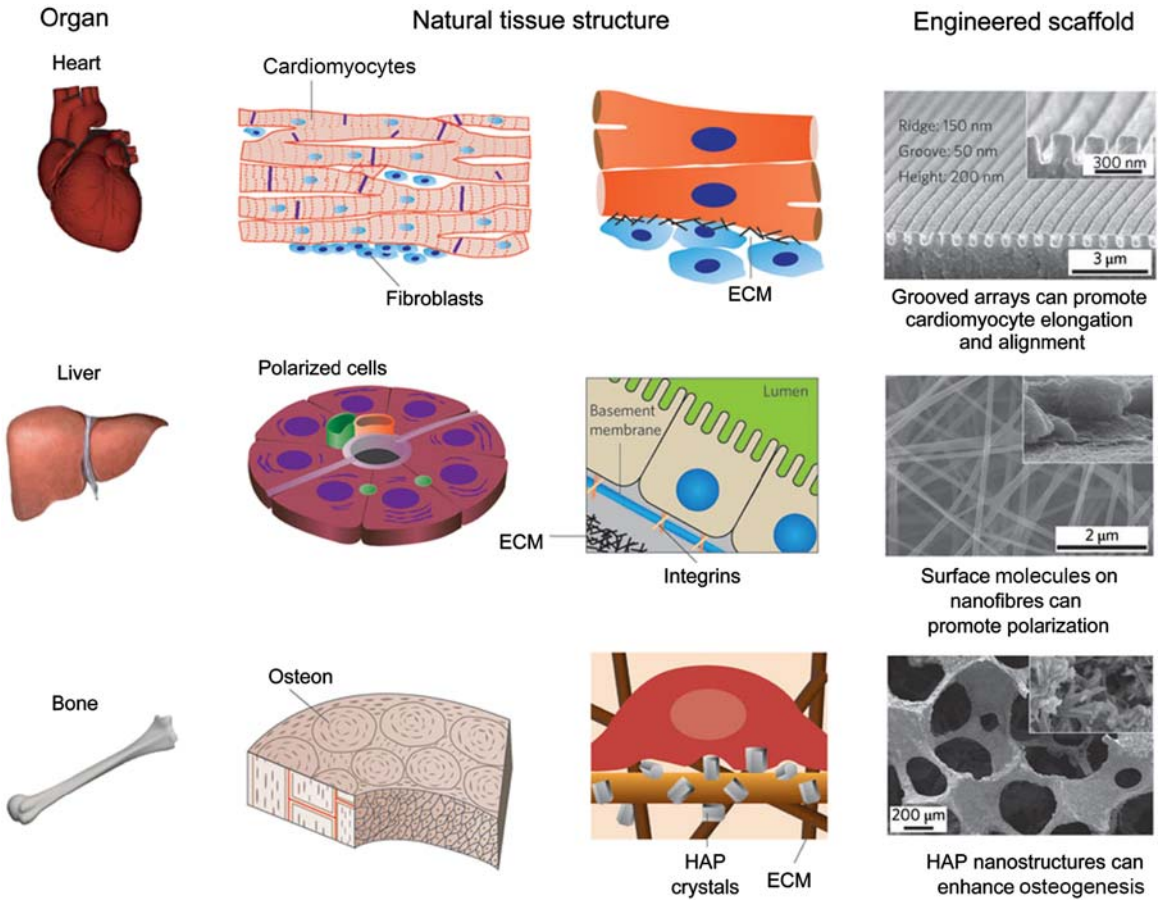

FIGURE 29.2 **Engineering nanostructured scaffolds for human tissues.** Heart tissue is composed of elongated and aligned cardiomyocytes that are mechanically coupled with the nanostructured extracellular matrix (ECM) to form anisotropic syncytium. Nanogrooved structures can be formed on substrates to promote the alignment of cardiomyocytes for cardiac tissue engineering. Liver tissue is composed of polarized epithelial cells between the ECM, lumen, and other cells for efficient mass transfer. This tissue polarity can be recapitulated on nanofibers by surface modification to enhance cell adhesion. Bone tissue is a composite of collagen and hydroxyapatite (HAP) nanocrystals. A bone-mimetic scaffold composed of HAP can promote osteogenesis and bone formation. *Adapted from Dvir T, Timko BP, Kohane DS, Langer R. Nanotechnological strategies for engineering complex tissues. Nat Nanotechnol 2011;6:13–22.*

biorheological properties and allows them to traverse blood vessels as small as 2–3 μm [13,14]. In addition, the surface texture of cell substrates, particularly at the nanoscale, can influence various cellular processes such as differentiation, motility, spreading, and apoptosis [13]. For example, epithelial cells grow in an elongated form on surfaces patterned with nanoscale grooves and ridges, whereas these cells have a rounded morphology on smooth surfaces [11]. These observations have promoted the development of nanomaterials with novel physical properties for applications in regenerative medicine.

Size

The delivery of drugs, genes, and peptides to a specific tissue can enhance drug efficiency while lowering systemic side effects; it is a useful approach in regenerative medicine for treating diseased or damaged tissues [5]. The small size of nanoparticles results in favorable properties compared with microparticle-based delivery methods, such as improved circulation and the ability to cross tissue barriers [15]. The size of the nanoparticle is correlated with the efficiency of cellular uptake and is determined by the avidity of ligand–receptor interactions between the nanoparticle and the cell surface [16]. In the range of 5 nm, nanoparticles cannot bind a sufficient number of receptors to induce membrane wrapping for efficient uptake. However, nanoparticles of sizes 50 nm or greater can bind multiple receptors but can limit the additional binding of nanoparticles. These properties can vary according to the cell type and culture conditions, which can cause variations in the number of receptors and internalization mechanisms [16].

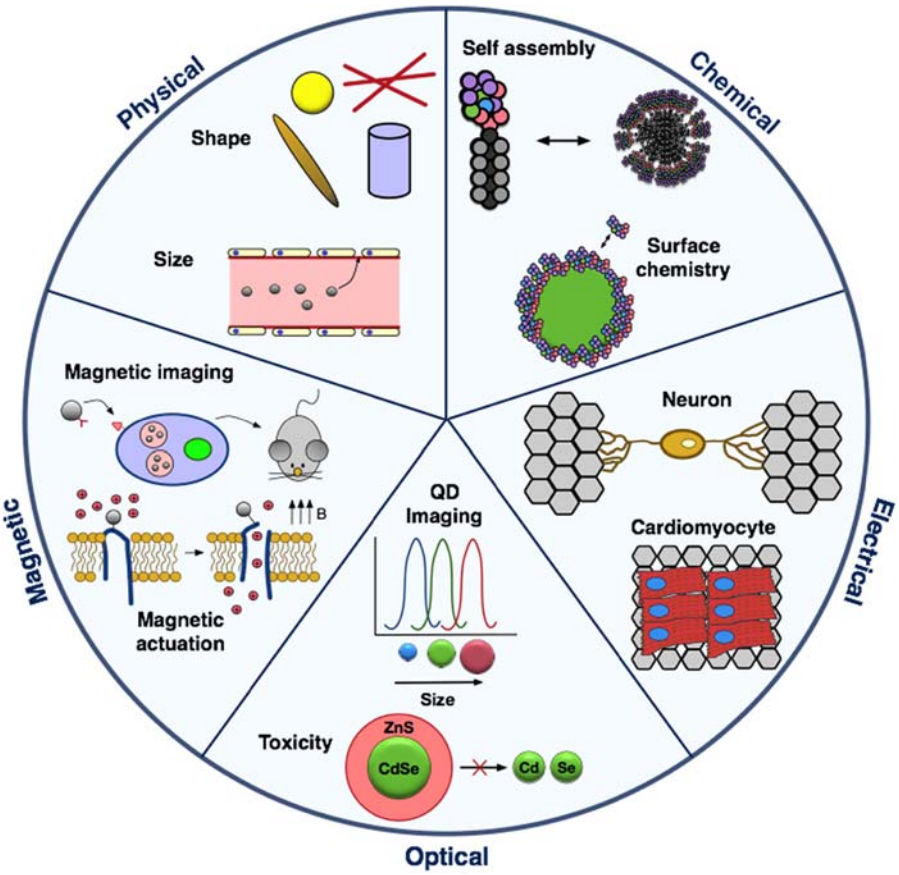

FIGURE 29.3 **Physicochemical properties of nanomaterials.** The unique physical features of nanomaterials include their size and shape. The small size of nanoparticles allows them to traverse tissue barriers. The shape of nanoparticles can vary from particles to fibers, needles, and tubes. These nanomaterials can self-assemble into a larger structural unit based on covalent or noncovalent interaction. For example, peptides with an amphiphilic structure can self-assemble into tubular structures. The high surface area and reactivity of nanoparticles can promote protein adsorption, which can affect their biological properties. Electrically conductive nanomaterials can be applied to restore the electroactive function of tissues such as nerve and heart. The optical properties of quantum dots (QDs) create variations in color according to size properties. The toxicity of QDs can be minimized by coating with a bioinert ZnS layer. The magnetic nanoparticles can be used for magnetic resonance imaging and can control magnetic actuation of individual receptors with a magnetic field (*B*).

The regeneration of brain tissue is particularly limited by the extremely low permeation rate (<1%) of small drugs or peptides, such as neurotrophins, through the blood–brain barrier (BBB) [17]. This barrier is formed by tight junctions between blood vessel endothelial cells (ECs), which restrict the passage of solutes [17]. To pass the BBB, gold nanoparticles (AuNPs) can be a potentially powerful drug carrier owing to their small size. In particular, 15-and 50-nm AuNPs could accumulate in the brain [18], which demonstrates their possible use in crossing the BBB for drug delivery applications.

Shape

The anisotropy and shape specificity of biological interactions are a critical parameter for functions at the cell, tissue, and organ levels [19]. For example, hydroxyapatite (HAP) ($Ca_{10}[PO_4]_6[OH]_2$) nanoparticles with a needle shape incorporated in a polycaprolactone (PCL) scaffold can promote osteoblast differentiation compared with rod or spherical-shaped HAP owing to their improved mechanical strength [20,21]. Therefore, the modification of nanoparticles into specific shapes such as cylinders, rods, and tubes has resulted in novel applications for tissue engineering.

In some cases, the shape of a nanoparticle can have a more significant effect than size on its functionality. For example, although micrometer-sized particles are cleared rapidly from circulation, 18-μm-long filomicelles with two nanoscale dimensions (20–60 nm) have a dramatically improved circulation half-life (∼5 days). This unique property allows filomicelles to cross tissue barriers such as in the spleen and to evade phagocytosis and degradation by the mononuclear phagocyte system (MPS) [22].

The incorporation of anisotropic nanostructures using materials such as carbon nanotubes (CNTs) and nano-HAP into scaffolds can also mimic the anisotropic structure of the ECM to provide ex vivo cues for tissue development [19]. For example, collagen fibrils in the ECM can be hundreds of micrometers long with diameters on the nanoscale (10−300 nm) and their longitudinal orientation results in high tensile strength. Similarly, CNTs have a high aspect ratio and their aligned structure in polymer scaffolds can impart high mechanical strength to scaffolds [23,24].

Surface Topography

Interest in adult and embryonic stem cells (ESCs) for applications in regenerative medicine has grown considerably, particularly for their ability to differentiate into multiple cell types to produce new tissues [25]. Materials with nanoscale topography can control cell behavior [25], based on the similar mechanism that cells can detect physical and topographical cues at the nanoscale of the ECM, such as cross-linking patterns, fiber length, fiber diameter, and surface irregularities [26]. This interaction occurs at the level of individual receptors on the cell surface, such as the transmembrane, heterodimeric protein receptors consisting of α- and β-integrin subunits [27]. These physical cues can guide cell orientation, adhesion, and differentiation, which are essential for the formation of functional tissues [5].

In a process termed "nanoimprinting," the shape and topography of the substrate (e.g., grooves, ridges, pits) can induce a similar shape in cells through integrin clustering and cytoskeletal reorganization [27,28]. For example, a nanoimprinted surface of grooves and ridges could promote the neurite growth and alignment of dorsal root ganglion neurons, which is a useful approach to sensory neuron regeneration [29]. The scale length of the substrate is also correlated with cell activity, because nanoscale island shapes ranging from 10 to 20 nm can promote cell adhesion and spreading of fibroblasts, mesenchymal stem cells (MSCs), and ECs, whereas a size of 100 nm can inhibit cell spreading and differentiation [27]. In accordance with this general observation, a spacing of 15 nm could promote the osteogenesis of MSCs owing to optimal integrin clustering [30].

Cell−substrate interactions can induce mechanical tension (i.e., mechanotransduction) and nuclear reorganization through cytoskeletal tension, resulting in gene expression changes that influence stem cell differentiation and function [31]. The influence of mechanotransduction on gene expression is a result of multiple synergistic effects such as the increased access of transcription factors to DNA, the alteration of nuclear pores for messenger RNA transport, and transcription complex formation [32]. A number of pathologies result from the loss of mechanotransduction, such as osteoporosis, cancer, and arteriosclerosis, which demonstrates its importance in cellular function [33].

In addition to physical signals, the interaction of cells on nanostructured substrates can induce chemical signals, particularly through the integrin-linked signal cascade [32]. The binding of integrin receptors to motifs in the ECM (e.g., the arginine-glycine-asparate [RGD] motif in fibronectin, vitronectin, and laminin) results in their clustering into supramolecular complexes, called focal adhesions [34]. The focal adhesion kinase (FAK) protein, which is a nonreceptor tyrosine kinase, remains constitutively bound at these sites through interaction with the β-integrin subunit. As an adhesion-dependent kinase, FAK can phosphorylate a number of molecules, such as the extracellular signal-regulated kinase (ERK) 1 and 2, to affect downstream cell signaling [32]. For instance, ERK 1/2 can translocate into the nucleus and modulate cellular activity by affecting transcription factor expression, such as the runt-related transcription factor 2, a key regulator of bone formation [32,35]. Evidence that the nanotopographical interaction of substrates can influence cell activity has promoted the development of novel nanostructured biomaterials for applications in bone and heart tissue regeneration.

Bone tissue is a nanocomposite structure of organic collagen nanofibers and inorganic materials such as HAP and whitlockite ($Ca_{18}Mg_2[HPO_4]_2[PO_4]_{12}$), which range in size from 20 to 50 nm in lamellar bone and 10 to 50 nm in woven bone [36−38]. However, conventional orthopedic bone implants are based on larger, micrometer-scaled grains, which can cause fibrotic tissue formation as a result of poor bone tissue integration [36]. The formation of a nanostructured coating layer on the surface of bone implant materials (i.e., ceramics and metals) can improve their biocompatibility and bioactivity by stimulating osteoblast adhesion, proliferation, and calcium deposition [5,36]. In particular, surfaces with random features at the scale of 100 nm can promote greater osteogenesis of human MSCs (hMSCs) compared with ordered surface, and can be incorporated into biomaterials for improved bone−material contact [27,39,40].

The myocardium of the heart is composed of many different cell types, such as cardiomyocytes and fibroblasts, which interact with the nanoscale topographical and molecular structure of the surrounding ECM [11]. In particular, the nanoscale structural and mechanical cues of the ECM can promote mechanical coupling between cardiomyocytes to form aligned, elongated bundles to create an anisotropic syncytium [11]. However, the in vitro expansion of cardiomyocytes results in the loss of this native organization and can compromise features crucial to tissue

function, such as cell geometry and conduction velocity [41]. The formation of cardiac tissue constructs with nanoscaled grooves can recapitulate cardiomyocyte elongation and alignment found in vivo through increased contraction-mediated stress and cell spreading [41].

Chemical Properties

The surface atoms of bulk solids represent a small fraction of their total composition, so the external surface contributes minimally to their material properties. However, as the surface-to-volume ratio increases to the nanoscale, the surface chemistry becomes dominant, affecting chemical properties such as solubility, luminescence, and catalytic activity [42].

Surface Chemistry

As a result of their surface reactivity, nanoparticles can adsorb endogenous proteins on their surface when placed in biological environments [43]. In the blood circulation, nanoparticles adsorb serum proteins such as immunoglobulins, complement factors, and lipoproteins, which can act as an opsonin for recognition by the immune system ultimately to influence its biodistribution [44]. In particular, negatively charged nanoparticles have a reduced level of serum protein adsorption, which can increase their circulation half-life and reduce accumulation in the liver and spleen [45,46]. In contrast, positively charged nanoparticles rapidly adsorb serum proteins, which act as a signal for clearance by the MPS in the spleen and liver [16]. For this reason, the grafting of hydrophilic polymers such as poly(ethylene glycol) (PEG) is a promising strategy for improving circulation time by blocking protein adsorption through steric hindrance [47].

The internalization of nanoparticles into cells also depends on its surface charge. In particular, positively charged nanoparticles demonstrate efficient cell uptake ability compared with neutral or negative nanoparticles because of favorable electrostatic interactions with the negatively charged cell surface [16]. The interaction with positively charged particles can induce local fluidity of the phospholipid bilayer, indicating a potential mechanism for the transportation of absorbates across the cell membrane [48].

Self-assembly

Nanostructures can be formed through the self-assembly of intricate and ordered structures through weak noncovalent forces such as ionic bonds, hydrogen bonds, hydrophobic interactions, and van der Waals interactions [49]. This bottom-up approach to the formation of supramolecular architectures such as collagen, keratin, and coral is common in nature and can be harnessed to fabricate novel biomaterials [49]. For example, amphiphilic peptides can form β-sheet structures through complementary interactions between their hydrophobic and hydrophilic surfaces. These nanoscale fibers (10−20 nm in diameter) result in an interwoven matrix and can function as a cell scaffold for tissue regeneration [49,50]. In particular, these scaffolds can mimic the gross architecture of the ECM, with a small pore size (5−200 nm) and high water content, which allows growth factors and nutrients to diffuse slowly and cells to reside in a three-dimensional (3D) environment [49].

Optical Properties

The transplantation of stem cells is an emerging therapeutic strategy in regenerative medicine to guide tissue regeneration [12]. An important factor in this approach is the development of noninvasive, biocompatible, and long-term strategies for monitoring stem cell proliferation, differentiation, and incorporation into the target tissue [12]. The development of nanomaterials such as quantum dots (QD) has enabled cell-specific imaging techniques with high spatial resolution and sensitivity for stem cell−based therapies [12].

QDs are colloidal semiconductor nanocrystals composed of compounds such as cadmium sulfide, cadmium selenide (CdSe), and indium phosphide [51]. At the scale of QDs (a few nanometers), quantum effects become more prominent, producing advantages over traditional fluorophores, such as an increased fluorescence life span and high fluorescence intensity [12,51]. These unique advantages can enable the long-term labeling of stem cells after they are transplanted or injected into the desired location. For example, QDs functionalized with RGD peptides remained labeled in hMSCs during self-replication and differentiation along adipogenic, androgenic, and osteogenic lineages [52]. In addition, QDs can enable the tracking of stem cells during their mechanical integration with surrounding tissue. The delivery of QD-labeled hMSCs to the heart demonstrated clear spatial distribution without nonspecific targeting to neighboring cells and could be imaged after 8 weeks [53]. In addition, the emission

properties of QDs could be altered based on their size and composition, from blue wavelengths to the near-infrared region [54]. This unique property of QDs allows for multiplex imaging of various cell types in a single organism using multiple types of QDs. For example, ESCs can be labeled with multiple QDs ranging in emission from 525 to 800 nm and can be simultaneously imaged using a single excitation wavelength [55].

However, a high concentration of QDs can lead to toxicity issues such as malformations in embryonic development [55a]. The release of heavy metal ions such as Cd^{2+} or Se^{2-} from CdSe-based QDs or the generation of free radicals by photoirradiation can have a detrimental effect on cell viability [51,56]. Therefore, techniques to reduce the toxic effects of QDs, such as coating with bioinert ZnS to block the release of Cd^{2+} ions, are essential for future clinical applications [56,57].

Magnetic Properties

Magnetic nanoparticles (MNPs) are a class of nanomaterials composed of metals such as cobalt, nickel, and iron, with paramagnetic, ferromagnetic, or superparamagnetic properties [58]. In particular, superparamagnetic iron oxide nanoparticles (SPIONs) are promising for in vivo applications because they are composed of biocompatible iron metals and do not agglomerate because of a lack of mutual attraction [58]. These nanoparticles have multifunctional applications in regenerative medicine, such as stem cell tracking and nanomagnetic actuation of cell surface receptors.

The high sensitivity of SPIONs as a contrasting agent in magnetic resonance imaging (MRI) can enable more effective in vivo stem cell tracking [59]. The modification of SPIONs with transfection agents such as poly-L-lysine can promote efficient internalization into cells, reducing the need for high concentrations that can induce cytotoxicity [60]. The transfer of magnetic properties to cells may enable the systematic study of delivery methods, optimal engraftment approaches, and cell migration for applications in stem cell therapy [58].

In addition, MNPs can attach to the cell membrane and activate mechanosensitive ion channels when a strong magnetic field is applied, which can be used to control cellular processes [61]. In particular, physical forces such as pressure-induced strain can direct the differentiation of MSCs into various lineages such as bone, muscle, and connective tissue [61,62]. The advantage of MNPs in this approach is their small size, which can allow the mechanical actuation of individual cell receptors by an external magnetic field [61]. For example, MNPs can be targeted to the mechanosensitive potassium ion channel TREK with anti-TREK antibodies and could promote the osteogenesis of MSCs when applied with a cyclic (1-Hz) magnetic field [63].

Electrical Properties

The incorporation of nanomaterials such as CNTs and graphene can increase the conductivity of scaffolds to promote the regeneration of electrically active tissues [11]. For example, CNTs are a promising material for use in neural implants because they are highly conductive and can promote the transmission of electrical signals between neurons [5]. In particular, CNTs can interface closely with neuronal circuits and synapses and can promote the formation of functional synapses [64]. Graphene has also been used to produce 3D conductive scaffolds for neuroregeneration [65]. In a model of the mouse hippocampus, graphene-based scaffolds could promote the growth of neurons and enhance their branching and outgrowth [65].

Because heart muscle tissue is underlined with conductive Purkinje fibers, the incorporation of conductive nanomaterials is relevant for myocardial tissue engineering [66,67]. For example, the homogeneous incorporation of CNTs in gelatin-based scaffolds can improve cardiomyocyte adhesion, maturation, and alignment [67]. Furthermore, to provide conductivity in cardiac scaffolds for the improved electrical communication of cardiomyocytes, they can be coupled with conductive materials such as gold nanowires [68].

NANOBIOMATERIALS

Nanobiomaterials describe biomaterials with a size between 1 and 100 nm in at least one dimension [69]. A major advantage of nanobiomaterials is their high surface-to-volume ratio, which is important for wound healing applications because a minimal amount of material can be used to cover a large area of defect while providing an extensive surface area to deliver drugs [70,71]. Nanostructured biomaterials can also interact directly with nanoscale cell surface receptors and cellular components to provide instructive signals to the cell. Nanobiomaterials have also

been applied in regenerative medicine because they can recreate the composition and structure of the ECM at the nanoscale. Nanobiomaterials can also improve the properties of engineered tissue constructs, such as mechanical strength [11,72]. For example, nanoclay and nano-HAP have been widely used as reinforcing fillers to strengthen the mechanical stability of dental implants and articular grafts [73]. Therefore, nanobiomaterials have great potential in regenerative medicine based on their ability to direct cellular activity [74].

Nanobiomaterials can be classified as metallic, inorganic-based, carbon-based, polymeric-based, and biological protein−peptide-based, depending on their compositions (Table 29.1) [75].

Examples of metallic nanobiomaterials include AuNPs, silver nanoparticles, and iron oxide nanoparticles [75,76]. AuNPs are useful for their simple synthesis techniques, adjustable optical properties and good biocompatibility [77]. In addition, AuNPs can convert absorbed light into heat via a series of nonradiative electron relaxation dynamics [78,79]. For these reasons, they have been broadly applied in various applications, particularly drug delivery [80], photothermal cancer therapy [81], and cell tracking [82]. Advantages of silver nanoparticles include their antimicrobial and antiinflammatory properties, which are useful for combating infections; these properties are further enhanced by their large surface area [83]. Silver nanoparticles can also accelerate wound healing owing to their antimicrobial activity and can be used in artificial joint replacements by reducing the levels of proinflammatory cytokines and minimizing the wear of implants [84]. In addition, iron oxide nanoparticles are a type of magnetic nanoparticle that can be employed to transfect DNA and antisense oligonucleotides for gene therapy [85,86].

Inorganic based nanobiomaterials include mesoporous silica nanoparticles and HAP-based nanobiomaterials [75,76]. Mesoporous silica nanobiomaterials are widely used in regenerative medicine applications such as drug delivery [87] and gene delivery [88] owing to their good biocompatibility and highly porous framework. In addition, mesoporous silica nanobiomaterials can be manufactured into different shapes, such as rod-like particles, fibers,

TABLE 29.1 Examples and Applications of Nanobiomaterials

Classifications	Examples	Applications	References
Metallic nanobiomaterials	Gold nanoparticles; silver nanoparticles; iron oxide nanoparticles	Drug delivery; photothermal therapy (breast cancer, skin carcinoma, and leukemia); detection of inflammatory and degenerative disease; cellular labeling and separation	[80−82,104−108,85]
Inorganic-based nanobiomaterials	Mesoporous silica nanoparticles; hydroxyapatite-based nanobiomaterials; carbon-based nanobiomaterials	Drug delivery; gene delivery; intracellular pathogen treatment; dental restoratives; bone defect repair platforms	[88,93,109−113]
Carbon-based nanobiomaterials	Carbon nanotubes; graphene; nanodiamonds; buckminster fullerene	Drug delivery; photothermal ablation of tumors	[76,113a]
Polymeric-based nanobiomaterials	Natural polymer-based nanobiomaterials (sodium alginate, starch, hyaluronic acid, chitin/chitosan and derivatives, dextran, albumin, and gelatin); synthetic polymer-based nanobiomaterials (poly[D,L-lactic acid], poly[D,L-lactic-*co*-glycolic acid]), poly (hydroxylalkanoates), polycaprolactone, polyacrylamide, polyanhydride)	Drug delivery; gene therapy; sensing; tissue regeneration	[98−100,114,115]
Biological protein −peptide-based nanobiomaterials	Gelatin; albumin; elastin; milk protein; gliadin; legumin	Gene delivery; gene therapy; antimicrobial substances to treat brain infections; antimicrobial substances to treat infectious diseases; intracellular delivery of proteins	[101,103,116−119]

films, and hollow and solid nanospheres for various functionalities. For example, nanotubes can be differentially functionalized based on their outer and inner surface [89]. Furthermore, because HAP is the most common inorganic biomineral in bone tissue [90], HAP-based nanobiomaterials are a promising candidate for dental restoratives and bone defect repair platforms [91,92]. In general, HAP-based systems can be combined with collagen or elastin nanofibers to recreate the composition and structure of bone tissues to treat bone defect sites. These systems are often loaded together with antibacterial drugs or growth factors, particularly bone morphogenic protein-2, to further enhance bone tissue regeneration [93].

Carbon-based nanobiomaterials mainly refer to CNTs, graphene, nanodiamonds, and buckminster fullerene (C_{60}), which possess strong optical absorption, good electrical conductivity, and high mechanical strength [94,95]. In addition, the surfaces of these carbon-based nanobiomaterials can be functionalized by oxidation treatments or conjugation with bioactive molecules to improve their solubility and biocompatibility [96].

Polymer-based nanobiomaterials can be fabricated into different structures and compositions; they possess a range of properties that are suitable for wide applications in regenerative medicine, such as bone plates, drug delivery carriers, and tissue engineering scaffolds [97]. For example, the surfaces of polymer-based nanobiomaterials can be modified with ligands of bovine serum albumin, glutathione, transferrin, or alkane thiols to develop actively targeted drug or gene delivery systems for enhanced therapeutic efficiency in biomedical applications [98–100].

Polymeric nanobiomaterials can be further categorized into natural biological and synthetic polymer-based nanobiomaterials. Compared with synthetic polymer-based nanobiomaterials, natural polymer-based nanobiomaterials have better biocompatibility, which is beneficial for cell adhesion and tissue regeneration. However, natural polymer-based nanobiomaterials can exhibit poor mechanical properties, such as low strength and stiffness, which can result in the instability of polymer-based nanobiomaterials and burst drug release within biological systems [76]. In comparison, synthetic polymer-based nanobiomaterials have greater mechanical strength and improved structural integrity, but they generally have lower biocompatibility compared with natural polymer-based nanobiomaterials [75]. Therefore, the concept of blended polymeric nanobiomaterials composed of natural and synthetic polymer-based nanobiomaterials was devised to meet both of these biological and physical requirements [97].

Biological protein–peptide-based nanobiomaterials mainly include gelatin, albumin, elastin, milk protein, gliadin, and legumin [76]. Biological protein–peptide-based nanobiomaterials can be applied as nanocarrier systems because they are biodegradable, biocompatible, stable in blood circulation, and amphiphilic for favorable interactions with drugs and solvents [101]. In addition, biological protein–peptide-based nanobiomaterials have the flexibility to acquire desirable biophysical characteristics by surface modifications such as self-assembly or binding with other various nanomaterials [102]. For example, antimicrobial cationic peptides can be self-assembled into core-shell nanoparticles and have enhanced antimicrobial properties to treat infectious diseases with a high therapeutic index [103].

NANOTECHNOLOGY-BASED STRATEGIES IN REGENERATIVE MEDICINE

Bone Tissue

Bone tissue forms the human skeletal system of a vertebrate, supporting the whole body, protecting organs, producing blood cells, and storing minerals. Bone tissue can be maintained in a healthy state based on continuous bone remodeling processes [120]. Specifically, osteoclasts can dissolve weak and old bone regions by locally secreting acidic substances such as protons, whereas osteoblasts can form new bone tissues by secreting proteins such as collagen. However, disruption of these cell activities, as well as various bone diseases such as nonunion bone fractures, osteoarthritis, osteoporosis, or bone cancers, can cause pain and disability.

Bone minerals incorporated in implants are commonly used to treat bone defect sites [120a]. For instance, synthetic HAP is a widely used component of bone implants because it is similar in composition to natural bone minerals [120a]. In an organic–inorganic hybrid, HAP incorporated in a poly(lactic acid) (PLA) scaffold can be fabricated by homogeneously mixing these two components in an ether-based solution, using sonication and freeze-drying to maintain its nanostructure [72]. These polymeric constructs have a high porosity (>90%) that can enhance cell ingrowth and survival, and the incorporation of HAP nanocrystals can improve the mechanical properties of the hybrid scaffold [72]. Furthermore, these HAP nanocrystals increase the adsorption of proteins, such as fibrinogen or bovine serum albumin, which can promote the osteogenic differentiation of MSCs [6].

The surface nanotopography of bone implants can improve osseointegration, which is the formation of a direct interface between implant materials and bone. For example, by using colloidal lithography techniques, titanium rods can be patterned with 60-nm polystyrene semispherical protrusions to enhance bone–implant contact [121]. When this nanostructured implant was placed in a rat tibial bone defect model, it showed higher bone–implant contact compared with the nonpatterned control group. Interestingly, when the size of protrusions was increased to 120 nm, bone–implant contact decreased, which suggested an optimal size range for bone cell contact. In addition, the formation of a coating layer with osteogenic nanoparticles can further enhance bone regeneration. For example, implant materials such as polyether ether ketone and titanium have mechanical properties similar to that of bone and have been applied to treat bone in the clinic [122,123]. However, these materials are biologically inert and can separate from the surrounding tissues after implantation. In this respect, the formation of a coating layer with bioactive nanomaterials such as HAP nanoparticles can enhance the attachment and growth of osteoblasts, promoting osseointegration and bone regeneration [124].

Nanoparticle-based drug delivery can be also used to treat osteoporosis and bone cancer. AuNPs are a widely used drug delivery vector because of their low toxicity and capability for surface functionalization [80,77]. In addition, AuNPs are known to accelerate the osteogenic differentiation of stem cells while suppressing the formation of osteoclasts [125,126]. AuNPs can also be readily functionalized with biological molecules by surface modification [127]. For example, AuNPs can inhibit the activity of osteoclasts and load and deliver alendronate (ALD), an antiresorptive drug that can induce new bone formation by promoting the proliferation and differentiation of osteoblasts [128]. ALD-conjugated AuNPs can easily be obtained by mixing AuNPs with ALD solution [129]. These ALD-conjugated AuNPs can enter cells by endocytosis and can enhance the formation of trabecular bone when applied in osteoporotic mice. In addition, dextran-based lipid nanoparticles can be used to deliver anticancer drugs such as DOX [130]. This DOX-loaded polymeric nanocarrier has a curative effect on drug-resistant osteosarcoma cell lines through the accumulation of drugs in the cell nucleus. As a result, DOX-loaded nanoparticles can increase the apoptosis rate of osteosarcoma cells compared with applying DOX alone.

Muscle Tissue

According to its function and location in the body, muscle tissue can be divided into three types: skeletal, smooth, and cardiac muscle tissues [131]. Skeletal muscle is responsible for carrying out movements and maintaining the posture of the body [132]. Smooth muscle can support hollow organ contractility, such as the gastrointestinal tract, the bladder, and blood vessels [133]. Finally, cardiac muscle is the muscle of the heart, which is autonomically regulated to self-contract in rhythmic fashion for the whole life of the organism [134].

Diseases related to dysfunction of muscle tissue include age-related muscle dysfunction, muscular dystrophy, localized muscle fatigue, muscle dysmorphia, muscle fiber necrosis, and progressive muscle weakness [135–139]. In addition, common clinical situations such as aggressive tumor ablation and severe denervation can result in significant muscle tissue loss, which can require additional surgical reconstruction. However, only few treatments can restore damaged functional muscle tissues effectively [140]. Among these treatments, free tissue transfer is widely used in the clinic, which is the transfer of living tissue obtained from a specific region of the body (e.g., skin, bone, tendon, muscle, and fascia) to another damaged region of the body through anastomosis to facilitate the reconstruction of complex defects [141]. However, limitations exist with free tissue transfer, particularly morbidity of the donor site [140]. In this respect, nanotechnology-based engineered tissue can recreate nanoscale features of the ECM to replace damaged muscle tissues [142,143].

To regenerate muscle tissue, various nanotechnologies have been employed to assemble nanobiomaterials, such as electrospinning [144], polyelectrolyte thin film deposition [145,146], and cell sheet technology [147]. Electrospinning is a fabrication technique that can be used to create complex 2D and 3D structures, based on ultrafine nanofibers [148]. Various types of polymers including collagen, cellulose acetate, PLA, poly(lactide-*co*-glycolide) (PLGA), PCL, and polyvinyl alcohol can be electrospun with diameters ranging from smaller than 3 nm to over 1 μm [149]. The seeding of myoblasts on the surfaces of parallel nanofibers is analogous to the native histological organization of skeletal muscle tissue and is beneficial for generating aligned cell layers to enhance myogenic differentiation [150].

In thin-film deposition, gaseous, liquid, or sol-gel precursors of biomaterials are deposited onto a given substrate; the film thickness can be controlled to within few tens of nanometers [151,152]. For example, PEG-linked multiwalled CNT films with nanoscale surface roughness can be engineered using the thin-film deposition method. This nanostructured film can resemble the nanoarchitecture of the ECM, which can facilitate protein adsorption and stem cell attachment and promote the differentiation of hMSCs to the skeletal myogenic lineage [152].

In the case of cardiac muscle tissue, it allows for the continuous beating of the heart because of its high contractile strength and endurance and includes tissues such as the myocardium, endocardium, and pericardium [153]. The damage of cardiac muscle tissue can cause critical health issues such as stroke, aneurysm, and peripheral artery disease [154–156]. In addition, cardiac disease accounts for approximately 40% of global mortality [153]. Diseases and defects of the cardiac system include myocardial infarction, heart failure, cardiomyopathy, ischemic heart disease, congenital heart disease, hypertensive heart disease, and chronic heart disease [157,158].

Among these heart diseases, heart failure after a myocardial infarction (MI) is a major cause of death in the United States. In particular, approximately 3 million Americans experienced heart failure in 2015, and it is anticipated that 100,000 new cases will have been diagnosed in the following 5 years [159]. Total heart transplantation is a possible treatment for end-stage cardiac failure, but the lack of donor hearts is a major bottleneck for this approach. In addition, because damaged myocardial tissue caused by MI cannot undergo self-regeneration, the left ventricle cannot remodel successfully, resulting in heart failure [160]. The use of scaffolds that can repair the infracted tissues and regenerate new cardiac tissues based on patient cells can overcome the drawbacks of limited donor organs and immunological rejection [161].

Cell sheet technology is a nanotechnology that was developed to produce polymeric scaffolds for myocardial tissue engineering. This technique mainly depends on the use of poly(*N*-isopropylacrylamide) (PIPAAm), a biomaterial with a typical surface thickness less than 100 nm [147]. Because PIPAAm is a thermoresponsive polymer, when the environment is cooled to a temperature lower than the low critical solution temperature of PIPAAm (32°C), the material surfaces becomes hydrophilic and intact cells sheet can spontaneously detach and easily be harvested from the polymer substrate [162]. This scaffoldless cell sheet technology has been successfully applied for 3D myocardial tissue reconstruction by harvesting and layering cardiomyocytes, which suggests the advantages of nanoscale-thermoresponsive surfaces [147].

Vascular Tissue

Cardiovascular tissue has an important role in circulating blood for the transport of oxygen, carbon dioxide, nutrients, blood cells, and hormones, to maintain the homeostasis of human body. Because it is a vital organ of the human body to sustain life, disease and/or damage of vascular tissue can result in critical health issues. According to the Centers for Disease Control and Prevention (CDC), cardiovascular-related diseases resulted in over 596,000 deaths in 2011 which was the leading cause of death in the United States [163]. Therefore, artificial vascular grafts that can substitute for damaged blood vessels have been widely explored to treat these vascular diseases [164]. In particular, vascular grafts with nanostructured surfaces can promote cell adhesion and proliferation. For example, the surface roughness of PLGA vascular grafts can be controlled at the nanoscale through etching with NaOH solution. As a result, cell adhesion on this vascular graft is significantly enhanced, which can promote the proliferation of ECs and smooth muscle cells (SMCs) to improve tissue integration in vivo [165].

In addition, metal stents composed of titanium and nitinol are widely applied to treat vascular diseases such as atherosclerosis and superficial femoral artery stenosis, because of their durability and mechanical properties [166,167]. However, the adhesion of blood platelets on bare metal stents can result in in-stent restenosis [168]. To overcome this limitation, the surface of cardiovascular metal stents can be modified with nanopatterns to enhance the adhesion of human umbilical vein endothelial cells (HUVECs) for rapid reendothelialization in vivo. Because human blood vessels are formed from an inner layer of ECs as well as an outer layer of SMCs, nanopatterns that mimic the patterns of SMCs can be used to modify the surface of metal stents to promote endothelialization [168]. For instance, when fibril structures of nanoscale width (700 nm) were formed on stainless-steel stents using a femtosecond laser, the adhesion and proliferation of HUVECs were significantly enhanced. These surface-modified stents were almost fully covered by ECs within 30 days after implantation into an iliac artery–blocking model in a rabbit model.

Nanomaterial-based drug delivery can be also employed for the early detection and treatment of vascular diseases such as atherosclerosis and thrombosis, by targeting ECs or blood vessels [169]. In particular, dendrimers are highly branched globular macromolecules, and their multivalency enables the binding of multiple drug molecules to achieve a concentrated payload [170,171]. Dendrimers can be used for drug delivery by binding molecules on its surface or encapsulating drugs in their interior structure based on electrostatic or hydrophobic interactions [172]. For example, positively charged PEGylated dendrimers can electrostatically bind negatively charged heparins to treat deep vein thrombosis with increased circulation time [173]. When heparin was encapsulated in dendrimers,

the half-long period of heparin was more than doubled; this heparin−dendrimer complex could reduce 85% of thrombus in a rat jugular vein thrombosis model.

Neural Tissue

Neurons exist mainly in the brain and spinal cord and their nerves are distributed throughout the whole human body. Their function is to transmit and receive external and internal stimuli such as body temperature and light [174,175] and elicit responses in the form of action potentials [176]. The human nervous system is composed of two regions: the central nervous system (CNS) and the peripheral nervous system (PNS).

The CNS forms the brain and spinal cord and the PNS consists of nerves (autonomic, cranial, and spinal) that are connected to the CNS [177]. Unlike hard tissue such as bone, nerve tissue is a soft tissue and can easily be impaired. In fact, injury occurring in other tissues, such as bone fracture, are usually accompanied by nerve damage [178]. In addition, injuries of the CNS, such as cerebral ischemia, can result in neuronal death [179]. Similarly, neurological diseases such as Alzheimer disease (AD) can cause CNS disorders, resulting in memory impairment [180]. A main obstacle to treatment of the diseased or damaged CNS with drugs is the difficulty of passing through the BBB [181]. However, nanotechnology-based drug delivery strategy can be used to overcome this barrier to treat specific cells in the brain [182]. For example, AD, a chronic and progressive neurodegenerative disease, can be alleviated by rivastigmine. AD patients experience from memory loss, problems with language use, and emotion control; rivastigmine is known to improve or maintain their cognition and behavioral symptoms. To enhance the efficacy of this drug, poly(*n*-butylcyanoacrylate) (PBCA) nanoparticles with a polysorbate coating layer can be used as a nanocarrier [183]. PBCA is a biocompatible and biodegradable polymer that can entrap drugs to prevent rapid release [184]. Coating PBCA nanoparticles with polysorbate allows for efficient crossing of the BBB, because polysorbate can adsorb proteins such as apolipoprotein B/E, enabling uptake by the epithelial cells of brain capillaries by receptor-mediated endocytosis [185]. Based on this nanodelivery system, the concentration of rivastigmine in brain could increase more than three times after an intravenous injection in rats.

The PNS consists of nerves that connect the CNS, which extends to all regions of the human body. The injury of peripheral nerves interferes with communication between the CNS and damaged tissues, which can cause neuropathic pain and the functional loss of tissues. Nerve autografts are a substitute to repair injured peripheral nerve based on its low risk of immunological rejection and a rich amount of neurotrophic factors [186,187]. However, limitations of using autografts include the shortage of nerve autografts as well as donor site morbidity [188]. To overcome these limitations, scaffolds composed of aligned nanofibers can be used to treat PNS injury [189,190]. For example, aligned nanofibrous PLA scaffolds can be fabricated by electrospinning techniques. When neural stem cells (NSCs) are seeded onto this scaffold, their neurite outgrowth was parallel to the aligned PLA nanofibers. Interestingly, the neuronal differentiation rate of NSCs was higher for nanofibrous than for microfibrous scaffolds, which suggests that NSCs can preferentially interact with a nanostructured environment [189].

Other Tissue

Nanotechnology can be applied to other diseased or damaged tissues including cartilage, bladder, and skin. Because cartilage tissue lacks blood vessels and cells, it has a limited regenerative capacity [191], so external treatment is often required when damage occurs. Peptide amphiphiles (PAs) can be used to regenerate cartilage based on their capacity to bind a high concentration of cartilage growth factors. These PAs can self-assemble into supramolecular nanofibers with a high aspect ratio and can be designed to have a large number of binding epitopes for transforming growth factor-β (TGF-β), a chondrogenic growth factor. As a result, TGF-β−bound PA scaffolds can be used to direct the chondrogenic differentiation of MSCs to promote cartilage regeneration in vivo [192].

In addition, nanostructured scaffolds are applicable for bladder tissue regeneration. For example, nanoscale roughness can be generated on the surface of poly(ether urethane) and PLGA polymers by chemical etching to enhance the proliferation of urothelial cells and reduce bladder stone formation [193].

Skin is another important tissue because it acts as a barrier to protect interior tissues; serious health complications can occur when skin tissues are damaged by severe incisions or burn wounds. Because fibroblasts have an important role during the wound healing process by dissolving fibrin clots, producing collagen and ECM structures, and retracting wounds [194], nanofibrous scaffolds that support the growth of fibroblasts can be beneficial for skin regeneration [195]. For example, human dermal fibroblasts can proliferate on biodegradable nanofibrous scaffolds composed of poly(L-lactic acid)-*co*-poly(caprolactone) and gelatin and can improve collagen secretion.

NANOTECHNOLOGY-BASED STEM CELL THERAPY

Stem cell–based therapeutics can improve the treatment of human diseases [196]. The use of nanotechnologies to control stem cell fate accurately, improve in vivo delivery and integration, and promote expansion and proliferation has led to rapid advances in stem cell therapy in regenerative medicine (Fig. 29.4).

Stem Cell Transfection

Stem cells can be directed into multiple lineages to replace damaged tissues to restore their vital functions. Therefore, the ability to control stem cell fate in a precise manner has promoted therapeutic applications for regenerative medicine. This control is particularly crucial in clinical applications, because transplanted cells often have low viability and occasionally form malignant teratomas [197]. In particular, stem cell differentiation can be regulated by gene delivery using viral transfection [196]. Although viruses such as retroviruses, lentiviruses, and adenoviruses are highly efficient gene delivery vectors, they are limited because of high manufacturing costs and the potential for an immunogenic response [196].

The use of nanoparticles offers several advantages for the delivery of these factors compared with viral vectors, such as low immunogenicity, the ease of fabrication, and high gene loading efficiency [196]. Therefore, the in vivo delivery of genetic cues by nanoparticles can improve the therapeutic effect of stem cells by directing their differentiation into a specific cell type [196].

Stem cells are a useful approach to treating ischemic diseases because they can release angiogenic factors including vascular endothelial growth factor (VEGF) or participate directly in the formation of new blood vessels (i.e., vasculogenesis) in the case of endothelial precursors [198,199]. However, stem cell viability after transplantation is low, and their ability to form new blood vessels is limited owing to insufficient angiogenic gene expression [199]. To promote the angiogenic phenotype of hMSCs, the gene encoding VEGF can be delivered using biodegradable poly(β-amino ester) nanoparticles [199]. The transfection efficiency of this approach was superior to physical methods (e.g., electroporation) or other nonviral vectors (e.g., lipofectamine), and the transplantation of these

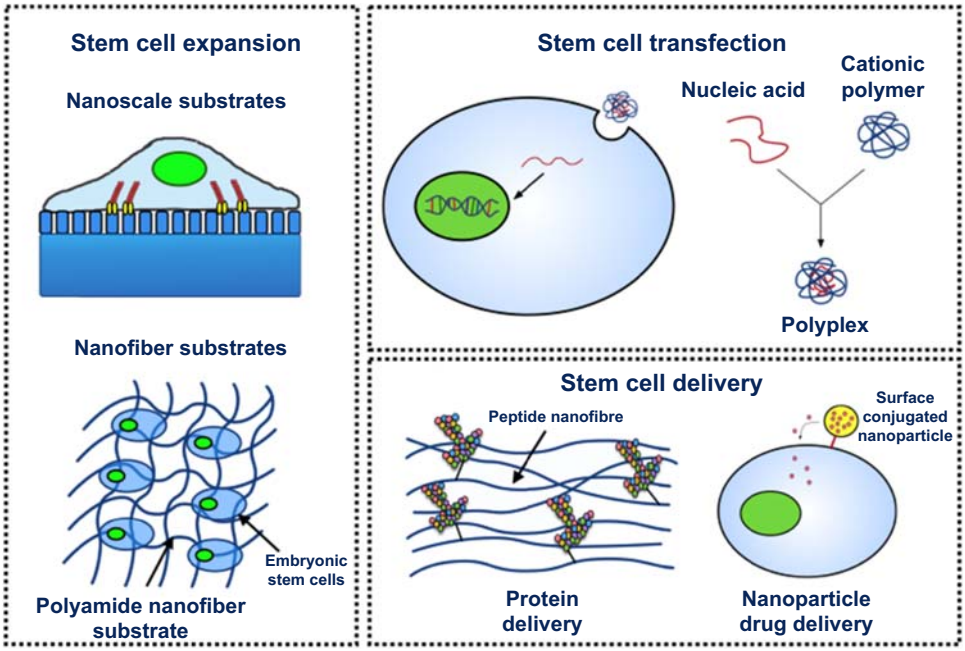

FIGURE 29.4 **Applications of nanotechnology for stem cell therapy.** Stem cell expansion in vitro can be promoted by nanoscale substrates, which can maintain their differentiation potential. Embryonic stem cells can be grown on polyamide nanofiber substrates to maintain their pluripotency and promote their proliferation. Stem cell transfection with nonviral polyplexes, which are nanoscale complexes of cationic polymers and anionic nucleotides, can enable genetic modification before implantation. Nanofiber substrates can also be used to enhance the recruitment of stem cells in situ by covalently attached peptides. Drug-loaded nanocarriers can be conjugated onto the cell surface and can improve stem cell delivery and promote their repopulation in vivo.

genetically modified stem cells could promote neovascularization in an ischemic mouse model [199]. These types of nanoparticles are termed polyplexes; they are formed by the interaction of a cationic polymer such as chitosan or polyethylenimine with negatively charged DNA to form structures with sizes of tens to hundreds of nanometers [200]. The close interaction of the polymer with DNA can promote its intracellular delivery and protection from degradation, resulting in transfection efficiency comparable to viral vectors [199,200].

Stem Cell Delivery

In addition to secreting trophic factors to promote tissue regeneration, transplanted stem cells can participate directly in the building of new tissues [201]. For example, after ischemic injury of the mammalian heart, MSCs can migrate to the myocardium to initiate repair by differentiating into cardiac muscle [202]. The integration of stem cells with host tissue requires multiple factors such as efficient migration from the site of injection, high cell viability, and effective engraftment into the target tissue [201]. However, the delivery of stem cells by injection, either systematically or at the tissue site, can result in high cell death and limited migration, resulting in low engraftment efficiency [201].

The incorporation of stem cells in a scaffold can improve the efficiency of transplantation by acting as a template to guide tissue regeneration, which can degrade simultaneously with the formation of new ECM by proliferating cells [201]. In particular, scaffolds based on nanofibers have a large surface area and high porosity and can affect cell behavior through interaction with nanoscale topographical features. These scaffolds can be constructed by electrospinning synthetic polymers such as PCL and PLA, or natural polymers such as chitosan and collagen, using an electric field on a rotating plate substrate [196]. In addition, nanofiber-based scaffolds can present bioactive factors to promote in situ tissue regeneration from the body's own stem cell and progenitor cell population [203]. In particular, to increase the adult stem cell population at the target tissue to accelerate tissue regeneration, they can be mobilized to the target site by cytokines and chemoattractants [203]. For example, stromal stem cell−derived factor-1α can be covalently bound to nanofibers composed of self-assembling peptides and can recruit endothelial progenitor cells for improved cardiac function by increased neovascularization [203,204].

The delivery of therapeutic stem cells often requires the concurrent delivery of adjuvant drugs such as TGF-β signaling inhibitors and γ_c receptor cytokines, which can promote their differentiation into an optimal therapeutic phenotype and enhance immune reconstitution [205]. However, the high dosage and systemic delivery required for these factors can cause toxicity issues because of their pleiotropic effects [205]. A clinically applicable alternative is to conjugate drug-loaded nanoparticles onto the cell surface, which can deliver low drug doses locally and follow the cell's migration patterns. For example, nanoparticles conjugated onto hematopoietic stem cells (HSCs) can locally release a glycogen synthase kinase-3β inhibitor to enhance the reconstitution of the HSC graft [205].

Stem Cell Expansion

The general protocol for regenerative therapies involves harvest of a patient's stem cells, expansion under in vitro conditions, and reintroduction into the patient to initiate regeneration [206]. However, stem cells such as MSCs show a decline in differentiation potential after prolonged passaging under in vitro conditions [207]. Therefore, the propensity of MSCs to differentiate spontaneously into a heterogeneous fibroblast phenotype on tissue culture plastic limits their clinical applications [206]. These limitations have prompted the development of nanoscale cell−material interfaces to direct the differentiation and growth of MSCs. In particular, the surface topography can regulate the balance of cell adhesion and cytoskeletal tension to affect the expression of MSC-specific markers such as CD63 [206].

In addition, a major bottleneck for stem cell therapy is the requirement for a large quantity of undifferentiated stem cells, especially to regenerate bulk tissues or organs [208]. This process is limited by the slow doubling times of stem cells, which can range from 36 h for human ESCs to 45 days for human HSCs [208]. Stem cells reside in specialized niches in vivo that promote their extensive self-renewal, so mimicking this environment ex vivo is a powerful approach to promoting stem cell expansion [209]. For example, the topography and texture of the basement membrane can be recapitulated on polyamide nanofibers and can promote the expansion of murine ESCs while retaining their differentiation potential [210]. The stem niche also contains multiple growth factors, including leukemia inhibitory factor and stem cell factor, which are sequestered in the ECM and can be presented to cells [209]. To mimic this microenvironment, growth factors can be covalently attached to nanofibers to prevent their degradation and can promote the expansion of stem cells such as human ESCs [211].

CONCLUSION

Nearly every human tissue has a nanostructure, and these nanostructures can influence cell activity such as cell adhesion, viability, and differentiation. Since the concept of nanotechnology was first proposed in 1959, this research field has developed rapidly for applications in regenerative medicine [212], especially in the fabrication of nanobiomaterials and nanoscale delivery systems. Nanomaterials can have a controlled shape, size, and topography that can be used to mimic the nanoarchitecture of tissue-specific ECM to direct cellular activity. Because of their small size and high surface area−to-volume ratio, nanomaterials can be internalized into cells to carry a large amount of growth factors and drugs. Nanomaterials with unique optical, magnetic, and electrical properties also can be used to track cells, stimulate cellular differentiation, or build functional tissue scaffolds. Depending on their composition, nanobiomaterials can be categorized as metallic-based, inorganic-based, carbon-based, polymeric-based, and biological protein−peptide based nanobiomaterials. These nanomaterials have been widely explored for potential applications in regenerating multiple types of tissues, including bone, muscle, cardiovascular, neural, cartilage, bladder, and skin, by creating nanopatterned tissue scaffolds or delivering biomolecules across tissue barriers. In particular, drugs, peptides, or nucleic acids can be delivered to a specific tissue, organ, or cell with high targeting efficiency, based on nanoscale delivery systems. In addition, nanomaterials can be used to track, deliver, and expend stem cells accurately, which are crucial factors for future clinical applications of stem cell−based regenerative therapies. We expect that advances in nanotechnology will contribute continuously to the field of regenerative medicine in the future.

Design Principles in Biomaterials and Scaffolds

Yang Zhu, William R. Wagner

University of Pittsburgh, Pittsburgh, PA, United States

When tissue deficiencies occur as a result of trauma, disease, or congenital conditions, there is a desire to provide functional replacement tissues to the patient. The use of autografts is ideal when this option is available and is often applied for both soft and hard tissue defects with a broad variety of approaches, although donor site morbidity is a problematic consideration. In many cases, such donor tissue is not available and allotransplantation is favored, albeit with the frequently accompanying disadvantages of a limited donor supply and immunosuppressive therapy. In tissue engineering, a central concept is the application of a temporary biomaterial scaffold at the defect site to facilitate healing that will provide some restoration of functionality. If this scaffold is used to carry precursor cells or other features that may induce a functional healing, the outcome potential may be further improved. In designing such solutions for tissue repair and replacement, the parameters that define the scaffold must be selected and optimized to provide the best possible outcome. If cells are to be used, this adds further design (and regulatory) complexity. This chapter focuses on the design principles affecting degradable biomaterial scaffolds used in tissue engineering. Although acellular scaffold approaches are considered, the cellular component of seeded scaffolds will not be explicitly addressed; relevant considerations are covered elsewhere in this text.

FUNCTION AND APPLICATION-ORIENTED DESIGN OF BIOMATERIAL SCAFFOLDS

The objective for a given scaffold design is to meet the clinical needs for a specific application or set of applications. The better the understanding of the clinical need, including the underlying tissue physiology, disease pathology, and other impactful environmental parameters, the more appropriately the design parameters can be defined. As cellular and molecular biology knowledge have rapidly advanced and pathological processes are better defined, the ability to harness this knowledge in designing more advanced scaffolds has grown. The early use of temporary scaffolds in medicine was for simple mechanical support (e.g., sutures), whereas research efforts in recent decades have expanded the potential functional role that the scaffold can have, including the designed modulation of cell behavior and the incorporation of controlled release for bioactive agents.

Mechanical Support

Tissue loss and mechanical failure can be caused by various reasons, including disease processes, trauma, burn, surgical resection, and chronic inflammation. Biomaterial scaffold implantation may provide permanent or temporary mechanical support, hence maintaining the structural and functional integrity of the host tissue. In some reconstructive or cosmetic applications, the implanted scaffold role may be to improve aesthetics in addition to providing appropriate tactile or load-bearing behavior.

Mechanical support structures comprise a major part of the implantable biomedical device industry. Most of these devices are permanent and made from nondegradable metals and polymers. For instance, vascular stents are commonly nondegradable metallics such as nitinol, stainless steel, and cobalt-chromium [1]. Vascular grafts and abdominal wall meshes for hernia repair are often made from polyethylene terephthalate, polytetrafluoroethylene, polyurethane, and polypropylene [2,3]. In the orthopedic field, orthopedic screws and plates, staples, and other fixation devices are commonly stable metals [4,5]. However, each case, there has been substantial research and clinical

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00030-8

investigation of degradable scaffolds [6–8]. The general cited advantages of using degradable scaffolds are (1) the potential for new tissue regeneration, (2) the reduced chronic stimulus for inflammation and ongoing foreign body response, (3) elimination of a nidus for infection risk once the material has degraded, and (4) the potential for reduced thrombotic risk and the elimination of anticoagulant therapy for blood-contacting scaffold applications. Despite these advantages, degradable scaffolds have not effectively displaced permanent scaffolds for a variety of reasons. Common factors limiting broader adoption include a higher risk for mechanical failure [9,10], increased early inflammatory response, and concerns with local tissue effects from degradation products and by-products [11].

It is common in the tissue engineering literature to find a hypothetical graph in which a hypothetical mechanical parameter is plotted versus time with three curves: scaffold, new tissue, and net construct (or combined). The scaffold curve slopes downward with time whereas the new tissue formation curve increases. Usually these curves are matched so that the net level of the mechanical parameter is maintained during the healing process. Of course, in reality this is often not the case; scaffolds remain longer than needed and potentially stress shield the tissue. Of greater concern is scaffold mechanical failure when the new tissue is insufficiently strong to take on the required load (Fig. 30.1). This is a serious concern in that such mechanical failures lead to morbidity and mortality that have limited the broader adoption of many degradable scaffold approaches, as indicated earlier. Also, such mechanical failure may be related to the underlying disease process in the treated population that may not be apparent in preclinical testing or in the application of such an approach in other populations. Therefore, in addition to selecting biomaterial scaffold designs with appropriate initial mechanical parameters approximating the host tissue, matching the degradation rate of temporary scaffolds to tissue integration and maturation is greatly important. In fact, sophisticated models seeking to capture the underlying physics and biology are under development [12].

At a cellular scale, a great deal of research in has examined how the microscale mechanical properties of biomaterial scaffolds can modulate cell behavior. Biomaterial substrate stiffness affects stem cell differentiation, including mesenchymal stem cells, induced pluripotent stem cells, and embryonic stem cells [13–15]. Many molecular pathways involved in this process have been described [16,17]. In addition to stem cell effects, substrate stiffness has been shown to affect primary cell phenotypes, including the macrophage and its polarization [18,19]. Macrophages are important cells involved in the foreign body response; thus, substrate stiffness also relates to the host tissue response to scaffolds. Researchers have shown that biomaterial stiffness modulates the adhesion, migration, and proliferation for other types of cells, as well [20].

Given the mechanical support functions that are defined for a specific clinical application of a scaffold, together with the increasingly appreciated effect that mechanical parameters can have on host response and cell behavior, selecting materials with suitable mechanical parameters is usually the first step in scaffold design. Generally, metals and ceramics have high stiffness and strength (Fig. 30.2A and B), as do many composite materials containing these two major categories of biomaterials for scaffolding. Between the two, ceramics have the disadvantage of the risk for brittle fracture. In comparison, synthetic polymeric materials and naturally derived materials are usually weaker in all major aspects. However, polymers and naturally derived materials have lower densities; thus, the differences in specific modulus and specific strength between them and metals and ceramics are not as large. Because most human tissues have stiffness values below the gigapascal range (Fig. 30.2C) [21], metals and ceramics are commonly used in hard tissue replacements (bone and teeth) and applications in which smaller scaffold dimensions are desired (e.g., coronary stents), whereas polymers and naturally derived materials are more often used for soft tissue substitutes.

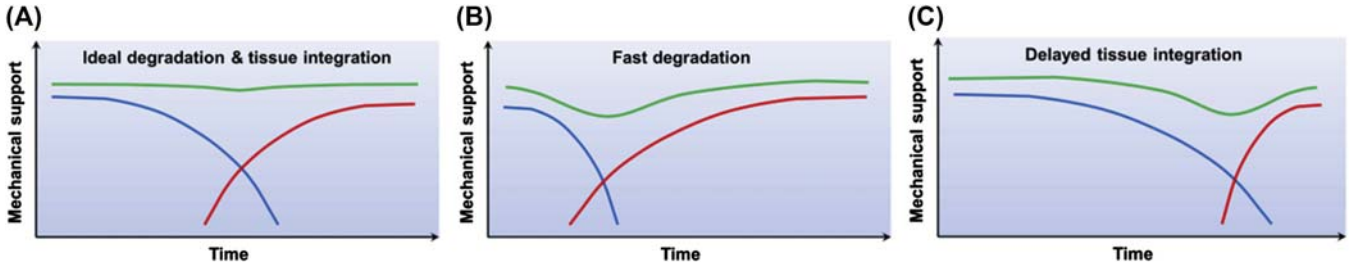

FIGURE 30.1 Mechanical support by scaffold–integrated tissue. The *blue line* indicates mechanical support by degrading scaffold; the *red line*, mechanical support by integrated tissue; and the *green line*, combined mechanical support by the scaffold–tissue combination. (A) Ideal matching between scaffold degradation and tissue integration. (B) The scaffold degrades too quickly and tissue generation is unable to compensate for some interim period, presenting a failure risk. (C) Slower scaffold degradation stress shields new tissue or prevents adequate cell migration and extracellular matrix (ECM) elaboration, leading to inadequate mechanical properties at a later time point.

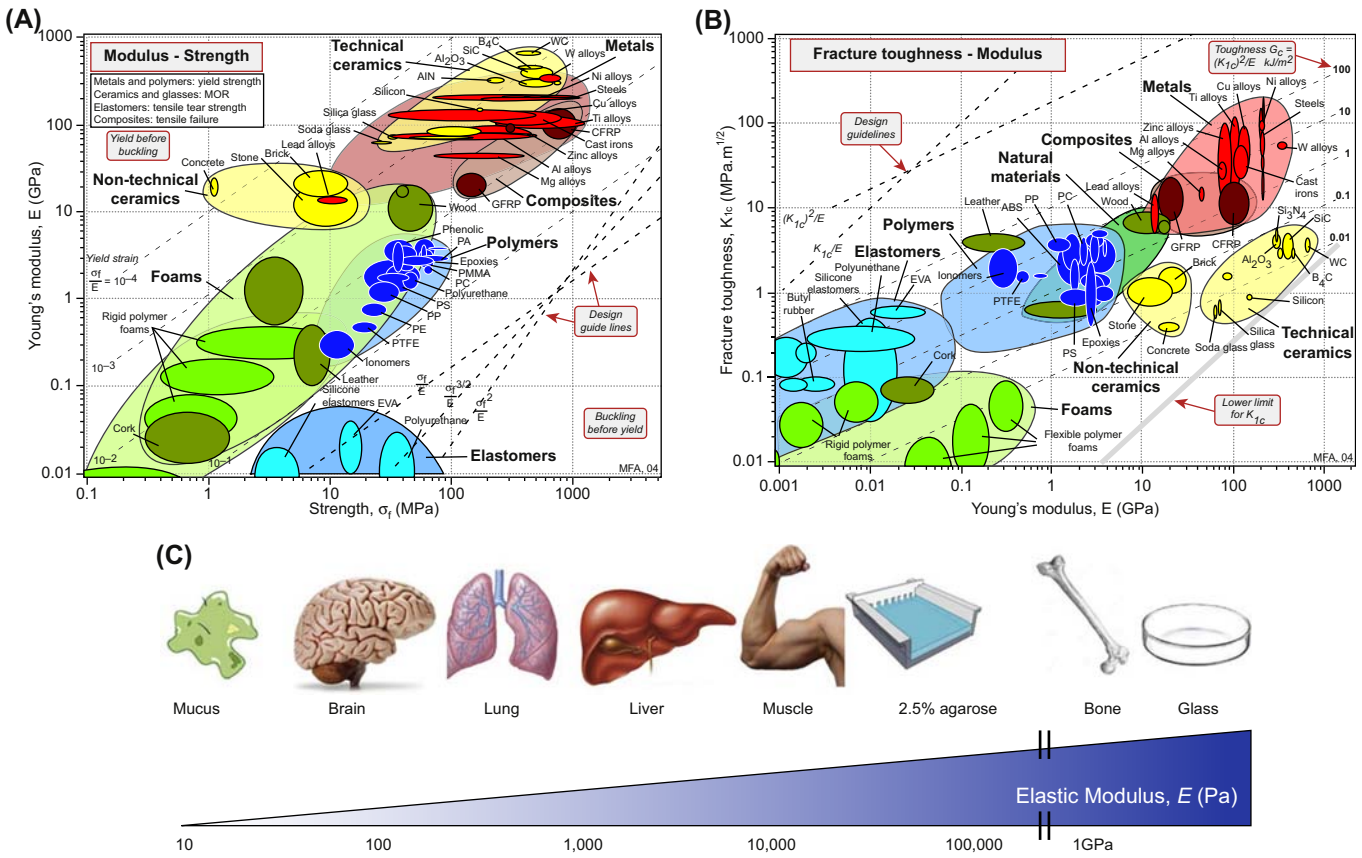

FIGURE 30.2 (A, B) Ashby chart of strength versus modulus. The "strength" for metals is the 0.2% offset yield strength. For polymers, it is the 1% yield strength. For ceramics and glasses, it is the compressive crushing strength, roughly 15 times larger than the tensile (fracture) strength. For composites, it is the tensile strength. For elastomers, it is the tear strength [22]. (C) Young's, or elastic, modulus of tissues [21]. *CFRP*, carbon fiber–reinforced thermoplastic; *EVA*, ethylene(vinyl acetate); *GFRP*, glass fiber–reinforced plastic; *MOR*, modulus of rupture; *PA*, phosphatidic acid; *PC*, phosphatidylcholine; *PE*, phosphatidylethanolamine; *PMMA*, poly(methyl methacrylate); *PP*, polypropylene; *PS*, phosphatidylserine; *PTFE*, polytetrafluoroethylene; *WC*, water cosolvent.

Degradation Profile

As noted previously, scaffold degradation is important for tissue integration and should be well-synchronized with the latter to maintain mechanical support in implantation sites. Aside from tissue integration, degradation can have a critical role in providing pathways for metabolite diffusion and angiogenesis, as well as the release of agents loaded into the material.

Degradation Mechanisms

The mechanisms at work in biomaterial scaffold degradation vary by material type. For polymeric biomaterials, the most commonly seen mechanism is hydrolytic cleavage of backbone bonds (ester, amide, urethane, and carbonate) in polymer chains by water molecules, producing oligomers and monomers with lower molecular weights and higher solubility (Fig. 30.3A) [23]. Enzymatic facilitation of such cleavage reactions can be an important factor in accelerating degradation in vivo, and the use of enzymes in degradation buffer solutions to study degradation in vitro is common. Polymer chains can also be cleaved by free radicals, irradiation, reduction reactions, and other reagents or stimulus, depending on the bonding mechanism [24–26]. Newer concepts in polymeric biomaterial degradation include increased solubility induced by side chain cleavage [27], self-immolating depolymerization [28], and the dissociation of supramolecular assemblies [29]. Metallic biomaterials are almost exclusively selected for their degradation (corrosion) resistance. However, a great deal of research has been focused on degradable metals such as magnesium and zinc alloys for use as temporary scaffolds in a broad variety of applications [30–32]. The corrosion process proceeds by coupled electrochemical reactions with electrolytes to produce oxides, hydrogen gas, hydroxides, or other compounds (Fig. 30.3B) [33]. A high concentration of Cl^- ions significantly accelerates

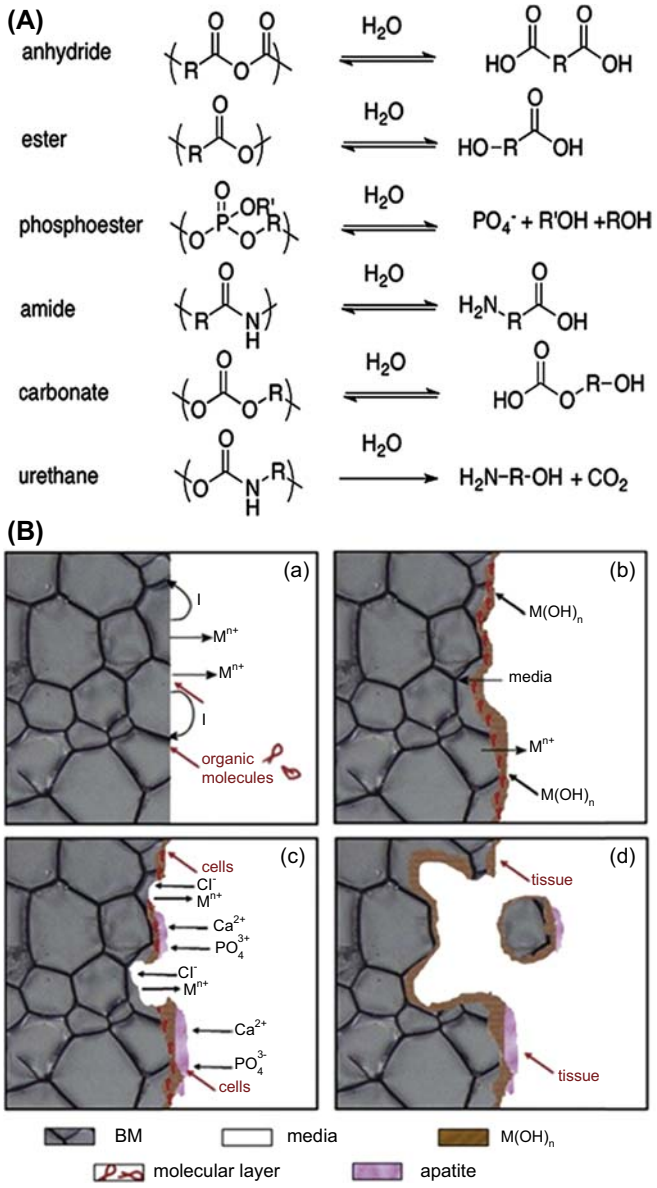

FIGURE 30.3 (A) Hydrolytically degradable linkages used in biomaterials. (B) Schematic diagram of biocorrosion at the biodegradable metal (BM)—medium interface [33].

the corrosion of metals. Cells are also subsequently involved in breaking down the metal substrate from the surface (Fig. 30.3B) [33]. The degradation of commonly used ceramic scaffolds (tricalcium phosphate, hydroxyapatite, and dicalcium phosphate) starts with the dissolution of CaP components, which is heavily affected by the solubility of the specific material. Various cell types (monocytes/macrophages, fibroblasts, and osteoblasts) are then involved in the degradation process by phagocytic mechanisms or via an acidic mechanism to reduce the microenvironmental pH that results in demineralization of the ceramic matrix and resorption [34]. For biologically sourced materials, specific enzymatic degradation has an essential role in degradation, and resistance to such degradation varies with the material composition, processing history and local tissue conditions.

Factors That Affect Degradation Rates

Several factors affect the degradation rates of biomaterial scaffolds, and these factors can be leveraged to modulate the degradation profiles of corresponding scaffolds. Most obviously, the molecular composition of the scaffold will dictate the degradation profile. For polymers with hydrolytically cleavable backbone bonds as introduced earlier, the bond type will heavily influence the degradation rate. For example, hydrolysis of anhydride bonds is

generally faster than ester bonds, which in turn is faster than amide and urethane bonds. Based on this effect, copolymerizing monomers that will result in different backbone bonds have been used to fine-tune the degradation rate of polyesters and other polymers [35]. The molecular environment around the labile bond and the relative density of labile bonds along the backbone are also important factors that can fine-tune the rate of degradation dramatically, despite maintenance of the same labile group. As a result, polyesters can vary as a class of polymer from very rapidly degrading to effectively nondegradable (e.g., polyethylene terephthalate). The hydrolytic cleavage of many of these susceptible bonds is acid catalytic and autocatalytic (degradation products of these bonds are acids); basic salts have been mixed with polyester substrates to slow down degradation whereas acidic monomers have been copolymerized purposefully to accelerate the degradation of polyesters [27,36]. Another obvious option in controlling polymeric scaffold degradation is to choose the initial molecular weight of polymer building blocks so that a greater or lesser number of cleavage events need to occur before solubility of the residual polymer is achieved.

For metallic scaffolds, innate factors affecting oxidation include the activity of the metal, phase organization (of alloys), impurities, the processing history, and the stability of the formed oxide layers [33,37]. For ceramics, the crystal type and degree of crystallinity are important parameters.

Enzymatic Degradation

Degradation on demand, or triggered degradation, is a concept receiving attention in the literature. For polymers, such triggers can include electromagnetic radiation, ultrasound, heating/cooling, or the delivery of a triggering molecule such as an enzyme. For metals, control of the oxidation/reduction reaction by the delivery of current is a ready means of control.

Looking at enzymatically triggered degradation, numerous examples of scaffolds employing this technique have been reported in which enzymes produced by the host tissue or delivered to the biomaterial scaffold accelerate degradation, particularly for naturally derived biomaterials and polymers. Matrix metalloproteinases, elastase, and other enzymes have been employed to cleave protein components in naturally derived biomaterials with high specificity, whereas enzymes such as hyaluronidase and glucanases cleave polysaccharides including hyaluronic acid, alginate, and chitosan. Some of these enzymes accelerate the degradation of synthetic polymers as well [38–42]. Segments of polypeptide, DNA, and other biomolecules have been deliberately covalently combined with synthetic materials at the molecular level or by physical mixing to provide cleavage sites for the composite scaffolds [43–45]. Because enzyme expression levels vary among tissues and some are specifically and temporally elevated in wound beds or sites of inflammation, they provide convenient local factors to be included and targeted in designing scaffold degradation profiles [46–48].

Surface to Volume Ratio

Scaffold morphology, particularly the ratio of the surface area to the volume, has a significant effect on the degradation of biomaterial scaffolds. Higher surface area ratios commonly lead to higher degradation rates of the scaffolds as a result of the greater access of backbone bonds to the surrounding aqueous environment and cofactors present in this environment. For example, electrospun nanofiber meshes made from certain polymers degrade faster than cast films with the same component [49,50]. However, in some important cases, porous structures can be associated with slower degradation [51]. This counterintuitive effect is postulated to result from the diffusion of catalytic reactants out of the scaffolds more readily in the porous case. Rapid transport facilitated by pores also serves to stabilize the pH in some Mg scaffolds, leading to a similar effect as that seen in some polymeric biomaterials [52,53]. Therefore, both opposing effects need to be considered when designing the porous structure in scaffolds. Methods of fabricating porous scaffolds are discussed in subsequent sections.

Surface Modification for Degradation Control

Another method for modulating scaffold degradation is to modify the surfaces. One mechanism is to change the surface hydrophilicity/hydrophobicity, thereby increasing or reducing water uptake that would affect the hydrolysis process. Generally, hydrophilic coatings increase degradation rates whereas hydrophobic coatings do the opposite [54–56]. For degradable metals, increasing corrosion resistance is usually the aim for surface modification, particularly when a given alloy is attractive for its processability, mechanical properties, or other considerations. Methods include simple polymeric coatings, molecular coatings that react with the surface oxide layer, plasma ion implantation, physical vapor deposition, thermal oxidation, and various electrochemical oxidation methods that have been widely applied to metallic biomaterials [56–60].

In considering scaffold degradation in general, many external factors such as mechanical load or irradiation can have a major impact on scaffold degradation rates. However, because the operational environment or processing requirements are often fixed, no further discussion of these factors will be made here.

Controlled Release of Bioactive Agents

Scaffolds may also serve as a reservoir for bioactive agent delivery including small molecule drugs, proteins, genes, cells and nanoparticles. Compared with the inherent physical and chemical features of scaffolds, the effects of released bioactive agents can extend beyond implantation sites to recruit or control circulating cells that are beneficial for tissue repair, and higher specificity can be achieved [61]. When two or more cargoes are loaded, corresponding release profiles may be programmable, which provides flexibility and can yield more desirable effects when orchestrated properly [62]. Logically, seeking synergy by combining the largely local benefits provided by the degrading scaffold with the diffusing effects from controlled-release agents has been a consistent direction explored in the effort to improve scaffold performance.

Many physical and chemical parameters of a scaffold affect the release profile experienced by the loaded cargo. Several of these factors overlap with factors regulating scaffold degradation, as degrading scaffolds open new channels for cargo diffusion. Some of the more important scaffold design parameters that influence the release of water-soluble agents are discussed subsequently.

Effect of Porous Structures

In diffusion-controlled delivery systems, porous structures provide an easier path for the molecules detaching from the material substrate to exit from the scaffolds and enter surrounding tissues, compared with diffusing through relatively dense material substrates. Therefore, easier access to pores and higher connectivity between pores facilitate faster soluble molecule release from a scaffold [63]. However, this theory does not always strictly apply because higher porosities may decrease the degradation rates of some polymer scaffolds, which would slow the accelerated delivery owing to the degradation effects.

At the molecular level, free volume will affect the diffusion rate. Taking hydrated hydrogel systems, for example, for gels with mesh sizes comparable to the size of the loaded agent, diffusion coefficients are decreased owing to steric hindrance provided by the cross-linked polymer chains [64]. Mesh sizes comparable to the size of the loaded agent increase the molecule diffusion path length compared with hydrogels with mesh sizes much larger than the releasing agent [64].

Affinity-Based Release

Affinity between the bioactive agent and the scaffold substrate affects the tendency of loaded molecules to permeate the material volume and approach the interface of the material−pore and materia−/tissue. Through transient interactions between the loaded cargo and the delivery scaffold, affinity-based systems (e.g., heparin-binding proteins for heparin, aptamers for nucleic acids, cyclodextrins for hydrophobic antibiotics) can minimize burst release while providing fine-tunable release profiles by attenuating diffusional release [65]. Related studies about affinity systems have shown that the addition of an affinity group to the therapeutic may be done so as not to affect the bioactivity of interest detrimentally, which supports the practicality of this strategy [66,67]. In addition, mathematical simulations have been developed to predict release profiles, which could be useful in predicting desired release profiles and designing release systems [65].

An alternative method to fabricate affinity-based release systems is to recognize a specific molecule selectively by the scaffold substrate known as molecular imprinting (Fig. 30.4) [68]. In molecular imprinting, the bioactive agents work as template molecules to create imprints in the polymer networks, which subsequently function as affinity binding domains [69]. Compared with nonaffinity systems, release retention was observed in imprinted systems [70]. Molecular imprinting systems would be advantageous for drug delivery because of their ability to sustain the release of a therapeutic agent, enhance the loading capacity, release the bioactive agents by in response to the stimuli intelligently, and enantioselectively load and release the eutomer (isomer of interest) [71].

On-Demand Release

The strategies mentioned earlier are effective passive methods to obtain sustained, prolonged release. However, it is often desirable to have a designed response to changing conditions as tissue healing or remodeling proceeds or to provide a more optimal delivery of an agent dependent on externally determined factors. More active, on-demand

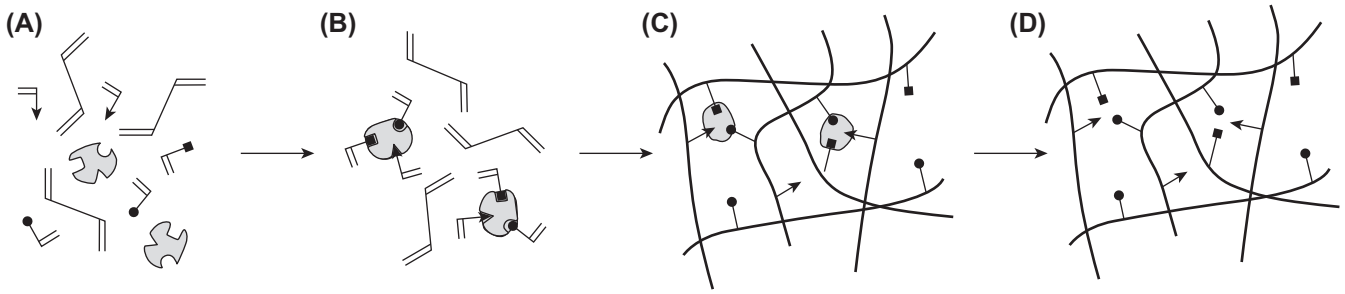

FIGURE 30.4 Molecular imprinting. (A) Solution mixture of template, cross-linking monomer, and functional monomers (triangles, squares, and circles). (B) Complex formation between functional monomers and template via covalent or noncovalent chemistry. (C) The formation of the polymer network typically via free radical polymerization. (D) Template removal step that leaves binding sites specific to the original template [68].

modulation of bioactive agent release can be achieved with on-and-off triggers. The most commonly used triggering mechanisms include (1) pH or temperature, (2) enzymes that cleave cross-linkers used to immobilize bioactive agents, or (3) drugs or ions that trigger the cleavage of an engineered substrate, resulting in the release of encapsulated cargoes [72–78]. Externally applied stimuli including light, electric or magnetic fields, and ultrasound can also modify scaffold structures or bioactive agent immobilization and regulate release [72,79]. The strategies introduced in this section can be applied to control the release of single bioactive agents and to program the delivery of two or more factors to obtain synergic effects [72,80,81].

Scaffold Morphology

As noted previously, scaffold morphology can greatly influence scaffold degradation, mechanical properties, and bioactive agent release. In this section, morphology is considered in terms of microscale pores and surface features, and progress in modulating scaffold morphological parameters is discussed.

Methods for Fabricating Porous Scaffolds

Conventional fabrication methods to generate porous scaffolds commonly used in tissue engineering include temperature-induced phase separation, salt leaching, gas foaming, electrospinning (for polymers and natural products); gas injection through the melt, gas foaming, plasma spraying, sintering, space holder methods (for metallic scaffolds); and dry-pressing, extrusion, and slip-casting (for ceramic scaffolds). The literature provides many excellent reviews covering these approaches and applications with materials processed in this manner [82–86]. Beyond these methods, newer technologies allow more design control over the scaffold geometry.

Solid free-form fabrication (SFF) technologies are the most important advances made in scaffold fabrication [87]. Among SFF, three-dimensional (3D) printing fabricates 3D structures by inkjet printing liquid binder solution onto a powder bed (Fig. 30.5A). Fused deposition modeling deposits molten thermoplastic materials through two heated extrusion heads with a small orifice in a specific lay-down pattern. The basic concept of stereolithography is to control the polymerization spatially of photocurable resin in a 2D pattern and to extend it to 3D by repeating in-plane polymerization in a layer-by-layer fashion (Fig. 30.5C). Selective laser sintering and melting employs a laser to scan the surface of powdered polymer or metal particles in a specific 2D pattern to sinter by heating them above the melting temperature. 3D plotting or direct-write bioprinting extrudes a viscous liquid material from a pressurized syringe into a liquid medium with matching density and deposits the materials in one long continuous strand or in individual dots to create desired 3D shapes (Fig. 30.5B) [87–91].

Anisotropic and Gradient Scaffolds

Anisotropy and gradient features are widely found in human tissues and organs, including the interfaces between tissues, such as the bone–cartilage interface. This morphology has important implications for the mechanical and biological behavior of these tissues. Therefore, it is interesting to fabricate anisotropic and gradient biomaterials as scaffolds to guide regeneration in a manner that provides greater biomimicry of the native state. Anisotropic and gradient cues include composition, pore structure, stiffness, and fiber orientation. A variety of scaffold processing methods have been developed. Listed here are several representative examples for both methodologic and therapeutic effects.

Concentration gradients of bioactive molecules such as growth factors are often desired to drive spatially distinct biological responses to a scaffold. Such gradients have been created using microfluidic platforms or allowing a limited period of diffusion from a reservoir connected to one edge of a scaffold. In a case where platelet-derived growth factor was differentially loaded, tissue invasion depth and blood vessel density increased with the magnitude of the gradient, whereas cortical neurites showed sensitivity to the magnitude of an insulin-like growth factor-1 concentration gradient [92,93]. By controlling the cross-linking density, a gradient modulus was achieved in a polyethylene glycol (PEG) hydrogel. The human osteoarthritic chondrocyte number and phenotype were maintained in regions with a lower storage modulus compared with stiffer regions [94]. A modified one-step gravity sintering method was used to distribute pores with gradient sizes in calcium polyphosphate scaffolds, which induced greater osteoblast differentiation and mineralization in gradient calcium polyphosphate scaffolds in contrast to homogenous calcium polyphosphate scaffolds [95].

Creating thermal gradients when fabricating temperature-induced phase separation scaffolds was effective in arranging unidirectional porous structures and induced anisotropic cell attachment, proliferation, and migration [96,97]. Aligned fibrous scaffolds could be prepared by 3D printing and electrospinning. These unidirectional features have been employed in organizing new tissues including nerve, cornea, tendon, and muscle [98–100]. Applying similar processing methods on both x and y directions could mimic alternating orientating cells and ECM such as that in laminar cardiac tissues [101,102].

Surface Feature Manipulation

It is widely known that surface features and patterns can have a significant influence on cell attachment, locomotion, survival, and differentiation [103,104]. However, discrete patterns can be challenging to fabricate across the surfaces of 3D scaffolds using many of the most common fabrication techniques. Less discrete control of the surface is

more readily achieved, effectively varying the roughness, to affect responses of adhering cells [105,106]. Appropriate creation of microsurface or nanosurface structures can either promote or reduce cell adhesion [107,108]. In addition, cell migration can be guided by micrometer-scale roughness and hydrophilicity gradients [109,110]. Using specific interactions with adsorbed proteins and cell surface receptors, cell migration can be modulated [111].

Injectable Scaffolds/Controlling Morphology In Situ

Traditionally, biomaterial scaffolds are formed in vitro before implantation. Technologies have allowed the minimally invasive delivery of scaffolds and the formation in situ of desired microstructures, which reduce the risk for invasive surgical procedures [112]. In addition, in situ–formed pores would allow cell infiltration before significant scaffold degradation, which may promote tissue integration.

Metallic scaffolds including coils and stents can be compressed with large deformation ratios to allow packaging on catheters for guided delivery. After deployment in targeted regions, these scaffolds can either revert to their original shape with high elasticity or be shaped by catheter-associated mechanisms such as inflatable balloons. Porous ceramic and polymeric scaffolds can be delivered by injection as solution precursors mixed with porogens [113,114]. As the biocompatible solvents absorb and the porogens dissolve in vivo, the result is porous structures. An alternative method to forming porous hydrogels in situ is to bind micrometer building blocks covalently via self-assembly in the tissue [115]. Elastic, high water–content hydrogels are squeezed through syringe needles and partially regain their porous structure in vivo [116,117].

Traceability and Imaging

Common to preclinical biomaterial and medical device evaluations is the recovery at different time points of implanted scaffolds from experimental animals or patients for subsequent histological, proteomic, and genetic assessments. Valuable information has been extracted by employing this paradigm. However, real-time monitoring options for the scaffold or tissue environment are limited and constrain the capacity of researchers and clinicians to monitor scaffold performance and sense potential negative events such as mechanical failure and detailed aspects of the biological response. Furthermore, as the tools to manipulate the status of smart, responsive biomaterials continue to expand, the desire is increasing for parameters that reflect scaffold status at given postimplantation time points.

Tracking scaffold material with noninvasive imaging techniques including magnetic resonance imaging, ultrasound, and computed tomography scanning is favored. Essential to scaffold tracking is the ability to differentiate the biomaterial signal from the tissue background. Different signal generation mechanisms are involved in these imaging techniques, with contrast originating from differences in parameters such as water content, radio opacity, stiffness, density, and magnetism. Contrast can be specifically created by adding contrast agents during scaffold formation [118–121]. However, the potential toxicity of contrast agents needs to be considered [122]. Greater contrast properties for the scaffold provide for improved resolution in the imaging techniques to reveal greater structural detail. Although not considered in this chapter, the labeling of loaded cells is commonly pursued in the context of tissue constructs [123].

SAFETY AND BIOCOMPATIBILITY REQUIREMENTS FOR BIOMATERIAL SCAFFOLDS

Achieving the desired level of functionality for a given medical application is obviously central to assembling the design objectives for a biomaterial scaffold system. However, the safety of such a system must explicitly be demonstrated as the pathway to clinical application is traversed. Several general concerns will apply to all scaffolds, whereas other considerations will be specific to the given application. The governing regulatory body (e.g., the U.S. Food and Drug Administration) will ultimately dictate the specific testing required for progression to early-stage clinical evaluation. Biomaterial scaffolds are medical devices by definition, and as the World Health Organization has pointed out in its guidelines: (1) absolute safety cannot be guaranteed, (2) the consideration of a given device's safety is a risk management issue, (3) safety is closely aligned with device effectiveness and performance, (4) safety must be considered throughout the life span of the device, and (5) the assurance of safety requires shared responsibility among the stakeholders [124]. As specifically addressed in International Standards Organization Document 10993, some of the principal considerations in demonstrating device safety include local and systemic

toxicity, carcinogenicity, pyrogenicity, sensitization, potential for infection, hemocompatibility, and adverse foreign body responses. Furthermore, because the scaffold system is biodegradable, the evaluation of biodegradation products both in vitro and in vivo must be explicitly addressed.

Infection and Sterilization

Bacteria can adhere to biomaterial scaffolds before, during, and after the implantation procedure. Although completely eliminating the possibility of bacterial contamination before implantation is impossible, major sterilization protocols including radiation, ethylene oxide (EtO), hydrogen peroxide, or steam can be designed to achieve a recommended sterility assurance level (SAL) (usually a risk of one nonsterile device in a million) [125]. The scaffold thus needs to be compatible with at least one of the sterilization methods and the design processes should reflect consideration for sterilization step. The various methods each have trade-offs in terms of their impact on the underlying material, expense, and integration with the manufacturing process. Specifically, the sterilization procedure may affect material performance by the same mechanisms used to kill bacteria, e.g., each of these sterilization methods can decrease the molecular weight of PEG-based polymers [126]. For scaffolds made from natural products (such as proteins or polysaccharides) and those containing naturally derived bioactive ingredients, EtO, heating, and radiation may denature and alter the structural or functional components of the scaffold. Although metals and ceramics are more stable compared with polymer and naturally derived materials, the labile versions of these materials can be more sensitive to some of the sterilization methods. For all of the scaffold types, because degradability is a feature, considerations must be given to packaging and storage methods, including the determination of shelf-life under prescribed conditions.

Across all implanted medical devices, the incidence of device-centered infections is much higher than the SAL, which has led to the conclusion that most infections occur as a result of exposure to bacteria during the implantation procedure or after device placement (Fig. 30.6). An attractive feature of biodegradable scaffold systems is the limited implant period, because the scaffold is replaced by native tissue, which removes the nidus for infection that remains with nondegradable devices. Current strategies that have been explored to reduce the potential for infection in nondegradable devices generally apply to scaffolds as well. These approaches fall into three general categories: (1) surface modification to impart resistance to bacterial adhesion [127,128], (2) loading of antibiotic agents into the biomaterial for controlled release [129,130], and (3) modifying or otherwise designing the surface to encourage

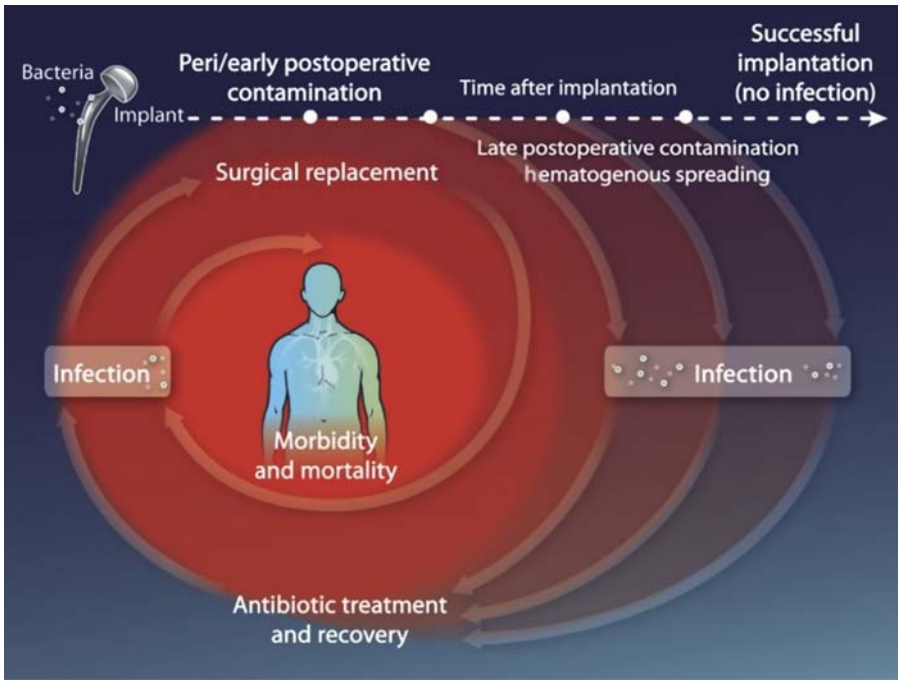

FIGURE 30.6 Patient risk factors for developing a biomaterial-associated infection. Revision surgery patients are at greater risk than primary surgery implant patients, whereas the risk of an implant or device becoming infected hematogenously decreases with time after implant placement due to more extensive host tissue integration [132].

rapid coverage and integration with host tissue, thus minimizing the likelihood of further exposure to and colonization by planktonic bacteria [131]. Because the scaffold design generally seeks to integrate and be replaced with native tissue, the latter approach is particularly attractive, although controlled antibiotic release in the early period may also be attractive.

Toxicity

Major components of scaffolds are not present in the human body (e.g., polycaprolactone) or at unnaturally high concentrations (e.g., high dosage of magnesium in magnesium scaffolds). These components and corresponding degradation products may induce acute, subacute, or chronic toxicities, especially with allo- and xeno-sourced products [133]. Pyrogenicity, genotoxicity, carcinogenicity, reproductive, and developmental toxicity are the main risks of scaffold toxicity.

Endotoxins are abundant in the environment and have high affinity to various biomaterials; they are the major factors that cause pyrogenicity [134]. In addition, endotoxins have strong proinflammatory effects. Different methods have been developed to lower the endotoxin level in scaffolds [135,136]. Resin monomers, glass ionomers, graphene oxide nanosheets, and other substances have been shown to be genotoxic [137–139]. On the other hand, much research has been focused on testing carcinogenicity in chemicals and small particles and has identified a variety of risky species that are dissolved components or wear debris of biomaterial scaffolds [140,141]. Improvements in scaffold design could mitigate the carcinogenic potentials, e.g., lower the possibility of generating debris production [142]. Organ-on-a-chip and laboratory-on-a-chip technologies have been employed to fabricate medical-device-on-a-chips as in vitro models for medical device toxicity tests [143].

Hemocompatibility

Scaffold hemocompatibility is a concern in the acute period when the device placement procedure involves some level of blood contact, and more chronically for scaffolds that will experience ongoing exposure to blood, such as with stents, cardiac valve scaffolds, or vascular grafts and patches. For all concerns regarding blood-contacting materials, the potential exists for the material to induce hemolysis, complement activation, and the formation of thrombus or embolus. Hemolysis can result from the material properties or the induced flow path created by a scaffold, such as high–fluid shear regions. The characterization of hemolysis for materials and devices is well-described in standards and in the literature [144,145]. Complement activation is generally related to surface properties; guidance exists to assess the activation of this immune system pathway [146–148]. Like hemolysis, thrombogenicity depends on both the material properties and the blood flow pathway near the scaffold surfaces. The status of the patient's blood is also a consideration, because anticoagulant and antiplatelet medications can be prescribed to reduce the safety risks associated with thrombosis.

Thrombogenicity remains a major cause of scaffold failure for blood-contacting biomaterial scaffolds, including vascular grafts and stents [149,150]. Thrombi formed on scaffolds may occlude vessels or embolize and lead to life-threatening ischemia in distal tissues (e.g., pulmonary emboli or embolic stroke) [151]. Because the coagulation pathway and platelet adhesion are initiated on artificial surfaces by protein adsorption, the design of scaffold surface properties to alter this adhesion process to reduce thrombogenicity has long been a focus of research in the biomaterials community. Common approaches include those that seek to reduce overall protein adsorption by increasing surface hydrophilicity, presenting zwitterionic groups, attaching specific bioactive molecules, or manipulating surface roughness. Surface attachment of the anticoagulant heparin or heparin analogs is one of the most widely employed strategies [152,153]. Surface modification with zwitterionic polymers such as phosphoryl choline or sulfobetaine derivatives can effectively reduce protein adsorption; it has been shown to reduce thrombogenesis for a variety of underlying surfaces [154–156]. Layer-by-layer assembly has also used to create antifouling surfaces [157]. Rough surfaces generally increase the potential for platelet deposition [158]. Therefore, smooth and even lubricious scaffold surfaces have been employed to reduce thrombogenesis [159,160], although an alternative approach of presenting rough surfaces to encourage rapid tissue integration has been used in chronically placed nondegradable devices [161,162]. With the theme of tissue integration central to scaffold placement, the development of an endothelial layer over the blood-contacting surfaces is an attractive way to reduce the ongoing risk for thrombosis and thromboembolism. This is a common vision for blood vessel, cardiac valve, and stent scaffold design. Such endothelialization may be encouraged by specific surface ligands or the controlled release of bioactive agents, as well as endothelial cell or endothelial progenitor cell seeding or recruitment from the circulation or nearby tissue [163–165].

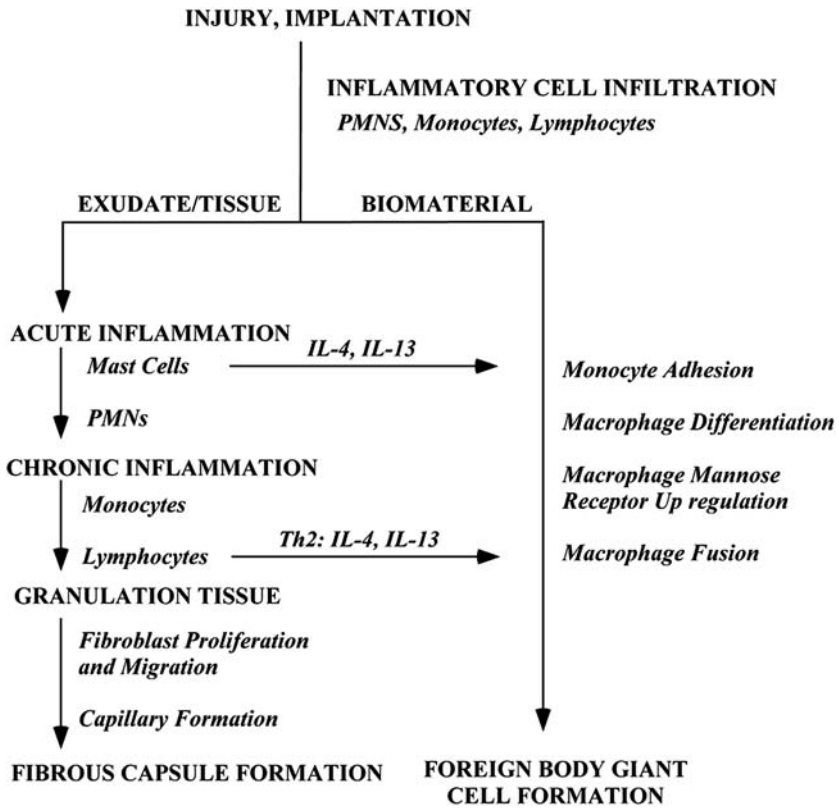

FIGURE 30.7 Sequence of events involved in inflammatory and wound healing responses leading to foreign body giant cell formation. This shows the potential importance of mast cells in the acute inflammatory phase and T helper 2 (Th2) lymphocytes in the transient chronic inflammatory phase with the production of interleukin (IL)-4 and IL-13, which can induce monocyte and macrophage fusion to form foreign body giant cells. *PMN*, polymorphonuclear leukocytes [167].

Foreign Body Response

Implantation of biomaterial scaffolds induces inflammatory and wound healing pathways, which result in a common response if the material is synthetic and nondegradable. Similarities of the response across materials and implant locations has led to the designation of these sequelae as the "foreign body response" (Fig. 30.7). Degradable scaffolds will ultimately remove a central feature of the chronic foreign body response (the implant immediately surrounded by encapsulating fibrous tissue), but during the degradation period of the scaffold, the response is roughly equivalent, although ultimately with more active phagocytosis by macrophages in the surrounding tissue. Of note, with materials based on decellularized tissue, this response outcome may follow a different pathway that has been termed "constructive remodeling," with important differences in the cellular and molecular components [166]. From a safety perspective, the extent of inflammation and fibrosis in the area of scaffold placement is a concern in terms of how this response may lead to failure of the device or inhibition of the device's function. Also of concern is the variability that may occur with this response such that in some patients a more vigorous inflammatory response may lead to accelerated scaffold degradation and early mechanical failure or other morbidity such as local pain and swelling. Readers are encouraged to refer to reviews for the latest concepts regarding foreign body responses [167–170].

Because macrophage behavior is a critical determinant in the direction of the foreign body response, there has been attention to examining how macrophage behavior can be influenced by scaffold topography, stiffness, surface chemistry, and naturally derived bioactive components [19,167,171,172]. Of interest to the biomaterial community are strategies that may serve to influence the foreign body response by modulating macrophage behavior. One approach is to passivate scaffold surfaces in an attempt to render the material substrate "invisible" or neutral to macrophages. Ultralow-fouling zwitterionic hydrogels resisted macrophage adhesion and capsule formation for at least 3 months in a mouse subcutaneous model [173]. In another study, triazole derivatives of alginate were identified to modulate immune cell populations at the surface of hydrogels made from these molecules, specifically

macrophages, in a manner that inhibited their activation and disrupted fibrotic processes, leading to the mitigation of foreign body response in nonhuman primate models [174]. A second strategy has been to polarize local macrophages actively toward an M2 phenotype (a phenotype associated with the promotion of tissue repair and regeneration in contrast to the proinflammatory M1 phenotype [168]). It was widely reported that a decellularized tissue-based material alternative referred to as ECM-based products can induce M2 polarization of macrophages. Thus, aside from fabricating scaffolds directly from ECM products, efforts have been made to produce composites of scaffolding material, usually synthetic polymers, and ECM-derived components as additives [168,175,176].

MANUFACTURABILITY

Even at the earliest stages of the design process for biomaterial scaffolds, it is worth considering how scaffold production ultimately might be scaled up in a manner consistent with good manufacturing practice to ensure stable quality. More broadly, translational and regulatory challenges from the manufacturing perspective will need to be addressed if the scaffold is to move toward a clinical impact, and early identification of design limitations in this area may allow the implementation of an approach with a greater likelihood of success.

As introduced earlier, selecting the scaffold material is often the first step in scaffold development. Regulatory agencies focus on application-oriented pathways in which a specific type or composition of material is approved for one application (device) at a time and reevaluation is needed for a different application. The selection of widely used materials in approved devices such as poly(lactic-co-glycolic acid), stainless steel, and hydroxyl apatite can be attractive because their safety as components in existing products has been demonstrated and general sterilization and biocompatibility protocols have been addressed in a manner that may greatly reduce the material-associated risk for the new application. Furthermore, supplier and manufacturing considerations, from raw material sourcing to material synthesis, and even scaffold formation may have been addressed successfully. Taking polymeric biomaterials as an example, despite the exploding diversity of material designs reported in the literature and the great advancement with controlled polymerization, a limited set of degradable polymers is still commonly implemented owing to practical considerations regarding regulatory approval, costs, and manufacturability. Although newer designs for degradable polymers may possess a better-controlled structure and molecular weight, enabling the integration of powerful biological and imaging functions, the synthesis and processing steps may be markedly more complex, require more strictly monitored controls and systems, and require a more extensive approval pathway compared with a less effective but still functional material. Some of these obstacles may be overcome by modifying laboratory fabrication protocols and considering trade-offs in complexity or benefit early in the design and evaluation process.

With rapid advances in SFF and the attractiveness of combining such technology with patient-specific imaging and even personalized medicine, the promise is presented of better designs suited for individual patient needs. One could imagine controlling the material, morphology, and bioactivity in a patient-specific manner. This will be an area of substantial investment in coming years, and if the patient benefits are great enough compared with nonindividualized solutions with simpler materials, the cost of implementing such technologies in a regulatory-compatible and economically attractive manner would be justified.

SUMMARY

The use of temporary biomaterial scaffolds for regenerative medicine approaches to tissue failure provides a means to support the transition from a synthetic, externally generated “bandage” to an autologous, functional tissue outcome. The potential to mediate a complete and effective transition remains elusive for many tissues and disease states. For the team designing such regenerative medicine solutions, the considerations for the scaffold are many, and there is much more potential for the scaffold than to serve as a well-designed physical support that appropriately transfers load to ingrowing tissue. As noted in this chapter, the team has an increasing array of tools to control the degradation process, design for tissue integration, deliver bioactive agents in an appropriate temporal fashion, and use these design options to meet specific hypothesized needs for the tissue and patient group in question. Ultimately, scaffold design considerations must fit within a much broader array of considerations that will touch upon many other topics covered in this text. As with many of those other topics, the field is dynamic, challenging, and ripe with the opportunity for new investigators to have an impact on the future of regenerative medicine.

Proteins Controlled With Precision at Organic, Polymeric, and Biopolymer Interfaces for Tissue Engineering and Regenerative Medicine

David G. Castner, Buddy D. Ratner

University of Washington, Seattle, WA, United States

WHY THE NEED FOR PRECISION CONTROL OF PROTEINS AT INTERFACES IN TISSUE ENGINEERING AND REGENERATIVE MEDICINE?

Evolution has crafted proteins to communicate information in biological systems with precision and accuracy. Living biological systems present the correct protein in the correct orientation and conformation to deliver protein signals. Such protein signal delivery typically occurs at cell surfaces or on the surfaces of extracellular matrix proteins. In areas where there should be no protein signals, nature uses nonfouling strategies to prevent nonspecific interactions. Overall, this leads to high signal-to-noise: the specific signal is optimally delivered and the "noise" from nonspecific proteins is minimized.

An example of such precision protein signaling that occurs in living systems is seen with bone morphogenetic proteins (BMPs), a family of proteins that have been evolutionarily important for over a billion years. BMP proteins are involved in biological signaling for skeletogenesis, limb regeneration, body axis determination, tissue morphogenesis, germ layer direction, and cell-fate determination, among other signal pathways [1]. BMPs affect so many different biological processes, and these processes are so critical to organism development, that the signals must be delivered with almost perfect specificity and temporal control. It has been found that BMP signals delivered after interaction with type I collagen show enhanced bioactivity compared with the soluble protein [2]. A similar observation was made with osteopontin noncovalently immobilized on type I collagen [3]. Important for this precision signaling are the specific BMP proteins involved, accessibility of the active site on the protein (molecular orientation and conformation), protein concentrations, concentration gradients and temporal persistence of the signal delivery.

In contrast, biotechnological approaches, particularly using nonbiological materials, do a poor job of delivering protein signals. Proteins are often nonspecifically adsorbed to surfaces with no control of orientation and conformation, and sometimes little or no control of which proteins adsorb. For example, consider cell culture. Billions of tissue culture polystyrene (TCPS) plates are sold each year for use in most every area of cell biology, biotechnology, and medicine. The medium pipetted into these plates is frequently supplemented with fetal bovine serum or related complex biological fluids that contain hundreds of different proteins. The TCPS surface interacts with some complex mixture of proteins that reach the surface, adhere (absorb), and are not displaced by other proteins. These proteins can adsorb with their biologically relevant faces up, or down, or in some intermediate orientation. Just a small fraction of the proteins that adsorb to the surface are integral to cell attachment and growth (for example, fibronectin or vitronectin). Furthermore, the multiprotein surface can be highly denatured, in a native conformation or partially denatured. Couple this lack of precision in control of the protein surfaces with irreproducibilities caused by animal-to-animal variation in the proteinaceous components of the media and

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00031-X

it is surprising that we have any reproducibility at all in our cell technologies. Where the absence of precision control becomes particularly evident is when we attempt to control cell differentiation at surfaces. TCPS is poor at preventing phenotype drift in cell lines on culture plates and poor at inhibiting stem cells from differentiating where we want to culture and replicate those cells in their stem-like state.

For implanted medical devices and tissue engineering scaffolds made of synthetic materials, these materials adsorb complex, nonspecific protein layers immediately after implantation. It has been hypothesized that such layers (many proteins in many states of orientation and denaturation) are responsible for the collagenous encapsulation (foreign body reaction) observed in most cases with synthetic material implants: the macrophages interrogating the implant do not recognize such multiprotein, multiconformation surface films as part of normal physiology and thus trigger an encapsulation reaction to isolate the implant from the body.

Nonspecifically adsorbed proteins have also been implicated in the thrombogenicity of synthetic surfaces in blood. Fibrinogen on surfaces has been implicated as the principal activator of blood platelets. In a study on fibrinogen adsorbed to a series of polyurethane polymers of different compositions, it was noted that the amount of adsorbed fibrinogen correlated directly with the platelet adhesion for most of the polymers [4]. However, there were some significant outliers and it was hypothesized that these were related to proteins in different states of denaturation on the different surfaces.

Decellularized tissue scaffold-based approaches to tissue engineering may also benefit from the controlled use of surface proteins. The processes used for decellularization may damage the recognizability of the proteins comprising these scaffolds. After decellularization, treating the scaffolds with signaling proteins can restore biospecificity [5] while taking advantage of the biocompatibility, biodegradability, unique pore geometries, and good mechanical properties of such scaffolds. Also, new functionality not present in nature can be added to the scaffolds.

SURFACE ANALYSIS AND ITS ROLE IN THE PRECISION DELIVERY OF BIOLOGICAL SIGNALS

Many proteins are roughly 5–10 nm in size. The recognition sites on proteins (protein-ligand binding sites) responsible for biological signaling are closer to 0.5–1 nm in dimension. These dimensions are appropriate for the analysis depths of many contemporary surface analysis methods (Fig. 31.1). Furthermore, preparing the

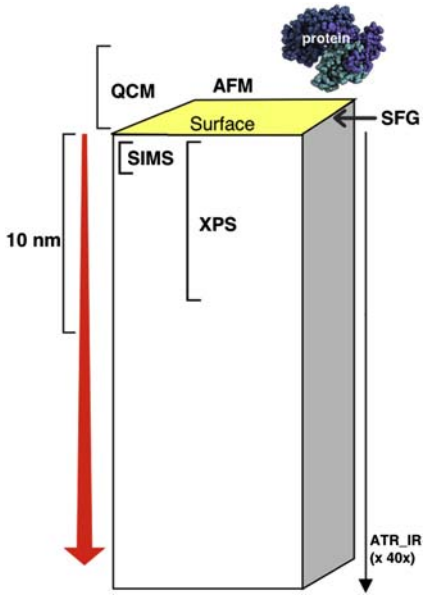

FIGURE 31.1 Consider a surface interacting with a protein. A typical protein molecule (about 5 nm) is shown to establish the size scale. Techniques such as sum frequency generation (SFG) and atomic force microscopy (AFM) are highly surface localized. Quartz crystal microbalance (QCM) methods, especially with dissipation monitoring can measure the protein and its viscoelastic response in the surface zone. Secondary ion mass spectrometry (SIMS) penetrates 1–2 nm into a surface or into a protein. X-ray photoelectron spectroscopy (XPS), also called electron spectroscopy for chemical analysis (ESCA), looks approximately 8 nm into a protein or surface. Other methods such as attenuated total reflection infrared (ATR_IR) look microns into a surface, provide vibration spectroscopy information, and are still considered surface analysis methods.

substrate surface for the immobilization of proteins often involves complex chemical modifications so that specialized tools are needed to monitor complex chemistry modifications. Protein–biomaterial interfaces are typically complex, and validation that a chemistry or surface organization is indeed as might have been envisioned in a Powerpoint image is essential for reproducibility and to achieving predicted functionality. Modern surface analysis methods offer exceptional abilities to probe surfaces chemistries and to compare hypothesized surface organizations with real-world data [6]. A few of the more powerful and versatile methods will be briefly described here. Their application to specific chemistries for delivering biological signals will be elaborated upon in the section on Techniques and Technologies for Precision Immobilization at Surfaces.

A SHORT REVIEW OF KEY SURFACE ANALYSIS METHODS AND SUPPORTING TOOLS

X-ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS) can determine compositional information in the uppermost 8–10 nm of the substrate surface [7–10]. XPS has been used to verify the quality (identity and contaminants) of the substrates and quantify protein adsorption. X-rays bombard the sample, and electrons from the atoms' core and valance bands, called photoelectrons, are ejected and analyzed [7]. The kinetic energy (*KE*) of the photoelectrons is measured and the binding energy (E_B) of the photoelectrons is calculated using the X-ray photon energy, which is a fixed, known energy. For example, for aluminum Kα, a common X-ray source, the X-ray photon energy ($h\nu$) is 1486.6 eV. The binding energy is given by: $E_B = h\nu - KE - \phi$, where the work function (ϕ) is the minimum energy required to eject a photoelectron into the vacuum from the highest occupied energy level. The work function can be calibrated using a clean bare gold sample and remains constant as long as the spectrometer is maintained in ultrahigh vacuum. Manufacturers of instruments usually provide a value for the work function. Insulating samples require charge neutralization using a low-energy (<20 eV) electron flood gun.

XPS provides both quantitative information (atomic percentage) and chemical-structural information (molecular bonding). The atomic percentage of each element is governed by the photoelectron yield at a particular binding energy. Elemental compositions (atomic percentages) are calculated from the measured peak areas by using appropriate instrumental sensitivity factors and accounting for instrumental conditions such as the photoelectron takeoff angle. For protein adsorption, the nitrogen atomic percentage can be monitored because the protein typically contributes a larger nitrogen signal compared with the substrate [10]. The binding energy of the photoelectrons depends on the type and environment of the atom. Therefore, high-resolution XPS spectra can be used to determine the type of chemical species (hydrocarbon, fluorocarbon, metal oxide, etc.) present in the sample surface.

Time-of-Flight Secondary Ion Mass Spectrometry

Time-of-flight secondary ion mass spectrometry (ToF-SIMS) can be used in the static mode to generate a mass spectrum or a two-dimensional (2D) chemical image of the outer 2 nm or so of a surface [11]. In the dynamic mode, ToF-SIMS can be used to generate depth profiles or 3D chemical images of a sample. In a ToF-SIMS experiment, surfaces are bombarded with a pulsed, primary ion beam that sputters atoms, molecular fragments, and entire molecules from the outermost surface. Most of sputtered material is neutral but about 1% is ions (secondary ions) that can be collected and mass-analyzed. Both positive and negative secondary ions can be analyzed. Identities for these secondary ions are proposed based on their masses and fragmentation patterns. In ToF-SIMS imaging, the analysis area is sectioned into pixels (2D) or voxels (3D) and a full spectrum is collected from each region. An image is then constructed by displaying the intensity of a given peak at each square on a color scale.

Because static secondary ion mass spectrometry (SIMS) probes to a depth less than 2 nm, and because proteins are 5 nm or more in size, SIMS looks at only one "face" of the protein molecule. This selective data set can be used to ascertain information of protein orientation and conformation [12] (Fig. 31.2).

Sum Frequency Generation

Sum frequency generation (SFG) spectroscopy can be used to determine the orientation of adsorbed proteins [13,14]. For SFG vibrational spectroscopy, visible and infrared light beams are overlapped in time and space at a surface or interface. The sum frequency signal is generated at locations without inversion symmetry (e.g., interfaces)

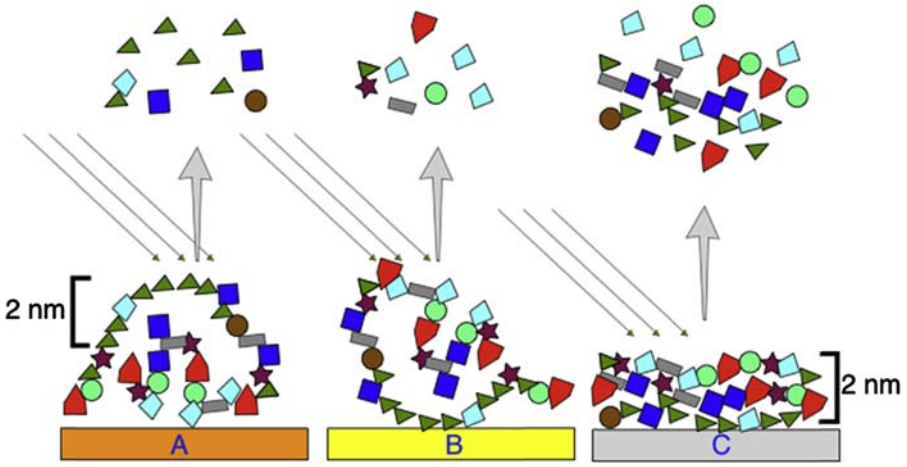

FIGURE 31.2 Graphical description of the mechanism by which static secondary ion mass spectrometry (SIMS) probes protein orientation and conformation. *Thin arrows* represent the SIMS primary ion beam that liberates amino acid fragments from a surface zone less than 2 nm deep. *Larger gray arrows* represent the direction of emission of amino acid fragments. *Colored geometric shapes* are various amino acids (20 different amino acids in most proteins). For surface "A," the *green triangles* are within the 2-nm sampling depth. Because most of the green triangles are in the outermost 2 nm of the protein, there are many green triangles in the emitted amino acid "cloud" (these amino acids are then detected and sorted by the mass analyzer). For a different surface, B, the "green triangle" face of the protein is buried at the solid–protein interface, so few green triangles are seen in the emitted amino acids. For case "C," the protein is highly denatured (flattened to the surface), and thus all of the protein is within the 2-nm sampling depth and all amino acids are seen in the SIMS emission.

owing to nonlinear optical frequency mixing. When the vibrations of interfacial species satisfy the SFG-selection rules (e.g., both Raman and infrared [IR] active), the SFG signal is enhanced. Owing to the nonlinear optical selection rules of SFG, only ordered protein layers at the interface are detected. Disordered proteins, either on the surface or nearby in solution, are not detected. In analogy to Raman or IR spectroscopy, the amide I modes can provide detailed information about the folding and structure of interfacial proteins.

SFG spectra can be calculated and compared with experimental data to aid in the spectral interpretation. For example, couplings between the amide groups can be determined from atom coordinates in protein structure files. Nearest-neighbor couplings between amide groups can be calculated using ab initio methods that give the coupling as a function of the dihedral angle between the neighboring amide moieties. Non–nearest neighbor couplings are calculated with a coulomb-like transition dipole coupling model. Then the IR and Raman modes of the protein can be calculated and used to calculate the vibrational SFG response.

Surface Plasmon Resonance

Surface plasmon resonance (SPR) takes advantage of the excitation and perturbation of surface plasmons (quantized vibrations of mobile electrons within a metal) to probe events occurring at a metal surface (usually gold). If solution-phase molecules adsorb or interact at a surface, this alters these plasmon vibrations and leads to changes in the vibration resonance frequency. We relate this frequency change to the mass and refractive index of the adsorbates. SPR instrumentation is well-suited for studying biomolecule (protein) adsorption and biomolecule interactions at interfaces [15,16].

Quartz Crystal Microbalance With Dissipation Monitoring

Quartz crystal microbalance with dissipation monitoring (QCM-D) can be used to measure changes in mass and viscoelastic properties of adsorbed and immobilized proteins as a function of time [17,18]. QCM-D is based on the piezoelectric effect. When a voltage is applied to a piezoelectric quartz crystal, the material begins to oscillate. The frequency of oscillation will change depending on the amount of material deposited onto the quartz crystal. The dissipation is determined by measuring the signal decay once the voltage to the quartz crystal is turned off (much like the decay in sound of a struck bell). Viscoelasticity, or the rigidity of the deposited layer, will cause the voltage to decay at different speeds. The mass adsorbed (in ng/cm^2) can be calculated using either the Sauerbrey or Voigt model. Analysis used a harmonic overtone (e.g., seventh) for calculating the Sauerbrey mass or multiple

harmonic overtones (e.g., third, fifth, seventh, ninth, and eleventh) for calculating the viscoelastic Voigt mass. The Sauerbrey model assumes an inverse relationship between the change in frequency (Δf) and mass (Δm):

$$\Delta f = -\frac{2f_0^2}{A\sqrt{\rho_q \mu_q}}\Delta m$$

where f_0 is the resonant frequency, A is the quartz crystal area, ρ_q is the density of quartz (2.648 g/cm^3), and μ_q is the shear modulus of quartz for AT-cut crystal (2.947×10^{11} g cm^{-1} s^{-2}). This model can be used only when the dissipation change is low, typically less than 5% of the change in frequency. In this case, the protein is considered rigid. If dissipation occurs, the Sauerbrey model will underestimate the mass. If the dissipation is too large to use the Sauerbrey model, the Voigt model can be used, which models the changes in viscoelastic properties as a damper and spring. A hydrated, flexible protein at a surface might be best modeled using the Voigt model.

Atomic Force Microscopy

Atomic force microscopy (AFM) has been widely used to image the organization, dynamics, and conformations of proteins directly at interfaces [19–23]. AFM generates images by passing a flexible, sharp-pointed stylus over a specimen and converting the x, y, and z position information of the stylus to electrical signals that can then be translated into image pixels representing the height and dimensions of the object being probed. Spatial resolution for contemporary instruments can approach 0.1 nm. From AFM data, one can also infer information on the molecular-scale biomechanics of proteins and their motions on surfaces [24].

Multivariate Methods for Analyzing Surface Molecular Information

Multivariate statistical methods, sometimes referred to as chemometrics, provides powerful mathematical tools to discover trends and correlations in large data sets such as are often obtained with modern surface analysis instrumentation [25–27]. The most widely used of these methods is principal components analysis (PCA), although many other methods are available. The application of multivariate analysis methods to study proteins at interfaces has been reviewed [28,29].

Conformational Stabilization for Biomolecules at Interfaces and Frozen-Hydrated Surface Studies

A challenge in the precise use of proteins at interfaces is to stabilize structures to permit analysis (especially for analytical techniques requiring high vacuum such as XPS and SIMS). Also, in stabilizing delicate conformational structures at interfaces, enhanced bioactivity can be realized. Three techniques have been especially useful for such structural preservation: freezing the proteins, freeze-drying (or critical-point) drying, and surrounding proteins with a stabilizing agent. Frozen-hydrated studies under ultrahigh vacuum for XPS have been described [30]. Key advances in cryogenic transmission electron microscopy [31] will probably lead to improved methods for studying proteins by cryo-XPS and cryo-SIMS. Freeze-drying can be effective for preserving protein structure and interfaces; coupled with preservation agents such as trehalose or sorbitol, excellent preservation can be realized [32,33]. The use of trehalose to preserve protein structure in surface studies was clearly demonstrated in a published study [34].

Iodine 125–Labeled Proteins

Labeling a protein with an I^{125} (gamma emitter) tag, although an older method, has excellent advantages for specificity and sensitivity in studying protein–surface interactions for medical devices or extracellular matrix scaffolds. An extensive review covering the methodology and rationale for I^{125} studies has been published [35].

TECHNIQUES AND TECHNOLOGIES FOR PRECISION IMMOBILIZATION AT SURFACES

This section will review many of the methods that have been used to deliver protein signal from surfaces with precision and specificity (in contrast to simply immobilizing the protein to the surface with little control of orientation or conformation). To anchor proteins to surfaces, we can consider three general classes of interactions:

noncovalent, covalent, and ionic. These are, respectively, weak bonds (although many of them to provide stronger interactions (i.e., cooperativity)), strong bonds (direct chemical attachment through directional chemical bond formation), and electrostatic ("plus–minus" interactions). A variety of potential attachment methods will be described that not only anchor the protein to the surface but permit some control of orientation and conformation to enhance signal delivery to living systems.

Hexahistidine Tags

A tag on a protein molecule consisting of a short chain of six histidine residues (HIS tag) can added precisely at the protein C or N terminus. Because the HIS tag will bind to a nickel–nitrilotriacetic complex (Ni-NTA), and the Ni-NTA complex can be bound to a surface of interest, this binding event can be used to orient the protein (Fig. 31.3). If the active or recognition site is near the C terminus, it would be best to place the HIS tag at the N terminus (and vice versa). There are many published examples of using HIS tags to control protein orientation [36,37].

Ionic Charge and Charge Control of Orientation

With an appreciation that protein molecules have many "faces," each with different molecular characteristics, some faces will be, on average, more positively charged and others will be more negatively charged. It follows that if a biomaterial or scaffold surface is positively charged, it should interact more strongly with a negative domain on the protein surface. This relatively straightforward rationale for orienting protein molecules has been shown in a number of studies to confer much enhanced recognition specificity to bound proteins.

In a study focused on engineering the orientation of surface immunoglobulin G (IgG) proteins via an electrostatic charge, a strong effect of surface charge was noted on the orientation of the protein [38]. This study is schematically illustrated in Fig. 31.4. Positively charged self-assembled monolayers (SAMs) (amino head group) and negatively charged (carboxylic acid head group) SAMs were used as substrates to adsorb and interact with IgG. A bare gold substrate was used as a control. IgG is made up of two Fab subunits and an Fc subunit (Fig. 31.4A). Because of their different amino acid compositions, the Fc subunit is more negatively charged at physiological pH and the Fab subunit is more positively charged. First, the IgG protein was enzymatically cleaved to Fab and Fc fragments. SIMS spectra were taken of Fab units and Fc units to form a "learning set" for subsequent PCA analysis

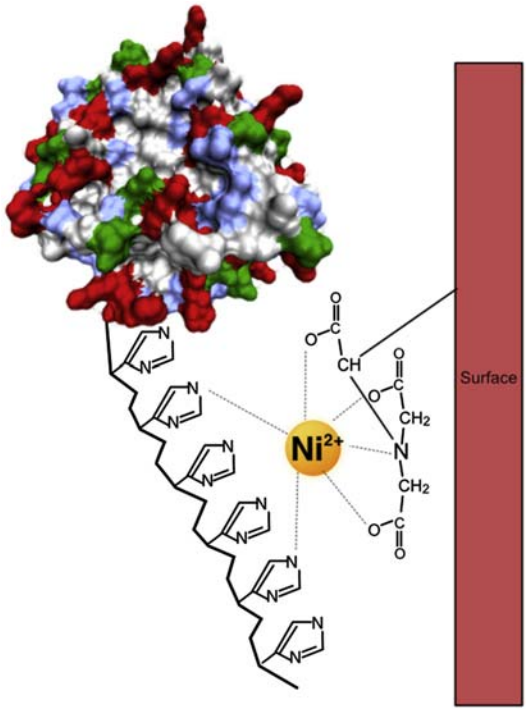

FIGURE 31.3 A nickel–nitrilotriacetic complex can bind to a short histidine chain introduced into a protein. Thus, depending on the specific, controllable site of the histidine chain on the protein, the protein can be oriented to the surface.

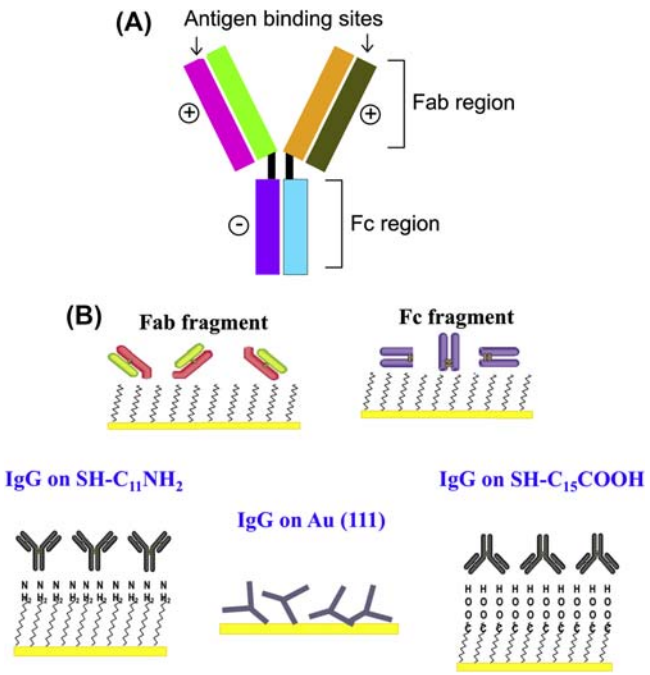

FIGURE 31.4 Schematic representation of a published study on antibody orientation [38]. (A) The subunits of an immunoglobulin G (IgG) molecule with an indication of their relative charge states at physiologic pH. (B) The IgG was dissociated into the Fab and Fc portions for secondary ion mass spectrometry (SIMS) analysis. Then the IgG molecules were adsorbed onto an amino-terminal self-assembled monolayer (SAM) (positively charged surface), a carboxylic acid terminal SAM (negatively charged surface), and a gold surface (control). (B) SIMS analysis was performed on all specimens, demonstrating that the images represent the predominant orientation based on an analysis of secondary ion amino acid fragments expected for the Fc portion of the molecule "up," the Fab portion "up," or random distribution.

(Fig. 31.4B). Then IgG was adsorbed to an amino-terminal (head group) SAM, a carboxylic acid terminal SAM, and gold. SIMS analysis looking into the top 1−2 nm of these films provided mass spectra showing amino acid distributions. For the amine surface, the SIMS amino acid distribution was suggestive of the Fab portion. For the carboxylic acid surface, the SIMS amino acid distribution was compositionally closer to that of the Fc portion. No such separation was seen for the molecules on the gold surface where no charge-directed orientation would be expected. An antigen to the IgG on the amine surface where the Fab portion was facing out to the liquid interface would be expected to have much higher molecular recognition.

Other studies using charged substrates to orient proteins (osteopontin, fibronectin subunit, and $FNIII_{7\text{-}10}$) demonstrated that the surface charge can strongly enhance bioactivity (antibody recognizability and cell attachment) (Fig. 31.5) [39,40]. This effect is presumably induced by orienting the proteins so recognition motifs interacting with cells and other proteins are more accessible to the biological environment.

Collagen to Control Protein Orientation

Although best known as a structural protein, collagen type I binds biospecifically to least 50 other biomolecules [41]. When biomolecules bind biospecifically to collagen I, they are conformationally stabilized in a geometry that is optimized to deliver signals or perform other functions. Collagen I can be exploited to deliver protein signals with precision. It is well-suited for this purpose for a number of reasons: it is inexpensive, well-tolerated in vivo, already approved for many medical applications, and chemically robust, and in its triple helix configuration, it is easily oriented and axially symmetrical, so there is no "up" or "down" when it is immobilized onto a surface. In a few studies, collagen was shown to be remarkably effective in enhancing the bioactivity of molecules bound to it. For example, in one study, collagen I surfaces were treated simply by dipping into osteopontin (OPN) solutions [3]. Such surfaces had much higher attachment of bovine aortic endothelial cells than surfaces onto which the same amount of OPN was covalently immobilized using carbonyl diimidazole chemistry. Collagen I with no OPN was relatively ineffective for cell adhesion. A similar amplification of OPN's ability to mediate cell adhesion when bound to collagen I was seen in a related study [42].

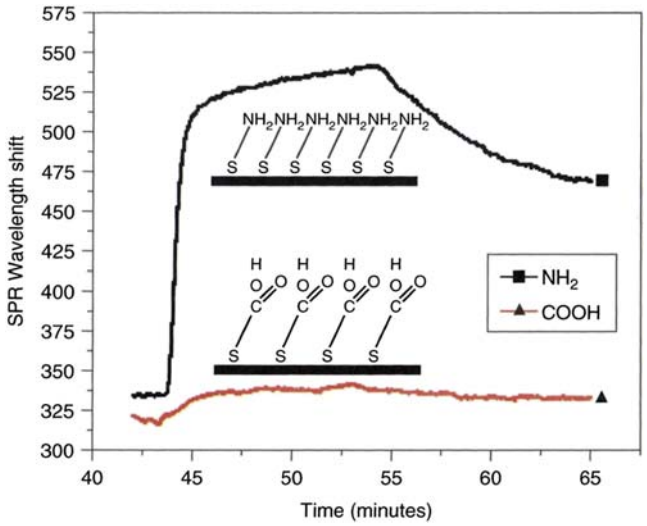

FIGURE 31.5 Surface plasmon resonance (SPR) measurement of the amount of a monoclonal antibody to the cell binding region of peptide $FnIII_{7-10}$ for peptide $FnIII_{7-10}$ on COOH− and NH_2− self-assembled monolayers, each adsorbed with equivalent amounts of $FnIII_{7-10}$. Although all surfaces have the same amount of adsorbed peptide, only peptide on the amine surface is strongly recognized by the antibody.

Immobilization of Proteins in Lipid Layers and Tethered Lipid Bilayers

The lipid bilayers of living cells are evolutionarily optimized system for delivering appropriate protein signals with high bioactivity and specificity. Proteins are conformationally stabilized in the lipid environment and oriented so their recognition elements are optimally available (Fig. 31.6).

In analogy to nature's method of delivering protein signals, using lipid bilayers, synthetic systems have been envisioned using assembled lipid layers to constrain and orient proteins. Fig. 31.7 offers some possibilities. A number of publications have described such strategies for controlling proteins at interfaces in some detail [43–46].

Streptavidin for Biomolecular Orientation Control

Streptavidin protein has a number of advantages as a tool for orienting proteins and delivering signals from proteins. Its symmetrical tetravalency offers many possibilities for surface tethering, protein tethering, and molecular orientation. Streptavidin is robust, it has an exceptionally high biotin binding affinity ($K_a = 10^{14}$), and it is not too large, which reduces steric concerns (53 kDa). Fig. 31.7B illustrates one option for using streptavidin to deliver signals from appropriately oriented proteins. Many publications are available on using streptavidin to immobilize other proteins and control their orientations [47–49].

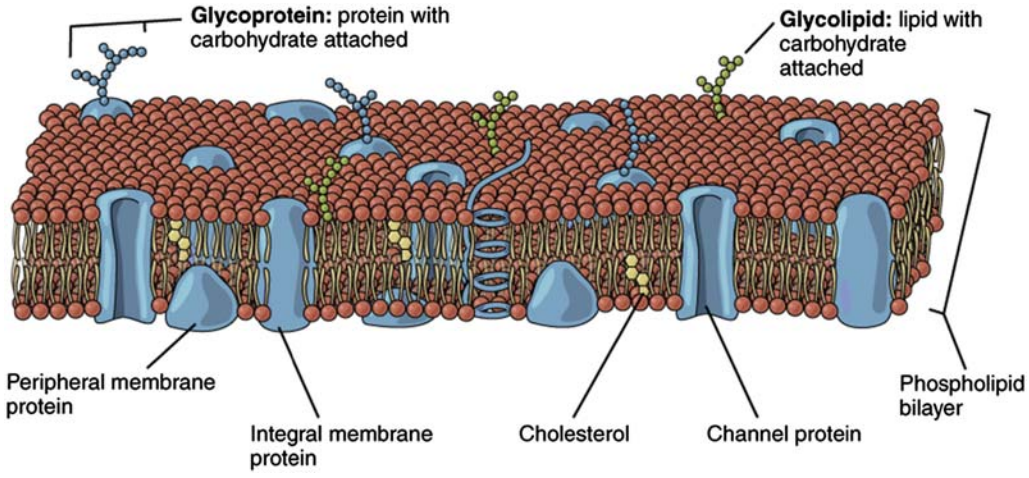

FIGURE 31.6 Proteins that are embedded within a cell's lipid bilayer membrane are conformationally stabilized and optimally oriented to deliver signals. *Figure from Wikimedia Commons.*

Hydroxyapatite for Protein Signal Delivery and Orientation Control

Hydroxyapatite (HA) calcium phosphate mineral [$Ca_{10}(PO_4)_6(OH)_2$] has long been known to interact biospecifically with proteins [50–52]. Indeed, HA–protein interactions are critical for bone formation and bone strength is improved by protein–HA interactions that inhibit the formation of large HA crystals. Thus, HA surfaces represent a unique option to control protein orientation and bioactivity. In one study using XPS and SIMS to compare osteocalcin adsorption with both calcium phosphate and silica surfaces, silica was found to induce the denaturation of the osteocalcin compared with calcium phosphate [52]. The specificity of HA for purifying antibodies has been well-described in the literature [53]. In excellent studies demonstrating the biospecificity of HA–protein binding as analyzed by nuclear magnetic resonance spectroscopy, the investigators determined precisely which portion of a statherin peptide interacts with HA and which is conformationally mobile and free from surface interaction [54,55].

Other Options to Control Proteins at Interphases With Precision

Not all potential methods for protein control at surfaces and interfaces have been elaborated upon in this article. Nevertheless, it is useful to mention a few other possibilities. If antibodies (particularly monoclonal antibodies) can be oriented at a surface, the possibilities of using those surface antibodies to orient and control other proteins in the surface zone become viable options for biosurface construction [48]. Strategies using NeutrAvidin Protein A complexes and protein G (antibody binding proteins) at the interface can also direct antibody orientation [56,57]. Electrical fields might be used to orient antibodies and other proteins at interfaces [58]. An extensive general review on antibody orientation (with particular focus on immunoassays) was published [59]. Finally, surface imprints prepared from protein templates might find application to create oriented, controlled protein surfaces [60–62].

In addition to the techniques for creating ordered protein surfaces, there are a few "platform" technologies that are important and supportive for such precision surfaces. One set of technologies deals with incorporating appropriate functional groups into the surface. These functional groups are the anchors or handles to affix proteins or the molecules that lead to organized protein films. Important functional groups are $-NH_2$ and $-OH$; other chemical groups are $-SH$, $-N_3$ (azide), alkynes, and acrylate double bonds. Glow discharge plasma deposition is a powerful method for surface modification to incorporate anchored functional groups [63,64], although many other methods are available [65].

Another set of platform technologies for precision-controlled protein surfaces uses nonfouling (cell and protein-resistant surfaces) regions on the surface [66]. Recognition elements (i.e., oriented protein molecules) can be spaced in a "sea" of nonbioadhesive chemistry so that the recognition event is not fouled by the nonspecific adsorption of proteins or by cell attachment. Many technologies have been developed to create nonfouling surfaces; the most commonly used ones are poly(ethylene glycol) surfaces [67] and zwitterionic polymer surfaces [68,69].

CONCLUSIONS

There are numerous possibilities for controlling the orientation, conformation, and density of proteins at surfaces with precision and specificity. Such precision control is sharply in contrast to nonspecific adsorption or nonspecific chemical immobilization, the protein–surface technologies that have dominated the field since the 1960s. Precision

engineered protein surfaces exhibit higher "signal-to-noise" (i.e., they are more effective in fulfilling their intended purpose) and are less likely to be interrogated by living systems as denatured proteins to be targeted for destruction. The shift in thinking from simply applying proteins to surfaces and/or scaffolds with little control, to engineering surfaces with biological specificity and control, is facilitated by newer methods for creating such surfaces and the technologies for analyzing these surfaces. This review is written to start the reader on the path to thinking about the merits of the precision control of protein structure and function at synthetic and biological interfaces. There is a huge literature on this subject; thus, starting from this basic tutorial, a sophisticated, nuanced approach to the subject of organized proteins at interfaces can be developed.

INTRODUCTION

Advances in the medical field have increased life expectancy worldwide and increased age-related pathologies that are responsible for reducing the quality of life for elderly people. Bone injuries may be severe among the aging population and can result in morbidity and significant socioeconomic costs. Thus, there is a need for new and efficient regenerative strategies to optimize patient outcomes.

Current options for treating large bone injuries are unsatisfactory because they rely on the use of autografts, allografts, and scaffolds associated with cells and/or biological factors. Each option has major limitations such as reduced bioactivity, the risk for the transmission of pathogens and inflammation, the need for additional surgery, limited supply, inadequate size and shape, and morbidity associated with the donor site. To address these limits, advanced tissue engineering-based approaches have been pursued to create grafts to repair and regenerate damaged tissues [1]. The engineered scaffolds should be cytocompatible and mimic the native tissue to present biochemical and mechanical cues. In this way, similar biological functions can be promoted, overcoming issues such as donor site scarcity, immune rejection, and the transfer of pathogens.

The bone tissue engineering field has progressed. The main strategies have focused on the combination of cells, biologically active molecules, and a temporary three-dimensional (3D) porous scaffold.

The evaluation of scaffolds for bone tissue engineering is generally composed of cellular interactions as well as an assessment of the scaffold microstructure and mechanical properties. These properties are important for the success of the scaffold for bone tissue engineering applications. The scaffold microstructure (e.g., pore size, shape, and interconnectivity) is an important characteristic for the success of the developed scaffold because it should allow cell migration, nutrient and waste exchange, neovascularization and angiogenesis, and bone ingrowth. Mechanical properties are also a critical parameter for bone remodeling because they should ensure the formation of a new tissue once implanted while maintaining its structural integrity.

Because load-bearing applications require porous structures with improved mechanical performance, we believe that solid porous structures can be more appropriate for connective tissue engineering applications than matrices from hydrogels. Therefore, special attention will be given to processing techniques used to prepare foams and meshes and their performance in vitro and in vivo, alone or combined with cells, in the context of bone tissue engineering. Table 32.1 provides a quick overview of natural-based polymers and ceramics and their properties, processing methods, and performance, which will be discussed in more detail later in the chapter.

TABLE 32.1 Natural-Based Polymers and Ceramics and Their Properties, Processing Methods, and Performance

	Materials	Properties	Processing Methods	Performance	References
Natural-Based Polymers	Chitosan	Crystallinity dependent on degree of deacetylation Degraded by lysozymes Insoluble in aqueous solutions pH < 7 Similar to glycosaminoglycans (GAGs)	Phase separation Lyophilization Porogen technique Melt-based technique Gas foaming Freeze gelation Particle aggregation Rapid prototyping Nanofiber production	Induce minimal foreign body response Accelerate wound healing Antimicrobial properties Low mechanical properties	[3,5–7,9–11]
	Collagen	Most abundant structural protein Can be isolated from different tissues and species Insoluble fibers High tensile strength and stability Degraded by matrix metalloproteinases Abundant functional groups	Freeze-drying Porogen technique Electrospinning Computer-aided manufacturing Solid free-form fabrication	Low antigenicity Biocompatible High porosity Facility for combining with other materials Low mechanical properties	[19–21,24–27]
	Gellan gum	Similar to GAGs Soluble in water Insoluble in ethanol Mechanical and gelation properties dependent on degree of acetylation Gelation upon interaction with monovalent and divalent cations Processed under mild conditions Easily modified	Casting approaches Freeze-drying Electrospinning Wet spinning Bioprinting	Biodegrades over weeks to months Induces low inflammation Not cytotoxic Low mechanical properties	[33–35,38,39]
	Polyhydroxyalkanoates	High melting points Low glass transition temperatures High crystallinity	Solvent casting Particle leaching Phase separation Freeze-drying Electrospinning	Biodegradable Biocompatible Brittle Slow degradation Induces secretion of cytokines necessary for wound healing Minimal inflammatory response	[46,47,49–51]
	Silk fibroin	Formation of β-sheets	Salt leaching Freeze-drying Lyophilization Inverse opal Electrospinning Three-dimensional (3D) plotting	Biocompatible Biodegradable High mechanical properties Not immunogenic Not cytotoxic	[55–60]

	Starch	Degraded by several enzymes (e.g., amylases)	Solvent casting Particle leaching Freeze-drying Supercritical assisted phase-inversion Wet spinning Water-in-oil emulsification Coprecipitation	Biodegradable Brittle	[68−71,73,74]
Natural-Based Bioceramics	Calcium phosphates	Crystalline Similar to minerals found in bone Low resorption rate	Foam replica Solid free-form 3D printing Gas foaming Electrospinning	Biocompatible Bioactive Osteoconductive Osteoinductive Not toxic Not inflammatory Not immunogenic Promotes osteogenesis and osteointegration Formation of apatite layer	[80,85−89]
	Silicate ceramics	Fine-tuned mechanical properties, bioactivity, and degradation rates	Sol−gel Foaming Particle leaching Melt-derived approach Melt spinning	Osteointegration Brittle Induces bone formation Slow degradation rates Formation of apatite layer	[91−97]

NATURAL-BASED POLYMERS

Natural polymers are widespread in nature. Those polymers are formed during the growth cycles of many organisms and are obtained from renewable sources such as plants, animals, and microorganisms. A large variety of natural polymers are available with potential interest for the production of scaffolds because their characteristics better mimicry tissue natural extracellular matrix (ECM). Natural polymers can be fine-tuned in terms of their degradation rate, biological activity, porosity, charge, and mechanical strength by changing the polymer concentrations or polymerization conditions, or by introducing functional groups. Moreover, their susceptibility to enzymatic or hydrolytic degradation may indicate great susceptibility to being metabolized under physiological conditions.

CHITOSAN

Chitosan is a deacetylated derivative of the biopolymer chitin. Chitin is a natural polysaccharide composed of β(1→4)-linked *N*-acetyl-D-glucosamine residues and is the most abundant polysaccharide in nature after cellulose. Chitin can be found in the exoskeleton of invertebrates such as crustaceans, insects, and spiders, and in the cell walls of most fungi and many algae [2].

Structurally, chitosan is a linear polysaccharide consisting of *N*-glucosamine (deacetylated unit) and *N*-acetyl glucosamine (acetylated unit) units linked by β(1 → 4) glycosidic bonds. The molecular weight may vary between 300 and 1000 kDa, with a degree of deacetylation (glucosamine/*N*-acetyl glucosamine ratio) that usually can vary from 30% to 95%. The degree of crystallinity of chitosan is mainly controlled by the degree of deacetylation that is maximum for both chitin (i.e., 0% deacetylated) and fully deacetylated forms (100% chitosan) and minimum for intermediate degrees of deacetylation [3].

Chitosan is degraded in vivo by means of lysozyme, which hydrolyzes glucosamine−glucosamine, glucosamine-*N*-acetyl-glucosamine, and *N*-acetyl-glucosamine-*N*-acetylglucosamine bonds. The reaction results in oligosaccharides that can be incorporated into glycosaminoglycans (GAGs) or glycoprotein pathways or metabolic pathways or excreted. The degradation rate is inversely related to the percentage of crystallinity that can be controlled mainly by fine-tuning the degree of deacetylation. Highly deacetylated forms (e.g., 85%) exhibit the lowest degradation rates and may last several months in vivo [3]. The degradation products are chitosan oligosaccharides of variable length.

Chitosan is insoluble in aqueous solutions above pH 7, but in dilute acids, the free amino groups are protonated and the molecule becomes fully soluble below pH 5. The pH-dependent solubility of chitosan provides a convenient mechanism for its processing under mild conditions. For example, at pH > 7, chitosan becomes insoluble and precipitates, resulting in hydrogels. Freeze-drying techniques also allow highly porous structures to be obtained by means of freezing a polymer solution (−20°C and −196°C), followed by the removal of solvent through lyophilization. Thus, chitosan can easily be processed into porous scaffolds [4]. If we consider its biological features, as such as an induced minimal foreign body response and accelerated wound healing, and its antimicrobial properties, chitosan is one of the most appealing biomaterials for tissue engineering strategies. In addition, much of the potential of chitosan as a biomaterial for tissue engineering can be partially justified by its structural similarity to GAGs, because it possesses glucosamine residues similar to those of the major components of the cartilage ECM. Because the properties of GAG include many specific interactions with growth factors, receptors, and adhesion proteins, the analogous structure in chitosan may also have related bioactivities. Moreover, the cationic nature of chitosan allows it to interact with anionic GAGs, proteoglycans, and other negatively charged species. This property is great interesting because it may serve as a mechanism for retaining or accumulating these molecules.

Processing Methods

An interesting property of chitosan is that it can be transformed into 3D highly porous structures with a high degree of interconnectivity that allows cells to grow and transport nutrients using various technologies. For example, porous scaffolds can be produced by lyophilizing a frozen solution of chitosan in acetic acid [5]. The freezing process can promote the phase separation of acetic acid from chitosan, which forms ice crystals. Then, acetic acid ice crystals are sublimated during the freeze-drying process, creating pores in the scaffold. The pore size of the obtained scaffolds can vary between 100 and 500 μm, depending on the process parameters, such as the chitosan concentrations, freezing temperature, and thermal gradients. The increase in chitosan concentration results in a decrease in pore size. The main limitation of these structures is that the mechanical properties of pure chitosan scaffolds are low,

which could compromise their use. Jana et al. optimized the solvent acidity and polymer concentration with this processing method [5]. In this way, they were able to produce scaffolds with a higher chitosan concentration (maximum of 12 wt%) than usual (4 wt%), which greatly improved the mechanical properties. In addition, the scaffolds that were produced had better rates of cell proliferation and cell differentiation (Fig. 32.1).

Using a different approach, Costa-Pinto et al. combined the use of porogens (salts, sugars, paraffin, and gelatin) with a melt-based technique [6]. With this approach they were able to increase the level of interconnectivity to 90%, which is adequate for the diffusion of cells into the inner regions of the scaffolds. The pore range obtained was 100–250 μm, which was shown in the literature to be suitable for bone regeneration [6]. An alternative to the use of porogen is a foaming or blowing agent (e.g., sodium bicarbonate) that creates gas bubbles, resulting in the formation of a porous structure [7].

Another method is to use freeze gelation, which is based on exposing a chitosan/acetic acid solution to a sodium hydroxide/ethanol solution at −20°C, inducing phase separation and gelation. Then, acetic acid ice crystals

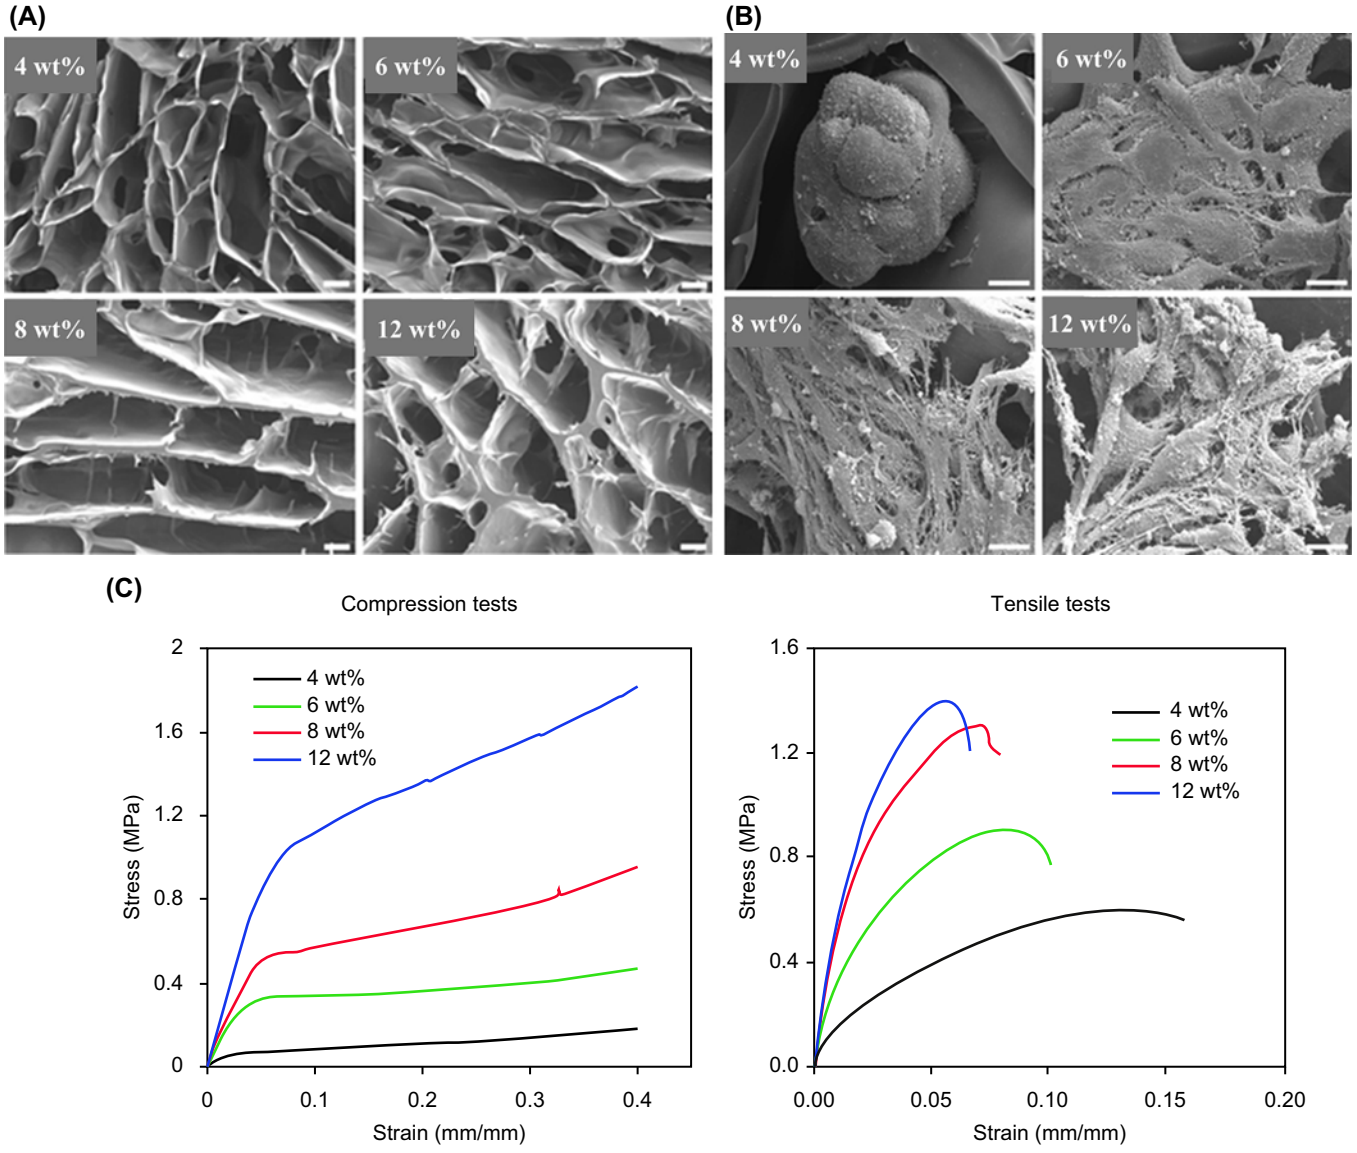

FIGURE 32.1 Scanning electron micrographs of (A) the structure of chitosan scaffolds prepared at different concentrations (scale bars = 100 μm), (B) the cell morphology observed when cultured in chitosan scaffolds at different concentrations (scale bars = 10 μm), and (C) the mechanical properties of chitosan scaffolds prepared at different concentrations. *Adapted with permission Jana S, Florczyk SJ, Leung M, Zhang M. High-strength pristine porous chitosan scaffolds for tissue engineering. J Mater Chem 2012; 22(13):6291–9. Copyright © 2016.*

are formed and the sodium hydroxide/ethanol solution is allowed to air-dry at room temperature instead of lyophilize [8].

Finally, with the intention of developing porous scaffolds, microparticles or microspheres of chitosan can be fused. For example, Malafaya et al. produced a chitosan particle-aggregated scaffold to release biomolecules [9]. With this method, it was possible to obtain a scaffold able to support cell attachment and differentiation and an adequate release profile.

In addition, chitosan scaffolds can be obtained by fiber bonding or, in a more controlled manner, using rapid prototyping technology. The first technology allows the production of a defined structure using computer design and manufacturing [10]. The second allows the production of structures similar to proteoglycans and fibrous proteins found in native ECM [11].

Chitosan in Bone Tissue Engineering Applications

Chitosan-based scaffolds have been designed to imitate some bone properties, which allows the adhesion and proliferation of osteoblasts to be improved. For example, chitosan scaffolds with bioactive ceramics can confer osteoconductive and even osteoinductive properties to the final structure that will guide bone formation. Moreover, they can improve mechanical characteristics. The inclusion of bioactive glass in chitosan scaffolds has been shown to improve scaffold stiffness and promote the deposition of an apatite layer, which is evidence of osteoconductive potential [12]. In addition, Mota Yu et al. showed an increase in cell proliferation and cell matrix mineralization compared with pure chitosan [12].

Calcium phosphate ceramics such as hydroxyapatite (HAp) and β-tricalcium phosphate (β-TCP) were also studied because they mimic bone composition. Maji Dasgupta et al. showed that HAp-chitosan−gelatin nanocomposite scaffolds resulted in mesenchymal stem cell (MSC) adhesion, proliferation, and differentiation [13]. Shavandi et al. studied the addition of HAp and β-TCP to chitosan and observed an increase in mechanical properties that indicated the potential of these scaffolds for bone tissue applications [14].

Calcium phosphate/chitosan biomaterials have been shown to be osteoinductive as well as to have the capacity to promote the formation of new blood vessels, which makes them attractive for bone tissue applications [15]. An in vivo evaluation of calcium phosphate/chitosan biomaterials implanted into rat calvaria defects showed the remarkably accelerated formation and mineralization of new woven bone and histological evidence of primary osteon formation [15].

Using a different approach, chitosan was mixed with a polyester, poly(butylene succinate). The biological assays showed that the scaffolds with amounts of chitosan had higher cell viability, adhesion, proliferation, and osteogenic differentiation [6]. In addition, in vivo tests showed that the scaffolds maintained structural integrity and displayed mild inflammatory response and good integration with the surrounding tissues, including the presence of new blood vessels.

The performance of tissue engineering constructs can be greatly enhanced by incorporating bioactive agents. Chitosan scaffolds with HAp were modified with the peptide Arg-Gly-Asp; its cellular affinity was higher compared with the HAp−chitosan scaffolds [16]. Furthermore, the developed scaffold demonstrated superior osteointegration and bone defect repair and possessed biomechanical properties comparable to those of normal bone.

In a different study, HAp microspheres with chitosan were loaded with recombination human bone morphogenetic protein-2 (rhBMP-2) and the bone-regenerative potential was evaluated in a rabbit radius defect model [17]. The results showed higher rates of new bone formation with rhBMP-2−loaded scaffolds than with rhBMP-2 scaffolds without HAp.

Chitosan has been exploited to increase the mechanical and biological properties of polymers of marine origin, as such as collagen, to provide an alternative to collagen derived from mammalian sources [18]. Overall, scaffolds of collagen extracted from salmon skin had improved mechanical properties and MSC proliferation owing to the addition of chitosan.

COLLAGEN

Collagen is the most abundant structural protein of the extracellular space in mammals. It constitutes around 30% of the total protein weight among which 90% is collagen type I [19].

Collagen has a characteristic triple helix that consists of two polypeptide chains (α1 chains) and a third chain that can differ in its chemical composition (α2 chains). Each chain is composed of approximately 1000 amino acids with a molecular weight of approximately 100 kDa. The amino acid sequence of this molecule is glycine-proline-X and glycine-X-hydroxyproline, in which X is any amino acid besides proline and hydroxyproline. A high proportion of tripeptide sequences found are composed of glycine-proline-hydroxyproline.

Each α chain can form a left-handed helix and the combination of the three chains forms a right-handed triple superhelix structure in which the glycine residues are within the core and the X and Y residues are located in the outer positions [19]. Among the 29 types of collagen, types I, II, III, IV, and V are the most common. Collagen type I is found in almost all vertebrae connective tissues, but especially in tendon and bone. In addition, this collagen has the capacity to form insoluble fibers, which provides high tensile strength and stability to the tissues.

Decades ago, researchers discovered that collagen type I could be isolated from different tissue and different animal species using a simple acid extraction protocol followed by neutralization [20]. Nevertheless, it is most frequently extracted from bovine, which may entail complications as such as the transmission of bovine spongiform encephalopathy [19]. To overcome this limitation, alternative sources have been investigated. For example, Raftery et al. studied collagen derived from marine sources such as salmon skin to work as a platform to promote tissue repair in orthopedics [18].

Human recombinant collagen has also been used for tissue engineering applications. It is a reliable, predictable, and chemically defined source that is free of animal components. Collagen possesses several advantages including abundance, low antigenicity, biocompatibility, and the facility to be combined with other materials. In the human body, collagen is degraded largely through the activity of matrix metalloproteinases [19]. By fine-tuning some features such as the degree of cross-linking, it is possible to modify the mechanical properties and degradation rate of collagen. Furthermore, the abundance of functional groups along its polypeptide backbone makes it highly receptive to binding with genes, growth factors, and other biological molecules.

Processing Methods

Collagen has been reported as a biomaterial to fabricate scaffolds for different tissue engineering applications including bone. Because of its abundancy, it is easy to envision collagen as a platform for tissue engineering and regeneration. One of the most highly used processes to produce collagen scaffolds is freeze-drying [21], in which collagen suspensions are prepared in acetic acid and collagen slurries are allowed to form before the freeze-dry process. The porosity of the obtained scaffolds varies with the conditions chosen for the process. Pawelec et al. showed that the freezing temperature and the addition of a thermal hold on the freezing cycle affect the freezing behavior of the collagen slurry and thus the final pore size [22]. The mechanical properties of the scaffolds that are produced using this technique are determined by the concentration of collagen that is chosen. Nevertheless, scaffolds of pure collagen have poor mechanical properties. To overcome this limitation, physical or chemical procedures (i.e., ultraviolet irradiation, γ-radiation, covalent amine/imine linkage, genipin) are essential to promote the intermolecular cross-linking of collagen [23].

Liu et al. reported an improved approach, i.e., they mineralized the collagen fibrils as a mimetic approach to bone regeneration and promoted intermolecular cross-linking and its superior mechanical properties [23]. This method consists of a synchronized precipitation in which the collagen self-assembles into fibrils and the amorphous calcium phosphate simultaneously transforms into crystalline apatite. The obtained mineralized fibrils are submitted to freeze-drying and then the intermolecular cross-linking of collagen is promoted using carbodiimide chemistry. Finally, the obtained scaffolds are lyophilized again, creating a porous scaffold.

In a different study, ice particulates with different sizes were used as a porogen material to produce scaffolds with different pore diameters [24]. For that, collagen was mixed with the ice particulates and freeze-dried, creating spherical pore structures of different pore sizes and good interconnectivity.

Electrospinning can also be used to produce scaffolds with nano to micron-scale diameter fibers that mimic the fiber's diameters observed in the ECM. Jha et al. concluded that the obtained scaffold did not necessary fully recapitulate the structure of the native fibril to generate a biologically relevant tissue engineering scaffold [25].

Computer-aided manufacturing appears to be a technique that allows the production of highly organized scaffolds. It produces highly porous patterned scaffolds using pure collagen, in which the pore size, shape, and spacing can be controlled [26]. By this method, it is possible to modulate the mechanical properties by changing the number of layers and the shape of the final structure or scaffold.

SeungHyun et al. applied a different approach to obtain a three-dimensional scaffold [27]. They combined a cryogenic plotting system, freeze-drying, and electrospinning to produce a stable scaffold with a controlled pore size. This scaffold had improved mechanical properties, cellular attachment, and a proliferation of MSCs.

Collagen in Bone Tissue Engineering Applications

Type I collagen is secreted by osteoblasts during the process of ossification; it has important roles during mineralization. Therefore, enhanced biological integration with the surrounding tissue may be foreseen when collagen scaffolds are used in vivo. Type I collagen is the basis of several commercial products including Orthopedic Osteon, Orthocell CelGro, Collapat II, Symbios Biphasic Bone Graft Material, Geistlich Bio-Gide, OssiPatch Collagen Bone Healing Protective Sheet, Collatene Fibrillar Collagen Dental Dressing, Collagraft, Infuse Bone Graft, and OssiMend.

Collagen-based scaffolds show great promise for bone tissue engineering applications (Fig. 32.2). In vitro, it was shown that collagen/cellulose scaffolds support cellular adhesion and the phenotype maintenance of cultured human osteoblasts [28]. High levels of osteogenic enzyme, alkaline phosphatase (ALP), and mineral deposition were observed. In vivo, collagen scaffolds implanted in critical bone defects in rat calvaria were biocompatible and highly osteogenic [29]. In addition, the rate of biodegradation was compatible with bone neoformation and vessel neoformation.

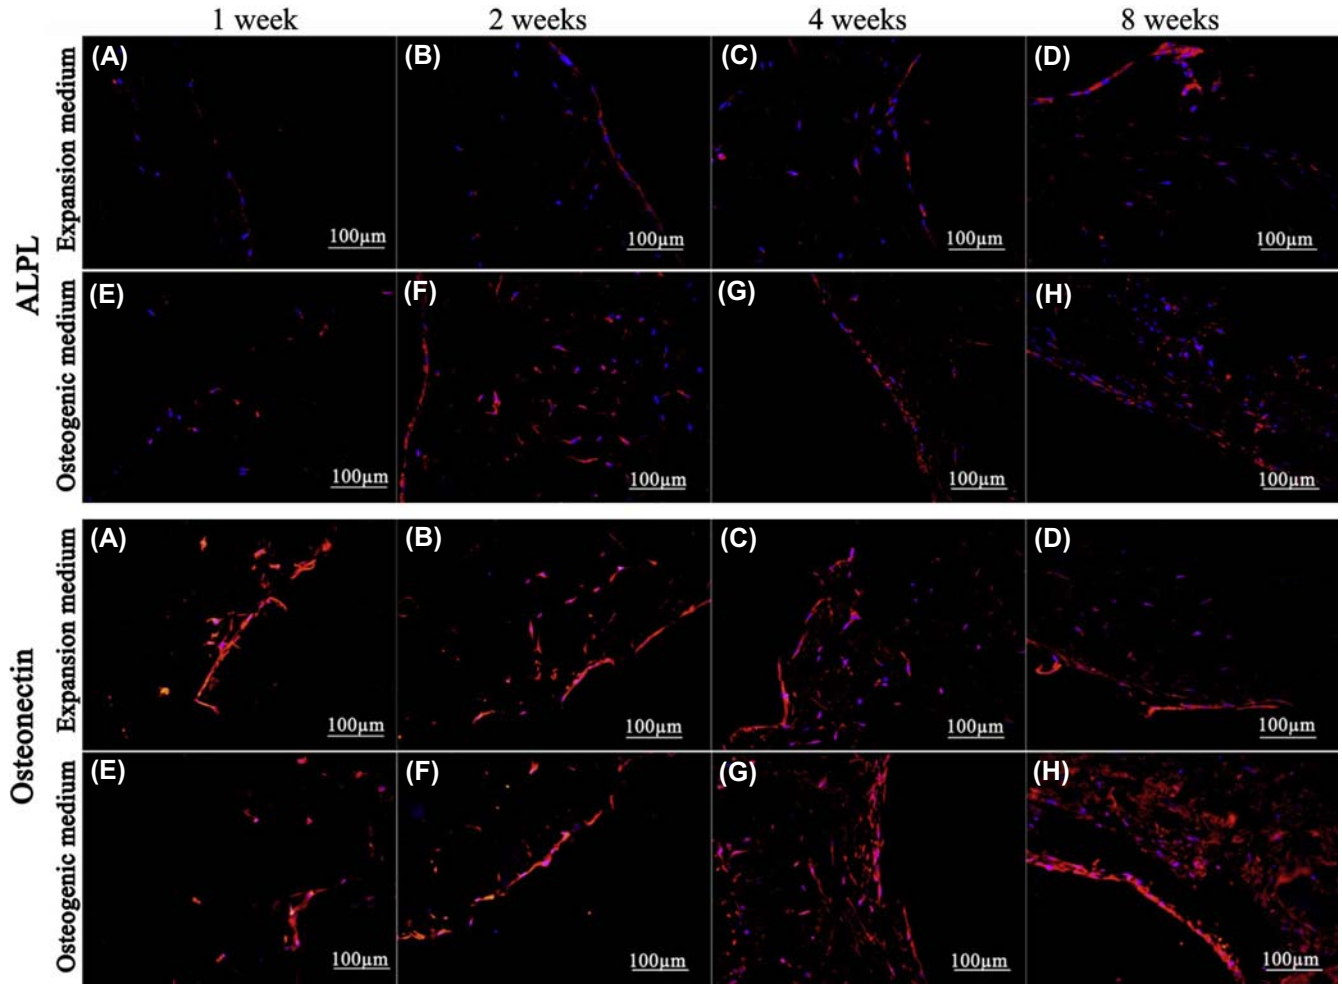

FIGURE 32.2 Immunohistochemical analysis of osteogenic markers (ALP and osteonectin) expressed by adipose-derived stem cells cultured on collagen–hydroxyapatite scaffolds: (A–D) in expansion or (E–H) in osteogenic medium, at different time points (1, 2, 4, and 8 weeks) (Magnification ×20). *ALP*, alkaline phosphatase. *Adapted with permission Calabrese G, Giuffrida R, Fabbi C, Figallo E, Lo Furno D, Gulino R et al. Collagen-hydroxyapatite scaffolds induce human adipose derived stem cells osteogenic differentiation in vitro. PLoS One 2016;11(3):e0151181. Copyright © 2016.*

In a different study, with the objective of mimicking the microstructure and composition of bone ECM, scaffolds were produced based on collagen combined with HAp [30]. It was shown that adipose-derived stem cells (ASCs) cultured in collagen−HAp scaffolds differentiated into mature osteoblasts even in the absence of inducing factors (Fig. 32.2). The same strategy was followed by Kon et al., who implanted collagen−HAp scaffolds to treat osteochondral defects of the knee [31]. In a 2-year follow-up report, it was observed that the approach favored osteochondral tissue regeneration in treating knees affected by damage of the articular surface compared with degenerative lesions. These observations represent significant clinical improvement.

GELLAN GUM

Gellan gum is a linear extracellular polysaccharide produced by the bacteria *Pseudomonas elodea*. Structurally, this high−molecular weight gum (≈500 kDa) contains a repeating unit composed of L-rhamnose, D-glucuronic acid, and two D-glucose subunits. The presence of glucuronic acid residues makes this polysaccharide structural similar to native glycosaminoglycans and supports its use for tissue engineering strategies. Gellan gum is soluble in water; it forms a viscous solution and is insoluble in ethanol, forming precipitates. Its ability to form precipitates enable its extraction from bacteria inoculates in a medium with glucose, nitrogen, and inorganic salts [32]. When submitted to a high temperature, it undergoes a reversible transition conformation from a coil to a double helix upon cooling. The temperature necessary for the transition depends on the polymer concentration, the degree of acetylation, and the presence of cations [32].

Gellan gum may be found as high-acyl gellan gum, which is the native acetylated form, and low-acyl gellan gum, which is the commercially available deacetylated form. The difference between these two forms resides in the presence of glycerate and acetate functionalities in high-acyl gellan gum, which in low-acyl gellan gum are reduced to hydroxyl residues. The reduction results from the hot alkaline conditions employed during extraction. The degree of acetylation can greatly influence the mechanical properties and gelation properties of gellan gum. In this sense, high-acyl gellan gum produces soft, elastic, thermoreversible gels after cooling from 65°C, whereas low-acyl gellan gum produces stiff, brittle, thermostable gels after cooling from 40°C. In terms of gelation, divalent cations (e.g., Ca^{2+} and Mg^{2+}) and monovalent cations (e.g., Na^{+} and K^{+}) can interact with polymer backbone. In the first case, gelation occurs owing to ionic cross-linking between the divalent cations and the carboxylate groups, and because of the screening effect, forming stable and strong bonds. In the second case, gelation occurs only as a result of the screening effect, resulting in less stable structures.

Gellan gum matrices have been mostly produced by casting; they biodegrade over weeks to months, which is an attractive characteristic for tissue engineering approaches [33]. However, to understand their degradation pathways and kinetics fully, more studies must be done. Furthermore, they were found to induce low inflammation in vivo [34]. If we consider their biological features, such as being processed under mild conditions and not being cytotoxic, and also their apparent influence during osteogenesis, one can envisage their potential as a biomaterial. Furthermore, because of the hydroxyl groups formed during deacetylation and the free carboxyl group in the glucuronic acid subunit, they can be modified to improve physicochemical and biological properties.

Processing Methods

Gellan gum has emerged as a biomaterial for tissue engineering because of its biological features but also owing to the possibility of its easily being modified on demand. One of the most well-used methods for developing gellan gum scaffolds is casting followed by freeze-drying [35]. For that, a solution of gellan gum is casted into molds, allowed to form a solid gel upon reaction with divalent cations, and then frozen and lyophilized. However, a limitation of these gellan gum structures that is in common with other biopolymers is their low mechanical properties. The scaffolds' pore size obtained using that technique can vary with the size of ice crystals formed during the freezing process. A rapid freezing process results in smaller ice crystals and consequently smaller pore sizes. Other parameters such as the cross-linking solution, stabilization time, and freezing temperature and time may influence the pore size, as demonstrated by da Silva et al. [36]. They showed that a higher degree of slowdown in the cross-linking formation of ice crystals led to the creation of larger pores. In terms of the time of stabilization, it was observed that an increase in stabilization time resulted in smaller crystals and a smaller pore size. Finally, in terms of the freezing temperature and time, sponge-like scaffolds frozen for longer periods of time and higher temperatures resulted in larger pores. The gellan gum sponge-like scaffolds produced by this method had pores ranging

from 100 to 500 μm in diameter. Interestingly, the researchers optimized the parameters, and using this technique, they produced sponge-like scaffolds with thicker wall pores. Pore wall thickening resulted from microstructure reorganization, which increased scaffold flexibility [36].

The structure of the obtained scaffold also depends on the drying process chosen, as shown by Yang et al. [37]. Oven-dried scaffolds had a crack in the surface of the structure, whereas vacuum-dried scaffolds had a relatively smooth surface, and freeze-dried scaffolds had a looser structure. The different methods also influenced the swelling rates and protein release (Fig. 32.3). In addition, the freeze-dried scaffolds had a sponge-like structure and possessed a high swelling rate, as confirmed by Cerqueira et al. [36]. Moreover, the integration of endothelial cells into these promising scaffolds maximized the neovessels' formation and integration of the transplanted cells into the new vasculature.

A different approach used electrospinning to produce ultrafine nanofibers, as performed by Vashisth et al. [38]. They produced blended fibers of gellan gum with polyvinyl alcohol (PVA) about 40 nm of diameter, because gellan gum alone did not form a fiber structure using electrospinning. The less viscous gellan gum–PVA solutions resulted in fibers with a higher diameter. In addition, the use of polymeric blends (e.g., gellan gum with chitosan) enhanced the mechanical properties [33]. To create fibers using gellan gum alone, wet-spinning must be used, as described by Oliveira et al. [35]. In this approach, they extruded a solution of gellan gum through a needle into a solution of ascorbic acid. Afterward, the fibers were allowed to dry at 37°C.

Bioprinting is a different technique that can also be applied to produce custom-made gellan gum–based scaffolds. This technique combines gellan gum with other polymers, producing mechanically stable and robust 3D scaffolds in a core–shell fashion [39].

Gellan Gum in Bone Tissue Engineering Applications

Gellan gum has been proposed as a novel biomaterial for regenerative medical applications. However, its low mechanical characteristics have prompt the need to mix gellan gum with other materials. For example, Gantar et al. used bioactive glass to reinforce gellan gum–composite, sponge-like scaffolds [40]. Even so, the improvements in mechanical properties did not reach values necessary to accommodate biomechanical loading. Nevertheless, human ACSs were able to adhere and spread within the scaffolds. Altogether, this improved scaffold has great potential for bone tissue strategies. A similar approach was pursued with bioactive glass reinforcement but with different amounts of calcium [41]. The formation of apatite was observed only in the presence of calcium. In addition, bioactive glass with higher amounts of calcium had a lower compressive modulus and higher antibacterial properties.

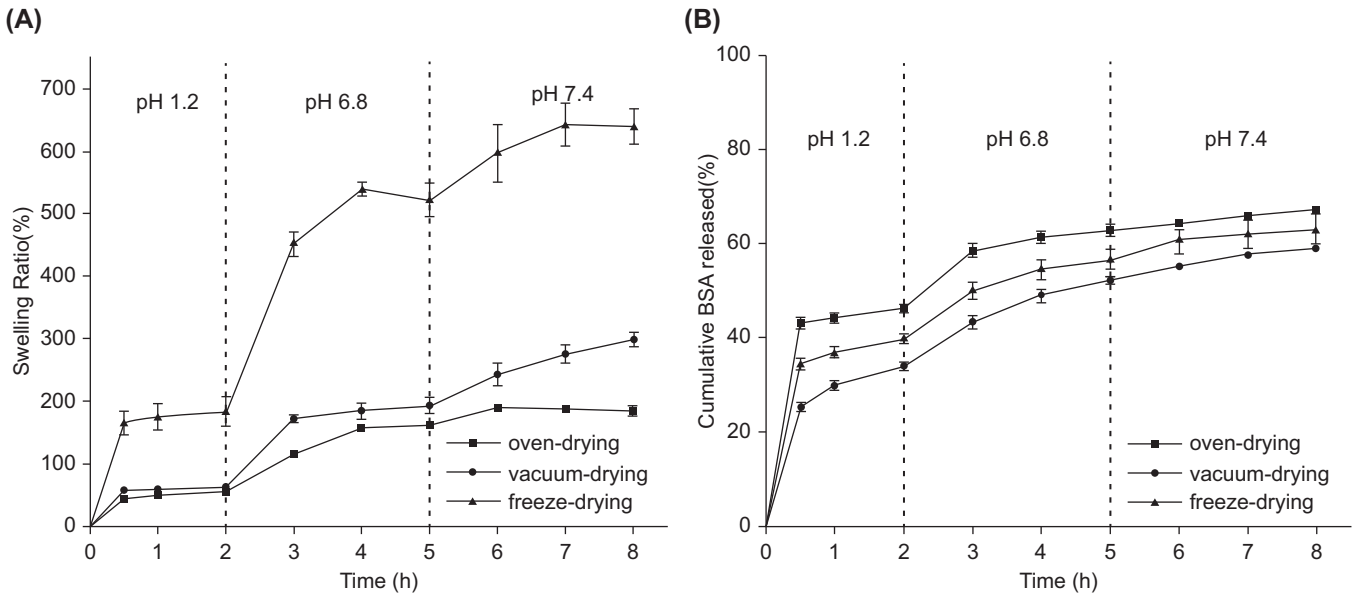

FIGURE 32.3 Effect of different drying processes on: (A) the swelling ratio and (B) protein release. *BSA*, bovine serum albumin. *Adapted with permission Yang F, Xia S, Tan C, Zhang X. Preparation and evaluation of chitosan-calcium-gellan gum beads for controlled release of protein. Eur Food Res Technol 2013;237(4):467–79.*

In a different strategy, Douglas et al. modified the hydroxyl groups present on the gellan gum backbone to improve its suitability for tissue engineering [42]. They incorporated alkaline phosphatase enzyme and observed the induction of an apatite layer and an increase in the scaffold's stiffness. Ultimately, in vitro studies have shown that the apatite layer also enhanced the attachment and viability of the cells. With the intent of improving these developed enzymatically mineralized scaffolds with antibacterial activity, the authors studied the incorporation of zinc [43]. Zinc caused a reduction in the size of the mineral deposits that formed; they had antibacterial activity and promoted the adhesion of bone-forming cells. The same authors compared the use of gellan gum scaffolds modified with alkaline phosphatase or with an extract of seaweed rich in phlorotannins to induce mineralization [44]. The extract of seaweed successfully enhanced mineralization and increased the compressive modulus of the scaffolds. However, when both were present, some mineral formation was observed.

Wen et al. use the fact that gellan gum is biodegradable and its potential as a substrate for apatite deposition to develop a scaffold to repair tissue [45]. For that, they mixed α-tricalcium phosphate and gellan gum, which resulted into a scaffold with increased compressive strength. In addition, the dissolving rate of α-tricalcium phosphate was controlled by adjusting the concentration of gellan gum.

POLYHYDROXYALKANOATES

Polyhydroxyalkanoates (PHAs) are produced by approximately 300 different bacteria upon environmental stress conditions; they function as energy storage. The molecular weight of the PHAs produced is in the range of 200−3000 kDa. PHAs are composed of hydroxy acid monomers connected by an ester bond creating linear polyesters [46]. Depending on the number of carbon atoms present in the monomers, they can be classified as short−chain length PHAs (three to five carbon atoms) or medium−chain length PHAs (6−14 carbon atoms). In addition, different bacteria and substrates result in more than 150 different type of polymers, such as poly 3-hydroxybutyrate (PHB), polyhydroxyvalerate, polyhydroxyhexanoate, polyhydroxyoctanoate, and their copolymers [46]. The PHA family is degraded in nature by a variety of microorganisms such as nonspecific lipases and esterases into carbon dioxide and water. Thus, they are considered biodegradable and biocompatible, which has prompted their use in the medical industry.

PHB, poly 3-hydroxyvalerate (PHBV) and poly 3-hydroxybutyrate-*co*-3-hydroxyhexanoate (PHBHHx) are the most common types of PHAs. Among these, PHB is the simplest occurring form and the first to be discovered. Moreover, it possesses a high melting point (173−180°C) and low glass transition temperature (5−9°C), which results in high crystallinity [46]. Because of this feature, PHB is relatively stiff and brittle and has a slow degradation rate, which is not appealing for most tissue engineering approaches. To overcome this limitation, many studies have used PHBV or PHBHHx [47]. Those have lower melting points and consequently lower crystallinity. In this sense, they are more flexible and undergo degradation at a much faster rate.

Processing Methods

Solvent evaporation is commonly used to prepare PHA scaffolds. For that, the polyester is dissolved in chloroform, allowed to evaporate, and vacuum dried. Nevertheless, other approaches have been studied as an alternative to chloroform for solvents. For example, Anbukarasu et al. used acetic acid to produce films with properties similar to those of films produced using chloroform (Fig. 32.4) [48]. The prepared PHB films possessed crystallinity ranging from 64% at 80°C to 78% at 160°C, whereas, the crystallinity of PHB processed with chloroform was approximately 60.5%. In a different approach, Nemati et al. produced scaffolds by compression molding and particle leaching without organic solvents [49]. For that, they heated a mixture of PHB with HAp and sodium chloride particles up to the melting temperature of PHB, compressed it by uniaxial pressing, and leached out the particles. The scaffolds showed improved mechanical properties in the range of the mechanical properties of cancellous bone and had an interconnected porous structure. The porosity of the scaffolds ranged from 77.2% to 77.5% with pores sizes from 150 to 300 μm.

Porous scaffolds were obtained using sucrose lumps that were soaked in a solution of PHB in chloroform (50). After drying, the sucrose was removed, producing scaffolds with 87.3% porosity and pore sizes of about 120 μm.

PHA scaffolds can also be produced by phase separation and freeze-drying, as was done by Ribeiro-Samy et al. [51]. The polymer was dissolved in organic solvents, and then acetic acid was added to produce two immiscible

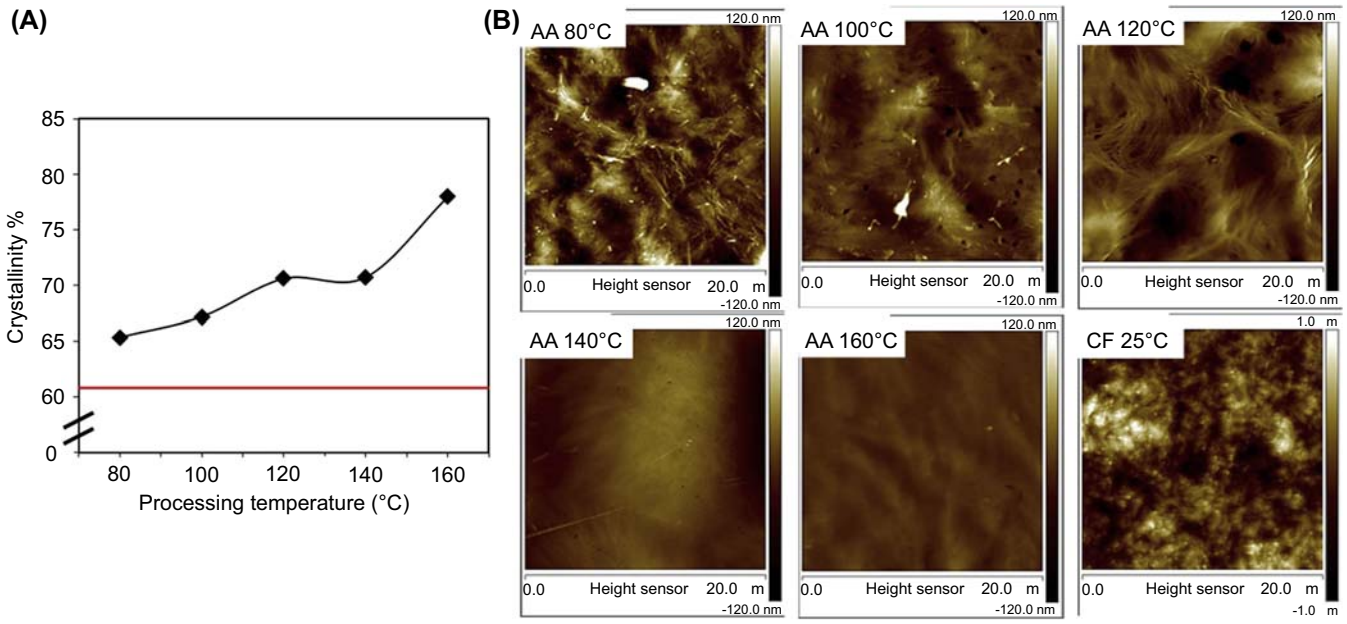

FIGURE 32.4 Properties of polyhydroxybutyrate (PHB) films produced using chloroform(CF) or acetic acid (AA): (A) Crystallinity of films produced using AA (*black line*) or CF (*red line*) with respect to the processing temperature, (B) atomic force microscopy scans of PHB samples processed at different temperatures in AA or CF. *Adapted with permission Anbukarasu P, Sauvageau D, Elias A. Tuning the properties of polyhydroxybutyrate films using acetic acid via solvent casting. Sci Rep 2015;5:17884.*

phases. Afterward, the mixture was frozen and lyophilized. In that way, they obtained scaffolds with a pore size of approximately 164 μm and a porosity of 88%.

Electrospinning is a different technique to produce polyhydroxybutyrate-hydroxyvalerate (PHB-HV) scaffolds [47]. For that, PHB-HV was dissolved in a solution of chloroform with dimethylformamide and a fiber mesh was electrospun. The fibers exhibited diameters ranging from 300 nm to 1.3 μm, similar to the diameters of collagen fibers present in the natural ECM. The developed fiber mesh supported endothelial differentiation, which showed its potential for improving the vascularization in engineered bone tissue.

Polyhydroxyalkanoates in Bone Tissue Engineering Applications

It has been shown that PHBV produced by a metabolic reaction-based model induced the secretion of cytokines necessary for wound healing. PHB scaffolds can easily be fine-tuned with an alkaline solution to increase the proliferation of human osteoblasts and inhibit the growth of bacteria [52]. These features reinforce its potential for tissue engineering applications.

In vitro, the incorporation of HAp into PHB increased biocompatibility and the ability to support the proliferation of human MSCs [53]. In addition, the scaffolds had a higher porosity and improved mechanical properties compared with scaffolds with just PHB.

Cylindrical pins of PHB were produced to evaluate the response of bone upon implantation in the femora of growing rats [54]. For that, the authors modified it with zirconium dioxide to increase radiological contrast values, and with Herafill to increase degradation. Compared with the clinically used poly(lactic-*co*-glycolic acid), poly(glycolic acid), and poly(lactic acid) materials, PHB composites had the advantage of not altering the pH upon degradation, but no degradation was observed after 36 weeks of implantation in vivo. Nevertheless, the composites with Herafill were the most attractive for bone cells and the zirconium dioxide positively influenced the radiological contrast. Nonetheless, it will be necessary to improve the mechanical properties to obtain an appropriate load-bearing material.

Porous 3D implants of PHB seeded with MSCs showed new bone tissue formation in bone defects [50]. It gradually biodegraded, allowing bone tissue ingrowth with a minimal inflammatory response; after 120 days, the defect completely closed. Moreover, the MSCs retained their viability and rate of proliferation, enabling a more effective regeneration.

SILK FIBROIN

Silk is composed of fibroin fibers enfolded by a glue-like coating of sericin. It is produced by several arthropods (e.g., silkworms and spiders). The most common and extensively used type of silk in the textile industry is produced by the silkworm *Bombyx mori*. The composition and structure of silk can vary with the species that produces it, which can influence its mechanical properties, bioactivity, and degradation behavior [55]. It has attracted attention because of its potential use in biomedical applications owing to its biocompatibility and biodegradability [55].

Silk fibroin can easily be separated from the sericin (degumming) using a boiling alkaline or surfactant solution. The result fibers are around 10−25 μm in diameter and are composed of a light chain (≈25 kDa) that is hydrophilic, and a heavy chain (≈350 kDa) that is hydrophobic. The chains are connected by a disulfide bond and are assembled with glycoprotein P25 (≈25 kDa). The heavy chain is composed of glycine-X (in which X is Ala, Ser, Thr, or Val) repeats, which form antiparallel β-sheets, usually called silk-II. The light chains are amorphous blocks in a random coil, which gives elasticity to silk, usually called silk-I [55]. The proportions of silk-I and silk-II may define the final properties of silk. For example, by increasing the amount of silk-II (β-sheet structures), the time of degradation increases.

Different parameters, such as processing techniques, can modify the mechanical properties of silk fibers. In addition, silk has no immunogenicity or cytotoxic effects [56]. When some immunogenic reaction to silk is observed, it is attributed to the sericin proteins.

Processing Methods

Silk fibroin can be processed using different techniques for different architectures, as shown by Correia et al. [57]. They produced scaffolds using different solvents (aqueous versus hexafluoro-2-propanol [HFIP]), different pore sizes (250−500 versus 500−1000 μm), and different structures (lamellar versus spherical pores). To obtain aqueous-derived scaffolds with spherical pores, they used a salt leaching technique employing sodium chloride particles that were removed with water. In the case of aqueous-derived scaffolds with lamellar pores, they cast the silk solution in a tube, froze it, lyophilized it, and induced the formation of β-sheet by autoclaving the scaffolds. On the other hand, to produce HFIP-derived scaffolds, they used salt leaching technique as previously described and induced the β-sheet by freeze-drying it. The first technique resulted in pores sizes ranging from 140 to 250 μm, high interconnectivity (97%), and high porosity (87%) whereas the second resulted in smaller pore sizes (126 μm), lower interconnectivity (63%), and lower porosity (64%). Moreover, the HFIP-based silk scaffold had a higher stiffness than did the aqueous-derived scaffolds.

Sommer et al. compared two different processes, salt leaching and inverse opal, to obtain reproducible highly porous scaffolds (Fig. 32.5) [58]. Salt leaching resulted in scaffolds with pore sizes varying from 6 to 678 μm and 92% porosity, whereas inverse opal resulted in scaffolds with pores sizes varying from 6 to 312 μm and 84% porosity.

Wang et al. used electrospinning to produce fibers about 167 nm in diameter but with a low tensile strength [59]. They also blended silk with poly(lactide-*co*-ε-caprolactone) to obtain higher fiber diameters (≈250 nm) and higher tensile strength, which showed improved cellular interactions in vitro and enhanced new bone formation in vivo.

3D plotting allows the development of scaffolds with a controlled hierarchical structure with different pore sizes, which facilitates cell attachment, proliferation, vascularization, and the delivery of nutrients and physical cues. Xu et al. fabricated hierarchically porous scaffolds using 3D plotting and freeze-drying [60]. The obtained scaffold had a first level with 1-mm pores and a second level with approximately 50- to 100-μm pores. This hierarchical structure increased cell attachment four times and enhanced cell proliferation, ALP activity, and bone-related gene expression compared with no hierarchical structures.

Silk Fibroin in Bone Tissue Engineering Applications

Silk fibroin is a biomaterial with attractive features for bone tissue engineering. Correia et al. showed that higher stiffness resulted in higher osteogenic induction and the formation of bone-like tissue [57]. Although the mechanical properties were inferior in developed silk scaffolds compared with those in decellularized trabecular bone scaffolds, the cellular activities were similar. Finally, they suggested that lamellar pores were beneficial for differentiation into lamellar bone, whereas spherical pores led to the development of woven bone.

Nevertheless, it is challenging to obtain scaffolds with mechanical properties that meet the high compressive properties of bone. Mandal et al. developed a high−compressive strength polymeric bone composite based on

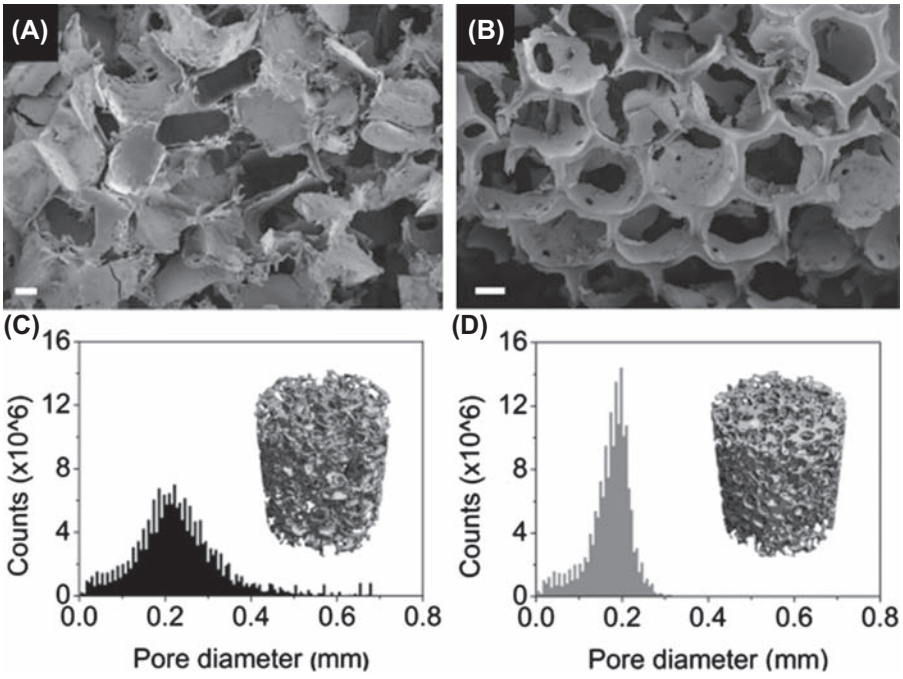

FIGURE 32.5 Scanning electron micrographs of silk scaffold pores produced by: (A) salt-leached process, or (B) inverse opal (scale bar = 100 μm). Pore diameter distribution of: (C) salt-leached scaffolds and (D) inverse opal scaffolds. *Adapted with permission Sommer MR, Vetsch JR, Leemann J, Muller R, Studart AR, Hofmann S. Silk fibroin scaffolds with inverse opal structure for bone tissue engineering. J Biomed Mater Res B Appl Biomater 2016.*

silk protein−protein interfacial bonding [61]. For that, they produced a micron-sized silk fiber and used it as filler for a silk matrix, increasing the mechanical properties 50- to 100-fold compared with control HFIP−silk scaffolds. The result, which was associated with surface roughness and porosity, favored stem cell differentiation into osteoblasts in vitro. In addition, a minimal in vivo immunomodulatory response was observed.

Using a different strategy, Yan et al. developed silk/nanosized calcium phosphate to improve silk scaffolds for bone tissue engineering [62]. The promising results had improved mechanical properties, architecture, and stability, bioactivity, and no cytotoxicity. Later, the authors conducted in an in vivo study in which the developed scaffolds promoted new bone formation [63]. The group demonstrated the use of a bilayer construct composed of a silk scaffold and a silk/nanosized calcium phosphate scaffold is a promising candidate for osteochondral defect regeneration [64].

To mimic the composition of bone, silk was mixed with HAp, the primary mineral found in bone, to produce an osteoinductive composite. HAp not only increased the compressive strength of the scaffolds, it enhanced the growth and osteogenic capability of cells [65].

Nanofibrous silk scaffolds also showed promising results owing to their similarity with the native ECM. The silk-based nanofibrous scaffolds facilitated cell proliferation and osteogenic differentiation in vitro [59]. Furthermore, in vivo, they promoted new bone formation, demonstrating their potential for bone tissue regeneration.

STARCH

Starch is naturally produced by plants and algae in the form of granules as an energy-storing compound. These granules have different sizes (1−110 μm) and composition depending on the source. There are two types of starch: transitory and storage. The first is produced during photosynthesis in leaves and is rapidly degraded; the second is stored for longer periods in seeds or roots [66].

This biodegradable and inexpensive natural polymer is composed of two types of α-glucan polymers, linear poly(1,4-β-D-glucopyranose) (amylose) and branched poly(1,4-β-D-glucopyranose) with branches of (1,6-D-glucopyranose) (amylopectin) occurring in nearly every 25 glucosidic moieties [66].

Starch is the main carbohydrate source in the human diet. It is degraded by the action of amylases, which act on α-1,4-glycosidic bonds. The degradation products are oligosaccharides that can be metabolized to produce energy.

Native starch can be recognized as waxy starch with a low amylose content, normal starch with 15%–30% amylose, and high amylose with more than 50% amylose. The crystallinity of these can vary from 50% in waxy starch to 15% in high-amylose starch [67].

To process starch using different methods and allow its use in various applications, it is necessary to disrupt and melt its semicrystalline granular structure, i.e., gelatinization. During gelatinization there is the diffusion of water into the interior of the granules, producing swelling and consequently disruption of the crystalline structure. The amount of amylose is inversely related to the energy necessary to initiate gelatinization. In this sense, high-amylose starch needs less heat to initiate gelation compared with waxy starch.

Starch is usually brittle, which limits its use in most applications. Thus, to improve the properties of starch, it needs to be modified or blended with other polymers.

Processing Methods

Because of the thermoplastic behavior of starch-based blends and composites, it is possible to produce scaffolds using traditional solvent casting methodologies [68]. For that, starch-based blends are dissolved in chloroform, cast onto a mold, and allowed to dry. In a different approach, blends of starch and cellulose were processed by combining solvent casting, salt leaching, and freeze-drying [69]. The obtained scaffolds had a porosity between 20% and 50%, depending on the components. The porosity increased with an increase in the amount of components. The authors also showed that adding cellulose promoted an increase in tensile properties, as demonstrated by the increase in Young's modulus and tensile strength. However, a decline in the compression modulus and compression strength was observed.

A different study used a supercritical assisted phase-in version process because it allowed control over the scaffolds' structure by fine-tuning the temperature and pressure [70]. In this case, the polymer solution was placed into a mold and immersed in a nonsolvent bath, which originated the phase separation under controlled temperature and pressure. The scaffolds had 64% porosity and 65% interconnectivity at 45°C and 80 bar. However, at 55°C and 150 bar, the scaffolds had a more compact structure with low interconnectivity (Fig. 32.6).

Wet spinning was also used to produce fibers of starch mixed with other polymers, such as poly(ε-caprolactone) [68,71]. This technique consisted of extruding a polymer solution loaded into a syringe into a coagulation bath (e.g., a

methanol or calcium silicate solution). The fibers' thickness was approximately 100–200 μm and the final scaffolds had a porosity of 60%–85%, depending on the coagulation solution used. When methanol was used, the porosity was higher than in the case of the calcium silicate solution [71].

A different approach was pursued to obtain fibers without using solvents, which can be risky for tissue engineering [72]. In that study, fibers were prepared using melt spinning followed by fiber bonding. The first step consisted of extruding the polymer at 150°C into a bath at 13°C. The fibers produced using this method were 120–500 μm in diameter. Then, to prepare the scaffolds, the fibers were chopped and placed into a mold and heated to 120°C. In a further step, pressure was gently applied to avoid crushing the fibers and to maintain porosity. The scaffolds produced using this method had about 75% porosity and 97% pore interconnectivity, in which the pore size was around 275 μm [72].

Furthermore, water-in-oil emulsification can be used to obtain starch–chitosan microparticles [73]. The microparticles' scaffolds had a pore size of 80–150 μm.

In a different study, nanocomposites of starch, HAp, and chitosan were produced using coprecipitation [74]. For that, a solution of starch and chitosan was prepared, followed by the addition of calcium nitrate and 3-deoxy-D-arabinoheptulosonate 7-phosphate synthase to promote the nucleation of HAp. Finally, the produced composites were allowed to dry at 85°C. The porous scaffolds obtained had a compressive strength of about 9 MPa, which is in the range of the compressive strength of trabecular bone.

Starch in Bone Tissue Engineering Applications

A number of studies used starch-based scaffolds for bone tissue engineering. Scaffolds composed of starch with polycaprolactone and stem cells improved bone regeneration upon implantation into a critical-sized defect [75]. In one study, several stages of osteoblastic differentiation were tested to improve bone regeneration when seeded on starch and polycaprolactone scaffolds [76]. The authors observed that scaffolds loaded with osteoblastic cells had a higher amount of new bone formation compared with scaffolds loaded with no differentiated cells. In addition, blood vessels were observed in the periphery of the scaffold with and without cells, which indicated that this strategy promoted not only new bone tissue formation but also angiogenesis.

In an improved approach, Leonor et al. modified scaffolds of starch and polycaprolactone with silanol groups [71]. Silanol groups were reported to promote osteoblast differentiation, which is an interesting feature for bone tissue engineering strategies. The developed scaffolds showed that the silanol functional groups promoted the differentiation of stem cells into osteoblasts.

Requicha et al. produced a double-layer scaffold for use in periodontal defects, composed of one membrane layer and a 3D scaffold layer [68]. The membrane layer prevents the ingrowth of the gingival epithelium into the periodontal defect and promotes the recruitment and adhesion of native cells. The 3D scaffold layer supports new bone tissue ingrowth. The assay showed that stem cells were able to adhere and proliferate, and that in the presence of silanol groups, they were able to express osteogenic markers. Taking into consideration these promising results, the authors tested the developed double scaffold in vivo in a mandibular rodent model [77]. After 8 weeks of implantation, the scaffolds had higher new bone formation than did the collagen control scaffolds. In addition, no proliferation of bone tissue was observed along the membrane layer, which indicated the success of the design of the first layer for preventing the ingrowth of tissue. However, no differences were observed between scaffolds with or without silanol groups.

NATURAL-BASED BIOCERAMICS

Bioceramics are used in tissue engineering as solid scaffolds (e.g., reconstruction of ear ossicles), powders (e.g., bone filling), and porous scaffolds (e.g., bone regeneration). Among those, bioceramics can be divided into nearly inert (e.g., zirconia), bioactive (e.g., bioactive glass), and resorbable (e.g., calcium phosphates). The first type, nearly inert, is not usually chosen for regenerative medicine because it promotes the formation of a fibrous capsule instead of tissue regeneration. The other two types, bioactive ceramics and resorbable ceramics, have been considered promising materials for bone regeneration and have undergone clinical trials. For example, calcium phosphate has been studied as a synthetic bone graft for donor site repair [78], and silica-based bioactive glasses have been used for the rehabilitation of canal-wall-down mastoidectomies [79]. Here, we will highlight the routes and natural origin sources for obtaining these materials and review their application in bone tissue engineering strategies.

CALCIUM PHOSPHATES

Calcium phosphates are crystalline ceramics with a structure and chemical composition similar to minerals found in bone. An example of calcium phosphate widely used is HAp, which is represented by the chemical formula ($Ca_{10}[PO_4]_6[OH]_2$); it has a structure similar to the main mineral found in bone, apatite.

HAp is available as a bone filler and as coatings on prostheses, owing to its good biocompatibility, bioactivity, high osteoconductive and/or osteoinductive capacity, nontoxicity, noninflammatory behavior, and nonimmunogenic properties [80]. Calcium phosphate scaffolds are described as promoting osteogenesis and osteointegration, which seems to be related to surface charge and the chemistry and topography of the scaffolds. However, this ceramic has a low resorption rate. Therefore, other calcium phosphates, such as β-tricalcium phosphate, which have fast resorption rates, have been studied. As an alternative, new sources of calcium phosphate have been explored (Fig. 32.7). Calcium phosphates can be extracted from different marine origins such as fish bones, corals, seashells, and algae. Sponges from the phylum Porifera have been explored because their skeleton is composed of bioceramics [81], and new methods have been developed to assess the overall regenerative and mineralogenic performance in zebrafish [82]. HAp has been extracted from the porous exoskeleton of corals owing to its similarity to bone and its mechanical, osteoconductive, and resorbable properties. This interesting material can be found commercially, such as in Pro Osteon 200R (Biomet), an osteoconductive bone graft.

Another marine source that is widely used is shells, which are mainly composed of calcium carbonate associated with approximately 2% polysaccharides and glycoproteins. Eggshells are also an interesting source for obtaining HAp [83]. Eggshells are an easily obtained, low-cost resource because they come from food waste and the HAp can be readily extracted by calcination and milling.

Synthetic HAp can be produced by different methods [1]: hydrothermal (in the presence of water and at a high temperature and pressure) [2]; sol–gel (formed by apatite crystals at a low temperature and pressure owing to the high reactivity of calcium and phosphorus reagents used) [3]; wet chemical (by mixing an aqueous precursor solution or hydrolyzing calcium phosphate); and [4] biomimetic deposition (the nucleation of HAp when subjected to

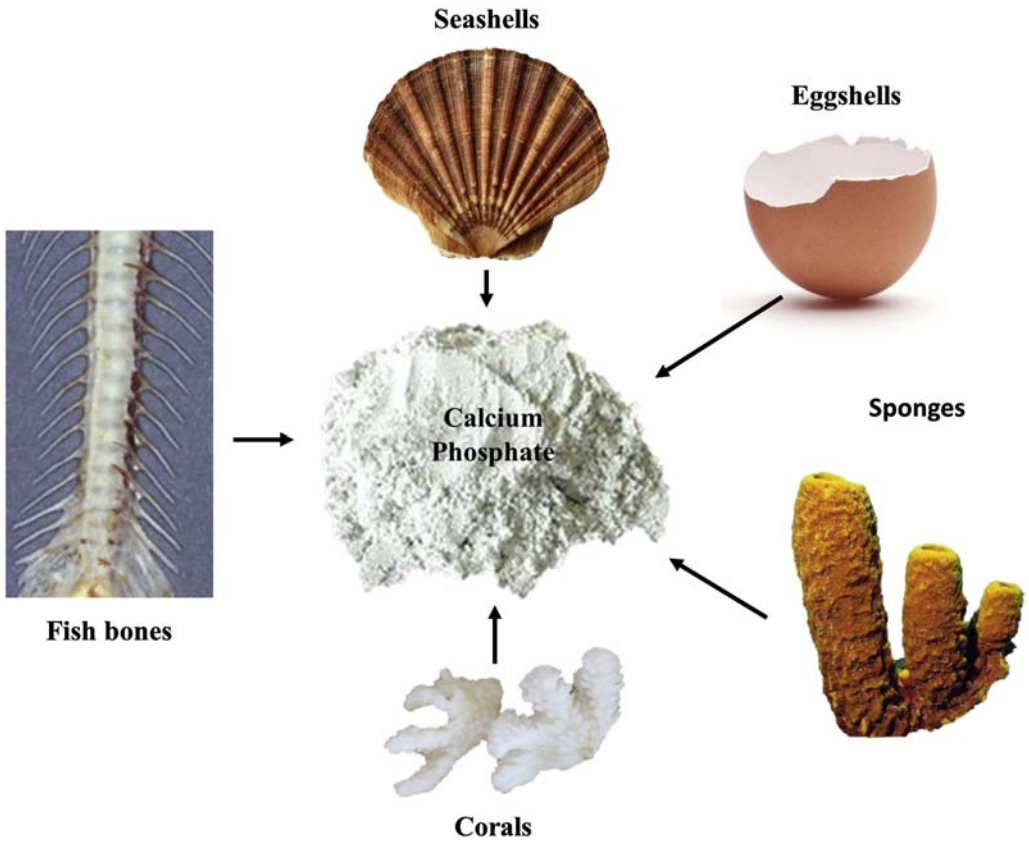

FIGURE 32.7 Some sources of calcium phosphate.

body fluids) [84]. In addition, parameters such as the pH, reaction time, temperature, and concentration of reagents during synthesis can influence the obtained HAp.

Apart from the differences observed caused by the different extraction or production method and origin, natural HAp had better outcomes than synthetic HAp [83]. This could be the result of significant differences observed between naturally derived HAp and synthetic HAp.

Processing Methods

HAp forms a bond with the host tissue. This feature has made this material the first choice for preparing scaffolds for bone tissue engineering.

HAp scaffolds can be obtained by foam replication, which requires the use of a polymeric mold and allows control over the scaffolds' structure. For example, polyurethane sponges can be used as templates [85]. During this procedure a suspension of HAp is mixed with porous synthetic polymeric foams until the pores are totally filled and sintered, allowing the development of a porous scaffold with a porosity of about 70%. The obtained pore size varies between 100 and 300 μm and the pore wall has a thickness of 50 μm. Moreover, it was shown that the pores are uniformly distributed. The compressive strength of the prepared scaffolds, 1.3 MPa, is close to that of cancellous bone.

Rapid prototyping technologies are being used to produce scaffolds with precise morphology (e.g., shape, porosity, and pore size). Control over mechanical properties, biological effects, and degradation kinetics is associated with control of the scaffold architecture. Furthermore, that approach can enable the development of dimensionally accurate prototypes of bone, which is an attractive feature for bone engineering. Solid free-form fabrication allows the production of inorganic complex-shaped scaffolds directly from 3D objects fabricated using computer-aided design [86]. For that, an HAp slurry is produced by mixing HAp powder with a freezing vehicle (e.g., camphene). Then the slurry is placed into a mold previously produced using a stereolithography device and allowed to cool. Finally, it is freeze-dried to remove the freezing vehicle and sintered to remove the mold and any freezing vehicle still present, which densifies the scaffold. This method allows the production of pores 100 μm in diameter. A similar approach that creates custom scaffolds is 3D printing [87]. The scaffold can be produced with complex internal structures and high resolution. Scaffolds prepared by this method had smaller pores (10−60 μm) and a porosity of about 50%. In addition, the compressive strength (0.88 MPa) was close to the lower limit of cancellous bone.

Gas foaming, in which the production of gas allows the development of pores, was used to produce an inorganic porous matrix [88]. Hydrogen peroxide was mixed with a ceramic slurry, which generated gas after heating. Then, the slurry was molded, dried, and sintered, resulting in a scaffold with interconnected pores and 75% porosity. The pore size ranged from 200 to 400 μm.

Franco et al. produced fibers of HAp of submicron dimensions using electrospinning [89]. They took advantage of the gel phase produced during the sol−gel technique for HAp production. At the end, the fibers were sintered. This technique produced fibers 122 nm in diameter for the lower viscosity tested and 567 nm for the higher viscosity.

Calcium Phosphate in Bone Tissue Engineering Applications

Scaffolds should meet some criteria to enable tissue regeneration. In addition to being biocompatible and porous (minimum pore size of about 100 μm for tissue ingrowth), scaffolds should be osteoconductive and osteoinductive, which are well-known features of HAp scaffolds. Moreover, some issues need to be overcome to fulfill all of the criteria, such as the ability to fine-tuning biodegrading and to improve mechanical strength. Tripathi et al. studied new methods for scaffold preparation that allowed scaffold architecture to be tailored [85]. Using sponges as a template, they successfully obtained scaffolds that enabled the attachment and differentiation of human osteoblasts.

Bone tissue is composed not only of HAp but also of collagen type I. To mimic bone composition, Changchun et al. developed a scaffold with a hierarchical structure composed of calcium phosphate, collagen, and HAp [88]. These scaffolds demonstrated better mechanical strength than scaffolds composed solely of calcium phosphate, and had good biocompatibility. In addition, the authors observed better osteoinductivity and increased bone formation in vivo compared with calcium phosphate scaffolds and calcium phosphate with collagen scaffolds. Thus, the developed scaffolds composed of calcium phosphate, collagen, and HAp are a promising material for bone engineering.

The mechanical properties of synthetic HAp scaffolds are still in the lower limit of mechanical properties presented by natural bone. Therefore, Nandi et al. pursued the possibility of HAp derived from natural sources such as marine corals, which are described as exhibiting mechanical properties and porosity similar to those of natural bone [90]. They developed coralline HAp scaffolds with growth factors to enhance the formation of bone tissue.

Upon mechanical evaluation, the authors observed adequate compressive strength values for coralline HAp scaffolds. Moreover, the in vivo assessment of scaffolds loaded with growth factors showed higher new bone formation compared with scaffolds without growth factors.

SILICATE CERAMICS

Silicate ceramics can be found in the skeleton of some marine sponges. This inorganic polymer is produced by an enzymatic reaction in siliceous sponges during the formation of the skeleton. Bioactive silicate ceramics have been studied for bone tissue engineering owing to their ability to induce the formation of an apatite layer on their surface. The apatite layer stimulates cell differentiation along the osteoblastic lineage and favors the adhesion of stem cells [91]. Silicate ceramics are described as enabling osteointegration with host bone. More than 20 different silicate ceramics have been developed with fine-tuned mechanical properties, bioactivity, and degradation rates. However, the low mechanical properties of this material have limited its application as a filler or coating for metal implants. Generally, silicate ceramics allow cell adhesion, but differences in chemical composition result in different adhesion rates. Their composition influences surface degradation, which could influence cell adhesion.

Among the silicate ceramics, the most well-studied is silicate-based bioactive glass 45S5, also known as Bioglass [92]. One of the most attractive characteristics of bioactive glass is the release of soluble ions during degradation, which that can induce bone formation [92]. Furthermore, bioactive glass 45S5 promotes the secretion of angiogenic growth factors in vitro and angiogenesis in vivo [91]. However, its use in clinics is limited and it is employed less often than calcium phosphates. Different limitations have been pointed out to explain this. For example, bioactive glass has slow degradation rates, which limit bone growth [91], and the preparation of porous scaffolds is challenging [92]. Some features of bioactive glass, such as brittleness and the promotion of nucleation, have prompted its use for improving the mechanical properties and bioactivity of other materials [40].

Processing Methods

Bioactive glass can be obtained through different techniques. The most widely used is the sol−gel process, which is composed of the formation of an inorganic network [93]. For that, metal alkoxides in solution are mixed and further hydrolyzed and gellified. Finally, they are submitted to low-temperature firing to produce a glass phase and then dried, sintered, and fractured. This method obtains pores with a diameter between 6 and 18 nm. A different method is the melt-derived approach, in which the glass components are mixed, melted, and homogenized at high temperature [96]. The melted solution is poured into a liquid and then cool and cracked into small pieces to obtain a powder.

Porous scaffolds of bioactive glass have been developed through different methods to adjust the pore size and interconnectivity, such as foaming [94]. This method is composed of mixing the ceramic slurry with the polymeric foam, which is eliminated at the end of the process. With this approach, the foam determines the final scaffolds' architecture, allowing pore sizes to be controlled.

Particulate leaching is a different method also used to produce glass scaffolds [95]. In this case, porogen particles are mixed with the ceramic slurry and leached out during the sintering step. The resulting scaffold has an interconnected network.

A different method is the melt-derived approach [96]. This approach consists of mixing the glass components followed by melting and homogenizing them at high temperature. Afterward, the melted components are placed into a mold to obtain the desired scaffold. A different approach is to use the melt glass to produce fibers, a technique known as melt spinning. For example, Deliormanli et al. prepared a solution of bioactive glass by mixing different precursors (tetraethyl orthosilicate, triethyl phosphate, calcium nitrate tetrahydrate, potassium nitrate, magnesium nitrate hexahydrate, and sodium nitrate) with aqueous PVA [97]. Then, this solution was electrospun under an applied voltage, aged at 60°C, allowed to dry at 120°C, and finally sintered.

Silicate in Bone Tissue Engineering Applications

As mentioned, silicate ceramic scaffolds fulfil many of the criteria of an ideal scaffold, but they are brittle. Therefore, new strategies have been pursued to improve they mechanical characteristics of these scaffolds, such as fabricating composite scaffolds composed of an inorganic and an organic phase. Moreover, some studies have used this

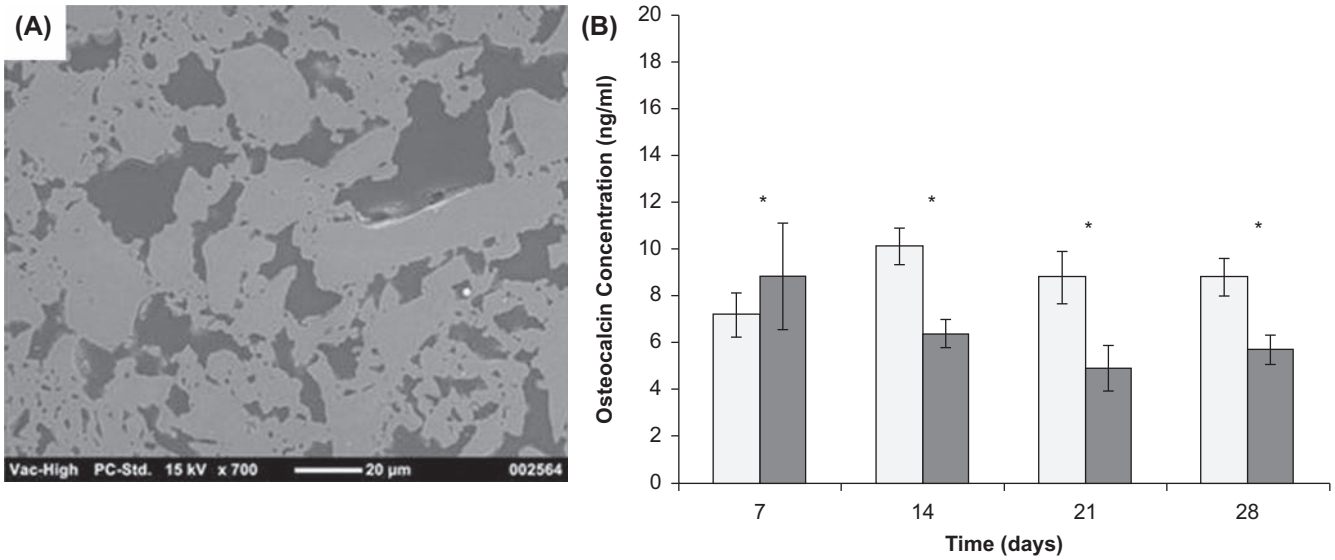

FIGURE 32.8 Effect of silicate-substituted calcium phosphate with enhanced porosity versus Bioglass on osteogenic marker expression. approach to improve the mechanical properties of other materials such as hydrogels [40]. Gantar et al. reinforced gellan gum hydrogels with bioactive glass nanoparticles and observed an improvement in mechanical properties and bioactivity. In addition, the developed composite sponge-like hydrogels allowed stem cell adhesion and spreading, showing great promise for bone tissue engineering. In a different study, bioactive glass was mixed with chitosan, promoting the enhancement of the scaffolds' mechanical properties [12]. The improvement in mechanical properties resulted from the formation of an apatite layer upon body fluid immersion.

In in vivo studies, bioactive glass was loaded with growth factors to promote repair of bone defects [98]. Upon implantation of the designed scaffolds into critical size defects, a bridging callus was observed only in scaffolds loaded with the growth factor. In a study conducted by Meretoja et al., poly(ε-caprolactone/D,L-lactide)-based scaffolds were filled with bioactive glass and implanted ectopically [99]. After 12 weeks, the authors showed that the developed scaffolds were able to induce ectopic bone formation.

Silicate-substituted calcium phosphate with enhanced porosity was developed by De Godoy et al. and compared with Bioglass in vitro [100]. Higher cell adhesion and enhanced cell differentiation along the osteogenic lineage were observed in cells cultured in silicate-based scaffolds, compared with Bioglass. The obtained results showed that the microstructure and chemistry of the scaffold influence cells behavior (Fig. 32.8).

CONCLUSIONS

The unique properties of natural-based materials have attracted the interest of many scientists, with the purpose of repairing and regenerating damaged bone tissue. Bioavailability, the possibility of blending, and the processability of each material guarantee its use, alone or in combination, in the continuous pursuit of an ideal approach to obtaining an efficient therapy. However, natural-based materials have some limitations that must be overcome. Although the future of bone tissue regeneration is promising, much work must be done, namely in what concerns to the need of promote the vascularization of implants when large bone defects regeneration is envisioned. The continuous development of new and personalized technologies such as high-resolution bioprinting has provided new tools that allow the exploration of the potential of natural-based materials in the clinic. At the same time, these new tools and other advanced processing technologies have encouraged the creation of personalized and safer medical devices, which may enhance their success rate and faster translation to the clinics. In addition, growing knowledge in the most diverse fields, such as an increasing understanding of interactions between biological tissues and materials, will boost progress of new strategies. Ultimately, this progress will result in the optimization of the performance of natural-based materials and their successful translation to clinics.

Synthetic Polymers

Michael C. Hacker[1], *Jan Krieghoff*[1], *Antonios G. Mikos*[2]

[1]University of Leipzig, Leipzig, Germany; [2]Rice University, Houston, TX, United States

INTRODUCTION

Regenerative medicine is an emerging interdisciplinary approach to repairing or replacing damaged or diseased tissues and organs. To reestablish tissue and organ function impaired by disease, trauma, or congenital abnormalities, regenerative medicine employs cellular therapies, tissue engineering strategies, and artificial or biohybrid organ devices. Typically, these techniques rely on combinations of cells, genes, morphogens, or other biological building blocks with bioengineered materials and technologies to address tissue or organ insufficiency.

Materials used in these approaches range from metals and ceramics to natural and synthetic polymers as well as their microcomposites and nanocomposites. When used in a three-dimensional context, these materials are processed into microporous and/or nanoporous cell carriers of various structures and properties, typically called scaffolds, a topic discussed elsewhere in this book. This chapter focuses exclusively on synthetic polymers used in regenerative medicine. Some synthetic derivatives of natural materials are briefly discussed where appropriate. In addition to the various facets of regenerative medicine, a plethora of synthetic polymers with different compositions and physicochemical properties have been developed and investigated; however, research is ongoing. Synthetic materials have an important key role in many applications of regenerative medicine, including implants, tissue engineering scaffolds, and orthopedic fixation devices. In a broader sense, sutures, drug delivery systems, nonviral gene delivery vectors, and sensors made from synthetic polymers are further examples.

This chapter provides a structural overview of these synthetic polymers and discusses their physicochemical characteristics, structure–property relationships, applications, and limitations. Synthetic polymers that are hydrolytically labile and erode (biodegradable polymers) are considered, as are as those that are bioinert and remain unchanged after implantation (nondegradable polymers). It is the authors' intention to provide a thorough overview of available classes of synthetic material. Some polymer classes are briefly mentioned and their chemical structures are provided; other more relevant materials are discussed in greater detail. For most polymer classes and properties, reviews are referenced for guidance to further reading.

In general, the history of biomaterials can best be organized into four eras: prehistory, the era of the surgeon hero (first-generation biomaterials), designed biomaterials and engineered devices (second-generation biomaterials), and the contemporary era leading into the new millennium (third-generation biomaterials) [1,2]. As far back as AD 600, the use of dental implants made from materials such as seashells or iron was reported. Also, there is evidence that sutures have been used to close large wounds for as long as 32,000 years. The word "biomaterials," however, was introduced within the half century. Almost at the same time, aided by rapid advancements in industrial polymer development and synthesis, the exploration of synthetic polymers for biomedical applications began. The development of plastic contact lenses, using primarily poly(methyl methacrylate) (PMMA), started around 1936, and the first data on the implantation of nylon as a suture were reported in 1941. This development was accompanied by studies on the biocompatibility of the new materials. From the beginning, differences in foreign body reactions to the materials became apparent. Additives such as plasticizers, unreacted monomers, and degradation products were discussed as possible causes leading to an awareness of polymer's quality for biomedical applications and biocompatibility testing.

At the end of World War II, a wide variety of durable, high-performance metal, ceramic, and especially polymeric materials was available, inspiring surgeons to break new ground in replacing diseased or damaged body parts.

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00033-3

Materials including silicones, polyurethanes (PUs), Teflon, nylon, methacrylates, titanium, and stainless steel were available "off the shelf" for surgeons to apply to medical problems [2]. Primarily medical and dental practitioners, driven by the vision to replace lost organ or tissue functionality, used minimal regulatory constraints to develop and improvise replacements, bridges, conduits, and even organ systems based on such materials. Those pioneering approaches laid the foundation for novel procedures and engineered biomaterials. Such early implants made from industrial materials available "off the shelf" were often poorly biocompatible, in many cases owing to insufficient purity. With a developing understanding of the immune system and foreign body reactions, the first generation of materials was developed during the 1960s and 1970s by engineers and scientists for use inside the human body. The primary goal of early biomaterial development was to achieve a suitable combination of physical properties to match those of the replaced tissue with a minimal toxic response in the host [3]. After this paradigm, more than 50 implanted devices made from 40 different materials were in clinical use in 1980. In the early 1980s, research began to shift from materials that exclusively exhibited a bioinert tissue response to materials that interacted actively with their environment. Another advance in this second generation was the development of biodegradable materials that exhibited controllable chemical breakdown into nontoxic degradation products that were either metabolized or directly eliminated. Biodegradable synthetic polymers were designed to resolve the interface problem, because the foreign material is ultimately replaced by regenerating tissues and eventually the regeneration site is histologically indistinguishable from the host tissue. By 1984, resorbable polymers were routinely used clinically as sutures. Other applications in fracture fixation aids or drug delivery devices quickly emerged. Despite the considerable clinical success of bioinert, bioactive, and resorbable implants, there is still a high long-term prosthesis failure rate and the need for revision surgery [2].

Improvements in first- and second-generation biomaterials have been limited for one main reason: unlike living tissue, artificial biomaterials cannot respond to changing physiological loads or biochemical stimuli. This limits the lifetime of artificial body parts. To overcome these limitations, a third generation of biomaterials is being developed that involves the molecular tailoring of resorbable polymers for specific cellular responses. By immobilizing specific biomolecules such as signaling molecules or cell-specific adhesion peptides or proteins onto a material, it is possible to mimic the extracellular matrix (ECM) environment and provide a cell-adhesive surface [1,4–6]. Biomimetic surfaces are promising tools for controlling cell adhesion, integrating implants, differentiating cells, and developing tissues. Synthetic polymer matrices can also be tailored to deliver drugs, signaling molecules, and genetic code and thus provide versatile technologies for regenerative medicine [7–9]. Constantly expanding knowledge of the basic biology of stem cell differentiation and the corresponding signaling pathways as well as tissue development provides the basis for the molecular design of scaffolds. In attempts at tissue engineering, which aim to regenerate lost or defective tissue by transplanting in vitro engineered tissue constructs based on a patient's own cells, one no longer strives to match scaffold mechanical properties closely to those of the replaced tissue. Instead, it is considered important for the engineered transplanted construct to be steadily remodeled in vivo to resemble the histological and mechanical properties of the surrounding tissue [10]. Owing to this paradigm shift, mechanically labile hydrogels, especially injectable systems that can be used to encapsulate cells directly, have gained great importance as the basis for biomimetic cell carriers. Hydrogels are characterized by a high content of water that allows encapsulated cells to survive and enables the sufficient passive transport of nutrients, oxygen, and waste. Hydrogel-forming materials typically offer functional groups for chemical modifications, and their degradation can be controlled by chemical composition and cross-linking content.

After a brief overview on synthesis techniques, inert and biodegradable synthetic polymers representative of all three generations will be presented in subsequent sections. Their structure, synthesis, physicochemical properties, and applications will be described.

POLYMER SYNTHESIS

Polymerization reactions for the synthesis of organic polymers are often categorized into chain-growth polymerizations and step-growth polymerizations, depending on how the chemical process of chain formation proceeds. The synthesis of polymers with a carbon–carbon backbone such as polyolefins and polyacrylates typically follows a chain-growth mechanism [11]. Chain-growth polymerizations involve the steps of chain initiation, chain propagation, and termination. Characteristics of this type of polymerization are that chain growth occurs only by the addition of monomers to the active chain end, generally at a high speed, and that only the monomer and polymer are present during the reaction. Depending on the nature of the reactive center of the propagation chains, chain-growth reactions are subdivided into radical, ionic (anionic or cationic), or transition-metal mediated (coordinative

or insertion) polymerizations. Suitable monomers contain an unsaturated carbon–carbon bond (double or triple) or are cyclic molecules with a sufficiently high ring strain. For the industrial synthesis of polyolefins, for example, free radical and transition-metal mediated polymerizations are commonly employed. Unlike radical polymerization, transition-metal coordinated mechanisms, such as with Ziegler–Natta catalysts, allow for the control of polymer tacticity [12]. A milestone in chain-growth polymerization history was the development of controlled or living radical polymerization techniques that allow for the precise control of polymer composition and architecture and yield polymeric products with low polydispersity [13].

Polymers that contain heteroatoms in the main chain are typically synthesized by a step-growth mechanism. During step-growth, the polymer molecular weight increases through the reaction of any two molecular species, i.e., monomers, oligomers, and polymer chains. In contrast to chain-growth, monomers disappear early on during the reaction and the polymer molecular weight slowly increases over the course of the reaction, which can last for days. Typical polymerization types that follow a step-growth mechanism are polycondensation and polyaddition reactions. In condensation reactions, small molecules such as water, alcohols, or hydrochloric acid are eliminated during step-growth. Polyethylene terephthalate and polyamides such as nylon and poly(propylene fumarate) [14] are examples of polymers that are synthesized by condensation reactions between carboxylic acid derivatives and diols or diamines (nylon). Most polyanhydrides are also synthesized by polycondensation reactions [15]. Polyaddition reactions follow a similar mechanism because nucleophilic groups react with electrophilic moieties during polymer chain buildup. In contrast to condensation reactions, addition reactions combine monomers without eliminating a small molecule. During PU synthesis, for example, diisocyanate monomers are reacted with diamines or dihydroxy-terminated molecules in the presence of catalysts under the formation of urethane and urea groups, respectively, to build up polymer chains [16].

Ring-opening polymerizations (ROPs) also yield polymers with heteroatoms in the main chain and are used to synthesize polyamines, polyethers such as poly(ethylene glycol)s (PEGs), and most biodegradable polyesters including polylactides, polyglycolides, and copolymers [17]. ROPs can follow chain-growth and step-growth kinetics and are executed in melts or solutions in the presence of catalysts and heat.

Driven by advances in drug design through combinatorial approaches in small-molecule chemistry, similar techniques have been adapted to polymerization chemistry [18]. Through the systematic screening of libraries of polymeric materials that have similar chemistries but are synthesized from a series of different monomers and comonomers in various combinations, structure–property relations can be identified and polymer properties can be fine-tuned for specific applications. Polymer properties that are screened using such approaches include the material's glass transition temperature, degradative properties, air–water contact angle, mechanical properties, cytocompatibility and cell proliferation.

NONDEGRADABLE SYNTHETIC POLYMERS

A common characteristic of most nondegradable synthetic polymers is their biological inertness [1]. These materials were developed to reduce the host response to the biomaterial to a minimum. Nondegradable synthetic polymers provide the basis for a plethora of medical devices as diverse as suture materials, orthopedic implants, fracture fixation devices, and catheters and dialysis tubing. These materials are also applied as implantable carriers for the long-term delivery of drugs, e.g., contraceptive hormones. Despite their excellent biological inertness and well-adjustable mechanical properties, orthopedic implants made from nondegradable synthetic polymers and nondegradable bone cements ultimately fail at a high rate from problems at the interface arising from a lack of integration with the surrounding tissue, infections, or bone resorption caused by stress shielding [19,20].

Major groups of nondegradable synthetic polymers are highlighted in the following section.

Polymers With a –C–C– Backbone

Polyethylene and Derivatives

Poly(ethylene), Poly(propylene), and Poly(styrene)

Poly(ethylene) (PE) (Fig. 33.1A), poly(propylene) (PP) (Fig. 33.1B), and poly(styrene) (PS) (Fig. 33.1C) are ubiquitous industrial polymers that have been applied as biomaterials. All three thermoplastic polymers are pure hydrocarbons and are synthesized by the direct polymerization of their corresponding monomers. Whereas PE can be synthesized by the radical or ionic polymerization of ethylene, special organometallic catalysts are required to

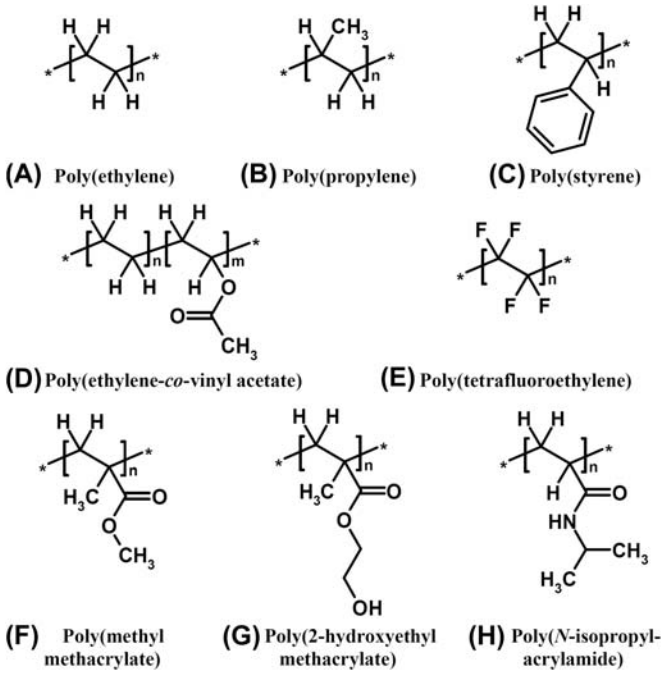

FIGURE 33.1 Chemical structures of nondegradable synthetic polymers (I).

polymerize propylene into useful PP. PE and PP are classified into several different categories based on their density, branching, and molecular weight. These parameters significantly influence the crystallinity and mechanical properties of the polymers. PE has been used to produce catheters. High-density PE, which is characterized by a low degree of branching and thus strong intermolecular forces and tensile strength, has been processed into highly durable hip prostheses. A three-dimensional fabric composed of PE fibers and coated with hydroxyapatite was used to regenerate hyaline cartilage in osteochondral defects in rabbit knees and showed successful biocompatibility [21]. The best-known application for PP is its use in syringe bodies. Copolymers of PE and vinyl acetate (poly[ethylene-*co*-vinyl acetate] [PEVAc]) (Fig. 33.1D) are widely used in nondegradable drug delivery devices [22]. PEVAc is one of the most biocompatible implant materials [23]; it has been approved by the US Food and Drug Administration (FDA) for use in implanted and topically applied devices.

Vitrasert , Implanon, and NuvaRing are examples of PEVAc-based drug delivery platforms [24–26] for ocular applications and long-term contraception. For the latter application, PE-based implants have also been developed.

PS is a hard, brittle polymer used to fabricate tissue culture flasks and dishes. By copolymerization with butadiene, copolymers with improved elasticity are synthesized that are used to make catheters and medical devices for perfusion and dialysis.

Poly(tetrafluoroethylene)

Poly(tetrafluoroethylene) (PTFE) (Fig. 33.1E), well-known as Teflon (DuPont), can be synthesized from liquid tetrafluoroethylene by radical polymerization and through the fluorination of PE. Among the known polymers, PTFE has the lowest coefficient of friction and excellent resistance to chemicals, and it is hemocompatible. Porous PTFE fiber meshes (Gore-Tex) have become a popular synthetic vascular graft material [27].

Poly(meth)acrylates and Polyacrylamides

Poly(meth)acrylate hydrogels are used in medical devices, especially for ocular applications (e.g., contact lenses and intraocular lenses), as drug delivery systems, and as cell delivery systems [28–30]. Three major types, PMMA, poly(2-hydroxyethyl methacrylate) (PHEMA), and poly(*N*-isopropylacrylamide), are discussed in more detail subsequently.

A variety of (meth)acrylate and acrylamide monomers with different functional groups are available; thus, poly(-meth)acrylates and polyacrylamides of different chemical compositions can be synthesized. Together with the free carboxylic acid moieties of (meth)acrylic acid, the presentation of different functional groups and charges along copolymer chains or within cross-linked hydrogels is possible. Using an imprinting technique, these moieties can

be oriented so that pouches are created that interact noncovalently with molecules, e.g., drugs or therapeutic peptides and proteins, via ionic interactions, hydrogen bonds, $\pi-\pi$ interactions, and hydrophobic interactions [31,32]. Besides intelligent hydrogels for controlled drug release, this technology has an impact on microfluidic devices, biomimetic sensors, intelligent polymeric membranes [33], and analyte-sensitive materials [34].

Poly(methyl Methacrylate)

PMMA (Fig. 33.1F) is a nondegradable polyacrylate and is the most commonly applied nonmetallic implant material in orthopedics. It was used as an essential ingredient to make dentures and then in the mid-1950s, PMMA was introduced for use in orthopedic surgery [35]. PMMA tissue biocompatibility became further apparent when Plexiglas fragments were accidentally implanted in the eyes and other body tissues of World War II fighter pilots during aircraft crashes.

PMMA can be polymerized in situ and cross-linked from a slurry containing PMMA and methyl (meth)acrylate monomers; thus, it is used as a common bone grafting material, mainly in the fixation of orthopedic prosthetic materials for hips, knees, and shoulders [36]. PMMA-based bone cements can be mixed with inorganic ceramics or bioactive glass to modulate curing kinetics and enforce mechanical properties. Antibiotics can be loaded within the cement to reduce the risk for prosthesis-related infection. Significant drawbacks of self-curing PMMA cements are that they are not degraded, that their high curing temperatures and toxic monomers can cause necrosis of the surrounding tissue, and that the cements have limited interactions with surrounding bone [37,38]. Therefore, the development of alternative injectable bone cements is directed toward biodegradable materials with improved curing properties and osteoconductive interfaces.

Because of its excellent biocompatibility and hemocompatibility and ease of manipulation, PMMA is used in many medical devices, including blood pumps and dialyzers. Its optical properties make it a candidate material for implantable ocular lenses and hard contact lenses [29]. PMMA also offers physical and coloring properties that are beneficial for denture fabrication [37].

Poly(2-hydroxyethyl Methacrylate)

PHEMA (Fig. 33.1G) was the first hydrogel to be successfully employed for biological use [39]. PHEMA has become the major component of most soft contact lenses and is also part of intraocular lenses [29]. Owing to their free hydroxyl groups, PHEMA gels contain relatively high amounts of water, which facilitates the diffusion of solutes and oxygen. PHEMA has excellent biocompatibility, which initiates the development of a plethora of hydroxyethyl methacrylate–containing copolymers. Hydrogels fabricated from PHEMA and copolymers have been intensively characterized for controlled drug delivery applications [40,41] and employed for biomedical uses. PHEMA gels, which have limited mechanical properties, have been used in attempts to reconstruct female breasts and nasal cartilages, and as artificial corneas as well as wound dressings [42].

In a subcutaneous rabbit model, porous PHEMA sponges promoted significant cellular ingrowth and neovascularization combined with good cytocompatibility [43]. A mineralization technique was demonstrated that exposed carboxylate groups on cross-linked PHEMA hydrogel scaffolds, promoting calcification [44].

Poly(*N*-isopropylacrylamide)

Poly(*N*-isopropylacrylamide) (PNiPAAm) (Fig. 33.1H) is important for injectable applications in drug and cell delivery using minimally invasive techniques because of its unique physicochemical properties [45]. PNiPAAm undergoes (lower critical) phase separation, resulting in the formation of an opaque hydrogel in response to a temperature above 32°C, the material's lower critical solution temperature (LCST). This thermoresponsive behavior is the result of strong hydrogen bonds between the polymer and water molecules and the specific molecular orientations of these bonds caused by the molecular structure of the polymer. The formation of hydrogen bonds between the polymer and the solvent lowers the free energy of the solution. Because of the hydrophobic *N*-isopropyl residues in PNiPAAm, the hydrogen bonds between water and the amide functionality require specific molecular orientation. Such ordered structures lead to negative entropy changes and positive contributions to the free energy. Because the enthalpic contribution to the free energy is temperature-dependent, the formation of strong but specifically oriented hydrogen bonds is no longer thermodynamically favored above a certain temperature. Consequently, PNiPAAm dissolves in water below the LCST. At and above the LCST, the polymer chains partially desolvate and undergo a coil-to-globule transition resulting in colloidal aggregation that may lead to gel formation or polymer precipitation [46,47]. Hydrogels formed by linear PNiPAAm at 32°C are instable and collapse substantially as the temperature is increased above the LCST. The synthesis of cross-linked networks and copolymers, typically with hydrophilic building blocks, has resulted in materials that demonstrate reversible thermogelation and form hydrogels with no

significant syneresis at body temperature. Different PNiPAAm-containing copolymers for cell delivery have been synthesized with acrylic acid, PEG, hyaluronic acid, and gelatin [45,48–50]. Detailed information is available for the in vitro and in vivo use of gelatin–PNiPAAm conjugates for the regeneration of articular cartilage [51,52]. A series of multifunctional *N*-isopropylacrylamide (NiPAAm)-based copolymers has also been developed [53]. One example is the injectable, thermosensitive macromer poly(NiPAAm-*co*-polylactide–hydroxyethyl methacrylate (HEMAPLA)–*co*-acrylic acid-*co*-*N*-acryloxysuccinimide) [54] that is composed of HEMAPLA for increased biodegradability via elevated backbone solubility upon PLA hydrolysis and reactive succinimide esters for the cross-linking of, e.g., type I collagen. Further examples of such advanced copolymers include a series of amphiphilic NiPAAm-based macromers with dual gelation properties [55,56], calcium ion–sensitive macromers of a similar design with vinylphosphonic acid as comonomer [57], and a series of anhydride group–containing oligomers synthesized with maleic anhydride and a key copolymer [58]. The latter have been used to formulate dual-component hydrogels with gelatin [59], cross-linked gelatin microparticles, as well as tubular conduits [60]. NiPAAm-based copolymers with at least dual functionality have also been synthesized with glycidyl methacrylate as comonomer [61]. The introduction of epoxides allowed for effective cross-linking and dual-component hydrogel engineering with polyamidoamine-based diamines [62]. Syneresis in NiPPAm-based hydrogels could be suppressed and their degradation improved by the integration of dimethyl-γ-butyrolactone acrylate as comonomer with a hydrolysable lactone structure [63,64]. The chemical incorporation of the comonomer monoacryloxyethyl phosphate and subsequent ester formation with glycidyl methacrylate allowed for the introduction of phosphatase degradable linkages in injectable hydrogels for bone regeneration [65,66].

Polyethers

PEG (Fig. 33.2A), often also called poly(ethylene oxide) (PEO), is a nondegradable polyether of the monomer ethylene glycol. Technically, PEG and PEO should not be used as synonyms because PEO is synthesized from the monomer ethylene oxide and typically is terminated by only one hydroxyl group and an initiator fragment [67]. Commonly, PEG is often used to refer to the polymer with a molecular weight less than 30,000–50,000 Da whereas PEO is used for higher molecular weights. PEG is water soluble and solutions of its high–molecular weight form can be categorized as a hydrogel. PEG hydrogels for biomedical applications are typically composed of polymer chains that are cross-linked. These cross-linked networks frequently contain chemical bonds between the PEG chains and the cross-linkable moieties, which are prone to aqueous hydrolysis and therefore are characterized as biodegradable systems. The molecular weight of the PEG chains cross-linked in such hydrogels is below a threshold molecular weight to allow for complete resorption by renal elimination of the individual chains. Consequently, these materials are discussed as biodegradable polymers in the Cross-linked Polyesters section.

Favorable characteristics of PEG and PEO include their high hydrophilicity, bioinertness, and outstanding biocompatibility, which make them candidate biomaterials [68]. PEG and PEO are frequently used as hydrophilic polymeric building blocks in copolymers with more hydrophobic degradable or nondegradable polymers for drug delivery [69], gene delivery, tissue engineering scaffolds, medical devices, and implants. PEG has also been immobilized on polymeric biomaterial surfaces to make them resistant to protein absorption and cell adhesion. These effects are attributed to highly hydrated PEG chains on the polymer surfaces that exhibit steric repulsion based on an osmotic or entropic mechanism [70]. Attempts to benefit from this phenomenon include the design of long-circulating nanoparticles or liposomes [71–74] and PEGylated enzymes or proteins with a prolonged functional residence time in vivo compared with unmodified biomolecules [75,76].

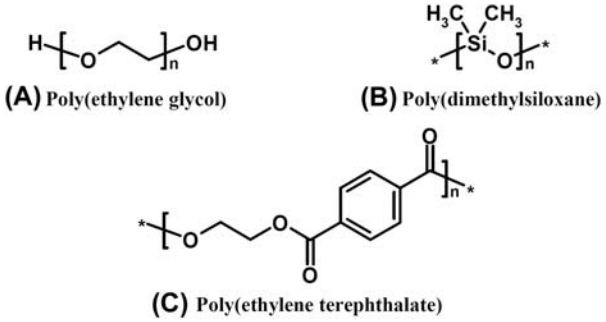

FIGURE 33.2 Chemical structures of nondegradable synthetic polymers (II).

A variety of PEG-containing block copolymers for injectable drug delivery have been developed [77]. The most prominent class is triblock copolymers composed of two hydrophilic PEO blocks and one hydrophobic poly(propylene oxide) (PPO) block, also known as Pluronics or poloxamers. These materials are designed to have phase transition behavior similar to thermogelling PNiPAAm-containing materials (see Poly(*N*-isopropylacrylamide) section). Poloxamers have been intensively investigated for the delivery of drugs and proteins [78]. Because Poloxamers are nondegradable, biodegradable structural analogues have been synthesized. They are described within the next section, Block Copolymers of Polyesters or Polyamides With Poly(ethylene glycol).

Polyglycerols (also called polyglycidols) have gained recognition as an alternative to PEG and PPO. The main distinguishing feature of this polymer is the presence of an additional hydroxyl group on the monomer. As a result, polyglycerols can have a linear structure with a free hydroxyl group per repeat unit or a hyperbranched structure, in which all three hydroxyl groups contribute to the formation of the polyether [79,80]. Linear polyglycerol was found to possess properties similar to PEG with regard to biocompatibility and protein absorption resistance. In addition, the materials exhibit thermoresponsive behavior [81].

Polysiloxanes

Polysiloxanes, or silicones, are a general category of polymers consisting of a silicon-oxygen backbone with organic groups, typically methyl groups, attached to the silicon atoms [82]. Certain organic side groups can be used to link two or more chains. By varying the silicon-oxygen chain length, side groups, and extent of cross-linking, silicones with properties ranging from liquids to hard plastics can be synthesized. Silicone synthesis typically involves the hydrolysis of chlorosilanes into linear or cyclic siloxane oligomers, which are then polymerized into polysiloxanes by polycondensation or polymerization, respectively. The most common polysiloxane is linear poly(dimethylsiloxane) (Fig. 33.2B).

Polysiloxanes, which are characterized by unique material properties combining biocompatibility and biodurability, have found widespread application in health care [82]. The materials' high biodurability is a result of other material properties such as hydrophobicity, low surface tension, and chemical and thermal stability. Silicone surfaces have been found to inhibit blood from clogging for many hours and thus have been used to fabricate silicone-coated needles, syringes, and other blood-collecting instruments. Silicone materials have also been employed as heart valves and components in kidney dialysis, blood oxygenators, and heart bypass machines owing to their hemocompatibility. Silicone elastomers have been used in numerous catheters, shunts, drains, and tubular implants such as artificial urethra. Significant orthopedic applications of silicones are joint implants in hands and feet. The most prominent application of silicones is their extensive use as cosmetic implants in aesthetic and reconstructive plastic surgery. Prosthetic silicone implants are available for the breast, scrotum, chin, nose, cheek, calf, and buttocks. Different silicone materials, including slightly cross-linked silicone gels, are combined to achieve a natural feel. Controversy arose regarding the safety of popular silicone gel-filled breast implants in the early 1990s. These discussions initially involved an increased risk for breast cancer; it then progressed to autoimmune connective tissue disease and evolved to the frequency of local or surgical complications such as rupture, infection, and capsular contracture. To date, no epidemiology study has indicated that the rate of breast cancer has significantly increased in women with silicone breast implants [83]. However, a slight increase in anaplastic large cell lymphoma, a rare cancer of the immune system, is being discussed as connected with breast implants [84]. Studies on autoimmune or connective tissue disease agreed regarding the lack of causal association between breast implants and these diseases [85,86]. A safety concern that was discussed involves the amount of platinum (the part of catalysts used during silicone synthesis) that is released from silicone implants and accumulated in the host organism [87,88]. Other complications, especially implant rupture, are persisting problems; in 1992, the FDA restricted the use of silicone gel-filled implants. Since then, the implants may be used only under certain controlled conditions [89]. In 2016, the FDA approved three types of saline-filled breast implants and five types of silicone gel-filled ones, and required the manufacturers of silicone gel-filled implants to conduct postapproval studies to characterize the safety and effectiveness of their implants.

Polysiloxane gels, which combine the high oxygen permeability of silicone and the comfort and clinical performance of conventional polyacrylate hydrogels, enable the fabrication of soft, gas-permeable contact lenses for extended wear. In contrast to conventional hydrogels, silicone gels render the surface of the lens highly hydrophobic and less "wettable," which frequently results in discomfort and dryness during lens wear. Surface modifications of the silicones or the addition of conventional hydrogels are suitable strategies to compensate for the hydrophobicity.

Overall, polysiloxanes have been increasingly applied in medicine since the 1960s; today, they are one of the most thoroughly tested and important biomaterials.

Other Nondegradable Polymers

Poly(ethylene Terephthalate)

Poly(ethylene terephthalate) (Fig. 33.2C), a linear polyester synthesized by polycondensation of terephthalic acid and ethylene glycol, is typically processed into fiber meshes. These meshes are applied as vascular grafts [27] or used to reinforce prostheses.

Hydrolytically Stable Polyurethanes

PUs are a heterogeneous class of polymers that consist of organic units joined by urethane links (Fig. 33.3). Generally, PUs can be synthesized from a bischloroformate and a diamine or by reacting a diisocyanate with a dihydroxy component. PUs used in biomedical applications typically have a segmented structure that results in useful physicochemical properties [90]. Such segmented PUs or PU copolymers are elastomers composed of alternating polydispersed "soft" and "hard" segments. These two segments are thermodynamically incompatible and phase-segregate, resulting in discrete, crystalline domains of the associated "hard" segments surrounded by a continuous, amorphous phase of "soft" segments. The segregated domains are stabilized by interchain hydrogen bonds and are responsible for the materials' mechanical properties [91]. Segmented PUs are synthesized in a two-step process that provides control over polymer architecture (Fig. 33.3A). The first step involves the synthesis of an isocyanate-terminated prepolymer from a diisocyanate (D in Fig. 33.3) and a hydroxyl group terminated polyether or polyester (P in Fig. 33.3). The prepolymer and excess diisocyanate are then reacted with a hydroxy or amine group-terminated chain extender (C in Fig. 33.3) to generate the final PU (Fig. 33.3A).

A chain extender terminated with hydroxy groups yields segmented PUs, whereas a diamine extender yields PU-urea (Fig. 33.3B). The "hard" segment of the PU copolymer is composed of the diisocyanate and the chain extender, whereas the "soft" segment contains the polymeric segment introduced during the first step. The extent of phase separation depends on the molecular weights, chemistry, and relative percentages of the building blocks [92].

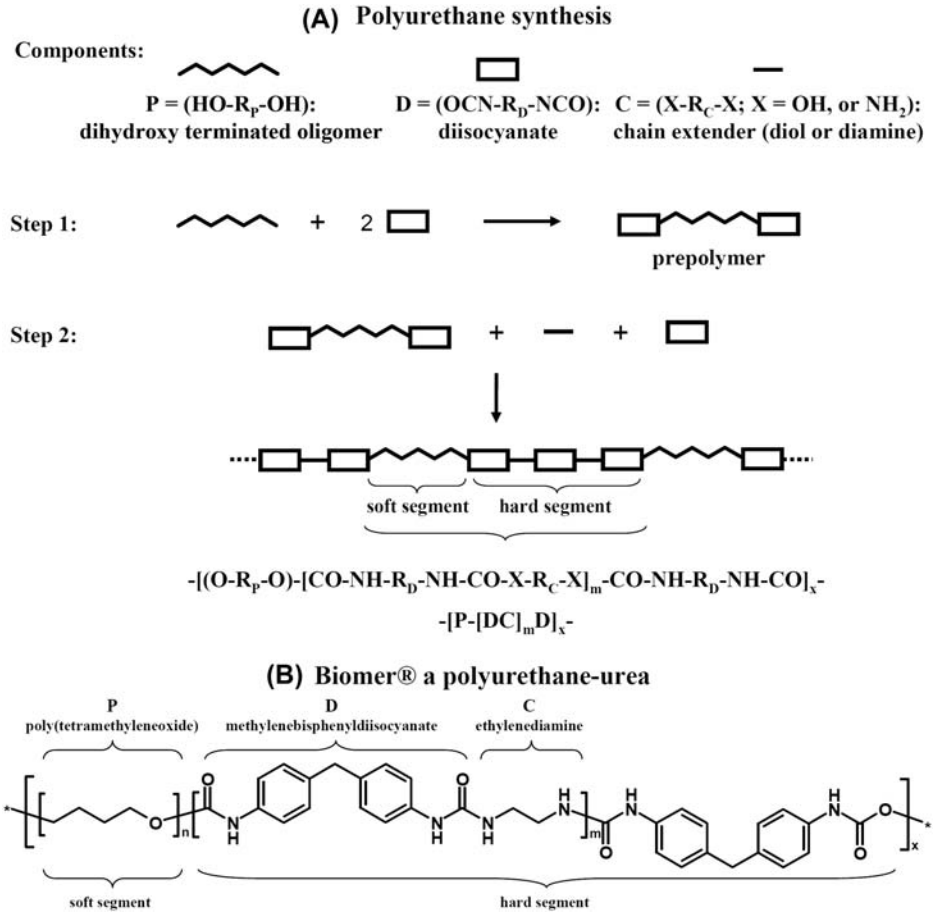

FIGURE 33.3 General synthesis scheme (A) and an example structure (B) for polyurethanes.

After almost 50 years of use in biomedical applications, PUs remain one of the most popular groups of biomaterials for the fabrication of medical devices. Their popularity results from a wide range of versatility with regard to tailoring their physicochemical and mechanical properties, blood and tissue compatibility, and degradative properties by altering block copolymer composition. Biomedical PUs are used in numerous medical devices such as breast implants, catheters, vascular and aortic grafts, pacemaker leads, artificial heart valves, and artificial hearts; they perform well in a variety of in vivo applications. PUs often have better blood and tissue compatibilities compare with numerous other synthetic polymers. The efficient removal of impurities from the polymer synthesis, such as catalyst residues and low−molecular weight oligomers, has critically determined PU biocompatibility [93].

Traditional PUs such as Biomer (in which the dihydroxy-terminated oligomer (P) is polytetramethylenen oxide, the diisocyanate (D) is methylene bisphenylenediisocyante and ethylenediamine is the chain extender (C)) (Fig. 33.2D), were materials of first choice. However, the assumption of polyetherurethane nondegradability had to be revised in response to the well-documented failures of pacemaker leads and breast implant coatings containing PUs in the late 1980s. Although PUs can be designed to be stable against hydrolysis, these materials have been shown to degrade in the biological environment by mechanisms including oxidation and enzyme and cell-mediated degradation [92,94,95]. Oxidation of PUs can be initiated by peroxides, free radicals, and enzymes. Metal-catalyzed oxidation was found to be most frequently associated with pacemaker lead failure. Another important oxidation-driven problem with long-term PU implants is environmental stress cracking. PU surfaces become coated with a protein layer that enhances the adhesion of macrophages. The macrophages, activated by proteins of the complement family, release oxidative factors that accelerate the degradation of the polymer [96].

Chemical design criteria have been identified for biostable PUs. To increase the degree of interchain hydrogen bonding, on which biostability partially depends, low−molecular weight oligomeric diols (P) are preferred as building blocks. To avoid oligomer hydrolysis, oligoethers are favored over oligoesters. Aromatic diisocyanates (D) have been found to yield more biostable PUs than aliphatic diisocyanates. The use of a diamine chain extender (C) instead of a dihydroxy-terminated one typically results in stronger PU-urea, but polymer fabrication is often hampered because of solubility problems. The use of soft segment building blocks with high crystallinity, such as polycaprolactone, or silicone-based oligomers is also assumed to improve polymer biostability [92].

PUs can be surface modified to reduce the risk of thrombosis or improve interactions with cells and tissues. Different strategies, including adsorption, covalent grafting, and the use of self-assembled monolayers, have been applied to distribute proteins such as fibronectin, or adhesion peptides, which contain the integrin-binding peptide motif RGD, across the PU surface [92,97].

BIODEGRADABLE SYNTHETIC POLYMERS FOR REGENERATIVE MEDICINE

Biodegradable synthetic polymers offer a number of advantages over nondegradable materials for applications in regenerative medicine. Like all synthetic polymers, they can be synthesized at reproducible quality and purity and fabricated into various shapes with desired bulk and surface properties. Specific advantages include the ability to tailor mechanical properties and degradation kinetics to suit various applications. Clinical applications for biodegradable synthetic polymers are manifold and traditionally include resorbable sutures, drug delivery systems, and orthopedic fixation devices such as pins, rods, and screws [98]. Synthetic biodegradables were widely explored as artificial matrices for tissue engineering applications [99−103]. For such applications, the mechanical properties of the scaffolds, which are determined by the constitutive polymer, should functionally mimic the properties of the tissue to be regenerated. Ultimately, the polymeric support is designed to degrade while transplanted or invading cells proliferate, lay down ECM, and form coherent tissue that ideally is functionally, histologically, and mechanically indistinguishable from the surrounding tissue. To engineer scaffolds suitable for different applications, a wide variety of biodegradable polymers are required ranging from pliable, elastic materials for soft tissue regeneration to stiff materials that can be used in load-bearing tissues such as bone. In addition to the mechanical properties, the degradation kinetics of polymer and ultimately scaffold also have to be tailored to suit various applications.

The major classes of synthetic, biodegradable polymers are briefly reviewed and their potential in regenerative medicine is discussed subsequently.

Polyesters

Polyesters have been attractive for biomedical applications because of their ease of degradation by the primarily nonenzymatic hydrolysis of ester linkages along the backbone. In addition, degradation products can be

resorbed through the metabolic pathways in most cases, and there is the potential to tailor the structure to alter degradation rates [104].

A vast majority of biodegradable polymers studied belong to the polyester family [105]. Polyester fibers, which also became popular in the textile industry, were used as resorbable sutures [106]. Promising observations regarding the biocompatibility of the materials led to applications in drug delivery, orthopedic implants, and tissue engineering scaffolds, particularly for orthopedic applications [98,102,107–110].

Polyesters of α-Hydroxy Acids

The family of polyesters can be subdivided according to the structure of the monomers. In poly(α-hydroxy acids), each monomer has two functionalities, a carboxylic acid and a hydroxyl group, located at the carbon atom next to the carboxylic acid (α-position), that form ester bonds. Poly(α-hydroxy acids) are linear thermoplastic elastomers that typically are synthesized by ROP of cyclic dimers of the building blocks [111,112]. Poly(lactic acid) (PLA) (Fig. 33.4A), poly(glycolic acid) (PGA) (Fig. 33.4B), and a range of their copolymers, including poly(lactic-*co*-glycolic acid) (PLGA) (Fig. 33.4C) are prominent representatives not only of biodegradable polyesters but of biodegradables in general. The cyclic dimers that are polymerized during PLA and PGA synthesis are called lactide and glycolide, respectively. Therefore, the polymers are often named polylactides or polyglycolides. For reasons of consistency with the general term poly(α-hydroxy acids), the terms PLA and PGA will be used here. Poly(α-hydroxy acids) have a long history of use as synthetic biodegradable materials in a number of clinical applications. Initially, resorbable sutures were made from these materials [113]. Later, poly(α-hydroxy acids) were the basis for controlled release systems for drugs, proteins and vaccines [114–118], and orthopedic fixation devices [119]. Langer and coworkers pioneered the development of these polymers in the form of porous scaffolds for tissue engineering [120].

Because of the chiral nature of lactic acid, several forms of PLA exist: poly(L-lactic acid) (P_LLA), for example, is synthesized from L-lactide. The polymerization of racemic lactide leads to poly(D,L-lactic acid) ($P_{D,L}LA$), which is an amorphous polymer. P_LLA, in contrast, is a semicrystalline polymer with a crystallinity of around 37%. P_LLA is characterized by a glass transition temperature between 50°C and 80°C and a melting temperature between 173°C and 178°C. Amorphous $P_{D,L}LA$ is typically used in drug delivery applications, whereas semicrystalline P_LLA is preferred in applications in which high mechanical strength and toughness are required, e.g., for sutures and orthopedic devices. PGA is also a semicrystalline polymer with a higher crystallinity of 46–52%. Thermal characteristics of PGA are glass transition and melting temperatures of 36°C and 225°C, respectively. Because of its high crystallinity, unlike PLA, PGA is not soluble in most organic solvents; the exceptions are highly fluorinated organic solvents such as hexafluoroisopropanol. Consequently, common processing techniques for PGA include melt extrusion, injection, and compression molding.

PLA, PGA, and PLGA undergo homogeneous erosion via ester linkage hydrolysis into the degradation products lactic acid and glycolic acid, which are both natural metabolites that are fully metabolized and excreted as carbon dioxide and water. Degradation of poly(α-hydroxy acid)s showed characteristics typical of bulk erosion. Bulk erosion occurs when water penetrates the entire structure and the device degrades simultaneously [121]. During the initial stages of degradation, almost no mass loss can be detected. Analysis of the average molecular weight of the polymer bulk over the same period, however, reveals a steady decrease in molecular weight. Once the polymer chains throughout the bulk are degraded below a certain threshold, the water-soluble degradation products are washed out and the system collapses, accompanied by significant mass loss. Because of its well-accessible ester group, PGA degrades rapidly in aqueous media. PGA sutures typically lose their mechanical strength over 2–4 weeks postoperatively [122]. To adapt these properties to a wider range of applications, copolymers with more hydrophobic PLA were synthesized and investigated. The two main series are those of P_LLGA (Fig. 33.4C) and $P_{D,L}LGA$. It was shown that the range of compositions from 25% to 70% glycolic acid (GA) for L-lactic acid (L-LA)/GA and from 0% to 70% GA for D,L-LA/GA are amorphous [104,105,123–126]. For the P_LLGA copolymers, the rate of hydrolysis was slower at either extreme of the copolymer composition range. It is generally accepted that intermediate PLGA copolymers have a shorter half-life in vivo than either homopolymer. Besides the polymer composition, the rate of degradation is affected by factors such as the configurational structure, copolymer ratio, crystallinity, molecular weight, morphology, stresses, the amount of residual monomer, bulk porosity, and the site of implantation [104].

Multiple in vitro and in vivo studies that were conducted on the biocompatibility of PLA, PLGA, and PGA have generally revealed satisfying results [127]. Consequently, PLA, PLGA copolymers, and PGA are among the few biodegradable polymers with FDA approval for human clinical use.

Concerns with poly(α-hydroxy esters) typically focus on the accumulation of acidic degradation products within the polymer bulk that can have detrimental effects on encapsulated drugs in delivery applications [128–130] or can cause late noninfectious inflammatory responses when released in a sudden burst upon structure breakdown

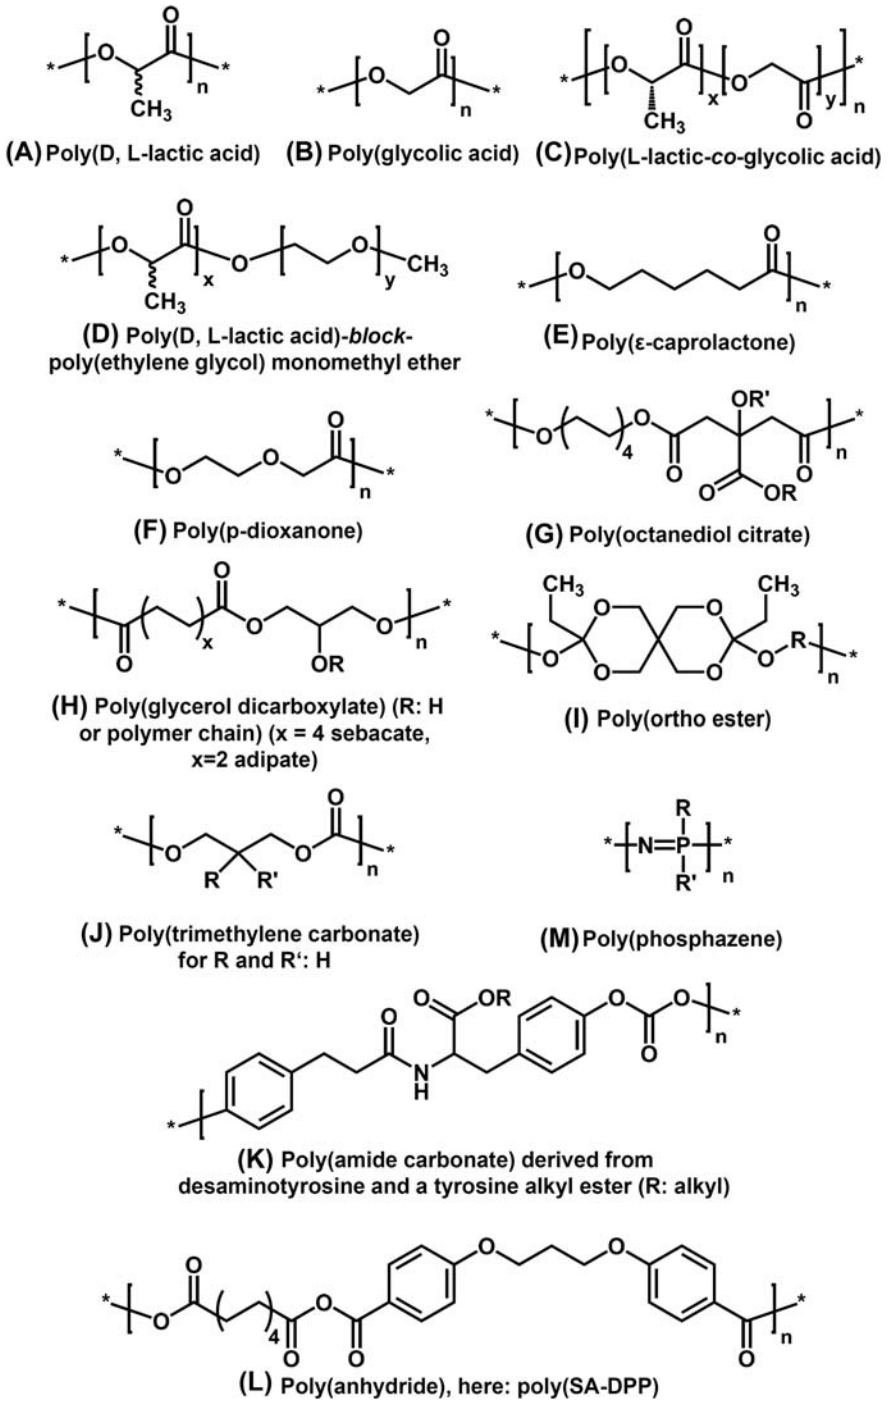

FIGURE 33.4 Chemical structures of biodegradable synthetic polymers.

[131–133]. This adverse reaction can occur weeks and months postoperatively and might need surgical drainage. This is a major concern in orthopedic applications, in which implants of considerable size would be required and which may result in the release of degradation products with high local acid concentrations. Inflammatory response to poly(α-hydroxy acids) were also found to be triggered by the release of small particles during degradation that were phagocytosed by macrophages and multinucleated giant cells [117,134]. In general, implant size as well as surface properties appear to be critical factors with regard to biocompatibility. Fewer concerns seem to exist regarding the application of poly(α-hydroxy acids) in soft tissues compared with hard tissue applications [127]. Injectable P_LLA has been employed for skin volume restoration by using its stimulating effect on collagen production [135].

Poly(α-hydroxy acids) were the materials of choice when one of the key concepts of tissue engineering, the de novo engineering of tissue by combining isolated cells and three-dimensional macroporous cell carriers in vitro, was first realized and developed [120,136,137]. Polymers based on lactic acid and GA are still popular scaffold materials, especially for orthopedic applications such as bone, cartilage, and meniscus, as outlined in several reviews [101,138–140]. Limitations of this class of materials include insufficient mechanical properties with regard to load-bearing applications [110] and inflammatory or cytotoxic events caused by the accumulation of acidic products during degradation.

To cover a broader range of mechanical and physicochemical properties, such as water absorption, polymer degradation, and polymer–drug interactions, block copolymers containing PLA and hydrophilic PEO or PEG were synthesized for drug delivery applications [141,142]. Solid particulate systems from these block copolymers were almost invisible to the immune system owing to the hydrophilic PEG chains that swell on the surface [71,143] (see Polyethers section) (Fig. 33.4D). The stealthiness of such surfaces is mainly caused by the suppression of protein adsorption, which also inhibits cell adhesion. Investigations into cell adhesion to PEG–PLA diblock copolymer surfaces revealed that cell adhesion can be controlled and cell differentiation can be modulated by the PEG content [144]. With the objective of specifically controlling cell–polymer interactions, PEG–PLA copolymers were further developed to allow for the covalent attachment of signaling molecules [145,146]. Because these polymers were insoluble in water, they could be processed into macroporous scaffolds for tissue engineering applications [147]. Furthermore, diblock and triblock copolymers of PLA with PEG were investigated as microscale and nanoscale vehicles for drug delivery [148,149], as well as for tissue engineering applications [150].

Another direction in which to broaden the range of mechanical and chemical properties of PLA centers on the use of α-hydroxy acids that possess longer alkyl or aryl side chains [151] or feature a side chain with an additional double or triple bond or a functional group [152]. An important effect of such an incorporation is the modulation of the glass transition temperature of the resulting polymer [153]. For example, a viscous copolymer of lactic acid and 2-hydroxy-octanoic acid was investigated as a delayed intravitreal release system for vasodilatory substances or as an excipient for sustained-release drug formulations [154–156].

Polyesters of Lactones

The most prominent and thoroughly investigated polylactone is poly(ε-caprolactone) (PCL) (Fig. 33.4E), an aliphatic, semicrystalline polyester with an interestingly low glass transition temperature (−60°C) and melting temperature (59-64°C) [105,157]. PCL is considered to be biocompatible [158]. PCL is prepared by the ROP of the cyclic monomer ε-caprolactone and is compatible with a range of other polymers. Catalysts such as stannous octoate are used to catalyze the polymerization and low–molecular weight alcohols can be used as the initiator and to control the molecular weight of the polymer [159]. ε-Caprolactone can be copolymerized with numerous other monomers. Copolymers with PLA and PEG are probably the most noteworthy and have been investigated extensively [160–163]. PCL degrades at a much slower rate than PLA and therefore is most suitable for the development of long-term implantable drug delivery systems. These copolymers of caprolactone with lactide were synthesized to accelerate degradation rates [105]. Tubular, highly permeable poly(L-lactide-*co*-ε-caprolactone) guides were found to be suitable for the regeneration and functional reinnervation of large gaps in injured nerves [164]. Although this study focused on tissue regeneration, the application of PCL in drug delivery devices is still far more common [165]. With the increasing popularity of electrospinning, a laboratory-scale technique that allows for the fabrication of nonwoven meshes composed of nanofibers and/or microfibers [166], PCL might find its way into cell-based therapies because slowly degrading polymers are preferred for this technique to ensure sufficient stability of the fibers [167].

Poly(p-dioxanone) (Fig. 33.4F), another polylactone, and its copolymers with lactide, glycolide, and/or trimethylene carbonate, are synthesized by catalyzed ROP and have been used in a number of clinical applications ranging from suture materials to bone fixation devices [168,169]. The use of analogues of p-dioxanone bearing methyl or more complex groups for homopolymerization or copolymerization allows for the fine-tuning of degradation properties of the polymer [170].

Another class of polymer that is accessible via the polymerization of lactones is poly(hydroxy-alkanoates) (PHAs), which are composed of hydroxy acids with the hydroxyl group located at least in the β-position relative to the carboxylic acid group [171]. PHAs are mostly produced biosynthetically; the resulting polymer is perfectly isotactic and highly crystalline. Synthesis via ROP of lactones, on the other hand, enables the production of syndiotactic and atactic PHAs with altered physicochemical and mechanical properties [172].

Polyesters of Polyols and Carboxylic Acids

In addition to using monomers bearing a hydroxyl and a carboxyl group on the same molecule, elastomeric polyester networks have been synthesized by combining two kinds of building blocks, one bearing two or more hydroxyl groups (a polyol), such as glycerol [173], and one bearing two or three carboxyl groups (a dicarboxylic acid or tricarboxylic acid), such as citric acid [174]. Polymers are synthesized from the two building blocks by polycondensation either by organometallic, metal-oxide [175], enzyme-based catalysis [176] or without using exogenous catalysts [177,178], depending on the employed building blocks.

Poly(diol citrates) are synthesized from citric acid and various low− or high−molecular weight diols [174]. Poly(1,8-octanediol-*co*-citrate) (POC) (Fig. 33.4G; R, R′: −H), one of the first poly(diol citrates), demonstrated mechanical properties such as tensile strength, Young's modulus, and elongation at break that justify applications in ligament reconstruction and vascular engineering [178]. Variations in chemical composition, especially diol chemistry, allowed for the synthesis of a variety of biodegradable elastomers covering a range of mechanical and degradative properties [179]. With regard to vascular tissue engineering, POC showed good hemocompatibility and exhibited decreased platelet adhesion and clotting relative to P_LLGA and expanded poly(tetrafluoro ethylene) [180]. Endothelial cell attachment and differentiation were supported with no modification of the surface. To improve the mechanical properties of the POC elastomer, unsaturated acrylate and fumarate diols were added during the condensation reaction and moieties for secondary cross-linking were introduced [181]. Further modification of the employed diols and functionalization of the pendant carboxyl and hydroxyl groups of citric acid led to citrate-based biomaterials with potential applications ranging from regeneration of hard and soft tissue to drug delivery, bioadhesive, and imaging functions [174].

Poly(glycerol sebacate) (Fig. 33.4H; $x = 4$) is an elastomeric polymer network made from the triol glycerol and sebacic acid (decanedioic acid) [182]. It is developed for use in the regeneration of soft tissues such as cardiac [183], vascular, retinal, and neural tissue. A similar polymer, poly(glycerol adipate) (Fig. 33.4H; $x = 2$), made from glycerol and adipic acid (hexanedioic acid), is being examined for use as a nanoparticulate drug delivery system after esterification with fatty acids [184].

Linear polymers of this type are synthesized from a diol and a dicarboxylic acid [185]. An example is poly(butylene succinate), which is synthesized from 1,4-butanediole and succinic acid [186] and which has been evaluated for use in the regeneration of cartilage [187] and bone tissue [188].

Polyorthoesters

Polyorthoesters (POEs) (Fig. 33.4I) were developed by Alza Corporation and SRI International in 1970 in the search for a new biodegradable polymer for drug delivery applications [189]. Since then, polymer synthesis has improved. POEs are synthesized by condensation or addition reactions typically involving dialcohols and monomeric orthoesters or diketene acetals, respectively. The use of triethylene glycol as the diol component produced predominantly hydrophilic polymers, whereas hydrophobic materials could be obtained by using 1,10-decanediol. Orthoester is a functional group containing three alkoxy groups attached to one carbon atom. In POEs, two of the three alkoxy groups are typically part of a cyclic acetal (Fig. 33.4G).

POEs were synthesized that degrade by surface erosion, which is characterized by a constant decrease in bulk mass while the polymer molecular weight within the polymer bulk is preserved [190]. It is known that materials built from functional groups with short hydrolysis half-lives and low water diffusivity tend to be surface eroding. Polymers that exhibit surface erosion can be used to fabricate drug delivery systems that release loaded drugs at a constant rate at a high aspect to volume ratio (e.g., as for wafers).

The addition of lactide segments to the POE structure resulted in self-catalyzed erosion and allowed for fine-tunable degradation times ranging from weeks to months [191]. POEs provide the material platform for a variety of drug delivery applications including the treatment of postsurgical pain, osteoarthritis and ophthalmic diseases, and the delivery of proteins and DNA. Block copolymers of POE and PEG have been prepared and their use as drug delivery matrices or as colloidal structures for tumor targeting are being explored [189].

Initial biocompatibility studies revealed that POEs provoked little inflammation and were largely absorbed by 4 weeks. In contrast, $P_{D,L}LA$ degraded more slowly and provoked chronic inflammation with multinuclear giant cells, macrophages with engulfed material, and proliferating fibroblasts within the same model. Ossicles with bone marrow had formed in the implants of POE combined with demineralized bone. In PLA/demineralized bone implants, bone formation was inhibited [192,193].

Polycarbonates

Polycarbonates have become interesting biomaterials because of their excellent mechanical strength and good processability. The degradation of most polycarbonates is controlled by hydrolysis of the carbonate group, which yields two alcohols and carbon dioxide, which alleviates the problem of acid bursting seen in polyesters [104,194]. The structural variation in the pendant side groups allows polymers to be prepared with different mechanical properties, degradation rates, and cellular responses.

The most prototypical polycarbonate is poly(trimethylene carbonate) (Fig. 33.4J), generated by ROP of the monomer 1,3-dioxan-2-one (trimethylene carbonate [TMC]). By using substituted analogues of this monomer, it is possible to introduce additional functionalities into the material [195]. Altered material properties resulting from these functionalities widen the prospect for the use of polycarbonates in tissue and bone regeneration [196,197] as well as in drug delivery [198,199] and as polymer-based antibiotics [200,201].

Because TMC-based polycarbonates degrade extremely slowly under physiological conditions [195], polyiminocarbonates [202] and tyrosine-based polycarbonates [203] (Fig. 33.4K) have been engineered to yield biodegradable polymers with good mechanical strength [204] for use in drug delivery and orthopedic applications. Tyrosine-based polycarbonates that contain a pendant ethyl ester group have been shown to be osteoconductive and to possess mechanical properties sufficient for load-bearing bone fixation. Long-term (48-week) in vivo degradation kinetics and host bone response to tyrosine-derived polycarbonates were investigated using a canine bone chamber model [205]. Histological sections revealed intimate contact between bone and the polymer. It was concluded that from a degradation-biocompatibility perspective, the tyrosine-derived polycarbonates appear to be comparable to PLA, if not superior, in this model. The incorporation of desaminotyrosyltyrosine units without a pendant ester and low–molecular weight PEG allows for the development of tyrosine-based polycarbonates with faster degradation without affecting the osteoconductive properties [206], which are further improved upon by combining the polymer scaffolds with calcium phosphate minerals and bone morphogenetic protein 2 (BMP-2) [207]. Variations in the composition of these terpolymers can be used to engineer ultrafast degrading and resorbing polymers that may be suitable for the coating of implants in brain tissue to minimalize adverse effects [208].

Block Copolymers of Polyesters or Polyamides With Poly(ethylene Glycol)

Amphiphilic block copolymers of biodegradable polymers with PEG have become popular materials for injectable drug delivery applications [78]. Inspired by the thermoresponsive behavior observed for nondegradable A-B-A–type triblock copolymers composed of hydrophilic PEO (block A) and hydrophobic PPO (block B), polymer development focused on synthesizing biodegradable analogs of these poloxamers (or Pluronics) that were water soluble at ambient temperature and formed stable hydrogels at body temperature. Biodegradable block copolymers were synthesized by substituting the hydrophobic PPO block with a biodegradable polymer block such as PLA or PCL [69,77,209].

Biodegradable, physically cross-linkable block copolymers of inverse structure (that is, B-A-B triblock copolymers with two biodegradable hydrophobic polymer blocks [block B] and a hydrophilic PEO block) were also investigated as protein delivery systems [148,210].

Polyurethanes

PUs represent a major class of synthetic elastomers that have excellent mechanical properties and good biocompatibility. PUs have been evaluated for a variety of medical devices and implants, particularly for long-term implants.

Knowledge gained about the mechanisms of PU biodegradation in response to implant failures throughout the 1990s has been translated to form a new class of bioresorbable materials [95]. Research has employed the flexible chemistry and diverse mechanical properties of PUs to design degradable polymers for a variety of regenerative applications. Segmented PUs with varied molecular structure have been synthesized to control the rates of hydrolysis [95,211]. To obtain biodegradable, segmented PUs, significant changes were required to the structural components historically used for their synthesis. Traditional aromatic diisocyanates (D; compare with Fig. 33.3) can yield toxic or carcinogenic degradation products when they are part of a degradable PU; therefore, linear diisocyanates are preferred, such as lysine-diisocyanate, which yields the nontoxic degradation product lysine. The soft segment, which is typically composed of an oligomeric diol (P; compare with Fig. 33.3), is typically the block of the PU used to modify the degradation rate. Biodegradable PUs have been synthesized with a variety of soft segments including PEO, degradable polyesters such as PLA, PGA, or PCL, and their combinations. Other strategies focus on the copolymers' hard segments. PUs were synthesized that contain enzyme-sensitive linkages introduced with

the chain extender (C; compare with Fig. 33.3). For example, the use of a phenylalanine diester chain extender yielded a PU that showed susceptibility to enzyme-mediated degradation upon exposure to chymotrypsin and trypsin.

Saad et al. investigated cell and tissue interactions with a series of degradable polyesterurethanes. In vivo investigations showed that all test polymers exhibited favorable tissue compatibility and degraded significantly over 1 year [212]. Polyurethane-urea matrices were shown to allow vascularization and tissue infiltration in vivo [213]. The flexible chemistry and diverse mechanical properties of PU materials allowed researchers to design degradable polymers to regenerate diverse tissues including neurons, vasculature, smooth muscle, cartilage, and bone [27,95,214].

To accelerate the degradation behavior of polyesterurethanes, polyester segments in the polymer backbone were partially substituted with polycarbonate, yielding poly(ester carbonate)urethane-ureas [215]. Flexible, low-moduli biodegradable PU, or poly(ether carbonate urethane)-ureas, were synthesized with polyether-based domains containing biodegradable sections as soft segments [216]. Examples of such soft segments include poly(trimethylene carbonate) (PTMC)-based triblock copolymers such as PTMC−PEO−PTMC and thermoresponsive pentablock copolymers such as PTMC−PEO−PPO−PEO−PTMC. For controlling the response of a biological system to materials, surface and bulk modifications are a common strategy. To this end, a series of biodegradable polyesterurethane-urea elastomers with variable amino content were developed. Via the amine groups, carboxylated phosphorylcholine was conjugated to polymer for bulk functionalization [217]. This modification significantly reduced platelet adhesion to the material and inhibited rat vascular smooth muscle cell proliferation. Such materials may find use as coatings in cardiovascular devices or as scaffolds for cardiovascular tissue regeneration. Enzyme-degradable PU was synthesized by using a collagenase-sensitive peptide as a chain extender [218].

Amino Acid−Derived Polymers, Poly(amino Acids), and Peptides

Amino acids are an interesting building block for polymers because of the biocompatibility of the degradation products and the degradability of the amide or ester bonds by which amino acids are typically polymerized or integrated in copolymers. Early studies on pure poly(amino acids)s revealed significant concerns regarding the materials' immunogenicity and mechanical properties [219]. To improve those unfavorable properties, amino acids have been used as monomeric building blocks in polymers that have a backbone structure different from that of natural peptides. Based on polymer structure and chemistry, four major groups have been used to classify such "nonpeptide amino acid−based polymers": (1) synthetic polymers with amino acid side chains, (2) copolymers of natural amino acids and non−amino acid monomers, (3) block copolymers containing peptide or poly(amino acid) blocks, and (4) pseudopoly(amino acids) such as α-peptoids [220].

As in tyrosine-derived polycarbonates (discussed in the Polycarbonates section), L-tyrosine is the predominantly employed amino acid in the synthesis of tyrosine-derived polyarylates and polyesters. These copolymers exhibit excellent engineering properties and polymer systems can be designed whose members have exceptional strength (polycarbonates), flexibility and elastomeric behavior (polyarylates), or water solubility and self-assembly properties (copolymers with PEG). Poly(DTE carbonate) (Fig. 33.4K; R: $-CH_2CH_3$) exhibits a high degree of tissue compatibility and is being evaluated by the FDA for possible clinical use [219].

A combinatorial library of degradable tyrosine-derived polyarylates was synthesized by copolymerizing 14 different tyrosine-derived diphenols and eight different aliphatic diacids in all possible combinations, resulting in 112 distinct polymers [221]. Significant differences were observed in the mechanical properties of the polymers and fibroblast proliferation assays with these materials. This illustrates that such combinatorial approaches provide a library of related polymers that encompasses a broad range of properties and permits the systematic study of material-dependent biological responses in order to choose a suitable material for a specific application.

Another amino acid that has received interest as a component in synthetic polymers for biomedical purposes is L-lysine. Lysine has been investigated as a component in urethane/urea esters, both as a linear block with a free carboxyl group for functionalization [222] and as a three-armed branching point in which the carboxyl group bears an ester with another amino functionality. Degradation studies of the latter material pointed to oxidative processes having an important role in the degradation of such a material in vivo [223]. Lysine was also employed in block copolymers with PEG and PLA that showed no cytotoxic effect [224], in an allylamine-initiated homopolymer copolymerized with PEG-diacrylate as a hydrogel for nerve regeneration [225] or in a genipin-cross-linked poly(L-lysine) hydrogel for drug delivery, and as a cell culture substrate [226].

In a more general context, the polymerization of amino acids with side chain functionalities yields polymer chains with pendent functional groups that can be used for further functionalization. In addition to lysine and tyrosine, other amino acids have been selected for their side chain functionalities [227], including glutamic acid [228] and

L- dihydroxyphenylalanine [229] to influence calcium phosphate mineralization and L-arginine for the synthesis of urethane/urea polymers as biodegradable gene therapy vector [230].

The most common route to generate homopolymers of amino acids or a poly(amino acid) segment in block copolymers uses the ROP of N-carboxy-anhydrides (NCAs) [231,232]. This process yields polymers that are composed of a single amino acid or a random sequence of amino acids when multiple NCAs are reacted simultaneously. Block copolymers can be obtained when NCAs of different amino acids are polymerized in a stepwise manner. An important issue of long chains of these synthetic poly(amino acids) is high immunogenicity [219]. In contrast, solid-phase peptide synthesis, pioneered by Merrifield, and genetic engineering allow for the automated and highly efficient synthesis of peptides of a predefined sequence. Synthetic peptides have become an important polymer class for biomedical applications. Specifically, peptides and peptide-amphiphiles that undergo self-assembly—driven in situ gelation in response to temperature, pH, or chemical stimuli are interesting because these materials can be minimally invasively implanted starting from aqueous solutions [233–235].

Genetically engineered elastin-like polypeptides, which are composed of a pentapeptide repeat and undergo inverse temperature phase transition, have been used to encapsulate chondrocytes. Cell culture studies showed that cartilaginous tissue formation was supported, characterized by the biosynthesis of sulfated glycosaminoglycans and collagen [236].

Self-assembled peptide-amphiphiles form hydrogels composed of nanofibers resembling the native ECM components, with the amphiphiles composed of a peptide with hydrophilic and hydrophobic domains, a hydrophilic peptide attached to a hydrophobic lipid chains, or copolymers composed of the peptide and a hydrophobic component [237]. These hydrogels have been demonstrated to be cytocompatible in cell encapsulation studies [238]. Peptide nanostructures designed through self-assembly strategies and supramolecular chemistry have the potential to combine bioactivity with biocompatibility [239]. In addition, such structures can be used to deliver proteins, nucleic acids, drugs, and cells.

Peptide-amphiphile nanofibers were shown to promote the in vitro proliferation and osteogenic differentiation of marrow stromal cells [240]. For dental tissue engineering, dental stem cells were encapsulated in peptide-amphiphile hydrogels containing adhesion peptides and enzyme-cleavable sites. The cells proliferated and differentiated within the gels and remodeled the matrices [241].

Polyanhydrides

Drug delivery technologies rely on engineered polymers that degrade in a well-controllable and adjustable fashion [22]. An increased understanding of erosion mechanisms led to a demand for synthetic polymers that contain a hydrolytically labile backbone while limiting water diffusion within the polymer bulk significantly to confine erosion to the polymer—water interface. Such surface-eroding polymers allow for the fabrication of drug delivery devices that erode at constant velocity at any time during erosion, thus releasing incorporated drugs at constant rates [242]. Polyanhydrides were engineered following this paradigm by selecting the anhydride linkage, one of the least hydrolytically stable chemical bonds available, to connect the building hydrophobic monomers.

Polyanhydrides (Fig. 33.4L) have been synthesized by various techniques, including melt condensation, ROP, interfacial condensation, dehydrochlorination, and dehydrative coupling agents [243]. Solution polymerization traditionally yielded low—molecular weight polymers. Different dicarboxylic acid monomers have been polymerized to yield polyanhydrides with various physicochemical properties. Examples are linear, aromatic, or fatty acid—based dicarboxylic acid monomers, and fatty acid—terminated polyanhydrides. Polyanhydrides made from linear sebacic acid (SA) and aromatic 1,3-*bis*(*p*-carboxyphenoxy)propane (CPP) (Fig. 33.4L) have been engineered to deliver carmustine (BNCU), an anticancer drug, to sites in the brain after primary resection of a malignant glioma [244]. Poly(SA-CPP) hydrolyzes into nontoxic degradation products and local chemotherapy with BCNU wafers was shown to be tolerated and to offer a survival benefit to patients with newly diagnosed malignant glioma, although this therapy revealed potentially problematic side effects [245,246].

The chemical composition of a polyanhydride can be used to custom-design its degradation properties. Whereas polyanhydrides from linear monomers such as poly(SA) degrade within a few days, polymerized aromatic dicarboxylic acids such as poly(1,6-*bis*[*p*-carboxyphenoxy]hexane) degrade much more slowly (up to a year) [247,248]. Combined with their unique degradation and erosion properties, the structural versatility of polyanhydrides make them precious materials for numerous medical, biomedical, and pharmaceutical applications in which degradable polymers that allow for perfect erosion control are needed [242]. With regard to tissue engineering applications, polyanhydrides have also been interesting polymers owing to their degradative properties and their good biocompatibility [249]. The use of polyanhydrides in load-bearing orthopedic applications, however, is restricted because of their limited mechanical properties. Poly(anhydrides-*co*-imides), which were developed to combine

the good mechanical properties of polyimides with the degradative properties of polyanhydrides, were shown to have compressive strengths comparable to human bone [250] and displayed good osteocompatibility [251].

Photopolymerizable polyanhydrides have been synthesized with the objective of combining high strength, controlled degradation, and minimal invasive techniques for orthopedic applications and were shown to be osteocompatible [252]. Depending on the chemical composition, these materials reached compressive and tensile strengths similar to those of cancellous bone [253].

An interesting strategy for the controlled release of bioactive substances has been explored with poly(anhydride-esters). Bioactive substances such as antiinflammatory drugs [254], analgesics [255], and antiseptics [256] have been used as monomers or comonomers for polyanhydrides. Upon polymer degradation, the active substances were released from the polymer bulk in a controlled manner. To guide bone regeneration, salicylic acid–containing, poly(anhydride-ester)-based flexible sheets were investigated as barriers to prevent excessive BMP-2–induced bone formation [257].

Polyphosphazenes

Polyphosphazenes (Fig. 33.4M), which are polymers containing a high–molecular weight backbone of alternating phosphorus and nitrogen atoms with two organic side groups attached to each phosphorus atom, are a relatively new heterogenic class of biomaterials. Because different synthetic pathways allow for a tremendous variety of derivatives, phosphazene polymers exhibit a diverse spectrum of chemical and physical properties. As a result of this variety, these polymers are suitable for many biomedical applications ranging from templates for nerve regeneration to cardiovascular and dental uses as implantable and controlled-release devices [258–261].

The best-studied and most important route to polyphosphazenes, whose synthesis is generally more involved than that for most petrochemical biomaterials but offers unique flexibility, is macromolecular substitution. A reactive polymeric intermediate, poly(dichlorophosphazene), is typically synthesized by a thermal ring opening cationic polymerization of hexachlorocyclotriphosphazene in bulk at 250°C, which yields a polydisperse high–molecular weight product. The intermediate is reacted with low–molecular weight organic nucleophiles, resulting in stable, substituted polyphosphazenes, which in this case are also addressed as poly(organo)phosphazenes. Depending on the substituent chemistry, the polyphosphazene is more or less susceptible to hydrolysis. Biodegradable hydrophobic polyphosphazenes have been synthesized using imidazolyl, ethylamino, oligopeptides, amino acid esters, and depsipeptide groups (dimers composed of an amino acid and a glycolic or lactic ester) as hydrolysis-sensitive side groups. Hydrolytic degradation products include the free side group units phosphate and ammonia as a result of backbone degradation [258]. Hydrogel-forming, hydrophilic polyphosphazenes can by synthesized by introducing small, hydrophilic side groups such as glucosyl, glyceryl, or methylamino. Ionic side groups yield polymers that form hydrogels upon ionic complexation with multivalent ions [262]. Hydrophilic, water-soluble polyphosphazenes with amphiphilic side groups such as poly(*bis*[methoxyethoxyethoxy]phosphazene) (Fig. 33.4M, R,R′: $-OCH_2CH_2OCH_2CH_2OCH_3$) display an LCST (see the Poly(*N*-isopropylacrylamide) section) and are responsive to changes in temperature and ionic strength [263]. Both hydrophilic and hydrophobic polyphosphazenes have demonstrated potential as biocompatible materials for controlled protein delivery. Ionic polyphosphazenes have been explored as vaccine delivery systems and poly(*di*[carboxylatophenoxy]phosphazene) has demonstrated remarkable adjuvant activity in the immunogenicity of inactivated influenza virions and commercial trivalent influenza vaccine in the soluble state [258].

Porous scaffolds from biodegradable polyphosphazenes have been shown to be good substrates for osteoblast-like cell attachment and growth with regard to skeletal tissue regeneration [264]. It was also shown that hydroxyapatite deposition was supported by polyphosphazenes with side groups containing antioxidative properties [265]. Tubular polyphosphazene nerve guides were investigated in a rat sciatic nerve defect. After 45 days, a regenerated nerve fiber bundle was found to bridge the nerve stumps in all cases [259].

Biodegradable Cross-linked Polymer Networks

The chemical cross-linking of individual linear polymer chains results in networks of increased stability. This concept has been extensively explored for applications in regenerative medicine and most likely represents the concept of choice for modern biomaterial research, especially if polymer cross-linking can be conducted inside a tissue defect [266]. The cross-linking of hydrophobic polymers or monomers results in tough polymer networks that can be used for orthopedic fixation. PMMA (Fig. 33.1F), the main component in injectable bone cements, is the most prominent example. Because of their hydrophobicity, the precursors are typically injected as a moldable liquid or paste free of additional solvents. In situ cross-linking can be initiated thermally or photochemically by UV-rich light. Both ways of initiation are also applicable to hydrophilic injectable systems that form highly swollen

gels (hydrogels) as a result of precursor cross-linking. In contrast to hydrophobic networks that scarcely swell in the presence of water, injectable hydrogels are characterized by a high water content and diffusivity, which allow for the direct encapsulation of cells and sufficient transport of oxygen, nutrients, and waste. Hydrophobic networks, however, often require the addition of a leachable porogen, such as salt particles, to facilitate cell migration and tissue ingrowth. Generally, injectable polymer systems have considerable advantages over prefabricated implants or tissue engineering scaffolds, which include the ability to fill irregularly shaped defects with minimal surgical intervention [267].

A number of demanding requirements have to be fulfilled by synthetic materials for applications in regenerative medicine. In addition to physicochemical properties that fit the application site, the polymer and any adjuvant component that is required to formulate an in situ cross-linkable system have to be biocompatible. Ideally, the resulting network should also have the ability to support cell growth and proliferation early in the tissue regeneration process [53,266].

The cross-linkable synthetic polymers that will be discussed in the following sections are reactive polyesters. The main chemical functionality involved in the chemical cross-linking mechanisms is the polarized, electron-poor double bond, such as in vinylsulfones and in esters of acrylic acid, methacrylic acid, and fumaric acid. Other chemically or thermally cross-linkable macromonomer functional groups are styryl, coumarin, and phenylazide; these will not be discussed here [268].

Cross-linked Polyesters

Fumarate-based polymers: The development of fumarate-based polyesters for biomedical applications began several decades ago. Fumaric acid is a naturally occurring metabolite found in the tricarboxylate cycle (Krebs cycle); it is composed of a reactive double bond available for chemically cross-linking reactions. These characteristics make fumaric acid a candidate building block for cross-linkable polymers. The first and most comprehensively investigated fumarate-based copolymer is the biodegradable copolyester poly(propylene fumarate) (PPF) (Fig. 33.5A). PPF was first polymerized from fumaric acid and propylene oxide [269]. Mikos and coworkers optimized the synthesis of PPF and broadly investigated the tissue compatibility and applications of PPF both in vitro and in vivo [14]. Synthesis progressed to the copolymerization of fumaryl chloride and 1,2-propanediol (propylene glycol) [270]. It

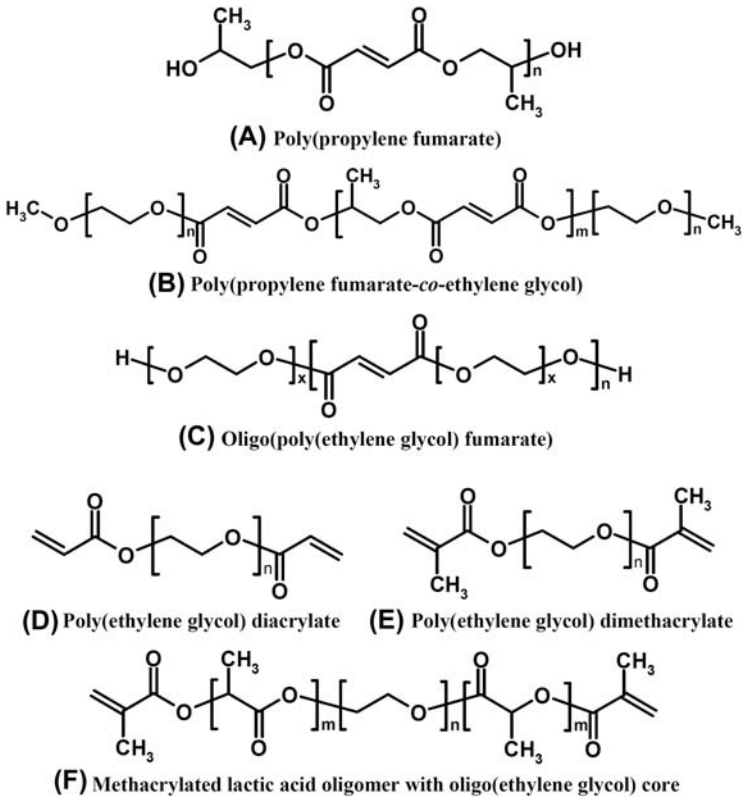

FIGURE 33.5 Chemical structures of synthetic polymers for the fabrication of cross-linked biodegradable networks.

now involves the transesterification of diethylfumarate with propylene glycol and subsequent polycondensation of the diester intermediate *bis*(2-hydroxypropyl) fumarate (PF) [271]. A variety of methods to synthesize PPF have been explored; each results in different polymer molecular weights and properties [272]. PPF has been developed as an alternative to PMMA bone cements. PPF can be injected as a viscous liquid and thermally cross-linked in vivo, eliminating the need for direct exposure of the defect site to light. Typically, PPF is cross-linked with either methyl methacrylate or *N*-vinyl pyrrolidone (NVP) monomers and benzoyl peroxide as a radical initiator [273,274]. Depending on the ratio of initiator, monomer, and PPF, the curing time can be controlled between 1 and 121 min. Compared with PMMA, which is not resorbable and is limited because its high curing temperatures (94°C) can cause necrosis of the surrounding tissue, the curing temperature of PPF has been shown not to exceed 48°C [275,276]. PPF can also be photocross-linked via the electron-poor double bonds along the backbone. Typical formulations include NVP, diethylfumarate, or PF-diacrylate (PF-DA) as comonomers together with a photoinitiator such as *bis*(2,4,6-trimethylbenzoyl) phenylphosphine oxide [277–279]. The mechanical properties of PPF, which depend on the composition, synthesis condition, and cross-linking density, are promising. However, these materials are probably not sufficient for load-bearing applications, especially when used as macroporous scaffolds [267,278,280]. One strategy to strengthen PPF scaffolds further includes the incorporation of nanoparticulate fillers. Reinforced PPF composites have been synthesized using aluminum oxide–based ceramic nanoparticles and chemically modified single-walled carbon nanotubes (SWNT). For just 0.05 wt% loading with the latter, a 74% increase was recorded for the compressive modulus and a 69% increase for the flexural modulus compared with plain PPF/PF-DA [281]. The chemical integration of alumoxane nanoparticles in cross-linked PPF/PF-DA networks resulted in a significantly increased flexural modulus [282]. Both the PPF/alumoxane nanocomposites and the PPF/SWNT nanocomposites were processed into macroporous tissue engineering scaffolds [283,284] and showed good biocompatibility in vitro [285,286] and in vivo [287,288].

Microparticulate ceramic materials such as β-tricalcium phosphate (β-TCP) were also employed as an inorganic filler to improve the mechanical properties of composite scaffolds and improve the material's osteoconductivity [289]. The composite scaffolds exhibited increased compressive strengths in the range of 2–30 MPa, and β-TCP reinforcement delayed scaffold disintegration significantly in vivo [290]. Rabbit in vivo studies also revealed the biocompatibility of photocross-linked PPF scaffolds in both soft and hard tissues [291].

PPF hydrolytically degrades at the ester bonds along its backbone. The degradation time depended on the polymer structure as well as other components such as fillers. In vitro studies identified the time needed to reach 20% original mass ranging from around 84 days (PPF/β-TCP composite) to over 200 days (PPF–$CaSO_4$ composite) [266]. Slow-degrading, porous antibiotic-releasing PPF exhibited properties suitable for craniofacial degradable space maintenance applications [292].

To broaden the application spectrum for in situ cross-linkable PPF, block copolymers with hydrophilic PEG of different compositions were synthesized. Poly(propylene fumarate-*co*-ethylene glycol) (P[PF-*co*-EG]) (Fig. 33.5B) was synthesized from PPF and PEG in a transesterification reaction catalyzed by antimony trioxide; propylene glycol was removed by condensation [293]. Behravesh et al. modified the synthesis to yield well-defined ABA-type triblock copolymers from 2 mol monomethoxy-PEG and 1 mol PPF [294]. Generally, P(PF-*co*-EG) copolymers are hydrophilic polymers with specific properties including crystallinity and mechanical characteristics that depend on the molecular weights of the individual blocks and the copolymer. As a result, platelet attachment to P(PF-*co*-EG) hydrogels was significantly reduced compared with the PPF homopolymer, which makes these copolymers candidate materials when direct biomaterial–blood contact is inevitable, such as for vascular grafts [295]. Most P(PF-*co*-EG) copolymers are amphiphiles and soluble in water; this makes them candidate materials for injectable applications. ABA-type copolymers showed thermoreversible properties comparable to other PEG-containing triblock copolymers discussed earlier. The thermogelling properties of P(PF-*co*-EG) depended on the PEG's molecular weight and salt concentration and the physical gelation temperature could be adjusted to values below body temperature [294]. In addition, the hydrophobic PPF block is highly unsaturated and available for additional chemical cross-linking, which could result in stiff cross-linked networks suitable for fabricating prefabricated cell carriers. In vitro degradation studies of macroporous, cross-linked P(PF-*co*-EG) scaffolds revealed considerable mass loss and swelling over 12 weeks. In these studies, the degradation rate depended mainly on the content of the PEG-DA cross-linker and was almost unaffected by the construct porosity. Overall, the results indicated a bulk degradation mechanism of the macroporous constructs [296]. In a subcutaneous rat model, P(PF-*co*-EG) hydrogels demonstrated good initial biocompatibility followed by the development and maturation of a fibrous capsule, which is often seen for polymeric implants [270]. Overall, the reported in vitro cytotoxicity and in vivo biocompatibility assays suggest that P(PF-*co*-EG) hydrogels have potential for use as injectable biomaterials. Fisher et al. demonstrated the suitability of thermoresponsive P(PF-*co*-EG) hydrogels for chondrocyte delivery in regenerating articular cartilage defects [297].

As previously discussed for stealthy PEG-containing biodegradables, PEG content and the hydrophilicity of cross-linked P(PF-*co*-EG) hydrogels are critical factors affecting cell adhesion [298]. Low-adhesive hydrogels enable a controlled surface or bulk modification with adhesion molecules specifically to enhance cell adhesion. P(PF-*co*-EG) hydrogels have been modified by the covalent integration of agmatine [299] and the adhesion peptide GRGDS [300]. Significantly increased numbers of smooth muscle cells and marrow stromal cells adhered compared with the unmodified networks.

An exclusively hydrophilic fumarate-based macromer is oligo(poly[ethylene glycol] fumarate) (OPF) (Fig. 33.5C). OPF macromers have been synthesized from PEG and fumaryl chloride by a simple condensation reaction in the presence of triethylamine. OPF cross-linking with or without the addition of a cross-linker such as PEG-DA can be initiated photochemically [301] or thermally [302]. In contrast to chemically cross-linked PPF and P(PF-*co*-EG), both of which form rigid polymer networks with a low water content, cross-linked OPF networks exhibit properties typical of hydrogels. Gel characteristics mainly depended on the molecular weight of PEG and the reactant ratio [301]. Cross-linked OPF hydrogels degrade hydrolytically along the ester bonds between fumaric acid and PEG, resulting in increased polymer swelling and a decreased dry weight. The weight loss of OPF hydrogels depended on their cross-linking density [303]. Studies investigating the mechanical properties revealed that cross-linked OPF hydrogels made from low−molecular weight PEG (1000 Da) swelled less, were stiffer, and elongated less before fracture compared with hydrogels composed of longer PEG chains. OPF hydrogels can also be combined in layers to form biphasic gels, with each phase having different material properties [302]. An in vitro investigation was conducted of the cytotoxicity of each component of OPF hydrogel formulation and the resulting cross-linked network employing marrow stromal cells (MSCs). After 24 h, the MSCs maintained more than 75% viability for OPF concentrations below 25% (w/v). A high−molecular weight (3400 Da) PEG-DA cross-linker demonstrated significantly higher viability compared with lower−molecular weight (575 Da) PEG-DA. Leachable products from cross-linked OPF hydrogels were found to have minimal adverse effects on MSC viability [304]. The in vivo bone and soft tissue compatibility of OPF hydrogels was demonstrated using a rabbit model [303]. Based on these promising biocompatibility data, OPF-based hydrogels were investigated as injectable drug, DNA, and cell delivery devices. Cross-linked OPF hydrogels that encapsulated gelatin microparticles were developed as a means of simultaneously delivering two chondrogenic proteins, insulin-like growth factor-1 and transforming growth factor-β1 [305], a strategy that promoted cartilage regeneration [306]. In a more complex approach involving a bilayered OPF hydrogel and the release of a chondrogenic and an osteogenic growth factor, the materials demonstrated the potential for osteochondral tissue repair [307].

Kasper et al. developed and characterized composites of OPF and cationized gelatin microspheres that released plasmid DNA in a sustained, controlled manner in vivo [308]. To control cell adhesion to the hydrophilic hydrogels, RGD adhesion peptide-modified OPF hydrogels were developed [309]. OPF hydrogels have also been shown to be useful as injectable cell delivery vehicles for bone regeneration. MSCs were directly combined with the OPF hydrogel precursors and encapsulated during thermal cross-linking. In the presence of osteogenic supplements, MSC differentiation in these hydrogels was apparent by day 21. By day 28, mineralized matrix could be seen throughout the hydrogels [310]. Hydrogel properties have been identified as affecting osteogenic differentiation within these systems [311]. Studies focused on combining cell and growth factor delivery using injectable OPF formulations [312].

Reactive cyclic acetal polymers: Current synthetic polyesters and polyanhydrides possess distinctive properties and are used extensively in clinical practice. Despite their popularity, the acidic degradation products liberated from the bulk of these polymers raise concerns regarding adverse effects and inflammation of the implantation site. In an effort to develop alternative materials, extensive research is being done to synthesize polymers that biodegrade hydrolytically without releasing pH-affecting moieties. Polymers based on acetals, cyclic acetals, and ketals degrade and form degradation products with hydroxyl, carbonyl, and/or aldehyde groups, depending on the structure of the monomers [313]. These polymers can be used for both soft and hard tissue repair. An example of a cyclic acetal-based building block is 5-ethyl-5-(hydroxymethyl)-β,β-dimethyl-1, 3-dioxane-2-ethanol (EH).

Relatively simple polymeric cyclic acetal networks can be fabricated by the radical polymerization of diacrylated EH (EHD). The resulting networks are hydrophobic; they do not swell in water and they support osteoprogenitor cell adhesion [314]. Using the traditional salt leaching technique, macroporous biodegradable scaffolds were fabricated that supported myoblast adhesion and proliferation; they were investigated for muscular tissue engineering [315]. Networks with increased hydrophilicity were designed by copolymerizing hydrophilic PEG-DA [316], generating water-swellable EHD/PEG-DA hydrogels that were formulated as an injectable system that allowed cross-linking under cytocompatible conditions and sustained encapsulated osteoprogenitor cells for up to 7 days [317]. Copolymerization with methyl-terminated PEG monoacrylate, on the other hand, resulted in nonswelling biocompatible networks with increased hydrophilicity [318].

Other groups of biomaterials are based on polyacetals and polyketals and have shown potential in drug delivery applications owing to their pH-dependent degradation [313]. The development of alternative synthetic polymers such as those described here is a critical step toward the future success of many tissue engineering and drug delivery applications.

Polymers containing acrylate, methacrylate or vinylsulfone functionalities: Precursors of cross-linked biodegradable polyester networks that bear vinylsulfone, acrylate, or methacrylate functionalities include PEG-DA (Fig. 33.5D), PEG-dimethacrylate (Fig. 33.5E), PEG vinylsulfones, diacrylated PLA-PEG-PLA block copolymers, acrylic modified PVA, methacrylate-modified dextran, and acrylated chitosan [45,99,268]. Because the last two examples are synthetic derivatives of natural macromolecules, they are not discussed further here. Besides such hydrophilic, natural macromolecules, which are considered to be candidate building blocks based on their inherent biocompatibility, PEG is the most prominent synthetic component of cross-linked polymer networks owing to its biocompatibility and inertness. As described earlier, PEG is hydrophilic and does not promote cell adhesion. To improve cell adhesion to cross-linked PEG hydrogels, adhesion peptides containing the tripeptide motif RGD were incorporated [319–321]. Research on engineered hydrogels has focused on mimicking the invasive characteristics of native ECMs by including substrates for matrix metalloproteinases (MMPs) in addition to integrin-binding sites. PEG hydrogels cross-linked in part by MMP-sensitive linkers were made degradable and invasive for cells via cell-secreted MMPs [322]. Critical-sized defects in rat crania were completely infiltrated by cells and were remodeled into bony tissue within 5 weeks when these gels were loaded with recombinant human BMP-2 and implanted in the defect site. As in natural ECMs that sequester a variety of cellular growth factors and act as a local depot for them, invading cells were presented with a mitogen that, in this case, specifically promoted bone regeneration [323]. The PEG-based hydrogels used in these studies were fabricated by a "click"-type conjugate addition reaction between vinylsulfone-functionalized branched PEG and thiol-bearing peptides under almost physiological conditions.

To enhance the initial mechanical stability and biodegradability of cross-linked PEG-based hydrogels, oligomeric biodegradable lipophilic blocks such as oligo(lactic acid) [324] (Fig. 33.5F) and oligo(caprolactone) [325], were included in the cross-linkable polymeric precursors. In a critical-sized cranial defect model, porous cross-linked scaffolds made from diacrylated poly(ethylene glycol[2]-lactic acid[10]) combined with osteoinductive growth factors showed potential as an in situ–forming synthetic bone graft material [326].

Biodegradable oligomeric macromers containing biodegradable segments were synthesized for hard tissue applications and drug delivery. To enable more flexibility in materials design and the degree of cross-linking, the central hydroxyl-bearing core molecule was changed from a linear diol such as PEG to a trivalent alcohol with different degrees of ethoxylation [327]. Oligomeric biodegradable domains were incorporated by ROP of lactides or caprolactone. Macromer reactivity for cross-linking was introduced by methacrylation of the chain termini. The degree of core ethoxylation as well as the content of lactic acid or caprolactone units per arm controlled the material properties and provided a material platform for different applications. A similar material system with higher molecular weights was developed for ocular drug delivery [328,329]. These macromers contained lactide- and trimethylene carbonate–based degradable domains and were end-functionalized for cross-polymerization with methylfumarate or methacrylate moieties. Acrylated poly(glycerol sebacate) has been used as an effective tissue adhesive [330].

Photopolymerized (meth)acrylated biodegradable hydrogels have been used in a wide range of biomedical applications. As described earlier, limited interactions with proteins are characteristic of hydrophilic surfaces. Consequently, applications such as the use of cross-linked hydrogels as a barrier applied after a tissue injury to improve wound healing or as a cell encapsulation material that immunoisolates transplanted cells capitalize on this property [99,331]. Islets of Langerhans encapsulated in PEG-DA hydrogels and transplanted to develop a bioartificial endocrine pancreas are a prominent example of the latter application. The hydrogels are permeable for nutrients, oxygen, and metabolic products and enable the entrapped islets to survive and secrete insulin that is released by diffusion. Hydrophilic tissue barriers from cross-linked polyesters such as P(EG-*co*-LA) diacrylate have been used to prevent thrombosis and restenosis after vascular injury and postoperative adhesion formation after many abdominal and pelvic surgical procedures.

Cross-linked hydrophilic polyesters are also promising depots for local drug delivery because of their compatibility with hydrophilic macromolecular drugs, such as proteins or oligonucleotides. The materials' tissue compatibility and hemocompatibility even allow for intravascular applications [332]. Drug release from cross-linked hydrogels generally can be well-controlled by adjusting swelling, the cross-link density, and polymer degradation [30,333,334].

Photopolymerized methacrylated polymer networks have also been widely explored for injectable tissue engineering [45,335]. Elisseeff and coworkers employed PEG-DA scaffolds for cartilage engineering by encapsulating

chondrocytes, MSCs, and embryonic stem cells. In these studies, the cross-linked PEG-based hydrogels served as an efficient scaffold for anchorage-independent cells and promoted tissue formation. Photogelation, which offers good spatial and temporal control of hydrogel curing, was used to control the spatial organization of different cell types within a three-dimensional system for osteochondral defect regeneration by sequentially polymerizing multiple cell and hydrogel layers. In an attempt to promote hydrogel−tissue integration, a tissue-initiated polymerization technique was developed that uses in situ generated tyrosyl radicals to initiate the photogelation of an injectable macromer solution [336].

Traditionally, photopolymerization is initiated by directly exposing materials to UV or visible light in accessible cavities or during invasive surgery. For PEG-dimethacrylate hydrogels, it was shown that light, which penetrates tissue including skin, can cause photopolymerization indirectly (transdermal photopolymerization). In vivo studies revealed that gels can be polymerized in 3 min with no harm to imbedded chondrocytes and subsequent cartilaginous tissue formation, as indicated by increasing the glycosaminoglycans (GAGs) and collagen contents [337]. In deep crevices, such as may be found in larger orthopedic defects, problems are expected to arise from limited light penetration and inconsistent photopolymerization. For those applications, thermally induced cross-linking techniques appear to be advantageous [266].

Hydrogel-forming macromonomers containing other functionalities: The development of injectable hydrophilic macromonomers that can be cross-copolymerized to hydrogels under physiological conditions using cytocompatible chemistries has become a major focus in biomaterial development. The process started with the development of protocols using photo- or heat-initiated free radical polymerization of hydrophilic, typically PEG-based macromonomers in the presence of cells [266,304]. Over the years, several alternative strategies have been explored employing specific addition reactions [6], classical bioconjugation chemistry, and “click” chemistry [338,339], as well as enzymatic conjugation [340]. Specific examples include the Michael-type addition between thiol groups of designed peptides and multiarm PEG vinylsulfone [341], or the conjugation reaction between amine groups and succinimidyl esters that was used to fabricate transparent PEG-hydrogels for ocular applications from branched PEG-succinimidyl propionates and bifunctional or multifunctional PEG-amines [342]. A more complex engineering approach was presented for the direct fabrication of biologically functionalized gels with ideal structures that can be photopatterned to generate specific microenvironments in situ, all in the presence of cells [343]. In this approach, an enzymatically degradable peptide macromer was reacted with a multiarm PEG-azide through a copper-free “click” chemistry that allows for the direct encapsulation of cells. Subsequently, biological functionalities, e.g., adhesion peptides, were introduced within the gel by a thiol-ene photocoupling chemistry in real time and with micrometer-scale resolution. Another approach to the design of biodegradable and biofunctional hydrogel hybrids focuses on integrating GAGs to synthetic polymer networks. Multiarmed PEG (star-PEG) was processed to covalent hybrid networks with GAGs, mainly heparin [344,345]. In the design of hydrogels, the importance of controlling degradation properties as well as externally triggered degradation mechanisms has become clear [346,347], in addition to optimizing the base material, in situ polymerization chemistries, and cell−material interactions.

APPLICATIONS OF SYNTHETIC POLYMERS

Synthetic polymers have a vital role in biomedical applications, including nano-, micro-, and macroscopic drug and gene delivery devices [115,348−350], orthopedic fixation devices [351], and cosmetic and prosthetic implants [98], and as artificial matrices for tissue engineering applications [101]. The interested reader may be directed to the referenced reviews that provide in-depth insight into current trends and technologies. Researchers have sought to develop and clinically explore third-generation biomaterials [1] that are designed to control protein adsorption, cell adhesion and differentiation, implant integration, and foreign body reaction, and to develop biomimetic synthetic materials [4,5,352].

CONCLUSION/SUMMARY

Synthetic biomaterials have progressed from testing “off-the-shelf” plastics not developed for biomedical purposes to a field of synergistic research by engineers, scientists, and physicians dedicated to tailoring material properties for specific applications. Current trends have shifted the focus toward biology to understand and then mimic physiological interactions and signaling.

Hydrogels, especially injectable systems, have attracted increasing attention due to the ease of their application, their structural similarity to native ECM, and their good compatibility for direct cell encapsulation because of their high water content. In tissue engineering, it is no longer believed that the biomaterial itself has to provide mechanical properties comparable to the diseased tissue; instead, the polymer has to promote defect site remodeling and tissue regeneration in vivo such that the regenerated tissue is histologically and functionally indistinguishable from the surrounding tissue. Hydrogels might be superior to hydrophobic polymers in that regard, because they can degrade more quickly, which solves the problem of the formation of nonfunctional fibrous tissue on the polymer−tissue interface. Also, hydrogel breakdown can be synchronized with cell proliferation and migration by using an enzymatically cleavable cross-linker.

Besides providing tailored degradative properties, synthetic materials for regenerative medicine should allow for minimally invasive application techniques, integrate well with the surrounding tissue, and promote cell adhesion, migration, and differentiation. The development and thorough characterization of injectable biodegradables provide the foundation for injectable tissue regeneration. Nevertheless, in situ gelation or polymerization concepts will have to be developed and optimized with regard to the cytocompatibility and stability of the resulting construct. The implementation of biomimetic design strategies will enable control and custom-designed cell−biomaterial interactions to guide tissue formation from transplanted cells. Strategies based on gene delivery or gene-activating biomaterials also have great potential in regenerative medicine, but the long-term safety of such therapies remains to be proven. Developments in stem cell biology and conjugation chemistry, such as biorthogonal "click" chemistries, have allowed for the convenient biofunctionalization of the polymeric base structures presented in this chapter with small molecules, peptides, proteins, GAGs, or DNA/RNA toward implant materials with tailored properties and bioactivity. Advances in additive manufacturing provide tools to process such engineered synthetic biomaterials into customized implants with optimized outer shapes and pore structures as well as porosity.

Overall, advances in the field of biomaterial synthesis and the design of physicochemical properties in conjunction with rapidly increasing knowledge in stem cell biology regarding adhesion, migration, differentiation, and signaling will reveal design concepts for improved injectable, biomimetic, polymer-based formulations for tissue engineering applications.

INTRODUCTION

With ever-increasing growth in the world's population and average life expectancy, chronic bone disorders such as osteoporosis have become more prevalent, resulting in nearly nine million bone fractures annually worldwide [1]. This development, coupled with the high prevalence of bone fractures caused by trauma, has created the need to develop novel therapies and strategies to treat fractures and augment other bone defects more efficiently and cost-effectively. Conventional approaches to overcoming these complications have involved the use of bone autografts and allografts, which provide the implant site with natural osteogenic growth and some structural support [2]. These standard treatment options have had relative success and are considered the reference standard in treatment, but several shortcomings associated with them have prompted clinicians to seek alternative strategies [3,4].

For example, the application of autografts is limited by the size of the implant site and the viability of the host tissue [4]. Furthermore, the graft will often be resorbed by the body before osteogenesis is fully complete for large bone defect sites. This phenomenon is attributed to the unpredictable bone resorption characteristics of the grafts [5,6]. Autografting also requires surgeons to harvest donor tissue, which is relatively scarce and requires a secondary procedure that increases the operating time and overall cost. In addition, this procedure runs the risk of donor-site morbidity, which can include long-lasting pain, infection, nerve damage, and hematoma once the donor graft is removed [3,4,7]. A major limiting factor of allografts relates to the immune response that is triggered by the introduction of a foreign tissue into the body. When using allografts, surgeons run the risk that the tissue may be rejected by the body and initiate an inflammatory response, resulting in complete resorption of the graft [3,7]. Transmission of disease and/or infection is also possible and is capable of causing partial or complete loss of the bone inductive factors [8].

The wide array of risk factors associated with these treatment options has prompted the need to develop alternative materials for use as bone substitutes. Furthermore, the need to improve bone filler materials for reconstruction of large orthopedic defects and the need for implants that are more suitable, both mechanically and chemically, for their in vivo environment has prompted the development of new biomaterials [4]. More specifically, calcium phosphate (CaP) bioceramics have been used as a bone substitute material to replace, augment, and promote new bone formation since the 1920s [9]. CaP bioceramics are considered to be a highly favorable bone substitute material because CaP compounds make up approximately 70% of the inorganic phase of bone, which gives these materials excellent osteoconductive and bioactive properties [10].

Calcium Phosphate Bioceramics

CaP bioceramics are usually manufactured in the form of blocks or granules that make up the bulk raw material of bone substitute materials [11]. From a chemical perspective, CaP compounds are salts that contain $H_2PO_4^-$, $H_2PO_4^{2-}$, or PO_4^{3-} ions. Of these three ions, only HPO_4^{2-} and PO_4^{3-} ions exist naturally in the inorganic mineral phase of teeth and bones [12], which gives them excellent biological properties for use as a bone substitute material for dental and orthopedic applications [13]. Table 34.1 lists CaP compounds along with their standard abbreviations,

TABLE 34.1 Calcium Phosphate Compounds and Their Major Properties [16]

Name and Abbreviation	Chemical Formula	Ca/P Ratio	Density (g/cm^3)	Solubility at 25°C (mg/L)
Amorphous calcium phosphate (ACP)	–	1.5	3.01	25.6–32.8
Hydroxyapatite (HA)	$Ca_{10}(PO_4)_6(OH)_2$	1.67	3.16	~0.3
Calcium-deficient hydroxyapatite (CDHA)	$Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}$	1.5–1.67	3.16	~9.4
Dicalcium phosphate anhydrous (DCPA)	$CaHPO_4$	1	2.92	~48
Dicalcium phosphate dihydrate (DCPD)	$CaHPO_4 \cdot 2H_2O$	1	2.27	~88
Monocalcium phosphate monohydrate (MCPM)	$Ca(H_2PO_4)_2 \cdot H_2O$	0.5	2.23	~18,000
Octacalcium phosphate (OCP)	$Ca_8(HPO_4)_2(PO_4)_4 \cdot 5H_2O$	1.33	2.61	~8.1
α-Tricalcium phosphate (α-TCP)	α-$Ca_3(PO_4)_2$	1.5	2.86	~2.5
β-Tricalcium phosphate (β-TCP)	β-$Ca_3(PO_4)_2$	1.5	3.07	~0.5
Tetracalcium phosphate (TTCP)	$Ca_4(PO_4)_2O$	2.0	3.05	~0.7

chemical formula, Ca/P molar ratio, density, and solubility data [14–16]. A more comprehensive review of the structure and chemistry of all CaP compounds can be found elsewhere [12]. Hydroxyapatite (HA) and β-tricalcium phosphate (β-TCP), or their biphasic combination, comprise most commercially available CaP bioceramics.

One of the most important properties of CaP compounds is its solubility, because this characteristic strongly influences the in vivo behavior of the bioceramics [14]. Specifically, the degradation rate, and therefore the rate of new bone formation, is directly related to the chemical solubility of the CaP compounds. Fig. 34.1 outlines the

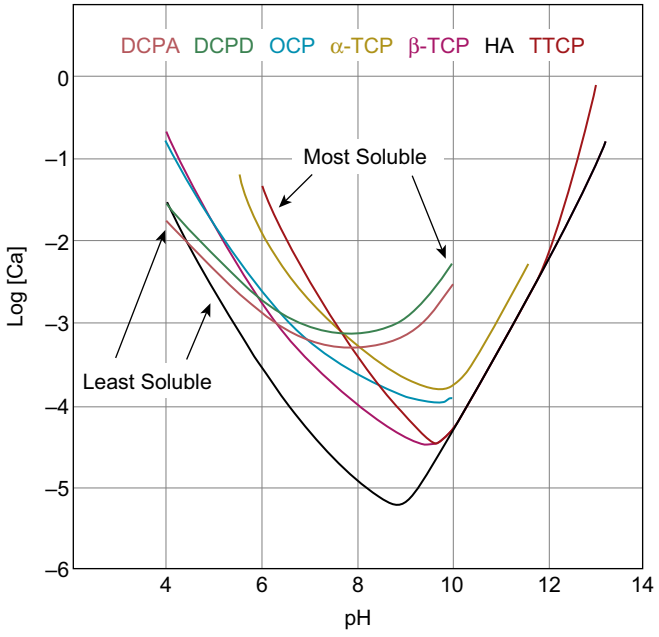

FIGURE 34.1 Two-dimensional solubility phase diagram for calcium phosphate compounds [17]. *DCPA*, dicalcium phosphate anhydrous; *DCPD*, dicalcium phosphate dehydrate; *HA*, hydroxyapatite; *OCP*, octacalcium phosphate; *TTCP*, tetracalcium phosphate; *α-TCP*, α-tricalcium phosphate; *β-TCP*, β-tricalcium phosphate.

solubility phase diagrams for all types of CaP compounds [17]. Based on these phase diagrams, it can be stated that generally, under neutral pH conditions, the degradation rate of CaP compounds follows a pattern from most soluble to least soluble [14]:

$$\text{MCPM} > \text{TTCP} > \alpha\text{-TCP} > \text{DCPD} > \text{DCPA} > \text{OCP} > \beta\text{-TCP} > \text{CDHA} > \text{HA}$$

where MCPM is monocalcium phosphate monohydrate, TTCP is tetracalcium phosphate, α-TCP is α-tricalcium phosphate, DCPD is dicalcium phosphate dehydrate, DCPA is dicalcium phosphate anhydrous, OCP is octacalcium phosphate, and CDHA is calcium-deficient HA.

By exploiting these solubility patterns, researchers are able to tailor and modify the biodegradation rate of these CaP bioceramics to better suit the rate of new bone formation. For example, biphasic CaP compounds composed of HA and β-TCP were designed by incorporating β-TCP into HA ceramics. As a consequence, these biphasic bioceramics exhibited a greater rate of resorption than pure HA ceramics [18]. More specifications regarding the biodegradability and solubility trends of CaP compounds can be reviewed elsewhere [12,19].

In the 1970s and 1980s, research into CaP bioceramics focused on their development for dental and orthopedic applications in the form of dense or porous blocks and granules [15,19,20]. Some of the most common dental applications include alveolar ridge augmentation, fillers for periodontal bony defects, tooth root replacement surgery, and coatings for metal screws for dental implants. Typical orthopedic applications included repair of bony defects as well as coatings for orthopedic metal implants usually used for hip and knee replacement surgery [19]. Although these more traditional CaP bioceramics have shown some clinical success, they still lack some important properties that severely restrict their clinical application, in particular with respect to their handling properties. CaP blocks or granules usually require invasive surgery to reach the desired implant site and achieve complete filling of the bone defect. Furthermore, because granules have poor cohesion, they run the risk of migrating out of the implant site, which can lead to unpredictable bone growth or other complications such as blood clotting [21]. From a surgeon's point of view, trying to shape granules or blocks to fit into an irregularly shaped bony defect site can prove challenging and lead to implant migration [22]. Therefore, these forms of CaP compounds have proven to be of limited value when the defect site is not easily accessible or when microinvasive percutaneous surgery would be a preferred method for implantation. Moreover, CaP in bulk form is considerably brittle in nature and exhibits poor mechanical strength and fracture toughness, which limits its uses to nonloading bearing sites [11]. These complications, coupled with the fact that most surgical trends lean toward the development of minimally invasive surgical techniques, have warranted the development of a bone substitute material that exhibits superior handling properties and can be injectable or moldable [23]. These demands have resulted in the development of calcium phosphate cements (CPCs).

Calcium Phosphate Cements

A current challenge for surgeons is to be able to place a bone substitute material directly into the defect site using the least invasive method possible. With the development of more advanced minimally invasive surgical procedures such as percutaneous surgery, there has been a demand for researchers to develop bone substitute materials that can be injectable, such as CPCs [11,24]. CPCs are a synthetic, self-setting bone substitute material that was first discovered by Brown and Chow in the early 1980s [19,25]. This "first-generation" cement consisted of an equimolar amount of TTCP and DCPA mixed with water in a liquid-to-powder ratio (LPR) of 1:4 to form a paste. This paste differed from the more traditional granule and block forms of CaPs in the sense that upon setting and hardening in vivo, the paste would sustain a rapid phase transformation resulting in the formation of HA or brushite with no hazardous acidic or basic by-products [25,26]. Details regarding this setting mechanism and the final products of the set cements are discussed further on in this chapter.

Basic Properties

The discovery of CPCs has opened up a new era for bone substitute materials in which handling properties are of upmost importance. This improvement in handling properties allowed for CPCs to be employed in minimally invasive surgery in which it also exhibited the unique ability to be molded and shaped to fill abnormal and complex defect sites where they were then able to set in situ [27]. In addition, because CPCs set in an aqueous environment at 37°C, their CDHA or brushite end product is more similar to that of natural apatites rather than CaP granules and blocks, which are sintered at high temperatures. This low-temperature formation also means that organic molecules such as polymers and living cells could be safely incorporated into the cement, which could further improve their biological response [28].

Similar to all CaP compounds, CPCs possess excellent biological properties owing to their chemical resemblance to the mineral component of bone [29]. As a consequence, several studies have shown that CPCs are highly biocompatible and osteoconductive materials with the ability to stimulate new bone growth by developing osteoconductive pathways [30]. Interestingly, it was shown that CPCs create chemical bonds to the surrounding host bone, which makes them suitable for fixating metal devices in mechanically weak bone. In addition, studies have shown that certain CPC formulations can even exhibit antimicrobial behavior as well as support osteoblast cell adhesion and gene expression in vitro [29].

CPCs also require several important properties to be employed to the best of their ability. For example, the cement requires suitable rheological properties with respect to viscosity and cohesion to ensure good bonding of the CaP particles to each other while providing adequate cell permeability. Conversely, CaP blocks and granules tend to be denser with minimal inherent porosity, which restricts their biodegradation and new bone formation. Good cohesion of CPCs is also needed to confine the CaP particles to the implant site and avoid migration throughout the body, which could lead to potential complications. CPCs also need to exhibit a suitable setting time with minimal heat output during the setting reaction to be relevant for clinical applications. Finally, the rate of resorption for the cements needs to be tailored to the rate of new bone formation so that the cement can provide adequate mechanical strength until it is replaced by new bone tissue [11,31]. CPCs are a rising class of bone substitute materials that have garnered much attention in the bone tissue engineering field. They are widely considered to be an ideal material for many bone repair and augmentation applications owing to their unique combination of biocompatibility, osteotransductivity, injectability, moldability and manipulation into bony defects, and self-setting ability in situ without producing toxic by-products. In this regard, CPCs are a more attractive material than prefabricated CaP blocks or granules for bone replacement applications [29].

CLASSES OF CALCIUM PHOSPHATE CEMENTS

In general, CPCs can be categorized into two main types based on the formed end products, i.e., apatite or brushite. The end product of the set cement is mainly determined by the solubility of the CaP precursor compounds and the pH of the setting reaction. Generally, a poorly crystalline HA or CDHA (apatite) forms when the pH value is greater than 4.2 whereas brushite, otherwise known as DCPD, forms when the pH value is less than 4.2 [32]. With respect to solubility characteristics, brushite-forming cements have a higher solubility rate than apatite-forming cements. Therefore, brushite cements tend to resorb faster than apatite cements both in vitro and in vivo [14,26].

Apatite Cements

All apatite-forming CPCs undergo a phase transformation that results in the formation of a poorly crystalline precipitated HA and/or CDHA as the final end product [32]. This end product has a strong similarity to the mineral phase in bone and teeth, which is primarily attributed to the fact that this type of cement is formed in an aqueous environment, resulting in a poorly crystalline structure. In some instances, a full phase transformation does not always occur and therefore small traces of unreacted CaP precursor compounds may remain in the matrix [29].

The most common CaP precursor compounds for apatite-forming cements include tricalcium phosphate (TCP) and/or TTCP [26]. For TCP-based cements, the particle size, degree of crystallinity, and crystal phase all strongly influence its degree of reactivity. For example, higher degrees of reactivity have been reported when the crystal phase was thermodynamically less stable. To this end, amorphous calcium phosphate (ACP) is considered to be the most reactive because it has the least stable crystal phase, followed by α-TCP and finally β-TCP [33]. Furthermore, the smaller the particle size, the more reactive the compound is, owing to the higher surface area available for reaction with the aqueous environment [32,34].

Interestingly, for apatite-forming cements, the forces holding the newly formed, highly interconnected CDHA crystals together are relatively weak, which means that detachment of the crystals in the network from each other can easily occur, especially once the passive dissolution process has been initiated. This is considered to be advantageous from biological and biodegradation points of view, because osteoclasts are better suited to ingest the smaller, fragmented apatite crystals [35]. The solubility of these cements also has an important role in regulating the biodegradation of the cements in vivo. For example, because apatite-forming CPCs and bone share a similar biological composition, they also exhibit similar solubility characteristics. Thus, like normal bone mineral, these CPCs are

relatively insoluble in aqueous solutions at a neutral pH but become more soluble as the pH becomes more acidic. This is a unique feature that allows osteoclasts to facilitate controlled dissolution during the bone remodeling process [36]. Although apatite cement degrades faster than stoichiometric HA, the rate of degradation is still relatively slow compared with brushite cements, resulting in degradation times that may take several years to decades [37].

Brushite Cements

As previously noted, all brushite-forming CPCs precipitate as DCPD as its final cementitious end product, in which the pH value of the setting reaction in the beginning is below 4.2. A wide variety of formulations have been proposed within the literature, but formulations of β-TCP + MCPM [38], and β-TCP + H_3PO_4 [29,39] tend to be most commonly used. Contrary to apatite cements, all brushite cements can form under only one type of setting reaction: the acid−base interaction, as described in more detail subsequently in this chapter. This characteristic is attributed to the chemical composition of brushite cement formulations and also the fact that DCPD can be precipitated only in a solution with a pH less than 6. Therefore, it is also understood that all formulations of this type of cement are acidic by nature during the setting and hardening phase [12,39]. For example, the pH of cements formed by a reaction between MCPM and β-TCP is initially low (∼2.5) before the pH eventually begins to rise to around 6 as the hardening phase progresses [39]. By modifying the starting formulations, the pH of the reaction, and thus several important properties of the cement, can be controlled. For example, replacing MCPM with H_3PO_4 in β-TCP−based formulations maintains a highly acidic cement paste for the first approximately 30 s of the setting reaction. Subsequently, the pH begins to rise in a similar fashion, as observed in MCPM + β-TCP formulations. Several major advantages can be obtained when MCPM is replaced by H_3PO_4 in β-TCP-based formulations, most notably: (1) more control over the reaction and chemical composition; (2) more homogeneity in the cement matrix, resulting in higher tensile strengths; and (3) prolonged setting times, which is desired specifically for brushite cements for which setting times are generally too fast [39].

The setting time of brushite cements is determined primarily by the solubility of the alkaline phase present within the CaP formulation. The more soluble the formulation, the faster the setting time is. Furthermore, a reduction in the solubility can be accomplished by increasing the alkalinity of the formulation, effectively prolonging the setting time. It is well-known that the alkalinity of HA is greater than β-TCP, which in turn is greater than α-TCP. In other words, the solubility of these three CaP compounds is: HA < β-TCP < α-TCP [14,40]. Therefore, by adding different types CaP compounds with varying pH and solubility characteristics to the formulation, the setting time can be modified. MCPM-based formulations, for instance, have been mixed with HA, β-TCP, or α-TCP. It was shown that the formulation containing HA took several minutes to set, whereas the formulation containing β-TCP took only 30−60 s to set, and finally the setting time for the α-TCP−containing formulation was further reduced to a matter of only several seconds [38]. Alternatively, incorporating additives into the cements that act by inhibiting the precipitation and growth of DCPD crystals has proven to be a successful strategy for increasing the setting time [41]. This effect has been observed for cements when setting retardants such as glycolic acid [42], sodium citrate, and citric acid were incorporated into the cement formulations [29].

Brushite cements set within a relatively short period of time from a liquid state, while these cements are highly bioresorbable and biocompatible. This latter feature is attributed to the fact that DCPD has a higher solubility and better stability under physiological conditions compared with apatite [12]. Therefore, it has been shown that brushite cements have a faster in vivo biodegradation rate than apatite cements. This rapid resorption rate also means that these cements have a rapid and significant decrease in mechanical strength after in vivo implantation [32]. Moreover, the setting times of brushite cements are generally so rapid that they require a large volume of liquid phase to keep the cement paste injectable and workable over a reasonable time. This means that high LPRs are often employed for these cements and this higher liquid content results in a more porous, inherently weaker cement as the final end product [11]. Poor mechanical strength coupled with short setting times and constricted handling properties have limited the clinical applicability of brushite cements, in particular with respect to load-bearing applications [29,43].

PHYSIOCHEMICAL PROPERTIES

Setting/Hardening Mechanism

The setting of CPCs is a continuous process that always begins with the dissolution of CaP precursor compounds into the liquid phase [17,26]. Generally, all CPCs are composed of two main phases: a solid/powder phase and a

liquid phase. Generally, the solid phase consists of one or more of CaP compounds listed in Table 34.1, whereas the liquid phase is typically either distilled water or an aqueous solution containing, e.g., phosphate-buffered saline, sodium phosphate, ammonium phosphate, citric acid, or sodium silicate [29]. Once the solid and liquid phases are combined and thoroughly mixed, dissolution of the CaP precursor compounds into the aqueous environment occurs. The rate of this dissolution highly depends on the pH of the liquid phase as well as the chemical composition of the CaP precursor compounds. Once the Ca^{2+} and PO_4^{3-} ions dissolve in solution, a supersaturation level is reached. Subsequently, these reactants begin to precipitate back onto the surface of the remaining powder constituents, usually in the form of CDHA (apatite) or DCPD (brushite) [32,44]. What is left is a highly viscous and moldable self-setting paste that can be placed directly into a bone defect site to aid in the healing process [11]. Generally speaking, once the cement is placed within the body, most of the phase transformation occurs within the first 6 h of setting; approximately 80% of the CaP precursor compounds convert to the final end products in this time frame [29].

An important factor behind the setting reaction of CPCs is the relative stability and solubility of the CaP compounds. This solubility is why a chemical transformation is induced once the CaP compound(s) are mixed with an aqueous solution. During the precipitation phase of the setting reaction, the newly formed CDHA or DCPD crystals grow epitaxially in the form of needle or rod-like microstructures that become highly interconnected and entangled. This highly entangled network of crystals provides structural rigidity to the hardened CPCs. Moreover, this highly interconnected web of crystals means that the microstructure and nanostructure of the cements possess an inherently intrinsic porosity usually between 40% and 60%, with pore sizes ranging between about 0.1 and 10 μm [11,29]. This formation of a web of needle or rod-like crystals during the setting reaction, as described previously, also leads to the adherence of crystalline grains, which results in hardening of the cement. After a sufficient time has passed, usually at least 24 h, most of the crystals have completely formed; a cement matrix is left composed of some areas of highly dense, compacted crystals whereas other areas are highly porous owing to large separations of the crystals [29].

For some apatite-forming CPCs, water is generally not employed as a reactant but rather acts as a medium. Because of this, the amount of water needed for setting to occur is minimal. Conversely, for brushite-forming CPCs, water always actively participates in the setting reaction because it is necessary for DCPD to form. Therefore, these cements are commonly referred to as hydraulic cements [30,44].

Chemical Reaction

The chemical reaction that takes place during the setting of CPCs depends on several key variables such as the pH of the reaction, the LPR, the particle size, and, most importantly, the chemical composition of the CaP precursor compounds. Two main types of setting reactions can be discerned: the acid–base interaction and hydrolysis [14,26,32].

Acid–Base Interaction

The first type of setting reaction, the acid–base interaction, employs the use of the general principles of chemistry in which, once an acidic compound and a basic compound are combined, they interact and produce a neutral compound [29]. In this instance, a relatively acidic CaP compound reacts with a relatively basic one to produce a neutral end product. A typical example of this reaction can be observed in what is considered the first CPC formulation developed by Brown and Chow in the 1980s [25]. This cement formulation consisted of acidic DCPA and basic TTCP compounds that, once combined in an aqueous liquid phase, reacted to form a relatively neutral, poorly crystalline precipitated HA, as shown in Eq. (34.1) [25,29]:

$$2Ca_4(PO_4)_2O + 2CaHPO_4 \rightarrow Ca_{10}(PO_4)_6(OH)_2 \tag{34.1}$$

It was initially thought that the reaction of DCPA with TTCP would result in the formation of stoichiometric HA (Ca/P ionic ratio = 1.67), but upon further investigation it was determined that only the first nuclei were stoichiometric HA. As the reaction continued, the nuclei would continue to grow and enlarge in the form of CDHA (Ca/P molar ratio of 1.5–1.67) crystals [25,29].

Hydrolysis Interaction

The second type of setting reaction involves the hydrolysis of CaP compounds in a liquid phase. This hydration process is mildly exothermic and is composed of five stages: (1) initiation, (2) induction, (3) the acceleration, (4) deceleration, and (5) termination [29]. Unlike the previous acid–base interaction reaction, this reaction employs the use of only one CaP precursor compound, and therefore the Ca/P molar ratio remains the same from the beginning to the end of the reaction [45]. Typical CaP precursor compounds include ACP, DCPA, CDHA, OCP, TTCP,

β-TCP, and α-TCP; α-TCP is the most commonly used in the literature. Once one of these single-phase CaP compounds is mixed with an aqueous solution, most reprecipitate into CDHA crystals during the setting of the cement. An example of the chemical reaction using α-TCP as the starting compound and water as the aqueous solution can be seen in Eq. (34.2) [29]:

$$3\alpha Ca_3(PO_4)_2 + H_2O \rightarrow Ca_9(HPO_4)\ (PO_4)_5(OH) \tag{34.2}$$

For the hydrolysis of α-TCP, the literature indicates that the reaction is controlled through the dissolution of Ca^{2+} and PO_4^{3-} ions at the surface of the α-TCP particles. Therefore, the surface area, or particle size, has a crucial role in the setting process as well as the time it takes for the cement to set fully [46,47]. Results from another study indicated that the incorporation of 2 wt% CDHA into the α-TCP powder phase to act as a nucleation sites accelerated the kinetics of the setting reaction [46]. A comparison of these two setting mechanisms, with examples from the most common CaP formulations for both apatite and brushite cements, is shown in Fig. 34.2.

Setting Times

Setting time properties are greatly important for all CPC formulations. This is especially true from the perspective of the surgeon, as the setting time dictates the amount of time the surgeon can mold and/or inject the cement as well

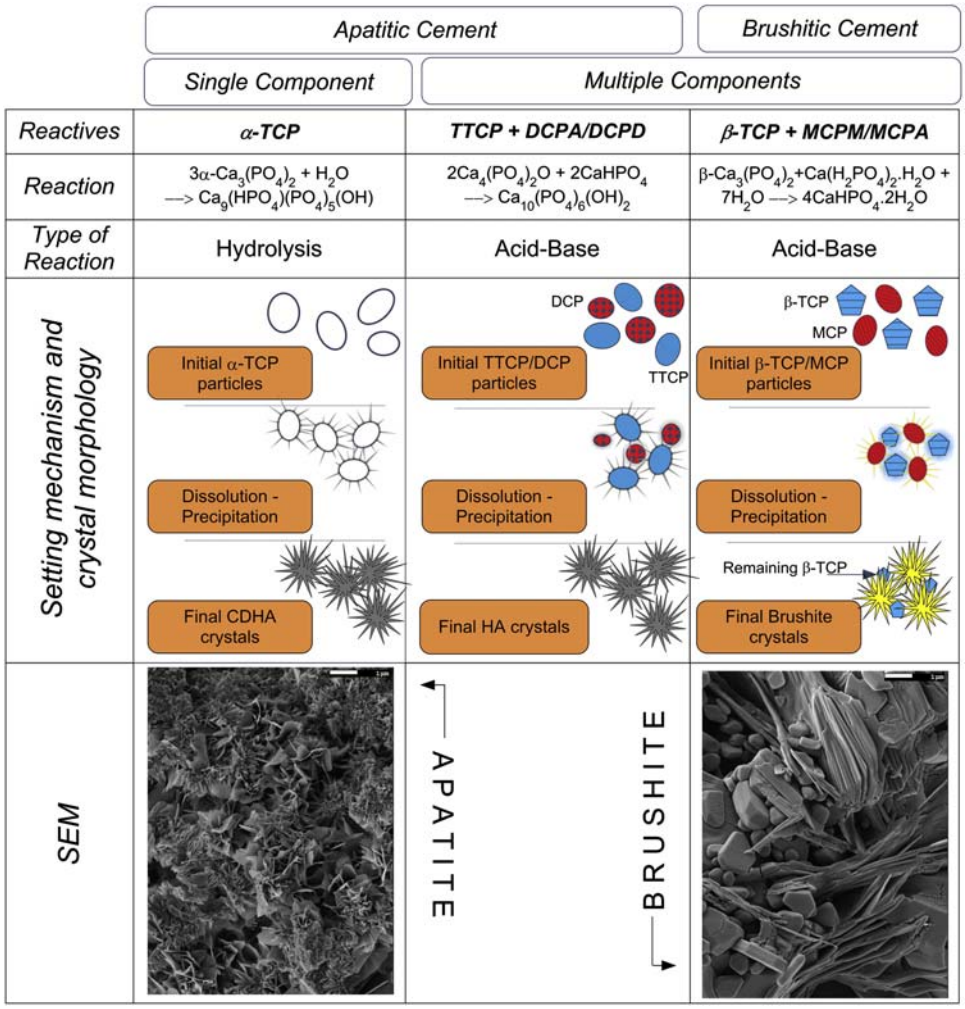

FIGURE 34.2 Classification of calcium phosphate cement setting mechanisms with examples from the most common formulations. Cements are classified based on their final phase transformation end product (apatite or brushite), the number of components in the powder phase (single or multiple), the type of setting reaction (hydrolysis interaction or acid—base interaction), and the microstructure progression during the setting reaction. *CDHA*, calcium-deficient hydroxyapatite; *DCP*, dicalcium phosphate; *DCPA/DCPD*, dicalcium phosphate anhydrous/dicalcium phosphate dehydrate; *MCP*, monocalcium phosphate; *MCPM/MCPA*, monocalcium phosphate monohydrate/monocalcium phosphate anhydrous; *SEM*, scanning electron microscopy; *TTCP*, tetracalcium phosphate; *α-TCP*, α-tricalcium phosphate; *β-TCP*, β-tricalcium phosphate. *Reprinted with permission from Ginebra M-P, Canal C, Espanol M, Pastorino D, Montufar EB. Calcium phosphate cements as drug delivery materials. Adv Drug Deliv Rev 2012;64(12):1090—1110.*

as close the wound safely in the operating theater. Setting times must be slow enough to give the surgeon time to implant and mold the cement into the defect site, and fast enough not to delay the operation. There are two main methods for how researchers can measure the setting time of the cements: the Gillmore needles method (ASTM C266-89) and the Vicat needle method (ASTM C191-92) [29]. Both involve placing a weighted needle onto the surface of the cement at different time points to visualize whether an indentation was created. Once a full indentation has not been created on the surface, the cement is considered to be set. More specifically, Gillmore needles have been used to measure the initial and final setting times of cements [48]. For instance, a lighter, thicker needle is used to determine the initial setting time whereas a heavier, thinner needle is used to determine the final setting time [49]. Both the Gilmore needle and Vicat needle methods are highly user-dependent because their results are based on the concept of "visible indentation," which can make reproducibility of data between research groups challenging. Moreover, these methods provide no information about the progression of the setting reaction that controls the setting process and time. Therefore, other methods such as impedance spectroscopy have garnered much attention as a way to monitor the setting reactions of CPCs in situ. More information regarding this technique can be found elsewhere [50].

With respect to its clinical use, the initial setting time translates to the amount of time the surgeon has to implant and work with the cement, whereas the final setting time translates to the time when the wound can be closed, as depicted in Fig. 34.3. The cement should not move or deform between the initial and final setting time because this could induce cracks. Therefore, setting time criteria have been defined as follows:

$$3\ \text{min} \leq I < 8\ \text{min}$$
$$I - CT \geq 1\ \text{min}$$
$$F \leq 15\ \text{min}$$

where CT = cohesion time, I = initial setting time, and F = final setting time. In this instance, CT is defined as the time when the cement paste no longer disintegrates in an aqueous solution [49]. The initial setting time window is relatively large and depends on the application procedure of the specific cement. For example, for dental applications, shorter initial setting times are usually preferred, whereas longer initial setting times are needed for orthopedic procedures. Regardless, the maximum final setting times for all applications generally should not exceed 15 min [49].

Strategies to Improve Setting Times

A wide array of strategies has been developed over the years to modify the setting rate of the cements so that they fall within the desired time window. Generally, brushite cements react and set much faster than apatite cements. This means that the setting reaction for brushite cements needs to be delayed whereas the setting of apatite cements needs to be accelerated to meet clinical requirements [14,40]. One of the most straightforward and common approaches toward this end is to change the particle size of the CaP precursor compounds [51]. Setting times can be significantly reduced by decreasing the mean particle size, because the size reduction increases the surface area of the particles that can then interact with the liquid phase, thus accelerating the setting reaction and hydration kinetics of the

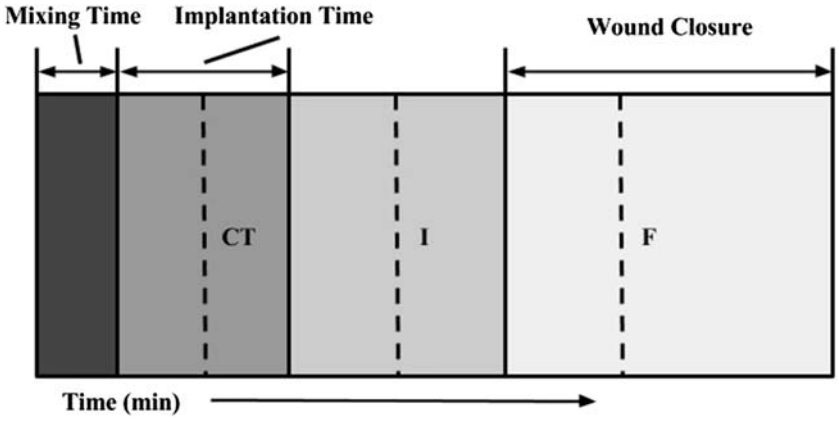

FIGURE 34.3 A diagram outlining the setting time stages of calcium phosphate cements from a clinical perspective where CT = cohesion time, I = initial setting time, and F = final setting time [29].

cement [26,34,46,47]. When this is the case, higher amounts of dissolved Ca^{2+} and PO_4^{3-} ions can be reached in a shorter time, increasing the degree of supersaturation that favors crystal nucleation and growth [52].

Another simple approach to modifying the setting time is to change the amount of liquid phase used in the cement. As is the case for most apatite cements, the amount of liquid phase used is brought to a minimum in an attempt to reduce the setting time, whereas the opposite approach is employed for brushite cements. This is one reason why apatite cements have a tendency to be more viscous and difficult to inject compared with less viscous brushite cements [26,29]. The setting time can also be reduced by incorporating soluble orthophosphates such as Na_2HPO_4 or NaH_2PO_4 into the liquid phase to reduce the pH. Creating a more acidic environment increases the solubility of the CaP compounds and accelerates the setting reaction, which shortens the overall setting time [33,53]. Furthermore, the presence of these sodium orthophosphates prevents unreacted CaP particles from becoming isolated, which could prolong the setting time [29]. Organic acids such as lactic, glycolic, tartaric, citric and malic have also been extensively used to influence the setting time of cements and have been well-described elsewhere [54].

It was also observed that for some cases, an initial thermal treatment of the CaP precursor compounds extended the setting reaction. For example, when α-TCP particles were first heated to 500°C, it increased the final setting time from the order of several minutes to upward of a few hours [55]. Finally, it is common practice to add a nucleating agent such as nanosized HA to the powder component of the cements to reduce the setting time [26,51].

Injectability

CPCs have the potential to be injectable, which sets them apart from other bone substitute materials, especially for applications involving minimally invasive surgery, in which injectability is considered a prerequisite [29]. Although there has been much debate in the literature in terms of defining injectability [15], the overall fundamental consensus is that it can be defined as the ability of the CPC paste to be extruded through a syringe, usually with a 12-gauge (i.e., 2 mm in diameter) needle 10 cm long attached to the end, although other needle dimensions have been reported [56–58]. Generally, it is measured by calculating the weight percentage of the CPC paste that can be extruded from the syringe either manually by hand or with the aid of a mechanical bench in which a force of no more than 100 N is applied [15,59].

To understand the injectability of these cements better, one must take into account the flow dynamics of the paste within the syringe. Because CPCs are composed of a powder and liquid phase, they are considered to be a biphasic material. When this biphasic material is subjected to a pressure gradient, as is the case during extrusion through a syringe, the liquid phase has a tendency to flow faster than the powder phase, which can result in local changes of the final cement composition. More specifically, because of the pressure gradient present in the syringe, the paste located closest to the plunger of the syringe is subjected to a higher pressure than the paste farther from the plunger. This higher pressure forces the liquid to flow faster than the CaP particles to the point where the paste in this region becomes depleted of liquid and all that is left is a wet powder instead of a paste [15,56,58]. The opposite effect occurs for the paste in the region farthest from the plunger, where the pressure is lower and the paste is saturated by liquid. Because these effects are dynamic, the size of the region that is depleted of liquid grows and enlarges during injection to the point where this wet powder zone eventually reaches the tip of the syringe and plugs it, rendering the remaining material noninjectable. This phenomenon, in which a phase separation occurs once pressure is applied to the paste, is commonly referred to as filter pressing [15]. As a result of the phase separation, the final composition of the extruded paste becomes compromised and not fully controllable. This is caused by the change in the LPR that takes place, which can influence the setting behavior, mechanical properties, and biological performance of the final cement product. Hence, good cohesion of the paste is of utmost importance to avoid problems associated with filter pressing [60].

Strategies to Improve Injectability

As mentioned previously, an important advantage of CPCs is their ability to be injected for use in minimally invasive surgical techniques, although this ability can become compromised when filter pressing occurs [54,56,57]. In fact, in some cases complete injectability cannot be attained even when relatively large-diameter syringe tips without a cannula are used. This implies that filter pressing can occur even under very small loading forces [11]. Thus, there is a need to develop strategies to improve the injectability of the cements. Strategies involving the addition and/or modification of certain variables have been shown to be successful for improving the injectable properties of CPCs. These variables include modifying the particle size and shape [56], the viscosity and rheology of the paste [54,57,61–64], and the LPR [15,57,65].

Particle Size and Shape

With respect to the particle size, it has been shown that the smaller the particle size, the greater the injectability [56,65]. For the particle shape, powders with a more spherical shape have been known to exhibit better injectability because the particles roll more easily and produce less shear resistance when they are extruded from the syringe. Interestingly, more spherical powders also require less liquid phase to turn into a slurry or paste, because no liquid becomes captured between the particles and therefore the liquid can be used more efficiently to wet the particles fully [11,15].

Viscosity

It is well-known that the ability of the cements to be injected is highly constrained owing to the rheological properties of the paste during extrusion. Reducing filter pressing or eliminating it from occurring by modifying the viscosity of the paste is one possible solution to improving injectability properties. One approach would be to reduce the ability of the liquid phase to pass through the powder phase. This could be achieved by increasing the viscosity of the liquid phase or by reducing the permeability of the powder phase [54,56,57,61–63]. The viscosity of the liquid phase can be modified by using additives. These additives must be nontoxic and not inhibit the phase transformation that takes place during the cement setting reaction [11].

In principle, the use of additives in the liquid phase can increase the viscosity by several orders of magnitude, resulting in the formation of a more putty-like paste. Furthermore, they can improve wettability and increase the surface charge of the CaP particles owing to the adsorption of ions on the surface [64]. Studies have shown that the addition of organic additives, such as citric acid, increased injectability by delaying the hydration time [11,66]. Furthermore, citric acid is a favorable additive for use in CPCs because it is present as citrate ions in bone and is a triprotic acid, which means that it can release or donate three hydrogen ions. This is advantageous in the sense that these citrate ions can be adsorbed onto the surface of CaP particles and give them a negative charge, and by doing so it can create a repulsion between the negatively charged particles. This repulsion enhances the mobility of the particles, increasing the injectability of the paste, because the formation of any particle agglomerations is eliminated [61]. The behavior of CPCs also depends on the type of acid additive used. For example, it was observed that the use of acetic acid, a monoprotic acid, resulted in an increase in the rate of apatite formation, which made the cement less injectable. Conversely, when citric acid was employed, the CPC became more macroporous and easier to inject, although the rate of apatite formation was reduced [59].

Another additive that was shown to improve the injectability as well as cohesion of CPCs is hydroxypropyl methyl cellulose (HPMC). HPMC, a polysaccharide gelling agent, has the ability to hydrogenate in water, forming a viscous solution in the process. This increase in viscosity improves the cohesion of the paste and makes it easier to extrude out of a syringe under minimal force with no occurrence of filter pressing [66,67]. In another study, researchers added xanthan, a type of polysaccharide, to the cement formulation to exert a lubricating effect on the interface of the CaP particles, which improved injectability [56].

Yet another technique decreases the viscosity to improve injectability. One way to achieve this is to increase the amount of liquid phase used. The idea behind this is that as more liquid phase is used, the viscosity becomes lower and the friction between the CaP particles as well as the cement paste between the syringe walls is reduced. This would make the cement easier to inject, although issues such as filter pressing are likely to occur [64,68].

Finally, the viscosity of CPCs is a constantly changing property because it is related to the setting mechanism. Traditionally, the viscosity decreases immediately after mixing the liquid and powder phases together, followed by a strong increase during the setting of the cement until hardening occurs. The viscosity needs to be at a high enough value to where extravasation of the liquid from the powder can be prevented. This can be accomplished if the viscosity falls between 100 and 1000 Pa s^{-1} and an appropriate window for injection is defined [11].

Liquid-to-Powder Ratio

Any adjustment to the LPR can have a significant influence on not only the injectability but also the setting time, porosity, cohesion, resorbability, and strength [68]. For example, high LPRs are known to increase the injectability of cements by reducing the friction between CaP particles and the syringe wall during extrusion, but this additional liquid can delay the setting time, result in poor cohesion [69], and reduce the mechanical integrity of the cement because the higher liquid content leaves behind a greater microporous structure upon dilution [11,56]. Studies have shown how the injectability of CPC formulations with LPRs between 3.85 and 4.50 g/mL have been relatively unaffected, but once this range increases to 4.50–5.00 g/mL the degree of injectability drops by nearly 100% [64]. Consequently, it seems that only major shifts in the general properties of CPCs occur once a certain LPR threshold is met.

Cohesion

Besides injectability, CPCs need to possess adequate rheological properties such as viscosity and cohesion to be employed successfully for clinical applications [15,70]. In this instance, cohesion is defined as the ability of a cement paste to keep its geometrical integrity during setting in an aqueous environment [15,26]. It can be measured by evaluating the amount of solid particles that are released from the paste under aqueous conditions, typically water or Ringer's solution before setting fully [71]. The level of cohesion is directly correlated to the degree of affinity among CaP particles within the cement, where stronger cohesive properties can result from an increase in attractive van der Waal forces and/or a decrease in repulsive electrostatic forces among the CaP particles [15]. The ideal cohesion of CPCs occurs when no disintegration of CaP particles can be observed while immersed in an aqueous environment for a period of time exceeding the final setting time of the cement [49,60]. This level of cohesion can be achieved by maintaining a high level of viscosity for the cement paste, usually through the use of gel-forming polymers or other cohesion promoters such as sodium alginate and carboxymethyl cellulose [71,72].

In the past, poor cohesive properties were associated with poor biocompatibility and negative in vivo reactions, such as inflammation triggered by the leaching and release of CaP microparticles in and around the implant site [37]. It was argued that CPCs could be considered a prime candidate for the use in vertebroplasty spinal surgery, provided that excellent cohesion of the CPC could be achieved and maintained [32]. Poor cohesive properties of CPCs used for vertebroplasty can lead to an increased risk for blood clotting. It was suggested that blood clotting is triggered by interfacial interactions between blood and CaP microparticles that fragmented off the cement and leached into the bloodstream. Coupled with the fact that vertebrae are highly perfused with blood and positioned in close proximity to the heart and lungs, this compounds the problem and exposes the patient to potentially life-threatening complications. Therefore, it is of utmost importance to maintain a high level of cohesion for CPCs to prevent the release of CaP particles and avoid in vivo complications [26].

Strategies to Improve Cohesion

The level of cohesion is directly associated with the interaction among CaP particles within the cement. Bearing that in mind, common approaches to improving cohesion are focused on reducing the mean particle size and liquid content, thus improving the van der Waal attractive forces and decreasing electrostatic repulsive forces among the CaP particles [60]. CPC pastes are considered to be non-Newtonian fluids, which means that their viscosity is a function of shear forces and time [65,70]. This poses a challenge to researchers to be able to maintain and control the viscosity, and therefore the cohesion, of the cements. However, some success has been achieved through the strategy of increasing the viscosity of the liquid phase by incorporating water-soluble polymeric hydrogels into the formulation [60,67].

Most notably, polysaccharides [32,53,67,71,72] polyacrylic acid [29], and gelatin [69] are among the most common hydrogels used owing to their biocompatibility and favorable rheological properties. Moreover, only small amounts of these polymers, on the order of just a few weight percent, need to be added to CPCs to improve their viscosity and cohesion significantly, which makes them less susceptible to washout effects [29]. In some instances, it has been shown that adding certain types of these water-soluble polymers can prolong the setting time of CPCs. To address this issue, sodium phosphate aqueous solutions have been used as the liquid phase to act as a catalyst in the setting time [73]. Other water-soluble polymers, such as sodium alginate, exhibit the unique ability to pectize (i.e., form into a jelly or gel-like substance) when placed in contact with calcium ions. This enables putty-like pastes to be fabricated, although only a few polymers displaying this unique property have been accepted for parenteral use [14,40]. Regardless, the addition of water-soluble polymers has been shown to be a promising technique to improve the viscosity and cohesion of CPCs so that the spectrum of their clinical applications can widen.

STRATEGIES TO IMPROVE THE MECHANICAL PROPERTIES

The development of CPCs has progressed significantly with respect to the optimization of their physiochemical, handling, and biological properties. Nevertheless, CPCs exhibit poor mechanical properties, because their tensile and shear strength is lower than that of teeth and bone [43]. Coupled with their inherent brittle behavior, this has limited their clinical applicability to non−load bearing or pure compression-loading sites [74,75].

The compressive strength of CPCs is the most commonly reported mechanical property in the literature, although this property offers minimal insight into the mechanical integrity and reliability of the CPC [15]. Generally, brittle materials are more likely to fail under tension or shearing rather than compression. This phenomenon is attributed

to the fact that fracturing of brittle ceramics such as CPCs initiates in preexisting flaws such as microcracks or macropores located throughout the cement matrix. It is easier to propagate a crack in tension rather than in compression [76]. Furthermore, loads within the body are generally cyclic, which indicates that fatigue properties should be reported as well [15,77]. Moreover, it is difficult to compare compressive strengths of CPCs with those of trabecular bone because bone is typically much less brittle than bioceramic cements. Therefore, it is highly recommended that the mechanical properties of CPCs be reported as more appropriate parameters such as the Weibull modulus to make a more comparative analysis between bone tissue and cement [77]. Another factor that should be taken into account regarding the mechanical properties of CPCs is that their mechanical performance in vivo may vary considerably from in vitro measurements under laboratory conditions. For example, brushite cements are highly soluble under physiological conditions compared with apatite cements, so their mechanical properties will decrease rapidly upon implantation. This sudden and spontaneous dissolution is also why brushite cements are typically combined with less soluble materials, e.g., HA or β-TCP, thus creating a biphasic CPC [15]. Based on these shortcomings, it is clear why CPCs are restricted to non−load bearing applications.

An improvement in the mechanical performance of CPCs would broaden their applicability in the operating theater to more load-bearing defect sites, e.g., spinal surgical procedures such as vertebroplasty and kyphoplasty [75,78]. To this end, the brittleness of the cements would need to be reduced along with an improvement in their fracture toughness. This toughening can be achieved by reducing the porosity of the cement matrix or combining CPCs with a polymer matrix to form a composite material [79]. Generally, these polymers are incorporated into the cement by modifying the liquid phase with polymeric additives [78] in the form of fibers [75], or by using a dual setting system in which dissolved monomers simultaneously cross-link during the cement setting reaction [80,81], as depicted in Fig. 34.4. More common formulations of various CPC−polymer composite materials have been comprehensively reviewed elsewhere [11,74].

Porosity

The mechanical strength of CPCs is directly related to their microstructural characteristics. The physical entanglement of crystals that precipitate during the setting reaction, as described earlier, results in the formation of a bulk cement matrix that determines its mechanical integrity. Several factors can affect the outcome of the cement matrix, such as the final setting products (i.e., apatite or brushite), the degree of phase transformation, the crystal size, and the porosity; with the latter being one of the most important factors. The porosity of CPCs mainly originates from the presence of an excess amount of liquid phase that has not fully reacted with the CaP particles. When this is the case, this excess liquid leaves behind open voids or pores within the entangled cement crystal matrix [78]. Generally, these pores can range from a few nanometers to upward of 8−12 μm in diameter and consume between 22% and 55% of the total cement volume [82,83]. The presence of these pores makes it much easier for microcracks to propagate throughout the cement matrix, increasing the cement porosity and decreasing the mechanical properties [29], as shown in the inverse exponential relationship [84]:

$$CS = CS_0 \exp(-KP) \tag{34.3}$$

where CS is the compressive strength of the cement at a set porosity, CS_0 is the maximum theoretical strength, K is a constant, and P is the porosity [84]. Therefore, the mechanical properties of cements can be improved by decreasing

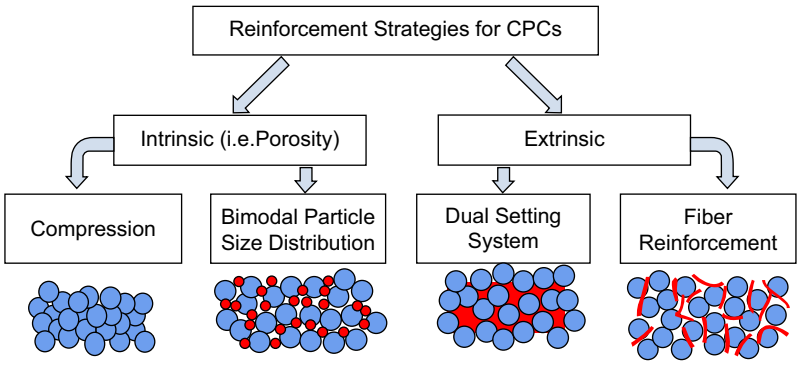

FIGURE 34.4 Mechanical reinforcement strategies for calcium phosphate cements used in load-bearing applications [78].

the matrix porosity [26]. As a rule of thumb, the tensile strength of CPCs seems to increase two-fold with every 10 vol% decrease in porosity. For example, tensile strength values of 5, 10, and 20 MPa would correlate to porosity values of 60%, 50%, and 40%, respectively [14,40]. Consequently, one method to achieve this reduction in porosity is to apply pressure to compact the CaP particles [73,84,85]. In some cases, this method has been shown to reduce the porosity from 50% to 31%, which resulted in an increase in compressive strength by almost one order of magnitude, but this method is typically unsuitable for most clinical applications [84].

Because porosity is directly attributed to the amount of liquid phase used, a more common approach to reducing it is to increase the LPR by reducing the amount of liquid phase added to the cement [14,40]. When this happens, the space between the CaP particles is reduced, enabling a more compact crystal structure to form, as illustrated in Fig. 34.5 [52]. The influence of the LPR on porosity explains why the porosity of apatite cements is usually different from that of brushite cements. The general trend is that for brushite cements the average pore size is larger than for apatite cements, but the total porosity is usually smaller than for apatite cements. This is because brushite cements have an increased water consumption during the setting reaction that also forms larger crystal sizes, which makes the average pore size greater but the total porosity smaller than apatite cements [78].

Although a reduction in the liquid content leads to a decrease in porosity, this approach is limited because all CPC formulations require a minimum amount of liquid to wet all of the CaP particles fully and create a paste [56]. Moreover, a large reduction in the liquid phase can have a negative effect on the rheological properties of the paste, such as increasing the viscosity to the point where the paste becomes noninjectable [29].

Therefore, another effective strategy for reducing the porosity of the cements is to minimize spacing between the CaP particles. This can be achieved by using a two-pronged approach: (1) create a bimodal CaP particle size distribution to fill the space among particles; and (2) create a high surface charge, or ζ-potential, on the particles. By using a bimodal particle size distribution, the smaller particles are able to occupy the space normally occupied by any

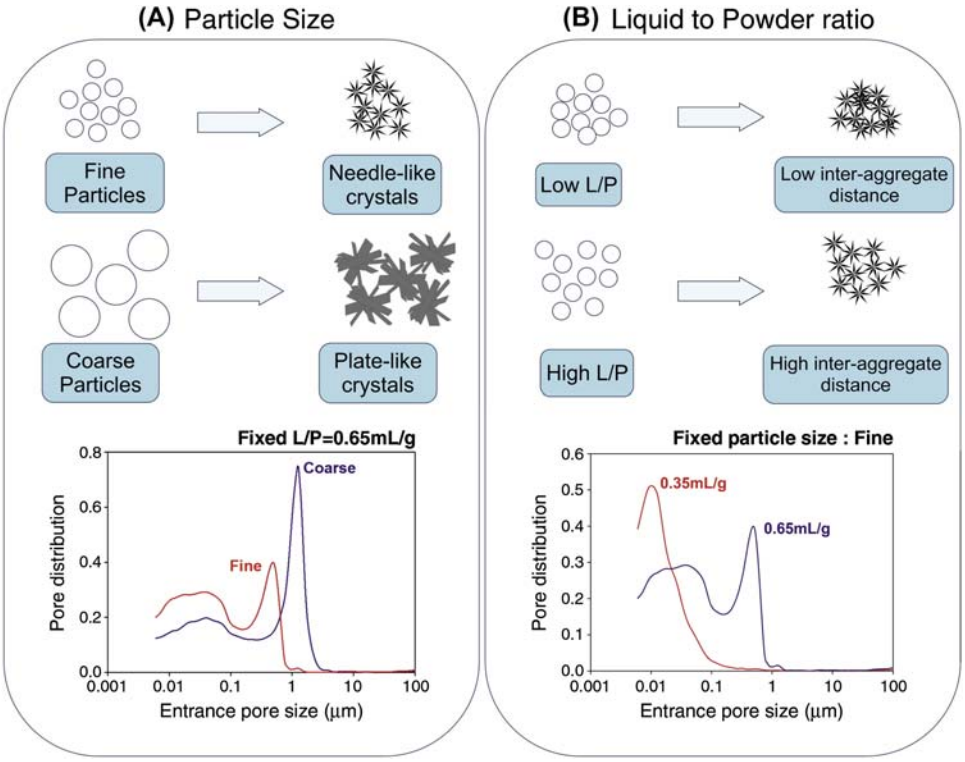

FIGURE 34.5 Schematic depiction of how the (A) particle size of the powder phase and (B) the liquid-to-powder ratio (LPR) influences the microstructure and porosity of calcium phosphate cement (CPCs). A reduction in calcium phosphate (CaP) particle size increases the particle surface area, which means a higher degree of supersaturation can be achieved that favors crystal nucleation. This leads to more frequent and smaller needle-like crystals to form instead of larger plate-like crystals that typically form when larger CaP particles are used, effectively changing the microstructure and porosity of the cement. Modifying the LPR can also fine-tune the microstructure and porosity of CPCs. Lowering the LPR reduces the spacing among CaP particles, leading to a more compact and dense crystal microstructure. The opposite effect can be seen by increasing the LPR. *Reprinted with permission from Ginebra M-P, Canal C, Espanol M, Pastorino D, Montufar EB. Calcium phosphate cements as drug delivery materials. Adv Drug Deliv Rev 2012;64(12):1090–1110.*

excess liquid, thus reducing the porosity for both apatite [86] and brushite cements [82,83]. Adding a high surface charge by increasing the ζ-potential on the CaP particles is thought to aid in dispersing and breaking up any particle agglomerates by reducing their attractive forces. This can be achieved by adding charged ions such as tartrates or citrates to the liquid phase of CPC formulations. These charged ions are then able to adsorb to the particle surface, effectively increasing the ζ-potential and removing particle agglomerations, leaving behind a more evenly dispersed particle network that exhibits smaller particle spacing [87]. Applying these two principles has been shown to increase the plastic limit (i.e., reduce the need to use more liquid) and reduce the porosity for both apatite and brushite cements. For apatite cements, a reduction in the porosity from 37% to 25% with an increase in the compressive strength from 50 to 79 MPa has been reported [86], and for brushite cements, a reduction in porosity from 30% to 23% resulted in an improvement in compressive strength from 23 to 42 MPa [82].

Finally, although a reduction in porosity leads to an improvement in the mechanical properties of CPCs, this change in the microstructure can have negative implications on the bioresorbability and osteotransductive properties of the cement. For example, the lack of an interconnected porous structure inhibits the growth of newly formed bone into the cement. This means that new bone formation would be dictated by the passive dissolution rate of the cements, resulting in a reduction in the rate of new bone formation. Therefore, it is important to understand and take into account how porosity may affect other properties of the cement, especially with respect to the biodegradability [14,40].

Dual Setting System

Another approach to increasing the mechanical strength of CPCs involves using a dual setting system. An example of this strategy involves adding polymeric components to the cement that can be cross-linked by binding Ca^{2+} ions with carboxylic acid or organic phosphate moieties within the polymer chain. The addition of the liquid phase then initiates the dual setting reaction composed of (1) the traditional dissolution-precipitation reaction of the bioceramic cement component, and (2) deprotonation of the acid groups of the polymer to induce the formation of intrachained or interchained Ca^{2+}-acid cross-links. The result of this process is a reduction in brittleness and an increase in the strength of the cement [88].

Another example of the dual setting system involves using reactive monomer units that are added to the cement formulation by first dissolving them in the liquid phase. An initiator is then added to the solid phase of the cement so that once the two phases are mixed, a simultaneous reaction is initiated that involves the traditional dissolution-precipitation setting reaction of the CaP particles and a gelation-polymerization reaction of the monomer units [78]. Within the first several minutes, a hydrogel matrix with embedded CaP particles is formed, followed by a phase transformation of the CaP particles that takes place during the setting reaction of the cement. Finally, a highly interconnected, reinforcing hydrogel matrix is formed that is located within the porous cement microstructure, as depicted in Fig. 34.6. This approach enables the possibility of adding a high amount of polymer to the cement, which translates to a potentially significant increase in its strength and toughness. Furthermore, the rheological properties of the cement paste can remain relatively stable. Both of these characteristics are attributed to the fact that the

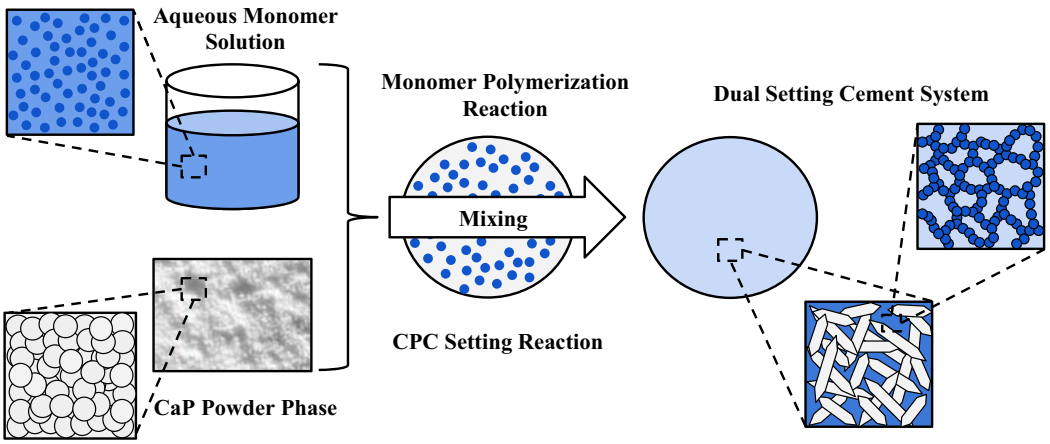

FIGURE 34.6 Schematic diagram depicting the setting mechanism of dual-setting calcium phosphate cements (CPCs) with the formation of interconnected matrices of hydrogel and precipitated calcium phosphate (CaP) crystals [78].

monomer units are small, water-miscible liquids that exhibit low viscosity such that even high concentrations of the monomers do not alter the initial viscosity of the cement [78]. Further studies regarding this concept can be found elsewhere [80,81,89].

A dual setting system can also be applied when using pure inorganic materials such as silica. Studies describing different approaches to adding silica to the cement, along with its influence on CPCs setting, handling, and mechanical properties can be found elsewhere [78,90,91].

Fiber Reinforcement

Toughening of brittle cements by using fibers has proven to be one of the most successful approaches, particularly when using long continuous fibers as a reinforcing matrix [32,75,79,92]. The mechanical performance of these fiber-reinforced CPCs depends on the complex interaction among all of the components of the composite cement [79]. The mechanical properties are also time-dependent because both the fibers and the cement matrix have the potential to degrade once they are implanted in the body to allow for tissue regeneration. These components are illustrated in Fig. 34.7, in which contributions to the mechanical behavior of the cement are associated with the strength and stiffness of the fibers and cement matrix, the toughness of the matrix, interfacial interactions between the matrix and fibers, and supplementary effects of the polymeric additives or agglomerations [79]. Excellent reviews detailing how various fiber parameters (i.e., type, volume fraction, orientation, aspect ratio, tensile modulus, and fiber–matrix interface properties) can influence the mechanical properties of CPCs can be read elsewhere [75,76,78,79].

Mechanics of Fiber-Reinforced Calcium Phosphate Cements

The concept of improving the mechanical performance of CPCs by producing fiber–cement composites was initially adopted from the field of materials engineering, where, for instance, the development of fiber-reinforced hydraulic cements and concretes for civil and industrial engineering purposes has been studied extensively. For these applications, the incorporation of fibers into the cement has been a highly effective strategy to improve fracture toughness as well as flexural and tensile strength [76].

To understand better how fibers can improve the mechanical properties of CPCs, the failure pattern of fiber-free CPCs must first be understood. Like most ceramics, CPCs are brittle materials, which means that their failure is characterized by a sudden, catastrophic fracture with minimal plastic deformation occurring before the failure point. Therefore, fracture deformation and the work needed to induce failure are relatively low. From an engineering

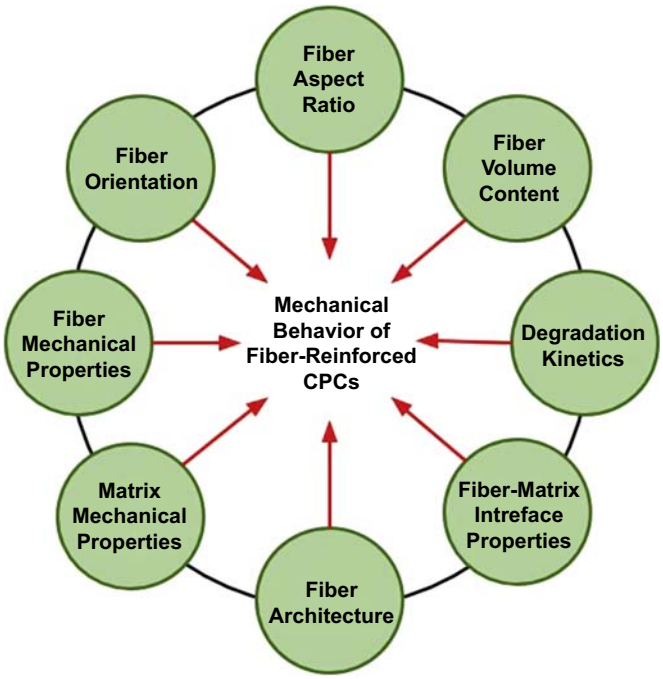

FIGURE 34.7 Illustration of the components for fiber-reinforced calcium phosphate cements (CPCs) that influence their mechanical performance [79].

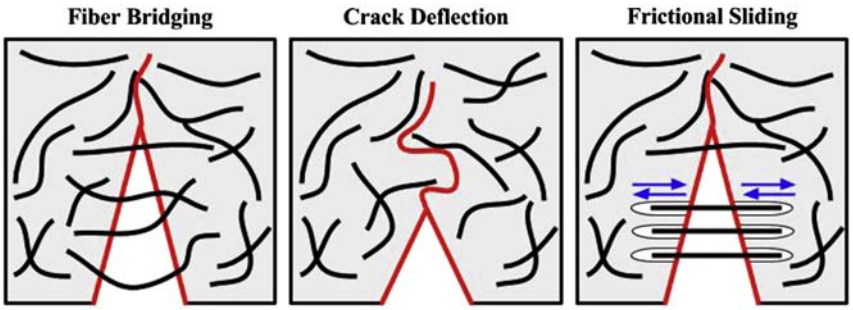

FIGURE 34.8 Schematic drawing of the three mechanisms of how fibers can mechanically reinforce cements [76].

standpoint, this brittle behavior is detrimental for mechanically loaded materials and therefore must be compensated for, in this case by incorporating fibers. The reinforcement effect of fibers in CPCs creates a tougher, more ductile cement that is more suitable for load-bearing applications because they will exhibit a higher tolerance to impact loading and sample flaws [79].

There are three main mechanisms according to how a fiber can mechanically reinforce a cement: fiber bridging, crack deflection, and frictional sliding (Fig. 34.8). In fiber bridging, fibers that bridge crack together within the matrix, thus effectively dissipating the fracture energy and delaying any further opening and propagation [79]. For crack deflection, fibers act as barriers that extend the path distance at which the crack needs to travel through the matrix. It has also been reported that these two mechanisms contribute to the high fracture toughness of human bone [93]. Frictional sliding consists of frictional sliding occurring at the fiber−matrix interface when fibers begin to pull out of the cement. This mechanism leads to a stress transfer that ultimately results in increased energy dissipation and fracture toughness of fiber-reinforced CPCs [76].

The load-bearing capacity of fibers increases with an increase in the elastic modulus as well as tensile strength. The diameter of the fibers dictates the total interface area for a given fiber volume fraction, which affects both the homogeneity and workability of the composite. Furthermore, the fiber length to diameter ratio, known as the aspect ratio, is greatly important because loading of the composite needs to be transferred from the matrix to the fibers via the interface. A reinforcing effect is observed only when the fiber length exceeds a critical value, l_c [94]. Extensive research from civil engineering revealed that the optimum fiber content to reinforce cementitious materials is typically less than 5 vol%, whereas the fiber content for fiber-reinforced CPCs is usually one order of magnitude higher. This higher fiber content is partially attributed to the fact that only a moderate load transfer has been achieved for fiber-reinforced CPCs because the interface strength has not yet been optimized for bioceramic cements [92].

Finally, because mechanical testing of CPCs is not strictly regulated, caution must be exercised when comparing mechanical values from different studies, because many variables during sample preparation and testing can strongly influence the final results [78]. For example, the strength of dried samples is typically superior to that of hydrated samples, because excess water acts as a lubricant within the entangled crystal network structure of the cement. Moreover, the macroporosity and microporosity of the cement can also be heavily influenced during sample preparation, in which any precompacting of the paste would result in a denser, less porous sample that would exhibit higher strength values compared with uncompacted samples [71,85].

CLINICAL APPLICATIONS

Oral, Maxillofacial, and Craniofacial Applications

CPC was first approved for human use by the US Food and Drug Administration in 1996. Since then, the number of CPC products and clinical indications has increased considerably, most notably in the oral, maxillofacial, and craniofacial fields [17]. CPCs are increasingly used in these fields because the CPC is stressed only moderately in these applications. Furthermore, the excellent handling properties of the CPC provide the ability to mold the material, which is highly advantageous from a surgeon's perspective. These cements have been used to repair neurosurgical burr holes, contiguous craniotomy cuts, and other cranial defects. They have also been indicated for use in sinus augmentation procedures and orbital reconstruction surgery [27,95]. Further information outlining CPCs use for oral, maxillofacial, and craniofacial applications can be found elsewhere [29].

Dental Applications

Clinical use of CPCs for dental and intraoral applications has been relatively lacking compared with their use in other fields such as craniomaxillofacial and orthopedic indications. However, research has indicated that CPCs can be highly beneficial in a number of dental and intraoral procedures. To understand better the potential of CPCs to stimulate new bone formation for dental applications, a group of researchers conducted a study in which they implanted prefabricated CPC blocks into the alveolar bone of dogs. They started by extracting all of the mandibular premolar teeth; then they waited 1 month for the alveolar bone to reduce in size to make room to implant 8-mm CPC preset blocks. Over the course of 1 month the researchers observed that the CPC block was slowly being replaced by bone. Histopathologic images further proved that the implant site exhibited features similar to those of natural bone. In addition, it was observed that the coronal half of the implanted CPC was firmly attached to the natural bone [96]. In another study, a CPC was injected into artificially created periodontal defect sites, where it was observed that the cement acted as a scaffold for new bone growth and promoted healing of the periodontal tissue [97]. CPCs have also been indicated for use in direct pulp capping, where investigators compared a self-setting CPC with that of calcium hydroxide. It was concluded that both materials were successful in producing secondary dentin after 24 weeks [98]. Finally, other studies have shown promising results for the use of CPC in restoring enamel carious cavities, for fillings in root canal procedures, for alveolar ridge augmentation, as sinus lifts, for repair of the cleft palate, and as supportive agents for dental implants [17,29]. It has been proven over the years that CPCs can exhibit superior results in these dental applications owing to their excellent osteoconductivity, unique self-hardening properties, excellent affinity to bone defect surfaces, and gradual resorption and replacement by new bone [17].

Orthopedic Applications

CPCs are predominantly used for orthopedic applications because of their distinctive handling and biological properties. The cements have been applied to a wide range of clinical procedures including: hip fractures, tibial plateau fractures, fixation of bone screws and titanium implants, vertebral body fillings and augmentation of osteoporotic-induced vertebral bodies, and distal radius fractures [36,99].

Vertebroplasty and Kyphoplasty

Two orthopedic procedures, vertebroplasty and kyphoplasty, have become increasingly popular areas in which CPCs have been employed. These procedures aim to treat osteoporosis-induced vertebral compression fractures by augmenting, stabilizing, and restoring weakened vertebra to their normal functional state and height as best as possible [100]. Vertebroplasty involves the direct injection of CPC into the fractured vertebral body, whereas an inflatable balloon tamp is used for kyphoplasty to create a cavity in the vertebral body into which CPC can then be injected to fill the cavity. Results from both procedures have shown promising results with respect to faster healing times of the vertebral body [32].

The type of CPC, and thus its properties, have a crucial role in the overall outcome and success of the procedures. For example, the CPCs must exhibit some key desirable properties such as easy injectability, excellent cohesion to prevent possible leaching of CaP particles into the bloodstream where blood clotting could be triggered, high radiopacity, mechanical properties similar to healthy vertebral bone, and a resorption rate that is comparable to normal bone remodeling times [31]. Owing to these demands, only a few CPC formulations have been allowed for clinical use in this field, and even these formulations are not necessarily considered ideal. For example, several major topics of interest still need to be investigated in more detail to optimize and tailor CPC formulations for future use. In particular, understanding the quasi-static compressive strength and fatigue performance of CPC formulations is highly interesting, especially when considering the in vivo life expectancy of the cement [32]. Overall, it has been demonstrated that the use of CPCs for vertebral bone compression fractures has substantial clinical benefits to the point where this treatment method is on the rise and is growing in popularity [11].

CONCLUSION

The rapid development of CPCs confirms that it exhibits unique characteristics that render these types of bioceramics highly suitable as a bone substitute material. CPCs are formed in a simple procedure by combining a CaP powder phase with a liquid phase to form a cementitious paste at body temperature. This paste undergoes a phase transformation at which it eventually hardens in vivo into a material that shares a composition similar to

the inorganic component found in natural bone. This self-setting capability allows for CPCs to be injectable so that they can be used in minimally invasive surgical techniques; they are also moldable so that they can adapt and fit into irregularly shaped bone defect sites. Their chemical similarity to natural bone gives them excellent osteotransductive properties. The setting times as well as cohesiveness and injectability of CPCs have improved considerably, indicating that CPCs have a promising future in the field of bone regeneration. However, the perfect bone grafting material does not yet exist, and CPCs have much room for improvement and development. In particular, CPCs are still regarded as an inadequate material for use in load-bearing sites, which severely restricts their clinical applicability. Nevertheless, many CPC products have become commercially available that are suitable for several applications, particularly in dental, maxillofacial, and craniofacial surgeries. It is anticipated that a better understanding of the fracture mechanics of CPCs will lead to an improvement in their mechanical properties, which would significantly expand their clinical relevance.

List of Acronyms and Abbreviations

ACP Amorphous calcium phosphate
CaP Calcium phosphate

α-TCP α-Tricalcium phosphate
β-TCP β-Tricalcium phosphate

Glossary

Cohesion The ability of a cement paste to keep its geometrical integrity during setting in an aqueous environment
Injectability The ability of the CPC paste to be extruded through a syringe, usually with a 12-gauge (i.e., 2 mm in diameter) needle 10 cm long attached to the end
Osteoconduction The ability to have bone tissue grow on a material's surface
Osteotransduction The ability of a material to be resorbed and replaced by new bone tissue
Stoichiometric The quantitative relationship between reactants and products within a chemical reaction

Biologic Scaffolds Composed of Extracellular Matrix for Regenerative Medicine

Michelle Scarritt, Mark Murdock, Stephen F. Badylak

University of Pittsburgh, Pittsburgh, PA, United States

INTRODUCTION

The goal of regenerative medicine is to rebuild or replace damaged tissues and enable structural and functional restoration of the tissue. Many regenerative medicine strategies involve the use of scaffolds composed of synthetic polymers or biologic materials. The purposes of these scaffolds are to provide at least temporary mechanical support and to act as a temporal and spatial guide to promote cell attachment, migration, proliferation, and/or differentiation during the development of site-specific neotissues. Synthetic scaffold materials have a known chemistry that permits controlled chemical and structural modification such that they can be manufactured to almost any physical and mechanical specifications. However, synthetic materials invariably elicit a proinflammatory host response and occasionally can elicit a foreign body response. Bioscaffolds composed of extracellular matrices (ECM) as well as those composed of purified individual components of ECM (such as collagen) have also been used as surgical mesh materials. Numerous biologic scaffolds have been used in human clinical applications to treat a variety of tissue defects (Table 35.1). Biologic scaffolds are not as fine-tunable as synthetic scaffolds; however, biologic materials are typically more biocompatible and have inductive properties that can modulate cell behavior [1]. This chapter discusses the production and application of biologic scaffold materials for regenerative medicine applications with a focus on intact acellular ECM scaffolds.

EXTRACELLULAR MATRIX: FUNCTION AND COMPONENTS

ECM consists of a complex mixture of structural macromolecules and bioactive factors which not only act as scaffolding for cellular growth and motility, which gives shape to tissues, but as a bioactive, instructional environment that can regulate multiple facets of cell behavior including adhesion, migration, differentiation, proliferation, and even survival.

All multicellular organisms produce ECM although the composition can vary greatly between species. Plant ECM, for example, includes components of the cell wall, such as the polysaccharide cellulose. Chitosan, a biopolymer that has abundant commercial and biomedical applications, is derived from chitin, a nitrogenous polysaccharide that is a component of the exoskeleton of insects and crustaceans, the radulae of mollusks, the scales of fish and amphibians, and the beaks or shells of cephalopods [2]. Although these polysaccharides can be considered naturally occurring scaffold materials, they will not be discussed in this chapter. Here, the focus is on mammalian ECM, which is highly conserved among species and includes the basement membrane and the interstitial matrix between cells.

The basement membrane is a thin, fibrous, sheet-like matrix that underlies an epithelium, mesothelium, or endothelium. The interstitial matrix, on the other hand, is a gel consisting of proteins and polysaccharides that surround cells and act as a compression buffer. Resident cells produce and assemble the components of the ECM intracellularly and then secrete them into the extracellular space by exocytosis. Once secreted, these components assemble to

TABLE 35.1 Examples of Extracellular Matrix–Based Products

Product	Company	Material	Processing	Applications
AlloDerm™	LifeCell Corporation	Human dermis	Natural, dry sheet	Soft tissue repair
AlloMax™	Becton, Dickinson and Company	Human dermis	Natural, dry sheet	Soft tissue repair
AlloPatch®	Musculoskeletal Transplant Foundation	Human dermis	Natural, dry sheet	Tendon and soft tissue repair
ArthroFlex®	Arthrex	Human dermis	Preservon proprietary preservation process	Soft tissue repair
Axis™	Coloplast	Human dermis	Natural, dry sheet	Pelvic organ prolapse and stress urinary incontinence
AxoGuard®	AxoGen	Porcine SIS	Multilaminar sheets	Nerve repair
BellaDerm	MTF Biologics	Human dermis	Natural, dry sheet	Repair integumental tissue or soft tissue
Biodesign®	Cook Biotech	Porcine SIS	Natural, dry sheet	Dura mater repair
CorMatrix®	Cook Biotech	Porcine SIS	Natural, dry sheet	Cardiac tissue repair
DermACELL®	Stryker	Human dermis	Preservon proprietary preservation process	Soft tissue repair
DermaMatrix™	DePuy Synthes	Human dermis	Natural, dry sheet	Repair integumental tissue or soft tissue
DuraGuard	Baxter	Bovine pericardium	Cross-linked, hydrated sheet	Dura mater and soft tissue repair
DuraMatrix®	Stryker	Bovine dermis	Natural, dry sheet	Dura mater repair
FlexHD®	Ethicon	Human dermis	Natural, hydrated sheet	Soft tissue repair
Glyaderm®	Euro Skin Bank	Human dermis	Preserved in 85% glycerol	Dermal repair and plastic surgery
GraftJacket™	Wright Medical Group	Human dermis	Natural, dry sheet	Tendon and ligament repair
Integra HuMend™	Integra LifeSciences	Human dermis	Natural, dry sheet	Soft tissue reconstruction
Integra® Reinforcement Matrix	Integra LifeSciences	Porcine dermis	Natural, dry sheet	Soft tissue reconstruction and tendon repair
MIRODERM®	MiroMatrix Medical Inc	Porcine liver	Sheet cut from decellularized organ	Wound repair
MIROMESH®	MiroMatrix Medical Inc	Porcine liver	Sheet cut from decellularized organ	Soft tissue repair
OASIS® Wound Matrix	Smith & Nephew	Porcine SIS	Natural, dry sheet	Wound repair
Peri-Guard®	Baxter	Bovine pericardium	Cross-linked, dry sheet	Pericardial and soft tissue repair
PerioDerm™	MTF Biologics	Human dermis	Natural, dry sheet	Dental, integumental, and soft tissue repair
Permacol™	Medtronic	Porcine dermis	Cross-linked sheet	Soft tissue repair
PriMatrix®	Integra LifeSciences	Fetal bovine dermis	Natural, dry sheet	Wound repair
SurgiMend®	Integra LifeSciences	Fetal bovine dermis	Natural, dry sheet	Soft tissue repair
Suspend®	Coloplast	Human fascia lata	Natural, dry sheet	Prolapse and stress urinary incontinence

TABLE 35.1 Examples of Extracellular Matrix–Based Products—cont'd

Product	Company	Material	Processing	Applications
TissueMend®	Stryker	Fetal bovine dermis	Natural, dry sheet	Tendon repair
Vascu-Guard®	Synovis Surgical	Bovine pericardium	Cross-linked, hydrated sheet	Vascular reconstruction
Veritas™	Baxter	Bovine pericardium	Cross-linked, hydrated sheet	Soft tissue repair
Xenform™	Boston Scientific	Fetal bovine dermis	Natural, dry sheet	Soft tissue repair
XenMatrix™	Becton, Dickinson and Company	Porcine dermis	Natural, dry sheet	Soft tissue repair
Zimmer Collagen Repair Patch®	Zimmer Biomet	Porcine dermis	Cross-linked, hydrated sheet	Tendon repair

SIS, small intestinal submucosa.

form a fibrous mesh. The composition of ECM is tissue-specific, highly dynamic, and crucially important in organ and tissue development, homeostasis, and response to injury. Each component of the ECM participates in the continuous cross-talk between cells and their environment. This general mechanism is known as dynamic reciprocity and is capable of influencing gene expression [3] (Fig. 35.1).

The ECM consists of proteins, glycosaminoglycans (GAGs), glycoproteins, and small molecules that function individually and in conjunction to support and influence cell behavior. The main components are discussed in more detail subsequently; there are excellent textbooks and reviews that describe the ECM in depth [4].

Collagen

Collagen is the most abundant protein in the human body. Fittingly, it is also the most common biologic scaffold material. The main function of collagen is to give structural support to resident cells. The domain structure of collagen is unique: a triple helix consisting of three distinct α-chains called "tropocollagen" [5]. Proper three-dimensional (3D) folding requires a glycine residue in every third position of the individual α-chains with prolines and hydroxyprolines often flanking the glycines. The helical structure is further stabilized via hydrogen bonds between the chains such that the resulting structure is highly stable.

The compliance of a tissue containing collagen depends on the form and arrangement of collagens as well as the degree of mineralization [6]. Accordingly, the 28 types of collagen have been categorized into several structural classes including fibrillar (types I, II, III, V, and XI), fibril-associated collagens with interrupted triple helices (types IX, XII, XIV, XVI, and XIX), short-chain (types VIII and X), basement membrane (type IV), multiple triple helix domains with interruptions (types XV and XVIII), membrane-associated collagens with interrupted triple helices (types XIII

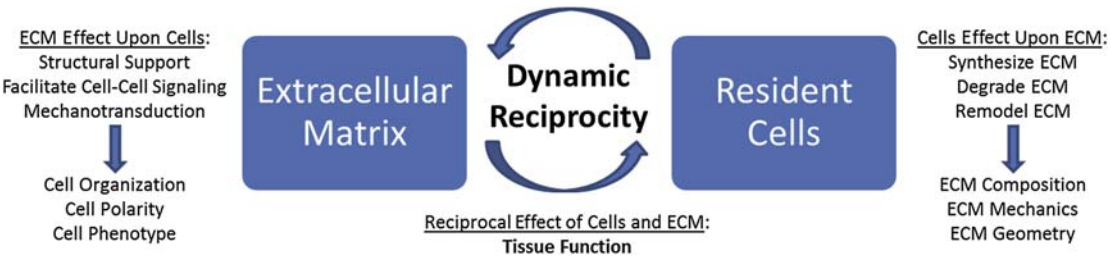

FIGURE 35.1 **ECM–cell interactions are a two-way street.** Although the ECM originates from the resident cells, the relationship between the ECM and cells is a feedback loop. Dynamic reciprocity, a mechanism whereby ECM could influence gene expression which in turn would modify and influence cell-secreted products, was proposed in 1982 by Mina Bissell [3a]. Multiple groups have since demonstrated that the ECM is able to affect cell signaling directly not only by acting as a reservoir for growth factors and other cell-secreted molecules, but also directly through mechanotransduction. Cells are constantly degrading, secreting, and remodeling their environment and thus dictate the composition, mechanics, and geometry of the ECM. In turn, the ECM is able to affect the morphology, polarity, and phenotype of cells, which ultimately affects cell and tissue function. *ECM*, extracellular matrix.

and XVII), and other (types VI and VII) [7]. Type I collagen accounts for over 90% of the collagen in the human body and is found in fibrous tissues such as skin and tendons. Fibroblasts are the most common cell type that produces collagen. In addition to its structural properties, collagen has inherent functional properties such as the stimulation or inhibition of angiogenesis and the promotion of cellular proliferation, differentiation, and attachment [8]. For these reasons, collagen is often used as a coating for cell culture vessels not only to promote cell attachment but also to influence cell phenotype.

As the main component of connective tissue, collagen is a highly conserved protein that is ubiquitous among mammalian species and accounts for approximately 25%–35% of all body proteins [9]. Inherent common amino acid sequences and epitope structures exist within collagen molecules across species [10,11]. These common antigens appear to account for the lack of an adverse immune response when xenogeneic collagen is used as an implantable scaffold material. Upon implantation, if left in its native ultrastructure, collagen implants are subjected to the fundamental biological processes of degradation and integration into adjacent host tissues. However, structural modifications such as chemical cross-linking may retard or prevent degradation and integration.

Collagen can be extracted from tissues such as tendons and ligaments, solubilized, and then reconstituted into fine strands that then can be fashioned to mimic body structures such as heart valves, blood vessels, and skin. Although collagen provides considerable mechanical strength in its natural state, the necessary mechanical and physical properties of tissue engineered products for cardiovascular and orthopedic use often require chemical manipulation of collagen-based materials. Extracted and reconstituted collagen is usually stabilized by chemical cross-linking methods and then terminally sterilized by irradiation or ethylene oxide treatment before clinical use. Chemical processing methods include glutaraldehyde treatment, carbodiimide treatment, dye-mediated photooxidation, exposure to polyepoxy compounds, and glycerol treatment. Most methods of chemical cross-linking increase the strength of collagen at the cost of decreasing the rate of in vivo degradation and negatively affecting cell attachment, proliferation, differentiation, and tissue remodeling. Exposure to chemical cross-linking agents can also change the biocompatibility of a collagen-based material, leading to a foreign body response.

Bovine and porcine type I collagen provide readily available sources of ECM scaffold material for numerous clinical applications. Isolated collagen and collagen scaffolds have been widely used in cosmetic surgery, bone grafts, artificial skin for burns, wound care, and multiple other reconstructive applications. Examples of collagen scaffolds include Contigen (Becton, Dickinson and Company, Franklin Lakes, NJ), CosmoDerm and CosmoPlast (Allergan, Inc., Santa Barbara, CA), CollaGUARD/Collieva and CollaRx (Innocoll, Inc., Ashburn, VA), Chondro-Gide (Geistlich Pharma AG, Wolhusen, Switzerland), and Menaflex (formerly Collagen Meniscal Implant [CMI]; ReGen Biologics, Inc., Franklin Lakes, NJ).

For these reasons, collagen has become a favorite substrate for many tissue engineering and regenerative medicine applications. The tissue and species source of collagen and its treatment before use are important considerations in the design of tissue engineered devices.

Fibronectin

There are two forms of fibronectin in animals: soluble plasma fibronectin and insoluble cellular fibronectin. The soluble form is produced by the hepatocytes of the liver and is a major component of blood. Deposition of plasma fibronectin at a wound site leads to the formation of a blood clot, which is critical to proper wound healing [12]. The insoluble form is a glycoprotein within the ECM. This form of fibronectin is secreted by cells, mainly fibroblasts, as a soluble protein dimer that is subsequently clustered with other fibronectins and arranged into an insoluble fibril matrix.

Fibronectin is a protein dimer consisting of two nearly identical approximately 250-kDa polypeptide chains linked by a pair of C-terminal disulfide bonds [13]. Each monomer consists of repeating units termed types I, II, and III [14]. Type I repeating units are approximately 40 amino acids long; they contain two disulfide bonds and appear 12 times in a single fibronectin. Type II units are approximately 60 amino acids long; they contain two disulfide bonds and appear twice in a fibronectin molecule. Type III units are 90 amino acids long; they contain no disulfide bonds and appear 15–17 times. The lack of disulfide bonds in type III units permits partial unfolding under applied force [15]. All three types form a β sandwich composed of two antiparallel β-sheets. Although a single gene encodes fibronectin, a number of splice variants exist, resulting in at least 20 variants in humans [16]. Splicing can occur within type III repeats, leading to "extra" units termed EIIIA (between repeats III_{11} and III_{12}) and EIIIB (between III_7 and III_8). Between III_{14} and III_{15} is a nonhomologous stretch of amino acids of variable length called the V-region, which represents another site for alternative splicing. This V-region can be partially or completely excluded, which subsequently leads to the exclusion of an integrin α4β1 binding domain. These repeating units

and splice variants are arranged into several functional domains that permit fibronectin to bind to collagen, heparin, chondroitin sulfate, heparan sulfate, fibrin, other fibronectins, and integrins α5β1, αvβ1, αvβ3, α5β6, α3β1, α8β1, αIIbβ3, and α4β1. Integrins are transmembrane receptors that facilitate cell−cell and cell−matrix interactions and can relay information to the cell about the composition and mechanics of the ECM. The sequence arginine-glycine-aspartate (known as the RGD sequence) is located within III_{10} and is the site for cell attachment via α5β1 and αVβ3 integrins. Thus, fibronectin is involved in cell adhesion, migration, differentiation, and growth.

Because of its cell-binding RGD sequence, recombinant fibronectin is often used to coat culture vessels to promote cell attachment and proliferation [17]. For these reasons, fibronectin has been conjugated to porous 3D poly(carbonate) urethane scaffolds for vascular tissue engineering and poly(D,L-lactide-*co*-glycolide) scaffolds for periodontal tissue engineering, among others [18,19]. One interesting preclinical study used modified fibronectin fragments to bind soluble growth factors and integrins simultaneously; injection of these growth factor−loaded fragments was able to improve wound healing and bone regeneration [20].

Laminin

Laminins are high−molecular weight, heterotrimeric proteins that are found in the basement membrane, specifically the basal laminae. Laminins contain an α-chain, a β-chain, and a γ-chain. There are five genetic variants of the α-chain, four of the β-chain, and three of the γ-chain. To date, 15 heterotrimers resulting from unique combinations of these chain variants have been identified in vivo, 12 of which were identified in mammals [21]. Unlike collagen, laminins do not form fibers. Instead, they self-assemble and self-bind to form independent mesh-like structures. Laminins also associate with nidogens and collagens via entactin, fibronectin, and perlecan. Through these intermolecular bonds, a network is formed that allows the basal lamina to resist tensile forces.

Heparan sulfates, β1 and β4 integrins, dystroglycan, and other surface receptors are able to bind directly to laminin moieties. The binding of laminin to these receptors and receptor-like proteins facilitates cell adhesion, migration, and differentiation [21].

With regard to the use of laminin as a biologic scaffold, laminins are a critical component of matrix materials generated from the basement membrane of tissues via decellularization, a topic that will be discussed later in the chapter. On their own, laminins have been used as a substrate for culturing cells in vitro. Two groups demonstrated that mouse embryonic stem cells can be grown on recombinant laminin-511 for long-term culture [22,23]. Human embryonic stem cells and induced pluripotent stem cells have also been grown with recombinant laminin 511 without the need for a feeder layer [24].

Elastin

As its name implies, elastin lends elasticity to tissues so that it can return to its original shape after stretching or contracting. Elastin is particularly prevalent in the ECM of the lungs, skin, ligaments, and blood vessels, where physiological forces result in intermittent stretching. Similar to fibronectin, elastin is synthesized from only one gene, but it can undergo extensive alternative splicing, resulting in tissue-specific elastin variants. Fibroblasts and smooth muscle cells secrete a soluble, nonglycosylated, hydrophobic form of elastin known as tropoelastin. These elastin precursors undergo posttranslational modification and are packaged inside chaperone molecules and secreted. In the extracellular space, tropoelastins covalently bind by patterning alternating hydrophobic and hydrophilic sequences to form a highly insoluble, cross-linked array, a process known as coacervation [25]. The tropoelastin coacervates are associated with microfibrils, particularly fibrillin-1, by the molecules fibulin-5 and fibulin-4 [26]. Lysyl oxidases cross-link the tropoelastins; after the formation of a multitude of cross-links between the tropoelastin monomers, the resulting elastin polymer becomes an insoluble fiber [27].

Electrospun recombinant human tropoelastin has been evaluated for use in wound healing [28]. Commercially, it is marketed as a product called Dermalastyl or Elastatropin for use in skin care to prevent wrinkles.

Glycosaminoglycans/Proteoglycans

GAG are long unbranched polysaccharides consisting of a repeating disaccharide unit. GAG are classified into four groups based on their core disaccharide: heparin/heparin sulfate, chondroitin sulfate/dermatan sulfate, keratan sulfate, and hyaluronic acid (HA). All GAG are synthesized in the Golgi apparatus except HA, which is synthesized at the cell membrane. Unlike protein or nucleic acid synthesis, GAG production is not template driven. GAG

are highly heterogeneous because they are subjected to dynamic modification by processing enzymes [29]. These modifications include sulfation and epimerization, which make GAG highly polar and allow them to attract water molecules and bind cations such as calcium, potassium, and sodium. Thus, GAG are able to act as a physiological lubricant or shock absorber.

One or more GAG covalently bonded to a protein are considered a proteoglycan. Proteoglycans are heavily glycosylated proteins. The protein core of the proteoglycan is synthesized in the rough endoplasmic reticulum and then posttranslationally modified with glycosylations in the Golgi apparatus. A tetrasaccharide bridge connects a GAG to a serine residue of a protein core.

Chondroitin sulfate is the most prevalent GAG. It is usually found as part of a proteoglycan, and its function largely depends on the protein to which it is attached. As part of a large aggregating proteoglycan, such as aggrecan, neurocan, versican, or brevican, chondroitin sulfate is critical to maintaining the structural integrity of a tissue. Aggrecan is a major component of cartilage in which chondroitin sulfate lends its highly charged sulfate groups to attract water and provide electrostatic repulsion to generate resistance to compression. Chondroitin can be extracted from the cartilage of cow and pig tissues for use as a biologic. Thus far, it has been investigated as a dietary supplement, drug, or injection in clinical trials to alleviate osteoarthritis; however, the symptomatic benefit is reported to be minimal [30].

Dermatan sulfate is distinguished from chondroitin sulfate by the presence of iduronic acid instead of glucuronic acid. Like chondroitin sulfate, dermatan sulfate is found in proteoglycans such as decorin, biglycan, and versican. Dermatan sulfate is mostly found in skin, but it is also present in tendons, blood vessels, heart valves, intestinal mucosa, and lungs, where it may have a role in coagulation, wound repair, response to infection, differentiation, morphogenesis, cell migration, carcinogenesis, and fibrosis [31]. Although the clinical application of dermatan sulfate is limited, companies such as Bioibérica (Barcelona, Spain) manufacture and sell it for potential use in enhancing wound repair or preventing coagulation.

Keratan sulfate is found in cornea, bone, nervous tissue, and cartilage, where it is part of proteoglycans such as lumican, mimecan, aggrecan, osteoadherin, keratocan, and fibromodulin. Like other GAG, it is highly hydrated and is able to absorb shock experienced by joints. Keratan sulfate has been demonstrated to be absent or aberrant in macular corneal dystrophy [32]; however, keratan sulfate has no widespread clinical uses.

Heparan sulfate is found in all animal tissues in various proteoglycan forms. Transmembrane heparan sulfate proteoglycans such as syndecans and glypicans are critical to cell signaling processes. Other proteoglycans are integral to the basement membrane, such as perlecan and agrin. Heparan sulfate can also be bound to a variety of extracellular proteins including collagen XVIII, growth factors, chemokines, cytokines, enzymes, and coagulation factors. Thus, heparan sulfate has a critical role in regulating developmental and biologic processes. Largely based on its ability to bind growth factors and cytokines, heparan sulfate and its mimics have been reported to promote wound repair and tissue regeneration [33,34].

Unlike other GAG, HA (also known as hyaluronan) is a polysaccharide that is not sulfated and is not found as a proteoglycan. HA is synthesized by integral membrane hyaluronan synthases that directly extrude it into the extracellular space [35]. HA is able to absorb significant amounts of water to act as a swelling force that permits tissues to resist compression. Thus, it is most commonly found in load-bearing joints and in the ECM of tissues such as skin, cartilage, connective tissue, epithelial tissue, and neural tissue [36,37]. HA is also found in nonanimal sources such as roots and tubers (potatoes and sweet potatoes) [38]. In addition to mechanical support, HA influences cell proliferation and migration. Moreover, HA facilitates these cellular functions during the late stages of wound healing and acts as a promoter of inflammation in the early stages [39]. HA has been extensively investigated as a natural scaffold material for tissue reconstruction. It has been used clinically in an injectable form for treatment of osteoarthritis of the knee, for cosmetic surgery as a dermal filler, and for ophthalmic surgery, among other applications. Examples of HA-based materials include Belotero (Merz Aesthetics, Raleigh, NC), JUVÉDERM (Allergan, Inc.), Hyalomatrix, Hyalofill, Hyalogran, Hyalosafe, and Elevess (Anika Therapeutics, Inc., Bedford, MA), and Restylane and Restylane Perlane (Q-Med Corporation, Fort Lauderdale, FL).

Matrix-Bound Nanovesicles

Matrix-bound vesicles (MBV) are a component of the ECM. They were first identified by Huleihel et al. as nanovesicles embedded within ECM scaffolds derived from porcine urinary bladder matrix (UBM), small intestinal submucosa (SIS), and dermis [40]. Like exosomes, MBV are nanosized, lipid membrane–bound vesicles with a size distribution from 10 to 200 nm. MBV were isolated from acellular porcine tissues by enzymatic digestion followed

by ultracentrifugation at increasing *g* values. MBV contain distinct profiles of microRNAs and proteins with some mutual cargo among the three ECM scaffolds evaluated. In vitro, MBV can recapitulate some of the regenerative effects observed when cells are treated with ECM, which highlights the potential of MBV as a key mechanism mediating the regenerative abilities of ECM scaffolds. For example, Huleihel et al. observed neurite outgrowth in neuroblastoma cells treated with MBV and activation of macrophages toward a phenotype associated with a more regenerative, anti-inflammatory, constructive remodeling response.

MBV may be useful for direct injection to a damaged site to encourage local anti-inflammatory and pro-remodeling pathways, or as an additive to enhance implanted scaffold performance. Identification of the variability and potential modification of MBV cargo will be critical to developing clinically relevant strategies with MBV.

INTACT AND SOLUBILIZED EXTRACELLULAR MATRIX AS A SCAFFOLD MATERIAL

Tissue Procurement

Intact ECM can be isolated from virtually any tissue. Decellularization protocols have been established for heart valves, blood vessels, skin, nerves, skeletal muscle, tendons, ligaments, ovaries, testes, small intestine, urinary bladder, liver, and other tissues. ECM is routinely harvested for research purposes and for clinical application from different species including humans, pigs, cows, and horses [1]. ECM may alternatively be collected from cells grown in vitro [41]. ECM scaffold materials harvested from different species, tissues, or cells have unique structural, functional, and biochemical characteristics. For instance, ECM scaffolds derived from porcine SIS (SIS-ECM) consist of about 90% collagen, most of which is collagen type I, and minor amounts of other collagen types III, IV, V, and VI [42]. On the other hand, although they contain the same collagen types as SIS−ECM, ECM scaffolds composed of porcine UBM (UBM-ECM) contain greater amounts of Col III as well as Col VII, which are important components of the epithelial basement membrane [43]. ECM from various sources also differ in the amount and distribution of GAGs, including heparin, heparin sulfate, chondroitin sulfates, and HA [36,37]; adhesion molecules such as fibronectin and laminin [43,44]; the proteoglycan decorin and the glycoproteins biglycan and entactin [1]; as well as various growth factors including transforming growth factor-β [45], basic fibroblast growth factor (b-FGF) [46], and vascular endothelial growth factor (VEGF) [47]. In addition, ECM scaffolds are distinctive in their protein composition from location to location within various tissues: for example, endocrine versus exocrine loci within the pancreas, or, the valvular versus mural loci within the heart. It is assumed that preservation of the intact ECM composition as well as its intrinsic ultrastructure and 3D architecture, especially its collagen fiber architecture, are fundamentally important in processes such as cell recruitment, migration, proliferation, and differentiation during neotissue formation in vivo [43,48].

Decellularization

Conceptually, intact ECM consists of all of the structural and functional components secreted by the resident cells in their native 3D microarchitecture. In reality, the content and microarchitecture of intact ECM are invariably altered during the decellularization process. ECM will necessarily lose some of its functional components as they are washed out by detergents or other liquid washes. The reagents used in these washes are occasionally retained to a small degree in the final ECM product. Moreover, various decellularization processes and reagents are known to alter the orientation, porosity, or fiber size of the main collagen network differentially, potentially affecting biocompatibility and bioactivity. Decellularization processes are designed to balance the removal of cellular material with the preservation of the composition, mechanical integrity, and biological activity of the remaining ECM. Decellularization processes attempt to achieve the metrics of decellularization established in 2011 by Crapo et al.: less than 50 ng of double-stranded DNA per milligram of dry weight ECM, no visible nuclei in hematoxylin eosin−stained histological sections, and any residual DNA being fewer than 200 base pairs in length [49]. The process from native tissue to ECM varies dramatically between tissue types, considering factors such as tissue density, vasculature, and lipid content. Decellularization processes necessarily include multiple steps, i.e., liberation of desired tissues from surrounding tissues, decellularization (several methods are described subsequently), disinfection, lyophilization, and terminal sterilization. Most commercially available intact ECM scaffolds are processed into a sheet form before decellularization by methods that include trimming and spreading of the original tissue to facilitate the removal of cellular components and debris. In addition, the decellularization of whole organs has been achieved through

perfusing detergents or other solutions through the tissue's native vascular network [50]. Common approaches to decellularization include a combination of physical and chemical treatments, e.g., sonication, agitation, freeze-thawing, and washes with various proteolytic detergents and solvents (reviewed in Gilbert et al. [51]). The decellularization process effectively removes xenogeneic and allogeneic cellular antigens that may be recognized as foreign by the host and results in an adverse inflammatory response or overt immune-mediated rejection [52,53]. The main ECM components are highly conserved between species and are well-tolerated by xenogeneic recipients [10,11]. Over 10 million patients have received ECM-based materials in clinical settings, most of which are of xenogeneic origin, and no immune rejection complications have been reported. Residual amounts of DNA and certain immunogenic species-specific antigens, such as galactosyl-α-1,3-galactose (α-Gal epitope), have been shown to be present in ECM scaffolds but fail to activate complement or bind immunoglobulin M antibody, possibly owing to the small amount and widely scattered distribution of the antigen [54–57].

Postprocessing

After decellularization, it is often desirable for the ECM to be processed further. Such processing may include lyophilization (freeze-drying) or vacuum pressing before terminal sterilization to avoid leaching of soluble factors (for example, VEGF and b-FGF), and extend the product's shelf life. The production of multilaminate forms of the ECM also improves the device's handling and allows various geometric constructs to be built, including tubes [58], cones [59], and multilaminate sheets [60,61]. Lyophilized scaffolds can be processed further to yield powdered ECM, solubilized ECM, or ECM in hydrogel form [62] for use as minimally invasive injectable scaffolds [63,64] or in combination with sheets of ECM to produce sheet-powder hybrid scaffolds. Whereas each of the processing steps will change the overall composition and structure of the prepared ECM compared with those found in vivo, intact ECM preparations retain a multitude of structurally and functionally active proteins [61,65].

ECM scaffolds that are not chemically cross-linked are rapidly degraded in vivo. Typically, 50% of a noncrosslinked SIS-ECM scaffold is degraded within one month postimplantation and the scaffold is usually completely degraded within a three month time frame, as demonstrated in the repair of a urinary bladder defect or the Achilles tendon [66,67]. ECM degradation leads to an initial decrease in overall strength during the early phase of in vivo remodeling, followed by an increase in strength caused by the deposition of site-specific ECM and the formation of functional site-appropriate neotissue by infiltrating cells in response to their experienced mechanical stresses [58,66,68,69]. Soluble factors within ECM scaffold materials (that is, growth factors, and the release of biologically active cryptic peptides resulting from degradation of the ECM material [8,70]) are thought to be directly involved in the processes of neotissue formation including angiogenesis, mononuclear cell infiltration, cell proliferation, cell migration, and cell differentiation [45,71,72]. The release of soluble factors along with the rapid degradation of the ECM appear to be essential processes for constructive remodeling to occur. This fact is highlighted by an altered remodeling profile in clinical applications using scaffolds that have been chemically cross-linked using glutaraldehyde, carbodiimide, or hexamethylene-diisocyanate, or nonchemical methods. Whereas chemical cross-linking can increase the mechanical strength and reduce the rate of scaffold degradation of an ECM scaffold, this modification results in the formation of a chronic, proinflammatory, foreign body type of tissue response and a reduced level of constructive remodeling [71,73]. Similar to the host response to synthetic polymer scaffolds, an adverse host response is heralded by a predominance of M1-like activated macrophages, a high level of proinflammatory cytokines, and the formation of a type 1 T helper (Th-1) (cell-mediated rejection) response [74]. In contrast, intact, nonchemically modified ECM scaffold materials show a host immune response characteristic of accommodation and integration, as demonstrated by the increased presence of M2-like activated macrophages resulting in low levels of proinflammatory cytokines and the establishment of a Th-2 type of response [75–77]. The initial host immune response to ECM scaffolds appears to be critically important in determining subsequent processes including scaffold degradation, release of matricryptic peptides, host cell recruitment, and angiogenesis, among others [8,72].

Hydrogels

A form of ECM that is receiving increased scientific and clinical attention is the ECM hydrogel. Unlike powder or sheet forms, ECM hydrogels are injectable, which makes them minimally invasive; and by virtue of their liquid state at room temperature, they can fill irregularly shaped volumes before they self-assemble into a gel at body temperature. The mechanical stiffness as well as the polymerization time of the resulting gel is fine-tunable by altering the concentration of solubilized ECM in the solution, which makes it a physically versatile biomaterial. Commonly used terminal sterilization methods including γ- or electron beam irradiation and ethylene oxide exposure have been shown to inhibit ECM hydrogel formation. However, supercritical CO_2 sterilization may permit sterile ECM

hydrogel formation [78]. ECM hydrogels have the benefit of retaining the inherent bioactivity of the native matrix despite the loss of its native 3D microarchitecture during the solubilization process [79]. Hydrogels are typically created using powdered ECM as a starting point and then enzymatically digesting the structural components until complete solubilization is achieved. Pepsin is popularly used to solubilize ECM, and it has been observed that proteolysis with other enzymes (papain, for example) can impede the polymerization behaviors of the resulting solution. Similar to solid ECM scaffolds, hydrogels will degrade under physiological conditions, typically within one month of implantation, depending on the source ECM and concentration, and it is supposed that this degradation is essential in achieving their favorable host response [79,80]. Many studies suggest that hydrogels from various source ECMs have vast potential to regenerate bone, adipose tissue, skeletal muscle, and even central nervous system tissue [81–83]. Ventrix, Inc. developed a hydrogel for cardiac repair and regeneration called VentriGel. To date, Ventrix is in Phase I clinical development for VentriGel.

Host Response

A unique feature of intact ECM compared with other types of bioscaffolds is the favorable host response that it elicits. As stated previously, over 10 million patients have received xenogeneic ECM-based materials in clinical settings and no immune rejection complications have been reported. The lack of an adverse immune response to the use of xenogeneic collagen in implantable scaffold materials has been attributed to the common nature of amino acid sequences and surface epitopes among species [10,11] although work has shown the immunomodulation effects of ECM degradation products [70]. Allogeneic and xenogeneic collagen is subjected to the fundamental biological processes of degradation and integration into adjacent host tissues when left in its native ultrastructure. However, structural modifications designed to alter the rate of degradation and remodeling (e.g., cross-linking) may impair the desired healing and regenerative response.

Beyond simply being tolerated by the host, intact ECM has been implicated in directing functional remodeling in many tissue types including skin [84], tendon and ligament [60], urinary bladder [85], skeletal muscle [86], heart [87], and esophagus [58]. Xenogeneic ECMs used clinically are typically of porcine origin; they are usually derived from the urinary bladder, small intestine, or dermis. In vitro, the biologic effect of different source ECMs can be diverse, which can be partly explained by the various methods used to decellularize different tissues [88]. In clinical settings, certain source ECMs are approved for specific applications and not others, although in a clinical trial for volumetric muscle loss including 13 patients, no distinguishable differences were found between patients receiving ECM from urinary bladder, small intestine, or dermis [89].

The exact mechanisms of action for ECM's favorable host response are unknown, although several observations provide a partial explanation. ECM has been shown to attract and/or facilitate differentiation of endogenous stem or progenitor cells [72], enhance mitogenesis in certain cell populations [90], and shift the innate immune response away from inflammation and toward remodeling [73]. In the clinical trial mentioned earlier, it was noted that the ECM scaffolds attracted muscle and nerve progenitor cells to the wound area, thus assembling the key players for muscle regeneration. In another study, an ECM hydrogel was applied to the volumetric lesion of a stroke infarct and within 24 h the host cell infiltrate was characterized. Approximately 60% of the cells were found to be of brain-derived phenotypes, including neural progenitor cells, which upon histological staining appeared to be differentiating into neuronal networks [81]. Another 30% of infiltrating cells were peripheral macrophages; importantly, the ECM hydrogel directed their phenotype away from the M1, classical proinflammatory activation and toward the M2, alternatively activated anti-inflammatory phenotype, putatively aiding in remodeling.

It is known that ECM and their degradation products have various effects on other immune cells as well. For example, ECM components such as entactin, nidogen, and fragments of laminin, elastin, and type IV collagen have been shown to attract neutrophils, a microbicidal cell type [91,92]. It was also found that tumor necrosis factor-α linked to fibronectin affected the signal transduction and cell adhesive properties of $CD4^+$ T cells, possibly helping to direct these immune cells toward inflammatory sites [93]. Another study showed that a 3D collagen matrix was essential for naive T cells to interface meaningfully with antigen-presenting dendritic cells, leading to signal induction and T-cell activation [94]. These studies illustrate how ECM bioscaffolds promote regenerative conditions and tissue development by priming the local immune response.

Whole-Organ Scaffolds

In 2008, perfusion of detergents through an intact donor heart was used to generate a 3D heart ECM scaffold [50]. This detergent-perfusion decellularization technique has since been applied to liver, lung, pancreas, kidney, and even a whole limb [95–99]. Whole-organ engineering using porcine-derived organ scaffolds seeded with

patient-derived stem cells provides an alternative to traditional transplantation that circumvents the need for immunosuppression and the shortage of organs available for traditional transplantation. Recellularization of organ scaffolds is the current focus of the field. To facilitate recellularization, bioreactors have been developed that can provide perfusion, monitoring, and organ-specific stimuli such as mechanical stretch, pressure gradients, or electric impulses (reviewed in Scaritt et al. [100]). These bioreactors permit the ex vivo culture of whole-organ scaffolds seeded with cells such as primary parenchymal cells, endothelial cells, or stem/progenitor cells. Bioengineered rodent organs that have been generated using this bioreactor-assisted recellularization method have been orthotopically implanted by several groups. These bioengineered organs were able to participate in organ function to a limited extent, but hemorrhage and/or edema occurred within the bioengineered organ as a result of incomplete recellularization [95,98]. Regardless of the challenges ahead, the promise and progress of whole-organ engineering have prompted companies such as United Therapeutics Corporation and Miromatrix Medical Incorporated to invest in developing whole-organ decellularization-recellularization technology toward clinical application using porcine organ scaffolds.

CLINICAL AND COMMERCIAL APPLICATIONS

As the science behind the generation and characterization of ECM scaffolds have expanded, the applications for these scaffolds have exponentially increased. Most commercially available ECM scaffolds are used as a surgical mesh for soft tissue reconstruction or topical wound healing (Table 35.1). Preclinical research has demonstrated the promise of using ECM scaffolds (and recellularized ECM scaffolds) for cardiac patches, vascular cuffs, heart valve replacement, tracheal reconstruction, and potentially even organ transplantation, among numerous other uses.

Regulatory Considerations for Extracellular Matrix Scaffolds

ECM scaffolds have a long history of commercial and clinical application. Most of these ECM scaffolds have been classified as a medical device by the US Food and Drug Administration (FDA). In 1997, the FDA created the Tissue Reference Group (TRG) to assist in categorizing products as a device, biologic, or combination, specifically in the realm of regulating human cells, tissues, and cellular- and tissue-based products (HCT/P). The TRG is composed of representatives from the FDA's Center for Biologics Evaluation and Research, the Center for Devices and Radiological Health, the Office of Combination Products, and the Office of the Chief Counsel. The TRG continues to update recommendations on the classification of products. As of this writing, the TRG indicated that secreted or extracted human products such as collagen are not considered an HCT/P (http://www.fda.gov/biologicsbloodvaccines/tissuetissueproducts/regulationoftissues/ucm152857.htm). In 2014, ground, defatted, decellularized adipose tissue was determined not to be an HCT/P because it is more than minimally manipulated. As a final example, in 2012, allogeneic, processed acellular dermis for breast tissue defects was determined not to be an HCT/P because it is used in a nonhomologous site. It is apparent that FDA regulation of commercial or clinical products is changing as the field of tissue engineering and regenerative medicine advances. For the present, it is hoped that new ECM scaffold-based products will be classified based on their predicates.

CONCLUSIONS

Biologic scaffold materials represent one facet of the multiple strategies used in regenerative medicine to construct functional tissue. Biologic scaffolds are derived from mammalian tissues and thus contain countless structural and functional moieties that have been shown to be necessary for tissue development, homeostasis, and response to injury. Such scaffold materials are currently used in clinical medicine and their use will likely expand as regenerative medicine strategies evolve.

List of Acronyms and Abbreviations

b-FGF Basic fibroblast growth factor
DNA Deoxyribonucleic acid
ECM Extracellular matrix
FACITs Fibril-associated collagens with interrupted triple helices

FDA Food and Drug Administration
GAGs Glycosaminoglycan
HA Hyaluronic acid
HCT/P Human cells, tissues, and cellular- and tissue-based products
MACITs Membrane-associated collagens with interrupted triple helices
MBV Matrix-bound vesicle
PLGA poly(D,L-lactide-co-glycolide)
RGD Arginine-glycine-aspartate
SIS-ECM Porcine small intestinal submucosa extracellular matrix
TGF-b Transforming growth factor-b
TRG Tissue Reference Group
UBM-ECM Porcine urinary bladder matrix extracellular matrix
VEGF Vascular endothelial growth factor

Glossary

Decellularization The process by which cells are removed from a tissue or organ to isolate the extracellular matrix scaffold of the tissue or organ for use in engineering or regenerating new tissue
Recellularization The process by which cells are delivered to and cultured within a tissue or organ extracellular matrix scaffold
Xenogeneic Relating to tissues, cells, or materials belonging to different species.

Hydrogels in Regenerative Medicine

David F. Williams

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

To discuss the role of hydrogels in regenerative medicine without extraneous and irrelevant information, it is necessary to set out the meaning and boundaries of regenerative medicine itself. The author of the current described regenerative medicine in 2014, especially in the context of the use of biomaterials in medical technologies [1]. Regenerative medicine addresses a major nonpharmacological, approach to treat disease and injury through the de novo development of functional tissue rather than the replacement of tissue through synthetic devices. Although implantable medical devices can give good performance in treating many conditions, they will always be limited to situations that involve mechanical or physical functions and will not in themselves be able to provide biological solutions to replacing tissue structure and function. Thus, the techniques of regenerative medicine rely on tools that result in regenerating the patient's own tissue; regenerative medicine involves alternative therapies to treat disease and injury by the regeneration of functional tissues or organs instead of replacement by medical devices, transplantation of viable structures or palliative care through the use of pharmaceuticals.

As depicted in Fig. 36.1, there are three main strands of regenerative medicine. The first, usually called cell therapy, involves using groups of cells derived from the patient or elsewhere, which can be injected or otherwise placed at the site of disease or injury in the expectation that they will facilitate the spontaneous regeneration of the required tissue. At its conceptually simplest level, cell therapy does not involve conventional biomaterials, but there are situations in which they may have a supportive role; as will be shown, hydrogels feature prominently here. The second strand is that of gene therapy, in which specific genes are inserted into specific cells to correct deficiencies in those cells, enabling certain processes in tissue expression. It is possible for some biomaterials to be involved in the delivery process, and gene and cell therapies may be combined. The third strand is that of tissue engineering, "the creation of new tissue by the deliberate and controlled stimulation of selected target cells through a systematic combination of molecular and mechanical signals" [2]. Molecular and mechanical signals do not directly imply that the use of biomaterials and tissue engineering may theoretically be carried out in the absence of biomaterials. However, three factors determine that biomaterials are most likely to be involved in tissue engineering processes. The first is that new tissue generated in this way usually needs form and structure, and in themselves, injected cells are unlikely to provide this without the assistance of biomaterials. Second, molecular signals are easily delivered with the appropriate spatial and temporal characteristics; a biomaterial that contains and delivers such signals to the required cells would be beneficial. Third, mechanical signals may be equally difficult to deliver without the sustained effects of a biomaterial support.

As implied earlier, the tissue engineering, cell therapy, and gene therapy modes have some overlapping features; it is not the intention here to become involved in the semantics of these terms or the details of interfaces between them. Instead, this chapter focuses on the role of hydrogels as the preferred exemplars of biomaterials that may be used to support the mechanisms of regenerative medicine and specifically facilitate the delivery of the mechanical and molecular signals, and to assist in generating new functional tissues with appropriate morphological characteristics.

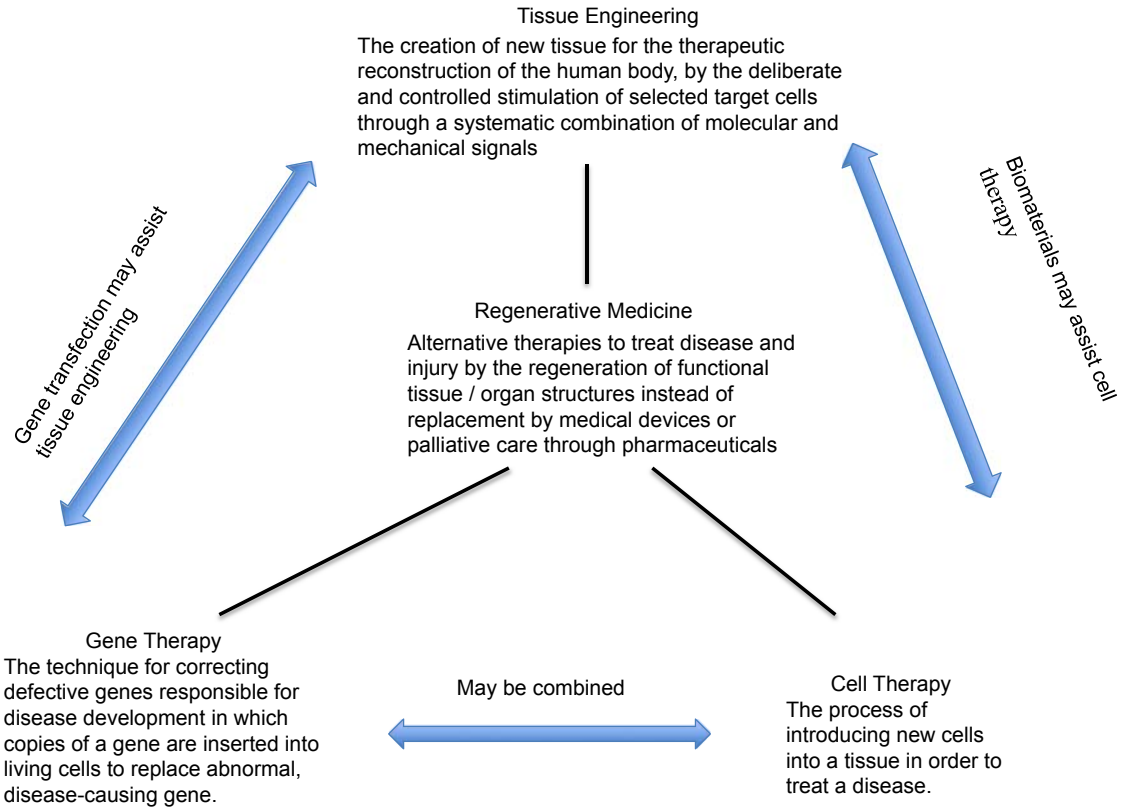

FIGURE 36.1 The essence of regenerative medicine and its components.

BIOMATERIALS TEMPLATES

Nevertheless, it is necessary to briefly address the principles underlying the specifications for the biomaterials that can support regenerative medicine. Specifically focusing on tissue engineering, it has been common practice to describe these material constructs as scaffolds [3]. Conventional scaffolds tend to be composed of discrete porous constructs, usually of polymers or ceramics, in which appropriate cells infiltrate the pores and are intended to express new tissue within these spaces, with the biomaterial degrading and resorbing at the same time. Such constructs have usually been produced by three-dimensional (3D) techniques such as solid free-form fabrication, electrospinning, and solvent casting with porogen leaching. Typical porous scaffolds are seen in Fig. 36.2.

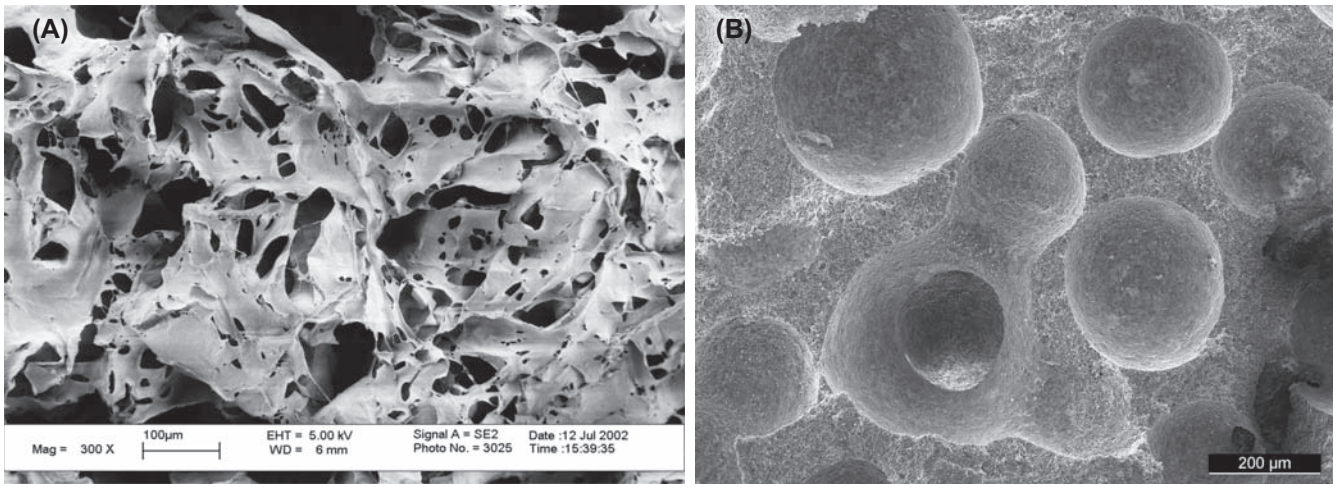

FIGURE 36.2 Examples of conventional porous solid polymer tissue engineering templates.

As discussed by Edalat et al. [4], a scaffold is required to provide an environment, or niche, that favors the natural behavior of cells. The in vivo microenvironment of a cell in general is composed of the relevant extracellular matrix (ECM), homotypic or heterotypic cells surrounding that cell, and cytokines and other bioactive agents around the cells associated with endocrine, autocrine, and paracrine secretions. The microenvironment also involves topographical and architectural features and mechanical forces. It immediately becomes obvious that the type of porous scaffold epitomized by Fig. 36.2 will have considerable difficulty in replicating this type of microenvironment.

This becomes even more significant when stem cells are involved, where the microenvironment is referred to as the stem cell niche. Fig. 36.3, reproduced from Scadden [5], indicates the factors that participate in regulating the system of a stem cell in its tissue state. These include "the constraints of the architectural space, physical engagement of the cell membrane with tethering molecules on neighboring cells or surfaces, signaling interactions at the interface of stem cells and niche or descendent cells, paracrine and endocrine signals from local or distant sources, neural input and metabolic products of tissue activity."

It is suggested here that conventional porous scaffolds do not represent the ideal format for a so-called tissue engineering "scaffold." It is further suggested that, as discussed by the author, the term "scaffold" falls far short of the characterization and specification required for these supporting constructs. The overarching term "template" is preferable [6].

To determine what type of template offers better chances of success than conventional porous solids, it is necessary to define the specifications of these constructs; this has rarely been done within tissue engineering. Edalat et al. [4] have addressed this issue, stating that the engineering of what they describe as scaffolds requires close attention to the 3D microgeometry of the construct (including porosity, pore size, and interpore connectivity), mechanical parameters such as linearity or nonlinearity, elasticity, viscoelasticity, or anisotropy and the successful delivery of biologics including cells, nucleic acids, and cytokines.

These generic requirements can be translated into detailed specifications, some of which are mandatory if optimal performance is to be achieved, whereas others are optional, depending on the precise application [1].

The mandatory specifications are:

- The material should be capable of recapitulating the architecture of the niche of the target cells;
- Because the cell niche is changeable over time, the material should be capable of adapting to the constantly changing microenvironment;
- The material should have elastic properties, particularly stiffness, that favor mechanical signaling to the target cells to optimize differentiation, proliferation, and gene expression;
- The material should have optimal surface or interfacial energy characteristics to facilitate cell adhesion and function;

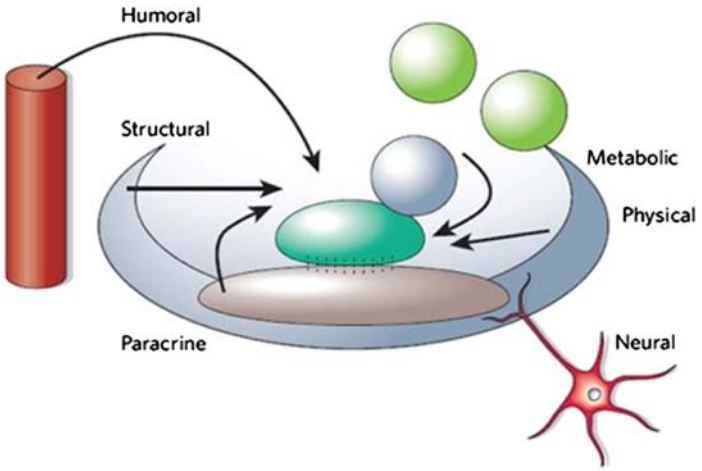

FIGURE 36.3 Components of the local environment that participate in regulating stem cells in their tissue environment. These include the constraints of the architectural space, the physical engagement of the cell membrane with tethering molecules in neighboring cells, signaling interactions at the interface of stem cells, and the niche paracrine and endocrine signals, neural input, and metabolic products. *Reproduced from Scadden DT. The stem cell niche as an entity of action. Nature 2006;44:1075–78, with permission of the Nature Publishing Group.*

- The material should be capable of orchestrating molecular signaling to the target cells by directing endogenous molecules or delivering exogenous molecules;
- The material should be of a physical form that provides appropriate shape and size to the regenerated tissue;
- The material should be capable of forming into an architecture that optimizes cell, nutrient, gas, and biomolecule transport ex vivo, in vivo, or both, and facilitates blood vessel and nerve development;
- The material should be intrinsically noncytotoxic and nonimmunogenic, and minimally proinflammatory.

Optional specifications that vary with the application are:

- The material should be degradable if that is desired, with appropriate degradation kinetics and appropriate morphological and chemical degradation profiles;
- The material should be injectable if that is desired, with the appropriate rheological characteristics and transformation mechanisms and kinetics;
- Where necessary, the material should be compatible with the processing techniques that simultaneously pattern both the material and living cells;
- Where multiple cell types are involved, the material properties should be fine-tunable to accommodate variable cellular requirements, with spatiotemporal control as appropriate;
- When used in a significantly stressed in vivo environment, the material must have sufficient strength and toughness;
- In situations in which the biomaterial encapsulates cells, optimal diffusion characteristics concerning critical molecules are required.

If porous solids are generically unable to comply with all of the mandatory specifications concerned with the cellular microenvironment, consideration has to be given to the type of material that is able to do so; universally the solution to this problem has involved the group of materials known as hydrogels, which are 3D networks composed of cross-linked hydrophilic polymer chains that contain large amounts of water [7–10].

In consideration of these specifications, it is necessary to focus on the characteristics of the composition, structure, and properties of the various forms of ECM [7]. In its natural form, an ECM is composed of water and a mixture of glycosaminoglycans (GAGs) and fibrous proteins, which collectively self-assemble into nanofibrillar supramolecular networks. The precise composition and specific structure vary from tissue to tissue, which implies that the hydrogel for any one construct will depend on the intended tissue application. The main fibrous proteins are the collagens, elastin, fibronectin, and laminin, whereas principal GAGs are hyaluronates, dermatan sulfates, heparin and heparan sulfates, chondroitin sulfates, and keratan sulfates. In addition, many of the GAGs link to core proteins to form proteoglycans. It should be of unsurprising that many of the currently favored hydrogels are based on naturally occurring molecules found in these ECMs. The water content also varies, both with the type of tissue and regionally within any tissue type. Articular cartilage water content varies from 65% to 80% on a regional basis. Within the intervertebral disk, the ECM water content is around 75% in the annulus fibrosis and 80% in the nucleus pulposus; importantly, this decreases with disk degeneration, typically by 10% in advanced cases [11].

From a purely compositional perspective, the ECM appears to be analogous to a hydrogel, albeit a complex one; this was pointed out clearly by a number of reports [12,13]. Naturally, the presence of cells appropriate for the tissue in question and the presence of mineral phases in tissues such as bone and dentin influence the biological and physical properties. The topology, or architecture, reflects the dynamic, reciprocal relationship between the cells and the molecular microenvironment, and the topology and biochemical composition of the ECM is markedly heterogeneous [14,15]. As a form of hydrogel, various types of ECM would be expected to have gel-like mechanical properties, especially those of viscoelasticity, and indeed this is the case [16]. These characteristics vary, especially the complex shear modulus, both regionally within a tissue and with physiological variables such as aging and disease [17,18].

The ECM not only provides the structural and physical support of cells and their biomechanical stimuli in tissue, it initiates critical biochemical cues that are required for tissue function, including morphogenesis, differentiation, and homeostasis. This has to be seriously considered when designing hydrogel templates for tissue engineering. One critical aspect is adhesion between the cells and their ECM, which is mediated by receptors such as integrins. The ECM also is responsible for morphological organization and physiological function by binding growth factors and interacting with cell surface receptors to generate signal transduction and regulate gene expression [14]. The complexity of tissue function requires the ECM to be a dynamic structure that is continually being remodeled and subjected to a variety of posttranslational modifications. Hydrogels used as tissue engineering templates have to address this multitude of characteristics and properties of the ECM.

STRUCTURE–PROPERTY RELATIONSHIPS IN HYDROGELS

As noted earlier, hydrogels are 3D networks composed of cross-linked hydrophilic polymer chains, which can contain large amounts of water, up to thousands of times their dry weight.

The structure–property relationships that characterize these networks depend on a number of factors relating to their source, the polymer composition, the type and nature of the cross-links, their electrical charge, and water-swelling behavior. Hydrogels may be natural or synthetic, or possibly a blend or composite of the two groups. They may be homopolymers (based on a single species of monomer), copolymers (involving two or more different monomer species, at least one of which is hydrophilic), or interpenetrating networks (containing two independent cross-linked components). The hydrogels may be crystalline, semicrystalline, or amorphous. Different properties are seen, depending on the presence or absence of electrical charge on the chains, which may be neutral, anionic or cationic, amphoteric (with both basic and acidic groups), or zwitterionic (with both anionic and cationic groups) in each repeating unit. One of most important characteristics is the ability to swell and deswell reversibly in water on the basis of environmental stimuli; chemical stimuli that induce this behavior include the pH, solvent composition, and ionic strength, whereas physical stimuli primarily include the temperature and electrical or magnetic fields.

As reviewed by Slaughter et al. [19], cross-linking is characterized by junctions, or tie points, formed by covalent or ionic bonds between polymer chains, or by physical entanglements or weak interactions, such as by hydrogen bonding (Fig. 36.4). The resulting network structure can be quantified through a number of parameters, including the polymer volume fraction in the swollen state, the average molecular weight between cross-links, and the distance between them, which is obviously a measure of the mesh size and porosity. This latter parameter is critical for determining the properties of solute transport in the hydrogel, which is obviously important for compliance with the requirement that a tissue engineering template facilitates the transport of nutrients and other molecules. Diffusion is considered to be the dominant mode of transport in tissue engineering hydrogels. This is influenced by the electrical charge, the mesh size, and environmental factors such as the pH and temperature. In complex biological media in which both the polymer and solute are likely to be ionized, interactions between them may have significant effects, generally decreasing solute transport. The precise mechanical characteristics of a hydrogel range from rapid elastic recovery from applied stress or strain to time-dependent viscous recovery; a major factor in tissue engineering hydrogels is the relationship between the glass transition temperature, T_g, and body temperature [19]. At temperatures below T_g there is a tendency for a greater viscous component, with contributions from creep and stress relaxation. However, the very high water content associated with these hydrogels tends to suppress T_g, favoring a more rubbery elastic regime.

We may use the arguments of Buwalda et al. regarding the historic development of hydrogels for biomedical applications [20] to capture the increasing sophistication of hydrogel design as attempts have been made to

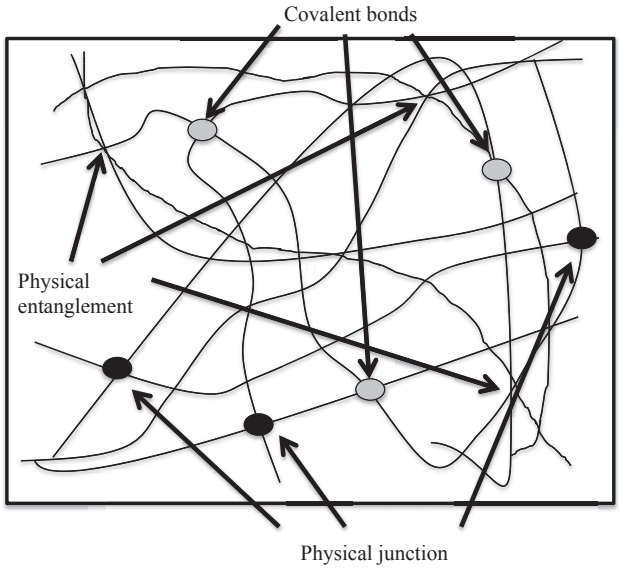

FIGURE 36.4 Hydrogel network with physical junctions, covalent bonds, and physical entanglements.

incorporate the ECM specifications described in the last section. As those authors noted, the first significant event in hydrogel design related to such applications was the introduction of water-swollen, cross-linked, macromolecular networks to construct poly(2-hydroxyethyl methacrylate) (pHEMA) soft contact lenses by Wichterle and Lim in 1960 [21]. The specifications for such a lens were simple and involved sufficient water content for optical transparency, the lack of extractable toxic components, resistance to degradation, good permeability to water-soluble substances (especially oxygen), and suitable mechanical properties; accordingly, the hydrogel structure that was developed was also simple. These first lenses were prepared by the free radical polymerization of 2-hydroxyethyl methacrylate (HEMA) in aqueous solution using ethylene glycol dimethacrylate as a cross-linker.

Buwalda et al. [20] defined this type of simple hydrogel as being a "first-generation" hydrogel. In general, the use of "generation" descriptors is not helpful in biomaterials science [1] because such classifications are subjective, but the use of increasing complexity with specifically designed hydrogels as a marker of suitability for tissue engineering templates serves a good purpose. The baseline of simple synthetic hydrogels encompasses a small group of hydrogels prepared by the polymerization of water-soluble monomers and a group based on cross-linking water-soluble polymers. pHEMA belongs to the first group. These polymers were successful in a number of applications but were soon shown to have several limitations, especially insufficient oxygen (and other solute) transport and mechanical fragility. *N*-Vinylpyrrolidone (nVP) was used as an alternative water-soluble monomer; polyvinylpyrrolidone had higher hydrophilicity and overall improved biocompatibility. Nevertheless, these were not ideal, and various copolymers of HEMA, such as nVP, substituted acrylamides, vinyl acetate, and substituted methacrylates, were subsequently developed. These produced hydrogels with variations in basic properties but with no significant change in the underlying philosophy.

The second group of simple hydrogels, based on the cross-linking of water-soluble synthetic polymers, largely involved poly(vinyl alcohol) (PVA) and poly(ethylene glycol) (PEG). PVA is a linear polymer produced by the free radical polymerization of vinyl acetate, followed by the hydrolysis of the acetate groups to alcohol groups [22]. Cross-linking has been achieved through the use of bifunctional or multifunctional agents that are able to react with the hydroxyl groups of the PVA molecules, including aldehydes such as glutaraldehyde, or through the use of electron beam or γ-irradiation. Obtaining the optimal balance of biocompatibility (potentially influenced by residual chemical cross-linking agents) and mechanical properties has not been straightforward. PEG and its higher–molecular weight counterpart, poly(ethylene oxide), are widely used hydrogels in pharmaceutical preparations; the highly water-soluble polymers are readily cross-linked by γ or electron beam radiation [23]. PEG hydrogels are versatile because molecular chains can have a variety of forms, such as linear or star-shaped, and because they can be biologically modified readily. This provides a good example of how the basic synthetic hydrogels have led to more sophisticated structures that can approximate the ECM paradigm discussed previously.

INCREASING SOPHISTICATION OF SYNTHETIC HYDROGELS FOR TISSUE ENGINEERING

Bioactive Forms of Poly(ethylene Glycol) as Exemplars of Increasing Sophistication

The PEG hydrogels discussed in the previous section provide a good example of how modifications, especially biological ones, can improve the performance of synthetic hydrogels [24,25]. The major limitation of these hydrogels with respect to regenerative medicine applications is the lack of cell-specific adhesion. One approach to overcoming this involves the use of cell-adhesive peptides in modifying the PEG structure. These have generally been derived from the major ECM proteins fibronectin, laminin, and collagen. The most widely used peptide has been arginine-glycine-aspartate (RGD) [26], which can be derived from the cell-binding domain of all three proteins; both linear and cyclic RGD have been employed, with preference for the latter in view of the greater affinity for the integrin $\alpha_v\beta_3$. The peptide may be linked to the PEG network by a number of different groups, such as monoacrylates.

A second modification to PEG involves incorporating growth factors. These are polypeptides that transmit signals to modulate cellular activity, which is important in tissue engineering processes. However, in their free form they have short half-lives because they are susceptible to proteolytic degradation. Growth factors may be incorporated into PEG directly during hydrogel formation, but this usually results in a burst release; this is likely to be unsatisfactory because the dosage response required to facilitate tissue formation is precise and sensitive. Several strategies have been used to address these difficulties, particularly using functional groups to modify the growth factors before tethering them to the PEG network, such as by using cysteine to tether recombinant vascular endothelial growth factor using multiarm PEG vinyl sulfone [27]. Among other growth factors that have been attached to PEG are basic

fibroblast growth factor, transforming growth factor-β, epidermal growth factor, and various bone morphogenetic proteins. Various methods have also been used to mimic the growth factor binding mechanism of GAGs in the natural ECM by the chemical modification of heparin, chondroitin sulfate, and hyaluronic acid, using reactive groups such as acrylate or thiol, and subsequent reaction with functionalized PEG derivatives [28].

With these PEG-based examples in mind, generic forms of hydrogel sophistication are now discussed.

Spatial Heterogeneity

As alluded to earlier, biological processes are usually regulated by spatially dependent signals, in which gradients of molecules are able to regulate cell migration, axon extension, angiogenesis, differentiation, and other processes. As discussed by Khademhosseini et al., control of the spatial location of molecules on a surface and/or throughout a material template could be beneficial for tissue engineering [29]. One approach to generating these gradients involves releasing molecules from a source over time to form a concentration gradient as the molecule diffuses away from the source; in general, however, these gradients are unstable and it is difficult to control their shape. An alternative concept that involves conjugating biomolecules to materials has been used to increase the stability of signaling molecules in a spatially controlled manner. For example, multicomponent, spatially patterned, photocross-linkable hydrogels may be fabricated to localize growth factors within hydrogels. In addition, microfabrication approaches provide attractive technologies because of their availability and cost-effectiveness. The ability to pattern fluids within microchannels has been merged with photopolymerization chemistry to form spatially oriented hydrogels. Hydrogels may be synthesized with gradients of signaling or adhesive molecules or with varying cross-linking densities across the material to direct cell behavior such as migration, adhesion, and differentiation.

These concepts of controlling the microstructure and spatial compositional character in relation to the connectivity between multicomponent tissues, especially the ECM, and hydrogels was discussed by several authors [7,10,12,30–32]. Burdick and Murphy [32] referred to the motivation to introduce spatial heterogeneity into hydrogels, and discussed the role of micropatterning (Fig. 36.5). They claimed that introducing spatially specific cues in hydrogels makes multicellular constructs possible through cocultures or multilineage differentiation.

One widely used micropatterning technique is photolithography, in which a hydrogel precursor material is exposed to ultraviolet light through a photomask that displays the required pattern. This provides reliable shape definition and is able to pattern multiple cells with materials to facilitate the selective adhesion of individual cell types to specific regions; photocross-linkable hydrogels are placed underneath the mask that controls the exposure to generate the structures in the shape of the mask. Soft lithography allows microfabrication at the micron scale, especially using silicon-based elastomers (e.g., polydimethylsiloxane) in microfluidic systems. This is of great potential interest in the development of constructs that have microchannels that resemble the vascular systems of tissues; so far, nutrient and metabolite diffusion has been observed only in relatively small hydrogel-based constructs owing to transport limitations, so microfluidic and nanofluidic techniques that allow for the creation of channels to overcome these limitations are immensely important [33–35].

Most techniques that have been investigated with respect to spatially heterogeneous hydrogels involve nanofibrous architecture [31]; these techniques include electrospinning, phase separation, and self-assembly. Electrospinning is an old technique; it dates back to the 1970s with respect to medical technology, but it is now considerably more sophisticated in relation to the materials used and the structures produced. For example, Sun et al. investigated the use of electrospun photocross-linkable hydrogel fibrous constructs for skin flap regeneration that possess the dual properties of a fibrous nanostructure and hydrogel softness, designed to allow cell migration into the scaffolds to develop 3D microvascular structures [36]. They hypothesized that such a hydrogel would be conducive to endothelial cell adhesion and growth, tubulogenesis, skin flap adhesion of the wound bed, and the formation of microvasculature. This should increase the number of capabilities to aid blood supply and enhance the survival rate of random skin flap after implantation. Gelatin methacryloyl (GelMA) hydrogel, fabricated by incorporating methacrylate groups to the amine-containing side groups of gelatin, was the photocross-linkable hydrogel used. The methacryloyl groups maintained the properties of gelatin and also allowed solidification from liquid to solid permanently via the chemical reaction of the methacryloyl groups. Also, by varying the polymer cross-linking density to control the hydrogel network structure, the mechanical, degradation, and biological properties could easily be fine-tuned. The study demonstrated the suitability of scaffolds for accelerated vascularization and that electrospun GelMA nanofiber scaffolds could support cell adhesion, proliferation, migration in vitro, and the formation of 3D vascular networks in vivo. The photocross-linkable gelatin exhibited controllable mechanical and degradation

properties, resulting in nanofibrous templates to provide the rapid regeneration and formation of cutaneous tissues with minimal inflammation.

Spatial heterogeneity is also important in other tissues and for different reasons, including applications in musculoskeletal engineering [37]. In electrospun constructs, fiber alignment promotes the formation of long lamellipodia extensions parallel to the direction of the fibers, resulting in directional cell orientation and migration through mechanisms of contact guidance similar to that seen in native tissue environmental signaling. Cellular orientation is particularly important in the biomechanics of musculoskeletal tissue, because it determines the pattern of ECM deposition, which is an essential factor in the functionality of bone, tendon, ligament, and cartilage. In bone tissue engineering, for example, fiber alignment and consequent cellular alignment have been shown to regulate cell adhesion and migration, promote osteogenic phenotype, differentiate stem cells toward osteogenic lineage, and enhance mineralization and osteogenesis. Fiber alignment associated with electrospun fibers also closely resembles that seen with collagen fibrils in tendon tissue. Such anisotropy promotes elongated physiological cell morphology, the phenotype maintenance of tendon-derived cells, and the transdifferentiation of other cell types toward tenogenic lineage. The porous 3D nature of electrospun materials also provides a good environment for chondrogenic phenotype maintenance, the chondrogenic differentiation of stem cells, and new tissue formation in vivo in both cartilage and osteochondral defects. Fiber size as well as alignment is an important variable in maintaining cell phenotype and function in cartilage and tendon engineering. One interesting strategy to enhancing the complexity of constructs is based on the use of emulsions or multiaxial nozzles to produce multicomponent core–sheath fibers with multiple, often immiscible components. Such systems have been used extensively for bone, cartilage, and tendon repair.

Electrospinning has also been combined successfully with other fabrication technologies with optimal outputs for various clinical targets. For example, multiphasic scaffolds can be fabricated using electrospinning and additive manufacturing techniques, yielding constructs with large size pores essential for cell and mass transportation, together with fibrous components that provide suitable substrates for cell attachment.

Molecular self-assembly, a ubiquitous biological process, is defined as an autonomous organization of components into patterns or structure without human intervention, and is identified across length scales ranging from DNA base pairing to microtubule fabrication, and up to macroscale tissue morphogenesis [31,37]; unsurprisingly, self-assembly features powerfully in the concepts of structural heterogeneity for the creation of hydrogel-based ECM mimics. The natural extracellular environment is synthesized and organized through self-assembly in hierarchical motifs in which, in a dynamic equilibrium, the structural and chemical milieu needed to promote a range of physiological functions are controlled, including cell morphology, proliferation, attachment, migration, and tissue morphogenesis. Self-assembled template fabrication aims to replicate the sophistication of nature to produce hierarchical 3D tissue equivalents, in which hydrogels have a dominant role. Molecules that are structurally conformable and have chemical complementarity can spontaneously self-assemble into supramolecular architectures under appropriate conditions of temperature, pH, and anionic strength. These will be held together by reversible, noncovalent bonds, which, although they are inherently weak individually, yield strong and stable complexes through their collective interactions. Self-assembled natural, synthetic, or peptide-derived hydrogels have the ability to capture and deliver living cells while controlling their fate. They may also immobilize and control the release of potent biological and bioactive molecules, preserving their molecular conformation and bioactivity. By way of example, collagen nanotextured microfibers, produced by extrusion into a series of neutral phosphate buffers and cross-linking or functionalization solutions at 37°C, represent a significant advance in the recapitulation of the hierarchical architectural organization of musculoskeletal tissues.

The self-assembly of peptides can result in the formation of nanofibers with very high aspect ratios, which may be able to mimic the physical microenvironment of cells, such as wrapping around cells and acting as ties between adjacent structures. One prominent area involves peptide amphiphiles. The development of tissue-engineered nerve conduits used in the setting of complex nerve injury has seen interesting developments with peptide amphiphile nanofibrous constructs. These should mimic the aligned architecture of native nerves to support directional axonal regeneration, but also provide the bioactivity found in the native ECM that facilitates Schwann cell attachment, proliferation, migration, and function. Stupp and colleagues used a series of aligned nanofiber gels formed by self-assembling peptide amphiphiles in peripheral nerve regeneration [38]. Because of their molecular design, these nanofibers can mimic the internal fascicular architecture of peripheral nerves, allowing for the incorporation of Schwann cells vital for peripheral nerve and inducing cellular and neurite alignment and guiding cell migration. They can also be engineered to possess bioactivity that is relevant to nerve regeneration; a peptide presenting the amino acid sequence IKVAV (derived from laminin) was shown to induce neural stem cell differentiation, stimulate neurite outgrowth, and result in functional improvement in acute spinal cord injury.

Matrix Mechanics

The biophysical properties of the ECM are important determinants of many biological processes. As discussed by Gattazzo et al. [39], every cell in its anatomical location has to balance external forces dictated by the mechanical properties of its environment resulting from compression exerted by neighboring cells and the stiffness of the surrounding ECM. The cells have to regulate their own cytoskeleton, generating internal forces that are transmitted to the environment by adhesion sites. These focal adhesion complexes include integrins and signaling proteins, and these physically link the cytoskeleton to the ECM. Mechanical forces are exerted on and by each cell, and this interplay generates a tension within the cytoskeleton that allows maintenance of cell shape and the dynamic response to external forces. This response to mechanical stimuli is referred to as mechanotransduction.

The current author explained elsewhere the pivotal role that mechanotransduction has in many biocompatibility phenomena [40]. Included here are interactions between hydrogels and other template materials with stem cells, as discussed a few years ago by Lutolf et al. [41]. Mechanotransduction profoundly affects the behavior of stem cells, both under natural circumstances and within tissue engineering systems, such as in in vitro bioreactors. The force-dependent cell signaling processes in stem cell differentiation were reviewed by Yim and Sheetz [42], with a special emphasis on focal adhesions, mechanosensitive ion channels, cytoskeletal contractility, Rho guanosine triphosphatase (GTPase) signaling, calcium signaling, and nuclear regulation. Many individual components of the various

pathways in these systems are clearly force-dependent, including the binding of vinculin to talin during initial stages of focal adhesion assembly [43] and the activation of RhoA and Cdc42 in neurogenesis in neural stem cells [44].

Dealing first with in vitro bioreactor-based tissue engineering, two separate types of mechanical cue influence stem cell behavior, only one of which is concerned with a biomaterial property. These aspects were discussed by Steward and Kelly with respect to the mechanical regulation of mesenchymal stem cell (MSC) differentiation [45]. The first type refers to the shear stress system imposed by the mechanics of the bioreactor, which include spinner flasks, rotating wall bioreactors, and perfusion bioreactors, as described by Yeatts et al. [46]. Each of these provides different stress systems and dynamic variations in shear stresses. A primary shear stress–driven signaling pathway in the differentiation of MSCs in both osteogenesis and chondrogenesis is that of mitogen-activated protein kinases. Mechanical stresses are involved in pathway activation and in the upregulation of the proteins on which the pathways depend. Although the physical characteristics of any biomaterial template, including porosity, have some influence on fluid flow, they are not the primary determinant of the shear stresses that affect the cells.

The second type of mechanical cue is that of structural stresses, perhaps best seen in cell-seeded scaffolds in static culture, in which hydrostatic pressure results in stress transfer between biomaterial surfaces and cell membranes. The precise nature of the stresses at these interfaces, including magnitude and type (especially tensile or compressive), has a strong influence on the gene expression of the cells and the differentiation pathway down which they are directed. The mechanisms here are likely to reflect the normal processes of stem cell–matrix interactions within the microenvironment of cell niche; the material property most likely to influence the cell fate is substrate stiffness, or elasticity. In particular, MSCs clearly respond to 3D hydrogel stiffness. They are modulated by integrin binding through the reorganization of ligand presentation at the nanoscale; matrices of 11–30 kPa stiffness induce MSC osteogenic differentiation whereas those of 2.5–5 kPa show adipogenesis.

At this stage, there is a lack of consistency in the details of the causal relationship between stiffness and cell fate when considering all types of cells and all practical conditions, largely because of the interactivity among different mechanisms, but it is clear that mechanotransduction is a primary controlling factor in the phenomena of biomaterial–bioreactor-induced stem cell differentiation. The situation is similar with in vivo tissue engineering, in which much evidence points to a role of mechanical stress in tissue regeneration associated with injectable scaffolds. Myocardial tissue engineering provides a good example. The disparity between the stiffness of myocardium and injectable hydrogels and the importance of associated stress fields were addressed by Reis et al. [47]. When cardiovascular progenitor cells are contained in cardiac ECM–fibrin hybrid scaffolds, their differentiation is affected by the stiffness as well as the composition of the hydrogel. For example, von Willebrand factor gene expression is upregulated with increasing gel stiffness, although such effects vary between adult and neonatal cell sources and with other relevant variables.

The potential role of biomaterials as stem cell regulators was extensively analyzed by Murphy et al. [48]. It is relevant to repeat here a major part of their conclusions: “Although there are many mechanisms at play at the cell/material interface, the fundamental interaction that all cells must have is a link between the cytoskeleton and the material. The consequences of this interaction include a cascade of events in the cell, all of which are initiated by the cytoskeleton or by structures that link it to the material … the cytoskeletal protein actin and its molecular motor myosin II bind and slide past one another to contract the cell. This mechanism is highly organized in muscle, yet it is present in all adherent cell types and in stem cells it enables them to ‘feel’ the stiffness and topography of the environment, as well as to control their size, shape and polarity. Although such inherent properties of the material may seem disparate, they are united by a common contractility-based mechanism that directs stem cells towards specific lineages based on the degree of activation.”

Two further points are worth mentioning. First, some tissues that are prime targets for tissue engineering solutions may be remarkably heterogeneous and/or anisotropic with respect to elasticity, so that replication of the matrix mechanics may not be easy. Within the myocardium, for example, even healthy ventricular ECM can show an effective Young’s modulus ranging from 30 to 75 kPa in different regions; infarcted myocardium can be much stiffer than this [18]. Second, it may be difficult to decouple matrix mechanics from inherent porosity and permeability [49], so that altering hydrophilicity and cross-link density, for example, can have varying effects on stiffness; this has to be taken into account in hydrogel design.

Hydrogel Degradation

It is usually considered necessary for tissue engineering templates to be degradable so that they are replaced as new tissue develops. A few general points need to be made about in vivo polymer degradation in relation to the

mechanisms of degradation and the biological consequences of degradation processes [1]. First, decades of development have shown that it is possible to design biomaterials that are essentially resistant to degradation in tissue environments (such as polytetrafluoroethylene) or are rapidly degraded (such as poly[glycolic acid]) and many that have characteristics in between. The principal mechanism of degradation is hydrolysis, so that susceptibility to degradation is largely controlled by hydrophilicity and the presence of hydrolyzable bonds. By definition, hydrogels are hydrophilic, so their degradation behavior will be determined by the hydrolyzable bonds. If these are numerous and homogeneously distributed, the hydrogel should be rapidly and uniformly degraded. It is also possible under some circumstances for polymers to be degraded by other mechanisms such as oxidation. Polyolefins such as polypropylene may experience oxidative degradation under some in vivo conditions, which is why implantable devices made of such polymers usually contain antioxidants. More important, many biological processes that occur in the vicinity of biomaterials, including inflammation, involve reactive oxygen species, which may become associated with degradation. Other reactions involve tissue enzymes, which may also be able to influence polymer degradation. Because these processes are not necessarily uniform, either spatially or temporally, it follows that degradation effects may be heterogeneous. As noted subsequently, this is an important point in the design of complex heterogeneous or anisotropic hydrogel templates. Second, degradation processes result in the generation of by-products. It is essential that these by-products be compatible with the tissue engineering environment. Ideally, the hydrogel should be bioresorbable: that is, the by-products should be metabolized and harmlessly assimilated into the tissue, such as water and carbon dioxide. It is very important that the by-products not be proinflammatory or cytotoxic. Third, degradation processes may be influenced by mechanical stress, which should be taken into account in template design.

As pointed out by Burdick on several occasions [32,49], uniform hydrogel constructs with homogeneous degradation profiles considerably oversimplify the complexity of the temporal dynamics that are present in tissue development. As implied in the earlier parts of this chapter, the natural ECM undergoes dynamic remodeling through a combination of matrix assembly and degradation, and this characteristic should be replicated in a hydrogel template. These processes occur through the effects of molecules such as proteolytic enzymes, such as matrix metalloproteinases (MMPs), which are produced by cells during migration and signaling. If hydrogels are simple uniform structures in which degradation is solely controlled by cross-link density, there will be no local control over degradation behavior.

In general, hydrogel degradation rates can be fine-tuned by manipulating network connectivity and mesh size. Increased the cross-linking density usually leads to a smaller mesh size, an increased elastic modulus, and slower degradation, because there will be an increased number of cleavable bonds that have to be broken for network mass loss and erosion. Decreased the mesh size also limits accessibility of the degradable moiety to larger molecules, including enzymes, because of a reduced diffusion rate. In addition, encapsulated cells, cell-secreted enzymes, and growth media can influence the degradation rates for chemically or physically cross-linked hydrogels [50]. Hydrogels can degrade by bulk degradation, surface erosion, or a combination of the two (Fig. 36.6). At high cross-link density, restricted diffusion of water and enzymes preferentially leads to surface erosion. In hydrogels with high water content and high diffusivity, bulk degradation occurs when cleavable groups are present throughout the bulk and may degrade simultaneously.

Physically cross-linked hydrogels can degrade by processes that reverse the gelation mechanism or disturb the noncovalent interactions of the cross-links. Chemically cross-linked hydrogels degrade via several mechanisms, including cleavage of the backbone chain, cross-linker, or pendant groups. Also, hydrogels prepared using polymers with degradable functional groups within the backbone chain may be degraded into smaller segments, depending on the location of the degradable groups. Many hydrogels include degradable cross-linkers, such as peptides, proteins, or polymers with chemically labile moieties. These networks degrade into high—molecular weight polymer backbone chains, with degradation products derived from the cross-linker. Polymer chains also can be end-capped with degradable functional groups followed by the addition of reactive functionalities, thus creating cross-linkable degradable macromers. Chemically cross-linked hydrogels may be degraded through hydrolysis, enzymatic cleavage, reversible click reactions, or photolytic degradation. Obviously, to engineer hydrogel degradability, it is necessary to understand the types of cleavable groups and modes of degradation, their by-products, and factors affecting degradation rates.

Polymerization Mechanisms

These sections have referred to the general mechanisms of hydrogel formation and the effects of, for example, different cross-linking processes on the resulting complexity and properties of the hydrogel. The development of

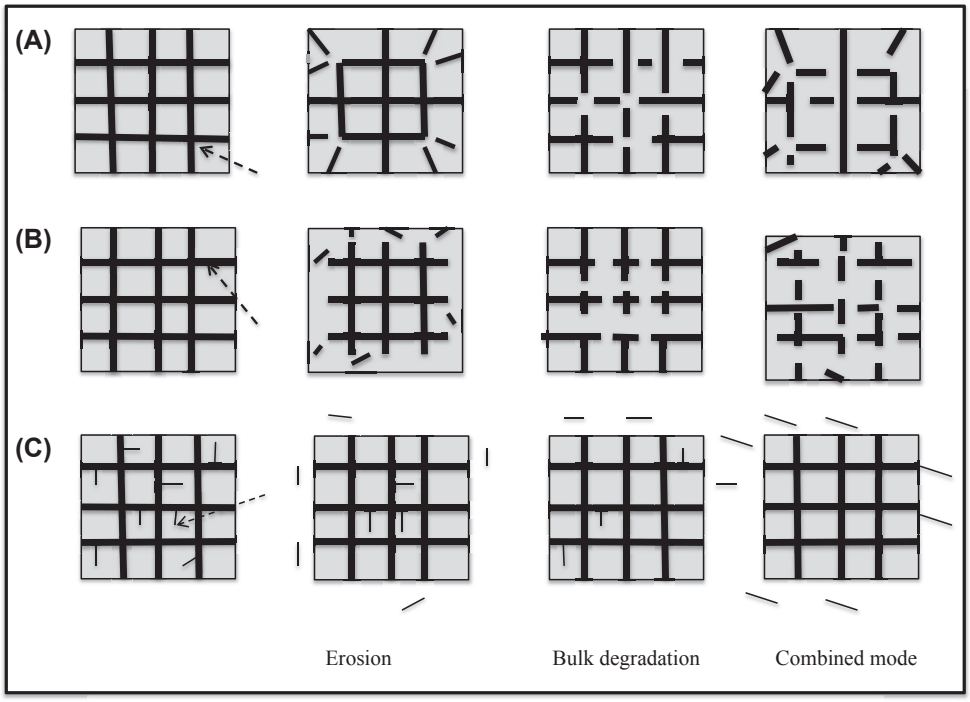

FIGURE 36.6 Degradation mechanisms for hydrogels, involving erosion, bulk degradation, or a combination of these. (A) Polymers subject to degradation at the cross-links. (B) Degradation of the backbone. (C) Release of pendant side groups.

new techniques of cross-link chemistry has led to new structures that are able to mimic the ECM better. Lin discussed such advances with respect to PEG hydrogels [51]; these examples are instructive. It will be recalled that although PEG-based hydrogels have a high water content, tissue-mimicking elasticity, solute permeability, and cytocompatibility, the lack of biological recognition sites is a significant disadvantage. Therefore, PEG hydrogels have been developed that are functionalized through copolymerization with peptides during network cross-linking. For example, acrylated or methacrylate peptides can be copolymerized within PEG-diacrylate or PEG-dimethacrylate hydrogels through chain-growth homopolymerization. PEG-based hydrogels can also be prepared by step-growth photopolymerization, giving a more homogeneous network structure and better mechanical properties. Photopolymerization has the advantage of excellent spatiotemporal control of gelation characteristics. Several bioactive motifs can be incorporated into the hydrogel using this technique.

Click chemistry has been embraced in hydrogel preparation [52] because of the high reactivity and selectivity that can be achieved, as well as the mild conditions that are involved. Click chemistry produces highly efficient, quantitative, orthogonal reactions between mutually reactive functional groups. With reference to PEG, MMP-sensitive peptide sequences can be incorporated into the hydrogels using nucleophilic Michael-type addition reactions between these cross-linkers with terminal cysteines, and multiarm PEG-vinyl sulfone [53]. Cell-adhesive ligands may be readily conjugated using similar Michael-type addition reactions. One major advantage of these types of nucleophilic additions reactions is that they avoid the generation of radicals, which often compromise the biocompatibility of the systems.

Biomimetic hydrogels with good biocompatibility may also be prepared by macromolecular or supramolecular self-assembly, especially where gelation is produced by physical processes, which again avoids the use of radicals. Amphiphilic cyclodextrins are widely used in this context, with physical interactions between their inner hydrophobic cavity and hydrophobic molecules; the hydrophilic outer surfaces facilitate dissolution in physiological environments.

Injectable Systems

In the context of different polymerization mechanisms, mention must be made of the possibility of forming in situ or in vivo gelling systems [54]. The attraction is obvious of being able to inject a viscous sol into the tissue at the site where regeneration is required, under ambient physiological conditions and in a short time (Fig. 36.7).

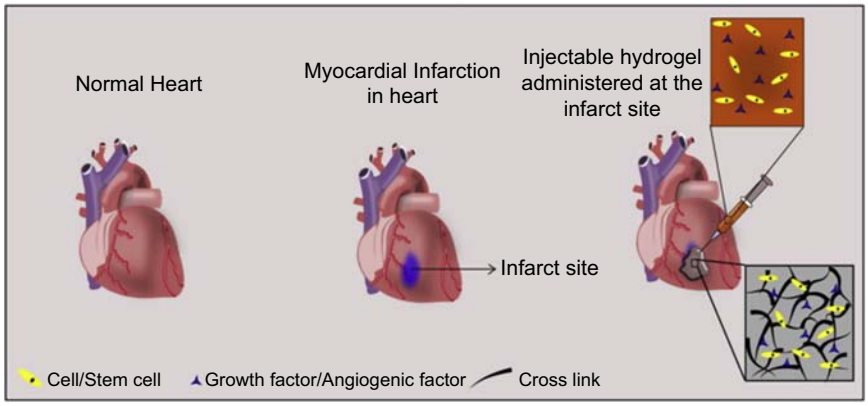

FIGURE 36.7 Example of potential benefits of injectable hydrogels in regenerative medicine. Epicardial delivery of hydrogel-based solution carrying cells and biomolecular signals, which upon administration forms three-dimensional hydrogel over the infarct site owing to cross-linked networks. *Reproduced from Radhakrishnan et al. Biotech Adv 2014;32(2):449–61, with permission of Elsevier.*

In situ–forming hydrogels may be prepared using noncytotoxic cross-linking agents, physical interactions, or self-assembly supramolecular chemistry. These resulting gels should be able to take on the shape and architecture of the site where they are injected and preferably adhere to the local tissue. However, success has been elusive owing to the narrow range of biologically acceptable stimuli for triggering the physical interactions, the generally low mechanical properties, the difficulty of incorporating bioactive agents, and often poor stability.

The range of options for gelling reactions follows the systems discussed in the previous section on general polymerization mechanisms. Much attention has been given to Michael-type addition reactions, especially in PEG, collagen, hyaluronic acid, and heparin systems. Click chemistry is also employed.

NATURAL BIOPOLYMERS AS EXTRACELLULAR MATRIX–ANALOG HYDROGELS

It is not the intention in the next two sections to provide detailed catalogs of tissue engineering hydrogels, but rather to give a summary of the salient features of the various species that are attracting attention. In both categories, i.e., natural and synthetic biomaterials, categories can exist in solid polymer, elastomer, and nanostructured forms as well as hydrogels. Biopolymer or naturally derived hydrogels include those based on hyaluronic acid, alginates, collagen, fibrin, and peptides. They tend to be considered superior to synthetic gels with respect to biocompatibility because they may offer better molecular and morphological cues to cells. However, they have potential disadvantages associated with the sourcing of raw materials from natural origins where purity and consistency may be less than ideal for a quality product used in health care.

Polysaccharides

Generically, a polysaccharide is a complex carbohydrate composed of a chain of monosaccharide units linked by glycosidic groups. Sugars are monosaccharides or disaccharides; polysaccharides have much larger molecules. They clearly have some similarities, but structural differences between different types mean that it is difficult to find common ground that distinguishes the group as a whole from other materials, and they are best dealt with individually. Some of those discussed here are GAGs (mucopolysaccharides), which are long, linear, unbranched polysaccharides of repeating disaccharide units. Some, such as hyaluronan (HA), are nonsulfated, but several, including heparan sulfate, dermatan sulfate, and keratan sulfate, are sulfated.

Hyaluronic Acid

HA, otherwise known as hyaluronic acid, is a linear glycosaminoglycan that has a molecular mass of 10^6–10^7 Da, with very long molecules that consist of linear chains of repeating units of disaccharides of glucuronic acid and *N*-acetylglucosamine.

Two main features of HA have contributed to its attractiveness as a biomaterial [55]. First, it is contained in the properties of many tissues in the human body and contributes to them, which suggests the possibility of

recapitulating some of these within therapeutic products. Among the specific biological properties of HA are its role in embryonic development and wound healing. It is present in high concentrations in synovial fluid and in the ECM of cartilage, so it has a significant role in the functioning of articulating joints. HA interacts with some cell surface receptors and is involved in angiogenesis, cell migration and motility, and tissue organization. It has a role in inflammation and the stimulation of cytokine activity. It can also be functionalized and chemically modified to present a wide range of physical characteristics, with wide-ranging solubility and mechanical properties. The carboxyl group can be functionalized through amidation, esterification, or oxidation. The hydroxyl group may undergo esterification or etherification and the acetyl group may be reacted by deacetylation or amidation.

HA can be derived from a number of sources; one of the most common is rooster comb. It is highly soluble, especially at a low pH, and has a high rate of turnover in human tissue. For the purposes of creating a practical biomaterial, HA is normally cross-linked, for which a number of methods are available, and it may be modified with other substances. Covalent cross-linking provides the opportunity to achieve hydrogels, sponges, and other solid forms while maintaining biological functionality. Cross-linking may take place using water-soluble agents such as a carbodiimide or by the use of photocross-linking using glycidylmethacrylate or methacrylic anhydride.

As a gel, it has high viscoelasticity, a major factor in its use in ophthalmic surgery and in therapies for osteoarthritis. It can be degraded by reactive oxygen intermediates; unmodified HA is rapidly degraded and cleared from the site of administration. To reduce the rate of degradation, cross-links may be introduced. It may also be modified with peptides to enhance cell attachment, spreading, and proliferation. For example, thiol-modified HA can be functionalized with the RGD sequence. These peptide-functionalized gels may also be used as in situ gelling injectable constructs for in vivo tissue engineering.

The areas of tissue engineering most relevant to hyaluronic acid templates are brain and neural regeneration, cardiovascular tissue engineering, skin regeneration, retinal regeneration, and cartilage repair [55]. Several factors have limited the clinical applications so far, including nonspecific protein adsorption and cell adhesion, which can lead to inflammation and the accumulation of degradation products at the site of application, which inhibits stem cell differentiation.

Alginate

Algae are living organisms that are mostly found in water; they can be harvested and provide substances for many industrial uses [56]. These uses are mainly based on their polysaccharide content, although they are often also rich in amino acids such as proline, glycine, and lysine, which accounts for their widespread application as food additives. Seaweeds constitute an important source of harvested algae-based substances because their cell walls contain polysaccharides, which can be readily extracted. Some seaweeds produce agar (from red seaweed); others produce carrageenans. Brown algae (Phaeophyta) produce alginates and several other polysaccharides. The alginates are probably the most important seaweed-derived products and certainly the most significant from a biomaterials perspective. These are harvested in their wild state; cultivation is too expensive, which accounts for some variability in the extracted alginates, because there is some species and seasonal dependence. Alginates are extracted from the seaweed using sodium carbonate and precipitated as either sodium or calcium alginate. This is treated with diluted HCl to produce alginic acid, which us purified and reconstituted into different ionic forms, depending on the application.

Alginates are linear block copolymers of 1,4-linked β-D-mannuronic acid (M) and α-L-guluronic acid (G). The properties of the material will depend on the M:G ratio. Alginates form gels and readily retain water. Different ionic forms have different solubilities; the transition from sol to gel can easily be achieved by conversion between calcium and sodium forms, a process that was extensively used in dentistry to produce elastomeric impression materials. In the solid state, alginates can form films and fibers of good structural quality. When prepared as meshes of nonwoven fibers, they make useful wound dressings, because they are able to absorb large amounts of exudate from the wound bed. Alginate products are used as food additives, moisturizing components of cosmetics, and ingestible preparations for treating inflamed mucosal surfaces. The most attention has been paid in tissue engineering and cell therapies. It is particularly notable that alginates present one of the best options for cell encapsulation, because the hydrated material will allow the diffusion of small molecules essential for metabolic activity but not the immunoglobulins that would attack the cells. The viscosity of alginates and the stiffness after gelling depend on the concentration of the polymer and its molecular weight distribution. Cross-linking between polymer chains can be arranged through multivalent cations (especially calcium) and with carboxylic acid groups in the sugars. Alginates have generally good biocompatibility and can be prepared as an injectable ionic solution. They have poorly controlled degradation and variable cell adhesion characteristics. γ-Irradiation may be used to break high−molecular weight chains to allow faster degradation and clearance in vivo, whereas partial oxidation such as with sodium periodate

increases susceptibility to hydrolysis. There is also interest in derivatization reactions on the polysaccharide backbone that enable, for example, hydroxyapatite nucleation and growth for bone tissue engineering applications and anticoagulation properties through the attachment of heparin [57].

Agarose

Agarose is also a polysaccharide that originates from sea algae; it is composed of repeating units of 3,6-anhydrous-L-galactose and D-galactose [58]. The agarose gels involve a rigid network that is porous and may be used for drug and gene delivery [59]. They can polymerize in situ and are attractive in the context of therapies for central nervous system injury and disease, where they support neurite extension [60]. It is also significant that agarose can form interpenetrating networks with some synthetic hydrogels, such as PEG diacrylate, into which bioactive molecules such as RGD peptides or aggrecan can be covalently immobilized or physically entrapped [61].

Chitin and Its Derivatives

Chitin was first prepared from the cuticle of beetles, from which it derives its name. It is widely distributed in both animals and plants, and is in the shells of crustaceans and mollusks, the backbone of squid, the cell wall of many fungi, within marine diatoms, and so on. Chitin is a linear polysaccharide of β-(1−4)-2-acetamido-2-deoxy-D-glucopyranose, where all the residues are composed entirely of *N*-acetyl-glucosamine: that is, it is fully acetylated. Chitosan is a derivative of chitin, which is a linear polymer of β-(1−4)-2-amino-2-deoxy-D-glucopyranose, in which all of the residues are composed entirely of *N*-glucosamine, which is fully deacetylated. In nature, it is rare for the material to exist as either pure chitin or pure chitosan, and the natural biopolymer will be a copolymer of the two. Generally, when the number of acetamide groups exceeds 50%, the material is referred to as chitin, and the actual percentage is termed the degree of acetylation. Conversely, when the amino groups dominate, the material is referred to as chitosan.

The dry shells of animal sources such as crabs and lobsters contain 20%−40% chitin; the remainder is proteins and calcium carbonate. Demineralization and deproteinization steps are used in the process to prepare raw chitin products. Chitosan can be prepared from the chitin by deacetylation methods involving sodium hydroxide. Moreover, chitosan is able to form a gel by itself without the need of additives. That may happen via hydrogen bonds, hydrophobic interactions, and chitosan crystallites. These hydrogels can also be formed by blending chitosan with other water-soluble nonionic polymers [62] or polyol salts. Because it is polycationic in nature under acidic conditions, chitosan can also form hydrogels through interaction with negatively charged molecules [63]. In addition, the gelation of chitosan could also be obtained through covalent bonding between polymer chains. These bonds make the hydrogel more stable because the gelation is irreversible.

Chitin can exist in three polymorphic states (the α, β, and γ forms); α-chitin is the most common. The biostability varies with the source of the material, the crystallinity, and the degree of acetylation. Chitosan hydrogels are pH-sensitive; they are soluble in dilute aqueous conditions and precipitate into a gel at neutral pH. Generally, chitosan is susceptible to enzymatic degradation. Within animal species, a variety of chitinases are able to break the chitin down into oligosaccharides, which can then be degraded by enzymes such as β-*N*-acetyl-glucosaminidase to yield *N*-acetyl-glucosamine. Similar mechanisms exist for the degradation of chitosan to *N*-glucosamine.

In neuronal repair, chitosan is commonly used to produce tubular structures, such as in the peripheral nervous system [64]. However, chitosan hydrogels have also been applied in neural tissue engineering. For instance, the use of chitosan−glycerophosphate salt hydrogels showed that this type of gel provides a suitable 3D environment for neurons. The addition of peptides such as poly-D-lysine may improve scaffold biocompatibility and nerve cell affinity for chitosan materials (Fig. 36.8).

Cellulose

Cellulose is a linear polymer of β-(1,4)-D-glucose units. It is the main component of the primary cell wall of plants. It forms as crystalline microfibrils that encapsulate the cell with a mesh-like structure, and controls, along with hemicellulose, pectin, and lignin, the mechanical properties of the plants. There is interest in using some derivatives of cellulose as biomaterials in scaffolds and drug delivery systems, for example. Microbial cellulose is a polymer that is synthesized be *Acetobacter xylinum*, a simple gram-negative bacterium. During the synthesis, various carbon compounds are used by the bacteria, polymerized into single linear β-1,4-glucan chains, and then secreted through pores to the cell exterior. These chains then self-assemble into subfibrils and then microfibrils and bundles, which yields a highly 3D crystalline structure with considerable mechanical strength. This nanostructure results in a large surface area that can hold a large amount of water. It can be prepared as a gelatinous membrane that is highly nanoporous. It may be treated with strong bases at elevated temperatures to remove the cells that are embedded in the cellulose

net; it is free of lignin and hemicelluloses so that the final material should be nonpyrogenic, noncytotoxic, and nonimmunogenic. It has shown considerable potential, with support from clinical evidence, for uses in wound healing and possibly as a tissue engineering scaffold. Economic large-scale fermentation systems have been difficult to optimize, which has restricted commercial applications so far.

Proteins and Peptides

Notwithstanding the challenges of purity and consistency mentioned earlier, a wide variety of proteins and their derivatives have been developed as biomaterials, which may be used in several different ways. Most proteins that are used as biomaterials are based on those found in mammalian tissue. These include the structural proteins collagen and elastin, and also some that are derived from plasma proteins, including fibrin and fibrinogen. These structural proteins could be used in what is essentially their natural form: that is, as the mammalian tissues themselves, with varying degrees of processing. Alternatively, they may be extracted from such tissues and subjected to some form of purification and reconstitution. Also, because of the inherent variability in such products, it may be possible to prepare the materials by recombinant technologies. There are some generic and important differences between the reconstituted and recombinant forms of protein biomaterials. In the former case, there is always a risk of contamination with prions and viruses, but this risk is not present with recombinant proteins. The latter are fully characterized, consistent, and reproducible, whereas the former depend on the source quality and batch-to-batch variability may be high. From the perspective of commercial manufacturing, recombinant proteins will usually be expensive but are amenable to proprietary processes that can be protected by patents and trademarks, which is not as readily applicable to the natural products.

Collagen and Its Derivatives

Collagen may be prepared in various forms of gel for tissue engineering applications, including those with the ability to form in situ. Many of these applications involve unmodified collagen; chemical cross-linkers can be used to inhibit degradation and resorption when necessary.

Collagen in one form or another has been used as a biomaterial for many years. Catgut sutures, which are rarely used now, were the mainstay of surgical wound closure for a long time and were made from the collagen of bovine intestines. Purified collagen has been used in injectable form as a tissue filler for both functional (vocal chords and urethra) and cosmetic (facial) effects. Some of these products are xenogeneic; they are derived from bovine dermis, for example, whereas others are allogeneic and are obtained from cultured human dermal fibroblasts or from human cadavers. Formulations vary considerably. Some are simple suspensions (at less than 5%) in buffered saline. Others

are prepared as micronized particles contained in syringes that are hydrated just before use. Depending on the source of the collagen, these products have the potential to be immunogenic. A small number of patients show immunological intolerance. Procedures usually involve prior testing of sensitivity. The collagen filler becomes incorporated into the patient's tissue, but some volume loss will occur over time.

The precise biochemical characteristics of the collagens used in these products are not significant because the material simply acts as a space filler. The applications of collagen in tissue engineering, wound healing, and drug delivery are more dependent on these characteristics. The structural order of collagen occurs at several different levels, and there are many different forms of the protein in mammalian tissue. Of relevance here is the need to balance the mechanical properties and biological activity of the products; this balance will change with the specific type of collagen.

At this stage, collagen types I and III, alone or combined, are most commonly used in products of regenerative medicine. Conduits for peripheral nerve repair are good examples. There are products made from type I or mixed types I and III in clinical use. These have different structures; some conduits are homogeneous fibrillar structure whereas others have heterogeneous structures with concentric cylindrical structures. The materials are processed in ways to minimize antigenicity, such as by cross-linking or the enzymatic removal of antigenic nonhelical telopeptides. Degradation rates vary from a few months to a year or so. In some situations, the collagen may be copolymerized, such as with GAG molecules. Collagen type I is also used in a number of products in bone tissue engineering, although not on its own. It is usually combined with hydroxyapatite or tricalcium phosphate, either as a reinforced composite or as phosphate-coated collagen fibrils.

It was noted earlier that recombinant collagen may have some advantages over animal- or human-derived materials. A number of methods are available for recombinant collagen production. This occurs in bioreactor-based eukaryotic systems, mammalian cell culture, insect cell culture, and many other systems. However, the best results and the formation of collagens most appropriate for human regenerative medicine applications are obtained with mammalian cells transfected with collagen genes, in which hydroxylated full-length collagens are produced. Recombinant human collagen of types I, II, and III can be reconstituted into fibrils that can be processed into forms such as fleeces, 3D gels, and sponges, in which it is anticipated that type I will be used in bone tissue engineering, type II in cartilage, and type III in vascular tissues.

In general, collagen products used in medical technology are structural materials rather than gels [65]. Antoine et al. reviewed the specific features of type I collagen that are associated with its use as a hydrogel in tissue environments [66], especially in relation to the encapsulation of viable cells in the constructs. As alluded to earlier, the properties of collagen biomaterials are variable, depending on a large number of fabrication parameters, and this is especially relevant for collagen hydrogels. The collagen source is particularly influential, with marked differences between animal sources (e.g., murine, porcine, bovine) and tissue types (tendon, skin, etc.) The method by which the collagen is extracted from the tissue is also critical. Acid solubilization is usually used for minimally cross-linked collagens whereas a combination of neutral salt solution with proteolytic digestion is needed for highly cross-linked collagens to denature them fully. The polymerization temperature affects the properties of the resulting hydrogel, with more rapid self-assembly and therefore less ordering as the temperature increases; the temperature used will reflect the need to avoid cell damage. Collagen concentration is also important, although correlations between this and resulting mechanical properties are not clear. As with the temperature, the pH is influential; cell viability will be negatively affected if the pH is outside the range 7.4–8.4, so the better properties that may be achieved at the extremes of pH are not relevant.

Gelatin is obtained by the partial hydrolysis of collagen obtained from bone and other connective tissues of animals. When obtained under acid conditions, it is known as type A gelatin, and under alkaline conditions as type B. It is used in foodstuffs and in many pharmaceutical formulations. It is also used as a gel to provide an initial seal within vascular grafts, in which situation it may also be a drug carrier, such as in the delivery of antibiotics.

Elastin Derivatives

Elastin is the dominant protein of elastic tissue fibers; as such, it is an important component of the ECM of tissues, such as those of the lungs, skin, and blood vessels, which depend on elasticity for their function. It is derived in vivo from cross-linking of the tropoelastin monomer and is essentially insoluble. The tropoelastin/elastin molecules have hydrophobic regions from which the resulting elasticity is derived, and hydrophilic regions, which provide sites for amine-dependent cross-linking and biological signaling. The elastin possesses a number of peptide motifs that are able to influence cell behavior, including proliferation and differentiation. Such interactions take place through several cell-surface receptors, including the elastin-laminin receptor. The signaling of cells in wound healing by elastin controls the relative activity of dermal fibroblasts and contractile myofibroblasts and hence determines the mechanical properties of the subsequent repaired skin.

The insolubility of elastin, which restricts processing, and its relatively poor strength, has limited the practical applications of this protein in biomedical applications. Thus, elastin-like or elastin-based materials have attracted more attention [67]. There are solubilized forms of elastin, including α-elastin, which is obtained under acid conditions, and κ-elastin, which is obtained under alkaline conditions. Recombinant techniques have allowed the preparation of materials that are able to mimic the important and desirable regions of the elastin. Synthetic analogs of elastin may also be prepared from the aqueous processing of replicas of tropoelastin. Many of these substances are amenable to scale-up manufacture, giving a range of elastin-derived products for biomedical uses. For tissue engineering applications, many of these derivatives may be processed by electrospinning or prepared as hydrogel matrices. It is also possible to prepare blends involving elastin derivatives and other proteins, such as silk and collagen.

Desai et al. discussed critical issues with elastin-based hydrogels [68] and noted that many applications requiring large and repeated deformations can benefit from rubber-like elastomeric hydrogels; there are examples in regenerative medicine that come into this category. However, hydrogels generally lack sufficient strength and elastic extensibility owing to cross-link inhomogeneity in the networks. Short, uneven intercross-link distances and poor chain extensibility limit the ability of the hydrogels to stretch. Various strategies have been used to improve hydrogel properties, such as extensibility and toughness through physical bonds. However, time-dependent recovery of physical cross-links in these hydrogels results in high hysteresis and stress softening that can lead to a loss of performance under repeated deformation. Creating a rubber-like elastomeric hydrogel requires control over the architecture of the cross-linked network, which should be homogeneous, and a careful choice of polymer. The chain length between cross-links should be constant to avoid local concentrations of stress, whereas the cross-linking scheme should ensure proper chain incorporation to avoid dangling chains that do not participate in the elastic network. Ideally, the polymer should behave like an entropic spring that recoils once unloaded, in which the driving force restoring an entropic spring is an increase in entropy as the chain goes from a stretched state with limited movements to a coiled state. Protein-based polymers may provide opportunities for engineering hydrogels with these network and polymer properties. To create elastomers, elastin-like polypeptide (ELP) sequences provide a natural choice because they have been characterized as entropic springs. ELPs are built on a repetition of the pentapeptide Val-Pro-Gly-X-Gly with a guest residue "X" that cannot be proline. They are thermoresponsive and undergo the process of inverse temperature transition in which they transition reversibly from a hydrophilic to a hydrophobic state. Thermodynamic factors including the hydrophobic interactions within the chains keep the polypeptides in an unstructured coil form after the transition and have a role in the elastomeric nature of the polypeptides. These elastomeric hydrogels are clearly interesting for tissue engineering applications.

Fibrin Derivatives

Fibrinogen is a soluble protein in blood that is converted to an insoluble fibrin network in the presence of thrombin during coagulation. The fibrinogen has three pairs of polypeptide chains that are joined by disulfide groups. The central domain contains fibrinopeptides A and B, which are cleaved in the presence of thrombin to form the fibrin monomer. These monomeric units form two-stranded fibrils that undergo covalent cross-linking to form the fibrin network, a process that is facilitated by $CaCl_2$. This process can be recapitulated artificially in biomaterial products, generally known as fibrin glues or fibrin sealants, in which separate preparations containing fibrinogen and thrombin are mixed just before application at sites of surgical injury, such as during cardiopulmonary bypass, to assist in sealing tissue defects such as fistulae and facilitate tissue repair as in peripheral nerves.

It is possible for fibrin glue to be derived from autogenous or allogeneic blood, although the latter is more common in commercial products. Blood components are obtained from the blood and undergo various screening and purification procedures, especially when pooled blood is involved. Fibrinogen may be isolated from the blood using centrifugation and cryoprecipitation. Typically, sodium citrate solution is added to the blood to anticoagulate it before centrifugation. The cryoprecipitation procedure may be carried out by a variety of regimes, usually using temperatures between $-20^{\circ}C$ and $-80^{\circ}C$. $CaCl_2$ and aprotinin are added to the solutions to optimize the gelation of the fibrinogen and thrombin solutions once mixed.

The role that fibrin has in response to the injury of vascularized tissue may also be recapitulated in the formation of tissue engineering scaffolds, which have been used in many experimental systems involving several different tissues. Fibrin hydrogels prepared, as discussed earlier, from commercially purified allogeneic fibrinogen and thrombin have some attractive features but are not ideal. Mechanically, they are weak and not stiff, and they have a tendency to degrade quickly. The gels also undergo considerable shrinkage during formation. In addition, the fibrin is not particularly active biologically in this format. Several procedures may be used to modify the gel to obtain better performance. Shrinkage may be minimized by incorporating poly-L-lysine. Using a variety of synthetic polymers or calcium phosphate additions, composite or copolymer scaffolds may improve the mechanical

properties. Cross-linking agents may improve stability. In addition, biologically active peptides or therapeutic proteins can be incorporated into the hydrogels, such as by incorporating functionalized PEG. Najjat et al. showed that it is possible to engineer fibrin gels incorporating proangiogenic growth factors that are able in a murine model to promote the engraftment of pancreatic islets in extrahepatic sites [69].

Silk

Silks are proteins that are synthesized by Lepidoptera larvae such as silkworms and spiders. They are biosynthesized in epithelial cells and secreted into the lumen of specialized glands, where they are stored and subsequently spun into fibers. The properties of silk vary considerably with their source, with different amino acid sequences and mechanical properties that are fine-tuned to their specific function. The most widely used and investigated silks with respect to biomaterials applications are derived from the domesticated silkworm, *Bombyx mori*, and from spiders such as *Nephila clavipes* and *Araneus diadematus*.

Silkworm silk is popular and has been used for medical devices such as sutures for many years; for general textiles, it has been used even longer. This silk has two major fibroin proteins, light (25-kDa) and heavy kDa chains, where the core sequence repeats include alanine-glycine with serine or tyrosine. These core fibers are encased in the glue-like sericin protein. Spider silk proteins range from 70 to 700 kDa; many such silks are characterized by polyalanine and glycine regions. Spider silk is not easy to harvest, and much emphasis has been placed on the use of genetic engineering techniques to produce synthetic versions. Cloning and expression of silks has been achieved in a number of host systems, because the sequences of complementary DNA and genomic clones encoding spider silks show highly repetitive structures that can be used to construct genetically engineered spider silk–like proteins.

Silk fibers have significant hydrophobic regions and high crystallinity with extensive hydrogen bonding, which give good environmental stability and mechanical properties. They are insoluble in most solvents including water. The crystallinity results from the presence of small β -sheets within the fibers. *B. mori* silk can have an ultimate tensile strength of 740 MPa, a Young's modulus of 10 GPa, and a 20% strain at break. Spider silk may have values of 950 MPa, 12 GPa, and 18% respectively.

The biocompatibility of silk products varies, largely because of the varying levels of nonfibroin components such as the sericin. When used as a suture material, silk elicits a greater inflammatory response than do most synthetic polymers. Although it is classified as nonabsorbable, it degrades slowly. Silk fibers losing their tensile strength over a year or so. Proteases such as chymotrypsin can cleave proteins to peptides, especially in amorphous regions. Various silks have found utility in tissue engineering applications because they are often able to support cell growth [70].

As discussed by Melke et al., silk fibroin can be used in several different formats in tissue engineering [71]. Sponges made by freeze-drying or porogen leaching techniques are easily produced and give good porosity, although the precise design of architecture is difficult. Fibers may be prepared by electrospinning, although reproducibility is problematic. 3D printing is used, with controllable geometry and cell encapsulation, although with low resolution. The hydrogel format (Fig. 36.9) is probably the most versatile; there are opportunities for in vivo injectable cell-encapsulation applications, although the small pore size is a disadvantage.

Self-assembled Peptides

An increasingly important class of hydrogels for regenerative medicine is those made from self-assembled peptides [72]. These are polypeptides that assemble under specific conditions to form nanoscale structures. One prominent example is the class of self-assembled peptides made from amphiphilic molecules, derived from polypeptides linked to a polycarbon chain. The polypeptide region is typically hydrophilic whereas the hydrocarbon chain is hydrophobic. They can self-assemble into rod structures because of the arrangement of the hydrophobic regions as well as the charge shielding of the hydrophilic end groups by ionic molecules in the solution. These molecules can be decorated with functional groups to facilitate cellular adhesion and signaling. A number of other self-assembling peptides have been produced with advantages such as the ease in which gels are formed and functionalization. They tend to be mechanically weak.

The significance of these engineered peptide hydrogels is that they epitomize this direction toward materials that can replicate cell niches, referred to earlier as the most important specification for tissue engineering templates. Considering the stem cell niche in particular, these contain ECM components such as laminin and hyaluronan, which present cell-adhesion ligands, and soluble factors such as cytokines and growth factors, with a constantly replenished supply of differentiation cues. Peptide materials can be designed at a molecular level to bestow combined structural and biological activity characteristics that start to address these niche characteristics. These engineered, self-assembled peptides contain relatively short chains of amino acids. Through the careful choice of amino acid monomer sequences, the peptides can fold into secondary structures such as β-sheets, which themselves

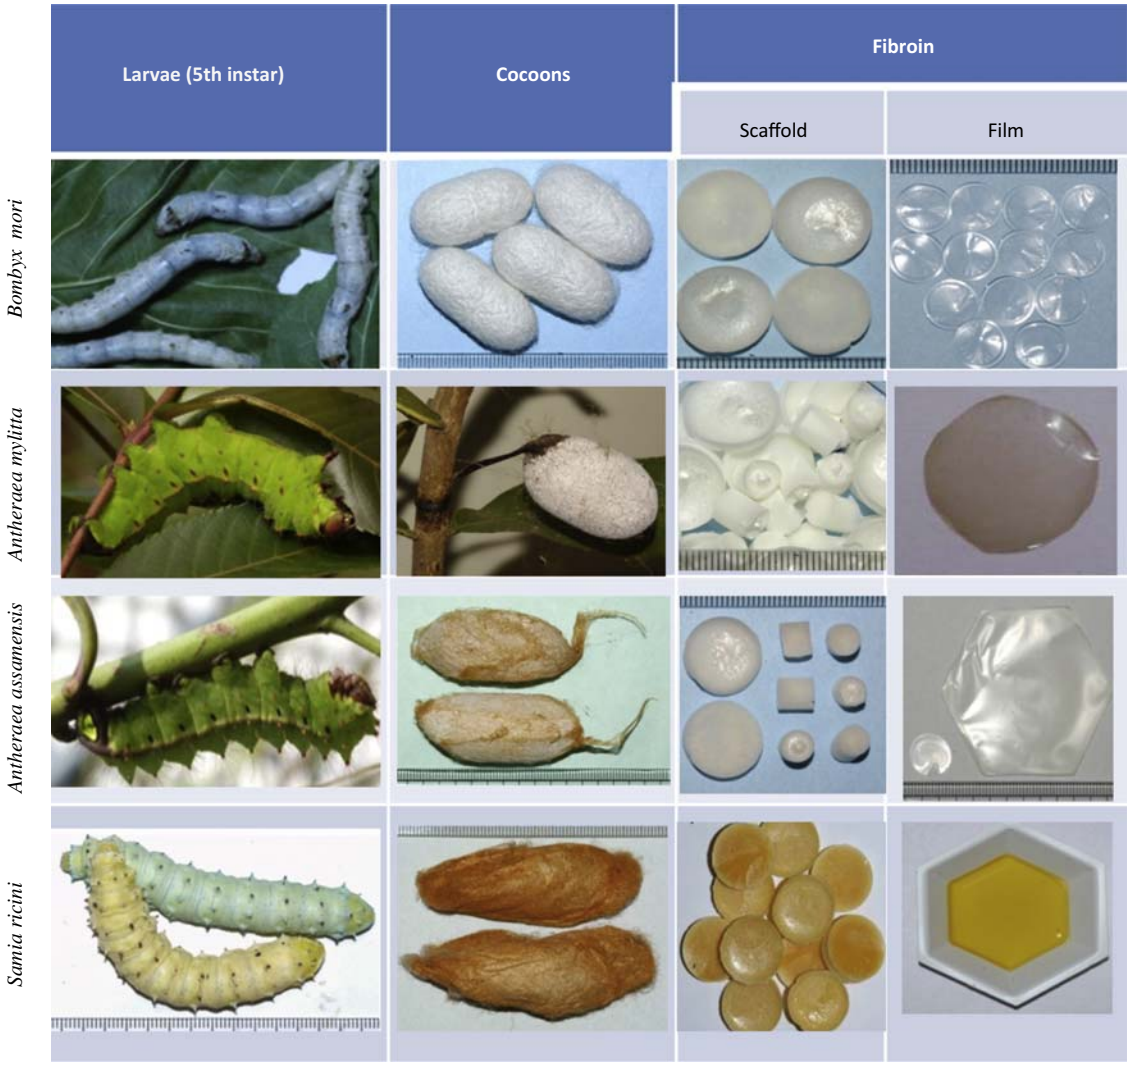

FIGURE 36.9 Different silkworms and silk-derived biomaterials. Sericin can also be fabricated into different biomaterials such as scaffolds, films, hydrogels, nanofibers, and particles. Images courtesy of Professor Kundu, Indian Institute of Technology Kharagpur, India.

self-assemble into hierarchical structures such as fibers and micelles. These fibrous hydrogels replicate the required cell niches far better than do other materials. It is possible that such structures may be reinforced by other nanoscale structures to give robust templates.

Several forms of self-assembled peptides have reached advanced stages of development, with good biocompatibility and degradation properties and without immunogenicity [72]. B-strand peptides, which assemble into discrete β-sheets, appear to be favored. For example, templates consisting of alternating amino acids that contain 50% charged residues may be prepared. The β-sheets have distinct polar and nonpolar surfaces; included here are several self-assembling peptides such as RAD16-I and RAD16-II, in which stable macroscopic matrix structures can be fabricated through the spontaneous self-assembly of aqueous peptide solutions introduced into physiological solutions. Such peptide structures support the cell attachment of a variety of mammalian cells.

SYNTHETIC HYDROGELS FOR TISSUE ENGINEERING TEMPLATES

An informed discussion about the current situation with synthetic hydrogels in tissue engineering is problematic; despite a vast amount of research and development in this area, and although such hydrogels have a reasonably good record in drug delivery systems, there has been little progress in introducing them into clinical tissue engineering products.

One important consideration is that of intrinsic biocompatibility. It is recognized that the chemicals used in preparing hydrogels may have some toxicity, and care has to be taken if the degree of conversion is not 100%; initiators, organic solvents, stabilizers, emulsifiers, unreacted monomers, cross-linking agents, and other substances have to be considered in this light and such chemicals may need to be removed. Synthesis typically should be followed by purification processes such as solvent washing or dialysis. When any of the materials are derived from natural sources, they may carry the risk of batch-to-batch variation, which also has to be taken into account. Synthetic hydrogels have some important advantages over natural biopolymer-based hydrogels, including easier large-scale production and fine-tunable and consistent properties. However, many are made using harsh synthetic chemistry, which requires care to ensure that contaminants and unreacted reagents present during synthesis are then removed. Reaction schemes for these hydrogels often rely on multifunctional cross-linking agents. Free radical polymerization is widely used with many tissue engineering systems that require in situ formation.

The main difficulty, as pointed out several times in this chapter, is that truly synthetic hydrogels usually do not have the biological functionality to provide for the specifications that have been defined for template materials. Thus, many of the newer developments have addressed this major deficiency by introducing functionalization methods and using hybrid or composite structures, often through blending or copolymerization with one of more of the biopolymers discussed earlier. Following the pattern of the Bioactive Forms of Poly(ethylene Glycol) as Exemplars of Increasing Sophisticationsection, the experiences with PEG may be used as an example.

PEG is a diol with two hydroxy end groups; it is formed by linking repeating units of ethylene glycol. The versatility arises from two facts; first, it has linear and branched forms' and second, these end groups can readily be functionalized, such as through carboxyl, amine, thiol, or azide groups. These functional end groups can be symmetric or asymmetric. The latter option is effective because it enables simultaneous but different properties to be achieved. A popular form of PEG is the four-arm-PEG, but other geometries are possible.

The versatility is also facilitated by the possibility of cross-linking by different methods under different conditions. Free radical polymerization, condensation reactions, enzymatic reactions, and click chemistry can all be used, but the most common cross-linking procedure is photopolymerization. This allows the conversion of liquid to solid state under ambient physiological conditions in situ, with good spatial and temporal control and with the possibility of the simultaneous incorporation of biological species or active agents. Best results are normally achieved through the use of acrylates such as diacrylates or dimethacrylates as the macromers. PEG is normally nonbiodegradable and has little intrinsic biological reactivity; a major use of PEG is as a coating to minimize protein adsorption to surfaces. Unmodified PEG is unattractive for tissue engineering applications because of the lack of support for cell function.

PEG itself, in a low−molecular weight, unmodified form, has a number of mundane medical uses, largely as over-the-counter preparations such as laxatives and skin moisturizing agents. The real attraction of PEG as a biomaterial is associated with its combination with other molecules. There are two main scenarios here: either the PEG is used to surface modify a structure to provide or hide properties, or other molecules are used to modify PEG hydrogels to capitalize on the hydrogel characteristics but provide some specific biological activity. The first of these options is referred to as pegylation. There are many examples ranging from pharmaceutical molecules to nanoparticles. It has long been known that pegylation of protein and polypeptide drugs can alter both their pharmacokinetic and pharmacodynamic properties, such as by increasing water solubility, minimizing cytotoxicity, and reducing renal clearance. At its simplest, PEG makes the drug molecule larger; each ethylene glycol subunit is tightly associated with two or three water molecules, which makes the pegylated molecules appear up to 10 times larger than the unmodified molecule. The PEG acts a shield around the molecule, protecting it from degradation and rapid clearance. The effect may be much more subtle, depending on the chemistry involved. For example, the bond between the PEG and the drug molecule may be intentionally unstable to improve targeting, such as when the bond is cleavable by enzymes within the endosomal compartment of cells, which releases the peptide or protein molecule within the cell.

Bioactive modification of PEG hydrogels for tissue engineering applications may facilitate cellular function. A variety of ECM protein-derived cell-adhesive molecules may be incorporated into the hydrogel to increase cell adhesiveness. The hydrogels may be made degradable by incorporating hydrolytically or enzymatically susceptible segments. Growth factors that have been functionalized may be covalently attached to the PEG hydrogels, especially those that involve multithiol or multiacrylate groups.

PEG has been combined with a variety of nonhydrogel biodegradable polymers such as poly(glycolic acid) [73] and reinforced with fibrous collagen [74]. Carbon nanotubes (CNTs) have also been used to create hydrogel composites [75]. CNTs can impart electroconductivity to otherwise insulating materials, improve mechanical stability, guide

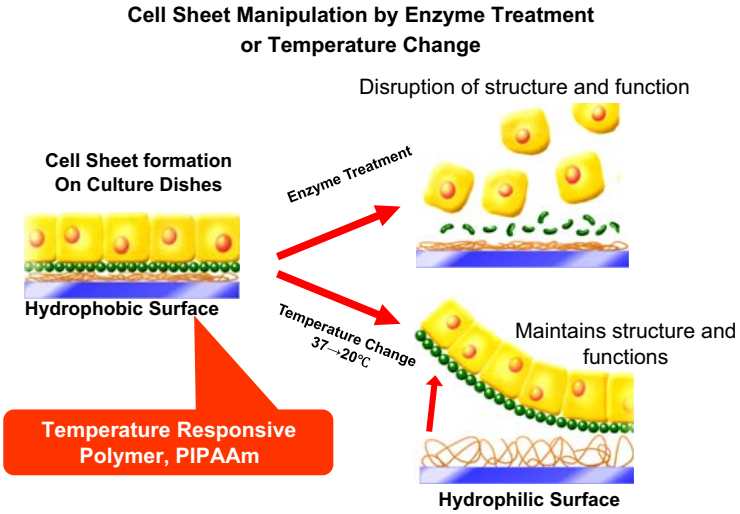

FIGURE 36.10 Principles of cell sheet engineering. Conventional techniques to release cells from biomaterials surfaces using enzymes result in disruption of the cells. Techniques of cell sheet engineering, which involve a change in the hydrophobic–hydrophilic balance of a thermally responsive hydrogel such as poly(*N*-isopropylacrylamide) (PIPAAm), produce the release of sheets of cells without disruption. *Courtesy of Professor Teruo Okano, Institute of Advanced Biomedical Engineering and Science, Tokyo Womens Medical University, Japan.*

neuronal cell behavior, and elicit axon regeneration. A PEG hydrogel composite was prepared in which the CNTs were entrapped in the hydrogel phase during gelation. The hydrogel cross-linking reaction was based on Michael-type addition, which is ideal for in situ cell and protein encapsulation, and in which sonication and surfactants were used to disperse the highly hydrophobic CNTs in the aqueous polymer solution. The inclusion of the CNTs impeded hydrogel crosslinking leading to longer gelation times, higher swelling and porosity, and lower storage modulus above a threshold CNT concentration. Unlike the PEG hydrogel alone, the PEG–CNT hydrogel composite was capable of supporting high neural cell viability in which the CNTs provided sites for cell attachment.

As a final point, mention should be made of thermoresponsive hydrogels, which have potential uses in regenerative medicine. Poly(*N*-isopropylacrylamide) (pNIPAAm) is a good example [76]; it is a polymer with lower critical solution behavior in aqueous solvents and a lower critical solution temperature (LCST) around 32°C. During the phase transition, the polymer chains undergo a change in conformation from an extended coil to a globular structure. The LCST of *N*-isopropylacrylamide (NIPAAm)-based polymers can be increased with copolymerization with more hydrophilic monomers, resulting in a transition temperature close to physiological, which can be useful in medical applications, including drug delivery, tissue engineering, and cell sheet engineering. The homopolymer of NIPAAm is not biodegradable, and many studies have focused on imparting biodegradation by adding various monomers into the polymer structure, such as by copolymerizing NIPAAm with benzomethylene dioxepane.

The development of in situ–forming materials with a dual solidification mechanism, a physical gelation imparted by NIPAAm and a covalent cross-linking reaction, is interesting. The dual gelation mechanism results in hydrogels with significantly enhanced mechanical properties compared with hydrogels solidified only by physical or chemical means. Covalent cross-linking mechanisms include Michael-type addition between thiols and vinyl groups, functionalization of thermogelling macromers with (meth)acrylate groups, cross-linking with a thermal initiator, and epoxy functionalities reacting with amines.

Substrates based on NIPAAm have been also used to fabricate cell sheets. When heated above the transition temperature, the hydrophobic nature of pNIPAAm favors cell attachment. The LCST of the pNIPAAm-based polymer can be fine-tuned to be below cell culture temperatures. When the temperature is lowered below the LCST, the polymer surface becomes more hydrophilic and cells can be harvested in a confluent monolayer (Fig. 36.10). This process eliminates the use of proteolytic enzymes or mechanical means for cell detachment from cell culture surfaces [77].

CONCLUSIONS

Much progress has been made in the development of hydrogels as templates in tissue engineering and regenerative medicine. However, there is a long way to go. The ultimate aim is to create templates that can meet all of the specifications set out in the early parts of this chapter, especially concentrating on replicating all of the characteristics of the ECM. Although hydrogels are superior to porous solid biomaterials in this respect, the architectural and

functional requirements are exacting. Most synthetic hydrogels are too far removed from ECM characteristics for us to have serious expectations for their scientific and clinical success. Natural biopolymers have many advantages, but they still have limitations. Hybrid, composite, and functionalized structures are showing attractive properties in many situations.

INTRODUCTION

Biomaterial Interfaces in Regenerative Medicine

Biomaterials, whether synthetic (e.g., polymers, metals, ceramics) or natural (e.g., proteins polysaccharides), have central roles in tissue engineering and regenerative medicine applications by providing three-dimensional scaffolds to support cellular activities, matrices for the delivery of therapeutic agents (e.g., drugs, proteins, DNA, small interfering RNA), and functional device components (e.g., mechanical supports, sensing/stimulating elements, nonthrombogenic surfaces, diffusional barriers). The bulk properties of the biomaterial are critical determinants of the biological performance of the material [1]. For example, the mechanical properties of a vascular substitute, including elastic modulus, ultimate tensile stress, and compliance, dictate the ability of this tissue construct to support the applied mechanical loads associated with blood flow. On the other hand, the biological response to a biomaterial is governed by the material surface properties, primarily surface chemistry and structure. Protein adsorption or activation and cell adhesion, events that regulate host responses to materials, occur at the biomaterial–tissue interface, and the physicochemical properties of the material surface modulate these biological events [2,3]. For instance, the chemical properties of the surface of a vascular substitute control blood compatibility (i.e., protein adsorption, platelet adhesion, thrombogenicity, patency). Hence, modification of biomaterial surfaces represents a promising route to engineer biofunctionality at the material–tissue interface to modulate biological responses without altering material bulk properties.

Overview of Surface Modification Strategies

Numerous surface modification approaches have been developed for all classes of materials to modulate biological responses and improve device performance. Applications include the reduction of protein adsorption and thrombogenicity, control of cell adhesion, growth and differentiation, modulation of fibrous encapsulation and osseointegration, improved wear and/or corrosion resistance, and potentiation of electrical conductivity [1]. Surface modifications fall into two general categories: (1) physicochemical modifications involving alterations to the atoms, compounds, or molecules or topography on the surface; and (2) surface coatings consisting of a different material from the underlying support. Physicochemical modifications include chemical reactions (e.g., oxidation, reduction, silanization, acetylation), etching, and mechanical roughening or polishing and patterning (Fig. 37.1). Overcoating alterations are composed of grafting (including tethering of biomolecules), noncovalent and covalent coatings, and thin-film deposition (Fig. 37.2).

Whereas the specific requirements of the surface modification approach vary with application, several characteristics are generally desirable. Thin surface modifications are preferred for most applications because thicker coatings often negatively influence the mechanical and functional properties of the material. Ideally, the surface modification should be confined to the outermost molecular layer (~10–15 Å), but in practice, thicker layers (10–100 nm) are used to ensure uniformity, durability, and functionality. Stability of the modified surface

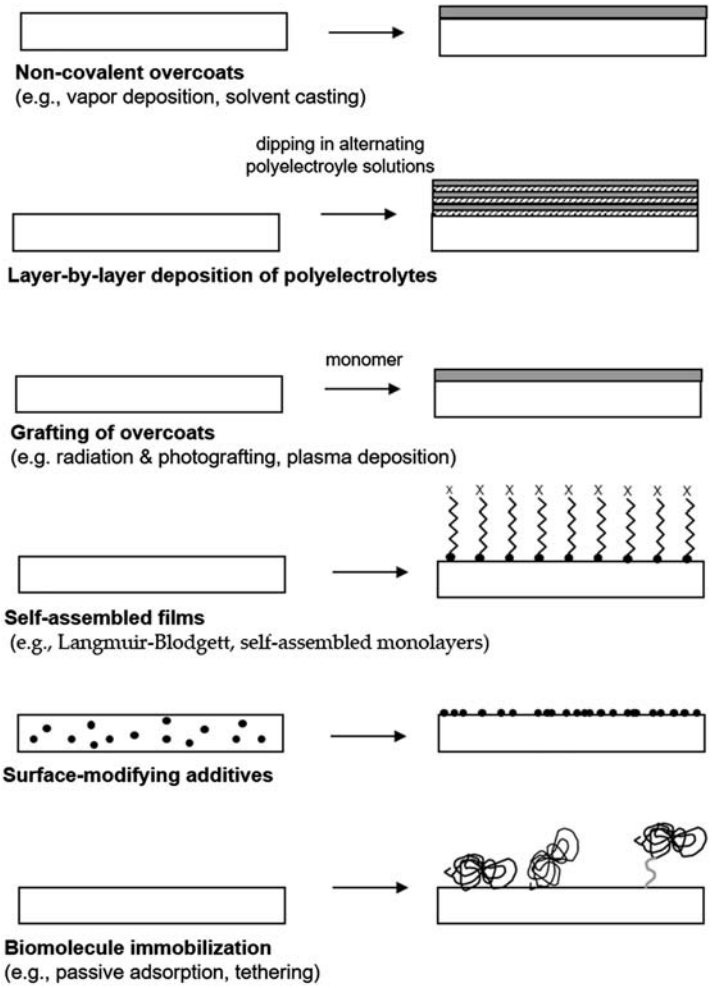

FIGURE 37.2 Schematic representations of common overcoating technologies for surface modification.

is a critical requirement for adequate biological performance. Surface stability refers to mechanical durability (i.e., resistance to cracking, delamination, and debonding) but also to chemical stability, especially in aggressive, chemically active environments such as the biological milieu. Several types of surface rearrangements, such as translation of surface atoms or molecules in response to environmental factors and mobility of bulk molecules to the surface, and vice versa, readily occur in polymers and ceramics after exposure to biological fluids.

Given the uniquely reactive nature and mobility or rearrangement of surfaces, as well as the tendency of surfaces to contaminate readily, rigorous analyses of surface treatments are essential to surface modification strategies. Surface analyses technologies generally focus on characterizing topography, chemistry or composition, and surface energy [4] (Table 37.1). Important considerations for these surface analyses technologies include operational principles (impact of high-energy particles or X-rays under ultrahigh vacuum, adsorption, or emission spectroscopies), depth of analysis, sensitivity, and resolution. For most applications, several analyses techniques must be used to obtain a complete description of the surface.

PHYSICOCHEMICAL SURFACE MODIFICATIONS

Physicochemical modifications involve alterations to the atoms, compounds, or molecules and/or topography on the material surface (Fig. 37.1).

Chemical Modifications

Countless chemical reactions, including UV and laser irradiation and etching reactions to clean, alter, or cross-link surface groups, have been developed to modify biomaterial surfaces [1]. Nonspecific reactions yield a distribution of chemically distinct groups at the surface; the resulting surface is complex and difficult to characterize owing to the presence of different chemical species in various concentrations. Nevertheless, nonspecific chemical reactions are widely used in biomaterials processing. Examples of nonspecific reactions include radio-frequency glow discharge in different plasmas (e.g., oxygen, nitrogen, argon), corona discharge in air, oxidation of metals, and acid–base treatments of polymers. In contrast, specific chemical reactions target particular chemical moieties on the surface to convert them into another functional group with minimal side (unwanted) reactions. Acetylation, fluorination of hydroxylated surfaces via trifluoroacetic anhydrides, silanization of hydroxylated surfaces, and incorporation of glycidyl groups into polysiloxanes are examples of specific chemical reactions. In addition, various chemical methods exist to tether biomacromolecules onto available anchoring groups on surfaces, as described in the Biological Modification of Surfaces section.

The reaction of metal surfaces to produce an oxide-rich layer that conveys corrosion resistance, passivation, and improved wear and adhesive properties (also referred to as conversion coatings) is a common surface modification in metallic biomaterials. For example, nitric acid treatment of titanium and titanium alloys to generate titanium oxide layers is regularly performed on titanium-based medical devices, and the excellent biocompatibility properties of titanium are attributed to this oxide layer [5]. Implantation of ions into surfaces by beaming accelerated ions has been applied to modify the surface properties of metals and ceramics. For example, ion beam implantation of nitrogen into titanium and boron and carbon into stainless steel improves wear resistance and fatigue life, respectively [6]. In addition, evidence suggests that ion beam implantation of silicone and silver can enhance the blood compatibility and infection resistance of silicone rubber catheters [7,8].

Topographical Modifications

The size and shape of topographical features on a surface influence cellular and host responses to the material. For example, surface macrotexture and microtexture alter cell adhesion, spreading, and alignment [9,10] and can regulate cell phenotypic activities, including neurite extension and osteoblastic differentiation [11,12]. Moreover, surface topography can have significant in vivo effects. For instance, the implant porosity modulates bone and soft tissue ingrowth [13,14], and the surface texture alters epithelial downgrowth responses to percutaneous devices and inflammatory reactions and fibrous encapsulation to materials implanted subcutaneously [15–17]. Although specific surface texture parameters that elicit particular biological responses have been identified in several cases, the mechanisms generating these behaviors remain poorly understood.

Methods for generating surface texture can be grouped into approaches for engineering either roughness or topography (Fig. 37.3). Surface *roughness* indicates a random or complex pattern of features of varying amplitude and spacing, typically on a scale smaller than a cell (10–20 μm). On the other hand, surface *topography* refers to

TABLE 37.1 Common Surface Analysis Techniques

	Principle	Operation	Spatial Resolution	Depth	Sensitivity	Texture	Chemical Composition			
							Elements	Compounds	Isotopes	Additional
Contact angle	Liquid wetting of surfaces	Air Liquid	NA	3–20 Å	NA	Indirect				Surface energy
Atomic force microscopy	Records interatomic forces between tip and sample	Air Aqueous	Atomic	NA	Single atom	Yes	No	No	No	
Scanning electron microscopy	Secondary electron emission caused by electron bombardment is imaged	Vacuum	40 Å	5–10 Å	High	Yes	No	No	No	Crystallinity

FIGURE 37.3 Surface roughness and topography.

patterns of well-defined, controlled features on the surface. Surface roughness has been traditionally modified via sandblasting, plasma spraying, chemical etching, and mechanical polishing; the nonspecific nature of these processes renders surfaces with random or complex topographies. Ion beam and electric arc (for conductive materials) texturing approaches have also been applied to modulate surface roughness. To generate controlled topographies, micromachining and nanomachining techniques have been exploited using silicon, glass, and polymers as substrate materials [10]. Photolithography combined with reactive plasma and ion etching has been extensively applied to generate surfaces with well-defined topographies. This technique enables the preparation of machined silicon and polymeric substrates and silicon templates that can then be used as molds to transfer features to polymers via solvent casting or injection molding. Similarly, *Lithographie, Galvanoformung, Abformung* electron beam and laser machining have been used to manufacture defined topographical features on various materials. Alternatively, hot-embossing imprint lithography represents a robust approach to the low-cost and rapid fabrication of microscale and nanoscale features on biomedically relevant polymers [18].

OVERCOATING TECHNOLOGIES

Coating strategies rely on the deposition of a surface layer consisting of a different composition from the underlying base material (Fig. 37.2). These surface modification approaches include noncovalent and covalent coatings [1].

Noncovalent Coatings

Major advantages of noncovalent coatings include simple application and the ability to coat a variety of different base materials. Examples of common noncovalent coating methods are solvent casting and vapor deposition of metals, parylene, and carbons. In the Langmuir–Blodgett deposition method, one or more highly ordered layers of surfactant molecules (e.g., phospholipids, amphiphiles) are placed at the surface of the base material via assembly at the air–water interface and compression of the surfactant molecules. Langmuir–Blodgett films exhibit high order and uniformity and provide flexibility in incorporating a wide range of chemistries. The stability of these films can be improved by cross-linking or internally polymerizing the surfactant molecules after film formation. Polymer coatings containing drugs can be applied by solvent dip-coating or spraying over the substrate. This is widely used to make drug eluting stents (Cypher, Cordis Corporation; and TAXUS, Boston Scientific Corporation) that result in a lower risk for restenosis [19]. However, coatings should be thin and mechanically stable because defects in such polymer coatings have potential risks for thrombosis and coronary microembolism [20]. Another surface modification strategy that takes advantage of intermolecular interactions is the deposition of multilayer polyelectrolytes (e.g., poly[styrene sulfonate]–poly[allylamine], hyaluronic acid–chitosan). In this simple layer-by-layer (LbL) method, a charged surface is sequentially dipped into alternating aqueous solutions of polyelectrolytes of opposite charge to deposit thin multilayers of a polyelectrolyte complex [21]. This technique enables the deposition of films on any topography and material in an aqueous environment. For instance, alternating layers of chitosan (positively charged) and hyaluronic acid (negatively charged) were deposited on titanium implants using LbL self-assembly and resulted in reduced bacterial adhesion because of the antibacterial properties of chitosan [22]. Another elegant strategy for surface modification is to use surface-modifying additives. These molecules are blended in the bulk material during fabrication but will spontaneously rise to and concentrate at the surface owing to the driving force to minimize interfacial energy; they have been shown to increase the hemocompatibility and stability of polymers such as polyurethane and poly(lactic-*co*-glycolic acid) [23]. Mussel-inspired surface modification strategies have gained significant interest. Mussels attach to all kinds of organic and inorganic surfaces using catechol groups on their adhesive proteins in aqueous environments [24]. Polymers containing catechol groups can be deposited by dip-coating in an aqueous solution to form the desired outer surface coatings over the base material.

Covalent Coatings

Covalent coating methodologies rely on direct tethering of overcoats onto the base material to improve film stability and adherence. Radiation grafting, with ionizing radiation and high-energy electron beams, and photografting have been extensively pursued to modify polymer substrates to introduce chemically reactable groups into inert hydrophobic polymers and polymerize overcoats onto the base support [1]. In principle, the radiation breaks chemical bonds in the base material into free radicals and other reactive species, which are then exposed to a monomer or presynthesized polymers. Use of presynthesized polymers is referred to as "grafting-to" approaches, and although it provides control over the molecular weight of the overcoat, the density of grafts is limited by the steric crowding of polymer chains. "Grafting-from" approaches involve a monomer reaction with the reactive species at the surface and propagation as a free radical chain reaction. Because of the use of low−molecular weight monomer, dense polymer brushes can be synthesized. These strategies enable the generation of a wide range of surface chemistries; unique graft copolymers can be synthesized by combining different monomers. Using such approaches, protein-resistant brush polymers can be produced on a variety of surfaces and can reduce bacterial colonization significantly. Plasma deposition (also referred to as glow discharge deposition) via radio-frequency or microwave has also been extensively applied to biomaterial surface modification [25]. In particular, radio-frequency glow discharge plasma deposition has received considerable attention because it can generate continuous conformal coatings (relatively free of pinholes and voids) that can be applied to many different types of supports (metals, ceramics, and polymers) with complex geometries. In addition, these films exhibit good adherence to the substrate and can be engineered to present different functionalities, although the resulting chemistry is complex and ill-defined. In contrast to these relatively low-energy/low-temperature plasmas, high-energy/high-temperature plasmas have been used to apply inorganic surface modifications onto inorganic substrates. For example, calcium phosphate ceramic particles such as hydroxyapatite have been deposited via flame-spraying onto titanium and cobalt chrome orthopedic implants to improve osseointegration [26].

Coatings consisting of self-assembled monolayers (SAMs) have gained significant attention as robust surface modification agents [27,28]. These films spontaneously assemble, form highly ordered, well-defined surfaces with excellent chemical stability, and provide a wide range of available surface functionalities. The basic structure of molecules that form SAMs is an anchoring "head" group, organic chain backbone, and functional "tail" group. Common SAM systems are alkanethiols on coinage metals (gold and silver), n-alkyl silanes on hydroxylated supports (glass and silica), and phosphoric acid or phosphate groups on titanium or tantalum surfaces. Assembly of these organic chains into highly ordered structures is driven by the strong adsorption of the anchoring "head" group of the monolayer constituent to the surface and van der Waals interactions of the backbone chains. The order and stability of the SAMs are strongly influenced by the length of the backbone chain; in the case of alkanethiols, molecules with backbones with 9−24 methylene groups assemble well on gold. Importantly, the terminal functional group is presented at the surface−solution interface and controls the physicochemical properties of the SAM.

BIOLOGICAL MODIFICATION OF SURFACES

Biomolecules (e.g., cell receptor ligands, enzymes, antibodies, pharmacological agents, lipids, nucleic acids) have been immobilized onto and within biomaterial supports for numerous therapeutic, diagnostic, and bioprocess applications. Table 37.2 lists examples of biological modifications to surfaces for biomedical and biotechnological applications. The rationale for these hybrid materials integrating synthetic and biological components is to convey biofunctionality and hence engineer materials that elicit desired biological responses or have attributes associated with biosystems. One of the earliest examples of this strategy is the immobilization of heparin onto polymer surfaces to improve blood compatibility. Drug-eluting stents (stents coated with a polymeric layer loaded with antihyperplasia drugs) have also been developed to reduce restenosis and improve patency. Another example of a widely used biological modification strategy is the immobilization of adhesive ligands, either adsorbed proteins (e.g., fibronectin, laminin) or tethered synthetic oligopeptides (e.g., arginine-glycine-aspartate [RGD]), on synthetic and natural supports to promote cell adhesion and function in various tissue engineering and regenerative medicine applications [29]. Important considerations in modifying surfaces with biological molecules include the density, distribution (uniform versus clustered), and activity (e.g., orientation, conformation, accessibility) of the immobilized biomolecule.

TABLE 37.2 Biomedical and Biotechnological Applications of Immobilized Biomolecules

Biomolecule	Applications
Heparin	Blood-compatible surfaces; growth factor immobilization
Fibronectin, collagen Arginine-glycine-aspartate peptides	Cell adhesion and function in biosensors, arrays, devices, and tissue-engineered constructs
Antibodies	Biosensors; bioseparations; anticancer treatments
DNA plasmids Antisense oligonucleotides Small interfering RNA	Gene therapy for a multitude of diseases; DNA probes
Growth factor proteins and peptides	Anticancer treatments; treatments for autoimmune and inflammatory conditions; enhanced wound repair
Enzymes	Biosensors; bioreactors; anticancer treatments; antithrombotic surfaces
Drugs and antibiotics	Antithrombotic agents; anticancer treatments; antihyperplasia treatments; antiinfection/inflammation treatments
Polysaccharides	Nonfouling supports for biosensors and bioseparations

Three major methods are used to immobilize biomolecules onto biomaterial surfaces: physical adsorption, physical entrapment, and covalent immobilization (Fig. 37.4) [30]. Passive physisorption of biomacromolecules (i.e., proteins, polysaccharides, nucleic acids) is a simple yet efficient method to render surfaces biologically active. Everyday applications include the coating of synthetic materials with extracellular matrix proteins such as fibronectin and collagen to improve cell adhesion. Protein adsorption is a complex, dynamic, energy-driven process involving hydrophobic interactions, electrostatic interactions, hydrogen bonding, and van der Waals forces. Protein parameters such as the primary structure, size, and structural stability, as well as surface properties including surface energy, and the chemistry influence the biological activity of the adsorbed biomacromolecules. These biologically modified surfaces can undergo further modifications, such as the displacement of adsorbed proteins and the cell-mediated deposition and remodeling of matrix components in the biological milieu. As an approach to improving the stability of these modified surfaces, the biological molecules can be cross-linked after adsorption. Finally, the use of high-affinity interactions, such as avidin–biotin and antibody–antigen, represents a special case of these physical immobilization methods that is particularly important in diagnostics and bioprocessing.

Physical entrapment methods rely on diffusive barriers or matrix systems to control the transport or availability of the biomolecule. For example, entrapment of enzymes within sol-gels with nanoscale porosity and drug or protein therapeutics within encapsulation matrices provide technologies for enhanced stability, separation, or recovery of the biological agent, and regulated delivery kinetics. The encapsulation systems can be engineered to isolate the biomolecule permanently or degrade in nonspecific (e.g., hydrolysis) or specific (e.g., enzymatic degradation) fashion for controlled-release kinetics.

An extensive and diverse group of strategies has been developed to immobilize or tether biomolecules covalently to soluble or solid supports (Fig. 37.4) [30,31]. Soluble polymers functionalized with biomolecules can then be polymerized into a network or grafted onto a solid support. These strategies rely on coupling reactions between groups in the biomolecule ($-NH_2$, $-COOH$, and $-SH$) and the biomaterial support, and often involve cross-linkers or coupling agents such as CNBr, carbodiimides, and *N*-hydroxysulfosuccinimide. Furthermore, chemoselective reactions such as "click" chemistry, provide unparalleled control over the tethering and presentation of biomolecules that are bio-orthogonal and hence provide specificity without unwanted side reactions [32]. In many instances, the biomolecule is covalently immobilized via an inert spacer arm (e.g., polyethylene glycol) that provides increased steric freedom and activity. In addition, the tether arm can be designed to be hydrolytically or enzymatically labile to allow for release of the tethered biomolecule. As expected, the properties of the underlying biomaterial support have central roles in the tethering efficiency and resulting biological activity of the immobilized biomolecule. In some cases, the surface needs to be modified via the techniques described earlier to introduce reactive groups for the subsequent immobilization step. For example, inert surfaces can be modified by overcoating with a polymeric adlayer that then presents anchoring groups suitable for the immobilization of biomolecules. For many

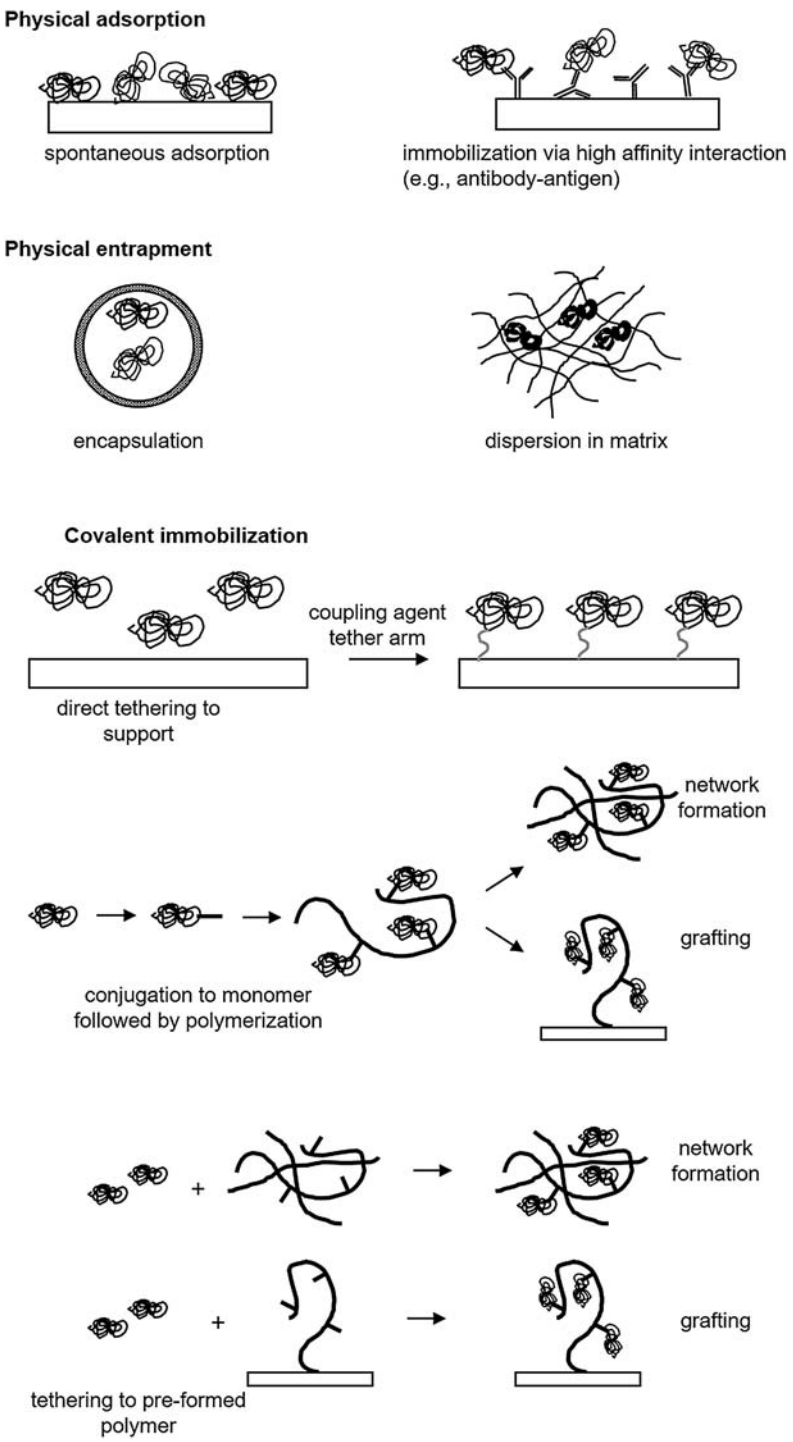

FIGURE 37.4 Schematic diagram of methods for immobilizing biomolecules onto and within biomaterials.

biomedical and biotechnological applications, it is desirable to tether biomolecules within a protein adsorption-resistant (nonfouling) background to eliminate effects associated with nonspecific protein adsorption. This is particularly important in biomaterials and regenerative medicine applications in which inflammatory responses to nonspecifically adsorbed proteins limit biological performance. Poly(ethylene glycol) (PEG) ($-[CH_2CH_2O]_n$) groups have proven to be the most protein-resistant functionality and remain the standard [33]. A strong correlation exists between PEG chain density and length and resistance to protein adsorption, and consequently cell adhesion. Other hydrophilic polymers such as poly(2-hydroxyethyl methacrylate), polyacrylamide, polycarboxybetaine, and

phosphoryl choline polymers also resist protein adsorption. In addition, mannitol, oligomaltose, and taurine groups have emerged as promising moieties to prevent protein adsorption [34,35]. Critical considerations for these approaches include the ability to apply these coatings to existing medical-grade materials and the long-term stability of these coatings in terms of their nonfouling character and whether protein adsorption can be reduced below threshold levels to suppress nonspecific biological responses. Emerging strategies combining passive and active characteristics (e.g., biotherapeutics that modulate blood clotting or inflammation, self-cleaning materials) provide promising approaches to reduce protein adsorption effectively while enabling the controlled presentation of bioactive molecules.

SURFACE CHEMICAL PATTERNING

Whereas the surface chemical and biological modification strategies described here were presented in the context of a uniform surface, many of these technologies can be used to generate surfaces that have chemical or biological functionalities in distinct geometrical patterns. Important applications of patterned surfaces include protein and oligonucleotide arrays, biosensors, and cell-based arrays [36]. In many instances, these patterned substrates contain spatially defined domains with biomolecules surrounded by a nonfouling background. Photolithography and other techniques relying on exposure through masked patterns or direct surface exposure (e.g., laser or electron beam) combined with chemical reaction or grafting are often used to generate chemically patterned surfaces. Importantly, "soft" lithography methods such as microcontact printing and microfluidic fluid exposure have been applied to produce micropatterned substrates in high throughput at a low cost and without the need for a cleanroom environment [37].

CONCLUSION AND FUTURE PROSPECTS

Surface modifications of biomaterials represent promising routes to engineer biofunctionality at the material–tissue interface to modulate biological responses without altering material bulk properties. Countless technologies have been developed to create physicochemical modifications involving alterations to the chemical groups on the surface and coatings consisting of a different material from the underlying support, including immobilized biomolecules. These approaches hold tremendous promise to enhance biomaterial performance in regenerative medicine. Future structure–function analyses on the effects of specific surface chemistries, topographies, and biological modifications on in vivo responses, especially in healing and regenerative environments, will further advance the understanding of host responses to implanted devices. These insights will result in the identification of surface modifications that synergize with biological elements (e.g., cells, growth and differentiation factors) to enhance tissue repair and regeneration. It is anticipated that technical breakthroughs in synthetic chemistry, biofunctionalization, microfabrication and nanofabrication, and surface characterization will lead to the engineering of advanced bioactive materials. In particular, complex patterns of bioligand presentation, such as clusters, gradients, temporal exposure, and multiple ligands, are expected to provide unparalleled control over cellular activities and healing responses.

THE NEED FOR REPLACEMENT TISSUES

Replacement of diseased tissues and organs is one of the biggest problems facing the medical industry. According to the US Scientific Registry of Transplant Recipients, there were over 97,000 patients on the National Organ Registry at the end of 2007 [1]. Of the patients awaiting life-saving transplants, approximately 10% died before they could receive donor organs. In addition, tissue disease and organ failure lead to an estimated 8 million surgical procedures annually in the United States [2]. From these statistics, one fact is clear: the need for replacement organs far outweighs the supply, and the discrepancy is only expected to worsen as populations rise and life expectancies increase.

Synthetic materials and tissue grafting have been employed throughout history in an effort to address the need for tissue substitutes, although each is marred by seemingly insurmountable challenges. In the case of synthetic replacements, the primary mode of failure comes through attack via the host's foreign body response. Disease transmission, in the case of xenografts or allografts, and donor site morbidity from autografts leave these tissues underused, although the primary constraint, as with whole organs, is a limited supply. Thus, tissue engineering, with its goal of recapitulating biological structure and function, has emerged as the most viable solution to the lack of suitable replacement tissues.

The idea that tissue function can be restored is as old as the medical profession. Historically, one of the most popular sites of implant was the nose, which, other than the hand, was the body part most likely to be injured in battle [3]. As a consequence, many cultures were performing successful nasal operations thousands of years ago. A pioneering technique for nasal tissue regeneration was developed in 1596, when a flap of skin from the arm, complete with underlying vessels, was reconnected to the face. In many cases, these tissues were able to reconnect with the local blood supply and successfully regenerate [4]. By the 19th century, numerous surgeons had successfully transplanted skin between individuals [4,5] and with World War II came the advent of large-scale tissue replacement using synthetic materials. Faced with high numbers of battlefield casualties, surgeons began experimenting with artificial materials for tissue replacement and augmentation in efforts to reduce battlefield mortality [6]. Although most of these attempts were unsuccessful for various reasons, the idea of replacing lost tissue with synthetic materials endured and continues to be used today.

Through the successes and challenges of previous replacement strategies, the medical community has gained a heightened appreciation for the complexity of biological tissues. It is recognized that each tissue is a carefully organized aggregate of cells and other factors specialized to perform a particular function [7], and that the complexity increases as tissues come together to form organs. Although still relying to a large degree on artificial materials and devices, the focus of tissue replacement research is moving toward regenerative medicine and total biological solutions. Along those lines, this chapter will focus on efforts to promote histogenesis in three-dimensional (3D) scaffold matrices.

TISSUE COMPONENTS

Biological tissues are composed of three components: cells, the extracellular matrix (ECM), and the signaling systems that are encoded by genes in the nuclei of the cells and then activated through cues from the ECM or other cells

Principles of Regenerative Medicine, Third Edition

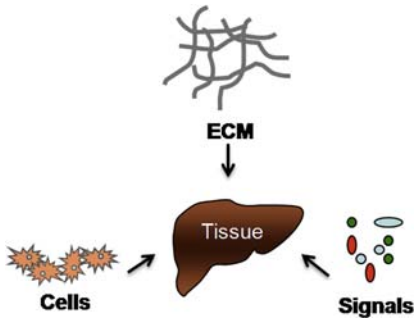

FIGURE 38.1 The basic components of mammalian tissue. *ECM*, extracellular matrix.

[8] (Fig. 38.1). Together, the three components interact in balance to form tissues and organs; mimicking these interactions is the focus of tissue engineering.

From an engineering design standpoint, the tissues of the human body are infinitely complex, and the dynamic processes that constitute organs are not confined to a single dimension. At the most basic level, cells reside in a complex ECM environment of proteins, carbohydrates, and other structural molecules. Cells respond to changes in their environment (e.g., injury or disease) by secreting proteases, growth factors, and other signaling molecules, which in turn lead to intramolecular and intercellular communications dictating the initiation of processes from proliferation and protein synthesis to migration and apoptosis.

The ECM can be broadly defined as a natural scaffold that supports tissues and organs, but it should not be viewed as merely providing strength and physical reinforcement. This matrix, which is composed of both a fibrillar and an amorphous component, is known to be intricately involved in the events that lead to tissue formation [9]. These two broad components interact with cells via cell surface receptors and various membrane proteins to influence processes such as cell orientation, growth and differentiation, and the secretion of bioactive molecules [9]. Cellular responses to changes in the tissue environment may result from direct interaction with the matrix, such as when physical stresses are transmitted through fibrillar ECM components to cell focal adhesion complexes within the cell, or they may arise as a consequence of the release of signaling molecules that are stored in the ECM reservoir. Understanding the complexity of tissue components and their roles in natural processes, such as embryogenesis and wound healing, will guide tissue engineering methodologies and lead to more functional replacement options.

REGENERATION OF DISEASED TISSUES

Regeneration is defined as the synthesis of physiologic tissue with the objective of restoring lost biological function. This is in contrast to the notion of tissue repair, which is simply the closure of a wound to allow for the return of homeostatic function at the site of injury [10]. Repair generally results in the contraction of tissue and the formation of a scar, which contains undifferentiated epithelial tissue with little or no physiological function. Although many tissue engineering strategies have been influenced by the principles at work in the wound healing process (especially with regard to cell−cell and cell−matrix interactions), the formation of scar tissue is regarded as an adverse event that directly inhibits the regeneration of new tissues [11].

Unlike an embryo, the adult human has limited capacity for self-regeneration. The precise reason for this inability is not understood, but research demonstrates that the removal of ECM, as in disease or injury, disrupts normal tissue regeneration and leads directly to the formation of scar tissue [10]. This observation signifies the importance of a structural support to direct and guide cell-mediated regeneration. Indeed, studies have shown that for large tissue defects, the implantation of cells alone is ineffective at initiating new tissue formation [11]. Depending on the size and location of tissue damage, cells must work in conjunction with the ECM to initiate repair or regeneration. Again, it is valuable to consider the natural process of wound healing when attempting to delineate these interactions.

Tissues are composed of three interconnected layers: the epithelium, basal lamina, and stroma. The epithelium is composed entirely of cells with little or no matrix component. In contrast, the basal lamina contains only ECM, whereas the stroma is composed of cells, ECM, and blood vessels [12] (Fig. 38.2). Both the epithelia and basal lamina can regenerate without inducing scar formation, but the stroma is usually nonregenerative, and injury to this layer leads directly to the repair state [13]. When tissue injury occurs, the inflammatory response is swift and quickly

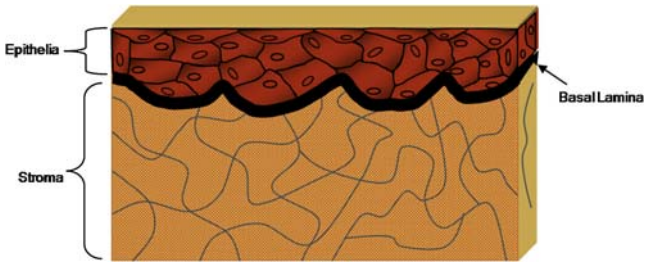

FIGURE 38.2 The three layers of tissue. The epithelia is the outermost layer of tissue and is composed mainly of cells. The basal lamina is a thin extracellular matrix (ECM) membrane that separates the epithelia from the stroma. The stroma is mainly composed of ECM fibers and is generally unable to regenerate spontaneously.

results in recruitment of fibroblasts and myofibroblasts to the wound bed [13]. The destruction of stromal tissue signals myofibroblasts to secrete collagen fibrils in an attempt to stabilize the wound. Unlike the random fibril orientation achieved by fibroblasts in normal tissue formation, myofibroblasts deposit collagen in a highly organized fashion along stress planes [10]. The stress forces generated by these contractile cells are generally in one dimension and both the myofibroblasts and matrix fibers align parallel to the force [14]. Deposition of ECM under stress results in contraction of the wound bed, bringing healthy tissue closer together and thus reducing the size of the defect to be healed. Unfortunately, the highly aligned scar fibrils inhibit subsequent infiltration by additional cell types, thereby limiting the extent to which the scar can be remodeled into functional, regenerated tissue.

With the goal of limiting wound contraction and subsequent scar tissue formation, much research has focused on implanting exogenous materials into the defect site to replace the lost matrix component. As example, Yannas and colleagues placed a collagen scaffold into a full-thickness skin wound and were able to block wound contraction and greatly reduce scar formation while inducing partial skin regeneration [13]. The collagen construct was shown to reduce the inflammatory response greatly, and consequently, the number of myofibroblasts recruited to the wound bed. In control studies, inhibition of contraction and subsequent tissue regeneration was not evident in defects treated with cytokines or cell suspensions, or in artificial scaffolds known to induce a high inflammatory response [11]. In addition, inhibition of contraction by steroids or other chemicals [15] is not sufficient for regeneration, which demonstrates the complex influence of scaffold materials in the healing process.

Although the need for a scaffold material has been validated, a complete tissue replacement strategy is composed of more than a single component. Successful histogenesis requires the presence of cells capable of producing new tissue matrix and must include the biochemical factors necessary for the cells to live and function. Furthermore, several important design parameters related to the scaffold itself have become evident. In addition to being biocompatible, scaffold materials should have the appropriate chemical structure and microarchitecture to support cell viability and tissue formation. As tissues mature, precisely tuned scaffold degradation will allow the transfer of mechanical properties to the newly formed matrix and materials permissive to vascular ingrowth will encourage incorporation with surrounding tissues and provide a blood supply for nourishment.

DESIGN PARAMETERS FOR HISTOGENESIS

Tissue engineers have recognized certain critical components to regeneration design strategies. Methodologies generally start by including the three components of tissue: cells, matrix, and signaling factors. From here, constituents are specialized based on specific tissue needs. In general, researchers seek to develop a scaffold material that can support viability of the appropriate cell type while acting as a temporary substitute for the ECM. Over time, this surrogate matrix will ideally be replaced by functional replacement tissue.

Cell Sources

Because scaffold materials alone are insufficient to stimulate regeneration of all tissue defects, cell sourcing is an important consideration in the histogenesis design strategy. Host cells have been shown to infiltrate acellular matrices in some instances, but generally this infiltration distance is limited to a few microns. By implanting cells into the biomaterial scaffold, it is believed that the time for tissue infiltration by the host will be minimized and

the cells can secrete bioactive factors in vitro that will encourage autologous ECM formation. Thus, a combination of cells and scaffold serves as the most common implant construct.

A variety of cell types have been investigated for regeneration applications, including differentiated cells, adult-derived stem cells, and embryonic stem cells [16]. Mature cells have historically come from three sources, autologous, allogeneic, and xenogeneic, although xenogeneic cell transplantations have mostly been abandoned because of concerns regarding immune rejection and cross-species disease transmission. Allogeneic cells are harvested from healthy adult donor organs and then expanded in vitro. Scaffolds with allogeneic cells are subject to immune rejection, but these cells have been successful in skin regeneration for burn patients [17]. Autologous cells biopsied from a patient, expanded in vitro, and then seeded onto a tissue scaffold are generally viewed as the ideal replacement in terms of compatibility. However, in many patients, the extent of tissue damage or disease makes it difficult to obtain a sufficient supply of healthy cells [16].

The field has seen an increase in the number of progenitor cells employed for regeneration applications. These stem cells have varying degrees of potential, depending on their source, but in general, adult-derived cells are considered multipotent and have the capacity to generate a limited number of cell types, whereas pluripotent, embryonic cells can be differentiated into cells of all three germ layers [18]. As example, murine embryonic stem cells have been differentiated in vitro into various tissue cells including neurons, myocytes, and chondrocytes [19]. This differentiation was initiated in vitro through the use of media containing cytokines and growth factors specific to the target cell lineage. Osteoblast differentiation has been accomplished in a similar manner and by incubating embryonic stem cells in preconditioned media transferred from a culture of mature bone cells [20]. Mechanical stimulation can also serve as a tool to guide differentiation for orthopedic [21] or cardiovascular [22] applications of embryonic stem cells. The advent of induced pluripotent stem cells, derived from reprogramming adult cells such as fibroblasts, further expands possibilities for the field [23].

Porosity

In most types of synthetic materials, successful histogenesis requires a porous microstructure. Scaffold porosity, pore size, and the overall pore structure all have important effects on tissue formation and infiltration into biomaterial constructs. Interconnecting pores facilitate the loading of cells into scaffold materials whereas the increased internal surface area provides sites for attachment and spreading. By allowing the diffusion of metabolites, oxygen, and growth factors into and out of the material, an open network structure permits cell viability and proliferation and allows room for the deposition of cell-secreted proteins. In vivo, a porous structure serves to encourage the infiltration of host cells and, importantly, the extension of vascular processes that offer nourishment to developing tissue.

Methods of creating pores or increasing the porosity of biomaterials include gas foaming [24], salt leaching [25], freeze-drying [26], and electrospinning [27], and the inclusion of biodegradable hydrogel microparticles [28]. As example, a microporous polyurethane urea was developed using a gas-foaming method. In these studies, sodium bicarbonate is added to a mixture of a polyurethane urea copolymer in dimethylformamide. The polymer is cast in a mold and the solvent evaporated. The cast polymer is next placed into an acidic solution to react with the salt. Both the removal of the salt and the bubbles formed during this foaming process contribute to the porosity of the resulting scaffold [29]. The final material is homogeneous in structure with a surface pore morphology and pore volume fraction similar to that seen throughout the bulk (Fig. 38.3). In addition, incorporation of the

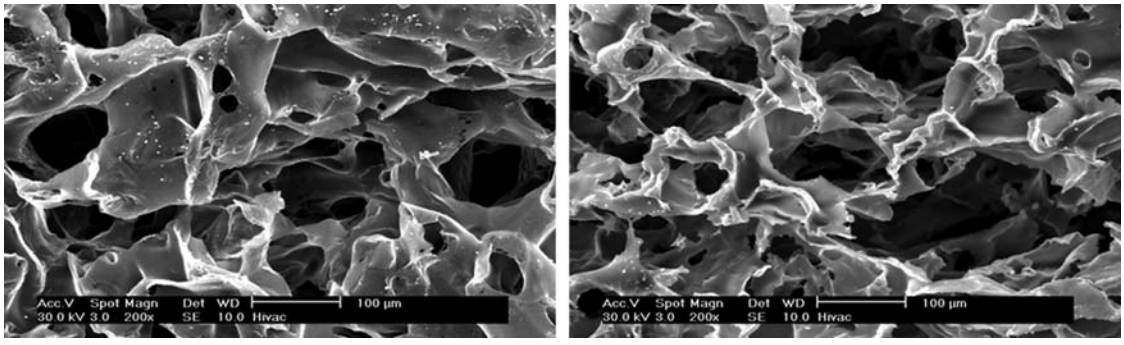

FIGURE 38.3 **Microporous polyurethane urea copolymer scaffold.** The scaffold formed by gas foaming exhibits a similar porous morphology on the surface (*left*) and in the bulk (*right*).

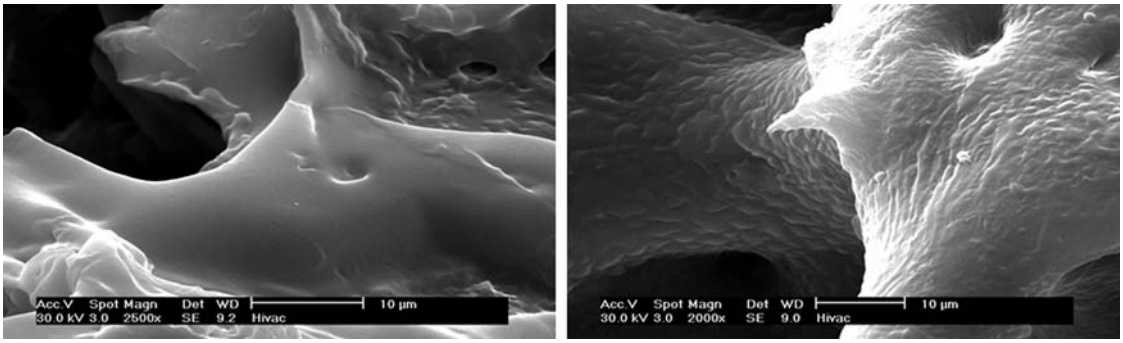

FIGURE 38.4 **Microporous polyurethane urea scaffold modified for cell adhesion.** The original scaffold porosity (*left*) was unaltered by the addition of the cell-adhesive peptide YIGSR (*right*).

laminin-derived peptide YIGSR permits cell adhesion to the otherwise nonadhesive polymer matrix without changing the overall porosity of the scaffold (Fig. 38.4).

It is important to consider how variations in pore architecture affect cell–material interactions. Experimental studies have led to the determination of a characteristic interaction parameter, Φ_c, which relates the number of cells bound, N_c, to the available surface area, A, of the scaffold, according to Eq. (1) [10]:

$$\Phi_c = \frac{N_c}{A}, \tag{38.1}$$

By careful analysis, it can be shown that two matrices with identical chemistries but differing pore diameters have vastly different abilities to provide for cellular attachment. For example, scaffolds containing pores of 300 μm have a much lower internal surface area than do matrices with pore diameters of less than 50 μm, and as such, they bind a much lower number of cells in the matrix. Because of the low cellular infiltration, tissue formation in these constructs is slow and in certain cases inhibited owing to a lack of interactions between cells [10]. From this calculation, it can be assumed that there is a maximum pore diameter that will allow cells sufficient area to attach and divide while maintaining the critical intracellular communication that leads to histogenesis. This parameter will be influenced by scaffold material properties (e.g., hydrophobicity) and limited by the size of the cell in each application. In general, research supports that pores larger than 10 μm (the average cell diameter) will permit cell infiltration [30].

In terms of successful histogenesis, both the pore size and the degree of porosity are tissue and scaffold specific. For example, in vivo osteogenesis occurs in biomaterials of high porosity (>70%) with average pore sizes larger than 300 μm [31]. However, in skin regeneration, successful scaffolds need only to exhibit pore sizes of 20–125 μm [32]. This discrepancy can be explained by the low vascular requirements of the skin and its convenient juxtaposition to an ample supply of atmospheric oxygen. However, there is an upper limit in the porosity and pore size set by constraints associated with mechanical properties. An increase in the void volume results in a reduction in the mechanical strength of the scaffold, which can be detrimental in applications where regenerated tissues must support significant mechanical loads (e.g., long bones, heart valves, and articular cartilage) [13]. The extent to which the porosity of a scaffold can be increased while allowing it to meet tissue mechanical requirements depends on many factors, including the intrinsic makeup of the biomaterial and the processing conditions used in fabrication [31].

As histogenesis progresses and gives way to organogenesis, the impact of the scaffold pore structure on material degradation and tissue vascularization becomes apparent. The size and distribution of pores within a scaffold greatly influence the manner and rate of in vivo degradation [33], which can affect tissue formation and construct mechanical integrity. In materials susceptible to hydrolytic cleavage, for example, the access of water molecules to the interior of a scaffold is limited by porosity. Similar parallels exist for matrices subject to enzymatic degradation, which rely on interaction with cell-secreted molecules for dissolution. A final, important consideration is the influence of pore structure on the establishment of a blood supply in newly developing tissue. In early stages of histogenesis, nutrients, metabolites and other factors essential to cell survival pass freely through scaffold pores. As these pores fill with new tissue, however, a functioning vasculature is necessary. New "designer" tissue-engineered scaffolds are composed of precisely controlled porous architectures that support and guide vessel ingrowth during tissue development [34,35]. The concepts of degradation and microvascularization are discussed in more detail in the following sections.

Degradation

Although nondegradable biomaterials have had success in many medical devices, complication primarily caused by chronic foreign body responses have yet to be overcome. For this reason, the ideal regeneration construct is one that can eventually be replaced by native tissues. Furthermore, the degradation rate of the construct is intrinsic to the success of the implant. This means that the material dissolution should complement tissue synthesis to ensure suitable mechanical stability during the process of histogenesis. The necessary scaffold residence time is tissue specific and must account for the time required for cells to populate the scaffold adequately and deposit a stable ECM. If a biomaterial degrades before sufficient ECM deposition has occurred, cells will lose important physiochemical factors for tissue regeneration and repair is likely to occur, resulting in scar formation. However, if the scaffold residence time is too long, ECM deposition and cell proliferation will be suppressed. An important balance must be established for successful regeneration.

In most currently employed scaffold materials, degradation in the in vivo aqueous environment occurs via hydrolysis of chemical bonds in the base material. Chemical functionalities, molecular weight, and the degree of cross-linking determine the degradation characteristics. For example, higher−molecular weight materials tend to degrade more slowly over time as do materials with a higher hydrophobicity and crystallinity. Using a combination of these factors, predictable degradation profiles can be developed to match expected tissue formation rates. However, the consequences of material dissolution must be considered. As mentioned earlier, scaffolds that undergo bulk erosion can rapidly become unstable owing to the formation of large pores with low mechanical stability [36]. In addition, the degradation products of some scaffolds can be toxic not only to cells of the surrounding tissue, but also to vital organs of the lymphatic system. For example, degradation of the frequently studied polylactic acid (PLA) and polyglycolic acid (PGA) scaffolds results in a marked drop in pH in the local vicinity because of the release of acidic degradation products [36,37]. The decrease in pH can be detrimental to cells and organs; over time, it can lead to an inflammatory response with possible capsule formation and tissue necrosis [38].

As an alternative to hydrolytic degradation, many investigators are developing smart materials that can be dynamically remodeled during histogenesis via cell-mediated processes. These scaffolds are designed to mimic the degradation of natural ECM proteins, which are subject to matrix metalloproteinases (MMPs) and serine proteases that are either secreted or activated by most cell types. Because proteolysis-induced degradation is required for cell migration and invasion, researchers have had success in introducing synthetic hydrogels that are sensitive to cell proteases. Hydrogels containing amino acid sequences that can be degraded by plasmin [39], MMPs [40], or both of these protease families [41−43] exhibit sustained degradation upon cellular infiltration.

In our own laboratory, we have fabricated MMP-degradable hydrogels that become fluorescent when degraded by cell proteases [44]. These = polyethylene glycol (PEG)-based hydrogels are synthesized with MMP-degradable segments in the polymer backbone that are labeled with fluorescent, self-quenching tags. Thus, intact substrates show no fluorescence, but upon degradation by cell proteases, quantifiable fluorescence is emitted. Cells seeded in these fluorogenic substrates are able to cleave the degradable hydrogel matrix, as visualized by a marked increase in fluorescence in the areas immediately around the cell (Fig. 38.5). In addition, cell migration trails could be seen in the hydrogels. It is believed these materials will contribute to an understanding of cell migration and cell-mediated scaffold degradation.

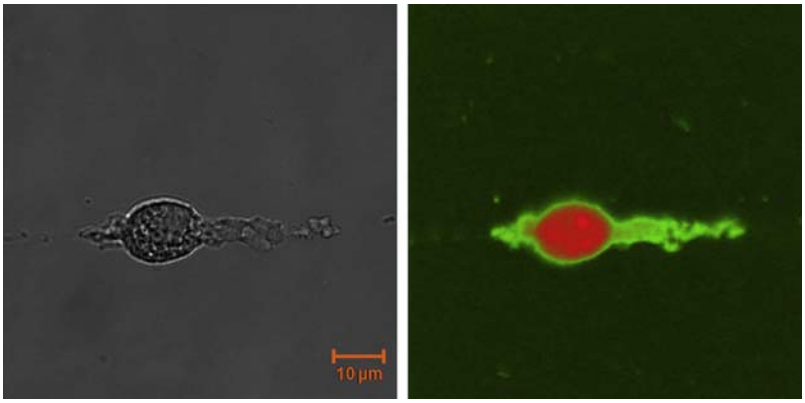

FIGURE 38.5 **Fibroblast encapsulated within a fluorogenic substrate.** Differential interference contrast image (*left*) and fluorescent image (*right*) showing green fluorescence generated by material degradation around cell (*red*).

Biomolecular Factors

In many cases, seeding cells inside a porous scaffold is insufficient to induce tissue regeneration because the material does not contain the chemical cues necessary to promote cellular remodeling events. Thus, researchers have attempted to modify biomaterials actively at the molecular level by incorporating cell-specific biomolecules. One strategy is to encapsulate molecules such as peptides or proteins into biomaterial carriers so that these molecules can be released from the material to trigger or modulate new tissue formation [8]. Another approach involves physically or chemically modifying scaffolds with specific cell-binding peptides to increase cellular interaction with the substrate. Cell-binding peptides are short amino acid sequences derived from much longer native ECM proteins that have been identified as able to incur specific, predictable interactions with cell receptors. Essentially the peptides function to mimic the signaling dynamic between the ECM and cells, and because many synthetic scaffold materials are not inherently adhesive to cells, the introduction of such sequences can be critical to encouraging cell retention and subsequent tissue formation [45]. The most well-studied cell adhesion peptide, arginine-glycine-aspartic acid-serine (RGDS) has been widely used to encourage cells of various types to interact with otherwise nonadhesive synthetic matrices [46] (Fig. 38.6). Other amino acid sequences have been found to promote adhesion by specific cell phenotypes including endothelial cells [29,47–49], smooth muscle cells [47], neural cells [50], and osteoblasts [51].

Various growth factors have also been employed in efforts to enhance the process of histogenesis. Because they have key roles in tissue differentiation and repair, molecules such as epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and transforming growth factor-β1 (TGF-β1) are popular for use in these applications. The release of PDGF from a polyurethane scaffold has been shown to encourage wound healing of in a rat model [52], whereas Griffith and colleagues used tethered EGF to promote osteogenic differentiation in an effort to improve connective tissue regeneration [53]. TGF-β1 has many roles in histogenesis [54] and has received particular attention for aiding the differentiation of stem cells and the development of new vasculature in vivo [55]. In other work, basic fibroblast growth factor (bFGF) and nerve growth factor were immobilized in fibrin scaffolds to facilitate cellular recruitment and differentiation [56]. Biomolecules have also been covalently coupled to PEG-based materials [57–60] with vascular endothelial growth factor and showed the potential to drive endothelial cell tubulogenesis. Furthermore, Delong and West formed gradients of bFGF and observed cellular alignment and migration that was directly influenced by growth factor presentation [61] (Fig. 38.7).

Importance of Microvasculature

One of the biggest limitations to histogenesis in 3D scaffolds is the lack of a functional vascular system. The most successful engineered materials to date have been for tissues such as skin, which are thin enough to be supported by diffusion from the host vascular, and cartilage, which is relatively avascular and as such contains cells that are tolerant of anoxic conditions. All other tissues require some form of vascular system to permit the long-term survival of cells within the material. There are two primary strategies for establishing a blood supply in implanted 3D scaffolds. Vessels can grow into the construct from host tissue or they can be preformed in vitro and interconnect with host vascular upon implantation.

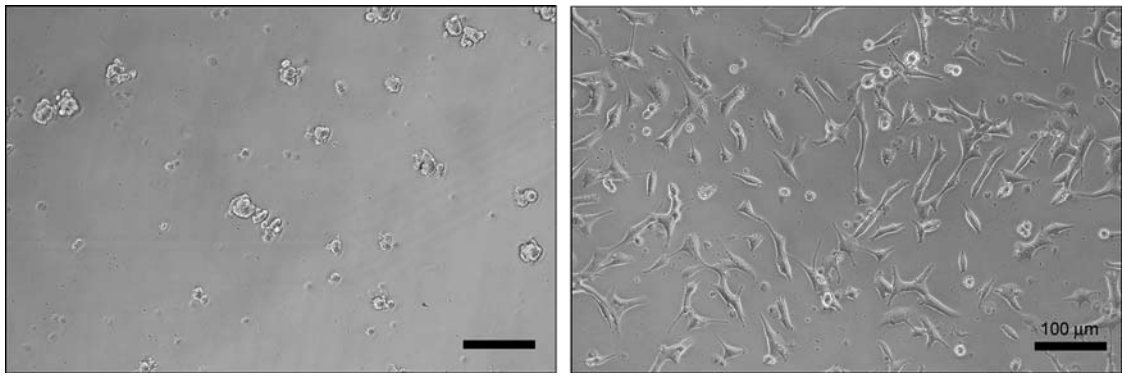

FIGURE 38.6 **Peptide modification promotes cell adhesion.** The nonadhesive nature of polyethylene glycol hydrogels (*left*) can be significantly altered by inclusion of an arginine-glycine-aspartic acid-serine peptide to promote cell attachment (*right*).

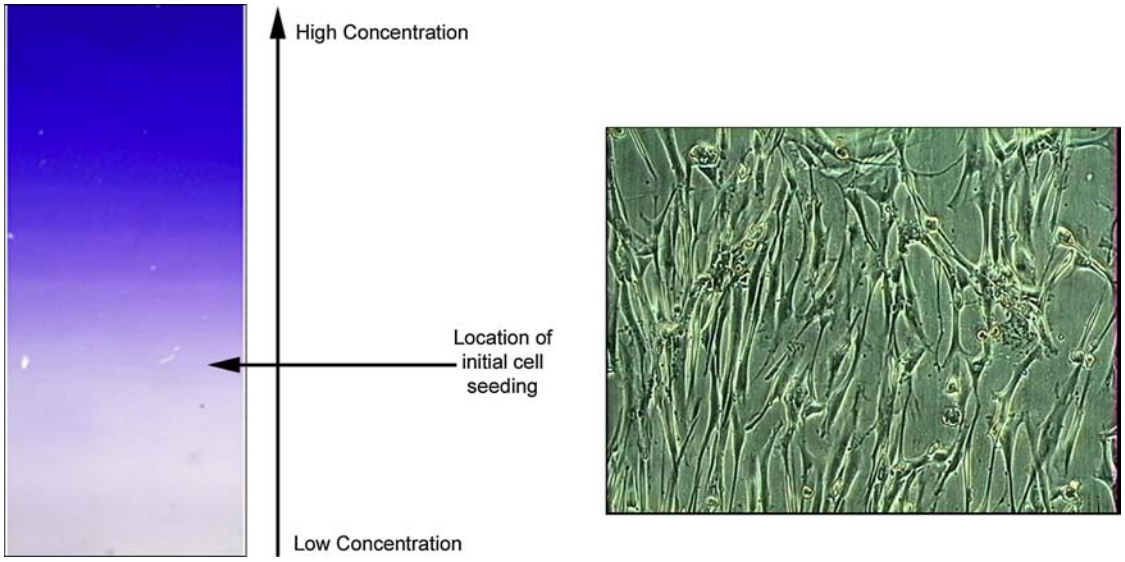

FIGURE 38.7 Gradient of basic fibroblast growth factor (bFGF) immobilized in a hydrogel scaffold. Cells seeded on hydrogels containing a bFGF gradient aligned and migrated along the axis of growth factor immobilization.

The premise behind the first strategy is to encourage vessels to enter an avascular construct from the host tissue by stimulating angiogenesis. To encourage this process, scaffolds can be fabricated with precisely designed pore structures or surface chemistries that support ingrowth [34,62]. In some cases, proangiogenic factors are immobilized on or released from implants to encourage the ingrowth of vessels from host tissue. Work from our laboratory showed extensive infiltration of functional vessels into a cell-adhesive, proteolytically degradable, PEG-based hydrogel that had been implanted in the mouse cornea [63–66]. The limitation of these strategies is the time required for vessels to extend into the entirety of the engineered construct. At an extension rate of approximately 5 μm/h [67], new vessels will not reach the center of large scaffolds until several days after implant, leaving any cells at these locations without sufficient supplies of oxygen and nutrients.

A second option is to create preformed vascular networks in vitro that are capable of anastomosing with host vascular upon implantation. This process of connecting two independent vascular networks is called inosculation and is the mechanism primarily responsible for the successes in plastic surgery and skin transplantations. To generate microvascular networks in vitro, researchers seed scaffolds with cells known to participate in vasculogenesis, including endothelial cells, stem cells, and pericytes. With appropriate biochemical and/or physical stimulation, these cells self-assemble into capillary-like structures. As an example, successful vascular networks have been formed by endothelial cells in fibrin scaffolds [68] and by adult and cord blood–derived progenitor cells in Matrigel [69]. In each study, the preformed vessels were functional upon implantation in vivo; and in the case of the endothelial cells, immature capillaries were further stabilized by host mural cells. Other work along these lines suggests that providing relevant physiomechanical stimulation in vitro will aid in developing functional prevascularized networks in engineered constructs [70–72]. A final approach exploits the body's own ability to form blood vessels. A variety of scaffold materials have been implanted in highly vascularized anatomical sites, where they are incubated for up to 3 weeks as host vessels infiltrate. Once the vessel network is established, the scaffold is explanted, loaded with cells, and finally implanted into the site targeted for regeneration [73].

The need for adequate blood flow in 3D scaffolds is readily apparent and of concern to all researchers interested in regeneration strategies. Advances are promising, although much work remains to be done. Inosculation of preformed microvascular networks with host vascular, for instance, provides functional transport of engineered materials much more rapidly than some other methods, but it is still too slow for sensitive tissue applications. A combination of this approach with proangiogenic strategies may encourage connection in a shorter time, thus leading to the better long-term regeneration of target tissue.

SYNTHETIC MATERIALS FOR HISTOGENESIS OF NEW ORGANS

Biomaterials investigated as scaffolds for histogenesis include natural polymers such as collagen and fibrin, as well as a range of synthetic substrates. Although natural matrices have certain advantages in that their chemical composition is generally amenable to cell growth, batch-to-batch variations in substrate quality and performance can make their use in clinical regeneration applications problematic. As such, the control and flexibility of synthetic materials make them attractive alternatives. As alluded to previously, control is an important element in tailoring the scaffold's material properties for appropriate cell−material and matrix−material interactions. The following sections highlight two popular classes of synthetic materials: hydrolytically degradable polymers and hydrogels.

Hydrolytically Degradable Polymers

The most widely used polymers for cellular scaffold materials are PLA, PGA, or a combination of these two polymers (poly[lactic-*co*-glycolic acid] [PLGA]). PLA, PGA, and PLGA are aliphatic esters that possess good biocompatibility [74] and have been used as drug delivery materials to administer biomolecules during tissue regeneration [75,76]. These polymers are also among the few synthetic polymers approved by the US Food and Drug Administration (FDA) for certain human clinical applications. PGA is extremely hydrophilic in nature; consequently, it will lose its mechanical strength within 2−4 weeks of implantation [77]. PLA, however, contains an additional methyl group and as a result is more hydrophobic. Degradation of PLA scaffolds can take from months to years [75,78]. In addition, the degradation rates of these polymers can be tailored by using copolymer blends (PLGA), which give distinct degradation profiles [75,79]. However, these scaffolds undergo acid-catalyzed hydrolysis and bulk erosion, which have the potential to result in structural instability and interruption of the regeneration process [80].

Polyanhydrides have been synthesized for a number of biomedical applications including tissue engineering and drug delivery [81]. Polyanhydride scaffolds exhibit excellent biocompatibility and contain a large aliphatic component that possesses an ester group that makes the material subject to surface erosion [82]. This deliberate surface erosion is mechanistically different from bulk hydrolysis and can be exploited to synthesize biomaterials scaffolds that have predictable degradation profiles. In addition, the erosion of only the surface of the material allows anhydrides to maintain structural integrity in support of histogenesis. Because they exhibit mechanical properties similar to bone and are ideal scaffolds for tissue infiltration, anhydrides have been widely employed as scaffolds for in vivo bone regeneration [83−85]. Polyanhydride networks can also be combined with other polymers to change their degradation and structural characteristics. Jiang and Zhu [86] showed that anhydride polymers could be polymerized in the presence of PEG to form a cross-linked network with both hydrophobic and hydrophilic components. The hydrophilic PEG chains increase the uptake of water to drive the hydrolysis of the ester bond in the hydrophobic anhydride. As such, the degradation properties can be tailored by altering the amount of PEG in the scaffold material.

Hydrogels

Hydrogels, which contain up to 90% water, are another widely studied class of materials for tissue regeneration. These materials are appealing because the polymer properties are controllable and reproducible [87] and the large water uptake promotes excellent biocompatibility. In many cases, hydrogel mechanical properties resemble those of native tissue and can be systematically controlled for specific applications. In addition, several hydrogel monomers contain vinyl chemical moieties, which are conducive to various free radical−initiated polymerizations schemes that can be employed to generate solid substrate materials. Photoinitiation, for example, enables polymers to be formed using specific wavelengths of light. Using this method, many researchers have had success forming complex 3D structures of varying stiffnesses. For example, polyacrylamide hydrogels have been shown to induce regeneration of soft tissue in facial defects [88], and 2-hydroxyethylmethacrylate has had good success as a fibrillar support for nerve regeneration [89].

Among the most well-studied hydrogel materials is cross-linked PEG, which has been approved by the FDA for use in certain medical applications [90]. As with other hydrogels, the hydrophilic nature of PEG discourages cell and

protein adhesion and therefore results in a low instance of immunorejection by the host. By changing the monomer chain length, adding biological molecules, or using copolymers, researchers have generated a wide array of PEG hydrogel formulations suitable for many different tissue engineering applications. To render an otherwise blank slate amenable to histogenesis, various biomimetic peptides and growth factors have been incorporated into the PEG hydrogel matrix [57,59,91–93]. These modifications have been successful in achieving selective cell adhesion and promoting the accumulation of secreted tissue matrix. As mentioned previously, similar methods have been employed to encourage vasculogenesis and angiogenesis in PEG hydrogel materials. In addition, these hydrogel materials show promise as small-diameter vascular grafts [94]. Incorporation of peptides subject to proteolytic cleavage in the backbone of the PEG monomer renders the scaffolds subject to cell-mediated remodeling, giving these materials an additional advantage as histogenesis conduits.

FUTURE DIRECTIONS IN THREE-DIMENSIONAL SCAFFOLDS: THREE-DIMENSIONAL MICROFABRICATION

Advances in the biomaterial field are providing tissue engineers with the means to generate complex and highly specialized 3D scaffolds. One of the earliest examples of such architectures was developed by Griffith and colleagues for hepatocyte culture and liver regeneration. Using a rapid printing technique, microporous PLGA scaffolds were fabricated by directing solvent streams onto polymer granules in a precisely controlled manner [95]. The hepatocytes seeded upon these constructs exhibited increased metabolic rates that mimicked cells in vivo more closely. In other work, 3D, microporous PLGA foams were prepared by drilling with dies of a specific size. The dimensions of these cylindrical scaffolds were reproducible with millimeter precision, and when placed in vivo, the materials supported bone regeneration in nonhealing defect models [96,97]. Porous scaffolds have also been micropatterned for vascular tissue engineering applications [35,98].

Several researchers have used photopolymerization techniques to mold and pattern hydrogel scaffolds for better control of cell–substrate interactions [99]. Peppas reported micropatterning of PEG hydrogels using UV polymerization to generate many different substrate morphologies on the order of 100 μm [100]. Liu and Bhatia also photopatterned PEG hydrogels using a layer-by-layer method to generate a 3D scaffold for hepatocytes [101].

Laser-based patterning of hydrogels is a relatively new technique for generating complex 3D microenvironments inside hydrogel materials and natural constructs. Liu et al. used a laser ablation technique to form lines, holes, and interconnected grids in collagen matrices [102], whereas growth factors and peptides were patterned by Roy and colleagues using laser-based stereolithography [103] inside a PEG hydrogel. Biomolecules have also been patterned inside agarose hydrogels [104]. In this case, RGDS peptides were patterned in cylindrical shapes within the hydrogel material. After 3 days, neuronal cells seeded on the surface of the materials were shown to have migrated into the hydrogel in only the selectively patterned areas. Additional studies of cell migration in hydrogel materials were conducted with micropatterned, PEG-based materials functionalized with several different bioactive moieties [60,105,106]. In the process of laser scanning lithography, photosensitive peptides or proteins are covalently incorporated into 3D hydrogels with the precision of a confocal microscope laser (Fig. 38.8). The technique is capable of generating features from 1 μm to 1 mm and can be extended to include multiple bioactive moieties in a single substrate. The image in Fig. 38.9 illustrates the 3D nature of a patterned ligand. These precisely fabricated regeneration matrices provide great opportunities for controlled tissue growth.

CONCLUSIONS

The need for replacement tissues and organs is driving tissue engineers to develop materials and strategies capable of generating biologically functional substitutes. The study of natural processes such as wound healing has provided insights into the complex mechanisms of tissue regeneration and allowed researchers to prioritize design parameters for 3D scaffolds. At the same time, advances in biomaterial synthesis and modification, as well as a better understanding of the signaling molecules important in tissue synthesis, are providing a wealth of tools for regeneration strategies. In a systematic approach to histogenesis, Nettles et al. developed a method of neural network analysis in which a self-organizing map delineates the relationships between scaffold parameters, such as cross-link density, and tissue outcomes [107]. The investigators employed this tool with the goal of optimizing and

accelerating the design of a cartilage tissue substitute. Tools such as these will focus the work of tissue engineers going forward. Good success has been seen in developing substitutes for skin and cartilage. Advances in scaffold microvascularization techniques will aid in progressing the field to larger, more complex target tissues.

CHAPTER

39

Biocompatibility and Bioresponse to Biomaterials

James M. Anderson

Case Western Reserve University, Cleveland, OH, United States

INTRODUCTION

Biocompatibility is generally defined as the ability of a biomaterial or medical device to perform with an appropriate host response in a specific application. A bioresponse or biocompatibility assessment (i.e., an evaluation of biological responses) is considered to be a measure of the magnitude and duration of the adverse alterations in homeostatic mechanisms that determine the host response. From a practical point of view, the evaluation of biological responses to a medical device is carried out to determine whether the medical device performs as intended and presents no significant harm to the patient. The goal of bioresponse evaluation is to predict whether a biomaterial or medical device presents potential harm to the patient. In regenerative medicine, biomaterials are used in a wide variety of ways ranging from carriers of genetic material to tissue-engineered implants that may contain autologous, allogeneic, or xenogeneic genetic materials, cells, and scaffold materials. Scaffolds may be composed of synthetic or modified-natural materials. A tissue-engineered implant is a biological–biomaterial combination in which some component of tissue has been combined with a biomaterial to create a device to restore or modify tissue or organ function. Thus, tissue-engineered devices with a biological component(s) require an expanded perspective and understanding of biocompatibility and biological response evaluation. The purpose of this chapter is to provide an overview of this expanded perspective. Each unique tissue-engineered device requires a distinctive set of experiments to determine its biological responses and biocompatibility.

This chapter presents an overview of host responses that must be considered in determining the biocompatibility of tissue-engineered devices that employ biomaterials. The three major responses that must be considered for biocompatibility assessment are inflammation, wound healing, and immunological reactions or immunity. For the purposes of biological response evaluation, immunological reactions or immunity are considered to be immunotoxicity.

Pathologists use the terminology of inflammation and immunity to describe adverse tissue reactions, whereas immunologists commonly refer to inflammation as innate immunity and activation of the immune system as being acquired immunity. Tissue–material interactions are a series of responses that are initiated by the implantation procedure, as well as by the presence of the biomaterial, medical device, or tissue-engineered device. In this chapter, we divide the series of tissue–material responses into inflammation (innate immunity) and wound healing, and immunotoxicity. After implantation, early, transient tissue–material responses include injury (implantation), blood–materials interactions, provisional matrix formation, and the temporal sequence of inflammation and wound healing including acute inflammation, chronic inflammation, granulation tissue development, foreign body reaction, and ultimately fibrosis or fibrous capsule (scar) development. Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction. Two significant failure mechanisms of tissue-engineered devices are fibrosis or fibrous capsule (scar) development surrounding and infiltrating the tissue-engineered device, or the initiation of acquired or cellular immunity by the biological component of the tissue-engineered device. Also, the biological component and the biomaterial component in a tissue-engineered device may act in concert or synergistically to facilitate either of these failure mechanisms.

INFLAMMATION (INNATE IMMUNITY) AND WOUND HEALING

The process of implanting a biomaterial or tissue-engineered device results in injury to tissues or organs [1–8]. This injury and the subsequent perturbation of homeostatic mechanisms lead to inflammatory responses, foreign body reaction, and wound healing. The response to injury depends on multiple factors that include the extent of injury, loss of basement membrane structures, blood–material interactions, provisional matrix formation, the extent or degree of cellular necrosis, and the extent of the inflammatory response. The organ or tissue undergoing implantation may have a significant role in the response. These events, in turn, may affect the extent or degree of granulation tissue formation, foreign body reaction, and fibrosis or fibrous capsule (scar) development [9]. These events are summarized in Table 39.1. These host reactions for biocompatible biomaterials are considered to be normal. They are also tissue-, organ-, and species-dependent. These dependencies thus provide perspectives on the biological response evaluation and the ultimate determination of biocompatibility. The reactions occur or are initiated early (that is, within 2–3 weeks of the time of implantation) and undergo resolution quickly, leading to fibrosis or fibrous capsule formation.

Blood–Material Interactions and Initiation of the Inflammatory Response

Blood–material interactions and the inflammatory response are intimately linked; in fact, early responses to injury involve mainly blood and the vasculature [1–8]. Regardless of the tissue into which a biomaterial is implanted, the initial inflammatory response is activated by injury to vascularized connective tissue. Because blood and its components are involved in the initial inflammatory responses, thrombus, blood clot, or both also form. Thrombus formation involves activation of the extrinsic and intrinsic coagulation systems, the complement system, the fibrinolytic system, the kinin-generating system, and platelets. Thrombus or blood clot formation on the surface of a biomaterial is related to the well-known Vroman effect of protein adsorption. From a wound healing perspective, blood protein deposition on a biomaterial surface is described as provisional matrix formation.

Although injury initiates the inflammatory response, released chemicals from plasma, cells, and injured tissue mediate the response [4,6,10,11]. Important classes of chemical mediators of inflammation are presented in Table 39.2. Several important points must be noted to understand the inflammatory response and how it relates to biomaterials. First, although chemical mediators are classified on a structural or functional basis, different mediator systems interact and provide a system of checks and balances regarding their respective activities and functions. Second, chemical mediators are quickly inactivated or destroyed, which suggests that their action is predominantly local (i.e., at the implant site). Third, generally acid, lysosomal proteases, and oxygen-derived free radicals produce the most significant damage or injury. These chemical mediators are also important in the degradation of biomaterials. Phagolysosomes in macrophages can have acidity as low as pH 4, and direct microelectrode studies of this acidic environment have determined pH levels to be as low as 3.5. Moreover, only several hours are necessary to achieve these acid levels after adhesion of macrophages [12–14].

The predominant cell type present in the inflammatory response varies with the age of the injury. In general, neutrophils, commonly called polymorphonuclear leukocytes or polys, predominate during the first several days after injury and then are replaced by monocytes as the predominant cell type. Three factors account for this change in cell type [1]: Neutrophils are short-lived and disintegrate and disappear after 24–48 h; neutrophil emigration is of

TABLE 39.2 Important Chemical Mediators of Inflammation Derived From Plasma, Cells, or Injured Tissue

Mediators	Examples
Vasoactive agents	Histamine, serotonin, adenosine, endothelial-derived relaxing factor, prostacyclin, endothelin, thromboxane a_2
Plasma proteases	
Kinin system	Bradykinin, kallikrein
Complement system	C3a, C5a, C3b, C5b–C9
Coagulation/fibrinolytic system	Fibrin degradation products, activated Hageman factor (FXIIA), tissue plasminogen activator
Leukotrienes	Leukotriene B_4, hydroxyeicosatetraenoic acid
Lysosomal proteases	Collagenase, elastase
Oxygen-derived free radicals	H_2O_2, superoxide anion, nitric oxide
Platelet-activating factors	Cell membrane lipids
Cytokines	Interleukin-1, tumor necrosis factor
Growth factors	Platelet-derived growth factor, fibroblast growth factor, transforming growth factor-α or β, epithelial growth factor

short duration because chemotactic factors for neutrophil migration are activated early in the inflammatory response [2]. After emigration from the vasculature, monocytes differentiate into macrophages, and these cells are very long-lived (up to months) [3]. Monocyte emigration may continue for days to weeks, depending on the injury and implanted biomaterial, and chemotactic factors for monocytes are activated over longer periods of time.

Provisional Matrix Formation

Injury to vascularized tissue in the implantation procedure leads to immediate development of the provisional matrix at the implant site. This provisional matrix consists of fibrin, produced by activation of the coagulative and thrombosis systems, and inflammatory products released by the complement system, activated platelets, inflammatory cells, and endothelial cells [15–18]. These events occur early, within minutes to hours after implantation of a medical device. Components within or released from the provisional matrix (that is, fibrin network [thrombosis or clot]) initiate the resolution, reorganization, and repair processes such as inflammatory cell and fibroblast recruitment. Platelets activated during the fibrin network formation release platelet factor 4, platelet-derived growth factor (PDGF), and transforming growth factor β (TGF-β), which contribute to fibroblast recruitment [19,20]. Upon activation, monocytes and lymphocytes generate additional chemotactic factors including leukotriene B_4 (LTB_4), PDGF, and TGF-β to recruit fibroblasts.

The provisional matrix is composed of adhesive molecules such as fibronectin and thrombospondin bound to fibrin as well as platelet granule components released during platelet aggregation. Platelet granule components include thrombospondin, released from the platelet α-granule, and cytokines including TGF-α, TGF-β, PDGF, platelet factor 4, and platelet-derived endothelial cell growth factor. The provisional matrix is stabilized by the cross-linking of fibrin by factor XIIIa.

The provisional matrix appears to provide both structural and biochemical components to the process of wound healing. The complex three-dimensional structure of the fibrin network with attached adhesive proteins provides a substrate for cell adhesion and migration. The presence of mitogens, chemoattractants, cytokines, and growth factors within the provisional matrix provides for a rich milieu of activating and inhibiting substances for various cellular proliferative and synthetic processes.

The provisional matrix may be viewed as a naturally derived, biodegradable, sustained release system in which mitogens, chemoattractants, cytokines, and growth factors are released to control subsequent wound healing processes [21–27]. Despite the rapid increase in our knowledge of the provisional matrix and its capabilities, our knowledge of the control of the formation of the provisional matrix and its effect on subsequent wound healing events is poor.

Temporal Sequence of Inflammation and Wound Healing

Inflammation is generally defined as the reaction of vascularized living tissue to local injury. Inflammation serves to contain, neutralize, dilute, or wall off the injurious agent or process. In addition, it sets into motion a series of events that may heal and reconstitute the implant site by replacing the injured tissue by regenerating native parenchymal cells, forming fibroblastic scar tissue, or a combination of these processes [4,6].

The sequence of events after implantation of a biomaterial is illustrated in Fig. 39.1. The size, shape, and chemical and physical properties of the biomaterial and the physical dimensions and properties of the prosthesis or device may be responsible for variations in the intensity and time duration of the inflammatory and wound healing processes. Thus, the intensity and/or time duration of the inflammatory reaction may characterize the biocompatibility of a biomaterial or device.

Classically, the biocompatibility of an implanted material has been described in terms of the morphological appearance of the inflammatory reaction to the material; however, the inflammatory response is a series of complex reactions involving various types of cells, the densities, activities, and functions of which are controlled by various endogenous and autacoid mediators. The simplistic view of the acute inflammatory response progressing to the chronic inflammatory response may be misleading with respect to biocompatibility studies and the inflammatory response to implants. In vivo studies using the cage implant system show that monocytes and macrophages are present in highest concentrations when neutrophils are also at their highest concentrations: that is, the acute inflammatory response [28,29]. Neutrophils have short lifetimes (hours to days) and disappear from the exudates more rapidly than do macrophages, which have lifetimes of days to weeks to months. Eventually, macrophages become the predominant cell type in the exudates, resulting in a chronic inflammatory response. Monocytes rapidly differentiate into macrophages, the cells principally responsible for normal wound healing in the foreign body reaction. Classically, the development of granulation tissue has been considered to be part of chronic inflammation, but because of unique tissue–material interactions, it is preferable to differentiate the foreign body reaction, with its varying degree of granulation tissue development, including macrophages, fibroblasts, and capillary formation, from chronic inflammation.

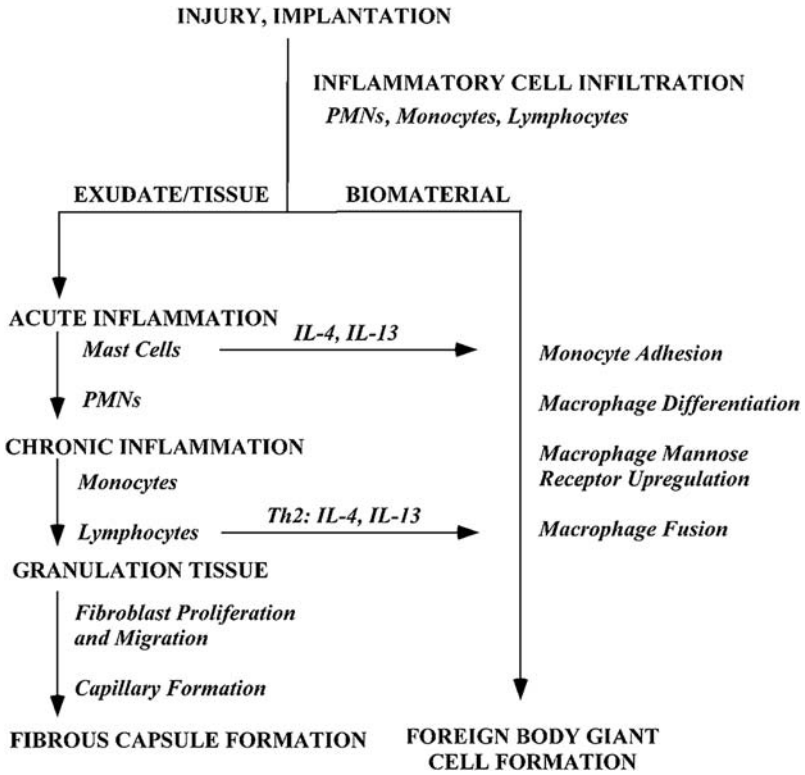

FIGURE 39.1 **Sequence of events involved in inflammatory and wound healing responses leading to foreign body giant cell (FBGC) formation.** This shows the potential importance of mast cells in the acute inflammatory phase and T-helper 2 (Th2) lymphocytes in the transient chronic inflammatory phase with the production of interleukin (IL)-4 and IL-13, which can induce monocyte/macrophage fusion to form FBGCs. *PMN*, polymorphonuclear.

Acute Inflammation

Acute inflammation is of relatively short duration, lasting from minutes to days, depending on the extent of injury. The main characteristics of acute inflammation are the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes (predominantly neutrophils). Neutrophils and other motile white cells emigrate or move from the blood vessels to the perivascular tissues and the injury (implant) site [30–32].

The accumulation of leukocytes, in particular neutrophils and monocytes, is the most important feature of the inflammatory reaction. Leukocytes accumulate through a series of processes including margination, adhesion, emigration, phagocytosis, and extracellular release of leukocyte products [33]. Increased leukocytic adhesion in inflammation involves specific interactions between complementary "adhesion molecules" present on the leukocyte and endothelial surfaces [34,35]. The surface expression of these adhesion molecules is modulated by inflammatory agents; mechanisms of interaction include stimulation of leukocyte adhesion molecules (C5a and LTB_4), stimulation of endothelial adhesion molecules (interleukin-1 [IL-1]), or both effects of tumor necrosis factor-α (TNF-α). Integrins are composed of a family of transmembrane glycoproteins that modulate cell–matrix and cell–cell relationships by acting as receptors to extracellular protein ligands and also as direct adhesion molecules [36]. An important group of integrins (adhesion molecules) on leukocytes include the CD11/CD18 family of adhesion molecules. Inflammatory mediators (i.e., cytokines) stimulate a rapid increase in these adhesion molecules on the leukocyte surface as well as increased leukocyte adhesion to endothelium. Leukocyte–endothelial cell interactions are also controlled by endothelial–leukocyte adhesion molecules (also known as E-selectins) or intracellular adhesion molecules (ICAMs) such as ICAM-1 and ICAM-2, and vascular cell adhesion molecules on endothelial cells [37].

Inflammatory cell emigration is controlled in part by chemotaxis, which is the unidirectional migration of cells along a chemical gradient. A wide variety of exogenous and endogenous substances have been identified as chemotactic agents [11,30–41]. Important to the emigration or movement of leukocytes is the presence of specific receptors for chemotactic agents on the cell membranes of leukocytes. These and other receptors also may have a role in activating leukocytes. After localization of leukocytes at the injury (implant) site, phagocytosis and the release of enzymes occur following activation of neutrophils and macrophages. The major role of the neutrophils in acute inflammation is to phagocytose microorganisms and foreign materials. Phagocytosis is seen as a three-step process in which the injurious agent undergoes recognition and neutrophil attachment, engulfment, and killing or degradation. With regard to biomaterials, engulfment and degradation may or may not occur, depending on the properties of the biomaterial.

Although biomaterials are not generally phagocytosed by neutrophils or macrophages because of the size disparity (i.e., the surface of the biomaterial is greater than the size of the cell), certain events may occur in phagocytosis. The process of recognition and attachment is expedited when the injurious agent is coated by naturally occurring serum factors called opsonins. The two major opsonins are immunoglobulin (Ig)G and the complement-activated fragment, C3b. Both of these plasma-derived proteins are known to adsorb to biomaterials, and neutrophils and macrophages have corresponding cell membrane receptors for these opsonization proteins. These receptors may also have a role in activating the attached neutrophil or macrophage. Because of the size disparity between the biomaterial surface and the attached cell, "frustrated phagocytosis" may occur [38,39]. This process does not involve engulfing the biomaterial but it causes the extracellular release of leukocyte products in an attempt to degrade the biomaterial. Neutrophils adherent to complement-coated and Ig-coated nonphagocytosable surfaces may release enzymes by direct extrusion or exocytosis from the cell [38,39]. The amount of enzyme released during this process depends on the size of the polymer particle, with larger particles inducing greater amounts of enzyme release. This suggests that the specific mode of cell activation in the inflammatory response in tissue depends on the size of the implant and that a material in a phagocytosable form (e.g., powder or particulate) may provoke a degree of inflammatory response different from that of the same material in a nonphagocytosable form (e.g., film).

Tissue-engineered constructs containing biomaterial scaffolds alone or with cells and/or chemokines, growth factors, or other biological components are thus subjected to an aggressive microenvironment that may quickly compromise the intended function of the construct [42].

Chronic Inflammation

Chronic inflammation is less uniform histologically than is acute inflammation. In general, chronic inflammation is characterized by the presence of monocytes and lymphocytes with the early proliferation of blood vessels and connective tissue [4,6,43–45]. Many factors modify the course and histological appearance of chronic inflammation.

Persistent inflammatory stimuli lead to chronic inflammation. Although the chemical and physical properties of the biomaterial may lead to chronic inflammation, motion in the implant site by the biomaterial may also produce chronic inflammation. The chronic inflammatory response to biomaterials is confined to the implant site. Inflammation with the presence of mononuclear cells, including lymphocytes and plasma cells, is given the designation chronic inflammation, whereas the foreign body reaction with granulation tissue development is considered the normal wound healing response to implanted biomaterials (i.e., the normal foreign body reaction). Chronic inflammation with biocompatible materials is usually of short duration (i.e., a few days).

Lymphocytes and plasma cells are involved principally in immune reactions and are important mediators of antibody production and delayed hypersensitivity responses. Their roles in nonimmunological injuries and inflammation are largely unknown [46–48]. Little is known regarding immune responses and cell-mediated immunity to synthetic biomaterials. The role of macrophages must be considered in the possible development of immune responses to synthetic biomaterials. Macrophages and dendritic cells process and present the antigen to immunocompetent cells and thus are critical mediators in the development of immune reactions.

The macrophage is probably the most important cell in chronic inflammation because of the great number of biologically active products it produces [44]. Important classes of products yielded and secreted by macrophages include neutral proteases, chemotactic factors, arachidonic acid metabolites, reactive oxygen metabolites; complement components, coagulation factors, growth-promoting factors, and cytokines [49–51].

Growth factors such as PDGF, fibroblast growth factor, TGF-β, TGF-α/epithelial growth factor, and IL-1 or TNF are important to the growth of fibroblasts and blood vessels and the regeneration of epithelial cells. Growth factors released by activated cells stimulate the production of a wide variety of cells; initiate cell migration, differentiation, and tissue remodeling; and may be involved in various stages of wound healing [19,52–56]. There is a lack of information regarding interaction and synergy among various cytokines and growth factors and their abilities to exhibit chemotactic, mitogenic, and angiogenic properties.

Granulation Tissue

Within 1 day after implantation of a biomaterial (i.e., injury), the healing response is initiated by the action of monocytes and macrophages, followed by the proliferation of fibroblasts and vascular endothelial cells at the implant site, leading to the formation of granulation tissue, the hallmark of healing inflammation. Granulation tissue derives its name from the pink, soft, granular appearance on the surface of healing wounds; its characteristic histological features include the proliferation of new small blood vessels and fibroblasts. Depending on the extent of injury, granulation tissue may be seen as early as 3–5 days after the implantation of a biomaterial.

The new small blood vessels are formed by budding or sprouting of preexisting vessels in a process known as neovascularization or angiogenesis [45,57–60]. This process involves proliferation, maturation, and organization of endothelial cells into capillary tubes. Fibroblasts also proliferate in developing granulation tissue and are active in synthesizing collagen and proteoglycans. In the early stages of granulation tissue development, proteoglycans predominate; later, however, collagen (especially type I collagen) predominates and forms the fibrous capsule. Some fibroblasts in developing granulation tissue may have features of smooth muscle cells. These cells are called myofibroblasts and are considered to be responsible for the wound contraction seen during the development of granulation tissue.

Macrophage Interactions

The inflammatory and immune systems overlap considerably through the activity and phenotypic expression of macrophages that are derived from blood-borne monocytes. Monocytes and macrophages belong to the mononuclear phagocytic system (MPS) (Table 39.3). Cells in the MPS may be considered resident macrophages in the respective tissues that take on specialized functions that depend on their tissue environment. From this perspective, the host defense system may be seen as blood-borne or circulating inflammatory and immune cells as well as mononuclear phagocytic cells that reside in specific tissues with specialized functions. In the inflammatory and immune responses, the macrophage has a pivotal role in both the induction and effector phases of these responses.

Two factors that have a role in monocyte or macrophage adhesion and activation and foreign body giant cell (FBGC) formation are the surface chemistry of the substrate onto which the cells adhere and the protein adsorption that occurs before cell adhesion. These two factors have been hypothesized to have significant roles in the inflammatory and wound healing responses to biomaterials and medical devices in vivo.

TABLE 39.3 Mononuclear Phagocytic System

Tissues	Cells
Implant sites	Inflammatory macrophages, foreign body giant cells
Liver	Kupffer cells
Lung	Alveolar macrophages
Connective tissue	Histiocytes
Bone marrow	Macrophages
Spleen and lymph nodes	Fixed and free macrophages
Serous cavities	Pleural and peritoneal macrophages
Nervous system	Microglial cells
Bone	Osteoclasts
Skin	Langerhans cells and dendritic cells
Lymphoid tissue	Dendritic cells

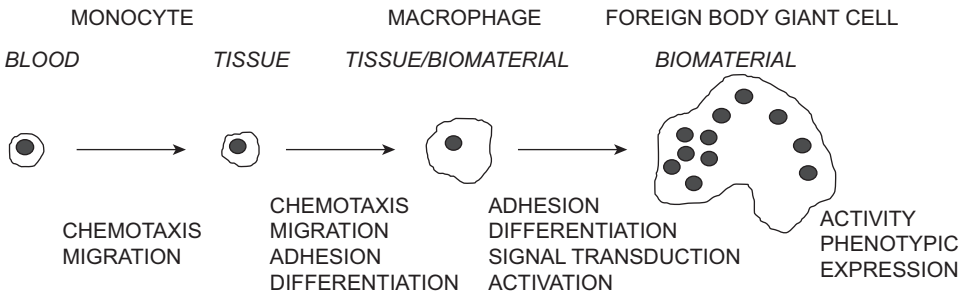

FIGURE 39.2 **In vivo transition from blood-borne monocyte to biomaterial-adherent monocyte/macrophage to foreign body giant cell (FBGC) at the tissue–biomaterial interface.** Little is known regarding the indicated biological responses that are considered to have important roles in the transition to FBGC development.

Macrophage interactions with biomaterials are initiated when blood-borne monocytes in the early transient responses migrate to the implant site and adhere to the blood protein adsorbed biomaterial through monocyte–integrin interactions. After adhesion, adherent monocytes differentiate into macrophages that then may fuse to form FBGCs. Fig. 39.2 demonstrates the progression from circulating blood monocyte to tissue macrophage to FBGC development that is most commonly observed. Because of the progression of monocytes to macrophages to FBGCs (Fig. 39.2), the following discussion of macrophage interactions includes perspectives on how macrophages are formed (i.e., monocyte adhesion) and what happens to macrophages on biomaterial surfaces (i.e., FBGC formation) [61,62].

Material surface property-dependent blood protein adsorption occurs immediately upon surgical implantation of a biomaterial; it is the protein-modified biomaterial that inflammatory cells subsequently encounter. Monocytes express receptors for various blood components, but they recognize naturally occurring foreign surfaces by receptors for opsonins such as fragments of complement component C3. Complement activation by biomaterials has been well-documented [63]. Exposure to blood during biomaterial implantation may permit extensive opsonization with the labile fragment C3b and the rapid conversion of C3b to its hemolytically inactive but nevertheless opsonic and more stable form, C3bi. C3b is bound by the CD35 receptor, but C3bi is recognized by distinct receptors, CD11b/CD18 and CD11c/CD18, on monocytes [61]. Fibrinogen, a major plasma protein that adsorbs to biomaterials, is another ligand for these receptors that, together with CD11a/CD18, constitutes a subfamily of integrins that is restricted to leukocytes [61,62]. Studies with monoclonal antibodies to their common β_2 subunit (CD18) and distinct α-chains have implicated CD11b/CD18 and CD11c/CD18 in monocyte/macrophage responses. Other potential adhesion-mediating proteins that adsorb to biomaterials include IgG, which may interact with monocytes via various receptors and fibronectin, for which monocytes also express multiple types of receptors [64–67].

Foreign Body Giant Cell Formation and Interactions

The foreign body reaction is composed of FBGCs and the components of granulation tissue, which consist of macrophages, fibroblasts, and capillaries in varying amounts, depending on the form and topography of the implanted material [68]. Relatively flat and smooth surfaces, such as those found on breast prostheses, have a foreign body reaction that is composed of a layer of macrophages one to two cells thick. Relatively rough surfaces, such as those found on the outer surfaces of expanded poly(tetrafluoroethylene) vascular prostheses or poly(methyl methacrylate) bone cement, have a foreign body reaction composed of several layers of macrophages and FBGCs at the surface. Fabric materials generally have a surface response composed of macrophages and FBGCs with varying degrees of granulation tissue subjacent to the surface response.

As previously discussed, the form and topography of the surface of the biomaterial determine the composition of the foreign body reaction. With biocompatible materials, the composition of the foreign body reaction in the implant site may be controlled by the surface properties of the biomaterial, the form of the implant, and the relationship between the surface area of the biomaterial and the volume of the implant. For example, high surface-to-volume implants such as fabrics or porous materials will have higher ratios of macrophages and FBGCs in the implant site than will smooth-surface implants, which will have fibrosis as a significant component of the implant site.

The foreign body reaction consisting mainly of macrophages and/or FBGCs may persist at the tissue−implant interface for the lifetime of the implant [1,2,69−71]. Generally, fibrosis (i.e., fibrous encapsulation) surrounds the biomaterial or implant with its interfacial foreign body reaction, isolating the implant and foreign body reaction from the local tissue environment. Early in the inflammatory and wound healing response, the macrophages are activated upon adherence to the material surface [50]. Although the chemical and physical properties of the biomaterial are generally considered to be responsible for macrophage activation, the nature of subsequent events regarding the activity of macrophages at the surface is not clear. Tissue macrophages, derived from circulating blood monocytes, may coalesce to form multinucleated FBGCs. FBGCs containing large numbers of nuclei are typically present on the surface of biomaterials. Although these FBGCs may persist for the lifetime of the implant, it is not known whether they remain activated, releasing their lysosomal constituents, or become quiescent. FBGCs have been implicated in the biodegradation of polymeric medical devices [72−74].

Fig. 39.1 demonstrates the sequence of events involved in inflammation and wound healing when medical devices are implanted. In general, the neutrophil (polymorphonuclear) predominant acute inflammatory response and the lymphocyte/monocyte predominant chronic inflammatory response resolve quickly (i.e., within 2 weeks), depending on the type and location of the implant. Studies using IL-4 demonstrate the role for type 2 (Th2) helper lymphocyte and mast cells in the development of the foreign body reaction at the tissue−material interface [75]. Th2 helper lymphocytes have been described as "antiinflammatory" based on their cytokine profile, of which IL-4 is a significant component. Th2 helper lymphocytes also produce IL-13, which has an effect similar to that of IL-4 on FBGC formation. In this regard, anti-IL-4 antibody does not inhibit IL-13−induced FBGC formation, nor does anti-IL-13 antibody inhibit IL-4−induced FBGC formation. In IL-4 and IL-13 FBGC culture systems, the macrophage mannose receptor (MMR) has been identified as critical to the fusion of macrophages in the formation of FBGC [76,77]. FBGC formation can be prevented by competitive inhibitors of MMR activity (i.e., α-mannan) or inhibitors of glycoprotein processing that restrict MMR surface expression.

Regarding the effect of lymphocytes on the foreign body reaction, studies have demonstrated that interactions with lymphocytes enhance adherent macrophage and FBGC production of proinflammatory cytokines. Interactions through indirect (paracrine) signaling showed a significant proinflammatory effect in enhancing adherent macrophage/FBGC at early time points, whereas interactions via direct (juxtacrine) mechanisms dominated at later points. Furthermore, lymphocytes prefer interactions with adherent macrophages and FBGCs, as opposed to biomaterial surfaces, resulting in lymphocyte activation [78−81]. In vivo studies using clinically synthetic biomaterials have demonstrated that there is a quantitative increase in T cells after secondary biomaterial exposure, but the T-cell subset distribution does not change, indicating nonspecific recruitment of T cells rather than an adaptive immune response. Studies in T cell−deficient mice have shown no change in foreign body giant cell formation. In vitro studies with clinical synthetic biomaterials showed no expression of the activation markers CD69 and CD25 and lymphocyte proliferation was not identified [82−85]. Results from these in vivo and in vitro studies do not suggest an adaptive immune response with clinically relevant biomaterials, because T cell markers CD25 and CD69 were not upregulated and T cell cytokines IL-2 and interferon-gamma were not present.

FBGC formation at the surface of implanted biomaterials occurs quickly and within days to weeks after implantation. Fig. 39.3 shows scanning electron micrographs of monocytes, macrophages, and FBGCs at various times after implantation of a biocompatible polyurethane material in the in vivo rat cage system. Monocyte adhesion

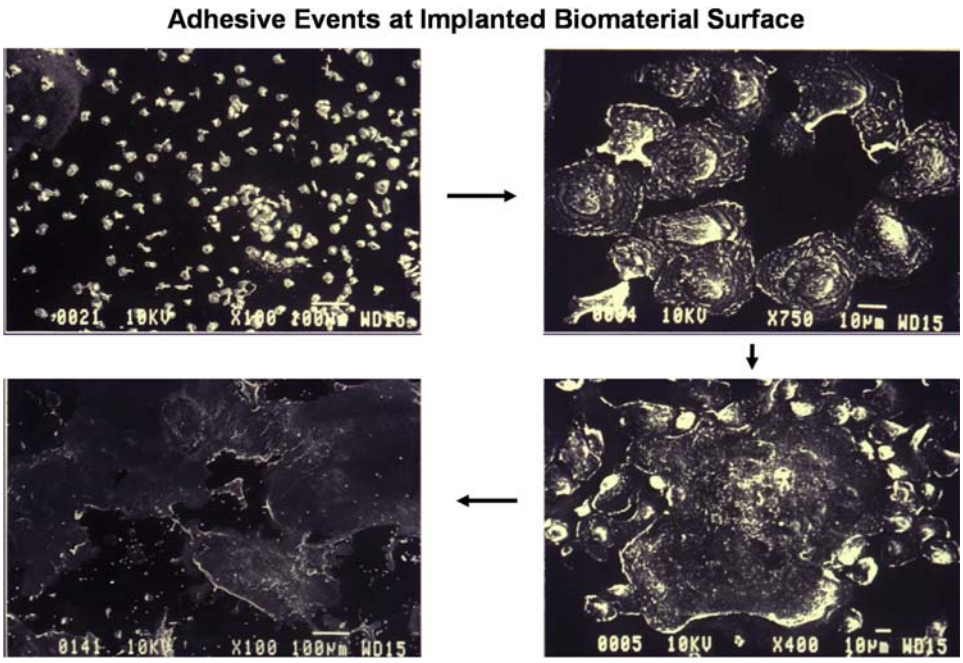

FIGURE 39.3 **In vivo time-dependent processes of monocyte adhesion (A), macrophage development (B), early macrophage fusion to form foreign body giant cells (C), and late macrophage and foreign body giant cell fusion to form large foreign body giant cells (D).**

(Fig. 39.3A) occurs quickly, at 2–4 days. Macrophage development is seen within 1 week after implantation (Fig. 39.3B). Macrophage fusion to form FBGCs can occur within 1–2 weeks after implantation (Fig. 39.3C); interestingly, FBGCs themselves can fuse to produce exceptionally large giant cells on the surface (Fig. 39.3D). Of interest in the use of porous scaffolds and other forms of topographical variations of implanted tissue-engineered systems, these large giant cells may be significantly large enough to cover the porous structure and thus inhibit cellular infiltration into the respective pores as well as inhibit diffusion from these porous structures. The formation of large FBGCs formed late (i.e., weeks) may compromise the function of tissue-engineered medical devices in which porosity and diffusion are important design criteria for the function of the device. Examples of such behavior are the development of biosensors and of complex tissue-engineered scaffolds in which proteins and other important modifying agents depend on diffusion from the device into the microenvironment. The potential for these events should be considered in the design of in vivo biocompatibility studies.

FIBROSIS AND FIBROUS ENCAPSULATION

The end-stage healing response to biomaterials is generally fibrosis or fibrous encapsulation. However, tissue-engineered devices may be exceptions to this general statement (e.g., porous materials inoculated with parenchymal cells or porous materials implanted into bone).

Repair of implant sites involves two distinct processes: regeneration, which is the replacement of injury tissue by parenchymal cells of the same type, or replacement by connective tissue that constitutes the fibrous capsule. These processes are generally controlled by either the proliferative capacity of the cells in the tissue receiving the implant and the extent of injury as it relates to the destruction or persistence of the tissue framework of the implant site. The regenerative capacity of cells permits classification into three groups: labile, stable (or expanding), and permanent (or static) cells. Labile cells continue to proliferate throughout life, stable cells retain this capacity but do not normally replicate, and permanent cells cannot reproduce themselves after birth. Perfect repair with restitution of normal structure theoretically occurs only in tissue consisting of stable and labile cells, whereas all injuries to tissues composed of permanent cells may result in fibrosis and fibrous capsule formation with little restitution of the normal tissue or organ structure. Tissues composed of permanent cells (e.g., nerve cells, skeletal muscle cells, and cardiac muscle cells) most commonly undergo an organization of the inflammatory exudates, leading to fibrosis. Tissues composed of stable cells (e.g., parenchymal cells of the liver, kidney, and pancreas), mesenchymal cells

(e.g., fibroblasts, smooth muscle cells, osteoblasts, and chondroblasts), and vascular endothelial and labile cells (e.g., epithelial cells and lymphoid and hematopoietic cells) may also follow this pathway to fibrosis or may undergo resolution of the inflammatory exudates, leading to restitution of the normal tissue structure. The condition of the underlying framework or supporting stroma of the parenchymal cells after an injury has an important role in restoring normal tissue structure. Retention of the framework may lead to restitution of the normal tissue structure, whereas destruction of the framework most commonly leads to fibrosis. It is important to consider the species-dependent nature of the regenerative capacity of cells. For example, cells from the same organ or tissue but from different species may exhibit different regenerative capacities and/or connective tissue repair.

The extent of provisional matrix formation is an important factor because it is related to wound healing by first or second intention. First intention (primary union) wound healing occurs when there is minimal to no space between the tissue and device, whereas second intention (secondary union) wound healing occurs when a large space is present, providing for extensive provisional matrix formation. Obviously, inappropriate or inadequate preparation of the implant site leading to extensive provisional matrix formation may predispose the implant to failure through mechanisms related to fibrous capsule formation.

The inflammatory (innate) and immune (adaptive) responses have common components. It is possible to have inflammatory responses only with no adaptive immune response. In this situation, both humoral and cellular components that are shared by both types of responses may only participate in the inflammatory response. Table 39.4 indicates the common components of the inflammatory (innate) and immune (adaptive) responses. Macrophages and dendritic cells are known as professional antigen-presenting cells responsible for the initiation of the adaptive immune response.

Many investigators have considered macrophages and dendritic cells to be distinctly different antigen-presenting cells (APCs). Hume summarized evidence that dendritic cells are part of the mononuclear phagocyte system and are derived from the same common macrophage precursor; they are responsive to the same growth factors, express the same surface markers, and have no unique adaptation for antigen presentation that is not shared by other macrophages [86].

IMMUNOTOXICITY (ACQUIRED IMMUNITY)

The acquired or adaptive immune system acts to protect the host from foreign agents or materials and usually is initiated through specific recognition mechanisms and the ability of humoral and cellular components to recognize the foreign agent or material as being "nonself" [18,87–92]. Generally, the adaptive immune system may be considered to have two components: humoral or cellular. Humoral components include antibodies, complement components, cytokines, chemokines, growth factors, and other soluble mediators. These components are synthesized by cells of the immune response; in turn, they function to regulate the activity of these cells and provide for communication between different cells in the cellular component of the adaptive immune response. Cells of the immune system arise from stem cells in the bone marrow (B lymphocytes) or the thymus (T lymphocytes) and differ from each other in morphology, function, and the expression of cell-surface antigens. They share the common features of maintaining cell-surface receptors that assist in recognizing and/or eliminating foreign materials. Regarding tissue-engineered devices, the adaptive immune response may recognize the biological components, modifications

of the biological components, or degradation products of the biological components, commonly known as antigens, and initiate immune response through humoral or cellular mechanisms.

Components of the humoral immune system have important roles in the inflammatory responses to foreign materials. Antibodies and complement components C3b and C3bi adhere to foreign materials, act as opsonins, and facilitate phagocytosis of the foreign materials by neutrophils and macrophages that have cell-surface receptors for C3b. Complement component C5a is a chemotactic agent for neutrophils, monocytes, and other inflammatory cells and facilitates the immigration of these cells to the implant site. The complement system is composed of classic and alternative pathways that eventuate in a common pathway to produce the membrane attack complex, which is capable of lysing microbial agents. The complement system (i.e., complement cascade) is closely controlled by protein inhibitors in the host cell membrane that may prevent damage to host cells. This inhibitory mechanism may not function when non-host cells are used in tissue-engineered devices.

T (thymus-derived) lymphocytes are significant cells in the cell-mediated adaptive immune response and their cell-adhesion molecules have a significant role in lymphocyte migration, activation, and effector function. The specific interaction of cell membrane adhesion molecules, sometimes also called ligands or antigens, with APCs produces specific types of lymphocytes with specific functions. Table 39.5 indicates cell types and function in the adaptive immune response. Obviously, the functions of these cells are more numerous than those indicated in the table, but the major function of these cells is provided to indicate similarities and differences in the interaction and responsiveness of these cells. Effector T cells (Table 39.6) are produced when their antigen-specific receptors and either the CD4 or the CD8 co-receptors bind to peptide−major histocompatibility complexes (MHCs). A second, costimulatory signal is also required, which is provided by the interaction of the CD28 receptor on the T cell and the B7.1 and B7.2 glycoproteins of the Ig superfamily present on APCs. B lymphocytes bind soluble antigens through their cell-surface Ig and thus can function as professional APCs by internalizing the soluble antigens and presenting peptide fragments of these antigens as MHC−peptide complexes. Once activated, T cells can synthesize the T-cell growth factor IL-2 and its receptor. Thus, activated T cells secrete and respond to IL-2 to promote T cell growth in an autocrine fashion.

TABLE 39.5 Cell Types and Function in Adaptive Immune System

Cell Type	Motor Function
Macrophages (antigen-presenting cell [APC])	Process and present antigen to immunocompetent T cells
	Phagocytosis
	Activated by cytokines (i.e., interferon-gamma) from other immune cells
T cells	Interact with APCs and are activated through two required cell membrane interactions
	Facilitate target cell apoptosis
	Participate in transplant rejection (type IV hypersensitivity)
B cells	Form plasma cells that secrete immunoglobulins (IgGs) (IgA and IgE)
	Participate in antigen−antibody complex mediated tissue damage (type III hypersensitivity)
Dendritic cells (APC)	Process and present antigen to immunocompetent T cells
	Use Fc receptors for IgG to trap antigen−antibody complexes
Natural killer cells (non-T, non-B lymphocytes)	Innate ability to lyse tumor, virus-infected, and other cells without previous sensitization
	Mediates T- and B-cell function by secretion of interferon-gamma

TABLE 39.6 Effector T Lymphocytes in Adaptive Immunity

T-Helper 1 Cells	CD41
	Proinflammatory
	Activation of macrophages
	Produces IL-2, IFN-gamma, IL-3, TNF-α, GM-CSF, macrophage chemotactic factor, and migration inhibitor factor
	Induces IgG2a
Th2 helper cells	CD41
	Antiinflammatory
	Activation of B cells to make antibodies
	Produces IL-4, IL-5, IL-6, IL-10, IL-3, GM-CSF, and IL-13
	Induces IgG1
Cytotoxic T cells	CD81
	Induces apoptosis of target cells
	Produces IFN-gamma, TNF-β, and TNF-α
	Releases cytotoxic proteins

GM-CSF, granulocyte macrophage—colony-stimulating factor; *IFN*, interferon; *Ig*, immunoglobulin; *IL*, interleukin; *Th*, T helper; *TNF*, tumor necrosis factor.

Cytokines are the messenger molecules of the immune system. Most cytokines have a wide spectrum of effects, reacting with many different cell types, and some are produced by several different cell types. Table 39.7 presents common categories of cytokines and lists some of their general properties. Whereas cytokines can be subdivided into functional groups, many cytokines such as IL-1, TNF-α, and IFN-gamma are pleotropic in their effects and regulate, mediate, and activate numerous responses by various cells.

Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction [93]. Adverse or immunotoxic effects occur when humoral or cellular immunity needed by the host to defend itself against infections or neoplastic disease (immunosuppression) or unnecessary tissue damage (chronic inflammation, hypersensitivity, or autoimmunity) is compromised. Potential immunological effects and responses that may be associated with one or more of these effects are presented in Table 39.8. Hypersensitivity responses are classified on the basis of the immunological mechanism that mediates the response. There are four types: I (anaphylactic), II (cytotoxic), III (immune complex), and IV (cell-mediated delayed hypersensitivity). Hypersensitivity is considered to be increased reactivity to an antigen to which a human or animal has been previously exposed, with an adverse rather than a protective effect. Hypersensitivity is a synonym for allergy. Type I (anaphylactic) reactions and type IV (cell-mediated delayed hypersensitivity) reactions are the most common [94]. Types II and III reactions are relatively rare and are less likely to occur with medical devices and biomaterials; however, with tissue-engineered devices containing potential antigens (i.e., proteins), extracellular matrix (ECM) components, and/or cells, types II and III reactions must be considered in biological response evaluations.

Type I (anaphylactic) hypersensitivity reactions are mediated by IgE antibodies, which are cytotropic and affect the immediate release of basoactive amines and other mediators from basophils and mast cells followed by the recruitment of other inflammatory cells. Type IV cell-mediated (delayed) hypersensitivity responses involve sensitized T lymphocytes that release cytokines and other mediators that lead to cellular and tissue injury. Type IV hypersensitivity (cell-mediated) reactions are initiated by specifically sensitized T lymphocytes. This reaction includes the classic delayed-type hypersensitivity reaction initiated by CD4+ T cells and direct cell cytotoxicity mediated by CD8+ T cells. The less common type II (cytotoxic) hypersensitivity involves the formation and binding of IgG and/or IgM to antigens on target cell surfaces that facilitate phagocytosis of the target cell or lysis of the target cell by activated complement components. Type II hypersensitivity (cytotoxic) is mediated by antibodies directed toward antigens present on the surface of cells or other tissue components. Three different antibody-dependent mechanisms may be involved in this type of reaction: complement-dependent reactions, antibody-dependent

TABLE 39.7 Selected Cytokines and Their Effects

Cytokine	Effect
IL-1, TNF-α, INF-gamma, and IL-6	Mediate natural immunity
IL-1, TNF-α, and IL-6	Initiate nonspecific inflammatory responses
IL-2, IL-4, IL-5, IL-12, IL-15, and TGF-β	Regulate lymphocyte growth, activation, and differentiation
IL-2 and IL-4	Promote lymphocyte growth and differentiation
IL-10 and TGF-β	Downregulate immune responses
IL-1, INF-gamma, TNF-α, and migration inhibitor factor	Activate inflammatory cells
IL-8	Produced by activated macrophages and endothelial cells
	Chemoattractant for neutrophils
Monocyte chemoattractant protein-1, macrophage inflammatory protein-α, and Regulated on Activation, Normal T Expressed and Secreted	Chemoattractant for monocytes and lymphocytes
GM-CSF and G-CSF	Stimulate hematopoiesis
IL-4 and IL-13	Promote macrophage fusion and foreign body giant cell formation

G-CSF, granulocyte—colony-stimulating factor; *GM-CSF*, granulocyte macrophage—colony-stimulating factor; *IFN*, interferon; *IL*, interleukin; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor.

TABLE 39.8 Potential Immunological Effects and Responses

Effects	Responses
Hypersensitivity	Histopathological changes
Type I: anaphylactic	Humoral responses
Type II: cytotoxic	Host resistance
Type III: immune complex	Clinical symptoms
Type IV: cell-mediated (delayed)	Cellular responses
Chronic inflammation	T cells
Immunosuppression	Natural killer cells
Immunostimulation	Macrophages
Autoimmunity	Granulocytes

reactions, cell-mediated cytotoxicity, or antibody-mediated cellular dysfunction. Type III immune complex hypersensitivity is present when circulating antigen—antibody complexes activate complement whose components are chemotactic for neutrophils that release enzymes and other toxic moieties and mediators leading to cellular and tissue injury.

Immunological reactions that occur with organ transplant rejection also offer insight into potential immune responses to tissue-engineered devices. Mechanisms involved in organ transplant rejection include T cell—mediated reactions by direct and indirect pathways and antibody-mediated reactions. Immune responses may be avoided or diminished by using autologous or isogeneic cells in cell—polymer scaffold constructs. The use of allogeneic or xenogeneic cells incorporated into the device requires the prevention of immune rejection by immune suppression of the host, induction of tolerance in the host, or immunomodulation of the tissue-engineered construct. The development of tissue-engineered constructs by immunoisolation using polymer membranes and the use of non-host cells have been compromised by immune responses. In this concept, a polymer membrane is used to encapsulate non-host cells or tissues, thus separating them from the host immune system. However, antigens shed by encapsulated cells were released from the device and initiated immune responses [42,95,96].

Although exceptionally minimal and superficial in its presentation, the previously discussed humoral and cell-mediated immune responses demonstrate the possibility that any known tissue-engineered construct may undergo immunological tissue injury. To date, our understanding of immune mechanisms and their interactions with tissue-engineered constructs is markedly limited. An obvious problem is that preliminary studies are generally carried out with nonhuman tissues, and immune reactions result when tissue-engineered constructs from one species are used to test the device in another species. Ideally, tissue-engineered constructs would be prepared from cells and tissues of a given species and subsequently tested in that species. Although this approach does not guarantee that immune responses will not be present, the probability of immune responses in this type of situation is markedly decreased.

The following examples provide perspective to these issues. They further demonstrate the detailed and in-depth approach that must be taken to evaluate tissue-engineered constructs or devices and their potential adverse responses appropriately and adequately.

The inflammatory response considered to be immunotoxic is persistent chronic inflammation. With biomaterials, controlled release systems, and tissue-engineered devices, potential antigens capable of stimulating the immune response may be present and these agents may facilitate a chronic inflammatory response that is of extended duration (weeks or months). Regarding immunotoxicity, this persistent chronic inflammation is of concern because immune granuloma formation and other serious immunological reactions such as autoimmune disease may occur. Thus, in biological response evaluation, it is important to discriminate between the short-lived chronic inflammation that is a component of the normal inflammatory and healing responses versus long-term, persistent chronic inflammation that may indicate an adverse immunological response.

Immunosuppression may occur when antibody and T-cell responses (adaptive immune response) are inhibited. Potentially significant consequences of this type of response are frequent, and serious infections result from reduced host defense. Edelman and colleagues demonstrated that incorporating endothelial cells into three-dimensional collage matrices has a downregulating effect on the humeral and cellular immune response elicited by the endothelial cells [97]. The strong MHC-dominant immune response that occurs when endothelial cells are the primary component of an implant can be significantly reduced when the endothelial cells are embedded in the three-dimensional collagen matrix. Although they retain many of the characteristics of quiescent endothelial cells, the endothelial cells evoke no significant humeral or cellular immune response in immunocompetent animals and also reduce the memory response to previous free endothelial cell implants. These studies are significant and demonstrate the influence of spatial matrix formation as well as matrix composition on endothelial cell immunophenotype. Thus, modulation of the matrix structure may be helpful in designing vascular conduits for tissue-engineered devices.

Using ECM scaffolds prepared under different conditions, Badylak and colleagues determined the participation of different macrophage phenotypes in the degradation and remodeling of the ECM scaffolds, demonstrating that the properties of the matrix can control the innate and possibly acquired immune responses to ECM scaffolds [98–100].

Immunostimulation may occur when unintended or inappropriate antigen-specific or nonspecific activation of the immune system is present. From a biomaterial and controlled-release system perspective, antibody and/or cellular immune responses to a foreign protein may lead to unintended immunogenicity. Enhancement of the immune response to an antigen by a biomaterial with which it is mixed ex vivo or in situ may lead to adjuvancy, which is a form of immunostimulation. This effect must be considered when biodegradable controlled-release systems are designed and developed for use as vaccines [101–103].

Patients implanted with polyurethanes used for left ventricular assist devices (LVADs) experience B-cell hyperreactivity and allosensitization [104]. There is evidence that T lymphocytes can be activated in response to biomaterials. T lymphocytes cultured in the presence of polyurethane particles from the flexible diaphragms of LVADs resulted in intracellular calcium flux, CD40 ligand expression, and nuclear translocation of nuclear factor (NFAT) of activated T cells. NFAT translocation was reduced by a calcineurin inhibitor and CD40 ligand expression was reduced by both a calcineurin inhibitor and CD25 blockade indicating IL-2–dependent activation pathways [104,105]. In response to polyurethane particles, T lymphocytes exhibited classic activation indicators: calcium flux, translocation of transcription factors, upregulation of activation cell surface markers, and proliferation.

Differences in human leukocyte antigen (HLA) gene inheritance can result in MHC diversity. MHC loci are among the most genetically variable loci in humans. The MHC class II proteins (DP, DQ, and DR) are found on APCs. Diversity in MHCII proteins results in individual variability in antigen presentation and thus immune responses. Because of this diversity, individuals mount immune responses to different epitopes of pathogens. LVAD recipients who are predisposed to develop B-cell hyperreactivity have HLA-DR3 expression, which indicates

that lymphocyte responses to biomaterials are variable and depend on the individual's genetic profile [106]. It is possible that only individuals with certain MHCII receptors can interact with biomaterials in a mechanism that results in a lymphocyte response.

Autoimmunity is the immune response to the body's own constituents, which are considered in this response to be autoantigens. An autoimmune response, indicated by the presence of autoantibodies or T lymphocytes that are reactive with host tissue or cellular antigens, may (or may not) result in autoimmune disease with chronic, debilitating, and sometimes life-threatening tissue and organ injury.

Representative tests to evaluate for immune responses are given in Table 39.9. The table is not all-inclusive; other tests may be applicable. The examples presented represent only the large number of tests that are currently available [87,88,92]. The table is informative but incomplete, because in the future, direct and indirect markers of immune response may be validated and their predictive value documented, thus providing new tests for immunotoxicity. Direct measures of immune system activity by functional assays are the most important types of tests for immunotoxicity. Functional assays are generally more important than are tests for soluble mediators, which are more important than phenotyping. Signs of illness may be important in in vivo experiments, but symptoms may also have a significant role in studies of immune function in clinical trials and postmarket studies.

As with any type of test for biological response evaluation, immunotoxicity tests should be valid; they have been shown to provide accurate, reproducible results that indicate the effect being studied and are useful in a statistical analysis. This implies that appropriate control groups are also included in the study design.

Immunogenicity involving a specific immune response to a biomaterial is an important consideration because it may lead to serious adverse effects. For example, a foreign, nonhuman protein may induce IgE antibodies that cause an anaphylactic (type I) hypersensitivity reaction. An example of this type of response is latex protein found in latex gloves. Low—molecular weight compounds such as chemical accelerators used to manufacture latex gloves may also induce a T cell—mediated (type IV) reaction, resulting in contact dermatitis. Tests for type I (e.g., antigen-specific IgE) and type IV (e.g., guinea pig) maximization hypersensitivity should be considered for materials with the potential to cause these allergic reactions. In addition to hypersensitivity reactions, a device may elicit autoimmune responses (i.e., antibodies or T cells) that react with the body's own constituents. An autoimmune response may lead to the pathological consequences of an autoimmune disease. For example, a foreign protein may induce IgG or IgM

TABLE 39.9 Representative Tests for Evaluation of Immune Responses

Functional Assays	**Soluble Mediators**
Skin testing	Antibodies
Immunoassays (e.g., enzyme-linked immunosorbent assays)	Complement
Lymphocyte proliferation	Immune complexes
Plaque-forming cells	Cytokine patterns (T-cell subsets)
Local lymph node assay	Cytokines (IL-1, IL-1ra, TNF-α, IL-6, TGF-β, IL-4, and IL-13)
Mixed lymphocyte reaction	Chemokines
Tumor cytotoxicity	Basoactive amines
Antigen presentation	**Signs of illness**
Phagocytosis	
Degranulation	Allergy
Resistance to bacteria, viruses, and tumors	Skin rash
Phenotyping	Urticaria
	Edema
Cell-surface markers	Lymphadenopathy
Major histocompatibility complex markers	

IL, interleukin; *TNF*, tumor necrosis factor; *TGF*, transforming growth factor.

antibodies that cross-react with a human protein and cause tissue damage by activating the complement system. In a similar fashion, a biomaterial or controlled-release system that has a gel or oil constituent may act as an adjuvant, leading to the induction of an autoimmune response. Even if an autoimmune response (autoantibodies and/or autoreactive T lymphocytes) is suggested in preclinical testing, it is difficult to obtain convincing evidence that a biomaterial or controlled-release system causes autoimmune disease in animals. Therefore, routine testing for the induction of autoimmune disease in animal models is not recommended.

Babensee and coworkers tested the hypothesis that by promoting an inflammatory response, the biomaterial component of a medical device can recruit APCs (e.g., macrophages and dendritic cells) and induce their activation, thus acting as an adjuvant in the immune response to foreign antigens originating from the histological component of the device [107–109]. Using polystyrene and polylactic-glycolic acid microparticles and polylactic-glycolic scaffolds together with their model antigen, ovalbumin, in a mouse model for 18 weeks, the researchers demonstrated that a persistent humoral immune response that was Th2, T-cell dependent, as determined by IgG1, was present. These findings indicated that activation of CD41 T cells and the proliferation and isotype switching of B cells had occurred. A Th1 immune response characterized by the presence of IgG2a was not identified. Moreover, the humoral immune responses for all three types of microparticles were similar, indicating that the production of antigen-specific antibodies was not material chemistry–dependent in this model. Babensee et al. suggested that the presence of the biomaterial functions as an adjuvant for initiation and promotion of the immune response and augments the phagocytosis of the antigen with expression of MHCII and costimulatory molecules on APCs with the presentation of antigen to CD41 T cells.

Babensee and coworkers identified differential levels of dendritic cell maturation on different biomaterials used in combination products [110–114]. The effect of biomaterials on dendritic cell maturation, and the associated adjuvant effect, are novel biocompatibility selection and design criteria for biomaterials to be used in combination products in which immune consequences are potential complications or outcomes.

Badylak and colleagues carried out extensive studies on the use of xenogeneic ECM as a scaffold for tissue reconstruction [115–117]. Use of the small intestinal submucosa (SIS) ECM in animals indicated a restricted Th2-type immune response. The presence of natural antibodies to the terminal galactose-α1,3-galactose (α-gal) epitope is considered to be a major barrier to xenotransplantation in humans. Cell membranes of all animals except humans express this epitope, and naturally occurring antibodies mediate hyperacute or delayed rejection of transplanted organs through complement fixation or antibody dependence cell-mediated cytotoxicity. Whereas ECM derived from porcine tissues, SIS, contains small amounts of the galactose epitope, it appears that the quantity or distribution of this epitope and/or the subtype of Ig response to the epitope is such that complement activation does not occur [118]. In addition, the resorbable characteristics of this nonchemically cross-linked ECM scaffold demonstrate constructive tissue remodeling and deposition of new matrix whereas chemically cross-linked ECM leads to active inflammation and eventually scar formation.

The role of Th1 and Th2 lymphocytes in cell-mediated immune responses to xenografts has been examined. Activation of the Th1 pathway leads to macrophage activation, stimulation of complement fixing antibody isotypes, and differentiation of CD8+ cells to a cytotoxic type phenotype that is associated with both allogeneic and xenogeneic transplant rejection. The Th2 lymphocyte response does not activate macrophages and leads to production of noncomplement fixing antibody isotypes; it is usually associated with transplant acceptance.

The use of appropriate animal models is an important consideration in the safety evaluation of controlled-release systems that may contain potential immunoreactive materials [91,119,120]. A study involving the in vivo evaluation of recombinant human growth hormone in poly(lactic-*co*-glycolic acid) (PLGA) microspheres demonstrated the appropriate use of various animal models to evaluate biological responses and the potential for immunotoxicity. Using biodegradable PLGA microspheres containing recombinant human growth hormone (rhGH), Cleland et al. used rhesus monkeys, transgenic mice expression rhGH, and normal control (Balb/C) mice in their in vivo studies [112]. Rhesus monkeys were used for serum assays in the pharmacokinetic study of rhGH release as well as tissue responses to the injected microcapsule formulation. Placebo injection sites were also employed, and a comparison of the injection sites from rhGH PLGA microspheres and placebo PLGA microspheres demonstrated a normal inflammatory and wound healing response with a normal focal foreign body reaction. To examine the tissue response further, transgenic mice were used to assess the immunogenicity of the rhGH PLGA formulation. Transgenic mice expressing a heterologous protein were previously used to assess the immunogenicity of sequence or structural mutant proteins [121,122]. With the transgenic animals, no detectable antibody response to rhGH was found. In contrast, the Balb/C control mice had a rapid onset of high titer antibody response to the rhGH PLGA formulation. This study pointed out the appropriate use of animal models not only to evaluate biological responses but also for one type of immunotoxicity (immunogenicity) of controlled-release systems.

The focus in tissue engineering traditionally has been on modulating the fate of transplanted host cell populations that participate directly in reconstructing tissues. However, new materials for tissue engineering are being considered that give greater control over the inflammatory and immune responses [123]. Biomimetic strategies based on viruses and bacteria are being used to develop immune evasive biomaterials [124]. Materials are being investigated that can promote tolerance to specific antigens and cells by directly signaling APCs such as dendritic cells, or by releasing growth factors or cytokines that promote tolerance. On the other hand, materials might promote a destructive immune response by directly providing immunity-promoting signals or releasing insoluble factors. This approach could be used to combat infections and cancer [125].

CONCLUSION

Tissue-engineered devices are biological−biomaterial combinations in which some component of tissue has been combined with a biomaterial to create a device for the restoration or modification of tissue or organ function. The biocompatibility and bioresponse require the ultimate achievement of four significant goals if these devices are to function adequately and appropriately in the host environment. These goals are (1) restoration of the target tissue with its appropriate function and cellular phenotypic expression; (2) inhibition of the macrophage and FBGC foreign body response that may degrade or adversely modify device function; (3) inhibition of scar and fibrous capsule formation that may be deleterious to the function of the device; and (4) inhibition of immune responses that may inhibit the proposed function of the device and ultimately lead to the destruction of the tissue component of the tissue-engineered device. This chapter has presented a brief and limited overview of mechanisms and biological responses that determine biocompatibility: inflammation, wound healing, and immunotoxicity. Given the unique nature of the combination of tissue components and biomaterials in tissue-engineered devices, coupled with the species differences in biological responses, a significant future challenge in developing tissue-engineered devices is to construct and use a unique set of tests that will ensure that these four goals are achieved for the lifetime of the device in its in vivo environment in humans.

INTRODUCTION

Damage and degeneration of tissues caused by disease, injury, and trauma to the human body necessitate treatments including transplanting tissue from one site to another in the same patient (an autograft) or from one individual to another (a transplant or allograft). All techniques have the serious constraints of being expensive and painful and having the risks for rejection by the patient's immune system and the possibility of introducing infection or disease from the donor to the patient. Therefore, the approach of tissue engineering to repair defects in tissues is perceived as a smart strategies because the repair process proceeds with the patient's own tissue. The field of tissue engineering is highly multidisciplinary; it has the aim of developing biological substitutes to regenerate damaged tissues and to restore, maintain, or improve tissue function [1,2]. The tissue engineering triad is mainly composed of three main key components of engineered tissues: cells, scaffolds, and the growth-stimulating signal. Typically, the three-dimensional (3D) scaffolds are made from natural or synthetic biomaterials in various formats, serving as a template to provide an appropriate environment for tissue regeneration. These tissue engineered scaffolds are mainly seeded with cells and growth factors or subjected to biophysical stimuli in a bioreactor (a device that applies different types of mechanical or chemical stimuli to cells) [3]. These cell-seeded scaffolds are then either cultured in vitro to produce tissues followed by implantation into an injured site or directly implanted into the injured target site using the body's own systems in which tissues regeneration is induced in vivo [4]. In this chapter, we outline various materials used for scaffolding, the functions of scaffolds, approaches to scaffolding, and tissue-specific considerations for scaffolding, using bone as an example.

Materials that are implanted to repair, replace, or augment existing tissues in the body are generally known as biomaterials. In the wider context covered in this chapter, biomaterials include all materials formed in biological systems, e.g., the specific products of biomineralization. The development of biomaterials, both as products and in understanding their in vivo behavior, has been driven largely by the desire to assist in caring for patients. The material-forming processes occurring in living organisms require much milder reaction conditions than are currently used in the laboratory, such that a new area of materials chemistry, "biomimetics," has been established in which scientists are taking ideas from biology to generate "softer" routes to useful materials.

Biomaterials present in nature provide the necessary structure and architectures of all animal and plant species on earth and function to maintain the structure of organs as well as the organism itself. In nature, materials that are used are polymers such as polysaccharides and proteins and a relatively small number of simple insoluble oxides and salts. These can be put together in a wide range of combinations to produce materials that are soft, hard, flexible, elastic, etc. In contrast, the range of available materials for biomedical applications is vast and includes metals, polymers, ceramics, and their composites. In designing medical devices, materials are chosen to suit their intended use and the proposed implantation area. The materials that are used must have properties that are compatible with the location in which they are placed. Properties such as the tensile strength, toughness, elasticity, and hardness have to be considered, and other factors such as material transparency may have to be thought about if, for instance, the device is to be used within the eye.

Principles of Regenerative Medicine, Third Edition

Although technologists have a wider array of materials at their disposal, it is not a simple matter to come up with a material or series of materials that fulfil all of the criteria required for successful implantation or biomedical use. In the wider context covered in this chapter, biomaterials include all materials formed in biological systems, e.g., the specific products of biomineralization. The development of biomaterials, both as products and in understanding their in vivo behavior, has been driven largely by the desire to assist in caring for patients. The material-forming processes occurring in living organisms require much milder reaction conditions than are currently used in the laboratory, such that a new area of materials chemistry, "biomimetics," has been established in which scientists are taking ideas from biology to generate "softer" routes to useful materials.

FUNDAMENTALS OF BONE DEVELOPMENT AND DEFECTS

Bone is a calcium reservoir in the body in the form of hydroxyapatite (HA) (85%), calcium carbonate (10%), calcium fluoride (~3%), and magnesium fluoride (~3%). There are two main structural types in the bone: cortical bone forms a dense outer shell and cancellous or trabecular bone forms the porous inner core. Cortical bone is highly dense structure consisting of hierarchical structures, each within a different size scale; it provides torsion, bending resistance, and compressive strength. On the other hand, cancellous bone is highly porous and possesses an interconnected trabeculae network filled with marrow, a hierarchical structure ranging from solid material to trabeculae, lamellae, and a collagen–mineral composite. The trabeculae have a large surface area for the diffusion of nutrients and the circulation of growth factors, which allows cancellous bone tissue to be metabolically active and which can be remodeled more frequently than that of cortical bone.

Bone formation occurs via two distinctive pathways: intramembraneous and endochondral. First, mesenchymal cellular condensation occurs and acts as a template for subsequent bone formation. Intramembraneous bone formation involves the differentiation of mesenchymal progenitor cells directly into osteoblasts; it further develops into parts of the mandible, clavicle, and many cranial bones. Most of the bones in the human body, including all of the long bones and vertebrae, were formed through endochondral bone formation, in which mesenchymal progenitor cells differentiate into chondrocytes, which are responsible for cartilaginous template formation, and then are further mineralized and reinstated by bone.

Upon fracture, the bone becomes repaired by recapitulating several events of endochondral and intramembraneous bone formation and heals with no scar tissue formation. Usually, the formation of hematoma involves an inflammatory response and many signaling molecules specific for the regulation of new bone formation (i.e., tumor necrosis factor-α, interleukins, fibroblast growth factors, platelet-derived growth factor, vascular endothelial growth factor [VEGF], bone morphogenetic proteins [BMPs], etc.). The formation of intramembranous bone occurs immediately at the cortex and periosteum. Then the fracture becomes stabilized by the external soft tissues via callus formation; subsequently, chondrocyte proliferation takes place. Then the ingrowing blood vessels carry chondroclasts, which reabsorb calcified cartilage and osteoblastic progenitors and initiate new bone formation. The mechanical continuity of the cortex is achieved via subsequent remodeling of the newly formed bone. In case of damage or disease requiring bone tissue regeneration, the formation of hematoma and an early inflammatory response occurs, which facilitates host cell recruitment and the release of critical signaling molecules. Thus, smart scaffolds mimicking the properties of normal bone tissue development are important to efficient bone tissue engineering. Fundamental developmental biology principles that should be considered for bone tissue engineering are: (1) the use of pluripotent or multipotent stem cells; (2) the establishment of required growth factors, involved genes, and signal transduction cascades facilitating bone formation; (3) an understanding of the bone formation process and normal tissue healing; (4) an understanding of complex interactions between mesenchyme and epithelium, and mesenchyme-encoding, tissue-specific patterns; (5) an understanding of the criticality of the tissue microenvironment's physical characteristics (mechanotherapy, etc.); and (6) neovascularization and angiogenesis of the newly formed and developed bone tissue.

FUNCTIONS OF SCAFFOLDING AND EXTRACELLULAR MATRIX

Various tissue engineered constructs or scaffolds have been extensively fabricated from numerous materials and a plethora of manufacturing approaches for the neoregeneration of different tissues and organs in the body. When designing an ideal scaffold for tissue engineering, a number of important features and functions must be considered regardless of the type of tissue:

Architecture: Scaffolds should possess an interconnected pore structure and high porosity and void volume for proper vascularization, the formation of neotissue, and remodeling, which facilitates cell penetration and host tissue integration upon implantation. The biomaterial must provide enough interconnected porous structure for efficient nutrient and metabolite diffusion to cells within the scaffolds and to the extracellular matrix (ECM) formed by these cells without significantly compromising mechanical scaffold stability. Moreover, the scaffold should have enough mean pore size for cell migration within the structure where they eventually bind to the ligands present in scaffold materials, but small enough to establish a sufficiently high specific surface leading to a minimal ligand density to allow efficient binding of a critical number of cells to the scaffold [5]. Thus, for any scaffold, a critical range of pore sizes exists that may vary depending on the cell type used and the tissue being engineered [6]. Furthermore, the materials must be degradable upon implantation at a rate corresponding to the newly formed matrix by the developing tissue. The issue of core degradation, which arises from the lack of vascularization and waste removal from scaffolds, is one of the major concerns in the tissue engineering field [7,8].

Cytocompatibility: An important criterion for any tissue engineered scaffold is that it must be biocompatible: seeded cells must adhere, function normally, migrate onto or through the scaffold surface, and start proliferating during both in vitro culture and in vivo implantation before laying down new matrix. After implantation, the scaffold must be compatible with the cellular components and endogenous cells in host tissue and thus must elicit a negligible immune reaction or inflammatory response to avoid reduced healing or rejection by the body.

Bioactivity: Scaffolds must interact actively with the cellular components of the engineered tissues to regulate their activities. The construct material must be composed of biological cues such as cell-adhesive ligands to enhance attachment or physical cues such as topography to influence cell morphology and alignment. It can also act as a delivery vector for exogenous growth-stimulating signals to speed up regeneration such as growth factors. For example, hydrogels synthesized by covalent or ionic cross-linking can encapsulate proteins and perform a responsive release by hydrogels swelling [9].

Biodegradability: Scaffolds implanted for tissue engineering purposes were intended to be eventually replaced by the body's own cells. Thus, the scaffold material must be biodegradable, facilitating cells to generate their own ECM and produce nontoxic by-products followed by their removal from the body with no interference from other organs. Moreover, an inflammatory response with the infusion of controlled cells such as macrophages is essential for the execution of materials degradation with the formation of tissues or cells.

Mechanical characteristics: From a practical point of view, a scaffold should be strong enough to allow surgical handling during implantation. Moreover, its mechanical characteristics must be similar to the implantation anatomical site, providing mechanical and shape firmness to the tissue defect. Especially for orthopedic and cardiovascular applications, it is critical to design a scaffold with sufficient mechanical integrity mimicking host bone or cardiac tissue integrity. This becomes more challenging with age-dependent defects or fractures; for example, generally, fractures heal to an acceptable weight-bearing point at about 6 weeks in young individuals, but the repair rate slows down in elderly people. With the evolution of tissue engineering and regenerative medicine, the focus has been mostly diverted to manufacturing scaffolds with good mechanical properties and reduced porosity, which have been shown to have potential in vitro; however, these were unsuccessful when implanted in vivo owing to their insufficient capacity for vascularization. Thus, a well-established balance between the scaffold mechanical features and porous architecture allowing cell infiltration and vascularization is a vital factor for the success of any tissue engineered scaffold [4].

Except for blood cells, normal cells in human tissues are anchorage-dependent and located in a solid matrix called the ECM. There are various types of ECM in human tissues consisting of multiple components and a tissue-specific composition. Generally, functions of the ECM in tissues can be divided into five categories: (1) it provides a physical environment and structural support to cells in specific tissues to attach, grow, migrate, and respond to signals; (2) it provides mechanical and structural strength to tissues including elasticity and rigidity; (3) it actively provides bioactive cues to native cells to regulate their activities; (4) it behaves as a reservoir for growth factors and potentiates their bioactivities; and (5) it provides a degradable physical platform, allowing vascularization and remodeling in response to developmental, physiological, and pathological challenges during tissue dynamic processes such as morphogenesis, homeostasis, and wound healing, respectively. Thus, it is important for any ideal scaffold material to mimic the dynamic nature of the ECM in native tissues, at least partially [10].

SCAFFOLDING APPROACHES IN BONE TISSUE ENGINEERING

In this section, we discuss various approaches employed in bone tissue engineering from a materials point of view; further details are elaborated on in later sections.

Osteoinductive Materials

Osteoinductive refers to materials having the ability to induce the formation of ectopic bone by summoning the surrounding environment to form neobone [11−13]; thus, it holds immense potential for bone tissue regeneration. Materials including natural and synthetic ceramics (for example, HA, alumina ceramic, and porous Bioglass) [14] and several calcium phosphate compositions and their composites (for example, HA−poly[lactic-*co*-glycolic acid] [PLGA]) have been reported to be efficient osteoinductive materials in various bone tissue engineering studies. In particular, calcium phosphate−based designs (i.e., cements [15,16], coatings [17−19], sintered ceramics, and coral-derived ceramic [20,21]) have illustrated osteoinduction in several animal models. Polymer-ceramic blends (i.e., HA−PLGA) have displayed osteoinductive properties and induced ectopic bone formation [22,23]. Other than the material's chemical composition, several other factors have a critical role in determining osteoinduction, including porosity, surface properties, and nanotopography and microtopography. To explain osteoinductivity, two main hypotheses were proposed. The first is based on biomaterial surface properties that absorb and present osteoinductive factors to the surrounding cells. The second hypothesis is that calcium phosphate−based materials release calcium and phosphate ions, which influence stem cell differentiation into bone cells [13].

Immunomodulatory Materials

These systems have the ability to manipulate or modulate the immune system in favorably so as to enhance tissue regeneration. In general, the host's immune system reacts to an external implant by initiating an acute reaction to the surgical injury and recognize the alien material innately; this followed by adaptive immunity-mediated chronic inflammation in response to the recognition of specific antigens. Therefore, myriads of approaches were proposed in immune-bioengineering, highlighting the relevance of rational control over host inflammation that suggest cell-specific responses, accelerated wound healing, and bone tissue regeneration (enhanced activity of bone-forming cells and decreased activity of natural killer (NK) cells and T and B cell−mediated immunity). This includes the appropriate selection of materials, material surface functionalization and modulating agents (i.e., surface treatments and topography) and the inclusion of artificial ECM and bioactive agents. One approach is to develop biomaterials mimicking ECM composition and structure. Smith et al. showed polydioxanone and collagen−elastin composites with immune-modulating features by decreasing NK cell activity and T- and B-cell proliferation [24].

Material microscale and nanoscale architecture and its surface topography have a key role in modulating the immune system and host acute immune response upon scaffold implantation. Thus, the biomaterial surface should be functionalized to limit macrophage adhesion and activation, shielding them from protein absorption via polymer coating, delivering bioactive molecules (i.e., growth factors, antiinflammatory drugs), and thereby facilitating their fusion into foreign body giant cells. Some studies evaluated the pharmacologic modification effects of inflammatory response upon in vivo bone regeneration including cytokine-specific agents, corticosteroids, prostaglandins, nonsteroidal antiinflammatory drugs, and selective prostaglandin agonists [25]. A few studies have shown the enhanced strength of healed bone, vascularization at the fracture site, or accelerated fracture repair and regeneration with the controlled release of TP508 from various biodegradable scaffolds (PLGA microspheres and poly[propylene fumarate]) [26,27]. Although these results are interesting and promising, further detailed and advanced studies are essential that integrate inflammatory modulation strategies into tissue engineering to enhance tissue regeneration.

Hybrid Materials

Any biomaterial chosen for tissue engineering scaffolding needs to possess certain biological and physiochemical characteristics specific for the target tissue. However, it is difficult for any material to meet all of these expectations by itself; thus, hybrid materials have been made by combining two or more materials complementing each other in terms of the required features. Various optimal and advanced hybrids were developed (i.e., copolymers, polymer−polymer blends, polymer−ceramic composites) These are described in detail in later sections.

Hydrogels

Hydrogels, which have the ability to mimic ECM topography and deliver bioactive substances to promote tissue regeneration owing to their physical characteristics and biocompatibility, have become popular in tissue engineering and regenerative medicine. Examples includes both nature-derived (collagen, silk, and gelatin) and synthetic biomaterials (poly[vinyl alcohol] and poly[ethylene glycol]). Self-assembling peptides have attracted the interest of

researchers for scaffolding applications because these systems are nonimmunogenic, biocompatible, and biodegradable, and can be readily manufactured chemically and biologically to serve as a starting scaffolding matrix [28,29]. For instance, self-assembling RAD16-I (i.e., PuraMatrix, Cambridge, MA) can form an injectable nanofiber network or hydrogel upon implantation [30–32].

SCAFFOLDING MATERIALS

Natural Polymers

The major goal of bone tissue engineering is to develop bioconstructs that substitute for the functionality of damaged natural bone structures as much as possible if critical-sized defects occur. Scaffolds that mimic the structure and composition of bone tissue and cells have a pivotal role in bone tissue engineering. Natural polymers have attractive properties for the construction of 3D scaffolds, such as biocompatibility and biodegradability. The porosity, charge, and mechanical strength can be controlled by changing polymer concentrations or polymerization conditions, or by introducing various functional groups. Bioactivity can also be tuned by adding chemicals, proteins, peptides, and cells. The most commonly studied natural polymers for the purpose of bone engineering are collagen/gelatin, chitosan (CHI), silk, alginate, hyaluronic acid (HAc), and peptides [33]. Here we discuss studies in which these natural polymers were studied as 3D scaffolds for bone regeneration and were modified in different manners to improve their osteogenic capabilities.

Silk

Silk fibroin (SF) is a fibrous protein that is produced mainly by silkworms and spiders. Its unique mechanical properties and fine-tunable biodegradation rate, and the ability to support the differentiation of mesenchymal stem cells along the osteogenic lineage have made SF a favorable scaffold material for bone tissue engineering. SF can be processed into various scaffold forms that can be combined synergistically with other biomaterials to form composites and chemically modified, which provides an impressive toolbox and allows SF scaffolds to be tailored to specific applications [34]. Silk is composed of two major proteins: SF (fibrous protein) and sericin (globular protein). SF is a protein isolated from different animals in the form of an aqueous protein solution. The ability to produce silk has evolved multiple times among insects such as *Bombyx mori*, spiders, mites, and beetles with diverse functions [35].

In one study, calcium phosphate (CaP)/silk powders were incorporated into silk scaffolds to improve the porous structure and distribution of CaP powders in the composite scaffolds [36,37]. The scaffolds tested contained pure silk, or silk with 5% or 10% CaP. The pure silk and silk composite scaffolds were prepared using a freeze-drying method. The addition of CaP did not affect the compressive strength of the material (all tested were ~70 KPa) or the compressive modulus (~250 MPa for all materials tested). All scaffolds tested supported bone marrow stromal cell (BMSC) proliferation to comparable levels. However, alkaline phosphatase (ALP) activity was significantly higher in CaP–silk scaffolds at days 7 and 14. The expression of the osteogenic markers ALP, type 1 collagen, and osteocalcin (OCN) was also significantly increased in CaP–scaffolds at day 7 and 14 compared with pure silk scaffolds. In vivo bone formation was assessed in a calvarial defect model by microcomputed tomography (μCT). Groups studied were silk scaffold, CaP–scaffold, silk scaffold plus mesenchymal stem cells (MSCs), and CaP–scaffold plus MSCs. Defect areas were collected after 4 weeks. When bone formation was measured, it was clear that the addition of CaP into the scaffold significantly increased bone volume in the area. These results suggest that the presence of CaP in the scaffold was sufficient to enhance osteogenesis, because it did had no effect on the scaffold's mechanical properties. Decellularized bovine trabecular bone was used for comparison. It was found that the values of these parameters approached those for bovine trabecular bone in scaffolds with 3.1% and 4.6% HA. Calcium content was studied in all scaffolds at up to 10 weeks; there was increase over time but no differences between groups. These studies demonstrate a system in which, although there was no improvement in other work, the relationship between scaffold degradability and osteogenesis was examined [38]. 3D porous SF scaffolds were prepared with two different degradation rates. The water-based scaffold was synthesized as the rapidly degrading scaffold (control) and a slower-degrading scaffold was obtained by adding hexafluoroisopropanol (HFIP) to induce insolubility in aqueous media (HFIP scaffold). Degradation studies were performed; the control scaffold lost more than 90% of its mass at day 7 and the HFIP scaffold's mass remained nearly the same at 7 days. Various biochemical assays were performed on both scaffolds after seeding with MSCs and culturing for 16 or 56 days. At 56 days, the DNA content in the control scaffolds was around sixfold lower than for HFIP scaffolds.

There was no significant difference in ALP activity between the two scaffolds. However, calcium content/DNA and total collagen/DNA showed a dramatic increase in the rapidly degrading scaffold compared with the slowly degrading scaffold. There was no significant difference in the expression of osteogenesis-related genes ALP, bone sialoprotein (BSP), Col1a1, or osteopontin (OPN) between control and HFIP scaffolds. However, at day 56, hypoxia-inducible factor-1 (HIF-1) expression was significantly higher in the control than the HFIP scaffold. Studies in transgenic mice have shown that HIF-1 is a critical component of bone regeneration.

Another study was conducted to evaluate the ability of fibroin scaffolds combined with human stem cells, such as human dental pulp stem cells (hDPSCs) and human amniotic fluid stem cells (hAFSCs), to repair critical-size cranial bone defects [39]. These scaffolds had 85% porosity and pore diameters ranging from 10 to 250 μM, and a compressive modulus of 25.69 ± 1.61 kPa. hDPSCs and hAFSCs were seeded onto the scaffolds and grown in osteogenic media for 10 days before implantation into the cranial critical-size defect. Groups tested consisted of scaffolds without cells, scaffold plus hDPSCs, scaffold plus hAFSCs, and empty defect. Thirty days after surgery, radiograph images showed that scaffolds without cells were able to repair the area slightly, but this effect was more pronounced when either kind of stem cell was present.

Hematoxylin–eosin staining showed that vascularization was present in all scaffolds tested; however, hASFCs seemed to have a greater potential for bone regeneration because it was the only scaffold tested that showed bone in scaffold areas distant to the dura matter. Another study reported the effects of different concentrations of SF protein on a 3D scaffold pore microstructure and its effects on bone formation when cultured with BMSCs transfected with BMP-7 [36,37]. At 1 wt% silk protein, scaffolds had a porosity of 94% and a pore size ranging from 250 to 300 μM. At 2 wt% protein, porosity was 87% and the pore size was 200–250 μM. At 3.5 wt% silk protein, scaffolds had a porosity of 80% and a pore size ranging from 150 to 200 μM. At 2 wt% protein, porosity was 71% and pore size was from 80 to 150 μM. MSCs proliferated on all scaffolds, but at day 14 there was a significant decrease in the 5% scaffold. ALP activity was shown to increase in all groups, but there was significantly higher expression in the 3.5% scaffold. After 2 weeks in osteogenic medium, expression of osteogenic markers in transfected and untransfected MSCs in the various scaffolds was analyzed by reverse transcriptase–polymerase chain reaction (RT-PCR). ALP, Col1, and OCN had similar levels of expression in all scaffolds tested when they were transfected with BMP-7, except in the 5% scaffold, where there was a significant decrease in marker expression. This study indicated that decreased scaffold porosity is detrimental to the promotion of bone formation and that the presence of BMP-7 greatly enhances cells' ability to express osteogenic phenotypes.

Collagen

The ECM provides physical support to tissues by occupying the intercellular space, acting not only as benign native scaffolding for arranging cells within connective tissues but also as a dynamic, mobile, and flexible substance defining cellular behaviors and tissue function [40]. For most soft and hard connective tissues (bone, cartilage, tendon, cornea, blood vessels, and skin), collagen fibrils and their networks function as an ECM, the highly organized 3D architecture surrounding various cells. Collagen has a dominant role in maintaining the biologic structural integrity of ECM and is highly dynamic, undergoing constant remodeling for proper physiologic functions [40]. As a primary component of bone, collagen (and gelatin) is an idyllic candidate for the design of 3D scaffolds [41]. It is inherently biocompatible and biodegradable and stimulates the proliferation and differentiation of cells as an ECM. However, it has poor mechanical properties. In many studies, collagen was used as a base for 3D scaffolds and modified by adding polymers and other biomolecules to improve osteoinductivity. In one [42], the authors combined the mechanical properties of a 3D macrochanneled poly-ε-caprolactone (PCL) scaffold, fabricated by robotic dispensing, with the bioactive properties of collagen. An MSC-loaded collagen hydrogel collagen was inserted onto the macrochanneled scaffold. In addition, they studied the effect of growing these cell-seeded scaffolds in a perfusion bioreactor to test how osteogenesis was affected by the continuous supply of fresh media and shear stress. The collagen–PCL scaffolds increased cell proliferation when grown in the perfusion chamber compared with cells grown under static conditions. The activity of ALP, an early osteogenic marker, and osteogenic genes OPN, OCN, and BSP were significantly upregulated at 14 days in cells grown in the perfusion chamber. Bone marrow MSCs (BM-MSC) have shown great potential for tissue engineering purposes as they are relatively easy to isolate, retain their multipotency even after several passages, and can be induced to differentiate into bone. However, there is a low amount that can be harvested from bone marrow and they have limited proliferation and high senescence [43]. It has been reported that MSCs can be isolated from the Wharton jelly found in the umbilical cord (UC-MSC), and they are more abundant, more easily expanded, and more resistant to cryogenic storage [44]. The adhesion, migration into scaffold, growth, spreading, osteogenic differentiation, ECM degradation, and synthesis of BM-MSCs versus UC-MSCs were compared. The tested collagen scaffold (CS) showed excellent cytocompatibility

with both cell types and could maintain high proliferation and viability. When stimulated with osteogenic induction medium, both cell types showed comparable osteogenic gene expression, migration and scaffold colonization, and the ability to contract the CS. UC-MSCs were much more capable of producing an ECM. They demonstrated at least 10-fold higher expression of the ECM marker genes collagen I, collagen III, collagen IV, and laminin than did BM-MSCs. Because the production of ECM is an integral component of bone regeneration, UC-MSCs could have a significant impact on bone tissue engineering; its osteogenic potential should be investigated in additional scaffold compositions.

In another study, the hydraulic permeability (k) of a collagen-based scaffold was manipulated to improve mechanical properties, cell−scaffold interactions, oxygen flow, and nutrient diffusion [45]. Permeability is the ability of porous structures to transfer fluids through their interstices under applied pressure. This can be controlled through pore size, number, orientation, distribution, and interconnectivity [46]. Collagen scaffolds were prepared and exposed to plastic compression using different static stresses to control permeability. Results showed that increasing compression reduced k. It was also found that a decrease in k correlated with an increase in the modulus and permeability of collagen gels. The authors then tested the effect of k on MSC proliferation, differentiation, and mineralization. Compared with noncompressed gels, compressed ones showed higher proliferation, ALP staining, and mineralization, but no significant difference was found between the different compressed gels. These findings suggest that decreasing k provides a good matrix for cell proliferation and osteodifferentiation, but the influence of k on osteoinduction and osteoconduction has not been fully defined.

BMP-4 was spatially immobilized in a collagen−PLGA hybrid scaffold and has been shown to induce the osteogenic differentiation of osteoblasts to promote bone formation. MSCs were loaded into collagen−PLGA scaffolds with or without BMP-4 and cultured in osteoinductive media before implantation into the dorsa of athymic nude mice. Type 1 collagen, OPN, and OCN showed a significant increase in expression compared with the control. However, there was no difference in ALP expression. This may have been because ALP expression increased before the analysis of the removed implants. In another study, a collagen-based silicified matrix was loaded with stromal cell−derived factor-1 (SDF-1) [47], which is a chemokine-receptor ligand that is involved in immobilizing and homing stem cells to injured tissues. The silicified collagen scaffold (SCS) was first compared with CS in terms of its mechanical properties. The tangent modulus values (KPa) from 0%−5% strain were 0.80 ± 0.21 for CS and 599.8 ± 166.0 for SCS. The modulus of resilience values (KPa) were 0.18 ± 0.06 for CS and 165.3 ± 4.0 for SCS. In vitro analyses showed that there was no difference in cell viability when MSCs or endothelial progenitor cells (EPCs) were in contact with CS or SCS. The formation of extracellular bone nodules in differentiated MSCs was significantly higher in SCS than in CS, and the formation of capillary-like tubes by EPCs was much higher in SCS than in CS. These results indicate that the presence of silica in collagen hydrogels increases its osteogenic and angiogenic potential. The release kinetics of the SDF-1 from SCS hydrogels was analyzed and it was found that at high concentrations, up to 80% release could be obtained at 30 days. In vitro cell homing experiments were conducted with MSCs and EPCs using a transwell migration assay, employing SDF-1 concentrations that corresponded to those used in the release assay. Both MSCs and EPCs showed higher migration with higher SDF-1 concentrations. For in vivo experiments, the ability to promote osteogenesis was compared between SCS loaded with MSCs (cell-seeding approach) and cell-free SDF-1 containing SCS (cell-homing approach). Scaffolds were implanted into subcutaneous pockets of Balb/c mice. Implants were studied after removal and it was found that ectopic bone formation was similar in both scaffolds. However, ectopic bone formation in scaffolds loaded with SCF-1 showed a statistically significant increase in capillary formation. The results indicate that cell-homing strategies such as this must be further explored, because it reduces the complications of cell seeding and increases angiogenesis, a requirement for the formation of healthy bone.

Hyaluronic Acid

HAc has also demonstrated potential as a bone scaffold material. It is naturally occurring, hydrophilic, and nonimmunogenic, and has been found in the cytoplasm of osteoprogenitor cells [48]. This natural polymer has been used in combination with other materials, factors, and drugs to enhance its osteogenic potential. HAc, a nonsulfated glycosaminoglycan present in all connective tissue as a major constituent of the ECM and particularly prevalent during wound healing, has been proposed for the preparation of biodegradable ECM-like constructs for tissue engineering applications [49]. The ECM is a hydrophilic matrix with a gel-like uniformity consisting primarily of collagen fibers, proteoglycan filaments, and entrapped interstitial fluid. Similarly, hydrogels are also usually composed of covalently cross-linked hydrophilic polymers that enable them to swell while retaining their 3D structure without dissolving. This results in scaffolds structurally similar to the ECM, with a high water content and excellent biocompatibility characteristics. Cross-linking of HA forms experimentally controllable hydrogels that

provide a microstructure similar to native ECM. Subsequent encapsulation of cells into permeable HA hydrogels thus provides both structural support and protection, as well as the ability for cells to interact in 3D, which has been shown to increase the viability of transplanted cells significantly [50]. Furthermore, cell encapsulation with biocompatible materials such as HA has been shown to reduce the immunogenicity of the tissue engineered construct, because biocompatible materials reduce the adsorption of proteins [51], which would normally stimulate the recruitment of immune cells such as macrophages.

In one study, a photocured HAc hydrogel containing an osteogenesis-inducing drug, simvastatin (SIM), was designed [52]. SIM was found to induce osteodifferentiation of human adipose-derived stromal cells. Hydrogel viscoelastic properties were fine-tuned through 2-aminoethyl methacrylate (AEMA) substitution (HAc-AEMA). Three different HAc-AEMA scaffolds were studied: HAc with 20% (wt/wt) AEMA (HAc-AEMA-20), 30% AEMA (HAc-AEMA-30), and 40% AEMA (HAc-AEMA-40). Rheological measurements showed that elastic storage of the hydrogel increased with increasing AEMA concentrations (from 40 to 80 Pa). Pore size increased with increasing AEMA concentration, but sizes were not reported. MC3T3 fibroblasts were seeded into the hydrogels to test for cytocompatibility; it was found that the material was cytocompatible and that there was no difference in viability between groups. After SIM was loaded into the hydrogel, release kinetic experiments showed that it could sustain release for up to 14 days. HAc-AEMA-40 hydrogel was chosen for the remaining experiments. Loading of 1 mg SIM into HAc-AEMA-40 significantly increased fibroblast proliferation and mineralization at all times tested. The presence of SIM also upregulated the expression of OCN and OPN at all times tested. The effectiveness of this system was then tested in vivo with and without SIM. Hydrogels were implanted in parietal bone defects in rabbits. Cone beam computed tomography was used to assess healing of the bone defect for up to 9 weeks. Healing was only slightly superior at 9 weeks in the SIM-containing hydrogel. These results showed that substitution with AEMA can improve viscoelastic properties and the addition of SIM into the hydrogel improved osteogenesis in vitro, although the results were not as notable in vivo.

Alginate

Alginate–HA composite scaffolds were prepared by internal gelation followed by freeze-drying to obtain a porous structure. The nanoparticles were prepared in presence of a lactose-modified CHI; this colloidal solution was adsorbed on the scaffolds by exploiting electrostatic interactions and was used as temporary resorbable bone implants [53]. A CHI–polypyrrole–alginate composite scaffold can act as a substrate for tissue regeneration and can be employed for bone tissue engineering using osteogenic cells by employing electrical stimulation with a bioreactor system, and thus evaluating the role of conducting substrate in bone regeneration [54].

CHI–alginate hybrid scaffolds displayed improved mechanical strength and structural stability and were shown to stimulate new bone formation and rapid vascularization [55]. CHI–alginate gel–MSC–BMP-2 composites should have become clinically useful injectable materials to generate new bone [56]. Porous HA–CHI–alginate composite scaffolds were prepared through in situ coprecipitation and freeze-drying for bone tissue engineering [57]. Two different types of polymer scaffolds, such as CHI–alginate and CHI–alginate with fucoidan, were developed by freeze-drying; each was characterized as a bone graft substitute by Venkatesan et al. [58]. Alginate microparticle and microfiber aggregated scaffolds were produced with alginate through the aggregation method. Such a porous structure will allow vascularization, oxygenation and cell migration, adhesion, and proliferation, which are biological events that are fundamental for bone tissue regeneration [59].

In another study, macroporous alginate scaffold was fabricated and mineral-coated using a biomimetic approach [60]. The nucleation of HA was achieved by incubating the scaffold in modified simulated body fluids for up to 4 weeks. Mineralization of the scaffold was determined by a change in mass, which increased steadily from weeks 1 to 4. Energy-dispersive X-ray spectroscopy revealed a Ca/P ratio of 1.61 when the Ca/P ratio of pure HA (HAP) was 1.67. Viability experiments demonstrated that the HAP coatings supported the attachment and proliferation of hMSCs. The cell number was significantly higher in the coated scaffolds at all times tested. This work showed that a simple scaffold modification, such as immersion in simulated biological fluids, can change the topography and environment of a scaffold to improve the osteogenic outcome of the scaffold. The in vivo application of a facile polyelectrolyte complexation (PEC) process was employed to condense heparin onto the surfaces of poly-L-ornithine (PLO), poly-L-arginine (PLA), and diethylaminoethyl–dextran-coated alginate microbead templates that entrap bioactive recombinant human BMP-2 (rhBMP-2). In vivo implantation of PEC shells loaded with rhBMP-2 resulted in new bone formation that could stimulate a mechanically stable posterolateral spinal fusion in rats (PLO- and PLA-based PEC shells). This ability to retain or regulate rhBMP-2 delivery and stimulate new bone formation from heparin-incorporated PEC shells could provide a powerful tool for entrapping and controlling the delivery of several growth factors in a variety of bone tissue engineering [61].

Chitosan

CHI, the deacetylated form of chitin, is the structural component found in the exoskeleton of crustaceans such as shrimp, crabs, and lobsters. It is a natural polymer, with a linear structure consisting of β(1−4)glycosidic bond−linked D-glucosamine residues with a variable number of randomly located *N*-acetyl-D-glucosamine groups [62]. CHI is bioactive, biodegradable, antibacterial, and biocompatible and possesses a hydrophilic surface, which is absent in many synthetic polymers. Here we describe several studies in which the osteogenic properties of CHI 3D scaffolds were modified by adding other polymers, cells, and bone-inducing factors. CHI and poly(butylene succinate) scaffolds were constructed and seeded with human MSCs to test their ability to induce osteogenesis [63]. The material was found to have 59% porosity, a 144.9-mm pore size, and 60.9% interconnectivity. MSC viability increased for 21 days in the scaffold and ALP activity also increased for 21 days after MSCs were exposed to osteogenic induction. The ability of the MSC-seeded scaffolds to repair a cranial critical-sized bone defect in mice was also examined. The cell−scaffold constructs were cultured in osteogenic-induced medium for 2 weeks before implantation. Cell-free scaffolds were used as a control. The crania were observed 8 weeks after implantation. Bone formation was analyzed using μCT. The results showed an elevated rate of bone formation in the cell-seeded scaffold, evidencing the importance of the existence of stem cells near the area where bone formation is needed. In another study, human bone marrow−derived stem cells (hBMSC) were encapsulated in hydrogels at CHI-collagen ratios of 100/0, 65/35, 25/75, and 0/100 wt%. β-Glycerophosphate was added to hydrogels, because it has been shown to be an osteogenic supplement when added to cultures of hBMSC, and it has also been used as a catalyst to sol-gel transitions in CHI hydrogels. The effect of adding collagen to CHI on matrix mechanical properties was assessed. Stress−strain profiles (0%−8% strain) showed that all collagen materials were approximately three times stiffer than pure CHI, which has a modulus of 6.3 kPa. When evaluating cell proliferation, the DNA content dropped by about half over 12 days in pure CHI materials whereas it increased twofold in materials containing collagen. For these reasons, only collagen-containing materials were examined for their effect on osteogenic gene expression. hBMSCs were encapsulated in CHI-collagen and collagen hydrogels and exposed to osteogenic medium. Hydrogels with a CHI-collagen ratio of 65/35 had the highest levels of osterix expression, bone sialoprotein expression, and ALP activity. These osteogenic markers started to decrease at lower CHI concentrations. These results suggest that the presence of collagen was highly beneficial for the osteogenic capabilities of the 3D scaffold, although it remains to be determined whether this was caused by the change in mechanical properties or the intrinsic biological properties of collagen.

Another research group prepared porous 3D scaffolds based on CHI, CHI/SF, and CHI/SF/HA. SF/HA scaffolds were previously reported to be unsuitable for bone tissue engineering owing to insufficient formability and inflexibility [64]. The CHI scaffolds had a porosity of 94.2% ± 0.9%, which was statistically higher than the one presented by CHI/SF/HA scaffolds, which had a porosity of 89.7% ± 2.6%. The CHI/SF scaffold had a porosity of 91.6% ± 1.2%, which was not significantly different from other materials. SaOs-2 cells were used to measure viability and differentiation. At day 21, there was a statistically significant increase in cell proliferation and ALP activity in the CHI/SF/HA scaffolds compared with CHI and CHI/SF. It is unclear whether it was the presence of HA or the changes in porosity that promoted osteogenesis.

CHI has also been used as an injectable biomaterial. Bi et al. [65] produced an injectable composite of tricalcium phosphate (TCP), CHI, and platelet-rich plasma (PRP). A TCP-CHI composite (TC) was used as a control. PRP contains a number of growth factors (i.e., PGDF, transforming growth factor-β, insulin-like growth factor, basic fibroblast growth factor [bFGF], and VEGF), which have often been shown to have an important role in bone tissue engineering applications. The composites were fabricated into cylinders for mechanical testing. It was found that the compressive strength (MPa) of both composites increased over time (∼9−16 over 7 days) but there was no difference between them. The MSCs were seeded onto TCP and TC scaffolds and cell proliferation was measured over 7 days; the number of cells on TCP was found to be significantly higher than on TC at every time point tested. MSCs grown in plates in osteogenic media (OM) were used as a positive control for osteodifferentiation analysis of the materials being tested. ALP activity was tested at 7 and 14 days. At 7 days, ALP activity was higher in PTC than TC, and PTC and OM had comparable levels. At day 14, ALP activity was significantly higher in PTC than TC and even OM. RT-PCR analysis was used to study the expression of osteogenesis-related genes. Runt-related transcription factor 2 (Runx-2), type-1 collagen and osteonectin expression in TCP were comparable to those in OM.

Peptide Hydrogels

Hydrogels are 3D networks composed of hydrophilic polymers cross-linked through covalent bonds or held together via physical intramolecular and intermolecular attractions. Hydrogels can absorb huge amounts of water

or biological fluids, up to several thousand percent, and readily swell without dissolving. The high hydrophilicity of hydrogels results from the presence of hydrophilic moieties such as carboxyl, amide, amino, and hydroxyl groups distributed along the backbone of polymeric chains. In the swollen state, hydrogels are soft and rubbery, resembling living tissues to a great extent. In addition, many hydrogels such as CHI and alginate-based hydrogels have desirable biocompatibility [66], can easily be modified to contain bioactive motifs and composed of self-complementary amphiphilic peptides, and when gelled they provide a 3D structure that has many similarities to the ECM. In one study, self-assembling peptide nanostructured gels were constructed using peptide amphiphile (PA) materials with or without phosphoserine residues near their surfaces and with or without Arg-Gly-Asp-Ser (RGDS) peptide [67]. The phosphoresidues contribute to mineralization and the RGDS peptide contributes to cell adhesion. The authors proposed that the architecture of these PA materials is highly biomimetic of the fibrous elements commonly found in ECM, such as collagen fibrils. The results of this study suggested that a 3D matrix that supports mineralization and cell adhesion is favorable for bone formation, but the outcome was not superior to implantation with demineralized bone tissue. In another study, the commercially available peptidic hydrogel PuraMatrix was evaluated as a candidate to assess its potential for the osteogenic differentiation of dedifferentiated fat cells (DFATs) [68]. PuraMatrix is composed of 8–16 L-amino acid residues and forms a 3D scaffold that is biocompatible and biodegradable. The cell suspension was mixed at a 1:1 ratio with the hydrogel. These results indicate that commercially available PuraMatrix can support the osteogenic differentiation route and that DFATs are a viable alternative to MSCs that should further be explored with regard to bone regeneration.

Synthetic Polymers

Copolymers

A range of polyethylene oxide (PEO)–polybutylene terephthalate (PBT) copolymers (70%–30% PEO) was investigated for non–load bearing bone replacement. In general, copolymers are attractive for tissue engineering applications because their physicochemical properties are highly controllable. Gel formation dynamics, cross-linking density, and material mechanical and degradation properties can be controlled by regulating molecular weights, block structures, degradable linkages, and cross-linking modes [69].

β-Keto nitrile tautomeric copolymers have demonstrated fine-tunable hydrophilicity and hydrophobicity properties according to their surrounding environment and mechanical properties similar to those of human bone tissue. These characteristic properties make them promising candidates as biomaterials for bone tissue engineering. Based on this knowledge, we designed two scaffolds based on β-keto nitrile tautomeric copolymers that differ in chemical composition and surface morphology. Two of them were nanostructured, using an anodized aluminum oxide template and the other two were obtained by solvent casting. They were used to evaluate the effect of the composition and their structural modifications on the biocompatibility, cytotoxicity, and degradation properties. The results showed that the nanostructured scaffolds exhibited a higher degradation rate by macrophages than the casted scaffolds (6% and 2.5% of degradation for the nanostructured and casted scaffolds, respectively), a degradation rate compatible with bone regeneration times. We also demonstrated that the β-keto nitrile tautomeric–based scaffolds supported osteoblastic cell proliferation and differentiation without cytotoxic effects, which suggested that these biomaterials could be useful in bone tissue engineering [70]. In one study, the authors had developed a novel BMP-2–related peptide (P24) that was shown to enhance the osteoblastic differentiation of BMSCs. The purpose of that study was to incorporate P24 into a modified PLGA-(PEG–ASP)n copolymer to promote bone formation [71]. PLGA and PLGA-(PEG–ASP)n membranes were fabricated by solvent coating and evaporating. In in vitro release studies, about 70% of peptide was released after 14 days. Adhesion and proliferation studies were performed with BMSCs and the PLGA-(PEG–ASP)n scaffolds, with and without p24, promoted cell adhesion and proliferation compared with the PLGA control. There was no difference between PLGA-(PEG–ASP)n and PLGA-(PEG–ASP)n-p24 scaffolds in either cell adhesion or proliferation. However, in cell differentiation studies, the PLGA-(PEG–ASP)n-p24 scaffold was shown to enhance differentiation at each time point tested for up to 20 days, as determined by ALP activity.

A novel three-component biomimetic hydrogel composed of triblock PEG–PCL–PEG copolymer (PECE), collagen, and nano-HA (n-HA) was successfully prepared [72]. The in vivo biocompatibility of the PECE–collagen–n-HA hydrogel composite was tested by implanting the composite into the dorsal muscle pouches of Wistar rats for 3, 7, and 14 days. Some inflammation occurred during the degradation process, but by day 14, the inflammatory response disappeared completely. The activity of bone regeneration was evaluated by reconstructing two rectangular defects in rabbit craniums. The untreated left defects were used as control and the right defects were packed

with PECE−collagen−n-HA hydrogel composite. At 20 weeks, as determined by histological staining, the right defect was filled completely with new bone and the amount of high-density tissue in the control defect was visibly less than the treatment defect. In another study, biodegradable and electroactive poly(ester amide)s containing conjugated segments of phenyl amino end-capped tetraaniline (PEA-g-TA) were prepared [73]. Composites were prepared under different feed weight percentages of tetraaniline (TA) (3.5%, 8.4%, and 15.5%). The copolymer solutions were cast onto a superflat polytetrafluoroethylene plate and placed for 5 h under room temperature to form thin films. Conductivity increased with an increasing percentage of TA (7.11×10^{-7}, 8.01×10^{-6}, and 2.45×10^{-6} S/cm for 3.5%, 8.4%, and 15.5%, respectively) but all scaffolds had conductivity values adequate to transfer bioelectrical signals in vivo. The PEA-g-TA number 2 copolymer (8.4% feeding ratio) was highly distensible with a breaking elongation rate of 105% ± 10%, and the tensile modulus of copolymer was 20 ± 2.5 MPa. These values were not reported for the other scaffolds. Mouse MC3T3-E1 cells showed more than 90% viability in all copolymers tested. Cells were stimulated by pulsed electrical signal for 2 hours every day for 14 days. Osteogenic differentiation of MC3T3-E1 cells was assessed by the intracellular free calcium concentration and ALP enzyme activity. After 14 days, there were no significant differences between the materials tested; however, cells that were stimulated by the electric signal had higher intracellular calcium concentration and ALP enzyme activity. This work illustrates that combining appropriate materials with physical stimulation such as electrical impulses can produce superior responses.

Polyesters

Polyphosphazene−polyester blends are attractive materials for bone tissue engineering because of their controllable degradation pattern with nontoxic and neutral pH degradation products. Aliphatic polyesters such as polyglycolic acid, polylactic acid, and polycaprolactone are the most commonly used polyesters for tissue engineering. Their degradation products are present in the human body and can be removed by natural metabolic pathways. 3D scaffolds from these materials can be fabricated through various techniques and fine-tuning the molar ratios of these polymers can influence mechanical properties and degradation rates [74,75]. In one study, PCL scaffolds incorporating HA particles were fabricated by combined solvent casting and particulate leaching [76]. The presence of HA slightly increased the density of the scaffold but had no significant effect on the porosity values of the scaffolds. With increasing HA concentrations, there was a significant correlation with an increase in the compressive modulus. Viability assays showed that the number of primary human bone cells that had been cultured on the PCL−HA scaffolds was greater than that of cells that had been cultured on the neat PCL scaffolds at both 24 and 48 h after cell culturing. Expression levels of type I collagen and osteocalcin were evaluated by RT-PCR and were significantly greater in cells cultured on the PCL−HA scaffolds than those in cells cultured on the neat PCL scaffolds on day 10. The formation of mineralized nodules of cells cultured on the PCL−HA scaffolds was significantly greater than that of cells cultured on the neat PCL scaffolds. For in vivo experiments, a circular calvarial defect in mouse was used as a model. Six weeks after implantation, histomorphometric analysis indicated a statistically significant increase in the amount of new bone formation in the PCL−HA scaffolding implants compared with neat PCL counterparts.

Ceramic Scaffolds

Bioactive ceramics have received great attention owing to their success in stimulating cell proliferation, differentiation, and bone tissue regeneration. They can react and form chemical bonds with cells and tissues in human body. These ceramics are recognized as bioceramics and are classified into two groups: bioinert or bioactive. Bioactive ceramics are categorized as resorbable or nonresorbable [77]. Ceramics are used because of their chemical properties and crystallinity, which is similar to bone mineral components. These materials exhibit excellent biocompatibility and bioactivity. The inorganic fraction of bone is composed of HA and CaPs, which allow the formation of bone tissue on its surface. This type of material is excellent as an implant, but it has particular problems with its mechanical properties in terms of fracture and fatigue. Common ceramic materials used for bone repair or regeneration are Bioglass, CaPs, and ceramic scaffold derived from corals. Here, we report some studies in which these materials were studied both in vitro and in vivo to assess their osteogenic potential.

Bioactive ceramics are known to enhance osteoblast differentiation as well as osteoblast growth. However, their clinical applications have been limited because of their brittleness, difficulty in shaping, and extremely slow degradation rate in the case of HAP. Also, they have poor fidelity and reliability, and new bone formed in a porous ceramic scaffold cannot sustain the mechanical loading needed for weight-bearing bone [78]. Wang and Shaw [79] reported that dense HAP ceramics with a fracture toughness of 0.61−1.06 MPa·m1/2 were fabricated via conventional sintering. Fielding et al. [80] fabricated TCP scaffolds with a compressive strength of 1.75−5.48 MPa using commercial 3D

printing technology. However, the mechanical properties of fabricated scaffolds were far below those of weight-bearing bone (fracture toughness = 2−12 MPa·m1/2; compressive strength = 130−180 MPa) in the human body [81]. Therefore, obtaining an effective method to overcome these limitations has become the focus of current and future research in bone tissue engineering.

Calcium Phosphate

Calcium phosphate ceramics (CPCs) are a class of fine-tunable bioactive materials that have been widely used for bone tissue repair and augmentation. They possess surface properties that support osteoblast adhesion and proliferation (i.e., osteoconduction) and stimulate new bone formation (i.e., osteoinduction) [82]. TCP was first used in 1920 by Albee [83]. The study reported cases of fracture with bone loss in which more rapid bone growth and union were observed when TCP was injected into the gap between the bone ends than did the controls without its use. Also, it was demonstrated that osteogenesis was stimulated by this material in conjunction with the fracture microenvironment. In 1951, Ray and Ward [84] reported the use of granular synthetic HA to repair defects in long bone and iliac wings of dogs and bur holes in the crania of cats; the study demonstrated that this material could be replaced by new bone, but it was not as effective as autologous bone grafts in repairing the defects. Calcium phosphate−based scaffolds exhibit osteoconductivity, bioactivity, and resorbability in vivo owing to their complex chemical composition (Ca/P ratio) and physical properties such as their crystallographic structure and porosity [85]. In studies combining CPC paste and hydrogel microbeads to encapsulate human umbilical cord MSCs (hUCMSCs) with CHI fibers [86], hUCMSC viability and differentiation capacity were observed.

Nanostructured CaP biomaterials and scaffolds mimic natural bone, and have high surface-to-volume ratios, improved wettability and mechanical properties, and increased protein adsorption and other desirable properties, compared to conventional counterparts. Nano-CaP biomaterials have emerged as a promising class of biomimetic and bioactive scaffolds capable of directing cell behavior and cell fate and enhancing tissue formation in vivo. In general, nano-CaP scaffolds can support stem cell attachment and proliferation and induce osteogenic differentiation, in some cases without osteogenic supplements. The influence of nano-CaP on cell alignment is less prominent than that of polymers and metals owing to the no-uniform distribution of the nano-CaP crystals. Nano-CaP biomaterials can achieve significantly better bone regeneration in vivo than conventional CaP biomaterials. The combination of various types of stem cells with nano-CaP scaffolds can further accelerate bone regeneration, the effect of which can be even further promoted by growth factor incorporation. Cell microencapsulation combined with nano-CaP scaffolds is a promising tool for bone tissue engineering applications to distribute cells throughout the interior of the scaffold [87]. More studies are needed to compare various types of nano-CaP compositions and nanostructures side by side in vivo and to compare the efficacy of various types of stem cells in bone regeneration.

Bioglass

Since the discovery of 45S5 bioactive glasses by Hench, they have been frequently considered scaffold materials for bone repair [88]. The need to find a material that forms a living bond with tissues led Hench to develop Bioglass repair tissues during the Vietnam War [89]. Bioglass offers advantages such as a controlled rate of degradation, excellent osteoconductivity, bioactivity, and the capacity to deliver cells, but they have limitations in certain mechanical properties such as low strength, toughness, and reliability [90]. Advantages of the glasses are ease in controlling the chemical composition and thus, the rate of degradation, which make them attractive as scaffold materials. The structure and chemistry of glasses can be tailored over a wide range by changing the composition or the thermal or environmental processing history. Therefore, it is possible to design glass scaffolds with variable degradation rates to match those of bone ingrowth and remodeling. A limiting factor in using bioactive glass scaffolds to repair defects in load-bearing bones has been their low strength [91]. Work has shown that by optimizing composition, processing, and sintering conditions, bioactive glass scaffolds can be created with predesigned pore architectures and with strength comparable to that of human trabecular and cortical bones [92]. Another limiting factor of bioactive glass scaffolds has been the brittleness. This limitation has received little interest in the scientific community, judging from the paucity of publications that report on properties such as fracture toughness, reliability (i.e., Weibull modulus), or work on the fracture of glass scaffolds.

Wu et al. [93] prepared 45S5 Bioglass by foaming with rice husks and sintering at a high temperature; they obtained favorable results in compressive testing and degradability in simulated body fluid. That study reported compressive strength values in the range of trabecular bone. Porous bioactive glass-ceramic (45S5) was tested with human umbilical vein endothelial cells (HUVECs) and human osteoblast-like cells (HOBs). The results of the study demonstrated that the proliferation of HOB and HUVEC cocultures seeded on scaffolds was higher than that of commercial HA scaffolds. Wu et al. [93] studied HOB attachment, proliferation, and differentiation

on a bioactive diopside scaffold ($CaMgSi_2O_6$). Cell proliferation increased with incubation time. In addition, porous $CaSiO_3$ and kermanite ($Ca_2MgSi_2O_7$) ceramic scaffolds were compared with β-TCP ceramic scaffolds, demonstrating in vivo bone formation and potential applications in bone tissue regeneration [94]. Other studies related to the formation of porous Bioglass were developed by Moawad and Jain [95]. They fabricated nanomacroporous soda lime phosphosilicate glass scaffolds using sucrose as a macropore former, and established process parameters such as the weight ratio of glass/sucrose, the particle size of glass/sucrose powders, and the time and temperature of sucrose dissolution.

Coral

Coral exoskeleton ($CaCO_3$), which has an interconnected pore structure that resembles that of natural human bone, has been used as a scaffold material to fill bone defects in both animal models and humans since the early 1970s. This natural material is biocompatible, osteoconductive, and biodegradable. Most important, the possibility of seeding coral scaffolds with stem cells or loading them with growth factors has provided a novel alternative for bone tissue engineering. Corals are attractive materials for scaffolds because they have microstructures with highly controlled pore sizes and an interconnected porous architecture similar to trabecular bone [96,97]. After 1991, Ripamonti reported the first study of the morphogenesis of bone in porous bioceramics (coral-derived HA) in the rectus abdomen in the muscle of adult nonhuman primates Papioursinus demonstrated the use of coral line replicas of HA with an average pore size of 600 μm as bone grafts for the controlled formation of bone in humans [98]. Coral scaffolds using adipose-derived MSCs (AMSCs) have been used to repair cranial bone defects in a canine model [99]. They showed adipogenic differentiation and good biocompatibility to support the proliferation of AMSCs in vitro. Subsequent implantation in vivo showed new bone formation. Certain types of proteins such as ALP, OPN, and OCN are employed to identify the activity of osteoblast-specific proteins. Suzina et al. [100] reported an increase in the expression of specific genetic markers from osteoblasts such as Runx-2, OPN, ALP, and OCN in the *Porites* Goniopora coral, which was implanted in orthotropic calvarial defects of the adult nonhuman primate *Papio ursinus*. In vivo results showed an increase in ALP activity from 2 to 12 months and induction of bone in the concavities; however, limited conversion of HA−calcium carbonate was observed.

A preliminary study in nude mice reported the vascularization of tubular coral scaffold with cell sheets [101]. The results showed that cells promoted new bone formation through an endocrine process. In addition, Zheng et al. [102] evaluated the feasibility of mandibular condyle constructs engineered from hBMSCs. In vitro studies reported that hBMSCs induced differentiation into osteoblasts and chondroblasts, and seeded scaffolds implanted into nude mice showed neovascularization in the temporomandibular joint detected by bFGF expression.

Metallic Scaffolds

Several biocompatible metallic materials are frequently used as implanting materials in dental and orthopedic surgery to replace damaged bone or provide support for healing bones or bone defects. Standard surgical implant materials include stainless steel 316 L (ASTM F138), Co-based alloys (mainly ASTM F75, and ASTM F799), and titanium alloys; Ti−6Al−4V (ASTM F67 and F136) is the most commonly employed. However, the main disadvantage of metallic biomaterials is their lack of biological recognition on the material surface. To overcome this restraint, surface coating or surface modification offers a way to preserve the mechanical properties of established biocompatible metals improving the surface biocompatibility. In 1909, the first patent of a metallic framework for an artificial tooth root for fixation by bone in growth was accredited to Greenfield [103,104]. He recognized the limitations of natural tooth implantation and started experimenting with implanting artificial hollow cylinders made of iridoplatinum wire soldered with 24 kt gold. In 1971, Galante et al. [105] were pioneers in developing open-pore fiber metals for clinical use as porous coatings in hip and knee arthroplasty. Because metals are materials with high mechanical strength and fracture toughness, they are frequently used as metallic biomaterials in the dental and orthopedic fields to replace and offer support for damaged and healing bone [106,107]. The commonly metals used as standard surgical implants were stainless steel 316 L (ASTM F138), Co-based alloys (mainly ASTM F75, and ASTM F799), and titanium alloys. where Ti−6Al−4V (ASTM F67 and F136). However, these metallic biomaterials have disadvantages such as the possible release of toxic metallic ions and/or particles through corrosion or wear processes that cause inflammation and allergic reactions, which affect biocompatibility and tissue loss. Also, they produce poor stimulation of new bone growth owing to the elastic moduli, which does not correspond with natural bone tissue. Despite this, it has been reported that Ti-based metals can be used as bone substitute because of its elasticity, mechanical properties, shape memory effect, porous structure, and biocompatibility [108]. Also, 3D microporous NiTi and Ti scaffolds have been produced by powder metallurgy that obtains a hydrophilic surface to facilitate the deposition of HA and stimulate cell attachment and proliferation.

Hybrid Materials

The material needs to be bone bioactive: that is, it should encourage bone ingrowth and degrade at a rate that allows the newly formed tissue to replace the scaffold gradually, both as a mechanical structure and in terms of the space occupied. Finally, and this is where most current materials fail, the material needs mechanical properties that allow the device to be implanted without failing. This last requirement allows a patient to use the implanted area without mechanical protection, such as a cast, but still enables sufficient loading of the newly formed tissue to stimulate the osteoblasts mechanically. As yet no one has reported a material that fulfils all of these requirements. One group of materials that attempts to fulfill many of these requirements is composites of degradable polymers reinforced with ceramics, glass-ceramics, or bioglasses. If the polymer is biodegradable and the ceramic, glass-ceramic, or bioglass phase is degradable or metabolized by the body, the degradation requirement is fulfilled. The use of ceramics or glass-ceramics can both stiffen and strengthen a low-modulus, low-strength polymer and increase the bioactivity of the composite [109]. Commonly, composite scaffolds are fabricated using a different type of matrix with a dispersed phase such as polymer−ceramics, ceramic−metals, and polymer−metals [110].

Polymer−Polymer Blends

A polymer−polymer blend defines a mixture of two different polymers addressing each other's drawbacks and giving synergetic advantage to the scaffold design. A miscible composite design with desired features can be fabricated by employing polymers with particular intermolecular or van der Waals interactions. One important example is PLGA and polyphosphazene bends [111]. PLGA is a well-known biomaterial in tissue engineering. Owing to PLGA acidic by-products upon degradation, it has been a critical issue for its further use, because its long-term tissue exposure to acidic products may lead to tissue necrosis and implant failure. On the other hand, polyphosphazene releases neutral or basic products upon degradation. Thus, PLGA has been blended with a wide arena of polyphosphazenes to achieve near-neutral degradation products as an efficient construct for tissue engineering [112−114].

Polymer−Ceramics Blends

Many researchers have studied polymer−ceramic-based scaffolds. Combinations of CaP−polyesters for scaffold production were investigated by Kaplan and coworkers [115], who developed a scaffold from SF−poly aspartic acid coated with CaP. In vitro studies showed cell viability, proliferation, and osteogenic differentiation; however, nonuniform distribution of cells resulting from mineral deposition was observed. Li et al. [115] used two biocompatible and biodegradable polymers, PLGA and PCL, with a layer of CaP and a gelatin coating. MC3T3 cells adhered to regions with higher CaP content along the scaffold, which indicated that the mineralization gradient affects the adhesion and proliferation of cells and the physical properties of the scaffold. Relative to the mechanical properties, the local strain varied along the long axis of the scaffold and the Young's modulus increased with increasing levels of CaP.

TCP has been used to generate biocompatible and biomechanical scaffolds [116]. In vivo studies using this type of scaffold reported significant biocompatibility, sufficient mechanical strength, osteogenic differentiation, and bone growth. It was also demonstrated that the incorporation of collagen into this type of system improves hydrophobicity and differentiation [117]. Wang et al. [118] reported a novel scaffold composed of the PLGA−β-TCP skeleton wrapped with type I collagen. The aim of that study was to analyze the physical properties and biocompatibility of the core−sheath structure composite scaffold in vitro compared with the PLGA−β-TCP skeleton. No differences were observed in the porosity ratio, compressive strength, or Young's modulus of the scaffolds. MTT assay indicated that BMSCs showed better adhesion and proliferation activity on the surface of the core−sheath structure composite scaffold than on the PLGA−β-TCP skeleton. In a previous study [119], this scaffold was fabricated via low-temperature deposition manufacturing but its hydrophobicity did not promote adequate cell adhesion, proliferation, or osteoblastic differentiation. Thein-Han and Xu [120] were the first to develop a novel scaffold from collagen−CPC using hUCMSCs for in vitro analysis. Good mechanical properties, hUCMSC attachment, viability, and osteogenic differentiation were observed. Previously, studies were conducted using collagen−CaP scaffolds, but they were not moldable or injectable [121]. HA was also employed to fabricate ceramic−polymer scaffolds [122−124]. Kim et al. [125] developed this type of scaffold and demonstrated that the combination of PGA−PLGA−HA improves their osteogenic capacity. Hollinger et al. [125] used a combination of poly(ε-caprolactone fumarate) −PVA−HA with rhBMP-2 and the preosteoblast cell line MC3T3-E1 obtained good cell viability and proliferation, bioactivity, and bone regeneration and an increase in compressive modulus with an increase in HA; however, μCT showed a nonuniform distribution of the porogen indicating that the degradation process, porosity, and pore

interconnectivity needed to be improved. Geng et al. [126] fabricated a scaffold from a magnesium phosphate (MP)−poly(ε-caprolactone) composite in which the mechanical analysis showed low values of the compressive modulus compared with trabecular bone; thus, this scaffold was found not to be appropriate for high−load bearing applications. It was also reported that the degradation rate of the composite scaffolds could be modulated by varying the amount of MP particles introduced into the polymer matrix.

Metal−Polymer Blends

The development of successful scaffolds for bone tissue engineering requires a concurrent engineering approach that combines different research fields. Researchers have tailored metallic scaffolds that are useful for a wide variety of medical and dental applications. Surface modification of already proved biocompatible metals is an essential requisite for their use in tissue engineering because the metal surface must be controlled to induce the adhesion and proliferation of cells and the adsorption of essential biomolecules. Chemical and physical properties have a crucial role in the osteointegration of implant surface; they allow protein adsorption between implanted biomaterials and the biological environment. Thus, numerous strategies have been developed to create a bond between the implant and the living host tissue. The use of metallic implants with a polymer coating has been reported by many for these purposes. Ti, TiO_2, and Ti-alloy combined with polyester coatings have been intensively studied to fabricate scaffolds. Lagoa et al. [127] developed a partially biodegradable implant from titanium, polylactide, HA, and calcium carbonate. The implant had mechanical stability, biocompatibility, and partial biodegradability. Helary and coworkers used poly(sodium styrene sulfonate) (polyNaSS) on oxidized or grafted Ti samples [128] and polyNaSS−(methylacrylic acid) MA grafted onto Ti_6Al_4V alloy surfaces [129] They reported that cell adhesion and differentiation on Ti (grafted) were higher than on oxidized titanium and titanium because of the presence of active sites that interact with extracellular proteins. In addition, polyNaSS−MA grafted onto Ti6Al4V alloy in femoral rabbit model showed lamellar trabecular bone with wide haversian canals lined by osteoblasts; however, the high levels of Na, P, Ca, Zn, etc., indicated that the piranha treatment used to oxidize the alloy surface was intense. Oughlis et al. [130] developed a scaffold from polyNaSS polymer and titanium. The results showed cell viability, proliferation, and osteoblastic differentiation of hMSCs on this scaffold.

Metal−Ceramic Blends

Many researchers have reported the development of metal−ceramic scaffolds that have been shown to possess favorable characteristics regarding their mechanical properties and bioactivity (cell attachment, proliferation, and differentiation). Yang et al. [131] developed a biodegradable and bioactive scaffold composed of magnesium with a coating of β-TCP. The in vitro results showed good cell adhesion and bioactivity. In similar studies, when tantalum and titanium were used as metals, osteoconductivity and osteoinductivity were improved in vivo. Wu et al. [132,133] reported the fabrication of a hypoxia-mimicking mesoporous bioactive glass (MBG) scaffold by incorporating Co^{2+} ions into the MBG scaffold. Results showed that MBG scaffolds had no significant cytotoxicity and that the incorporation of ionic Co^{2+} ions enhanced VEGF secretion, HIF-1a, expression, and bone-related gene expression in BMSCs. Also, the CoMBG scaffolds supported BMSC attachment and proliferation. It was reported that ZrO_2 itself does not have good cellular and tissue affinity [134] although in vitro and in vivo studies demonstrated that ZrO_2 is not toxic [135]. Lee et al. [136] fabricated a scaffold composed of (biphasic CaP) ZrO_2 and PCL layers. The scaffold had a compressive strength of 12.7 MPa and a porosity of 78 vol% and showed excellent MG63 cell attachment, and OCN and collagen expression. It was also shown that PCL incorporated into biphasic CaP gave scaffolds high biodegradability, cell attachment, and proliferation.

Li et al. [137] reported a novel ion doping method applied in calcium polyphosphate (CPP)-based bioceramic scaffolds to be substituted by potassium and strontium ions (K/Sr). The K/Sr CPP scaffolds had a higher compressive strength, cell biocompatibility, biodegradability, osteoinductivity, and osteoconductivity and better degradation properties than the pure CPP scaffolds; however, the mechanical strength of K/Sr-CPP was not good after degradation. Studies suggested that directly mixing Cu^{2+} ions with bioactive materials improves angiogenesis [138]. Xiao et al. (2013) prepared copper (Cu)-containing mesoporous bioactive glass (Cu-MBG) scaffolds with interconnected large pores. Attachment, proliferation, and ALP activity of hBMSCs on Cu−MBG scaffolds were observed, and ionic products of Cu−MBG extracts enhanced the osteogenic differentiation of hBMSCs. Studies using porous ceramic−coated TiO_2 as scaffolds were reported by Dimitrievska et al. [139]. They evaluated the cell adhesion, growth, and osteoblastic differentiation of hMSCs in the TiO_2−HA nanocomposite; however, applications in bone implants were limited by their bioinertness. Also, Haugen et al. [140] reported in vitro results that showed the cell viability of the mouse osteoblastic cell line MC3T3-E1. No cytotoxic effects from the TiO_2−HA scaffolds were found. It was also reported that healing occurred when this scaffold was implanted into rabbit defects.

CONCLUSIONS AND FUTURE PROSPECTS

We have summarized the current state of the art of materials technology and the development requisites for successful bone graft substitute. Clearly, the smart selection of materials is the key to successful tissue engineering. Nevertheless, various other factors also influence the overall outcome. Scaffold composed of natural or synthetic biomaterials or their combination should closely mimic the ECM in native tissues, provide the required support, promote neovascularization, and allow access to nutrients to support the entire process of tissue regeneration. All of these areas of advanced, fast-growing interest and expanding research demonstrate the multidisciplinary nature of tissue engineering and the field of regeneration medicine. There are vast challenges as well as wide opportunities to improve human health immensely in a variety of areas. However, much study is needed to explore various novel materials and the dynamics of the bone tissue microenvironment for proper simulation.

INTRODUCTION AND OVERVIEW OF CANCER IMMUNOTHERAPY

The immune system is composed of two primary cellular subsets; innate and adaptive. Cells of the innate immune system are often the first responders to reach a site of injury. One of their primary functions is to contain locally and eliminate, if possible, any potentially dangerous substances, which are commonly termed pathogens. In addition, a number of innate immune cells function to collect small pieces of the dangerous substance, termed antigens, and present them to cells of the adaptive immune system. Macrophages and dendritic cells (DCs) are two key cells that perform this function, and thus are appropriately known as antigen presenting cells (APCs). After successful presentation and stimulation by APCs, adaptive immune cells, namely antigen-specific cytotoxic T cells, can mount a more pathogen-specific immune response with long-term components that can protect the host more rapidly if reexposed to that particular antigen. In response to identifying features of pathogens, APCs can release specific combinations of cytokines, chemokines, and other cues to promote T-helper 1 (Th1) or T-helper 2 (Th2) adaptive immune responses. Th1 immune responses induce cell-mediated responses, typically provoking T-cell proliferation and investigation of intracellular pathogens. Alternatively, Th2 immune response induce humoral immunity, promoting B-cell antibody production targeting primarily extracellular pathogens. Although greatly simplified, this is one of the primary processes that the immune system uses any time it encounters potentially harmful substances, whether that be a virus, bacteria, or cancer cell.

Cancer presents a variety of challenges for the immune system as evidenced by the fact that avoidance of immune destruction has been recognized as a primary hallmark of cancer [1]. One of the most difficult challenges is the fact that cancer cells are not foreign entities, and thus look similar to normal healthy tissue, which makes it difficult for the immune system to identify and eliminate them. As a result, the adaptive immune system often struggles to present tumor-associated antigens in an immunogenic context that is critical for generating a productive immune response. However, cancer has long been recognized as a disease mediated by genomic mutations, whether naturally or virally induced, and if these genomic mutations result in mutated proteins, the immune system theoretically has the potential to recognize that. As proof of this, tumors with a higher mutational burden are typically more immunologically active, with higher immune cell infiltrate and a greater potential for immune-mediated attack [2]. In addition to mutated antigens, differential expression of self-antigens provides another mechanism of immunologic recognition of cancer (i.e., human estrogen receptor 2 in breast cancer, prostate-specific antigen in prostate cancer, cancer-testes antigens). Another challenge that hinders immune recognition and destruction of cancer is the highly immunosuppressive protumor microenvironment observed in solid tumors. This occurs largely through a wound healing–like intratumoral inflammation and an increase in suppressive immune cell populations such as myeloid-derived suppressor cells (MDSCs), tumor-associated macrophages (TAMs), and T-regulatory cells (Tregs) [3]. In light of these obstacles, cancer immunotherapeutic strategies are warranted to direct and stimulate an effective immune response against cancer.

The idea of using one's own immune system to fight cancer is by no means a novel concept; in fact, this concept has existed for over 100 years. Perhaps the oldest recorded evidence came from an American surgeon, William B. Coley, when he demonstrated successful remission in numerous inoperable cancer patients after intratumoral

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00041-2

injection of a mixture of bacterial lysates known as Coley's toxin [4]. In the 90 years after Coley's findings, the fields of immunotherapy and immunology matured in concert with one another. Significant immunotherapy achievements include the development of the first immune adjuvants [5], proposal of the immune surveillance theory or the idea that cancer cells could be recognized and killed by components of the immune system [6], proof that tumors have tumor-specific antigens that can be targeted by the immune system [7–10], and proof of tumoral immune escape through the loss of tumor-specific antigens [11]. During this same time, we note the discovery of numerous important immune mediators such as the Treg [12], DCs [13], natural killer cells [14], and interferons (IFNs), which are a family of critical protein mediators that act as signals for the immune system to regulate various aspects of an immune response [15]. Each of these discoveries and countless more were monumental in the development of the field of cancer immunotherapy.

These discoveries led to some of the first organized cancer immunotherapy clinical trials. Pioneering trials by Steve Rosenberg and colleagues, and others, aimed to use systemic administration of interleukin-2 (IL-2), a potent T cell–activating cytokine, in treating melanoma and renal cancer [16,17]. Despite promising preclinical data, clinical trials with IL-2 appeared to generate little improvement in overall survival and were often associated with concerning side effects. The early 1990s also saw the development of several promising new cancer vaccine strategies. One such strategy was GVAX, a vaccine that used irradiated cancer cells genetically modified to secrete granulocyte macrophage–colony-stimulating factor (GM-CSF), a potent APC activator [18]. A second successful strategy involved the use of autologous DCs pulsed with cancer peptides that could be reintroduced to the patient [19]. Both strategies were found to elicit potent antigen-specific T-cell responses and led to the development of Sipuleucel-T, or Provenge, for the treatment of prostate cancer. Sipuleucel-T treatment requires the isolation of patient-derived DCs and incubation with both an antigenic target overexpressed on most prostate cancers (i.e., antigenic prostatitic acid phosphatase) and GM-CSF for stimulation. Blinded, placebo-controlled phase III clinical trials showed a 4-month improvement in median survival for patients receiving Sipuleucel-T compared with placebo-treated cohorts [20]. This eventually led to the US Food and Drug Administration (FDA) approval of Sipuleucel-T for the treatment of prostate cancer in 2010. Sipuleucel-T represents the first major cancer immunotherapy to receive FDA approval and ultimately paved the way for numerous immunotherapies. A variety of other cancer vaccine strategies are currently under investigation, which vary according to what stimulus they provide and whether they deliver only a single antigen, termed subunit vaccines, or a whole library of tumor antigens (i.e., tumor lysates, irradiated whole tumor cells) [21]. During this period, adoptive T-cell therapies were also showing promise as an effective cancer immunotherapy. Applications include genetically modified T cells made to recognize and kill specific tumor antigens or chimeric antigen receptor (CAR) T-cells and adoptive T-cell therapies in which tumor reactive T-cells isolated from the patient were stimulated ex vivo and then reinfused [22–24]. Despite showing significant success in blood-borne cancers (i.e., lymphoma, leukemia), T-cell therapies continue to show minimal benefits against established solid tumor cancers; however, numerous technical advances and clinical trials are under way investigating new approaches and combinatorial treatment strategies with these therapies.

The mid 1990s saw the emergence of an immunotherapy platform termed immune checkpoint inhibitors (ICIs), which continue to show significant potential as a solid tumor therapy. Two ICI targets of extensive investigation are cytotoxic T lymphocyte–associated antigen-4 (CTLA-4) and programmed cell death protein-1 (PD-1). CTLA-4 is expressed on activated T cells and functions as the "brakes" of a T-cell response by saturating away costimulatory molecules on activated APCs and promoting overall deactivation of the T cell [25,26]. Blockade of CTLA-4 using monoclonal antibodies has been shown to prolong T-cell activation and promote significant antitumor effects in murine models [27,28]. Phase III clinical trials of Ipilimumab, a humanized antibody targeting CTLA-4, improved median survival by 4 months for patients with advanced melanoma, with a small subset of patients maintaining cancer-free progression up to 10 years later [29,30]. This led to the FDA approval of Ipilimumab in 2011 to treat advanced melanoma. CTLA-4 blockade is currently being tested in numerous other cancers both as a monotherapy and combined with other treatment modalities. Success of CTLA-4 inhibition led to the investigation of numerous other ICI targets, one of particular success being PD-1. PD-1 functions to deactivate T cells after engagement with either of its known ligands, PD-L1 or PD-L2 [25]. Of interest in cancer, high PD-L1 expression has been observed in numerous solid tumor cancers and has been correlated with a poorer prognosis [31–33]. In addition, cancer-induced exhaustion of T cells appears to upregulate PD-1 drastically on their surfaces, making them more susceptible to deactivation through this pathway [34]. Strong evidence suggests that blockade of PD-1 can restore functionality to these exhausted T cells and promote significant antitumor effects [35,36]. Thus, after clinical investigation, both nivolumab and pembrolizumab, two humanized anti-PD-1 monoclonal antibodies, received FDA approval in 2014 for the treatment of unresectable melanoma. Since then, they gained FDA approval

for the treatment of lung and kidney cancers in 2015 and Hodgkin lymphoma in 2016 and are actively being investigated in numerous other cancer types, again as both monotherapies and combined with other treatment modalities.

Despite preclinical and some clinical success of immunotherapies in treating cancer, it should be noted that although small subsets of patients have full durable responses, most patients do not benefit from these therapies. In addition, many of these therapies result in a number of systemic side effects, many of which could have life-threatening or long-term consequences for the patient's health. This leaves much to be desired from the field of immunotherapy in treating cancer.

ADVANTAGES AND DISADVANTAGES OF CANCER IMMUNOTHERAPY

Cancer immunotherapy offers numerous advantages compared with other standard of care treatments. Most notably, immunotherapy optimizes the patient's own natural immune system as the primary therapeutic source. This allows use of the intricate biologic features of the immune system that engineered therapeutic systems cannot currently achieve. Examples of these features include the natural ability of T cells to traffic and extravasate into tumor tissue, the ability to target cells preferentially harboring specific aberrations while leaving surrounding healthy tissue relatively unharmed, the ability to seek and destroy cancer cells throughout the entire body, even micrometastatic lesions, and finally, features of immunologic memory that can protect against recurrence. These advantages are highly unique to immunotherapy and thus provide the rationale for why it remains an exciting and highly investigated therapy in the fight against cancer.

Despite these numerous advantages, current immunotherapy applications face a number of challenges. Most notable is their inconsistent efficacy, because the majority of patients do not benefit from current immunotherapeutic strategies. Even more challenging is that currently few correlative biomarkers can predict patient success from these therapies. This has led numerous groups to investigate combinatorial treatment strategies in the hope of achieving synergistic treatment effects. Some examples include combinations of immunotherapies with chemotherapy, radiation, small molecule inhibitors, and even combined with other immunotherapy strategies [37]. In addition to low success rates, a number of immunotherapies have shown concerning side effects. Most often, these side effects are associated with systemic hyperactivation of the immune system, which can promote autoimmune responses against vital organ systems, leading to long-term and sometimes deadly health consequences for patients. The last major challenge of immunotherapy is affordability. Many current immunotherapies require isolation of patient-derived cells (i.e., T cells, DCs, tumors cells), which are then modified and readministered to the patient. This personalized medicine approach requires an extensive manufacturing pipeline and is often associated with vastly higher costs than a typical "off-the shelf" cancer drug such as chemotherapy or small molecule inhibitors. Non—patient derived immunotherapies are often expensive as well, typically requiring months to years of clinical visits for therapeutic administration. This creates major issues in terms of patient affordability and compliance. Thus, despite significant efforts and advances in the field of immunotherapy, it continues to remains significantly hindered by its limitations. This is where biomaterials-based approaches could have a significant role.

Whether macro-, micro-, or nanoscale, biomaterials offer the potential for sustained and/or targeted release of drugs (Fig. 41.1). For immunotherapeutic applications, this simple feature could provide a significant opportunity to overcome many of its current challenges. Biomaterials would provide a platform to contain an immune response locally within target areas. This would greatly benefit immunotherapies because the desired immunomodulation could occur in important areas such as in a subcutaneous zone, within the tumor itself, or even within critical immunologic tissues (i.e., lymph nodes and spleen). This could benefit the safety of immunotherapies by eliminating systemic immune activation and also would likely improve their efficacy, because more of the delivered drug would come into contact with the effector cell types rather than being removed from the systemic circulation or be degraded through normal physiologic routes. In addition, advances in biomaterial technology allow for accurate and highly controllable fine-tuning of drug release, in some cases providing extended release for up to years. Numerous groups have also developed systems for the controlled release of more than one drug with the potential to control the release kinetics of each drug individually. These multidrug release systems could enable the delivery of combinatorial immunotherapies to mimic the true response progression of the immune system more closely (i.e., first priming the innate system and then providing activation markers for the acquired immune system to maintain that response). This has the potential to enhance the poor response outcomes of immunotherapy greatly and could minimize the necessary time that patients need to spend in the clinical

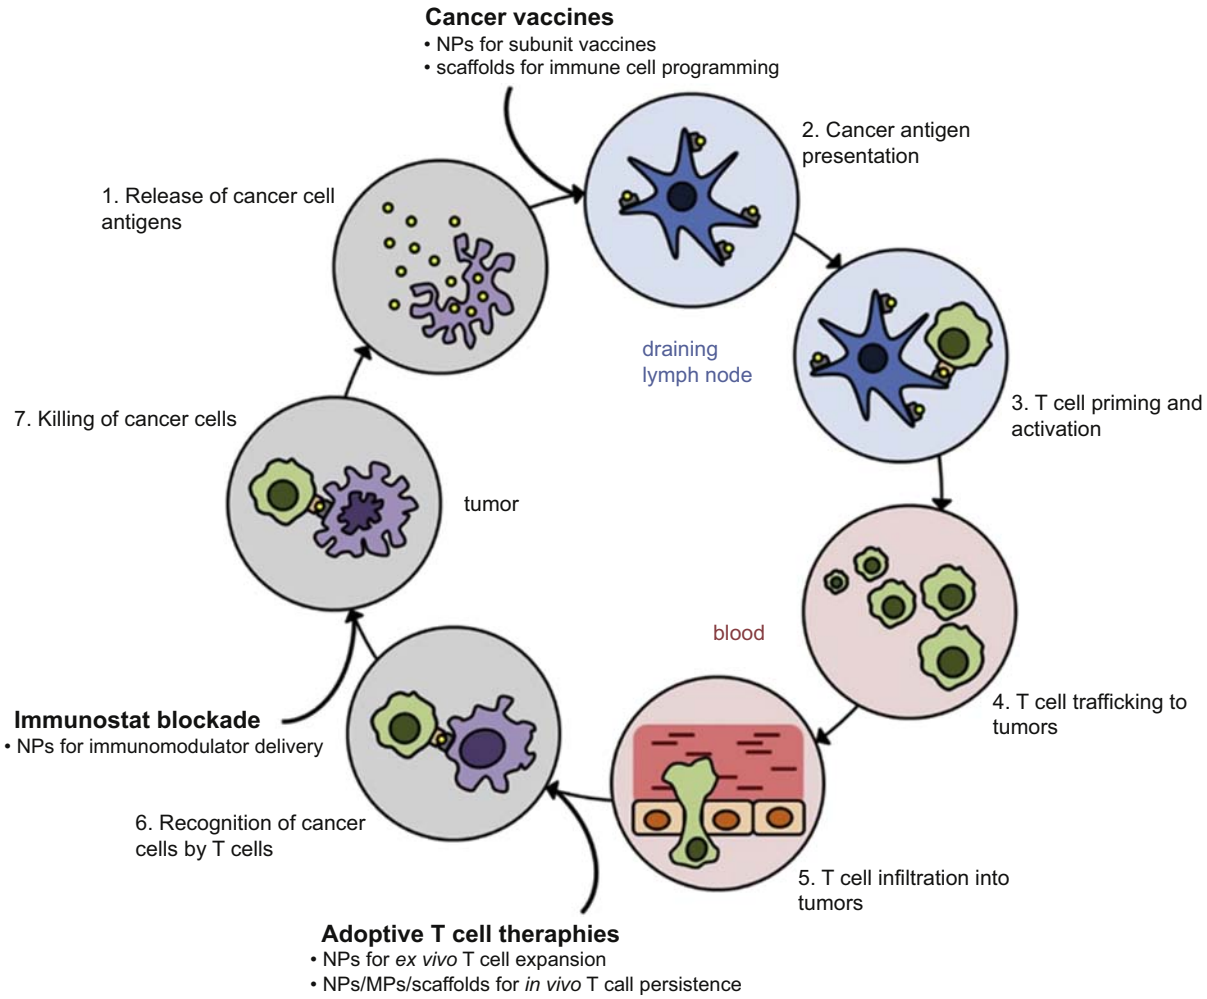

FIGURE 41.1 Schematic of the cancer-immunity cycle illustrating each sequential step with the labeled physiologic location needed to generate an efficient immune response against a tumor. Current immunotherapy approaches are shown at their point of augmentation (*bolded*) and biomaterial-based strategies used to benefit those immunotherapeutic strategies are listed below (*bulleted points*). *MPs*, microparticles; *NPs*, nanoparticles. *Reproduced with permission from Cheung AS, Mooney DJ. Engineered materials for cancer immunotherapy. Nano Today August 1, 2015; 10(4):511–31, Elsevier.*

setting, because the biomaterial could be implanted and release the drug continuously for extended times. Finally, although biomaterial approaches in immunotherapy seemingly make it more expensive, there are many opportunities for biomaterials to make these strategies cheaper. Biomaterials approaches allow the more efficient use of immunotherapeutic drugs by targeting them to key areas and cells types while minimizing physiologic clearance and drug degradation, and thus could minimize the necessary time patients need to spend in the clinic receiving the drugs. By providing a platform for immunologic modification of patient-derived cells in situ, biomaterial systems could also cut the costs of adoptive cell therapies. Thus, biomaterials have the potential to remove many of the challenges that immunotherapy currently faces.

NANOPARTICLE BIOMATERIALS FOR CANCER IMMUNOTHERAPY

Introduction of Nanomedicine in Cancer

Since its original discussion and conception in 1959 by Richard Feynman during his famous lecture, "There's Plenty of Room at the Bottom" [38], nanotechnology has continued to show exciting potential in the field of cancer therapy. The National Nanotechnology Initiative defines nanotechnology as the manipulation of matter at sizes

between 1 and 100 nm; however, many consider materials under 1 μm to warrant nanoparticle status. Because nanotechnology applications are so broad, the term "nanomedicine" further defines the application of nanotechnology in medicine. Most nanomedicine approaches rely on their intrinsic ability to accumulate in tumor tissue owing to a phenomenon known as the enhanced permeation and retention effect. Essentially, leaky tumor vasculature and inadequate lymphatic drainage result in the preferential localization of nanoparticles in the intratumoral space [39]. Thus, many groups have attempted to localize various therapeutic agents in tumors using nanoparticles to limit systemic toxicity and maximize drug efficacy [40]. In these attempts, a number of nanoparticle formulations have been widely optimized (i.e., metallic, liposome, dendrimer, and polymeric) (Fig. 41.2).

Nanoparticles offer a number of unique properties that make them an attractive approach to improving current immunotherapy applications. The biocompatibility of the formulation material, surface charge, size, and shape of the nanoparticle all have critical roles in how it interacts with the body. In particular, these features greatly influence where it localizes in the body, with what cell types it interacts or by which it is internalized, and its cytotoxicity effects [41,42]. Thus, when designing nanoparticles for a specific application, these features must be taken into careful consideration. A more detailed description of these various nanoparticle design criteria will be provided subsequently.

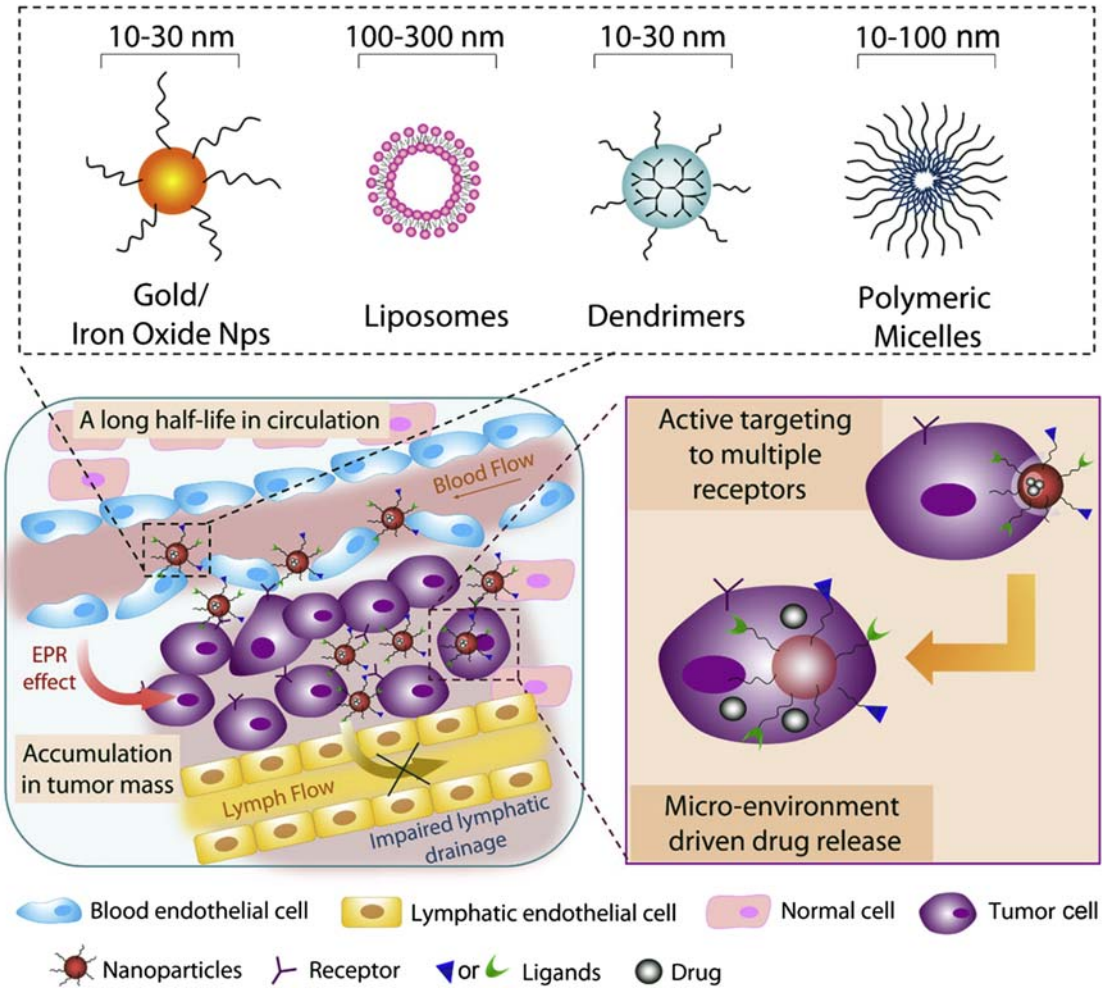

FIGURE 41.2 Schematic of the four most common nanoparticle platforms (*top*) and their application as tumor drug delivery vehicles. Optimally designed particles with adequate shape, size, surface charge, hydrophilicity, and surface modifications will promote a longer circulating half-life and accumulation in the tumor through the enhanced permeation and retention (EPR) effect (*bottom left*). Surface modification of the particle with ligands or other targeting moieties can be used to target receptor on tumor cells and promote the intracellular delivery and release of drug payloads in response to specific intracellular stimuli (*bottom right*). *Nps*, nanoparticles. *Reproduced with permission from Shao K, Singha S, Clemente-Casares X, Tsai S, Yang Y, Santamaria P. Nanoparticle-based immunotherapy for cancer. ACS Nano January 27, 2015;9(1):16—30, American Chemical Society.*

Effects of Nanoparticle Size and Shape

With improvements in nanoparticle manufacturing techniques, it is possible to make a variety of nanoparticle shapes. This has led to a number of studies determining how cellular and physiologic systems interact with different nanoparticle shapes. Cellular particle uptake rates depend on both size and shape. It appears that for particle sizes larger than 100 nm, rod-shaped particles have the highest uptake rates, followed by spheres, cylinders, and cubes. However, with particles smaller than 100 nm, sphere-shaped particles surpass rods in terms of cellular uptake rates [43]. Other more exotic shapes with various surface characteristics are being investigated; however, it remains unclear whether these will provide differential uptake.

When introducing nanoparticles to a physiologic system, several other effects such as pharmacokinetics and tissue distribution influence nanoparticle size and shape design criteria. For nanoparticles delivered intravenously, particles smaller than 6 nm are readily removed from the circulation by the kidneys. Nanoparticles larger than 200 nm typically accumulate in the liver and spleen and encounter a variety of immune cells tasked with removing large particulates from the circulation known as the mononuclear phagocytic system (MPS). Cells of the MPS typically phagocytose the nanoparticles, degrade them if possible, and then exocytose them for either filtration and removal or potential distribution in other physiologic tissues. Nanoparticle shape also is important in the physiologic systems, as evidenced by the fact that cells that circulate in the blood are typically not spherical. Thus, unsurprisingly, rod- or disk-shaped nanoparticles can promote longer circulation times compared with spherical nanoparticles [44]. Particle sizes between 10 and 200 nm are optimal in cancer nanomedicine for promoting long-term circulation, which ultimately provides more opportunities for delivery into tumor tissue. Within the tumor interstitium, particles in the upper end of this optimal range (100−200 nm) cannot extravasate far beyond the blood vessel and often remain stuck in the extracellular region between cells. Smaller particles (10 nm) have the potential to penetrate much farther into tumor tissue; however, without some form of targeting agent, they are not well-retained for more than 24 h [45]. Although many of these design optimization studies aimed for tumor drug delivery applications, in which the primary goal was to enhance nanoparticle localization within the tumor, an understanding of how particle size and shape dictate particle fate continues to shape the design characteristics of its newer applications in immunotherapy.

Effects of Nanoparticle Surface Charge and Hydrophilicity

Nanoparticle surface charge and hydrophilicity are also features that have major implications in the design of nanoparticles. These features are easily modifiable through a number of technologies such as layer-by-layer, conjugation of surface moieties, and careful selection of particle material. Generally, positively charged particles are taken up by cells at a much higher rate than are neutral or negatively charged particles. Many researchers postulate that this is the result of the slightly negative surface charge of cellular membranes, which provides an electrostatic interaction that draws positively charged particles to the surface of the cell. In addition to having higher uptake, positively charged particles induce higher cytotoxicity effects because of detrimental disturbances that they cause in cellular membranes [46]. Similar to size, however, introduction into a biologic environment creates a number of additional considerations. Most notable is that the nanoparticle surface is rapidly covered by a variety of serum proteins, forming what is known as the corona on the particle surface. The surface charge and hydrophobicity of the particle largely dictate the composition of this corona and thus influence the future fate of the particle. Most highly charged particles, positive or negative, rapidly and strongly bind a number of serum proteins that tag them for removal through the MPS system [47,48]. Particles containing a more hydrophobic surface experience a similar fate, with high serum protein binding and removal. Thus, neutral particles with highly hydrophilic surfaces are the most optimal for naturally promoting long-term circulation; however, depending on the application of the nanoparticle, this may not be the desired surface features. With these understandings, many groups have developed ways to alter the surface characteristics of their nanoparticles to provide beneficial delivery features.

Effects of Nanoparticle Surface Functionalization

As previously described, the surface characteristics of nanoparticles are a major parameter in the development and design of nanomedicine applications. Thus, numerous surface modification techniques have been developed to create favorable surface features without having to modify the bulk material of the nanoparticle. Surface attachment of hydrophilic polymers such as polyethylene glycol (i.e., PEGylation) is one of the most widely studied

nanoparticle functionalization techniques. Many groups have shown significant improvements in the particle circulation time as a result of decreased protein absorption and MPS recognition after PEGylation [49]. Another surface modification commonly used is the attachment of targeting agents. A variety of targeting moieties have been developed, the most prominent of which are variable antibody fragments, peptides, receptor ligands, and aptamers. These are often made specific to a receptor or surface target on the target cell; upon binding, they promote the internalization of the nanoparticle carrier. The small size of nanoparticles provides a vast improvement in the total surface area exposure compared with many micromaterials and macromaterials, which allows for drastic advantages for targeting applications. Numerous groups have further shown that there are a variety of parameters that must be optimized for targeting ligands to make them maximally effective; these typically rely on targeting the agent density on the nanoparticle surface and the nanoparticle size [50]. With beneficial surface characteristics, nanoparticles can be considerably improved in nanomedicine applications. These important findings have promoted many of the design criteria for applying nanoparticles in immunotherapy.

Nanoparticle Targeting Applications in Immunotherapy

Nanoparticle targeting often occurs through two primary methods, active or passive. Active targeting requires conjugating targeting moieties to the surface of the nanoparticle to encourage localization in specific areas or uptake by critical cells. Alternatively, passive targeting relies on the natural properties of the nanoparticle (i.e., surface charge, size, shape) to promote preferential uptake. Drug targeting is a unique ability of nanoparticles that has been widely studied in the field of drug delivery, with extensive success including a number of FDA-approved nanoparticle drug targeting formulations [51].

Compared with standard cancer nanomedicine targeting, immunotherapeutic applications require slightly more consideration of the intracellular or extracellular compartment in which the therapeutic payload will be released. For example, proinflammatory cytokines or other agents that target surface-bound cell receptors must be released into the extracellular tumor space. A number of strategies have been used to promote extracellular release, typically aiming to discourage phagocytosis of the particle. Notable examples include PEGylation or coating of the particle's surface with antiphagocytic signals such as CD47 [52]. In addition, fine-tuning of the particle's physical properties can be used to diminish cellular uptake, as previously discussed. In opposition to extracellular acting agents, delivery of other therapeutics such as specific Toll-like receptor (TLR) agonists, short interfering RNAs (siRNAs), or tumor-specific antigens for cancer vaccine applications require the delivered cargo to be released in specific intracellular compartments (i.e., endosome, lysosome, or cytosol). Enhancement of the particle surface with ligands targeting endocytosis-associated receptors and optimization of a particle's physical characteristics can be used to promote more enhanced cellular uptake, especially in phagocytic cells [53]. In addition to targeting key compartments, particles must be designed to release their payload within a target environment. This can be achieved by chemically modifying the particle drug carrier to release its payload upon encountering some form of location-specific stimuli. The most common release cues include low pH and specific intracellular or extracellular proteases [54]. A number of triggered release systems have also been developed in which the release stimuli is delivered exogenously (i.e., light, magnetic field, heat) and promotes particle degradation and payload release [55,56]. Certain nanoparticle systems also provide the ability to fine-tune the rate of drug release by altering various particle features such as porosity, degradability, and the drug incorporation method (basic encapsulation versus stimuli-cleavable chemical conjugation). Thus, optimizing these various features has allowed for highly efficient, selective, and fine-tunable targeting of immunotherapeutic agents. This which will be discussed in more detail subsequently.

Nanoparticle Targeting of the Tumor Microenvironment

Most solid tumor cancers harbor a wound healing–like inflammation and a highly immunosuppressive microenvironment. This feature of solid tumors is elicited by an intricate network of numerous cell types including the cancer cells themselves, a highly active stroma (i.e., cancer-associated fibroblasts), and a number of immune cells such as MDSCs, Tregs, and TAMs. Through a variety of mechanisms, this tumor microenvironment can drastically prevent effector T-cell infiltration into the tumor and abrogate the cytotoxic function of effector cells that manage to infiltrate it. The tumor microenvironment has even been shown to promote tumor growth and induce tumoral immune tolerance [3]. Thus, modulating this tumor microenvironment would provide a significant therapeutic opportunity, especially in situations in which a notable population of cancer-specific T cells exists but is unable

overcome the immunosuppressive state of the tumor. The most common immunotherapeutic applications targeting the tumor microenvironment aim to inhibit or downregulate immunosuppressive features of the tumor, stimulate suppressed effector immune cells within the tumor parenchyma, or combinations of these approaches. Bolus delivery of immunomodulatory agents (i.e., cytokines, ICIs) have rapid saturation and/or degradation, which limits the effective dose delivered to the tumor and generates significant concern for systemic inflammatory toxicities. Thus, leveraging the advantages of nanoparticles to deliver these agents selectively to the tumor is an obvious application of nanomedicine in immunotherapy.

Rather than attempt to discuss the robust amount of preclinical application of nanomedicine targeting the tumor microenvironment, we will provide a few examples of the diverse applications that are currently being explored. One interesting application involves targeting dysregulated genetic pathways within tumor-infiltrating immune cells. Signal transducer and activator transcription 3 (STAT3), a transcription factor that has previously been shown to promote Th2-based inflammation and enhance the survival of Tregs, is an intriguing target. Using tumor-targeting liposomes delivering intracellular agents to deplete STAT3 (i.e., small-molecule inhibitors [siRNA]), a few groups have shown impressive tumor immunosuppression reversal effects [57]. This strategy provides a valuable platform for the inhibition of numerous other dysregulated immunologic genetic pathways within the tumor. In addition to inhibiting immunosuppressive mechanisms directly, many groups have aimed to activate naive, suppressed, or tolerogenic effector cells within the tumor microenvironment. A number of strategies have been employed for this, including tumor localized delivery of proinflammatory and T cell−stimulating cytokines (i.e., IFN-gamma, IL-1α, IL-2, IL-12, tumor necrosis factor-α) and APC-activating agents (i.e., CD40 ligand, cytosine-guanosine oligodeoxynucleotides [CpG], lipopolysaccharide, monophosphoryl lipid A [MPL-A], polyinosinic−polycytidylic acid [poly I:C]) [58−60]. Nearly all of these nanoparticle delivery systems showed benefits compared with bolus delivery of the same agents because they provided less systemic toxicity and extended release for up to many weeks in some cases, thus promoting more potent immunomodulatory effects. These strategies have shown relatively minimal therapeutic benefits as monotherapies; however, they are readily being investigated as combination modalities with more conventional immunotherapeutic strategies. Toward this combinatorial theme, a few groups have developed dual therapeutic delivery systems encapsulated within a single nanoparticle platform. One particular group used a polymeric liposome system, termed nanolipogels, to codeliver a small molecule inhibitor for transforming growth factor-β (TGF-β) (an immunosuppressive cytokine) and a potent T cell−activating cytokine, IL-2 (Fig. 41.3A). Their system was able to extend the release of these agents for many days and promoted significant survival benefits in preclinical models (Fig. 41.3B and C) [61]. In addition to releasing proinflammatory markers, some nanoparticle systems have been shown to promote the activation of target cell types by surface engagement with effector cells. One group optimized liposomes enhanced with IL-2 fragments and costimulatory 4-1BB, which were retained at the tumor site and promoted marked T-cell activation within the tumor through active engagement [62].

Applications of nanomedicine in targeting the tumor microenvironment are extensive; the example listed earlier represents only a portion of the vast work that has been done in this area. Overall, nanoparticles provide major advantages over the bolus delivery of immunomodulatory drugs. First, they enable the agent to be localized and concentrated at the tumor site, which benefits not only its efficacy but also its systemic toxicity. Second, they allow for extended immunomodulatory drug release, which provides sufficient time for effective immune responses to be generated and mounted against the tumor. Finally, they enable the targeting of drugs not only to important cells but also to necessary spatial and temporal locations. Overall, this renders these applications highly warranted and provides the rationale for the extensive past and current investigation of these systems.

Nanoparticle Targeting of Antigen Presenting Cells

In addition to targeting the tumor directly, significant efforts have been made to target immunologic stimuli and antigenic information to key lymphoid cells or tissues using nanoparticles, primarily targeting APCs in the lymph node and spleen. DCs are commonly recognized as the most potent APCs, which makes them a logical cellular target of nanoparticle systems. By providing DCs with the appropriate “danger signals,” they have the ability to generate potent T-cell responses against antigens that they have acquired. This creates two unique applications for nanoparticles: one in which they could deliver only stimulus to DCs, in the hope that they have already acquired tumor antigens, and a second in which they could deliver both antigen and simulation to generate highly antigen-specific immune responses. Using nanoparticles, DCs can be targeted through a number of delivery routes. Because a subpopulation of DCs dwells in peripheral tissues, nanoparticles delivered into the dermal or subcutaneous space

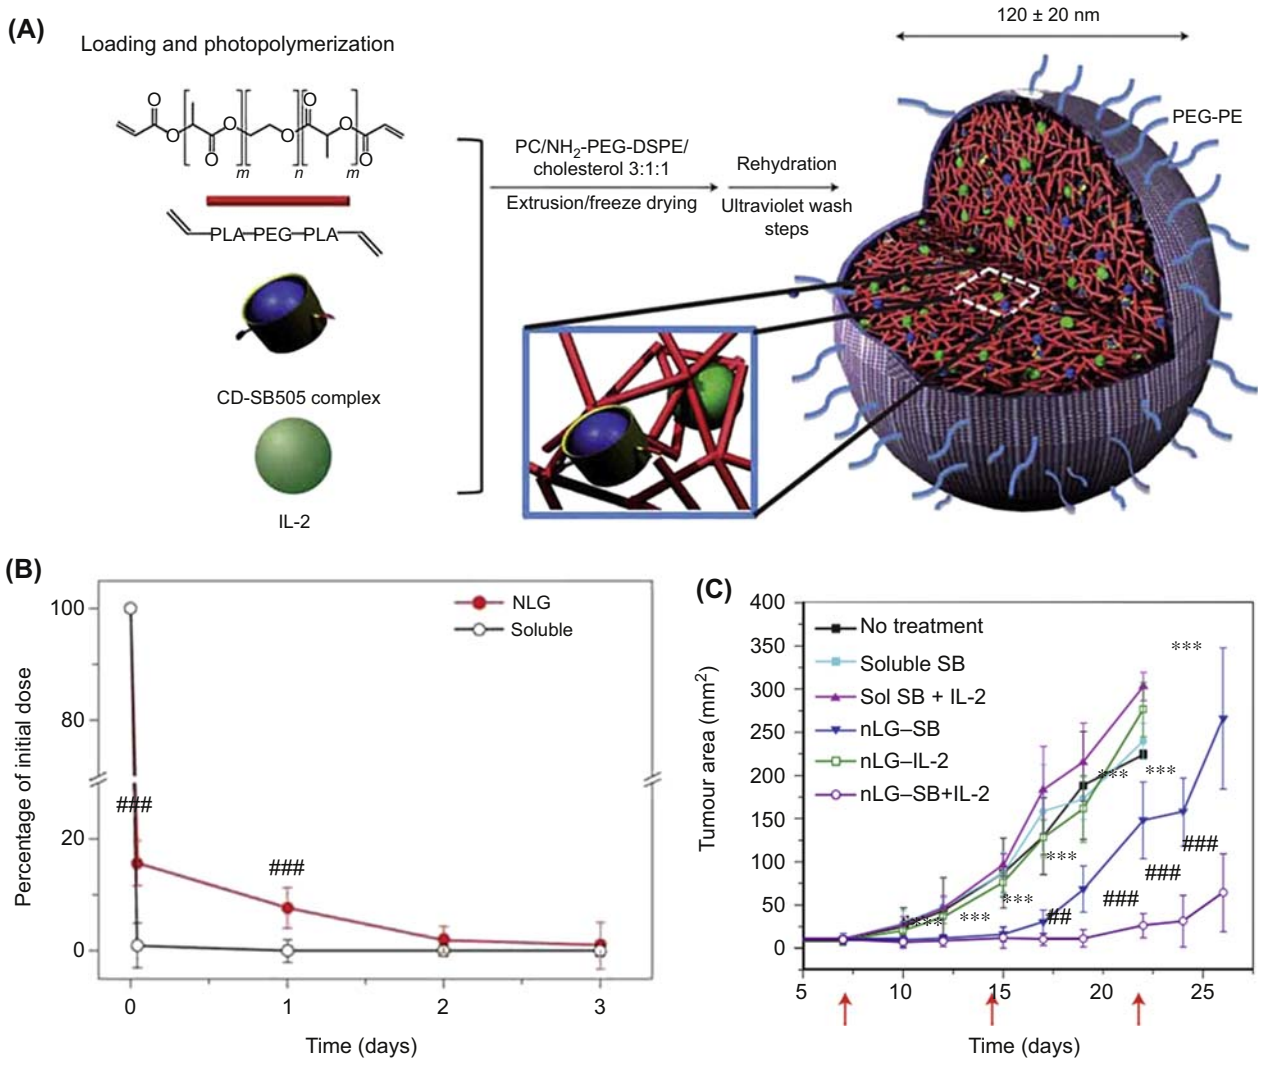

FIGURE 41.3 Nanolipogels (NLGs) are an effective immunotherapy codelivery platform (A) Synthesis illustration of NLGs. Lyophilized liposomes were loaded with a tumor growth factor-β receptor 1 inhibitor that was solubilized using methacrylate-conjugated β-cyclodextrins (SB), interleukin-2 (IL-2) cytokine, and a biodegradable cross-linking polymer. This allowed the formation of a core-shell structure with entrapped CD-SB505 (*blue*) and IL-2 (*green*) in a biodegradable polymer matrix (*red*), all within a PEGylated liposome. (B) Percentage of intravenously delivered rhodamine (a fluorescent pseudodrug) remaining at 1, 24, 48, and 72 h postinjection. Rhodamine was either encapsulated in their NLGs or bolus delivered in saline. (C) Plot of tumor area following treatment of established B16—F10 melanoma in B6 mice. Treatment groups include no treatment or intratumoral injections of soluble SB, soluble SB and IL-12, NLG-encapsulated SB, NLG-encapsulated IL-2, and NLG-encapsulated SB and IL-2. Combination delivery of TGF-β inhibitor and IL-2 by nanoscale liposomal polymeric gels enhances tumour immunotherapy. Nat Mater October 2012;11(10):895—905, Nature Publishing Group.*

can be phagocytosed by DCs, activate them, and promote their migration to the lymph nodes, where they can induce T cell expansion. Alternatively, nanoparticles can be designed to drain into the lymphatics and encounter lymphoid tissue—residing DCs. Both of these strategies provide a unique application for nanomedicine, because they essentially allow for DC priming and activation without the need for ex vivo cell isolation and manipulation. Thus, cancer vaccine applications using nanoparticles have promoted great excitement in the field and continue to show promising effects.

A number of groups have developed nanoparticle formulations that can be targeted to the lymph node. Lymph nodes are obviously a useful target organ because of their primary function in the priming and generation of clonal T cell expansion. Various groups have demonstrated that 20- to 100-nm particles are optimal for lymph node targeting through lymphatic drainage, with markedly faster lymph node localization and uptake at the smaller sizes [63]. At this size, particles can extravasate from vascular beds and are driven into the lymphatic network, where

they are transported to lymph nodes via interstitial pressure. Once in the lymph node, particles are readily taken up by DCs, providing an efficient route to promote immunologic priming. Various groups have then used this feature for subunit vaccine strategies, typically optimizing a model antigen ovalbumin (OVA). A study using subcutaneously injected PEGylated lipid nanoparticles with encapsulated OVA and cyclic dinucleotide stimulus promoted significant lymph nodal immune responses. Using their system, they noted a 15-fold improvement in adjuvant localization to the lymph node and a threefold improvement in OVA-specific CD8+ T-cell generation compared with bolus antigen and adjuvant delivery [64]. To improve on poor liposome serum stability, another group developed multilayered liposomes with intralayer cross-linking, termed interbilayer-crosslinked multilamellar vesicles (ICMVs). PEGylated ICMVs with OVA loaded into the particle center and MPL-A, a TLR-4 agonist, embedded within the ICMV wall promoted a 14-fold enhancement in antigen-specific T cells compared with bolus delivery [65]. Another group developed an alternative strategy using the natural trafficking phenomenon of serum albumin to traffic nanoparticles to the lymph node efficiently and selectively. Their most successful lipid formulation was composed of a lipophilic albumin-binding tail, a polar linking chain, and either a potent APC agonist or a target antigen peptide (Fig. 41.4A) [66]. When delivered together, this adjuvant and antigen nanoparticle formulation complexed with albumin and was highly localized to the lymph nodes, where they promoted significant activation and expansion of target antigen-specific CD8+ T cells (Fig. 41.4B and C). Impressively, when delivered in combination with a tumor-targeting antibody, modified IL-2 cytokine, and ICI therapies, the lymph node−targeting nanoparticles were also able to promote the rejection of large established tumors (Fig. 41.4D) [67]. Overall, these subunit vaccine nanoparticle strategies provide a promising method for generating antitumor T-cell responses.

Despite the relative success of subunit vaccine strategies, they have a number of limitations. Most notable is that targeted vaccine strategies against a single antigen will not benefit cancers with unknown or unpredictable antigenic features. In addition, these strategies do not consider the vast patient-specific tumor antigen repertoire, which could ultimately promote immunoediting (i.e., selection of only the minimally immunogenic cancer cell populations) and eventual immunologic escape by the tumor. This has driven a number of groups to investigate the delivery of adjuvant nanoparticles to the tumor-draining lymph nodes (tdLNs). The tdLNs are an attractive target for simulation because they are continuously exposed to a plethora of cancer-specific antigens throughout the course of tumor progression. However, they also represent a relatively challenging stimulation site, with depleted effector cell populations and high levels of cellular suppression and exhaustion, especially at later stages of tumor progression [68]. Nevertheless, numerous nanomedicine attempts have been made to stimulate tdLNs, most often involving the delivery of APC stimulatory agonists in the hope of promoting clonal T cell expansion targeting numerous cancer antigens. One example includes the use of a 30-nm pyridyl disulfide (PDS) nanoparticle surface conjugated with CpG. The CpG conjugation was performed using pH-sensitive chemistry to promote release in the endolysosomal compartment of DCs for TLR-9 stimulation. PDS−CpG nanoparticles delivered intradermally near the tumor (B16−F10 melanoma) allowed for efficient draining and uptake by DCs in the ipsilateral lymph node, which the researchers verified to be tdLN by intratumoral injection of fluorescent dextran. These stimulatory particles increased the percentages of activated DCs and promoted a marked increase in CD8+ T cells specific for tyrosinase-related protein-2 (TRP2), a tumor-specific antigen known to be associated with this tumor model; they also significantly slowed tumor growth [69].

Although targeting of lymph nodes using an intradermal or subcutaneous injection of nanoparticles has shown promising immunologic effects, this approach raises a number of questions when considering applying them in the clinical setting. The most obvious question is which specific lymph nodes these systems should target, because the tdLN may contain the most tumor antigen−experienced DCs, however, it also contains the highest levels of immunosuppression and exhaustion, which could hinder effective stimulation. This issue spurred the development of a systemically delivered nanoparticle vaccine strategy that could be delivered intravenously and would naturally accumulate in a variety of lymphoid tissues such as spleen, lymph nodes, and bone marrow. Using systemically delivered RNA liposome complex (RNA-LPX) nanoparticles, one group demonstrated an impressive ability to target lymphoid tissues and resident DCs and macrophages passively simply by altering the net surface charge of their particles (Fig. 41.5A and B). Even more impressive was the fact that systemic delivery of their optimally charged RNA-LPX could promote significant activation of DCs and strong expansion of antigen-specific T cells (Fig. 41.5C). This ultimately promoted considerable rejection and survival benefits in a variety of established murine tumor models (Fig. 41.5D) [70].

The application of nanoparticles as APC targeting agents is one of the most exciting developments in the field of nanomedicine. Numerous groups have shown the potent effects that APC-targeted nanoparticles can induce, especially in terms of generating tumor-specific T-cell expansion. The unique ability of small nanoparticles to traffic to

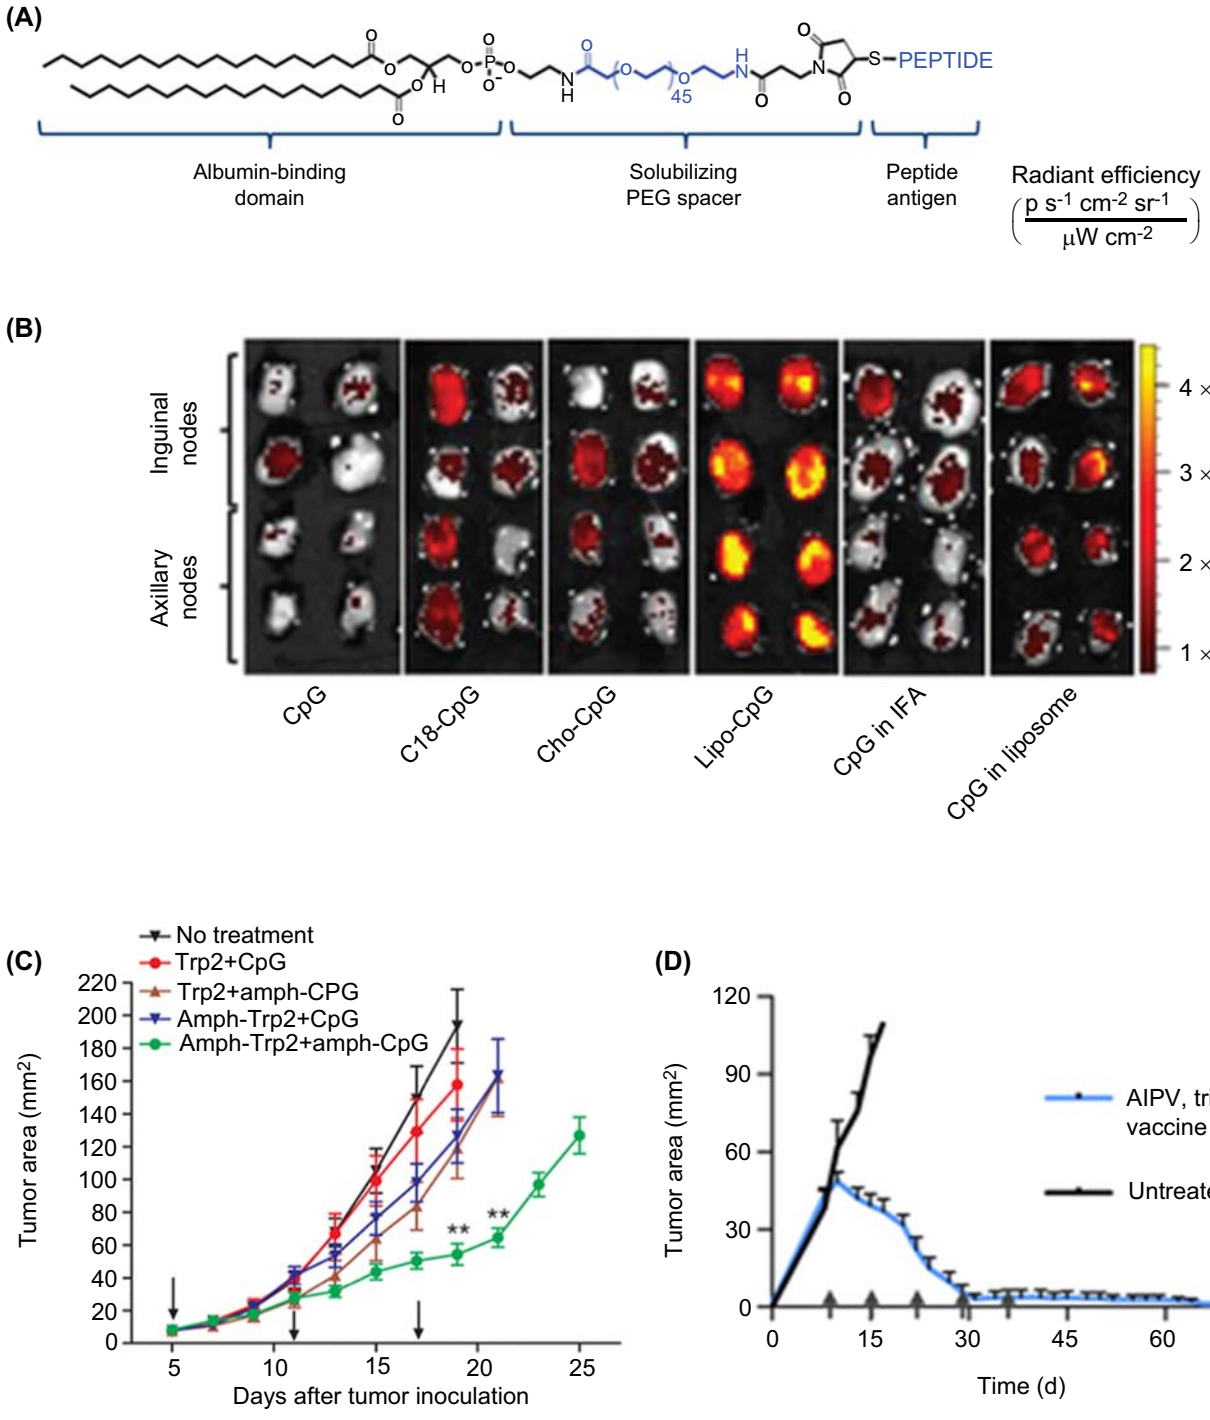

FIGURE 41.4 Amphiphilic peptide and adjuvants efficiently target lymph nodes and promote antigen-specific immune responses. (A) Structure of amphiphilic peptide used to complex with serum albumin and target peptide antigens the lymph nodes. For treatment applications, this was codelivered with liposome cytosine-guanosine oligodeoxynucleotides (CpG). (B) IVIS fluorescence imaging showing both axillary and inguinal lymph node accumulation of various targeted molecular adjuvant formulations. CpG was conjugated with fluorescein amidite to make it fluorescent. Higher intensity indicates higher CpG localization to the lymph node. Groups tested include free CpG, CpG in incomplete Freund's adjuvant (CpG in IFA), CpG encapsulated in a poly(ethylene glycol) (PEG)-coated liposome (CpG in liposome), or various amphiphile CpG conjugates; mono-acyl-conjugated CpG (C18-CpG), cholesterol-conjugated CpG (Cho-CpG), and diacyl lipid-conjugated CpG (lipo-CpG). Of note, lipo-CpG was found to associate strongly with albumin in serum (not shown), a likely mechanism of this delivery. (C) Plot of tumor area after vaccination treatment of established B16−F10 melanoma tumors in C57/BL6 mice. Mice were vaccinated with CpG and Trp2 peptide, an antigen known to be associated with B16−F10 tumors in bolus form or in designed amphiphile (amph) forms at the days indicated by *black arrows*. (D) Similar tumor area curves in B16−F10 melanoma tumors. AIPV trivalent-treated mice received vaccination with amphiphilic CpG and peptide antigens (Trp1, Trp2, and gp100) known to be associated with this tumor model, systemic administration of tumor targeting antibodies (targeting Trp1), systemic administration of albumin-fused interleukin-2, and administration of α-programmed cell death protein-1 immune checkpoint inhibitor. *(A−C) Reproduced with permission from Liu H, Moynihan KD, Zheng Y, Szeto GL, Li AV, Huang B, et al. lymphoid tissues and readily be internalized by APCs, namely DCs, provides a unique application of nanomedicine in treating cancer. Furthermore, the improved efficacy and safety that nanoparticle targeted systems provide compared with the bolus delivery of immune stimulatory agents and/or antigens is unparalleled. Thus, many of these systems have translated to the clinical setting and likely will continue to do so, where it is hoped that they will provide immunotherapy applications with these pronounced benefits.

Conclusion of Nanomedicine Applications in Immunotherapy

Unsurprisingly, nanomedicine applications have demonstrated amazing potential for the enhancement of cancer immunotherapies. This section focused largely on their targeting applications, such as targeting of the tumor microenvironment or targeting of APCs in important lymphoid sites. However, nanomedicine is being applied in many other applications in immunotherapy as well [71–73]. Most of these applications apply the extended release features of nanoparticle systems to the delivery of immunomodulatory agents. One such example involves the ex vivo conjugation or the in vivo targeting of T cells using nanoparticles that provide the extended release of T-cell stimuli or inhibitors of T-cell inactivation. These "T-cell piggyback" nanoparticle systems have shown amazing potential for prolonging the persistence of adoptively transferred T-cell therapies, a major hindrance for those therapies [74,75]. This demonstrates just one example of how nanoimmunosystems could theoretically be applied to target any immune cell population and deliver any number of immunomodulatory agents, which thus providing much future work for the field of nanomedicine immunotherapy. Overall, the applications of nanomedicine in immunotherapy will likely continue to exploit the unique ability of nanoparticles to prolong the release kinetics and selectively deliver immunotherapeutic agents to important cell types or physiologic locations. This simplistic-seeming ability has the potential to benefit immunotherapeutic strategies greatly in cancer, making them safer, more efficacious, and applicable to far more cancer settings than was previously thought achievable.

MACROSCALE BIOMATERIAL SCAFFOLDS FOR CANCER IMMUNOTHERAPY

Implantable Biomaterial Scaffolds as Cancer Vaccines

As we have discussed, the ability of nanoparticles to target bioactive factors toward important cell populations at specific physiologic locations is an example of how biomaterials have evolved over the past decades to be more than just inert, biologically compatible replacement parts. This paradigm shift toward the design of "smart," biologically active materials that can manipulate and interact with cells in their environment is a fundamental concept familiar to those in the field of tissue engineering and regenerative medicine. For example, macroscale drug delivery biomaterial platforms (i.e., with at least one dimension large than 1 mm) are widely used to control the spatiotemporal delivery of multiple bioactive molecules and/or cells to direct cell behavior and drive functional tissue formation [76]. The ability of these engineered scaffolds to perform in situ cell programming has made them an attractive technology to improve DC and T cell function in the context of therapeutic cancer vaccines.

In contrast to nanoparticulate vaccines, which target antigen and/or adjuvant components to DCs located in tumor-draining lymph nodes, the paradigm for using microscale and macroscale cancer vaccines is to recruit large numbers of immature DCs to the scaffold itself, where in situ programming takes place in a controlled microenvironment. This has the potential to reduce the financial and regulatory burdens associated with conventional methods of DC-based cancer vaccinations such as Sipuleucel-T, which require cell isolation, ex vivo cell culture and manipulation, and multiple patient procedures [77]. With the in situ DC vaccination approach, the implanted biomaterial scaffold is designed for controlled release of a recruitment factor that promotes the trafficking of immune cells to the implantation site. Once there, recruited cells such as immature DCs infiltrate the scaffold and are simultaneously presented with tumor antigen and proinflammatory "danger signals" in the form of a pattern recognition receptor ligand adjuvant. The mature, antigen-loaded DCs that are generated then traffic out of the scaffold toward draining lymph nodes, where they can facilitate anticancer immunity through T cell priming and activation (Fig. 41.6).

This approach was first described by Ali et al. [77], who used macroporous scaffolds composed of the copolymer poly(lactide-*co*-glycolide) (PLG) as subcutaneously implanted DC cancer vaccines (Fig. 41.7).

Incorporated into the PLG matrix were GM-CSF as a recruitment factor for immune cells, cationic nanoparticles of CpG as the danger signal, and melanoma tumor lysate as the antigen. Sustained release of bioactive GM-CSF was

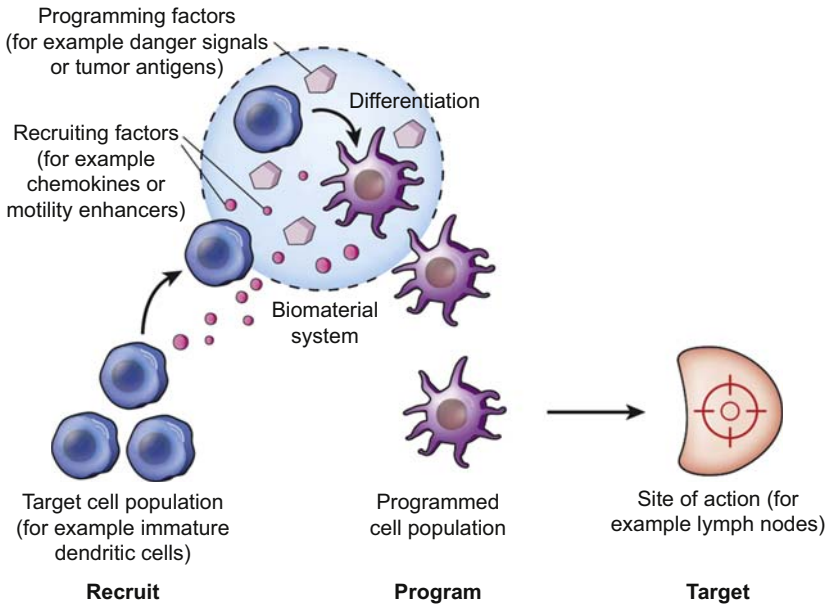

FIGURE 41.6 Schematic of an implantable biomaterial system that can be used for in situ dendritic cell programming. Recruitment factors released from the implant promote the trafficking of immature dendritic cells to the scaffold, where they encounter programming factors such as adjuvant and tumor antigen. The activated, antigen-presenting dendritic cells then leave the scaffold and migrate to draining lymph nodes, where they trigger downstream events such as the activation of antigen-specific cytotoxic lymphocytes. *Reproduced with permission from Huebsch N, Mooney DJ. Inspiration and application in the evolution of biomaterials. Nature November 26, 2009;462(7272):426–432, Nature Publishing Group.*

achieved over 15 days in vivo, resulting in a significant number of DCs infiltrating the scaffold (on the order of 10^6 cells, similar to the number of cells administered by ex vivo protocols). Scaffold-infiltrating DCs were shown to be activated by the CpG immobilized within the scaffolds and then subsequently dispersed to draining lymph nodes. After vaccination, cytotoxic lymphocytes targeting the melanoma-associated antigen TRP2 were markedly expanded in the spleen, and a threefold increase in CD8+ T-cell infiltration into tumors was noted for vaccinated mice compared with controls. Further work to characterize the multiple DC subtypes recruited to the implanted vaccine revealed the accumulation of a heterogeneous DC network including CD8+ DCs (important for cross-presentation of tumor antigen to Th1 T cells and cytotoxic lymphocytes) and plasmacytoid DCs (known to generate

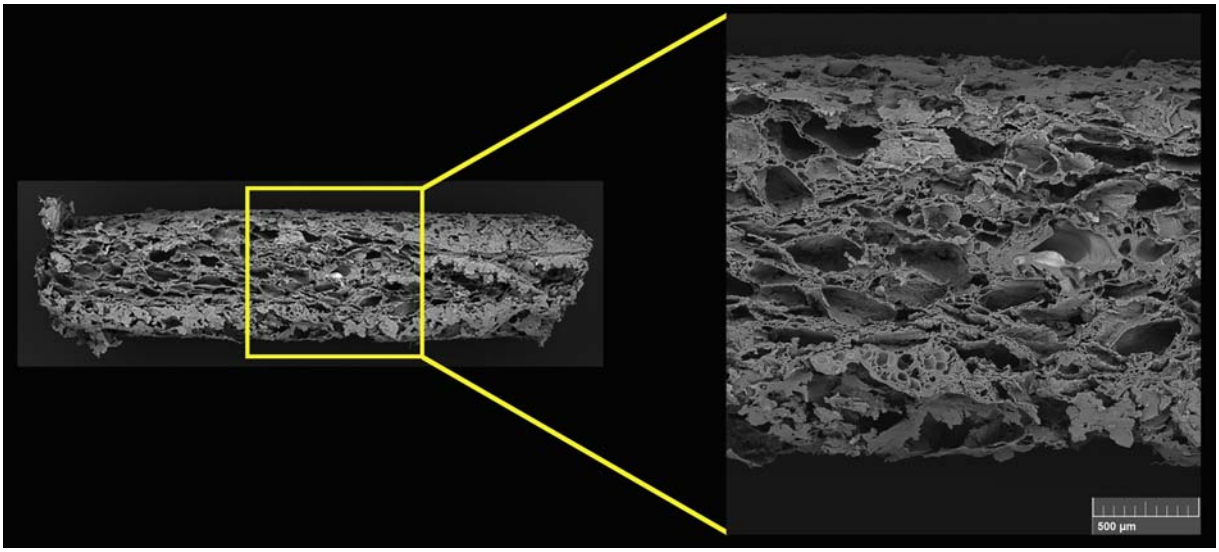

FIGURE 41.7 Low- and high-power scanning electron microscopy cross-sectional images of a macroporous poly(lactide-*co*-glycolide) cancer vaccine scaffold containing granulocyte macrophage–colony-stimulating factor, cytosine-guanosine oligodeoxynucleotides, and tumor antigen. The image on the left (low power) is 1X and the image on the right (high-power) is 125X.

type I IFNs, helping to activate CD8+ DCs) [78]. Prophylactic vaccination resulted in a 90% survival rate, whereas mice bearing established melanoma tumors and treated twice with the PLG vaccine resulted in 47% survival (Fig. 41.8). Subsequent work investigated the use of alternative adjuvants in the PLG vaccine including MPL-A and poly I:C [79], and alternative recruitment factors such as chemokine (C−C motif) ligand 20 (CCL20) and Fms-related tyrosine kinase 3 ligand [80], which illustrates the ability of this implantable, polymeric vaccine system for use as a versatile macroscale biomaterial platform to deliver multiple immunomodulatory factors. The PLG-based cancer vaccine is undergoing a phase I clinical trial under the name "WDVAX" (NCT01753089), investigating its safety in metastatic melanoma patients.

Injectable Biomaterial Systems as Cancer Vaccines

Drawbacks of macroporous scaffolds composed of PLG are their relative stiffness and brittleness, which necessitate a small surgical procedure to enable subcutaneous implantation. To address this shortcoming, macroporous Cryogel scaffolds have been developed that can undergo large amounts of reversible deformation and rapid volumetric recovery, enabling the minimally invasive delivery of these scaffolds through small-bore needles [81]. Bencherif et al. [81] investigated an alginate-based Cryogel system as an injectable cancer vaccine scaffold, incorporating GM-CSF as the DC recruitment factor, CpG as an adjuvant, and irradiated B16−F10 melanoma cells as the antigen source (Fig. 41.9) [82]. To enhance the retention of the irradiated cells within the pores of the sponge-like vaccine scaffold, arginylglyclaspartic acid (RGD) peptides were covalently coupled to the alginate, allowing the preloaded cancer cells to adhere via integrin binding and remain localized to the scaffold microenvironment. Akin to the strategy used by the PLG-based cancer vaccine, this macroporous Cryogel-based cancer vaccine was designed to provide a localized immunogenic niche for recruited DCs and irradiated tumor cells to interact in the presence of the CpG danger signal without the tolerogenic factors present in the tumor microenvironment. Successful encapsulation of GM-CSF and CpG into the sponge-like alginate cancer vaccine construct was followed by sustained release of these factors over 1 month, enabling the recruitment and activation of both CD8+ and plasmacytoid DCs and a strong effector T cell response. Mice bearing B16−F10 melanoma tumors and treated with the Cryogel vaccine at days 3 and 10 after tumor inoculation displayed a 40% survival rate compared with unimmunized mice, illustrating the potent antitumor response that can be generated with this system.

Another injectable, materials-based cancer vaccine platform was described by Kim et al. [83] and is based on high−aspect ratio mesoporous silica rods (MSRs). Using the same paradigm of host immune cell recruitment and

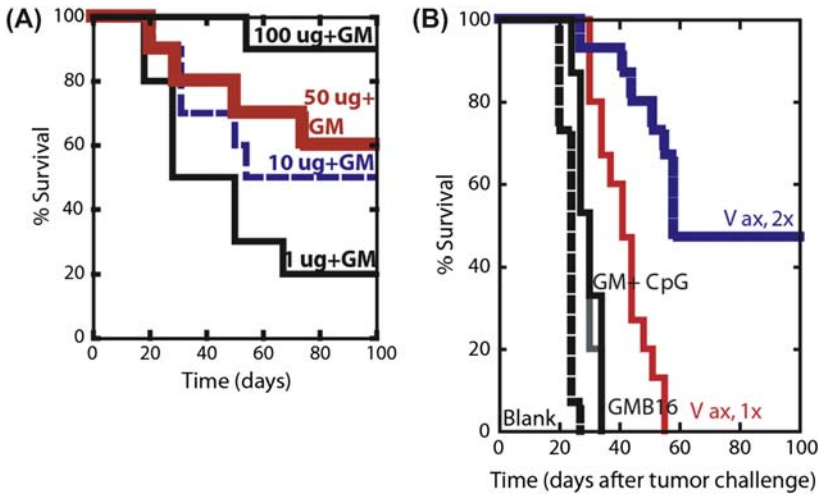

FIGURE 41.8 Kaplan−Meier survival curves of mice vaccinated with poly(lactide-*co*-glycolide) (PLG) vaccines. (A) PLG vaccine implanted 14 days before B16−F10 melanoma tumor challenge, comparing groups receiving either blank PLG scaffold or PLG scaffolds loaded with tumor lysate, granulocyte macrophage (GM)−colony-stimulating factor (GM-CSF), and 1, 10, 50, or 100 μg of cytosine-guanosine oligodeoxynucleotides (CpG). Mice receiving vaccines with 100 μg of CpG had a survival rate of 90%. (B) PLG vaccine implanted 9 days after B16−F10 melanoma tumor challenge, comparing groups receiving either blank PLG scaffold or PLG scaffolds loaded with tumor lysate, GM-CSF, and 100 μg CpG administered either once (on day 9, labeled Vax, 1×) or twice (days 9 and 19, labeled Vax, 2×). *Reproduced with permission from Ali OA, Emerich D, Dranoff G, Mooney DJ. modulation in vivo, a suspension of MSRs loaded with GM-CSF, CpG, and antigen was injected subcutaneously, leading to spontaneous nonspecific self-assembly in situ to form a 3D macroporous structure akin to "thrown matchsticks" (Fig. 41.10) [83].

The high pore volume and large surface area associated with the MSRs allowed for the continuous release of bioactive GM-CSF and CpG over several weeks in vitro and promoted the persistence of a model antigen (OVA) at the vaccination site compared with bolus control by an order of magnitude (Fig. 41.11) [83]. The MSR vaccine generated a potent adaptive immune response, not only increasing the frequency of antigen-specific cytotoxic lymphocytes but also eliciting strong and durable titers of antigen-specific serum immunoglobulin G_{2a} (IgG_{2a}) antibodies associated with a Th1 inflammatory immune response. By comparison, the conventional adjuvant alum combined with the model antigen ovalbumin was able to elicit only serum anti-ovalbumin IgG_1 antibodies, skewing toward a Th2 more tolerogenic immune response. A single injection with the MSR-based cancer vaccine in the prophylactic setting was able to reduce tumor growth rate significantly and enhance survival over unvaccinated controls in a murine model of lymphoma; this illustrates the potential utility of MSRs for use as an injectable biomaterial scaffold in cancer immunotherapy.

Implantable Biomaterial Scaffolds to Enhance Autologous T Cell Therapy

Macroscale biomaterials have also been used to augment other steps in the cancer-immunity cycle [84]. Whereas the work of Ali and coworkers focused on designing systems for the in situ programming of DCs in the context of cancer vaccines, others used a biomaterials approach to address downstream events in the cancer-immunity cycle. Adoptive T cell therapy, for example, involves the infusion of autologous tumor-reactive lymphocytes to target malignancies. Maintaining the presence and antitumor potency of the bolus-injected T cells has been challenging, however. Furthermore, infused lymphocytes have difficulty tracking to the site of the tumor and overcoming the immunosuppressive tumor microenvironment when they reach it, which results in limited efficacy of this modality against solid malignancies [85]. To improve the in vivo expansion and potency of lymphocytes used for adoptive cell therapy, Stephan et al. [86] described the use of a macroporous alginate scaffold to deliver T cells to accessible or resected tumors. The scaffolds were covalently modified with a lymphocyte adhesion peptide and stimulatory cues were presented to the loaded T cells by incorporating lipid-coated silica microparticles containing the soluble factor IL-15 superagonist and bound to costimulatory anti-CD3, anti-CD28, and anti-CD137 antibodies (Fig. 41.12) [86].

Adhesion peptide-modified scaffolds increased the transit of loaded lymphocytes by 6.3-fold in vitro versus unmodified scaffolds whereas the addition of the stimulatory silica microparticles boosted in vitro T cell proliferation by 22-fold. In a mouse 4T1 breast tumor resection model, tumor-reactive T cells were delivered to the resection

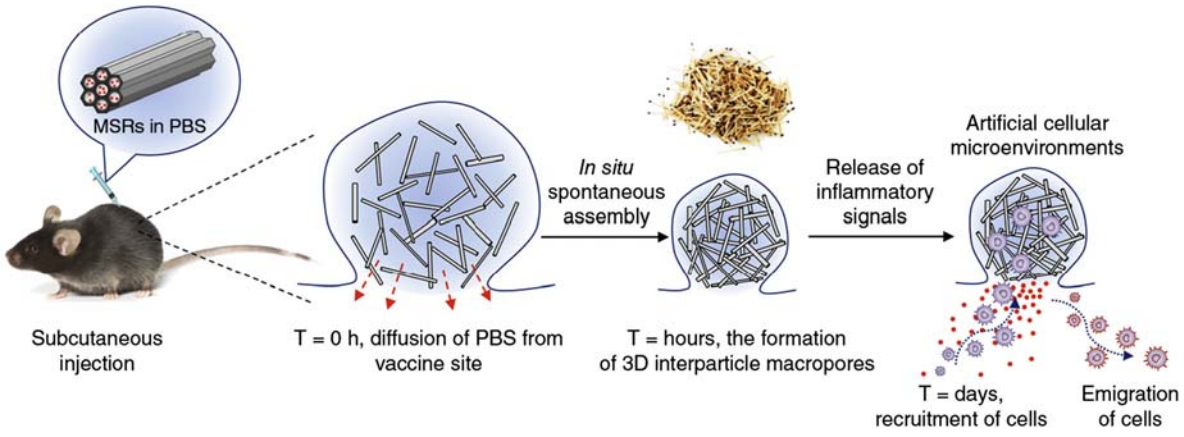

FIGURE 41.10 Schematic of mesoporous silica rod (MSR)-based vaccine in situ self-assembly and mechanism of action. MSRs dispersed in phosphate-buffered saline (PBS) are injected subcutaneously, forming a pocket. As PBS diffuses away from the site of injection, MSRs randomly and spontaneously self-assemble into a macroporous structure, allowing for host immune cell recruitment (via release of recruitment factors from the MSRs), programming (via antigen and danger signals incorporated into the vaccine), and finally emigration of programmed cells to target structures such as draining lymph nodes. *Reproduced with permission from Kim J, Li WA, Choi Y, Lewin SA, Verbeke CS, Dranoff G, et al. All other groups showed tumor recurrence at varying time points. *Reproduced with permission from Stephan SB, Taber AM, Jileaeva I., Pegues EP, Sentman CL, Stephan MT. Biopolymer implants enhance the efficacy of adoptive T-cell therapy. Nat Biotechnol. January 2015;33(1):97−101, Nature Publishing Group.*

cavity using this macroporous scaffold system loaded with stimulatory microparticles, resulting in no recurrences. In contrast, intravenous injection of T cells had a metastatic relapse rate equal to negative controls, whereas injecting prestimulated T cells directly into the resection cavity had only a modest effect (improving median survival versus controls by an additional 11 days, but not preventing recurrence) (Fig. 41.13) [86]. T cells delivered to the resection cavity via the biomaterial scaffold were found to proliferate at the resection site (167-fold versus injected, prestimulated cells delivered without the scaffold) and maintain a nonexhausted phenotype, whereas intravenously injected T cells accumulated in the spleen and liver instead. In addition, the use of the polymeric scaffold to deliver NKG2D CAR-transduced T cells in a mouse model of stage 3 ovarian carcinoma with peritoneal metastases produced complete tumor clearance in 6 of 10 mice whereas locally injected T cells were unable to show tumor eradication in any animals. The efficacy of this system in preclinical models of improperly resected or metastatic cancer illustrates the potential for a biomaterials approach to provide localized delivery of antitumor immune cells while enabling their proliferation and activation in the face of an adverse tumor microenvironment.

CONCLUSION

The unprecedented scale and scope of ongoing investments in immunotherapy by pharmaceutical companies illustrate the excitement regarding this area [87]. Despite this heavy investment, thus far single-modality immunotherapies such as ICIs have proven effective in only a small fraction of cancer patients. Although rational combinations of immunotherapies that affect multiple points in the cancer-immunity cycle have been shown to be more efficacious, our understanding of cancer immunobiology is still far from complete. Nonetheless, rapid progress witnessed in the field of cancer immunotherapy justifies confidence that increasingly effective immunotherapies can be designed as the components required for a robust antitumor response become increasingly clear. The ability of engineered biomaterial systems to control the spatiotemporal distribution of cells and bioactive factors will allow them to have an important key role in learning how biomaterial−immune system interactions work, but then also to exploit these characteristics to shape an evolving anticancer immune response. It remains to be seen whether the most successful biomaterials-based cancer immunotherapies will be used to improve current therapies such as targeting immune-modulating antibodies and/or adoptively transferred immune cells more effectively to the tumor, enhancing the generation of antigen-specific immune effector cells through better priming, or curtailing the adverse tumor microenvironment. Perhaps an as yet−undiscovered pathway may

present another opportunity for engineered systems to address. Regardless, the continued development of safer and more effective immunotherapies will depend on the effective integration of ideas across a broad spectrum of disciplines and collaboration between scientists and clinicians to allow for the effective translation of these technologies to the clinic.

List of Acronyms and Abbreviations

APCs antigen presenting cells
CAR T-cell Chimeric Antigen Receptor T-cell
CCL20 Chemokine (C-C motif) ligand 20
CpG cytosine-guanosine oligodeoxynucleotides
CTLA-4 Cytotoxic T lymphocyte-associated antigen-4
DCs Dendritic cells
DOPE 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine
DOTMA 1,2-di-O-octadecenyl-3-trimethylammonium propane
EPR effect Enhanced permeation and retention effect
FDA Food and Drug Administration
GM-CSF Granulocyte colony stimulating factor
HER2 Human estrogen receptor 2
ICIs Immune Checkpoint Inhibitors
ICMVs Interbilayer-crosslinked multilamellar vesicles
IFN-gamma Interferon gamma
IL Interleukin
IL-12 Interleukin 12
IL-1α Interleukin 1α
IL-2 Interleukin 2
LPS Lipopolysaccharide
MDSCs Myeloid-derived suppressor cells
MPL-A Monophosphoryl lipid A
MPS Mononuclear phagocytic system

NK cells Natural killer cells
NLGs Nanolipogels
OVA ovalbumin
PD-1 Programmed cell death protein-1
PDS Pyridyl disulfide
PLG Poly(lactide-*co*-glycolide)
Poly I:C Polyinosinic−polycytidylic acid
PRR pattern recognition receptor
RGD Arginylglyclaspartic acid
RNA-LPX RNA liposome complexes (lipoplex)
siRNA Short interfering RNAs
STAT3 Signal transducer and activator transcription 3
TAMs Tumor-associated macrophages
tdLNs Tumor-draining lymph nodes
Th1/Th2 T-helper 1/T-helper 2 adaptive immune response
TLR Toll-like receptor
Tregs T-regulatory Cells
TRP2 Tyrosinase-related protein-2

Glossary

Active nanoparticle targeting Nanoparticle targeting applications that require the surface conjugation of a targeting moiety (i.e., ligands, antibody) to target nanoparticles to a desired cell or location.

Adaptive immune system The response of antigen-specific lymphocytes to antigen, including the development of immunological memory. Adaptive immune responses are generated by the clonal selection of lymphocytes. Adaptive immune responses are distinct from innate and nonadaptive phases of immunity, which are not mediated by clonal selection of antigen-specific lymphocytes.

Adjuvant An adjuvant is any substance that enhances the immune response to an antigen with which it is mixed.

Adoptive T-cell therapy A specific immunotherapy strategy which involves the isolation and ex vivo expansion of tumor-specific T cells, and then reinfusion to the patient.

Antigen presenting cells Highly specialized cells that can process antigens and display their peptide fragments on the cell surface together with molecules required for T-cell activation. The main antigen-presenting cells for T cells are dendritic cells, macrophages, and B cells.

Autoimmune responses An adaptive immune response directed at self-antigens is called an autoimmune response; likewise, adaptive immunity specific for self-antigens is called autoimmunity

B Cell One of the two major types of lymphocyte. The antigen receptor on B lymphocytes, usually called the B-cell receptor, is a cell-surface immunoglobulin. After activation by antigen, B cells differentiate into cells producing antibody molecules of the same antigen specificity as this receptor.

Cancer vaccine A specific immunotherapy strategy that aims to train the immune function to recognize and destroy cancer cells. This is typically done by providing both an antigen expressed by the cancer cells and an adjuvant to stimulate generation of T cells specific to that cancer antigen.

Chemokines Chemokines are small chemoattractant proteins that stimulate the migration and activation of cells, especially phagocytic cells and lymphocytes. They have a central role in inflammatory responses.

Clonal T cell expansion Clonal expansion is the proliferation of antigen-specific lymphocytes in response to antigenic stimulation; it precedes their differentiation into effector cells. It is an essential step in adaptive immunity, allowing rare antigen-specific cells to increase in number so that they can effectively combat the pathogen that elicited the response.

Corona A serum protein shell that forms around a nanoparticle, especially charged nanoparticles, after introduction into a protein-rich environment such as blood.

Costimulatory molecules The proliferation of lymphocytes requires both antigen binding and the receipt of a costimulatory signal. Costimulatory signals are delivered to T cells by the costimulatory molecules B7.1 and B7.2, related molecules that are expressed on the surface of antigen presenting cells, and which bind the T cell surface molecule CD28.

Cytokines Cytokines are proteins made by cells that affect the behavior of other cells. Cytokines made by lymphocytes are often called lymphokines or interleukins, but the generic term "cytokine" is used in this book and most of the literature. Cytokines act on specific cytokine receptors on the cells that they affect.

Cytotoxic T cells or lymphocyte T cells that can kill other cells are called cytotoxic T cells. Most cytotoxic T cells are major histocompatibility complex class I–restricted CD8 T cells, but CD4 T cells can also kill in some cases. Cytotoxic T cells are important in host defense against cytosolic pathogens.

Dendritic cells Dendritic cells, also known as interdigitating reticular cells, are found in T-cell areas of lymphoid tissues. They have a branched or dendritic morphology and are the most potent stimulators of T-cell responses. Nonlymphoid tissues also contain dendritic cells, but these are not able to stimulate T-cell responses until they are activated and migrate to lymphoid tissues. The dendritic cell derives from bone marrow precursors. It is distinct from the follicular dendritic cell that presents antigen to B cells.

Effector immune cells Armed effector cells, most often effector T cell, that can be triggered to perform their effector functions immediately upon contact with cells bearing the peptide–major histocompatibility complex for which they are specific. They contrast with memory T cells, which need to be activated by antigen-presenting cells to differentiate into effector T cells before they can mediate effector responses.

Enhanced permeation and retention effect A phenomenon by which molecules of a certain size, typically nanoparticles and/or drugs, tend to accumulate in tumor tissue more so than they do in normal tissue. Many believe that this is a result of leaky tumor vasculature and inadequate lymphatic drainage of solid tumors.

Helper T cell A class of T cells, a specific subclass of CD4+ T cells, that can help B cells make antibody in response to antigenic challenge. The most efficient helper T cells are also known as Th2 cells, which make the cytokines interleukins-4 and 5.

Hydrophilicity/hydrophobicity The physical property of a material to either repel or promote water from binding to its surface.

Immunoediting A dynamic process by which tumors survive attack by the immune system. Typically described as three phases: elimination of immunologically susceptible cells, equilibrium, and finally, immunologic escape.

Immunogenic Any molecule that can elicit an adaptive immune response on injection into a person or animal is called an immunogen, and thus is classified as being immunogenic. In practice, only proteins are fully immunogenic because only proteins can be recognized by T lymphocytes.

Immunologic escape The point at which a tumor is no longer susceptible to immune surveillance and begins to progress in terms of growth and malignancy.

Immunologic memory When an antigen is encountered more than once, the adaptive immune response to each subsequent encounter is speedier and more effective, a crucial feature of protective immunity known as immunological memory. Immunological memory is specific for a particular antigen and is long-lived.

Immunosuppressive A characteristic of something that promotes the inhibition or downregulation of immune responses.

Immunotherapy The prevention or treatment of disease by using or stimulating components of the immune system.

Innate immune system Cells that are responsible for the early phases of the host response to an injury or immunologic insult in which a variety of innate resistance mechanisms recognize and respond to the presence of a pathogen. Innate immunity is present in all individuals at all times, does not increase with repeated exposure to a given pathogen, and discriminates between a group of related pathogens.

Interferons Cytokines that can induce cells to resist viral replication. Interferon-alpha and interferon-beta are produced by leukocytes and fibroblasts, respectively, as well as by other cells, whereas interferon-gamma is a product of CD4 Th1 cells, CD8 T cells, and natural killer cells. IFN-gamma has the activation of macrophages as its primary action.

Interleukins A generic term for cytokines produced by leukocytes. The more general term "cytokine" is often used, but the term "interleukin" is used to name specific cytokines such as interleukin-2.

Macrophages Macrophages are large mononuclear phagocytic cells important in innate immunity, in early nonadaptive phases of host defense, as antigen-presenting cells, and as effector cells in humoral and cell-mediated immunity. They are migratory cells deriving from bone marrow precursors and are found in most tissues of the body. They have a crucial role in host defense.

Monoclonal antibodies Antibodies made from the same clonal cell line and have monovalent affinity, meaning that they bind the same epitope (the part of the antigen that is recognized by the antibody).

Mononuclear phagocytic system A network of phagocytic cells located in the reticular connective tissue that are highly responsible for the clearance of nanosized and microsized materials from the blood.

Myeloid-derived suppressor cells A heterogeneous group of immature myeloid immune cells that have been shown to induce significant immunosuppressive effects, especially in pathogenic situations such as in chronic infections or cancer.

Nanomedicine The applications of nanotechnology in medicine.

Nanotechnology The manipulation and engineering of materials that are in the nanometer-size range, typically less than 100 nm.

Natural killer cells Large granular, non-T, non-B lymphocytes that kill certain tumor cells. Natural killer cells are important in innate immunity to viruses and other intracellular pathogens, as well as in antibody-dependent cell-mediated cytotoxicity.

Passive nanoparticle targeting Nanoparticle targeting applications that use the nature physiochemical properties (i.e., size, shape, and surface charge) to target nanoparticles to a desired cell or location.

Pattern recognition receptors Receptors that bind to pathogen-associated molecular patterns, which are typical of bacteria or many commercially used adjuvants.

PEGylation The process of attachment of poly(ethylene glycol) to molecules, nanoparticles, or macrostructures.

Phagocytosis/endocytosis The internalization of particulate material by cells. If the material is being taken up by a phagocytic cell via invagination of the cellular membrane to form a phagosome, it is referred to as phagocytosis. If the material is taken up by a nonphagocytic cell through membrane invagination to form a vacuole, it is referred to as endocytosis.

Plasmacytoid dendritic cells A class of dendritic cells that circulate in the blood and are found in peripheral lymphoid organs (i.e., spleen, lymph node).

RNA-lipoplex nanoparticles A complex of RNA and lipid material to form liposome-like nanoparticle.

Self-antigens By convention, natural antigens in the body of an individual are called self-antigens. Lymphocytes are screened during their immature stages for reactivity with self-antigens; those that respond undergo apoptosis.

Spatiotemporal delivery Delivery of drug to its optimal location and with optimal time kinetics.

Subunit vaccine A vaccination strategy that uses only part of the disease-causing pathogen. Cancer subunit vaccines typically involve the stimulation of an immune response against a single antigen known to be associated with the cancer cells.

T-helper 1 (Th1)/T-helper 2 (Th2) adaptive immune response Th1 immune responses are adaptive immune responses that are primarily driven by Th1 cells. Th1 cells are a subset of CD4 T cells that are characterized by the cytokines they produce. They are mainly involved in activating macrophages and are sometimes called inflammatory CD4 T cells. Th2 immune responses are adaptive immune responses typically driven by Th2 cells. Th2 cells are a subset of CD4 T cells that are characterized by the cytokines they produce. They are mainly involved in stimulating B cells to produce antibody and are often called helper CD4 T cells.

Therapeutic cancer vaccine Stimulation of the immune system so as to allow for the targeted attack of antigens present on cancer cells, typically through by generating tumor antigen−specific T cells.

Toll-like receptor (TLR) agonists Any agonist aiming to target a TLR. TLRs are a common pattern recognition receptor on antigen presenting cells and other innate immune cells. Binding and activation of TLRs promote inflammatory effects and stimulation of the cell. There are numerous TLRs, each with a different activation potential. They are all named TLR, followed by a number, as in TLR-4.

T-regulatory cells Regulatory or suppressor class of T cells that can inhibit T-cell response.

Tumor interstitium The space within a tumor that is not taken up by cancer cells; essentially all of the remaining space within a tumor.

Tumor microenvironment An intricate network of cancer cells, tumor stroma, and immune cells within a solid tumor that generally promote an overall immunosuppressive state.

Tumor stroma The fibroblast, vasculature endothelial cells, pericytes, and other structural proteins that make up the extracellular matrix component of a tumor.

Tumor-associated macrophages Macrophages found in close proximity or within solid tumors. Tumor-associated macrophages have been shown to induce significant protumor and antitumor effects and induce major immunosuppressive effects.

Tumor-specific antigens An antigen that is overexpressed or specifically located on or within tumors. Often this is an antigen that is unique to the tumor, thus providing a targetable feature.

GENOME EDITING TOOLS

Genome editing can be defined as the modification of the genome within a living cell through the insertion, deletion, or replacement of one or more segments of DNA. Currently, the commonly accepted view of genome editing entails genome modifications via site-specific nucleases. Although the current view is valued, it is also important to include other genome editing approaches that do not use targeted nucleases, because many downstream applications in regenerative medicine require much higher efficiency editing rates than site-specific editing can supply. These approaches include gene insertion, recombination, and translocation.

Targetable Nucleases

All genome editing approaches that use targeted nucleases share a similar mechanism. The function of targeted nucleases is to induce a double-strand break within the cellular genome at a particular site. After the cleavage is established, inherent cellular DNA repair mechanisms are initiated to fix the double-strand break spontaneously. Three major types of targetable nucleases have been developed and widely applied within the genomic engineering field: clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated systems (CRISPR-Cas), transcription activator-like effector nucleases (TALENs), and zinc-finger nucleases (ZFNs). Among these three systems, CRISPR has attracted considerable attention owing in part to its simplicity, although great work has also been performed using TALENs and ZFNs. Because the three systems share the same DNA repair mechanisms inherent in the cell, therapeutic concepts investigated using one system could be pursued via the other two if certain conditions are met.

Clustered Regularly Interspaced Short Palindromic Repeats

Genes that can be targeted by a CRISPR system are CRISPR-Cas genes. This system, which was first noticed (but not immediately pursued) in *Escherichia coli* by Ishino et al. in 1987 [1], involves repeated sequences of DNA that do not appear in tandem. As time went on and more repeat sequences were identified and characterized in different strains of archaea, bacteria, and mitochondria [2], the repeat sequences became a focus of interest, with the term "CRISPR" being coined in 2002 by Jansen and Mojica and the involvement of Cas proteins being observed at the same time [3].

CRISPR-Cas systems are thought to be parts of a primordial immune system in which bacteria acquire immunity to certain viruses by inserting a fragment of the viral genome into a CRISPR locus. The bacterial immune process basically consists of chopping up the genome of a viral invader into small fragments of approximately 20 bases. Focusing on a single fragment, it will be placed into a special location in the bacterial genome. The locus, now modified with the viral gene fragment, will be transcribed and processed into CRISPR-RNA (crRNA), which we will refer to as guide RNA (gRNA) when discussing applied genome editing.

*Author was at Rutgers University when the chapter was written.

Principles of Regenerative Medicine, Third Edition

Cas proteins are restriction enzymes (endonucleases) that have a tunable recognition sequence. The enzyme specificity is determined by the crRNA (gRNA) introduced earlier. The Cas protein binds to a region on the 3′ side of the crRNA (gRNA) known as the "scaffold sequence," leaving a section at the 5′ end of the gRNA, termed the "spacer sequence," free to act as a probe for locating homologous regions within DNA (Fig. 42.1). In wild-type bacterial systems, the crRNA is used to identify DNA as foreign; in engineered systems, the gRNA is used to locate a region in the genome for editing in a site-specific way. After binding of the Cas-bound crRNA or gRNA spacer sequence to a homologous region of DNA, the Cas protein will cleave the DNA in one of several ways. Three different paradigms for gene editing with CRISPR will be discussed subsequently: double-stranded breaks, nickases, and homology-directed repair.

Knockouts via Double-Strand Breaks

Isolated cells can be made to express specific gRNA sequences that can be used to target other DNA sequences for knockout. There are three requirements for the transcribed gRNA: (1) It must have a scaffold sequence that will bind to a given Cas. Cas is inactive unless gRNA is bound. (2) The target sequence must be unique; otherwise, several genes may be bound and produce off-target effects. (3) The target must be just upstream of a protospacer-adjacent motif, also known as a PAM sequence. (For discussion purposes, we will focus on a specific Cas: Cas 9 from *Streptococcus pyogenes*, also known as spCas9. The CRISPR/spCas9 system is one of the most well-characterized and widely used gene editing systems.) The PAM sequence for spCas9 is 5′-NGG-3′. The PAM sequence is an absolute requirement for this system: If the spCas9/gRNA binds to a target sequence that is not next to a PAM, there will be no cleavage by spCas9. However, with the PAM present, cleavage will take place three to four bases upstream of the PAM (Fig. 42.2). SpCas9/gRNA can bind to any portion of the DNA with a PAM, but it is the matching with the spacer sequence that determines whether DNA cleavage will take place.

The spCas9 protein has six domains, including two endonuclease domains: HNH and RuvC. If there is a good match between the gRNA spacer sequence and the target DNA sequence, a conformational change in the Cas9 occurs, thereby activating HNH (which cleaves the target DNA strand) and RuvC (which cleaves the nontarget strand) domains. A double-strand break is thereby introduced.

The double-strand break will be repaired by the cell in one of two ways: nonhomologous end joining (NHEJ) or homology-directed repair (HDR). NHEJ is the more common of the two pathways in the cell. It is also more error-prone because insertions and deletions can easily occur, and these can cause frameshift mutations. The result of a frameshift can cause codons to be translated differently, as in different amino acids being assembled onto a growing

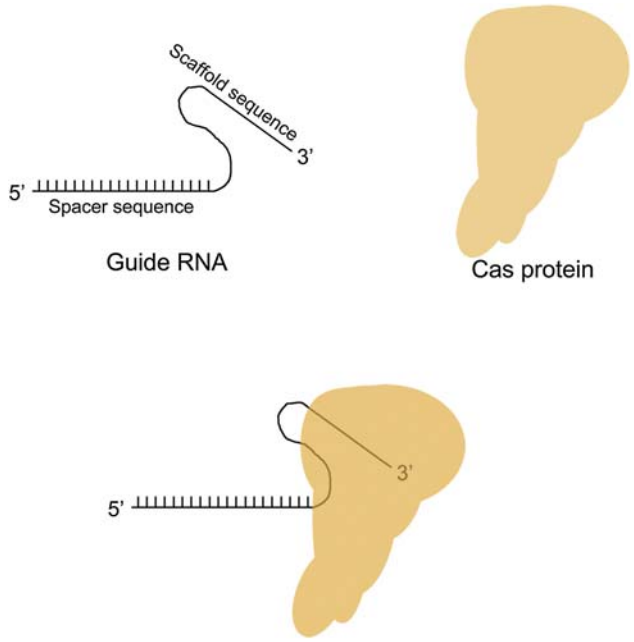

FIGURE 42.1 The DNA recognition and cleavage functions carried out in the clustered regularly interspaced short palindromic repeats (CRISPR) gene editing systems come from a complex consisting of a CRISPR-associated systems (Cas) protein interacting with a CRISPR RNA (crRNA). The crRNA, known as guide RNA in applied gene editing, consists of a scaffold sequence that will bind to the Cas protein, and a spacer sequence that will extend from the complex, allowing it to interact with chromosomal DNA as a probe. The wild-type Cas protein has domains that are responsible for inducing double-stranded breaks in DNA after homology with the spacer sequence has been established.

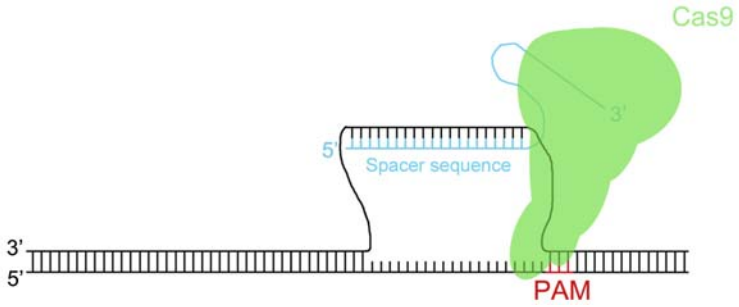

FIGURE 42.2 Interaction of CRISPR-associated systems 9− guide RNA (Cas9/gRNA) with double-stranded DNA. Although a homologous DNA sequence may be recognized by a Cas9/gRNA complex, DNA cleavage will only take place if a protospacer-adjacent motif (PAM) sequence is present in the DNA. It is the PAM sequences, which appear in numerous, nearly evenly spaced copies in the DNA, that are referred to by the CRISPR acronym (**C**lustered **R**egularly **I**nterspaced **S**hort **P**alindromic **R**epeats).

polypeptide, the elimination of a stop codon, or the introduction of a premature stop. In each of these cases, a nonfunctional protein is likely, so this type of DNA repair often results in knocking out a gene by lowering or halting the production of a functional protein product.

HDR has a much higher fidelity, but it is not used as much in the cell. We will return to HDR in a moment.

Nickases

One problem with generating knockouts via double-strand breaks is that despite using a 20-base recognition (spacer) segment on the gRNA, sequences with near-homology may also be cut. One logical solution to this problem would be to use gRNAs with longer spacer sequences. The problem with this idea is that the CRISPR-Cas system is set up for approximately 20-nucleotide spacers, so using a gRNA that has a 40-nucleotide spacer sequence would not work well. An alternative approach is to modify the Cas protein so that it cuts only one DNA strand. By creating a Cas9 with an inactivated HNH domain, or a Cas9 with an inactivated RuvC domain, and by loading the mutated Cas9 protein with respective gRNAs that are specific to separate areas on one of the two strands of DNA, one can essentially require homology at 40 nucleotides (20 for each of the two gRNAs) before the formation of a double-strand break (Fig. 42.3). Only one type of mutated Cas9 is required: HNH-mutated or RuvC-mutated. Unmutated HNH cuts the strand that pairs with the guide RNA, while unmutated RuvC cuts the strand with the PAM sequence. It is through the selection of guide sequences with spacers complimentary to sequences on each of the host DNA strands that is used to generate what amounts to a staggered double-strand break.

The single-stranded breaks introduced by the mutated Cas proteins are known as "nicks"; hence the term "nickases" used to describe the proteins. Nicks are usually repaired quickly by the HDR system and with high fidelity. With the Cas nickase system, a double-nick, in which both strands are cut, will only occur if both of the spacer sequences line up with good homology.

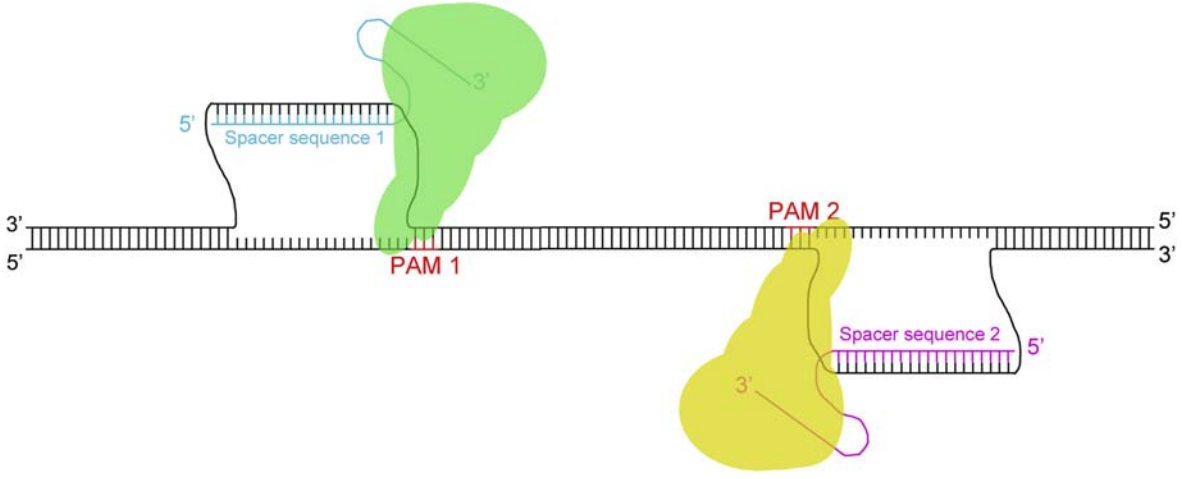

FIGURE 42.3 Nickases working simultaneously to generate single-stranded breaks surrounding a targeted region of DNA. The requirement of homology matching in two distinct guide RNA spacer sequences improves specificity over wild-type clustered regularly interspaced short palindromic repeats (CRISPR)-associated systems (Cas), resulting in a reduction in off-target cleavage. *PAM*, protospacer-adjacent motif.

Homology-Directed Repair

HDR is how CRISPR is used for specific gene edits, such as altering the identity of a single base. Three components are requisite to this system: a Cas protein such as spCas9 or Cas9 nickases, gRNA, and a repair template with homology arms.

The mechanism used for this precise form of gene editing is similar to what has already been covered, except that DNA (linear or plasmid) containing the desired insertion or repair is codelivered with the Cas9/gRNA. Consider a linear repair template designed to correct a point mutation in the genome. Although only one base pair (bp) will differ from the genomic sequence, the length of the repair template must be longer than one bp. The bases to the left and right of the repair bp, called the "homology arms," will have the same sequence as the genomic DNA. The length of each depends on the size of the insert (Fig. 42.4).

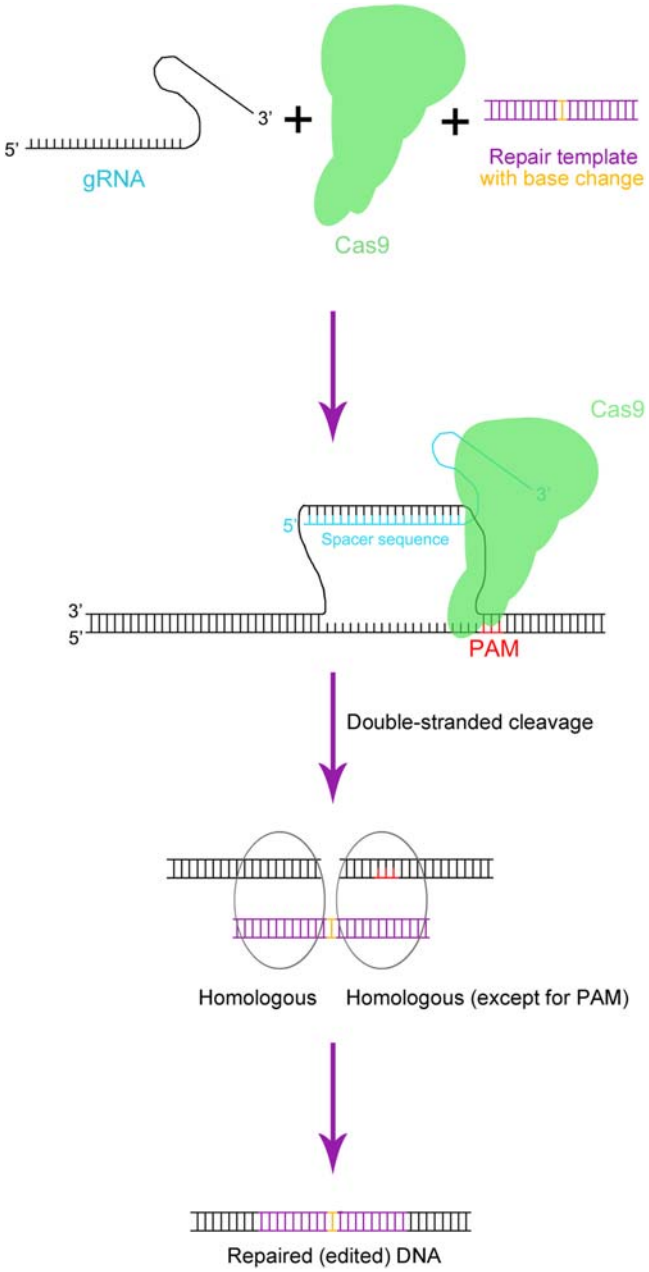

FIGURE 42.4 Homology-directed repair. In this scheme of genome editing, clustered regularly interspaced short palindromic repeats (CRISPR)-associated systems (Cas)—guide RNA complexes (Cas9 shown here) are codelivered with a repair template. The template will be introduced into the genome via homologous recombination after the introduction of a double-stranded break. *PAM*, protospacer-adjacent motif.

It is important for the repair template not to contain a PAM sequence; otherwise it would be cut by the Cas proteins. If the section to be inserted happens to contain a PAM sequence, the insertion sequence should be reengineered with a silent mutation to remove the PAM. For example, an AGG sequence, which codes for arginine and is also is a Cas9 PAM sequence, could be modified to AGA, which still codes for an arginine but is no longer a PAM sequence.

Recall that the HDR, while having high fidelity, is not used by the cell as much as NHEJ, which means NHEJ will still be at work. Because somatic mammalian cells have two alleles, the result of this type of gene editing for a given cell will be a combination of:

- wild-type,
- NHEJ-mutated, and/or
- HDR-inserted (repaired) alleles.

It is therefore imperative for the researcher to perform a screen to isolate HDR−HDR clones.

SpCas 9 Variants and Orthologues

Although the SpCas9 system has been widely accepted for laboratory applications worldwide, some limitations still must be overcome. For example, SpCas9 depends on the specific (*S. pyogenes*) PAM sequence 5′−NGG−3′, and the cleavage site must be close to this PAM. Although NGG is abundant throughout the mammalian genome, the appearance of the sequence might not be close enough to the desired target to effect the desired modification. To address this issue, multiple novel Cas9 variants that use different PAM sequences have been engineered or discovered. Benjamin et al. developed a series of Cas9 variants by mutating the particular site of SpCas9 (D1135/R1335/T1337 or D1135/G1218/R1335/T1337) or screening various Cas9 orthologues from nature [4,5]. The PAM library has been expanded to include 5′-NGCG-3′ (SpCas9 VRER variant), 5′-NGAG-3′ (SpCas9 EQR variant), 5′NGAN-3′ (SpCas9 VQR variant), 5′-NNAGAAW-3′ (Cas9 from *Streptococcus thermophilus* [St1Cas9]), and 5′-NNGRRT-3′ (Cas9 from *Staphylococcus aureus* [SaCas9]) [4]. These Cas9 variants and orthologues provide great convenience to scientists by expanding the editable areas within the genome.

Off-target effects pose a potential risk to future therapeutic applications of CRISPR [6,7]. These occur when the nuclease induces a double-strand break at an unwanted site, leading to unwanted cellular changes such as transformation. To reduce the possibility of off-target effects, SpCas9 has been mutated by rational design with apparent success. One such set of mutations, designed to reduce potential interactions between SpCas9 and the phosphate backbone of DNA through direct hydrogen bonds, produced what is referred to as the *S. pyogenes* Cas9 High-Fidelity variant 1 (SpCas9-HF1). (The specific mutations to the wild-type SpCas9 were N497 A, R661 A, Q695 A, and Q926 A [8].) SpCas9-HF has editing activity that is comparable to wild-type SpCas9, but off-target events have been nearly eliminated. Another set of mutations designed to reduce the affinity between a positively charged groove (located between the HNH, RuvC, and PAM-interacting domains) and the negative charges of genomic DNA have served to neutralize positively charged residues in the Cas9 (K810 A, K848 A, K1003 A, and R1060 A) [9]. The mutated enzyme was named “enhanced specificity” SpCas9 (eSpCas9), and like SpCas9-HF1, it has been shown to have activity similar to the wild-type enzyme but with a clear reduction in off-target events.

A novel CRISPR system from the genera *Prevotella* and *Francisella*, called Cpf1, has introduced several specific features to these systems [10]. Usually, the double-strand breaks introduced by a Cas protein are blunt ended. The Cpf1 system is different in that it creates overhangs of four to five bases [10]. The overhangs present an opportunity to increase the efficiency of gene insertion. In addition, the Cpf1-associated system does not require the transactivating crRNA to perform the DNA interference function [10]. Cpf1 is able to process pre-crRNA into crRNA without relying on host RNase, which makes it possible to edit multiple genes simultaneously. Because of the large size of a single gRNA expression cassette (∼400−500 bp), for SpCas9, each single gRNA must be placed in different vectors or driven by a different set of promoters [11,12]. However, thanks to the feature of Cpf1 being guided by a small (39-nucleotide) crRNA, a single promoter within one vector is enough to drive many crRNA together. Published experiments have achieved simultaneous modification of four different targets by using Cpf1 with a single construct [13] (Fig. 42.5).

Another interesting system employs CRISPR-C2c2, which comes from the bacterium *Leptotrichia shahii* [14]. Instead of working on DNA, CRISPR-C2c2 can serve as an RNA-guided RNase that can cleave certain single-stranded RNAs via pairing with a 28-nucleotide sequence in the crRNA. This system could be used to downregulate gene expression via posttranscriptional knockdown, similar to RNA-induced silencing complex−mediated RNA

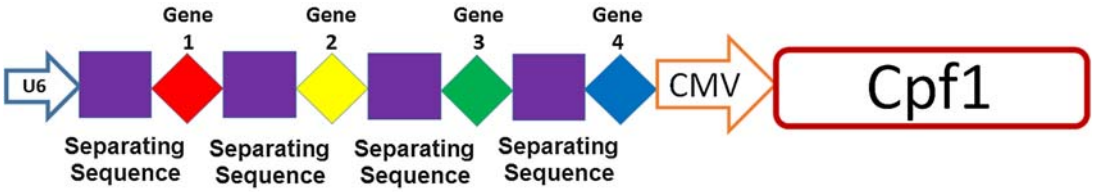

FIGURE 42.5 Schematic outlining the components of a multiplex gene pre−clustered regularly interspaced short palindromic repeats RNA array. The outline represents a single construct consisting of guide sequences for four genes and Cpf1. Two promoters are included: the U6 promoter directs transcription of the four guide sequences and the cytomegalovirus promoter drives transcription of the Cpf1 nuclease gene. *Figure adopted from Zetsche B, Heidenreich M, Mohanraju P, Fedorova I, Kneppers J, DeGennaro EM, et al. Multiplex gene editing by CRISPR-Cpf1 using a single crRNA array. Nat Biotechnol 2016.*

interference [14]. Moreover, fluorescent labeling of C2c2 makes it possible to tag specific messenger RNA (mRNA) sequences and linking dC2c2 with a splicing factor makes it possible to affect mRNA splicing [15]. However, the function of the system has been shown only in bacteria. Further investigation is necessary before it can be used reliably in mammalian cells.

Transcription Activator-like Effector Nucleases

TALENs are chimeric proteins which contain two functional domains: a DNA-recognition transcription activator-like effector (TALE) and a DNA nuclease domain. They work for gene editing by recognizing a specific sequence, which the user can design, and introducing a double-stranded break with an overhang. TALENs therefore serve as a form of customizable restriction enzyme.

The DNA-recognition TALEs used in TALEN technology are secreted by the genus *Xanthomona*, a type of phytopathogenic bacteria [16]. A TALE consists multiple domains, including a translocation domain at the N terminus, a nuclear localization signal and a transcription-activation domain that are close to C-terminus, and multiple repeats in the center that serve to recognize DNA molecules [16]. The repeat sequences are composed of a highly conserved 33− to 34−amino acid sequence, with positions 12 and 13 being variable. The variable portion of the sequence is termed the "repeat variable di-residue" (RVD). By changing the RVD sequence of a specific repeat, that particular repeat can be made to bind a specific nucleotide [17]. As examples, a monomer with an RVD consisting of asparagine-asparagine will bind with a purine, asparagine-isoleucine will bind with adenine, asparagine-glycine will bind with thymine, and histidine-aspartate will bind with cytosine (Table 42.1) [17]. By manipulating the RVDs of its repeated sequences, a TALE can be made to serve as a probe for a specific site within the genome.

The nuclease portion of a TALEN is the catalytically active domain of the restriction enzyme FokI. (The DNA recognition domain has been removed.) FokI can be used in mammalian cells to cut genomic DNA, but it must be dimerized to be functional. Both homodimeric and heterodimeric domains can be used [18].

One challenge in using TALENs is that the enzyme construct is hard to build owing to the numerous repeat sequences that must be customized for targeting. This is why much effort has been directed toward improving the construction of TALENs. One method, called Golden Gate assembly, is widely accepted for its relative simplicity [19]. This method employs type IIS restriction endonucleases, which cleave outside their recognition sequences. By selecting appropriate type IIs endonucleases, the recognition sequence can be removed from the fragment of interest, thus allowing for digestion and ligation in the same reaction mixture. Similarly, because the site where

TABLE 42.1 The Identity of the Variable Sequences (Repeat Variable Di-residues [RVDs]) in a Transcription Activator-like Effector Determine the Nucleotide Targets

RVD Sequence	Nucleotide Bound
Asparagine-asparagine	Purines
Asparagine-isoleucine	Adenine
Asparagine-glycine	Thymine
Histidine-aspartate	Cytosine

the DNA cleavage itself occurs is not sequence-specific (is outside the recognition sequence), the compositions of the resulting overhangs are not dictated by the enzyme, so multiple, specific overhangs can be created simultaneously, allowing for the creation of multiple assemblies.

Compared with the CRISPR system, which requires only the design of a single gRNA, the TALEN system requires significantly greater effort devoted to sequence design and cloning. As a result, CRISPR is the more widely accepted method for genome editing. TALENs have certain advantages over CRISPR in specific situations, though. For example, TALENs can theoretically target any site within the genome, as opposed to CRISPR, which requires the presence of a PAM site. Therefore, when no PAM site is available for a given application, one can still turn to a TALEN system. In addition, TALENs are associated with lower off-target effects versus wild-type SpCas9. For perspective, a study of off-target cleavage by CRISPR-Cas9 (using SpCas9) versus TALENs was performed using six different genes. The TALENs produced no off-target cleavage, whereas half of the applications (three of six) using SpCas9 nucleases yielded off-target events [20]. Published comparisons of TALENs with the high-fidelity forms of CRISPR were not readily available at the time this chapter was written.

Zinc Finger Nucleases

ZFNs are another type of DNA recognition/cleavage construct that acts like a restriction enzyme. They combine the Cys2-His2 zinc finger motif as the DNA recognition domain with the FokI DNA cleavage domain [21]. The Cys2-His2 zinc finger motif consists of a single zinc atom with about 30 amino acids in a β sheet−β sheet−α helix conformation [22]. Each zinc finger contacts three DNA bases through amino acids on the α helix of the motif [23]. The selectivity between a zinc finger and target triplets can be modulated by adjusting the amino acid sequence. A library of zinc-finger domains that can target nearly all of the possible triple nucleotide combinations has been developed [24]. By connecting three to six zinc finger motifs via conserved linker sequences, 9−18 nucleotides will be targeted by a monomer [25]. As with TALENs, because ZNFs use FokI as the nuclease, they are also designed for use as dimers, so a total of 18−36 nucleotides will be targeted.

The primary hurdle for using ZFNs is that of enzyme design and construction. The cloning process used to produce the correct amino acid sequence is labor intensive, but the correct primary sequence is also imperative for achieving high targeting specificity. As a result, the number of studies applying this technique has dwindled since TALENs and CRISPR were introduced to the field. However, unlike the TALENs and CRISPR systems, ZFNs originated from mammalian cells, so there has been less concern regarding immunogenicity. Phase I clinical trials that infused ZFN-modified autologous CD4 T cells as a treatment for HIV have been completed, with the treatments being deemed safe (NCT00842634) [26]. This implies that ZFNs may be suitable for other clinical applications.

Other Genome Manipulation Tools

Transposons and Transposase

There are two types of transposons: class I transposons, also known as retrotransposons, which are transcribed and reverse-transcribed as part of the translocation mechanism, and class II transposons, which do not require transcription−reverse-transcription but use transposases to catalyze the translocation mechanism. The transposons used for genomic engineering are class II. Combined with the enzyme transposase, a transposon can be moved efficiently between plasmid and genome in a cut-and-paste fashion. Transposase acts by recognizing a sequence of inverted terminal repeats (ITRs) that appear at each end of the transposon and introducing a pair of double-stranded breaks in the DNA. A gene flanked by ITRs can be cut out of a plasmid and transferred to a site within the genome that is flanked by the same ITRs. This method can also be used to delete genes that appear between two ITRs sites in the genome. There is no size limit for transposons. This system has been used, for example, to reprogram primary cells into induced pluripotent stem cells (iPSC) through virus exclusion [27].

Recombinase

The major function of recombinase is to exchange strands between two DNA segments that have partial sequence homology. The most widely used recombinase systems for genome manipulation are Cre-loxP and Flp-FRT. The Cre and Flp enzymes are site-specific recombinases that recognize 34-bp recognition sites. The loxP recognition site contains two 13-bp palindromic sequences and an 8-bp spacer (5′-ATAACTTCGTATA-atgtatgc-TATACGAAGTTAT-3′, [spacer shown in lowercase]) [28]. Similar to loxP, FRT consists of two 13-bp palindromes surrounding an 8-bp spacer (5′-GAAGTTCCTATTC-tctagaaa-GTATAGGAACTTC-3′) [28]. The Cre and Flp recombinases can be used for gene

insertion, excision, inversion, or translocation combined with their respective recognition sites and are often applied in genome engineering [29], such as for generating conditional mutants. The International Knockout Mouse Consortium has been launched to produce mutant murine embryonic stem cells for every gene in the mouse genome (more than 20,000 genes) by incorporating the loxP and FRT sites [30]. Using Cre and Flp, knockout mice for any gene can be produced from these cells.

Integrase

In the past, gene insertion typically was achieved by plasmid integration with stringent antibiotic selection or via infection with lentiviral vectors. Insertions occurred randomly and the copy number, location, and direction of insertion were difficult to control. Homologous recombination with or without a targetable nuclease addressed the problem of directionality, but the size of the inserted gene was limited and integration efficiency was still lacking, especially in primary cells [31].

A technology named "dual integrase cassette exchange" (DICE) provides an alternative route whereby the copy number, location, and direction gene integration are controlled, and with higher efficiency [32]. DICE adopts the phage integrases phiC31 and Bxb1, which have the ability to insert a gene into their own recognition sites by unidirectional recombination. However, these recognition sites do not exist in the mammalian cell genome. To get around this problem, a "landing pad" was introduced into a safe region of the mammalian genome by integrating those recognition sites through TALEN-assisted homologous recombination. As a result, desired genes could be efficiently implanted into the landing pad by codelivery of the two integrases and donor template. It is claimed that there is no size limitation for the inserted gene [32].

DELIVERY CARGO

The genome-editing tools just described can be delivered into cells via multiple routes based on whether DNA, RNA, or protein is the tool being used.

DNA

DNA is often delivered as a plasmid, which is typically constructed via standard molecular cloning techniques. When properly preserved, DNA has a long shelf life. The efficiency of DNA delivery into cells is the major limiting factor for the associated methods. DNA for genome editing can also be engineered into a viral genome, and plasmids can be adapted for use with viruses for delivery into cells [33]. Although viruses typically generate higher gene delivery efficiencies than do nonviral gene delivery agents, immunogenicity is a concern for in vivo applications, especially if repeated delivery events must be performed.

Another concern regarding the delivery of DNA into cells is that the foreign DNA could integrate into the host genome through homologous recombination. If this occurs in an untargeted fashion, vital host genes may be disrupted or inactivated, tumor suppressor genes may be knocked out, or oncogenes might be activated. Whether targeted or untargeted, genomic integration could cause the encoded nuclease to be expressed in a sustained manner, potentially causing continuous formation of double-strand breaks and serious off-target effects.

RNA

The editing methods that use delivered RNA avoid the possibility of genomic integration. RNA can be produced by cells transfected in vitro, harvested, and applied to cells of interest in subsequent experiments. With RNA delivery, the efficiency of enzyme production may be enhanced because genetic materials do not have to reach the nucleus and the transcription step is eliminated. However, RNA is more difficult to handle and store than is DNA because RNases are abundant in the cell, on the skin, and throughout most research environments. The immunogenicity of RNA produced in vitro should also be considered [34].

Proteins

Instead of delivering genetic materials, delivering proteins into cells for gene editing is now a commercially available option. Multiple CRISPR Cas9 protein delivery kits exist on the market; TALENs and ZFNs can also be

delivered into cells. For the CRISPR system, the ribonucleoprotein complexes are formed in vitro by combining a Cas nuclease with the appropriate gRNA, and the constructs are delivered into cells without fear of genomic integration. Another advantage to delivering proteins instead of (deoxy)ribonucleotides is that the amount of enzyme that will reside within the cell is more precisely controllable.

DELIVERY METHODS

Microinjection, gene gun, electroporation, and hydrodynamic delivery are all methods that have been used to deliver genome editing tools into cells [35–38]. These methods are not widely used because they either need specialized equipment and experienced professionals (microinjection) or they are associated with cell or tissue damage (gene gun, electroporation, and hydrodynamic delivery). These methods are also restricted in their ability to reach host tissues in vivo.

Chemical agents such as cationic lipids, polymers, and dendrimers have been widely used for gene delivery, but they are associated with gene delivery efficiencies that are generally lower than those of viral vectors. However, chemical delivery methods are still preferred compared with viral methods in some cases owing to their ease of preparation, lower immunogenicity, and lower expense [39].

All of the chemical gene delivery methods can be applied to genome editing because there is no chemical difference between plasmids encoding targetable nucleases and plasmids encoding other genes. However, different mechanisms may be involved for the delivery of proteins. Cationic liposomes have been used to this end with relative success. The delivery of Cas9–gRNA complexes or TALENs via cationic lipids is evident by the multiple commercially available agents that are in the marketplace [40,41]. The cationic polymer poly(ethylenimine) has been used to coat self-assembled DNA cages to delivery Cas9/gRNA complexes successfully into mammalian cells [42]. Cell-penetrating peptides have been used to deliver targetable nuclease proteins, including Cas9 and TALEN [43,44]. Interestingly, ZFN has inherent cell-penetrating capabilities and can pass into cells without a carrier [45].

Viruses have been used for gene delivery for decades [46]. For gene editing applications, several viruses have been evaluated, including lentivirus [47], adenovirus [48], and adeno-associated virus (AAV) [49]. Lentiviral vectors have been shown to have a high transduction efficiency in multiple primary cell types and are capable of having genes integrated into the genome of the host [39,50]. As mentioned, incorporating a gene encoding a nuclease into the genome can lead to constitutive expression of the enzyme, which can lead to off-target events. Even worse, lentiviral integration occurs randomly, which can potentially induce various malignancies [51,52]. One solution to these problems of integration is to knock out the viral gene that encodes integrase, a technique that has been used to transfer genes encoding ZFNs, TALENs, and Cas9 [20,53]. Another solution is to develop lentivirus-derived particles to carry nuclease proteins. ZFN, TALEN, and Cas9 proteins have been successfully packed into such lentiviral particles [47,54]. Donor templates have been copacked into the particles to achieve targeted DNA insertion and gene correction [54]. It has been reported that this approach has lower off-target activity than traditional delivery methods [47,54].

Adenoviral vectors allow transient transgene expression in both dividing and nondividing cells. These vectors carry a much lower risk of genomic integration than their retroviral counterparts. A set of third-generation adenoviral vectors named "helper-dependent adenoviral vectors" have increased cargo sizes (36 kb, as opposed to ~8 kbp) [55], which provides more versatility for the delivery of donor DNA templates for gene insertion and correction. However, immunogenicity is still a concern, as it is for all virus methods [56], especially when multiple gene delivery events must be carried out.

Like adenovirus, AAV can produce transient transgene expression in both dividing and nondividing cells. In gene delivery, certain AAV serotypes are preferred because their delivered genes will be integrated into the host genome in a targeted fashion. Keeping in mind the previous discussion about problems with constitutively expressed nucleases, recombinant AAV have been produced that lack the viral *rep* gene to lower or eliminate the frequency of genomic integration [57]. Some strains of AAV carry lower immunogenicity concerns for a single administration, but repeated administrations require different serotypes to avoid a secondary immune response. These viruses are relatively small so they have limited DNA loading capacity (~5 kb) [58]. The ZFNs with double monomers [59] are usually compatible with this limitation, but it is difficult to package double TALEN monomers (~3 kb each) or SpCas9 (~4.2 kb) and associated gRNA within a single AAV vector [60]. For in vitro genome editing, this limitation can be overcome by packaging the functional units separately and cotransducing cells. Edited cells can then be screened and selected. However, this is not practical for in vivo editing because the selection step

cannot be performed, and every abnormal cell is expected to be treated. One could reduce the size of the gene encoding the enzyme: a Cas9 orthologue, named *S. aureus* Cas9 (SaCas9), which is 1 kb smaller than SpCas9, was identified [60]. The smaller gene has been successfully copacked with gRNA in a single AAV construct, with precise genome editing still being attainable.

APPLICATIONS OF GENE EDITING IN REGENERATIVE MEDICINE

Stem cells are characterized by two properties: self-renewal, in which they are able to divide numerous times while remaining undifferentiated, and pluripotency, which means they can differentiate down any of the three germ cell lineages (ectodermal, mesodermal, and endodermal). Because of these characteristics, stem cells are attractive progenitors to a broad range of regenerative medicine applications. Stem cells can be harvested and isolated from various tissues such as bone marrow [61], amniotic fluid [62], umbilical cord blood [63], or brain [64]. In addition, they can be induced from differentiated cells by introducing genes encoding specific transcription factors [65]. In contrast to embryonic stem cells, adult-derived stem cells and iPSCs can be harvested or produced autologously, thus eliminating the need for immunosuppression and providing a means of personalized medicine as new applications are developed. As genome-editing technologies develop, gene-edited stem cells may be produced for the repair and regeneration of various tissues and organs [66]. Various applications of genome editing to the regeneration of specific tissues or organs are presented in this section.

Liver

The liver is a vital organ containing numerous enzymes that are involved in a wide range of bioprocesses such as glucose storage and gluconeogenesis, cholesterol synthesis, bile production, urea production, the synthesis of certain blood proteins, red blood cell turnover, and the detoxification of metabolites and drugs (such as ethanol). Because of the importance of this organ and the numerous diseases that can arise to affect its function, the liver is a prime target for regenerative medicine and gene editing therapy.

α1-Antitrypsin (A1AT) deficiency is an autosomal recessive disorder that is caused by a single point mutation (Glu342Lys). Copies of the mutated protein aggregate in the endoplasmic reticulum of hepatocytes instead of being secreted into the blood and body fluids [67,68]. A1AT deficiency may further develop into cirrhosis of the liver and necessitate the need for liver transplantation [69]. ZFNs and PiggyBac transposons have been used in conjunction to correct the point mutation in the *A1AT* gene in human iPSCs derived from a patient with A1AT deficiency [69]. The cells were then differentiated into hepatocyte-like cells, which displayed normal A1AT function. This pioneering work demonstrated the potential for applying genome-editing and iPSC technologies for an autologous cell-based therapy.

Several disorders are related to deficiencies in one or more of the enzymes of the urea cycle, a biochemical pathway that is involved in removing nitrogen from the body. Hyperammonemia is one such condition that can lead to encephalopathy and, potentially, death. Arginase, which is an enzyme of the urea cycle, has a part in ureagenesis. Defects in the gene encoding arginase can lead to hyperammonemia. Gene editing has been used with patient-derived iPSC to restore arginase activity in arginase-deficient patients [70]. In these experiments, CRISPR-Cas9 was used to add an arginase-1 cDNA expression cassette into the first exon of the hypoxanthine-guanine phosphoribosyltransferase locus in the isolated cells. The cells were then differentiated into hepatocyte-like cells, which displayed both arginase activity and ureagenesis [70].

Another potential cause of urea cycle disruption is ornithine transcarbamylase deficiency, caused by a mutation in the associated gene. Gene editing research toward addressing this malady has included a dual AAV system used to deliver Cas9-gRNA and donor DNA separately into newborn mice with a partial deficiency in ornithine transcarbamylase [71]. Results have been weak but encouraging, with correction of the mutated gene in about 10% of hepatocytes and improved survival in treated mice that were given high-protein diets.

Tyrosinemia, which is characterized by a buildup of tyrosine (and some of its breakdown products, depending on the type), is a severe genetic disorder stemming from an inability to break down the amino acid tyrosine. There are three types of tyrosinemia, each characterized by the specific enzyme that is mutated in the degradation pathway (Fig. 42.6). Tyrosinemia type I is caused by a deficiency in the enzyme fumarylacetoacetate hydrolase (FAH), which catalyzes the conversion of fumarylacetoacetate into fumarate plus acetoacetate [72,73]. A deficiency

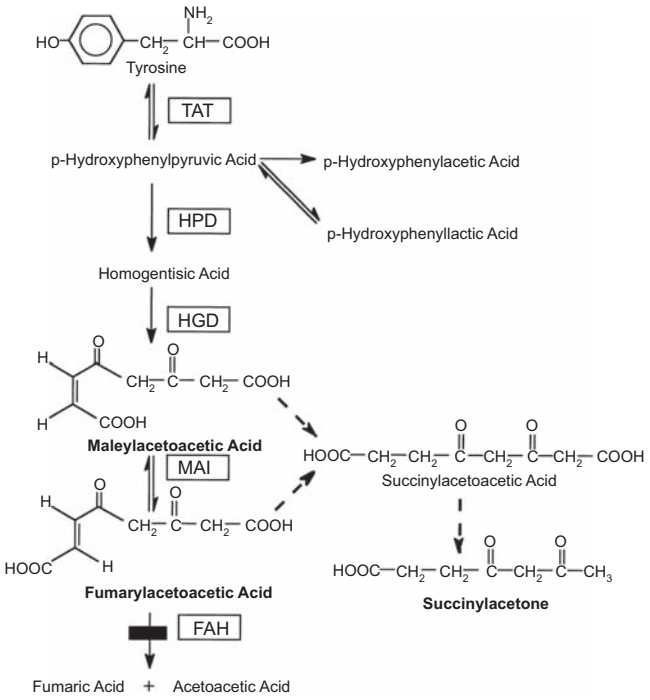

FIGURE 42.6 Partial degradation pathway of tyrosine, highlighting the steps associated with tyrosinemia type I, catalyzed by fumarylacetoacetate hydrolase (FAH). Tyrosinemia type II has a deficiency in the enzyme tyrosine aminotransferase (TAT) and type III tyrosinemia has a deficiency in the enzyme 4-hydroxyphenylpyruvate dioxygenase (HPD). *Figure from Jorquera R, Tanguay RM. Cyclin B-dependent kinase and caspase-1 activation precedes mitochondrial dysfunction in fumarylacetoacetate-induced apoptosis. FASEB J 1999;13(15):2284—98.*

in FAH results in the accumulation of fumarylacetoacetate and maleylacetoacetate, which induce cellular damage [74]. CRISPR-Cas9 has been examined for use as a treatment for hereditary tyrosinemia type I, in which the gene encoding 4-hydroxyphenylpyruvate dioxygenase was deleted. This deletion caused hepatocytes associated with tyrosinemia type I to be converted into hepatocytes that would be associated with the more-benign tyrosinemia type III [75]. Rather than relying on genetic deletion, a different laboratory group used a gene editing approach to deliver mRNA encoding Cas9 via lipofection, along with AAV containing DNA encoding gRNA, to correct mutant *fah* in mice with human hereditary tyrosinemia. This method yielded modest recovery of FAH function in approximately 6% of hepatocytes [76].

Angiogenesis

Angiogenesis is a process in which new capillaries grow from preexisting vessel networks to form more complexed vessel networks [77]. It is essential for the regeneration of tissues and organs if the component cells are to receive oxygen and nutrients and have carbon dioxide and other waste products removed. Therefore, procedures designed to enhance angiogenesis are related to regenerative medicine.

Genome editing using TALENs has been used to induce cells to express hepatocyte growth factor (HGF) to induce angiogenesis [78]. The common theme of editing the genomes of progenitor cells was used on mesenchymal stromal cells isolated from human umbilical cord blood. In this case, a TetOn sequence preceded a gene encoding HGF pUC19-TetOn-*HGF* expression cassette, and the DNA was inserted into chromosome 19. The TetOn sequence was used as a safety measure. It allowed for control of the *hgf* gene by requiring that tetracycline be present for the gene to be transcribed. After the establishment of HGF expression in the cells, the cells were encapsulated in alginate and transplanted to correct a hind limb ischemia model. The entire procedure worked well, yielding angiogenesis in the in vivo model.

Muscle: Muscular Dystrophy

Muscular dystrophy is family of diseases characterized by a gradual loss of muscular strength and control. There are nine forms of the disease, each with its own characteristic set of symptoms and time of onset. Some affect only

TABLE 42.2 Types of Muscular Dystrophy and Some Defining Characteristics [79]

Type	Sexes Affected	Typical Time of First Appearance	Characteristic Muscles Affected
Duchenne	Males	Ages 3–5	Upper legs and pelvis; heart and diaphragm in advanced cases
Becker	Males	Ages 11–25	Upper legs, pelvis; similar to, but milder than, Duchenne
Limb-girdle	Both	Teens to early adulthood	Begins in hips, spreads to shoulders, legs, and neck
Myotonic	Both	Ages 20–30	General: prolonged stiffening of muscles after use
Facioscapulohumeral	Both	Teens to forties	Face, shoulders, and back
Congenital	Both	Present at birth, symptoms by age 2	General weakness, progressing to muscle shortening
Oculopharyngeal	Both	Ages 40–60	Muscles of the eye, face, and throat
Distal	Both	Ages 40–60	Hands, forearms, feet, and lower legs
Emery–Dreifuss	Males	Ages 10 to mid-twenties	Shoulders, upper arms, and lower legs

males whereas others affect either sex. The symptoms of some appear in infancy whereas others present in adolescence or adulthood. The areas affected are also varied and are characteristic of the form of the disease being experienced (e.g., limbs, eyes and throat, face and shoulders, hips, hands, or even heart and diaphragm). A brief description of the types of muscular dystrophy appears in Table 42.2.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is an X-linked genetic disease arising from mutations in the *dystrophin* gene, a large gene consisting of 2.4 million bp and containing 79 exons. Exons 45–55 hold the mutational hot spot for the gene. Frameshift mutations lead to dysfunction of the dystrophin protein, which has an important role in skeletal and cardiac muscle function. In the absence of functioning dystrophin, patients experience progressive muscle weakness and wasting. In conventional virus-mediated gene therapy, owing to the size limitations imposed by the viral capsid, the full-length DMD cDNA must be replaced by a truncated complementary DNA (cDNA) that will yield proteins with compromised function, yielding minimal efficacy and a T cell response after gene delivery in vivo. Exon *dys* 51 (from Sarepta Therapeutics, Inc.) was developed using an oligonucleotide exon-skipping strategy [80]; after a controversial argument regarding its efficacy [80], it was approved by the US Food and Drug administration in 2016 as the first drug to treat DMD [81]. One drawback of the treatment, however, is that patients must receive regular intravenous infusions.

Genome editing provides the ability to correct mutations in genes without the need for introducing overly long sequences. Because of this, editing tools hold a different promise than do conventional gene delivery techniques for providing a more complete treatment for cells with mutations to the dystrophin gene. For instance, paired ZFNs have been delivered to DMD patient-derived myoblasts using electroporation, with the purpose of removing exon 51 of the dystrophin gene. This led to restoration of the dystrophin reading frame in approximately 13% of DMD patient mutations [82]. Long et al. [83], Nelson et al. [84], and Tabebordbar et al. [85] used CRISPR-Cas9 systems on the mdx mouse model of DMD to delete the mutated exon 23 from the dystrophin gene, resulting in the restoration of expression of functional dystrophin in the murine skeletal and cardiac muscles, plus enhancements in skeletal muscle function in the mice. Long et al. [83] delivered SpCas9 using AAV9, whereas Nelson et al. [84] and Tabebordbar et al. [85] delivered SaCas9 via AAV8 and AAV9, respectively. Iyombe-Engembe et al. used a pair of gRNAs to target exons surrounding exons 51–53 to bring about their deletion from the *DMD* gene, which restored the correct reading frame with 62% efficiency [86].

The CRISPR-Cas9 system has been delivered by "all-in-one" adenoviral vectors into patient-derived muscle progenitor cells for the purpose of removing mutations from the major *DMD* mutational hot spot [87]. This blanket approach has been asserted to counteract multiple mutations and provide treatment coverage in more than 60% of patients with DMD. Another investigation that targeted the DMD mutational hot spot deleted up to 725 kb using CRISPR-Cas9 with NHEJ. The efforts reportedly restored the function of dystrophin in cardiomyocytes and skeletal muscle cells derived from edited human iPSCs [88].

TALENs have been used to target a point mutation (A > G) associated with muscular dystrophies in iPSCs isolated from a canine golden retriever model of muscular dystrophy. The corrected canine progenitor cells were implanted into immunodeficient mice after ischemia-induced myocardial injury and cardiotoxin-induced hind limb skeletal muscle injury, yielding encouraging levels of regeneration in both cardiac and skeletal muscles [89].

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophy types 2B and 2D are muscular dystrophies that are induced by mutations in the dysferlin and α-sarcoglycan genes, respectively. The dysferlin nonsense mutation (c.5713C > T; p.R1905X) and the α-sarcoglycan missense mutation (c.229C > T; p.R77C) have been corrected using the CRISPR-Cas9 system in iPSCs isolated from patients with the respective diseases [90].

Another treatment aimed at the dysferlin mutation involved site-specific cDNA insertion via DICE, or TALEN-assisted homologous recombination for insertion precise, carried out in iPSCs isolated from patients with the disease. Expression of dysferlin was restored in the corrected iPSCs [90]. The typical next step would be to reintroduce the cells into the patient with the hope of restoring muscle function. Although the gene corrections were significant, using the corrected cells to restore function is a task that is more easily said than done.

Blood

The β-hemoglobinopathies, including β-thalassemia and sickle cell disease, are a group of genetic blood diseases caused by mutations in the β subunits of hemoglobin (HBB). These mutations are responsible for the decreased production of functional or mature β-globin subunits and therefore reduce the oxygen-carrying capacity of the blood [91]. β-Thalassemia can be caused by different mutations, whereas sickle cell disease is caused by a single DNA base mutation (A > T) in the sixth codon of the *hbb* gene [92,93]. Allogeneic stem cell transplantation is an effective way to treat β-hemoglobinopathies but it is difficult to find a fully matched donor, so immune rejection of the transplanted cells is often a concern. The combination of genome editing with (autologous) stem cell technology has brought about a potentially improved approach to treat these blood disorders.

For instance, a CRISPR-Cas9 system consisting of Cas9 ribonucleoproteins and a homologous, unmutated DNA sequence (carried by AAV) was used to achieve homologous recombination at a site of mutation in the *hbb* gene in isolated hematopoietic stem cells. These *hbb*-corrected cells were further enriched and transplanted into nonobese diabetic, severe combined immunodeficiency mice, yielding edited cells in the bone marrow of the mice [94]. In the same study, Dever et al. used a CRISPR-Cas9 system to correct the (A > T) mutation seen in sickle cell disease, following the standard logical scheme of isolating progenitor cells (in this case, hematopoietic stem and progenitor cells [HSPCs]) taken from patients with the disease, and then performing gene editing. The corrected HSPCs were able to differentiate into erythrocytes expressing β-globin mRNA.

Two more examples of gene editing directed toward correcting sickle cell disease again used a CRISPR-Cas9 system. This time, a ribonucleoprotein complex consisting of the Cas9 protein and an unmodified gRNA was delivered with a single-stranded DNA oligonucleotide to patient-derived HSPC cells by electroporation. Correction efficiencies of up to 25% were reported [95]. The corrected HSPCs were used to restore the expression of wild-type hemoglobin after differentiation into erythroblasts, with the correction being maintained through 16 weeks after injection [95]. A remarkable correction efficiency of up to 67.9% was reported by Li et al. when they used CRISPR-Cas9 with adenovirus, followed by nucleoporation with a single-stranded DNA template, to correct the sickle cell disease mutation in patient-derived iPSCs [96].

As we have seen, the CRISPR-Cas9 system is a popular route for gene editing for treatment of β-hemoglobinopathies. In fact, this system could be deemed the preferred method for editing. A series of studies have demonstrated that CRISPR-Cas9 nucleases are relatively efficient and specific in gene editing in human iPSCs [91,97–99], with advantages over ZFNs and TALENs, even when used to correct a point mutation such as that seen in sickle cell disease [100]. However, this certainly does not invalidate efforts made with the other editing systems, which have been shown to be superior to CRISPR-Cas9 in certain situations.

TALENs have been used to correct separate mutations (the intron 2 mutation IVS2-654C > T and the TCTT deletion) in the *hbb* gene of patient-specific iPSCs, made to enter cells via electroporation. The corrections were achieved with high efficiency: 68% and 40%, respectively [101]. TALENs and CRISPR-Cas9 have been separately employed, combined with a PiggyBac transposon DNA donor, to correct IVS2-654C > T mutations in the globin gene [102]. In this case, contrary to findings reported in the previous paragraph, TALENs performed with higher efficiency than CRISPR-Cas9 (33% versus 12.3%). In addition, the TALENs generated fewer off-target events. Not all such CRISPR-Cas9 applications display off-target effects, however. Fei et al. employed CRISPR/Cas9 combined

with the PiggyBac transposon to correct a −28 (A/G) mutation and TCTT deletion seamlessly in the *hbb* gene in patient-derived iPSCs to restore HBB expression after hematopoietic differentiation [103]. In this case, off-target events were not observed.

In addition to therapeutic applications toward β-hemoglobinopathies, genome editing has been employed to increase red blood cell production for transfusion purposes. The *SH2B3* gene encodes a protein that serves as a negative regulator of cytokine signaling. Naturally occurring dysfunctional variants of the protein can increase the population of red blood cells. CRISPR-Cas9 has been used to delete the *SH2B3* gene in pluripotent stem cells, allowing for the increased production of erythroid cell populations in vitro [104].

Skin

Epidermolysis bullosa dystrophica is a genetic disease caused by mutations within the gene encoding the collagen α-1 (VII) chain (COL7A1). Afflicted patients have fragile skin that is susceptible to minor injury and they easily form blisters and skin erosions.

Efforts targeted to correct this genetic abnormality have been made by codelivering Cas9 and gRNA into iPSCs generated from patients with dominant dystrophic epidermolysis bullosa [105]. After the editing, the iPSCs were differentiated into COL7-secreting keratinocytes and fibroblasts. Another approach was to deliver TALENs, via electroporation, into primary fibroblasts isolated from a patient with the disease in an effort to correct the COL7A1 mutation [106]. The corrected fibroblasts were then driven into iPSCs and placed into the flanks of SCID mice. Results showed that the cells expressed normal COL7A1 protein and that skin-like structures were formed after implantation.

Nerve

As with so many of the applications that have been covered thus far, the CRISPR-Cas9 system has been used to correct genetic mutations associated with neural disorders. The common scheme is to isolate progenitor cells (or to induce isolated cells into iPSCs) from a patient with the affliction and then to correct the mutation with the editing system. The resulting corrected cells are then differentiated and implanted back into the patient. This scheme has been performed on, for example, cells from patients with Alzheimer disease to correct a point mutation in the presenilin 1 gene [107]. It has also been used in conjunction with the PiggyBac transposon system to correct point mutations that result in disruption of tetrahydrobiopterin synthesis or recycling, which affects tyrosine and dopamine levels that are important for proper brain function [108]. The system has also been used to bring about genetic deletions, such as to combat fragile X syndrome, a type of inherited intellectual disability that is caused by an expansion of an area of CGG repeats in the *fragile X mental retardation 1* gene [109].

As mentioned in the Nickases section, Cas9 can be mutated to alter its endonuclease activity, resulting in enzymes known as nickases. Whereas wild-type Cas9 allows for genome editing by introducing targeted double-strand breaks in the genome, mutations of the HNH or RuvC domains in Cas9 can yield nickases that cut only one strand of DNA [110,111]. Some have introduced mutations that stripped Cas9 of all endonuclease activity [112,113]. These mutants, called nuclease-deficient Cas9 (dCas9), have been used for transcriptional repression and activation. CRISPR interference technology uses a fusion of Cas9 with repressor domains to yield effective gene repression. CRISPR-mediated gene activation incorporates a fusion of dCas9 with activation domains to recruit transcription activators in the nuclei of mammalian cells [114].

As an example, consider an application that targeted α-synuclein, which is encoded by the *SNCA* gene and is associated with mediating the pathogenesis of Parkinson disease. Under the mediation of carefully designed gRNA, a dCas9 fused with a hybrid VP64-p65-Rta tripartite activator (dCas9-VPR) [115] was used to obtain upregulation of *SNCA* expression by eightfold compared with iPSC-derived neurons expressing normal α-synuclein levels, whereas dCas9-KRAB served as a transcriptional repressor to downregulate *SNCA* expression by 40% in α-synuclein triplication iPSC-derived neurons [116].

Retina

Retinitis pigmentosa is a group of inherited eye diseases that are caused by mutations within a group of genes. Patients with retinitis pigmentosa have impaired vision caused by the degeneration of photoreceptor cells within the retina. A point mutation (c.3070G > T) in the *retinitis pigmentosa GTPase regulator* gene was corrected using

CRISPR-Cas9 with about 13% efficiency in patient-derived iPSCs, which laid the foundation for autologous iPSC transplantation to treat retinal diseases [117]. In another study, CRISPR-Cas9 was used to disrupt a mutation in the rhodopsin gene in the S334ter rat model of retinitis pigmentosa, halting retinal degeneration and improving optomotor reflexes (a possible indicator of improved visual function) [118].

CLOSING REMARKS

Gene editing involves the cleavage of double-stranded DNA in a targeted fashion. Although restriction enzymes have been used in molecular biology for about half a century, the field of genome editing has arisen relatively recently. The breakthrough in the field of genome editing came with the discovery of endonucleases that have tunable targeting and can be used in living cells. Three major forms of such systems were presented in this chapter: CRISPR/Cas, TALENs, and ZFNs.

For the researcher, the choice of editing system should take into account both the efficiency of a given method and the number of off-target effects generated. A system that produces the desired genetic change in 99.9% of treated cells would not be desirable for clinical use if an off-target insertion, deletion, or base change caused 0.1% of the cells to be transformed into cancer cells. As covered earlier, much work has been performed to generate enzymes that operate with greater specificity in the hope of eliminating off-target effects.

The general scheme used for gene editing for regenerative medicine includes isolating cells from the patient, which will greatly reduce the chances for an immune response to the therapy. The cells may be pluripotent, multipotent, or differentiated, but a common theme is to use or produce stem cells (such as iPSCs). The cellular genomes are then edited and the cells are reimplanted into the host in a pluripotent or differentiated form, with the differentiated form appearing to be more common. Differentiation of the cells before implantation gives the investigator a chance to verify that expression of the edited gene is at a clinically relevant level, whereas implantation of undifferentiated cells may allow for differentiation into multiple cell types in the proportions that the body needs. The implantation itself can occur in the form of the injection of cells into a given organ or tissue, or it could include cellular encapsulation or the embedding of cells into a scaffold construct. These implantation methods are options that are addressed elsewhere in this book.

The regenerative applications presented in this chapter addressed congenital aberrations, or disease states, that were dealt with via gene editing. In the future, it may be possible to regenerate noncongenital tissue defects, such as those arising from injury, by editing cells to be specifically responsive to an engineered repair environment. Editing may be used to create cells that can be used as tools to guide the differentiation of stem cells in vivo, recruit other cells to an area, induce angiogenesis, or proliferate into a tissue that has an enhanced property to aid the host at the organismal level. With new applications and advances appearing in the literature nearly weekly, it is difficult to predict the precise directions that this burgeoning field will take next.

Preclinical Bone Repair Models in Regenerative Medicine

Elvis L. Francois[1], *Michael J. Yaszemski*[2]

[1]Department of Orthopedic Surgery, Mayo Clinic, Rochester, MN, United States; [2]Departments of Orthopedic Surgery and Biomedical Engineering, Mayo Clinic, Rochester, MN, United States

INTRODUCTION

Bone tissue engineering (BTE) is a promising avenue of research that has the goal of providing novel methods to add to our clinical capabilities for treating difficult segmental and contained skeletal defects. Bone tissue demonstrates the intrinsic properties of regrowth and self-repair, which is a process marked by a complex array of biologic, structural and metabolic functions. The primary building blocks of bone tissue regeneration center on the recapitulation of the natural signaling pathways of bone development and healing, which are modified toward developing modalities to stimulate bone formation in a clinical situation in which the skeletal defect may not heal using currently available methods.

Of the many tissues under investigation, bone repair models continue to be a promising avenue of study primarily owing to the ever-increasing demand for and short supply of bone substitutes [1]. It is estimated that two million bone graft procedures are performed annually worldwide [2]. In the setting of large bony segmental defects that are often caused by polytrauma, pathological fractures, and osteonecrosis, the capacity for the normal process of fracture healing to repair the skeletal defect and restore load-bearing function to the injured bone is often insufficient, and the result is a fracture nonunion. This further marks the importance of preclinical bone repair models and their value for clinical application. This chapter will provide a general focus on the biological processes of preclinical bone repair in vitro and in animal models.

Ethical issues must be addressed when animals are used as preclinical models as part of the testing program. The appropriate conduct of experimentation using live animals is important to progress in the care of both humans and animals. The responsibility for the appropriate use of animals in research is incumbent on the investigators. The three "R's" of animal experimentation are replacement, reduction, and refinement. Replacement is the process of seeking to replace animals in an experimental design by either using an in vitro method or a phylogenetically lower animal whenever possible. The reduction process is constant assessment of the experimental design in an effort to reduce the number of animals by asking whether the desired data can be obtained in a statistically valid manner using fewer animals. Finally, the refinement process is an attempt to improve existing experimental methods to obtain the desired data with reduced ethical costs in terms of any painful or stressful procedures that are done on the animals.

BIOMINERALIZATION AND BONE REGENERATION

The triad of building blocks for bone tissue regeneration are: functionally active osteoblastic cells to secrete new bone matrix (osteogenesis), scaffolds upon which these anchorage-dependent cells attach and from which signaling

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00043-6

molecules can be delivered to the bone regeneration space (osteoconduction), and growth factors to drive the regeneration process (osteoinduction) [2].

CELL SOURCES

Stem Cells in Bone Tissue Engineering

Stem cells require two fundamentally important characteristics: the ability to self-renew and generate daughter lineages with identical potentialities, as well as the ability to differentiate along one or more lineages [3]. In the field of BTE, commonly used sources of stem cells include embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs), and adult mesenchymal stem cell (MSCs).

EMBRYONIC STEM CELLS

Human ESCs (hESCs) are derived from embryos generated via in vitro fertilization. Embryos are most often obtained from donors after they are deemed unsuitable for implantation and appropriate consent has been obtained. The preparation of embryos occurs via an antibody application process in which the inner cell mass from the blastocyst stage of the embryo is separated from the trophectoderm. The cells that are derived from the blastocyst inner cell mass are initially plated onto feeder cells. The cells that constitute the inner cell mass then expand to form an hESC cell line [4]. ESCs have two distinctive properties: the ability to proliferate infinitely and the property of pluripotency to differentiate into all three germ layer cell types: ectoderm, endoderm, and mesoderm [5].

Of specific interest in BTE, hESCs can be guided toward differentiation into osteoblast cells in vitro. One method of differentiation was described by Bielby, in which osteogenic cells are derived from three-dimensional (3D) cell spheroids (embryoid bodies [EBs]) [5]. EBs are formed via suspension or hanging drop methods from a single cell suspension. EBs provide the potential for differentiation into precursor cells of all three germ layers. Committed cells in the EB matrix are cultured in monolayer and are induced to osteogenic cells under the presence of exogenous factors (e.g., dexamethasone-ascorbic acid and sodium-β-glycerophosphate). These exogenous factors work in concert to promote an environment conducive to bone regeneration. Dexamethasone stimulates the osteogenic differentiation of precursor cells harvested from multiple tissues. Ascorbic acid facilitates collagen secretion and deposition, and sodium-β-glycerophosphate acts to mineralize the deposited matrix. Working in concert with biochemical exogenous factors, the extracellular matrix (ECM) has an important role in the direction and differentiation of ESCs. Alternatively, undifferentiated ESCs or dispersed EBs are sometimes implanted directly into 3D scaffolds and driven to form multiple tissues for later implantation [6].

Induced Pluripotent Stem Cells

iPSCs are somatic cells reprogrammed to exhibit pluripotent properties. Historically, mouse skin fibroblasts were first reprogrammed to iPSCs by overexpression of a set of four key transcription factors [7]. Subsequently, adult human cells were reprogrammed [7,8]. Systematic reviews of the literature on the osteogenic potential of iPSCs suggest that osteo-induced iPSCs demonstrate an osteogenic capability equal or superior to MSCs [9]. Furthermore, studies demonstrate that cell sources for iPSCs do not appear to affect the osteogenic potential of iPSCs [9]. In their early use, it was noted that iPSCs were met with complications of teratoma formation. In an attempt to address these complications, studies have demonstrated that the addition of resveratrol to the osteogenic medium and irradiation after osteogenic induction reduce teratoma formation in animal models [9].

Mesenchymal Stem Cells

The most common stem cell type used in the BTE field is the MSC [10]. First identified in 1966 by Friedenstein, MSCs were discovered via the isolation of bone and cartilage-forming cells from rat bone marrow cells that had fibroblast-like morphology [11]. MSCs have since been isolated from multiple tissues (liver, fetal blood, and umbilical cord), but the most well-investigated and readily available source of MSCs is the bone marrow. MSCs harvested from different sources may not be identical in their biological characteristics. A comprehensive report on the

proteome and transcriptome profiles of MSCs revealed source-specific markers [12]. Furthermore, differences that exist in colony-forming unit efficiency, surfactome profiles, multilineage differentiation, and paracrine functions may suggest a specific optimal clinical application for that particular MSC cell line [13,14].

MSCs comprise roughly 0.001%−0.1% of the total population of bone marrow nucleated cells. In turn, these can be specifically separated from other nucleated cells by their adherence properties to plastic culture flasks. They can then be expanded in vitro without a loss of phenotype. The process of harvesting MSCs and then exploiting their pluripotent ability to differentiate them into osteoblasts, chondroblasts, myoblasts, and tenocytes is primarily why they are often used in musculoskeletal tissue engineering applications [15]. MSCs have the ability to differentiate into a variety of adult musculoskeletal cells as well as an inherent ability to secrete a variety of cytokines that modulate inflammatory and immune response pathways [16]. The synergistic benefit of these immunomodulatory effects is a reduction in the risk for host rejection. Another beneficial property of MSCs is their ability to be driven down various mesenchymal cellular pathways including chondrogenic, osteogenic, and adipogenic lineages when provided the necessary in vitro or in vivo environments [17] or 3D scaffolds [18]. MSCs are driven toward osteogenic differentiation when stimulated with dexamethasone, ascorbic acid, and sodium-β-glycerophosphate. When appropriately stimulated, MSCs upregulate alkaline phosphatase, osteocalcin, and the expression of osteopontin, and they direct calcium deposition within the ECM. In vivo preclinical BTE models also benefit from the use of MSCs, in that the MSCs have been shown to facilitate bone repair when they have anchored onto artificial matrices such as hydroxyapatite scaffolds [19].

SCAFFOLDS

BTE scaffolds allow for the adherence of osteogenic cells and serve as an appropriate microenvironment to permit those cells to secrete osteoid, the matrix of newly formed bone tissue. Scaffolds are often subdivided into three classes based on their material composition: polymers, metals, and bioceramics. Scaffolds may contain more than one of these three material types. Further stratification is delineated by the derivation of the material (i.e., natural versus synthetic) and their ability to undergo degradation (i.e., resorbable versus nonresorbable).

The benefits of naturally derived scaffolds (i.e., collagens, fibrin, elastin, alginate, hyaluronic acid) are their resorbable qualities in vivo as well as their intrinsic biocompatibility and minimal adverse immunological properties. Synthetic scaffolds have the benefit of often being able to be fabricated with a wider range of degradation rates and mechanical properties compared with their natural counterparts. This ability is based on their polymeric composition, the copolymer ratio, and the interactions of their polymeric side chains. The choice of the synthetic polymer's chemical composition and 3D configuration often determines its cell adhesion properties and ability to incorporate and deliver bioactive molecules in a controlled fashion [20].

A novel arena within scaffold design has been the adoption of additive manufacturing technologies (3D printing) in scaffold fabrication. The term "3D printing" describes a group of additive manufacturing technologies that are collectively referred to as solid free-form fabrication. These include laser stereolithography, fiber electrospinning, fused deposition modeling, fiber extrusion from the melt, and injection molding [21]. The benefits of 3D printing are conferred by its immense flexibility in fabricating scaffolds of varying structural complexity. This process allows for a great deal of control over the construct architecture and flexibility in scaling up fabrication, and it has the added benefit of technically precise reproducibility, which is sometimes lacking in subtractive fabrication techniques (e.g., milling).

Biochemical Signaling: Growth Factors and Cell Signals

BTE cell signals are environmental factors that directly or indirectly influence the regeneration of skeletal tissues. The importance of appropriate cell signals and growth factors cannot be overstated in terms of their importance for bone formation. Common growth factors of particular importance in bone regeneration include bone morphogenic protein (BMP)-2, BMP-7 (also called osteogenic protein 1), fibroblast growth factor, platelet derived growth factor, parathyroid hormone (PTH), PTH-releasing peptide, transforming growth factor-β3, vascular endothelial growth factor, and the Wnt proteins [22]. The interplay between signaling molecules and growth factors is complex and multivariable. Factors critical to cell signaling include the spatiotemporal release of growth factors and their bioactivity. The delivery of biochemical signaling cues is generally categorized as unbound, bound within the implant with a designed controlled delivery, coated on the implant surface, or coded within the cells via gene delivery mechanisms [23,24]. Unbound delivery systems are marked by the rapid efflux of the growth factors followed by rapid clearance from the microenvironment. Bound delivery systems allow the advantage of controlled or specific variable release of the biochemical signal over time. Generally speaking, bound delivery

systems are more applicable for the requirements of BTE. Hydrogels are the most commonly investigated polymer for cell encapsulation and the in situ delivery of biochemical cues [22]. To mimic the function performed by the ECM, bioactive hydrogels containing protease sensitive sites, cell adhesion molecules such as Arg-Gly-Asp–containing peptides, and/or biological cues in the form of growth factors, inorganic minerals, or drugs have also been developed [25,26].

Of the many growth and differentiation factors in BTE, BMPs possess the unique ability to stimulate the differentiation of mesenchymal precursor cells to chondrocytes and osteoblasts; this in turn allows for the induction of new bone at ectopic and orthotopic sites. Marshall Urist discovered that demineralized bone matrix induced ectopic bone formation in subcutaneous and intramuscular pockets in rodents [27]. Further investigation over the next several decades led to the isolation of BMPs as the causative factor in this induction of the bone formation cascade [28]. Clinically, BMPs are often used at the sites of intended bone regeneration in skeletal defects with the goal of osteoblastic cell proliferation and differentiation. The delivery of BMPs can be either direct application to the intended site of bone regeneration or via controlled release. There are several drug delivery systems under investigation that allow for measured controlled delivery. BMPs as well as other proteins may be encapsulated in poly(D,L-lactic-*co*-glycolic acid) microspheres [29] or embedded into collagen carriers [30]. Among other delivery systems, these allow for the temporal and spatial release of growth factors and cell signals in a controlled fashion.

PRECLINICAL MODELS OF BONE TISSUE REGENERATION

In Vitro Preclinical Models

In vitro studies offer the advantage of focused manipulation of specific biomaterials in well-controlled experiments. In targeting specific cascades, investigators are more capable of understanding specific variable responses in a closed environment with the goal of predicting future responses in preclinical animal models and in subsequent translational first-in-human applications. In vitro studies afford the opportunity to simulate complex interactions among cells, scaffolds, and growth factors in relatively controlled environments. Bone-forming cells (osteoblasts) are often procured from three primary origins:

- pluripotent stem cells that differentiate into osteoblasts [31],
- primary osteoblasts and osteocytes from different species [32,33], and
- immortalized cell lines [34,35].

To maintain translational validity, bone in vitro models must incorporate the classic triad of cells, scaffolds, and growth factors in a fashion that closely mimics both the biochemical and biomechanical bone formation characteristics that are seen in vivo. The bone matrix is composed of cells surrounded by an ECM made up of an inorganic phase that is approximately 70 wt% hydroxyapatite and an organic phase that is approximately 30 wt% type I collagen and other noncollagenous proteins [36,37]. Biomechanical studies have demonstrated that greater than 90% of bone cells within the ECM are osteocytes that sense and transduce mechanical forces exerted on the bone, in turn governing the rates of resorption and deposition that occur during bone remodeling [38].

Historically, the study of the interplay between bone physiological and pathological processes has been performed on 2D plastic plates. Although great strides in understanding bone formation, bone resorption, and bone remodeling have been made via this medium, the 2D cell cultures have been shown to mimic the 3D microenvironment of native bone and the interactions between the bone cells and the ECM incompletely [39]. In vitro studies provide great insight into the translational validity of a model, but the biomechanical environment in vivo is much more complex and the stresses exerted on the bone dictate its resorption and deposition rates. This complex interplay between the microscopic cellular level and the macroscopic mechanical level are greatly important in BTE, because understanding these interactions is critical to the success of in vivo BTE preclinical models.

In Vivo Preclinical Models

The benefit of in vivo models rests in the ability to assess biomaterials in more complex tissue environments that have variable loading conditions. Among the limitations of BTE animal models is the interspecies variation of bone tissue. It has been well-illustrated that bone composition, density, and mechanical properties of various animal models (i.e., cow, sheep, pig, dog, chicken, and rat) often differ from those properties in human bone [40].

There are a host of factors to be considered when selecting a specific animal model for in vivo preclinical studies. Chief among these is that the animal model demonstrates physiological and pathophysiological processes that mimic those in humans. The attributes of a "good" animal model are that in addition to being similar to those in humans, as mentioned earlier, the animal's anatomy and physiology are suitable for the requirements of the study design. The animal chosen should be economical and available. The animal management and care issues must have been considered and are optimal for the chosen study (e.g., housing requirements and ease of handling).

Selection Considerations Based on Animal Species

Animal species that are under consideration for in vivo preclinical studies include mice, rats, rabbits, sheep, goats, pigs, dogs, cats, and nonhuman primates. There are pros and cons to the use of any of these animals. Mice and rats are readily available and inexpensive and have minimal housing requirements. On the negative side, their small size is an issue in some experiments, and their life span postskeletal maturity places a time limit on the study. Human clinical conditions that have been modeled by rats and mice include heterotopic bone formation, trabecular bone defects, segmental bone defects, and spinal cord injury. Given their size, robustness, and cost efficiency, rodents are particularly useful in preclinical studies in assessing biomaterials as bone substitutes and are generally regarded as the prime model for in vivo testing of the regeneration of bone tissue [41]. Disadvantages, in addition to those listed earlier, include the lack of Haversian-type remodeling in the rodent bone cortex and thin, fragile cortices in the long bones [42]. The rat, which is the most often used animal model, has been shown to have the most significant difference from human bone compared with other animal models [43]. Rodents are primarily useful for the surgical implantation stage of substitute bone materials. For example, β-tricalcium phosphate (β-TCP), calcium phosphate, and collagen experiments have been commonly conducted in rodents. A prime example of applications of rodent bone defect models is exemplified by investigations of the biocompatibility of highly purified β-TCP bone graft substitutes using a rat femoral defect model. The study demonstrated that purified β-TCP was both biocompatible and resorbable [44]. In another study, investigators successfully used small animal rodent models to establish a 4-mm-diameter calvarial critical-sized defect model in mice. This model was successful in the analysis of the in vivo osteoconductive and osteoinductive abilities of bone substitute materials [45].

Similar to mice and rats, rabbits are also readily available and inexpensive, and have minimal housing requirements. They are larger than mice and rats but are still considered a small animal model. Rabbit models rank as the most commonly employed models in musculoskeletal research [46]. Applications that have used rabbit models include calvarial critical-sized bone defects, posterolateral spine fusion, and cartilage regeneration. Rabbits have similarities to humans in bone mineral density and fracture toughness of middiaphyseal bone.

Large animal models allow for the assessment of a larger volume of bone regeneration and repair over a longer time frame than is possible in mice, rats, and rabbits. Large animal models permit the assessment of bone remodeling and implant integration in a manner that better mimics the biomechanics and loading characteristics seen in humans. Large animal models that are often used in musculoskeletal investigations include sheep, goats, pigs, dogs, cats, and nonhuman primates. The use of sheep, goats, and pigs provides an animal model in which bones and joints are more similar to their counterparts in humans than are those in the small animal models discussed previously. Sheep, goats, and pigs have good availability and can serve as an alternative to dogs in some applications. Dogs and cats are companion animals, which often causes their use to receive greater scrutiny. Negative issues associated with the use of sheep, goats, and pigs include the increased cost, housing requirements, and the need for a formal operating room setup to perform surgery on them. Applications for which sheep, goats, and pigs have been used include radius nonunion (and other bone healing or bone defect applications), femoral head osteonecrosis, anterior cruciate ligament reconstruction, and meniscal repair.

Dogs and cats share the same pros and cons as sheep, goats, and pigs. In addition, as mentioned earlier, their status as companion animals often attracts greater scrutiny in their use in experimental designs that include surgical procedures. Several applications that have used dogs and cats as experimental animals include many of the same applications for which sheep, goats, and pigs were used: radial nonunions, tibial defects, other fracture healing or bone defect models, femoral head osteonecrosis, and craniomandibular reconstruction. In addition, dogs and cats have been used in surgical studies for total joint arthroplasty, spinal cord injury, and distal radius osteosarcoma.

Nonhuman primates have an anatomy and physiology that more closely parallel those of humans than any of the other animal models discussed here. They are not readily available, they are expensive, and they have the highest housing requirements than any of the other animals. The scrutiny that they receive from the Institutional Animal

Care and Use Committee when their use is requested is even higher than that of the companion animals. Applications in which nonhuman primates have been used include osteoporosis, bone healing, fracture nonunions, prosthetic implant studies, spinal fusion, and organ transplantation studies.

Surgical studies using animals are essential for the analysis of novel treatments for both humans and animals. However, we must treat them humanely, take whatever measures are necessary to control their surgical pain, and constantly seek to apply "the three R's" of replacement, reduction, and refinement to obtain the data that we need, and simultaneously try to do so while using increasingly fewer animals.

CONCLUSIONS

No amount or type of preclinical (in vitro and animal) studies can predict with certainty the implant behavior in humans. The first in-human use must consider clinical equipoise: the anticipated balance between potential benefit and potential risk in the human study subject who receives the implant. Consider the regulatory implications of potential preclinical experimental pathways, because different but feasible may pose different regulatory burdens. Plan to speak with US Food and Drug Administration colleagues early and often as the various potential preclinical paths are being considered. Remember that animal models are an essential but insufficient component of the preclinical evaluation for new medical products. The choice of model depends on several factors, including the biologic and structural goal of the study, the applicability of the model to the human condition under evaluation, the cost and technical feasibility of the chosen model, and historical experience with the model. Eventually, the safety and efficacy of new treatment modalities will be determined by well-controlled studies in humans, and postevaluation use in the general population of patients who have the condition to be treated. Be certain that clinicians who care for patients with the disease in question are members of the planning and execution of the preclinical study team. The ultimate determination as to whether your product will become the standard of care for the surgical care of the disease condition under consideration will be made one patient at a time, within the physician–patient relationship as the treating doctor and the patient discuss the various treatment options available to them to treat the patient's clinical problem.

INTRODUCTION

Current drug development strategies do not include adequate models to predict drug efficacy or safety in humans. There is a considerable need for the high-fidelity in vitro representation of integrated human physiology to test both the beneficial and potential detrimental effects of drug candidate compounds in the body [1,2]. Animals (rodents, in particular) have been the reference standard of scientific experimentation for centuries. These animal models have served as the cornerstone of research in cell biology, pathobiology, molecular biology, and many other biomedical research fields [3]. Two-dimensional (2D) cell lines and animal models have been used extensively to determine the toxicity of new drugs before the initiation of human clinical trials. It has become clear that these models have significant limitations owing to phenotypic differences in physiology compared with humans. This is especially critical for the assessment of toxic side effects of drugs that might target the liver, heart, and other organs because of the differences in enzymatic expression profiles among humans, rodents, and cell lines, which often results in significant differences in drug metabolism, efficacy, and toxicity. In vitro drug screening platforms use human cells; however, by definition, the genotype of cell lines is altered from the natural state, and primary cells change phenotype after removal from native tissue. These phenotype changes in culture result from the failure of traditional 2D systems to recapitulate several aspects of the native 3D cellular microenvironment [4,5]. As a result, 2D cultures exert selective pressures on cells, significantly altering their phenotype as they adapt to their new conditions. Drug diffusion kinetics are not modeled accurately in 2D tissue culture, drug doses effective in 2D are often ineffective when scaled to patients, and the lack of cell−cell/cell−matrix interactions in 2D often lead to loss of cell function [4,6,7].

In contrast, advances in tissue engineering, biomaterial development, and microfluidics and electronics have resulted in the successful fabrication of multicellular human tissue equivalents and microorgans (organoids) that demonstrate many of the functional properties of normal human tissue and organs. For example, liver organoids exhibit normal metabolic activity, skeletal and cardiac muscle constructs contract in a physiologically normal manner, lung organoids "breath," and gut/vessel/brain microvasculature constructs maintain normal barrier functionality [8,9].

"Body-on-a-chip" devices that recapitulate 3D tissue architectures and physiological fluid flow conditions are more effective at supporting normal cell function than static 2D culture [10]. These engineered platforms can include sophisticated hardware systems, potential for scale-up, capacity for high throughput, and user control over physical factors such as fluid shear stress and mechanical deformations. Microfabrication techniques based on a variety of nanotechnologies have resulted in the development of microscale fluidic systems with predictable fluid dynamics

Principles of Regenerative Medicine, Third Edition

throughout the entire fluid circuit [11]. Tissues and organoids can be immobilized within platform microreactors using sophisticated hydrogel biomaterials, providing a proper microenvironment and allowing for long-term perfusion. A variety of iterations on these basic concepts are in use by laboratories around the world [12–14]. In addition, a variety of on-chip disease models have been investigated [13]. The most pressing challenge in advancing the body-on-a-chip field is to combine multiple organs within a common microfluidic circuit, to model an entire human, on-chip. Such a system would represent the pinnacle of in vitro platforms for modeling integrated human physiology. Ideally, as in the human body, such a system would recapitulate the interdependent and synergistic functions of all tissues and organs within a cell culture or body-on-a-chip platform. The microfluidic circuit connecting organoid microreactor chambers allows for fluid flow across each organoid type in a sequence that mimics blood flow throughout the human body [8]. Compound metabolites and other secreted factors would likewise be transported to downstream organoid types in a physiologically relevant sequence. As such, these advanced body-on-a-chip platforms would be ideal for testing newly developed drugs and assessing potential toxic side effects in human tissues and organs. Furthermore, the body-on-a-chip platform would offer tremendous benefits for pharmacological studies aimed at determining the specific effects and toxic levels for newly developed drugs, allowing for the better prediction of appropriate doses for human trials. In this chapter, we highlight a variety of organoid-on-a-chip systems for applications such as drug screening and disease modeling and look to the future of multiorganoid body-on-a-chip systems and applications in personalized precision medicine.

ADVANCE OF IN VITRO ORGANOID DEVELOPMENT: PROGRESSION FROM TWO-DIMENSIONAL TO THREE-DIMENSIONAL MODELS

The development of novel drugs that are safe and effective in humans has been significantly hampered owing to the inability to model human cell phenotype, function, and intercellular signaling accurately in vitro. Animal models used extensively in preclinical drug studies are traditionally regarded to be the reference standard for drug testing. However, animal models do not reflect human drug metabolism accurately; thus, animals are often not predictive of results in humans. The second type of conventional model system, in vitro 2D culture, fails to recapitulate many aspects of the 3D cellular microenvironment, leading to poor support for cell viability and cellular function [4,15]. In addition, drug diffusion kinetics are completely nonphysiological in traditional cell culture and drug doses that are effective in 2D are often ineffective when scaled to patients [6,7]. Cells grown on tissue culture plastic experience several properties in their environment that are inconsistent with the tissue from which the cells were originally isolated. These include surface microtopography, stiffness, oxygen tension, mechanical loading, biochemical composition, and most important, a 2D rather than 3D architecture. These unnatural characteristics can significantly alter the phenotypic properties of cells, because they are forced to adapt to these new conditions.

The functional differences between 2D cultures and 3D constructs have begun to be appreciated. A myriad of studies have demonstrated these differences across a variety of cell types. 3D systems consistently outperform 2D cultures in many aspects including accurately representing in vivo function and demonstrating a physiologically normal response to drugs and toxins [16]. The current drug development pipeline (Fig. 44.1A) has not yet evolved to include newer 3D cell culture technology, which results in countless discrepancies between in vitro drug screening outcomes and later performance in patients, during or even after clinical trials [17]. As an example, our team demonstrated that metastatic colon carcinoma cells adopted an epithelial appearance in 2D tissue culture. However, when transitioned to a 3D organoid form factor, the cancer cells "switched" to a morphology that resembled mesenchymal metastatic cells, which were much more representative of malignant tumor cells in vivo [18]. These kinds of documented benefits of 3D cell culture beg the question: Why are 2D cell cultures still being employed in drug development and toxicology screening?

Fortunately, tissue engineering technologies have evolved to the point that microengineered tissue constructs can better mimic the structure, cellular heterogeneity, and function of in vivo tissue. These organ models can often be maintained in viable states for longer periods and are designed to preserve the functional properties of native tissues. They can also recapitulate the microenvironmental roles of cell–cell, cell–extracellular matrix (ECM), and mechanical interactions that cells experience inside tissues. Oxygenation can be a concern in 3D tissue models. If they are too large in diameter, an oxygen gradient develops across the organoid that can lead to phenotypic changes and potentially a necrotic core. However, oxygen gradients exist in vivo. As such, as long these gradients are taken into consideration and controlled, either by limiting the size of the organoids or by creating perfusable channels within the construct, maintaining an oxygen gradient may actually provide a better representation of native tissue. Overall, these relatively new 3D model systems are greatly superior to their 2D predecessors for drug and toxicology testing.

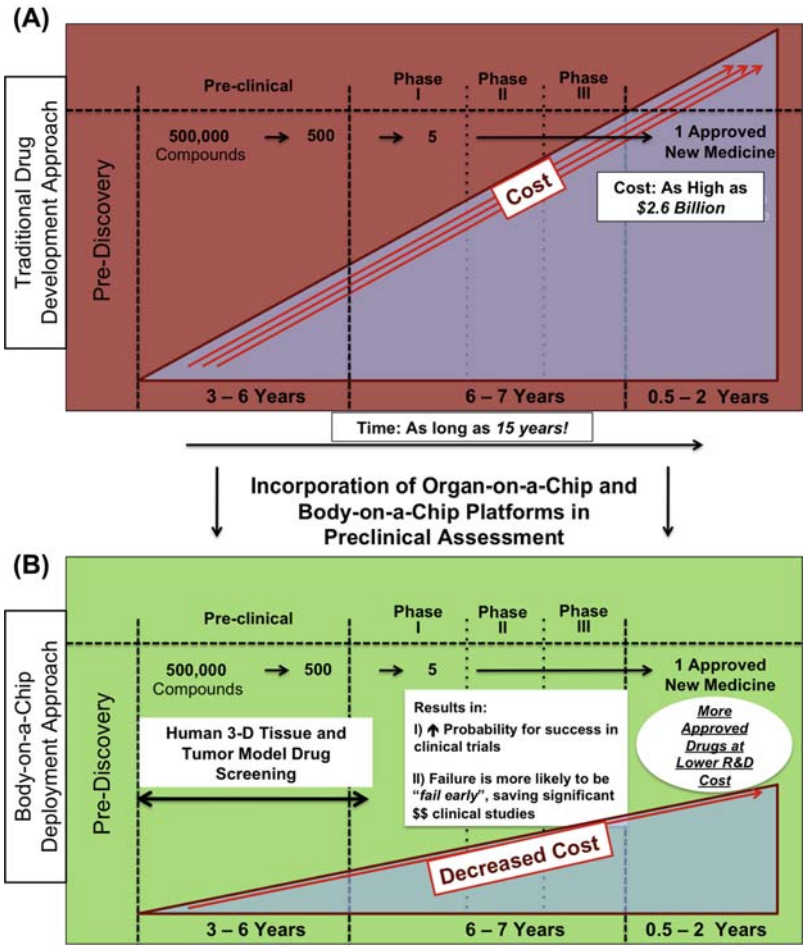

FIGURE 44.1 **Potential improvements in the drug development pipeline as a result of deployment of organ-on-a-chip and body-on-a-chip technologies into pharmaceutical research and development.** (A) The current drug development pipeline requires many years and multiple billions of dollars to bring a drug to market. (B) Plugging in human-based, biofabricated on-a-chip platforms into preclinical stages can potentially drastically improve the efficiency of the drug development pipeline. *R&D*, research and development.

Fortunately, the general concept of performing research using 3D versus 2D cultures has gained significant traction. However, hurdles and challenges remain. 2D cell culture is an established practice that will certainly remain a widely used tool for many years. This is primarily because it is easy and inexpensive compared with 3D culture systems. Implementing 3D systems in a laboratory can be complicated, requiring the mastery of new technologies including biomaterial development and biofabrication techniques. Furthermore, once 3D culture technologies have been established, processes regarded as trivial in 2D culture, such as cell harvesting and cell passaging, can be difficult and in some cases impossible without harming the cells. For example, if cells are cultured within a 3D hydrogel construct, one must effectively dissolve the matrix to isolate or harvest the cells. Some biomaterials support cell retrieval by building specific features into the material [19], but most do not; instead, they require enzymatic dissolution that in some cases can influence cell viability or phenotype. Also, most cell imaging techniques were developed for 2D cell cultures, environments in which cells exist in a narrow focal plane. In 3D, cells reside in many focal planes. Consequently, high-quality imaging in 3D may be obtained only by confocal or macroconfocal microscopy, requiring expensive equipment to which many laboratories do not have access. In addition, there are a variety of assays that can be significantly more difficult to perform on 3D models or that require significant modification for adapting to 3D models. Finally, some body-on-chip device materials (polydimethylsiloxane, for example) are prone to fouling and drug and protein adsorption. However, new materials for device hardware are being developed to solve this problem.

All things considered, it is generally understood that 3D or dynamic on-a-chip platforms outperform static 2D systems in modeling normal human physiology [16]. As a result, these more capable 3D platforms have an immense potential to influence the drug development pipeline positively, decreasing development costs and increasing success rates of drug candidates in clinical trials (Fig. 44.1B). Perhaps just as important, these models can be used to identify nonoptimal drug candidates early before human trials are initiated.

ORGAN-ON-A-CHIP TECHNOLOGIES AND THEIR APPLICATIONS

Advances in biotechnology areas such as tissue engineering [20], biomaterials [21], and microbiofabrication [22] have allowed the derivation of new biological systems with massive potential as test platforms. Researchers have developed a wide variety of human-derived in vitro models that can be used to test drugs, toxins, and drug candidates in a more normal physiological environment [14,23–25]. Furthermore, advances in molecular genetics and tissue engineering technologies have enabled the development of 3D models of specific diseases [13,26–28]. Advances in related technologies such as microfabrication and microfluidic technology have improved 3D cell models by supporting cell and organoid culture, fluid flow, high-throughput testing, environmental sampling, and biosensing. These organ-on-a-chip systems can vary widely in design, allowing for the representation of a range of tissue types. Some of these systems have already been implemented in drug discovery [12] and purport to affect the future of medicine significantly. Here, we highlight just a few microengineering technologies and discuss examples of liver-on-a-chip, vessel-on-a-chip, lung-on-a-chip, and cancer-on-a-chip systems. However, there are many variations of these systems, as well as many additional models for virtually any tissue type.

Microengineering and Biofabrication

The cellular content of a body-on-a-chip model is only one piece of the puzzle. Even with a physiologically normal composition of cells, normal cell function and appropriate responses to pharmacological agents are not guaranteed. Another environmental characteristic that must be considered is the interaction of cells with specific ECM proteins. As mentioned, cells receive a lot of information from their immediate local microenvironment that directly influences cell phenotype. Thus, it is critically important to reproduce as many of the components of the microenvironment as possible. Several techniques have been developed to incorporate natural structural and functional components of tissue ECM into cell culture systems.

Micropatterning is the precise placement of proteins within a cell culture substrate. Micropatterning can be accomplished by a variety of methods including (1) microcontact printing, in which a stamp is coated with specific ECM components and is pressed against a solid substrate to create a specific pattern; (2) photopatterning using UV light projected through a photomask to catalyze the adherence of ECM proteins, or compounds that bind ECM proteins to a cell substrate in a predetermined pattern; and (3) laser patterning, in which laser light is used to mediate protein binding to a substrate in any desired pattern with very high resolution [29].

Many bioregulatory components of the ECM can be distributed in a controlled manner by using micropatterning techniques. For instance, depositing islands of ECM cell adhesion proteins that restrict cell spreading will induce apoptosis in bovine adrenal capillary cells while maintaining the differentiation state of epidermal keratinocytes. Conversely, micropatterning of ECM proteins that induce cell spreading promoted proliferation of both the bovine adrenal capillary cells and epidermal keratinocytes. These experiments demonstrate a clear link among the local ECM composition of a cell substrate, cell cycle, and differentiation [30,31]. This notion is further highlighted by another study involving micropatterning. Mesenchymal stem cells grown on small micropatterned patches that restrict cell spreading promoted differentiation toward adipogenic lineages, whereas micropatterning of factors that induce cell spreading promoted differentiation toward osteogenic lineages. These studies also showed that modulating cell shape was sufficient to induce the expression of signaling proteins Rac1 and N-cadherin, which have an important role in cell lineage specification [32,33]. Micropatterning represents a powerful tool for precisely controlling the protein composition of the cellular microenvironment within a cell culture substrate. By modulating the biochemical and geometric properties of the microenvironment, global cell phenotype and cell viability may be greatly influenced. Micropatterning has a wide variety of applications in advanced in vitro models and will become increasingly used to tune physiologic output from these systems.

Whereas micropatterning technologies are generally used to control the cellular microenvironment in 2D culture systems, bioprinting provides a method for doing the same in a 3D space. Bioprinting involves the layer-by-layer deposition of structural material, cells, and bioregulatory factors in a controlled manner. Bioprinting technologies enable the fabrication of complex cellularized 3D constructs that may include components of the ECM, including both intrinsic and bound bioregulatory factors that modulate cell organization and function within a 3D space.

Bioprinting is highly customizable across a wide range of resolutions and biochemical or physical characteristics. Applications requiring a more rigid structure can be printed using biomaterials with high mechanical stiffness. For stiffnesses beyond that which may be directly printed, methods have been developed for cross-linking structural components of the biomaterial subsequent to bioprinting. For example, dental implants have been bioprinted

from polycaprolactone and hydroxyapatite [34]. On the other end of the stiffness spectrum, soft tissues such as vascular grafts have been printed using very low stiffness poly(ethylene glycol) hydrogels [35]. Because of the increasing resolution and speed of bioprinters, the structures that may be fabricated are becoming highly complex. The ability to precisely reproduce the structural and biochemical microarchitecture of tissues will most certainly result in more physiologically normal cellular function in bioprinted constructs.

Several biological constructs have been fabricated using current bioprinting technology. Liver organoids have been generated using microextrusion bioprinting technology that includes several liver cell types suspended in a supportive hydrogel. These constructs demonstrated exceptionally high levels of liver tissue function and maintained viability in the long term, which makes them ideal candidates for tissue-on-a-chip applications [36]. Skin substitutes have also been created using a laser-based bioprinting technology, which allowed the precise placement of cells associated with specific layers of the skin. The resulting skin constructs were implanted into rodent wound models and demonstrated robust neovascularization, differentiation of mature keratinocytes, and the generation of a normal dermal basal lamina, all hallmarks of native skin [37].

3D printing may still be considered a nascent field. Logistical obstacles continue to limit applications in whole-organ biofabrication. However, the speed, reproducibility, and scalability of bioprinting make it an ideal complement to body-on-a-chip modeling. 3D printing can be used to generate an industrial-scale volume of biological constructs with low run-to-run variability, with the complex structure required for high-function tissue organoid models.

Liver-on-a-Chip

Early tissue/organoid-on-a-chip devices were geometrically designed to drive cell aggregation, thereby creating multicellular organoids. For example, devices were designed with microwells with a convergent geometry that terminated in a cell substrate of some type. Based on the microwell design, liver-derived cell lines could be formed into either spheroid or cylindrical constructs in a highly controlled manner. These 3D constructs maintained much better cellular function than did 2D controls [38,39]. In another example, spheroids were created from a cell line using an array of channels connecting inverted, pyramid-shaped microwells, allowing for the delivery of cells and test compound to multiple chambers simultaneously. This integration of microfluidics with an array of microreactors greatly increased the throughput potential for drug screening [40].

Liver-on-a-chip devices have become much more complex. They often employ controlled fluid flow to address nutrient circulation, drug or toxin administration, sample collection, and the integration of liver organoids with other tissue types. The latter will be discussed in detail later in this chapter. In one such liver-on-a-chip, hydrogels were used to encapsulate HepG2 cells with National Institutes of Health (NIH)-3T3 fibroblasts. These arrays of 3D organoids had increased liver function compared with 2D controls and produced an appropriate toxic response to acetyl-para-aminophenol (acetaminophen [APAP]) in a drug screening experiment [41]. Our group employed a versatile photopolymerizable hyaluronic acid biopolymer system for in situ photopatterning of HepG2 cells to generate 3D liver constructs. The constructs were formed in parallel channel fluidic devices that were fabricated by soft lithography and molded polydimethylsiloxane. This system was used for toxicity screening by administering multiple alcohol concentrations within each chip. As expected, alcohol administration resulted in a dose-dependent decrease in viability and cellular function [14]. Efforts within our group are focused on miniaturizing this and other systems to increase throughput further. Miniaturization and microfabrication approaches can be employed to generate more intricate biological microarchitecture such as liver sinusoids. Precise seeding and layering of hepatocytes and endothelial cells within microfluidic circuits can be used to generate structures with the resolution required to produce sinusoid-like models [42]. Another approach to generating biologically relevant microarchitecture involves mating synthetic and biological components. As an example, semiporous membrane to separate two adjacent chambers may be used to partition human hepatocytes from sinusoidal endothelial cells. Such a design was shown to generate higher albumin and urea production compared with traditional hepatocyte cultures; it demonstrates another strategy for recapitulating normal microarchitecture to increase cell function [43].

Vessel-on-a-Chip

The term “microfluidics” carries with it the assumption of controlled fluid routing. Thus, microfluidic devices are effective for modeling vascular networks. Moreover, because drugs are generally introduced directly to the bloodstream or enter the bloodstream shortly after oral or airway introduction, fluidic systems that mimic the role of the

vasculature contribution to pharmacokinetics represent a beneficial component for any drug screening technology. A substantial number of vascular-like fluidic devices have been developed, including both straight channels devices [44,45] and fluidic devices with more complex, branching features [46,47]. One major role of the vascular system, beyond transporting nutrients and oxygen among tissues, is to transport drugs and other molecules to sites throughout the body, where they pass through the endothelium into adjacent tissues. Many microfluidic systems have been designed to model the transendothelial delivery of test compounds to a target tissue. As an example, a device was developed that includes two perpendicular channels that cross at a single point. A semipermeable membrane colonized with an endothelial cell monolayer was positioned at the point where the two channels cross. Fluorescently labeled albumin was introduced into one channel and transport through the endothelial monolayer was quantified by laser excitation of the fluorophore in the other channel [48]. In another example, an endothelialized construct was designed with a mechanism to control shear stress experienced by the endothelial cells. The device was used to determine the effect of fluid shear on nanoparticle translocation across the endothelial monolayer. These studies were intended to define the ability of flow and shear stress to model different types of vasculature in terms of the contribution to pharmacokinetics and drug biodistribution [49]. Other microfluidic devices with integrated vasculature have been developed to determine how the atomic structure of drugs and nanoparticles can influence the rate of translocation across an endothelium [50]. The integration of vascular function in organ-on-a-chip microfluidic design shows great promise in providing more accurate modeling of drug pharmacology in next-generation in vitro cell platforms.

Lung-on-a-Chip

The lungs, which represent a fluid−air interface between the aqueous in vivo environment and the extracorporeal environment, serve as a common port of entry for drugs, toxins, pathogens, and other xenobiotic compounds. Accurate modeling of the lung in organ-on-a-chip systems is likely important for relevant modeling of the effects of agents that enter the circulation through the alveoli. Significant advancements have been made in the on-chip modeling of lung tissue [51]. Many of these lung constructs consist of lung epithelial cells and endothelial cells situated on opposing surfaces of a semipermeable membrane. The cellularized membrane forms a barrier that can model the transport of aerosols or vapors from the gaseous alveolar compartment into the aqueous circulatory compartment. Contact of the alveolar epithelial cells with air in the alveolar compartment has the added advantage of promoting normal cellular function and maintaining the differentiated state. In more complex devices, multiple independent pneumatic channels were incorporated into the design. Cyclic deformation of the pneumatic channel walls paired with controlled shear within the fluid channel promoted exceptional cell morphology and function [52,53]. These advanced models have proven to be valuable for modeling several lung pathologies including inflammation, pulmonary edema, mucus plug rupture, alveolar epithelial cell damage, and advanced drug screening [54−57]. Although planar air−fluid interface models have shown incredible promise for modeling exchange across the alveoli and certain pulmonary disease states, more simple, acinar lung organoids may be sufficient for screening drug toxicity for compounds delivered orally or directly into the circulation.

Heart-on-a-Chip

Models for cardiac tissue are generally straightforward in design. The heart's sole function in the human body is to drive the circulation of blood, and most in vitro cardiac models are designed to model this function. Simple monolayer cultures of human cardiomyocytes will beat spontaneously in culture when grown on Matrigel [58]. Sheets of human cardiomyocytes may be layered to produce 3D cardiac constructs that retain the ability to contract in synchrony [59]. These planar construct designs are sufficient for modeling the heart's beating action but are not ideal for modeling 3D mechanics such as contractile force. 3D cardiac constructs consisting of human cardiomyocytes embedded in collagen I hydrogels molded into ring structures self-organize into circumferentially aligned cell architecture and support physiologically relevant action potential propagation [60]. These types of constructs have been integrated into microfluidic circuits to form dynamic, contractile heart-on-a-chip systems [61−65].

Cancer-on-a-Chip

In addition to modeling normal tissue such as liver and heart, excellent models for tumor tissue have been developed. These models have been integrated into microfluidic platforms to form tumor-on-a-chip devices capable of

modeling both tumor growth and metastasis. The microenvironments of tumors are often more complex than their normal counterparts. The ECM often varies greatly from tumor to tumor, and cells within the tumor display varying degrees of reliance on the tumor stroma. Tumors possess a range of degrees of vascularization and have different structural and regulatory protein compositions within the stroma. The physical and biochemical characteristics of tumors can be monitored and controlled using microfluidic and microfabrication techniques. Tumor microphysiological systems derived from a patient's tumor sample can be used to determine the selection of an effective chemotherapeutic agent and an optimal dose on a patient-by-patient basis [66,67].

Advancements in tumor-on-a-chip modeling include the development of integrated hardware to monitor the tumor tissue. These include advanced imaging technology and onboard molecular biology assays that provide detailed characterization of tumor behavior, on-chip. The microscale of on-a-chip systems has been shown to influence cell metabolism significantly. This results from the bioavailability of oxygen within these platforms. Studies demonstrated that microfluidic systems provided greater access to oxygen compared with standard 2D culture systems. This increased oxygen level results in increased Krebs cycle activity and decreased expression of hypoxia-regulated factor-1 [68]. Constant perfusion of with oxygenated media provides a better model for a normal tumor microenvironment.

A device was designed with multiple drug gradient mixers and parallel cell culture chambers to facilitate multidose drug screens. This system was paired with a cell-labeling strategy and high content-imaging data collection on-chip [69]. Another tumor model design includes microscale bioreactors that contain hepatocytes, nonparenchymal cells, and breast cancer cells. This system is intended to simulate the hepatic microenvironment. The device contains oxygen sensors, micropumps for controlling nutrient distribution, and real-time sampling capabilities [70]. This device was used to demonstrate that breast tumor cells will spontaneously become dormant when placed within the hepatic niche. This effect was postulated to result from the microenvironmental cytokine profile created by the presence of hepatic cells within the liver bioreactor. Breast cancer has also been studied using a developed system that includes both the ductal and lobular components of breast tissue [71,72]. This system is intended to model the interaction among these two microanatomical compartments during tumor initiation and progression. In another device, HCT-116 human colorectal carcinoma cells and HepG2 hepatoma cells were encapsulated in Matrigel in separate chambers. Myeloblasts were embedded in alginate gels within an additional chamber to simulate bone marrow. Using this platform, the cytotoxic effects of the 5-fluorouracil (5-FU) prodrug tegafur could be determined for each cell type. Interestingly, using 3D tumor organoids, the liver constructs were able to metabolize tegafur to 5-FU, resulting in cell death within the other two tumor organoid types. Tumor models constructed in 2D were unable to metabolize the prodrug to its activated form [73].

Lung tumor models have also been developed in microfluidic devices. Human non−small cell lung cancer in both 2D and 3D organoid configurations were evaluated for sensitivity to several common chemotherapeutic agents [74]. In another example, lung cancer spheroids were formed from cell lines or derived from patient lung tumor biopsies, both with and without the addition of a pericyte population. Each of these constructs was tested for susceptibility to the drug cisplatin. Systems that included the pericyte population demonstrated higher levels of chemoresistance to the anticancer drug, which indicated the importance of considering all cell types within the tumor when developing an organoid design strategy [75]. These examples of tumor-on-a-chip platforms demonstrate the benefits of 3D organoid models and microfluidic technologies for cancer research as well as patient-specific drug and dose selection.

BODY-ON-A-CHIP: MULTIORGAN SYSTEMS AND FUTURE APPLICATIONS

On-a-chip technologies have gained significant momentum. Although these technologies are relatively new, they have shown great promise for applications in research and drug development. However, systems of increased biological complexity have begun to emerge that feature multiple organoids integrated within a single platform [76−79]. These multiorganoid devices [80], sometimes referred to as "body-on-a-chip" systems, have demonstrated greatly increased potential for modeling relevant physiology compared with single organoid systems. Until recently, these multiorganoid platforms were composed of cell lines and animal cells [73,81] More recent systems have begun to use human primary cells or fully differentiated cells derived from stem or progenitor populations. These human platforms have required the development of more advanced cell substrates and microfluidic devices to support primary cell populations. Several notable published studies have demonstrated complex human multitissue systems. In one such system, a four-tissue circuit was developed in a pumpless microfluidic perfusion platform, housing 2D tissue cultures of liver, cardiac, skeletal muscle, and neuronal integrated within

a single microfluidic circuit. This platform was designed as a screening tool to determine cell toxicity in experiments using doxorubicin, atorvastatin, valproic acid, APAP, and *N*-acetyl-*m*-aminophenol [82]. This pumpless concept was also employed in a dual-tissue gut−liver system including transepithelial electrical resistance sensors to monitor gut epithelial barrier function [83]. In another study, a dual-organoid microfluidic platform was developed with integrated intestine, skin, liver, and kidney epithelial barrier tissue. In that system, basic cellular function, appropriate gene expression, and viability were maintained for 28 days [77]. These examples represent important steps toward systems that can mimic complex, multitissue responses and interactions during drug and toxicology testing.

The Importance of Multiorganoid Integration

In vitro models that recapitulate human tissues and model disease accurately are rare. Fewer still contain multiple tissues integrated in series on a single platform. Such models are required for testing drug toxicity and effects at the organism level, because tissues do not exist in isolation in the body. Moreover, for cells within a microphysiological platform to function normally, it is essential that they receive signals and support, such as vascular, neural, metabolic, and hormonal cues from other cell types. With respect to drugs, effects in secondary tissues can be as important as those at the intended target site, particularly if they induce toxicity. If undetected, detrimental secondary effects can lead to the failure of expensive clinical trials or withdrawal from commercial or clinical use after US Food and Drug Administration (FDA) approval. Multiorganoid platforms are also useful for disease modeling. Cancer metastasis, in which malignant tumor cells are able to migrate to and establish tumors at a secondary site, may be modeled in multiorganoid platforms. Although they are useful for many applications, single-organoid models have a limited ability to model these types of physiologically relevant events. Here, we describe several examples of multiorganoid platforms that demonstrate the importance of these systems.

Cancer

As described earlier, cancer metastasis is a disease process that may be modeled only in a multiorganoid system. In developing metastatic potential, certain tumor cells gain the ability to intravasate through endothelium into the bloodstream or lymphatic system. They may then migrate to a distant tissue and extravasate into a secondary tissue site. Few in vitro systems have been developed that employ a multiorganoid approach to model the kinetics of metastasis. One system developed by our team demonstrated that it is possible to recapitulate the metastatic process in vitro. This metastasis-on-a-chip platform was designed to enable tracking of the migrating metastatic tumor cells from a bioengineered colon organoid to a bioengineered liver organoid within a simple recirculating microfluidic device (Fig. 44.2A). It was shown that metastatic colorectal cancer cells were able to migrate out of the colon tumor organoid into the microfluidic circuit and engraft in the downstream liver organoid. Conversely, a nonmetastatic colorectal cancer cell type proliferated at the primary site but never migrated to the liver within the study time frame [84].

Tumor metastasis-on-a-chip platforms, as described previously, may be composed of multiple organoids that enable tumor cells to metastasize from a primary location to a secondary site. On-a-chip devices have also been designed to assess certain discrete aspects of metastasis. For example, one system includes a microfluidic device that can model the process by which multicellular tumor aggregates migrate through both a collagen matrix and an endothelial cell layer [85]. Another device includes an endothelial cell layer that partitions a microfluidic circuit from a chamber that houses a 3D bone construct. This system allows modeling of the extravasation of metastatic tumor cells from the vasculature into bone [86,87]. Other devices include a system to assess the effects of interstitial pressure on cell migration [88] and a system for screening antiangiogenic drugs [89]. These systems illustrate the potential benefits that on-a-chip cancer technologies are capable of delivering. However, there is still a major lack of platforms that model both the primary and metastatic sites, as well as the barriers that separate these locations (i.e., basement membranes, circulation, ECM, and endothelium) in a single platform. By providing circulating flow through a system containing both vasculature and multiple organoids, recapitulating the migration of tumor cells from primary tumor organoids into the microfluidic circulation and engraftment into a downstream target organoid may be accomplished. The results of these systems seem to be well-aligned with what is seen clinically. For example, this system has demonstrated that colorectal cancer cells preferentially engraft into liver organoids, a well-established target tissue for colorectal metastatic tumors [84]. These examples represent several components of the metastatic process that have been modeled in multiorganoid systems; future studies will likely rely on these types of platforms to uncover other factors that influence metastasis.

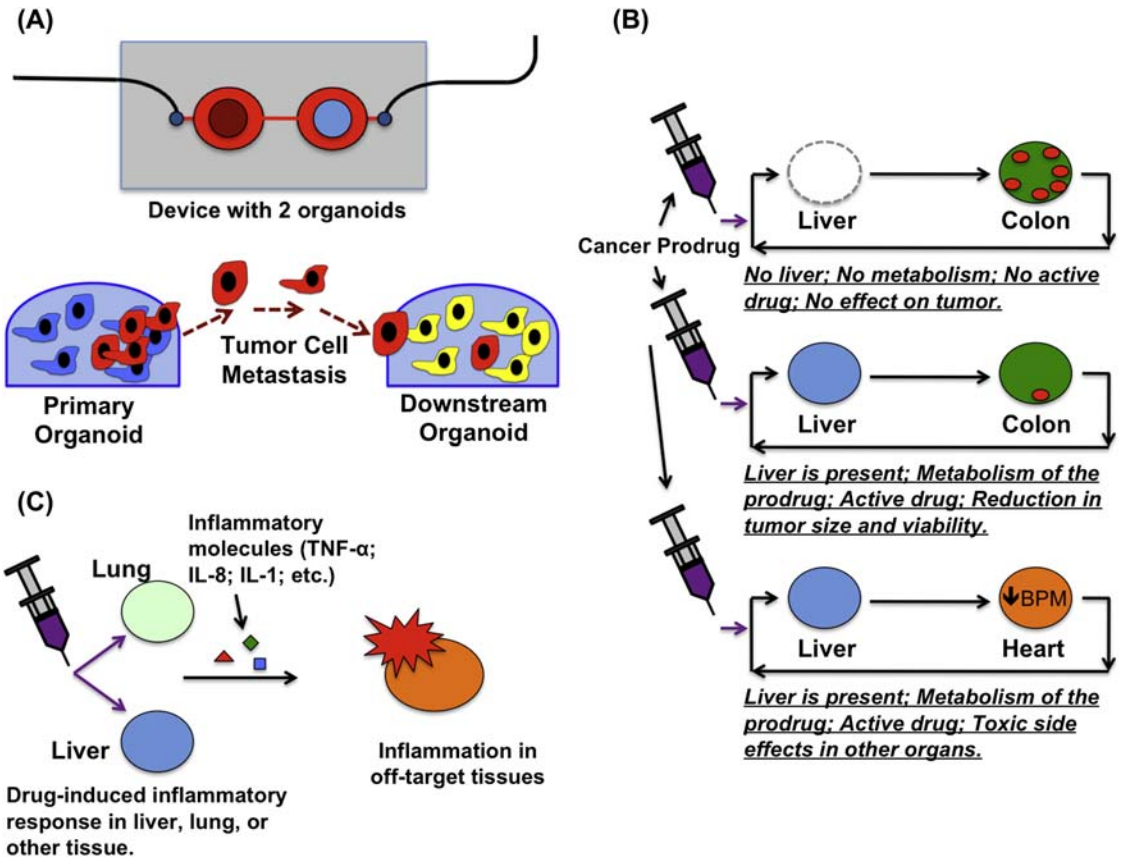

FIGURE 44.2 **Examples of multiorgan interactions that cannot be modeled with single-organoid systems.** (A) Migration and metastasis of tumor cells from one organ or organoid site to another, demonstrated in vitro in a metastasis-on-a-chip device in which colorectal carcinoma metastasizes from the colon to the liver. (B) Reliance of a prodrug therapy such as the anticancer 5-fluorouracil prodrug tegafur on liver metabolism to activate the drug to generate a positive effect by targeting tumor cells successfully. (C) Inflammatory molecules secreted from organs such as the liver and lung upon drug injury can cause detrimental inflammatory responses and cell injury in downstream tissues. *BPM*, beats per minute; *IL*, interleukin; *TNF-α*, tumor necrosis factor- α.

Drug Testing and Toxicology

As has been discussed throughout this chapter, a major area of interest addressed by the body-on-a-chip field is understanding how multiple organs and tissues respond to the administration of particular drugs within an integrated platform. A variety of examples demonstrate this concept. For example, 5-FU is a common chemotherapy agent employed in treating colorectal cancer. Unfortunately, 5-FU can induce a variety of detrimental side effects in patients, including cell damage in the gastrointestinal tract. In an attempt to reduce toxicity, several prodrugs have been developed, such as tegafur. Tegafur and other prodrugs are inactive in the administered form. The prodrug is activated by hepatocytes in the liver to 5-FU that are able to kill tumor cells. Consequently, without including a metabolically active liver organoid in the system, no active drug would be produced and experimental results would be irrelevant. Including functional liver organoids, along with intended target tumor cells and potential tissues that may experience unwanted toxicity, a more complete understanding of the benefits and risks associated with administration of a chemotherapeutic agent may be determined (Fig. 44.2B).

Additional strides are being made toward deploying organoids and organ-on-a-chip technologies in drug and toxicology screening applications. For example, our group demonstrated the use of 3D cardiac organoids in screening for drugs and toxins. We consistently observed expected changes in cardiac beat kinetics in response to these compounds. By employing a minimicroscope with custom-written software to analyze cardiac beating kinetics, the precise determination of beat frequency and magnitude could be recorded [64]. These toxicity screening efforts were expanded to include both cardiac and liver organoids, assessing toxic outcomes from a panel of environmental toxins and a set of drugs that were recalled from the market owing to unanticipated toxicity in human patients (Fig. 44.3). Fig. 44.4 highlights some of these studies, in which the dual-organoid systems were able to model

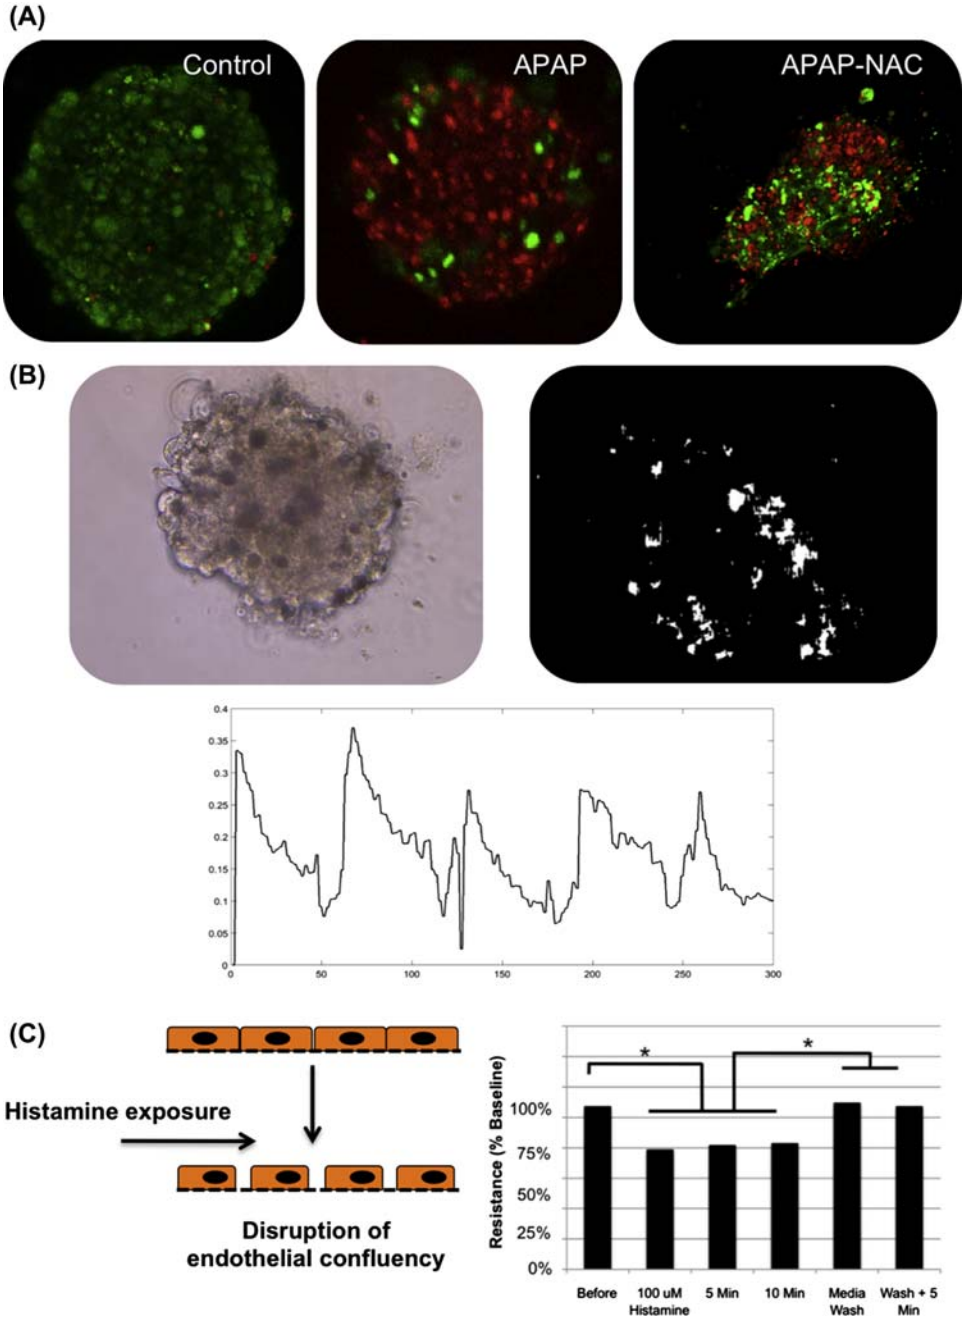

FIGURE 44.3 **Highly functional organoids for a multiorganoid body-on-a-chip platform.** (A) Acetaminophen (toxicity in liver organoids and reduction in toxicity by *N*-acetyl-L-cysteine. (B) Cardiac organoids remain viable long-term and support transport of fluorescent dyes (lucifer yellow [*yellow stain*] and fluorescein [*green stain*]) through interconnected ion channels suggesting high levels of cell–cell communication. (C) Beating analysis of cardiac organoids: An onboard camera captures video of beating organoids, after which beating rates are calculated by quantifying pixel movement, generating beat plots. (D) Vascular endothelium devices respond to changes in endothelium integrity as measured by a transendothelium electrical resistance sensor. Organoid diameter - 250 μm.

these toxicities. In addition, the integration of different tissue organoids into a singular system allows for screening studies that can identify unanticipated toxicities (Fig. 44.2C) [90].

Additional Disease Modeling

Research into human pathologies other than cancer may also benefit from the capabilities of multiorganoid systems. Many drugs and that are known to cause inflammatory responses. For example, large doses of the common analgesic APAP (Tylenol) causes significant inflammation and toxicity in the liver. Other drugs, including

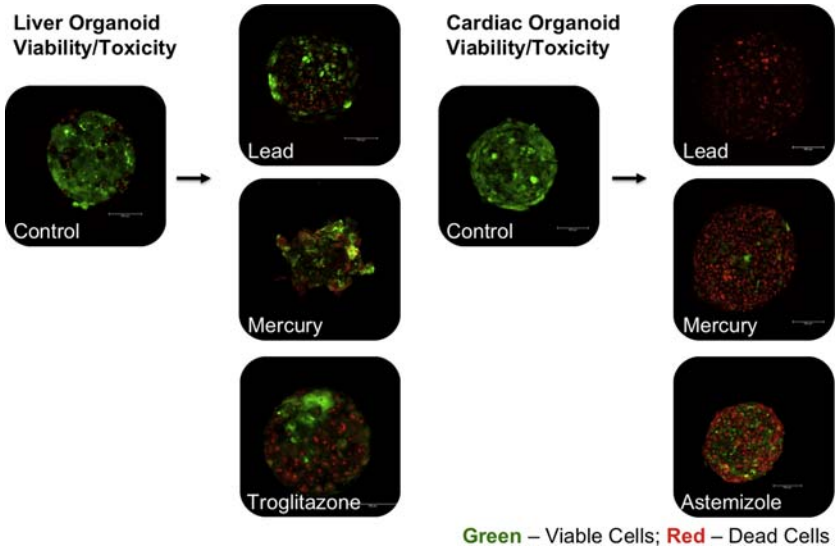

FIGURE 44.4 **Drug and toxicology screening in liver and cardiac organoids.** Live/dead stains show the presence of dead cells (*red*) after treatment with lead, mercury, troglitazone, or astemizole. Organoid diameter - 250 μm.

chemotherapeutics such as bleomycin, cause inflammation, toxicity, and irreversible fibrosis in the lungs or other organs. In most of these cases, toxicity and apoptosis lead to the release of proinflammatory cytokines such as tumor necrosis factor-α and interleukin-1 into the circulation. These molecules can cause a series of downstream responses, including recruitment of inflammatory cells, activation of fibroblasts, and changes in vascular protein expression and permeability (Fig. 44.4C). Integrated multiorganoid model systems, including integrated vasculatures, can model these complex, multiorgan drug responses in a reproducible and physiologically relevant manner, whereas single organoid systems cannot.

Cutting-Edge Body-on-a-Chip: The First Highly Functional Multiorganoid Systems

As described previously, there is a paucity of truly integrated multiorganoid platforms that are able to model and test the complex responses accurately to drugs, toxins, and disease across a range of human tissue types. However, progress is being made.

The Ex Vivo Console of Human Organoids Platform

Our team has developed an advanced, modular, multiorganoid integrated, body-on-a-chip system for use in drug development and toxicology screening. The multiorganoid body-on-a-chip platform is named Ex Vivo Console of Human Organoids (ECHO). This platform was initially developed to include four engineered tissue organoid types (liver, cardiac, vascular, and lung), which were developed independently and integrated into a single system that provides real-time monitoring of physiological responses to toxic agents and pharmaceuticals.

Using the ECHO platform, a comprehensive set of data was developed providing a characterization of each organoid. In general, the 3D organoids are bioprinted into platform microreactors using tissue type−specific supportive hydrogels. The result is an array of organoids suspended in a substrate containing tissue-specific, ECM-derived bioregulatory factors [36,91]. Liver organoids are fabricated using liver ECM−derived hydrogels that maintain viability and function in vitro for 4 weeks [91]. The production of important liver markers (e.g., albumin, multiple cytochrome P450 enzymes, epithelial cell−cell adhesion markers, dipeptidyl peptidase IV, organic solute transporter-α, etc.) have been confirmed and are stable over a month. These organoids respond to toxins such as APAP at appropriate doses and in a dose-dependent manner. The organoids may also be rescued by the clinical countermeasure for APAP intoxication, *N*-acetyl-L-cysteine (Fig. 44.4A). Cardiac organoids also remain for 4 weeks and beyond. These organoids demonstrate the transport of fluorescent dye molecules among cells within the organoids, indicating a high degree of cell−cell communication. The organoids beat spontaneously and change their beating rates appropriately in response to a variety of drugs. These kinetics are captured using an onboard camera system [92,93] and custom software for analysis (Fig. 44.4B). In addition, an engineered vasculature has been incorporated into the platform that responds to agents such as histamine by disrupting the endothelial cell monolayer

(Fig. 44.4C). This results in increased transendothelial transfer of larger−molecular weight molecules that are normally sequestered within the microfluidic circuit.

Several integrated, multiorganoid studies were performed using the ECHO platform. Experiments including integrated liver organoids, cardiac organoids, and endothelial modules in microfluidic devices (Fig. 44.5A and B) under common media demonstrated long-term viability and produced multiorganoid responses to drugs that largely mimic the responses that would be expected in an experimental animal, or even in a human. For example, Fig. 44.5C describes the effects of propranolol and epinephrine on cardiac organoids, both with and without integrated liver organoids in the microfluidic platform. Normally, epinephrine induces an increase in the beating rate in cardiomyocytes. Without liver, propranolol, a β-blocker, blocks the β1- and β2-adrenergic receptors, preventing an increase in the cardiac beat rate after epinephrine administration. However, in the integrated system that includes the liver organoids, propranolol is metabolized to an inactive form, resulting in the recovery of much of the epinephrine-induced increase in beat rate. To our knowledge, these experiments are the first interdependent multiorganoid studies performed successfully in a single integrated system.

The ECHO platform has been used to screen drugs that were withdrawn from the market owing to unanticipated toxicities. Because of the lack of accurate models to predict drug toxicity, many drugs have passed through preclinical studies and clinical trials, received FDA approval, and remained on the commercial market for years in some cases, before being recalled because they cause toxic effects in humans. Approximately 90% of drugs that were removed from the market were because of toxic effects in the liver and the heart. A panel of these drugs were tested in the ECHO platform. These include the drug troglitazone (Rezulin), an antidiabetic and antiinflammatory that was recalled for causing liver failure, and mibefradil, an ion channel blocker that was recalled for having fatal interactions with other drugs, including antibiotics. In our platform, troglitazone and mibefradil both result in liver toxicity. We also screened the drug rofecoxib (Vioxx), a nonsteroidal anti-inflammatory drug that was recalled because it caused serious vascular-based pathologies such as heart attack, stroke, skin reactions, and gastrointestinal bleeding. Astemizole, an antipsychotic that caused slowing of potassium channels, torsade de pointes, and QT prolongation. We also tested terodiline, a drug for bladder incontinence that caused QT prolongation and toxicity, in ECHO and showed functional changes and loss in viability among several cell types within the platform. The anticancer drug 5-FU and isoproterenol, a β-adrenergic agonist, both of which are known to induce cardiac toxicity, were evaluated in ECHO. Each of these drugs resulted in increased levels of cell death within the cardiac organoids in a dose-dependent manner. Using the onboard camera, beating effects were observed to decrease with dose increases as well. Effects on beat kinetics were detected at doses well below the toxic threshold. This is an important point, because drugs withdrawn from the market for cardiac toxicity are generally not withdrawn for killing cells in the heart, but rather for causing changes in heartbeat kinetics.

Other Body-on-a-Chip Programs

In addition to the ECHO platform initiative, a variety of other high-profile programs have been working to develop integrated systems. In particular, the Advanced Tissue-Engineered Human Ectypal Network Analyzer (ATHENA) program designed a millimeter-scale multiorganoid system, and a program sponsored by the Defense Advanced Research Projects Agency (DARPA) sponsored a 10-organoid project [94].

These projects have stressed aspects of microphysiological systems that are often different from the main goal of ECHO (i.e., organoid integration within a common microfluidic circuit). Specifically, the ATHENA program, which is based in Los Alamos National Laboratory, developed a system composed of four organs: liver, heart, lung, and kidney [95]. These organoids are three orders of magnitude larger than the ECHO organoids. This scale allows for more relevant mechanical testing and the system fluid volume is sufficient to collect samples that may be analyzed using standard clinical diagnostic equipment. The DARPA program, based in Harvard's Wyss Institute, is working with a collection of 10 organoids, including representations of endocrine, gastrointestinal, immune, musculoskeletal, and reproductive tissues [96].

In addition, the NIH are supporting a major organ-on-a-chip program through the National Center for Advancing Translational Science, the National Institute for Biomedical Imaging and Bioengineering, the National Cancer Institute, the Eunice Kennedy Shriver National Institute of Child Health and Human Development, the National Institute of Environmental Health Sciences, the NIH Common Fund, and the NIH Office of Research on Women's Health. However, the NIH initiative differs in that the funding is divided among a variety of individual research laboratories; between them, they are working on organoid representations of a wide range of tissue types [97]. The

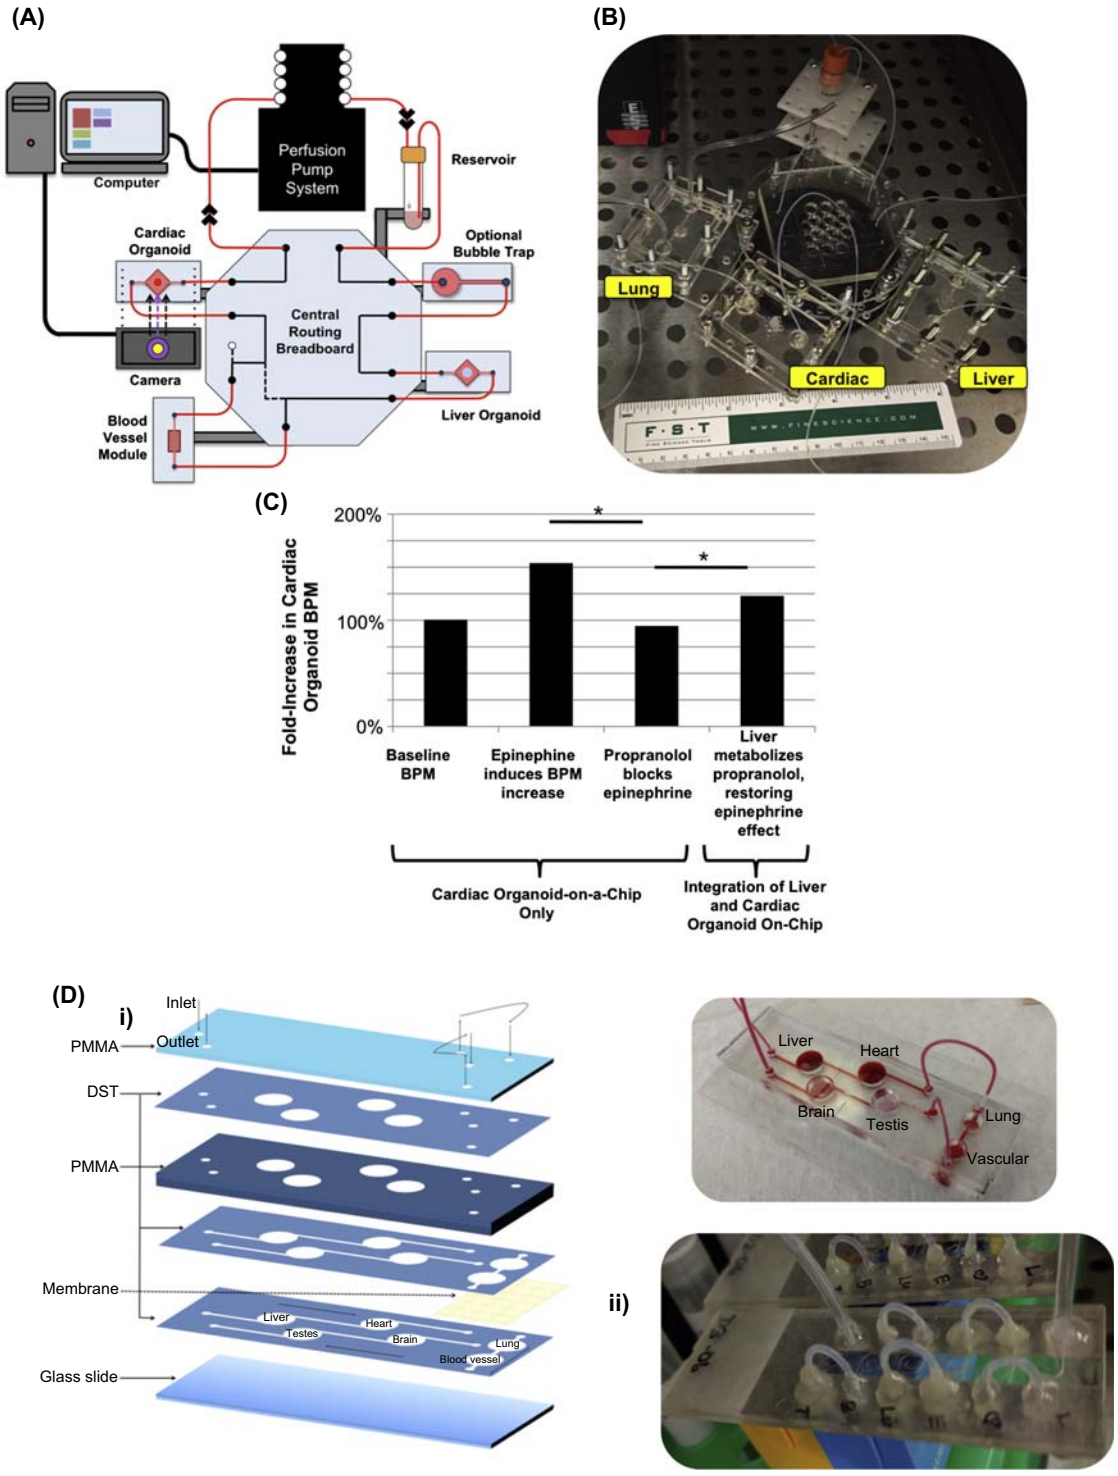

FIGURE 44.5 **Multiorganoid body-on-a-chip.** (A) Depiction of a liver, cardiac, and vascular organoid-containing body-on-a-chip platform. (B) Photograph of the three-organoid system. (C) Description of the effects of propranolol and epinephrine on cardiac organoids, with or without liver organoids, illustrating the importance of multiorganoid systems. Without liver, propranolol, a β-blocker, blocks cardiac beating increases by epinephrine. However, with both organoids present, propranolol is metabolized by the liver organoid, resulting in a measurable epinephrine-induced increase in beating rates. (D) (i, ii) Future body-on-a-chip platforms for increased capabilities for linking multiple organoids within a single circulatory system. *BPM*, beats per minute; *DST*, double-sided tape; PMMA, poly(methyl methacrylate).

program stresses the derivation of organoids from induced pluripotent stem cells (iPSCs), and many of the organoids developed by members of this program are excellent models for specific tissue types. However, the potential for integrating these organoids into a multiorganoid system remains to be seen.

Organ-on-a-Chip Systems for Personalized Precision Medicine

Numerous in vitro systems are being developed for general drug development screening, but few have been developed to benefit specific patients. This is an unmet clinical need, because finding the most effect drug and dose for a specific patient is often a trial-and-error process. With personalized organoid models (Fig. 44.6A and B), therapies can be screened using a patient's own cells in a 3D tissue organoid system. For example, accurately predicting a patient's tumor progression and response to therapy is one of the most challenging aspects of oncology. Prescribed treatments are often made based on the general success rate of a drug within a population, not on the specific response that may be expected within an individual. The concept of precision, or personalized, medicine has evolved to address these problems by using the patient's genetic profile to identify "druggable" targets for treatment [98–100]. However, in real-world practice, the results of this approach to personalized medicine do not reach the desired goals [101]. After identifying key mutations through genetic profiling, physicians can still be left with a variety of drug options, with no concrete data regarding potential side effects or actual drug effectiveness in the patient. As such, there is a clear need to develop tools that can predict the response of individual patients to drugs [102,103]. Our group is working to develop a multiorganoid platform that contains patient-specific tumor organoids, and in which drug therapies that are selected based on genetic profiling can be tested for efficacy. By using

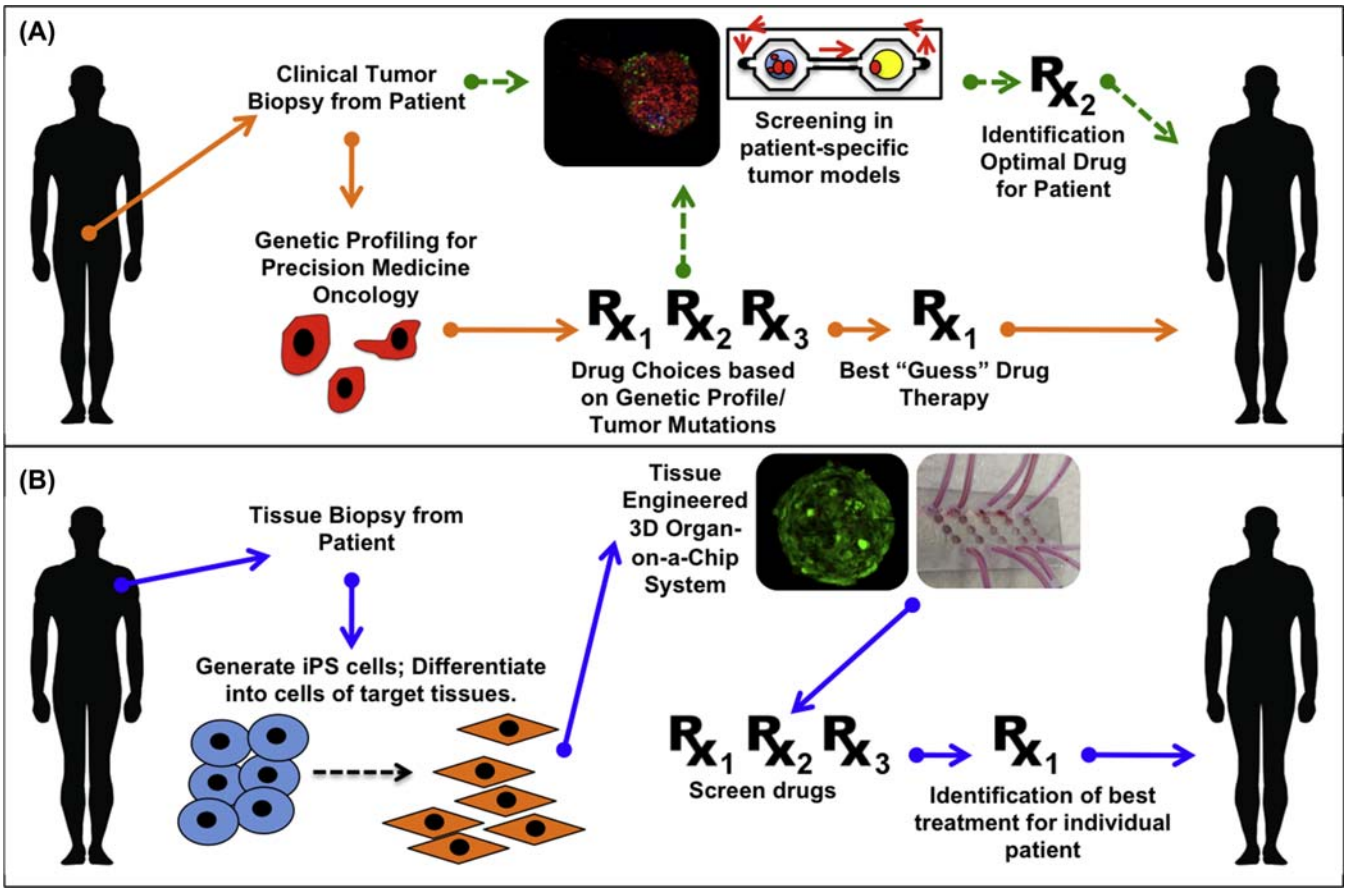

FIGURE 44.6 **Employing biofabricated tissues in personalized medicine.** (A) In personalized precision medicine for cancer patients (*red arrows*), a potential list of drugs is determined based on mutations found in the tumor genetic profile, from which best-guess therapies are prescribed. In the future, cells from tumor biopsies could be used to create in vitro tumor models specific to a given patient (*green arrows*). Potentially effective drug therapies can then be screened in the models, thus identifying the optimal drug therapy for that patient in terms of both safety and effectiveness. (B) In genetic diseases, cells can be harvested from alternative tissues, such as skin, translated into induced pluripotent stem cells (iPS), differentiated into cells of the tissue of interest (e.g., lung or heart), and bioengineered into three-dimensional (3D) organoids and organoid-on-a-chip systems, after which generic and genome-specific drug therapies can be screened for the original patient.

microfluidic devices, a circulatory system containing multiple tissue organoids may be fabricated. This may allow for the prediction of tissues to which metastatic cells will migrate [84]. By combining all of these capabilities described, it may soon be possible to generate accurate prognoses regarding tumor progression and metastases and to develop an informed treatment plan that is personalized to each patient's tumor. In the near future, iPSC technology may allow for the generation of an array of patient-specific normal tissue organoids that could provide information about the sensitivity of these tissues to a specific treatment regimen. This would enable the selection of an agent that reduces stress on the healthy tissues within a cancer patient. These exciting and powerful new in vitro technologies may soon revolutionize the treatment of cancer and other diseases.

CONCLUSIONS AND PERSPECTIVES

Although the benefits of multiorganoid systems are clear, several challenges remain regarding their acceptance and widespread deployment for drug development and personalized medicine. Most single cell−type systems do a respectable job in mimicking a few specific aspects of in vivo physiology and are amenable to high-throughput drug screening. The few single- and multiorganoid platforms, including multiple cell types within each organoid, provide a much better model for human physiology but have not yet been optimized for high throughput [104]. As such, these more complex systems are best-suited for evaluating drugs that are in the later stages of development. Many groups are actively developing strategies for multiorganoid systems and automating their production [14]. A significant reduction in size, automated fabrication, improved onboard biosensing, and in-line diagnostic technology would greatly increase the throughput potential for multiorganoid platforms across all potential applications [92,93,105,106]. Another perceived challenge in the development of advanced, multiorganoid, platforms is the requirement of a common cell medium to support a wide variety of cell phenotypes. Typically, human primary cells and iPSC-derived cells require complex, highly specialized media formulations that are tailored to each specific cell type. Surprisingly, there is growing evidence that 3D cell constructs are intrinsically supportive and much less reliant on complexed media supplements or serum. Our group has repeatedly demonstrated the maintenance of a variety of cell types in human cancer models [84,107] using serum-free medium and customized hydrogen substrates [36,91,108]. Even more remarkable is the ECHO platform described earlier in this chapter. In this platform, up to six organoid types, each containing up to five human primary cell types, have been maintained under a serum-free common medium for at least a month with minimal loss in viability and function. It is likely that the organoids themselves produce the autocrine and paracrine factors that are required for long-term viability and function. The compact architecture, scant interstitial space between cells, and accumulation of ECM proteins would allow these factors to become concentrated within each organoid and diminish reliance on exogenous factors delivered through the medium. Multiorganoid body-on-a-chip technology is advancing at a rapid pace and is likely be deployed soon for drug screening [10]. These platforms have significant utility in many areas and will dramatically change the way in which precision medicine, cancer modeling, and drug development are performed.

Bioreactors in Regenerative Medicine

Jinho Kim, Kelsey Kennedy, Gordana Vunjak-Novakovic

Columbia University, New York, NY, United States

INTRODUCTION

The goal of regenerative medicine is to restore the structure and function of damaged, diseased, or lost tissues and organs. Most human tissues have limited regenerative capacity after injury and heal with scar formation or inflammation [1]. Accordingly, approaches to regenerative medicine use tissue-specific cells, biomaterials, and biologically active molecules to enhance regenerative responses and promote the formation of matured and functional tissues. In particular, tissue constructs and whole organs can be produced in vitro by providing physiologically relevant culture conditions and by subjecting the cells to biomimetic physical and biochemical cues [2]. By closely recapitulating the native environments of tissue development, bioreactors can provide conditions for growing fully functional and viable tissues and organs for transplantation in vitro (Fig. 45.1).

DESIGN CONSIDERATIONS FOR CREATING BIOREACTORS

When appropriate conditions are provided, cells can survive and grow, and eventually form tissue units outside the body. Conventional two-dimensional (2D) cell culture protocols enable the efficient generation of cells with controllable properties and phenotypes, but simple cell assemblies grown on 2D surfaces would be insufficient for applications in regenerative medicine, which typically require three-dimensional (3D) and functional tissue constructs. Using a bioreactor, physiologically functional 3D tissues can be bioengineered in vitro by recreating the microenvironmental and macroenvironmental niche conditions to cells seeded into scaffolds such as the extracellular matrix (ECM) [3]. To this end, several physical and biological aspects must be considered in designing bioreactor systems to produce tissues or even whole organs with desired physiological properties.

To promote cell viability, proliferation, and differentiation, it is essential to provide adequate amounts of oxygen, nutrients, and biochemical factors to the cells or tissues cultured in a bioreactor. In addition, metabolic waste generated by the cells must be removed effectively to further facilitate cell and tissue growth. As the cell density and tissue size increase, mass transfer through bioengineered constructs becomes challenging. Under static culture conditions, diffusion is the major mechanism for the transport of nutrients, most critically oxygen. However, diffusional transport is efficient only within a superficial layer (usually about 100–200 μm) of the 3D tissue constructs, which can be at least several millimeters to centimeters thick. Accordingly, to enhance the efficiency of gas and mass transfer, convective flow can be generated within bioreactors by stirring, rotating, or perfusing culture medium [4–6].

Mechanical forces can regulate the physiology of cells, in particular osteocytes, chondrocytes, cardiomyocytes, and skeletal muscle cells, via mechanotransduction pathways by which mechanical signals are converted into biochemical signals [7]. Thus, tissue formation and development can be promoted by mechanical stimuli, motivating the use of various mechanical stimulation regimes to regenerate tissues and organs with desired properties. For example, tissue-engineered cartilage with enhanced functionality was produced by applying physiological levels of compression to hydrogels seeded with articular chondrocytes [8,9]. Similarly, enhanced cell proliferation and tissue organization were achieved by repeatedly stretching scaffolds embedded with heart cells [10] or skeletal muscle cells [11]. Shear forces induced by fluid flow increased osteogenic expression and chondrogenic responses [12].

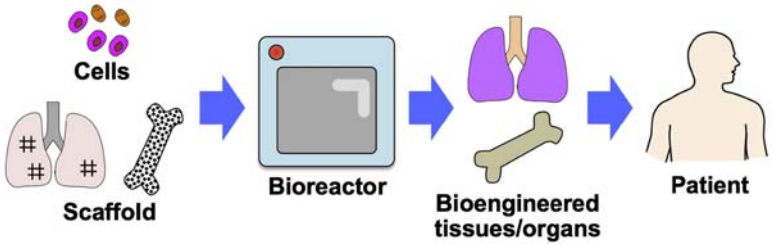

FIGURE 45.1 **Schematic of tissue or organ regeneration in vitro using bioreactor systems.**

Cell behaviors such as proliferation, differentiation, and migration can also be influenced by electrical stimulation in electrically excitable cells [13]. In particular, when appropriate electrical stimulation is applied, cardiomyocytes cultured in vitro, combined with biomaterials such as collagen, can differentiate and form into functional cardiac tissue constructs [14]. Development of contractile and electrophysiological function in bioengineered tissue constructs can be facilitated by cyclic electrical stimulation and mechanical strain. Tissue contractions resulting from the stimuli can promote cell elongation, orientation, organization of connexin-43, and the formation of structural features similar to those of native myocardium. The electrical stimulation also increases the expression of myosin heavy chain, creatine kinase-MM, and cardiac troponin-I in the bioengineered cardiac constructs. Notably, the positive effects of the electrical stimulation on tissue development strongly depend on the time of its initiation, which indicates that the timing of stimulation must be carefully determined to bioengineer cardiac tissues [15].

In addition to physical stimuli, regeneration of tissues and organs of interest requires the addition of biochemical cues that can modulate cellular and tissue behaviors [16], in particular, soluble biochemical factors such as growth factors and cytokines that are provided to local cells through secretion from neighboring cells or through supply from the blood instruct cells during development and tissue regeneration [17]. Because the concentration and spatial gradient of the biochemical factors strongly influence the microenvironment that dictate the fates of the cells, tight control of the biochemical parameters within the in vitro system is essential to obtain tissue and organs for specific applications.

In the body, cells reside in a complex 3D microenvironment that is composed of tissue- and organ-specific cell types, the ECM, and physical and biochemical factors Accordingly, the regeneration of tissue and organs for transplantation requires 3D scaffolds, in which cells seeded are provided with a biomimetic niche microenvironment that can promote the formation of functional tissue or reconstruct viable organs [18]. Various synthetic ECM materials such as poly(ethylene glycol) and poly(vinyl alcohol), which are typically soft and porous and have a high water content, have been employed as scaffolds that can facilitate the organization of cells into a 3D architecture by presenting the necessary structural, physical, and biochemical characteristics [19]. On the other hand, biological scaffold materials obtained from the native ECM have been shown to promote regeneration of functional tissues greatly [20]. Although the mechanisms mediating the cell behavior by the natural ECM are not well-understood, ECM derived from many different tissues such as heart, blood vessels, skin, and tendons have been tested in both preclinical and clinical applications [18].

Methods that allow monitoring of the tissue growth and maturity, and generation of tissue- and organ-specific functionalities are needed for the successful applications of bioengineered tissues and organs in regenerative medicine [21]. Typical assays that are used to analyze the structure and biochemical composition of the tissue, such as histology and microscopy, involve tissue-sampling procedures, which is destructive in nature. On the other hand, advanced imaging techniques such as molecular imaging and deep-tissue imaging techniques allow noninvasive assessment in vitro and enable real-time and long-term evaluation of bioengineered tissues and organs.

LUNG BIOREACTORS

Bioengineering Functional Lungs

For many patients with end-stage lung disease, lung transplant is the only definitive treatment option available. Although timely organ transplant is important to increase the life span and overall life quality of the recipients, this treatment procedure is significantly hampered by the severe shortage of viable donor lungs [22]. Furthermore, less than 20% of donated lungs are acceptable for transplant whereas the rest are unsuitable because of poor lung

conditions caused by various reasons including contusion or edema [23]. Accordingly, to increase the number of lungs suitable for transplant, tissue-engineering methods are being developed to salvage donor lungs that are marginally unacceptable and rejected for transplant. In these approaches, endogenous cells in the donor lungs are replaced with fresh cells to restore the lung function to a level acceptable for transplant.

Important processes for lung regeneration using tissue-engineering technologies include (1) removal of the cellular components from the donor lungs (i.e., decellularization), and (2) repopulation of the resulting lung scaffold with the new cells such as lung airways cells or stem/progenitor cells (i.e., recellularization) [24]. The 3D lung scaffold provides organ-specific environment with structural and biochemical cues for the transplanted cells to facilitate lung remodeling and regeneration. In particular, functional ECM components preserved in the decellularized lung matrix, such as collagens, elastin, fibronectin, laminin, and glycosaminoglycans, can promote cell engraftment and differentiation during recellularization.

For the accelerated regeneration of viable and functional lungs, a bioreactor is an essential component that can offer suitable environments to the bioengineered lung [25]. For instance, normothermic (37°C) perfusion and sterile support of the lungs during reconditioning can be achieved by using a bioreactor. An ideal bioreactor would provide mechanical and biochemical cues to the lungs mimicking physiological stimuli during the native lung development. Furthermore, physically and biologically relevant conditions including the air−liquid interface and breathing movement should be generated in the lung bioreactor to promote precisely regulated differentiation and organization of the transplanted cells in the lung scaffolds created by decellularization.

Bioreactors for Regeneration of Small Animal Lungs

Because of their relatively easy access, lungs harvested from small animals such as rodents [26,27] have been widely used to establish protocols for lung tissue engineering (Fig. 45.2A). Accordingly, various lung bioreactors

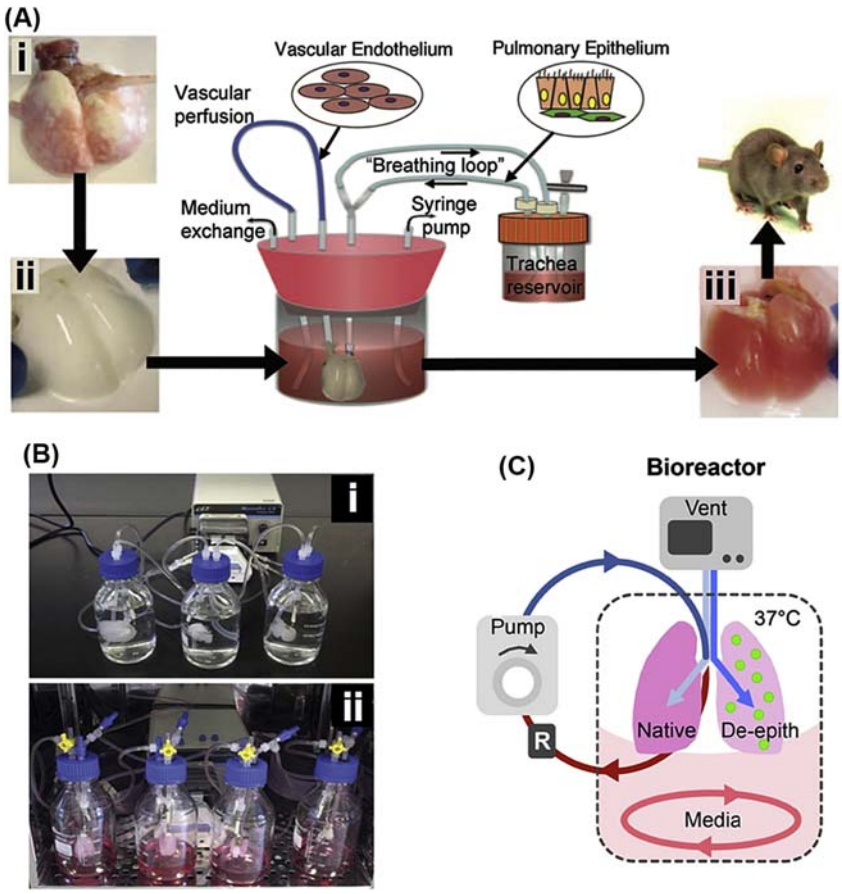

FIGURE 45.2 **Bioreactors for ex vivo regeneration of small-animal lungs.** (A) Schematic for lung regeneration process [26]. (B) Photograph of bioreactors for (i) decellularization and (ii) recellularization of rat lungs [28]. designed for small animals have been evaluated for the long-term preservation of explanted lungs during cell-based organ regeneration via decellularization followed by recellularization (Fig. 45.2B). It is imperative that the lung bioreactors provide physiologically relevant conditions (e.g., sterile conditions, isothermic perfusion, and air ventilation) to the lungs throughout the regeneration procedures.

While lungs are kept in a bioreactor, chemical or biological decellularization agents can be perfused sequentially through the airways and vasculatures to remove entire cellular components from the lungs [30]. This perfusion-based decellularization requires precisely controlled fluid flow to maximize preservation of the structural integrity and biological activity of the lung ECM. Decellularization agents include detergents such as 3-([3-cholamidopropyl] dimethylammonio)-1-propanesulfonate, sodium dodecyl sulfate, and Triton X-100 and enzymes such as nuclease, trypsin, and collagenase. After cell removal, the lungs are seeded with therapeutic cells (e.g., epithelial and endothelial) through the airway and vasculature. During recellularization, the lung is ventilated and perfused, respectively, via ventilator and pump integrated into the bioreactor, recapitulating physiological lung developmental conditions (Fig. 45.2C).

A novel bioreactor for the rat lungs was developed in which one lobe of the lung could be bioengineered while the other one remained intact to serve as a control [29]. This bioreactor allowed removal of the epithelial cell layer (de-epithelialization) from the airways of the small animal lungs (i.e., rat) while the underneath lung tissue was preserved (Fig. 45.3D). The selective cell removal was achieved by introducing a mild decellularization solution through the airway while the solution entering the blood vessels was quickly cleared by continuously perfusing the vasculature. As a result, the vasculature network in the lung could be maintained undisrupted, allowing structural and biological integrity of the blood−gas barrier that facilitated bioengineering of functional lungs after reepithelialization.

Bioreactors for Regeneration of Large Animal Lungs

To generate bioengineered lungs on a clinically relevant scale, bioreactors have been developed that could maintain the function of large-animal lungs (e.g., porcine and human) during ex vivo regeneration [31,33,34] (Fig. 45.3A and B). Similar to bioreactors for small animal lungs, these clinical-scale bioreactors allow sterile, normothermic perfusion and ventilation to promote lung regeneration and functional recovery. In addition, large-lung bioreactors have been further optimized to support the lungs for a sufficient time to allow diagnostic and therapeutic interventions that would be needed to improve marginal lungs. Automated lung perfusion and ventilation with integrated sensors (e.g., flow, pressure sensors) and lung monitoring components (e.g., video cameras) into the bioreactor would be desirable to achieve more tightly controlled lung regeneration.

Whereas ex vivo lung perfusion (EVLP) has typically been used to preserve donor lungs during transport, its utility for assessment and reconditioning of marginally unacceptable donor lungs has also been pursued (Fig. 45.3C). Benefits of using EVLP include the recruitment of collapsed lung areas, removal of bronchial secretions, and clearing of clots from the circulation. In addition, because the lungs are connected to the EVLP system externally, direct and targeted treatments of the lungs are possible via endotracheal and intravascular routes. Owing to the absence of other organs in the circuit, higher doses of therapeutics for accelerated disease treatment can be administered to the lungs supported by EVLP (Fig. 45.3C). However, the lack of other organs also implies that the metabolic clearance and systemic factors are absent. Nevertheless, EVLP systems have served as excellent platforms for human lung support and bioengineering [35]. The adaptation of EVLP for reconditioning marginal donor lungs increased the total number lung transplants at least by 15% [36].

In Vivo Bioreactors for Lung Regeneration

Allogeneic solid organ transplants typically require nonspecific and lifelong immunosuppressive therapy to prevent and treat organ rejection. Although immunosuppression improves graft survival, the patient becomes susceptible to infections, in particular to pulmonary infections that may cause morbidity and mortality [37]. An effective approach to reducing the immunogenic response would be using the recipient as an "in vivo bioreactor," in which donated organs or tissues are implanted heterotopically, thus taking full advantage of the natural regenerative capacity of the recipient's body [38]. This elegant method was demonstrated for trachea (Fig. 45.4A), with the donor trachea implanted subcutaneously into the recipient's forearm for over 9 months. During this time, the neovascularization occurred and the endogenous mucosal lining was partially replaced with the recipient's own buccal mucosa. After transplantation of the regenerated trachea, the immunosuppressive therapy was suspended and the recipient's

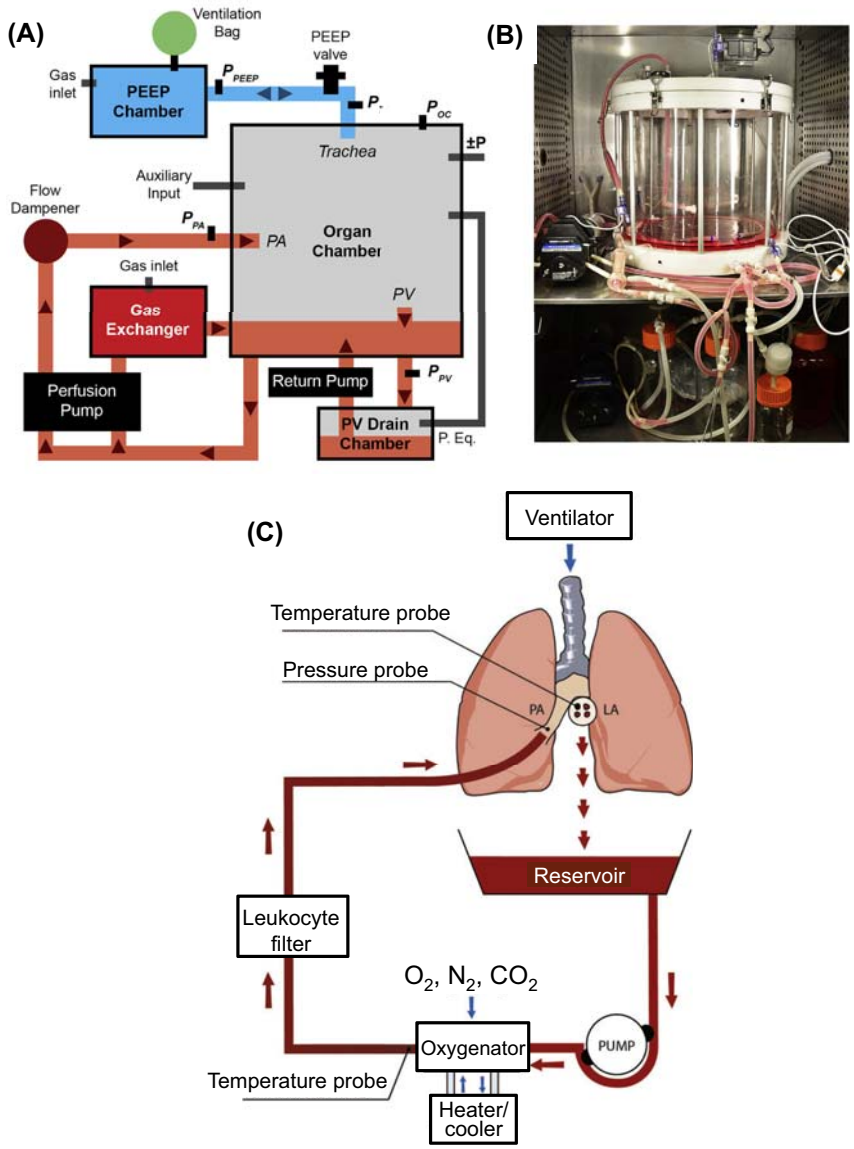

FIGURE 45.3 **Bioreactors for ex vivo regeneration of large-animal lungs.** (A) Schematic layout of a clinical-scale lung bioreactor and (B) photograph of the bioreactor setup in an incubator [31]. (C) Schematic drawing of an ex vivo lung perfusion (EVLP) unit [32]. *LA*, left atrium; *P.Eq.*, pressure equilibrium; *PA*, pulmonary artery; *PEEP*, positive end-expiratory pressure; *PV*, pulmonary vein.

buccal mucosa gradually grew over the graft. Significantly, the allogeneic trachea was stable and functional for several years even after immunosuppression was discontinued [39,41].

Smaller tissues or organs such as trachea and bone segments can be heterotopically regenerated within the recipient's own body before orthotopic transplantation. However, this in vivo approach can be difficult for the regeneration of solid organs such as whole lungs or liver owing to their large size and the need for perfusion. A potential solution for this can be cross-circulation (extracorporeal circulation), in which donor organs are connected externally to the recipient's circulatory system during organ recovery or repair [42,43]. Using a preclinical swine model, this novel cross-circulation approach has been demonstrated for prolonged lung support during therapeutic interventions undertaken to recover the injured donor lungs [40] (Fig. 45.4B and C). Because the donor organ is placed outside the recipient's body, the organ is more accessible for diagnostic and therapeutic interventions that can improve the

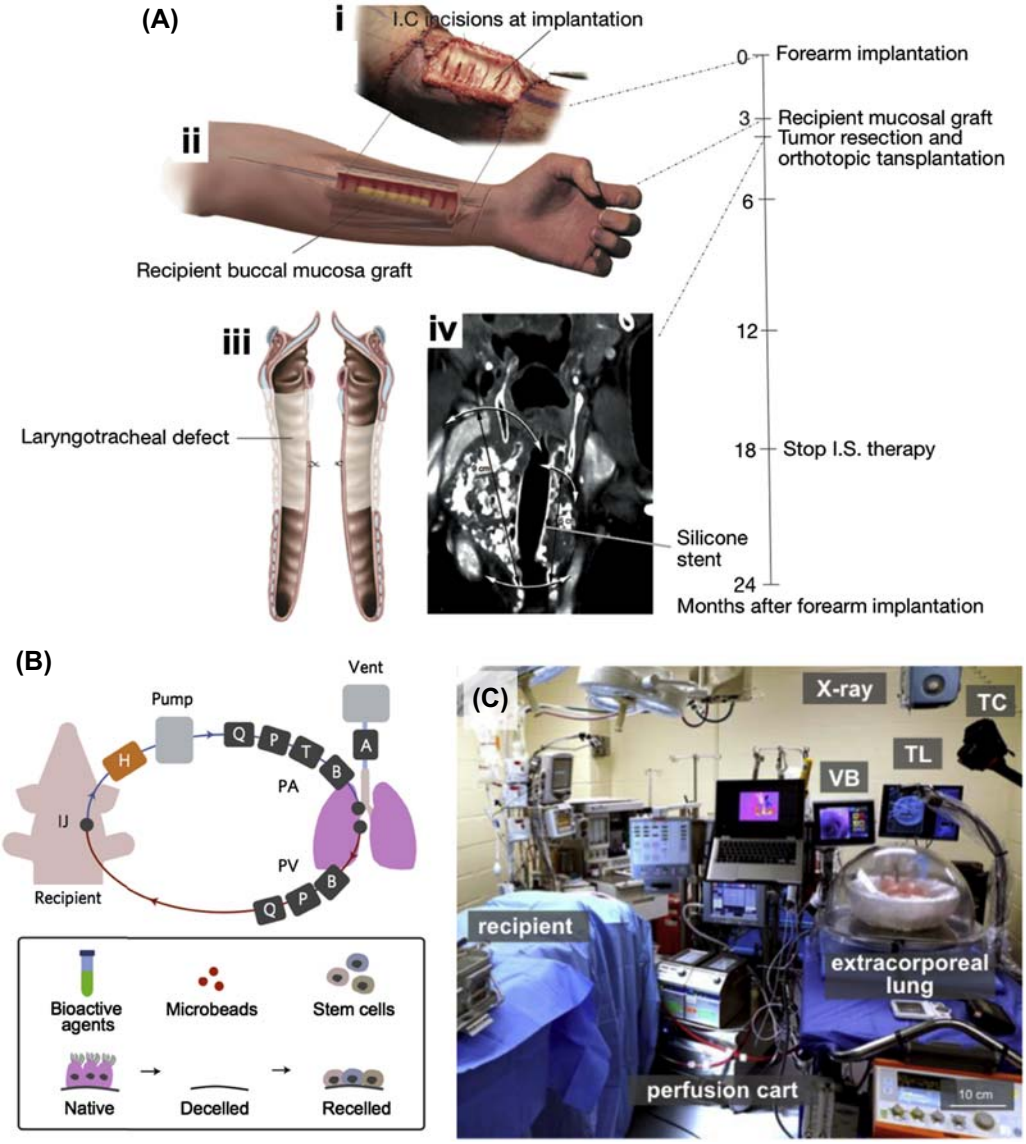

FIGURE 45.4 **In vivo bioreactors** (A) Tracheal allotransplant after revascularization in a heterotopic position (forearm) of the patient [39]. organ conditions, and minimally invasive evaluation of the lung function recovery. In addition, lung regeneration through cross-circulation can be accelerated when combined with the cell-replacement therapy using the patient's own cells, because the recipient provides the necessary biochemical cues needed by the transplanted cells.

Bioreactors for Study of Lung Biology

Lung regeneration and repair involve complex processes for which the underlying mechanisms are not fully understood [44]. More detailed study of lung development can enable the establishment of effective treatment modalities for a number of respiratory complications including immature lungs in preterm babies and inflammation-induced disruption of alveologenesis. In addition, such study would also inform strategies for stem cell–based ex vivo lung regeneration [45]. Microengineered lung models in microfluidic culture devices (i.e., "lung-on-a-chip") have great value for high-throughput in vitro studies of the lung at the molecular, cellular, and tissue levels [46–48] (Fig. 45.5A). Thus, these biomimetic lung-on-a-chips can recapitulate the structure, function, and microenvironment of human lung, permitting the study of lung development, regeneration, disease, and responses to drugs.

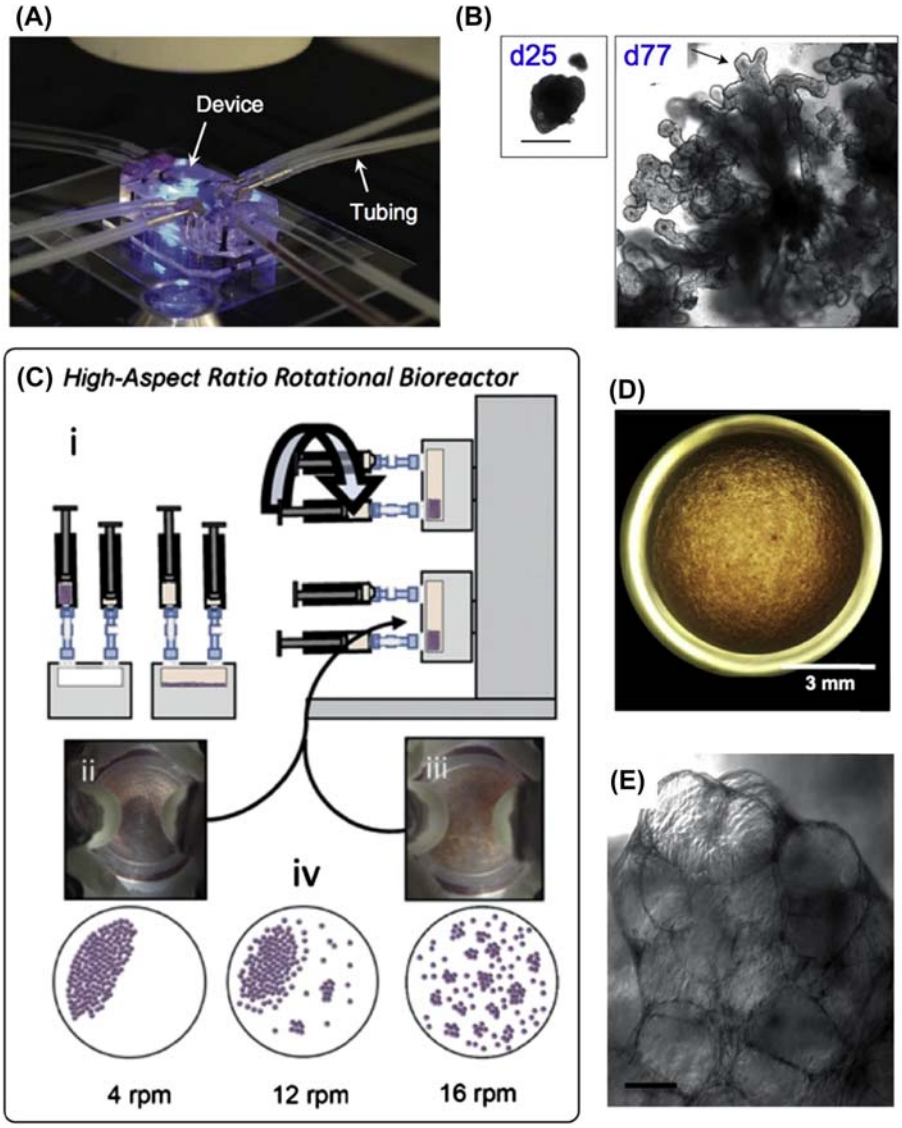

FIGURE 45.5 **In vitro (iv) devices for studies of lung development and regeneration.** (A) A lung-on-a-chip model for microengineering small airways [48]. (B) Lung bud organoids grown in vitro in a hydrogel [49]. (C) Bioreactor for lung organoid generation [50]. (D, E) Bright-field microscopy of a lung organoid [51].

When provided with suitable biochemical and physical conditions, stem cells can be formed into 3D tissue structures (i.e., organoids) that contain self-organized cell clusters. For example, human pluripotent stem cells cultured in 3D hydrogel (e.g., Matrigel) formed lung bud organoids resembling branching human airways and early alveolar structures [49] (Fig. 45.5B). Whereas model systems such as 2D monolayer cell cultures, 3D cell spheroids, and tissue explants have limitations in recapitulating the complex and multilevel human physiology, organoids can faithfully recapitulate many biological parameters, providing a unique opportunity to perform more physiologically relevant studies in vitro. Using custom-built bioreactor systems, generation of organoids can be facilitated in terms of organoid number and size, establishing the use of organoids in applications of drug testing, regenerative medicine, and disease modeling [51] (Fig. 45.5C–E).

Evaluation of Bioengineered Lungs

Various imaging and tissue processing techniques are used to evaluate the bioengineered lungs and assess their structural and biochemical integrity [21]. For example, removal and repopulation of cells such as epithelium of the

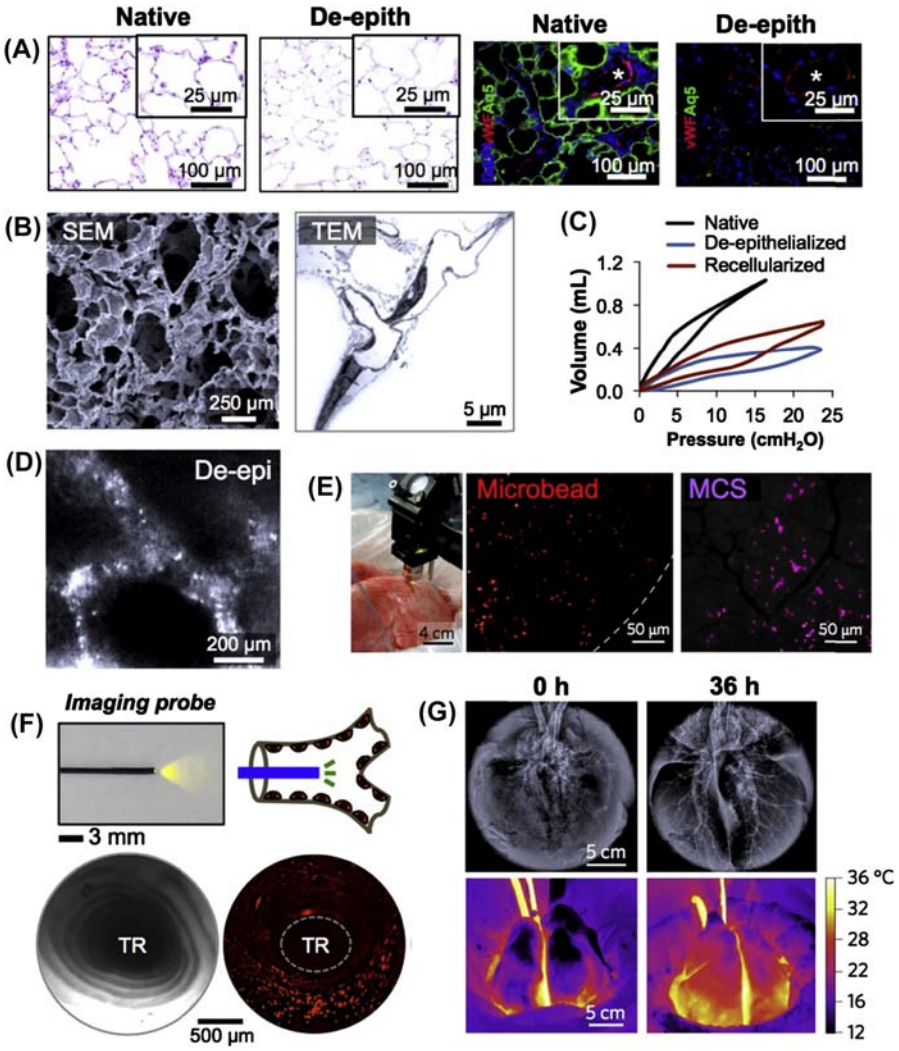

FIGURE 45.6 **Evaluation of the microstructure and composition of the lung tissue.** (A) Hematoxylin–eosin and immunofluorescence staining of lung tissue samples of airways. lung can be visually assessed by hematoxylin and eosin staining of the tissue samples obtained from the lung. In addition, immunofluorescence staining can reveal the presence or absence of biological molecules in the lung tissue (Fig. 45.6A). Detail about cell and tissue structures can be probed by using powerful imaging techniques such as scanning electron microscopy and transmission electron microscopy, which provide high-resolution images [29] (Fig. 45.6B).

To evaluate the lungs without the need for tissue sampling, nondestructive and real-time assessment have been employed [29,40,52]. A simple method to determine the quality of the bioengineered lung is to measure the pressure–volume relation of the lung, which can provide lung compliance and resistance (Fig. 45.6C). In addition, the structural integrity of the blood vessels can be evaluated by directly monitoring traveling paths of microbeads (diameter of approximately 1 μm) added into the blood flow (Fig. 45.6D). Similarly, cells added into the lung parenchyma (Fig. 45.6E) or airways (Fig. 45.6F) can be visually inspected using a custom-built microscope and optical-fiber imaging probe, respectively. Airway recruitment and blood perfusion of the lung during regeneration can be inspected using X-ray and thermal imaging (Fig. 45.6G).

BONE BIOREACTORS

Bioengineering Bone

Bone tissue has an inherent ability to regenerate, except in critical-sized defects caused by congenital abnormalities, trauma, or disease. Autologous grafts are the reference standard treatment, but these grafts are limited by the tissue volumes that can be harvested and patient morbidity. Engineered bone substitutes rely on bioreactors to provide nutrients throughout the large tissue constructs and to deliver the mechanical stimuli needed to promote bone development [53]. In this section, we examine bioreactor design for bone tissue engineering, including an advanced example of clinical translation, and the important role of bioreactors in delivering dynamic loads to cells within the engineered bone. Like lung, bone is a vascularized organ, and we summarize efforts to use the body as its own bioreactor to mitigate the challenge of vascularizing implants. Finally, we consider the use of bioreactors as platforms for biological studies of bone development and disease, and how nondestructive modalities may be used to monitor bone structure and function within bioreactor environments.

Nonperfused Bioreactors for Bone Regeneration

Static tissue culture relies on diffusion to deliver nutrients and biophysical stimuli to tissue, resulting in cell viability and matrix deposition only at the border of a 3D construct. To drive nutrient distribution in bone tissue engineering, two types of bioreactors for dynamic culture have been introduced: rotating wall vessels that use concentric, rotation cylinders to create laminar flow; and spinner flasks that use a magnetic stirrer or similar device to create flow through constructs suspended in the flask. Both setups have shown improvements in cell viability and distribution compared with static culture; however, in both cases, flow remains restricted to the periphery and necessary nutrients and signaling cannot reach deep within critical-sized scaffolds [54].

Perfusion Bioreactors for Bone Regeneration

Perfusion bioreactors, in which media are pumped throughout the construct, have shown improved cell distribution and viability and matrix production throughout large 3D scaffolds [55,56]. Perfusion bioreactors pump media from a reservoir throughout a construct within a liquid-tight vessel. Flow may be directed around the outside of a construct, or it may be forced directly through a construct by press-fitting the scaffold within the bioreactor casing. The latter setup offers superior mass transport, although flow patterns need to be customized to fit the construct geometry [57]. Perfusion bioreactors have been used for engineering bone from various stem cell sources, including embryonic [58], induced pluripotent [59], bone marrow–derived [60], and adipose-derived stem cells [61,62].

Bone marrow–derived and adipose-derived mesenchymal stem cells (MSCs) have shown particular promise for clinical translation, because both have demonstrated success in perfusion-bioreactor engineering of large-animal, anatomical bone replacements [60,61] (Fig. 45.7). These custom-shaped bioreactors relied on preoperative imaging of the targeted defect from which a mold was fabricated. Two elastomer pieces were then molded and press-fit onto a decellularized bone scaffold, which was milled to the anatomical shape and loaded with stem cells (Fig. 45.7A). To ensure optimal mass transport and shear stress throughout the construct, computational flow simulations were used to determine the channel size and placement (Fig. 45.7B). The engineered bone closely resembled the resected, native bone after 3 weeks in culture (Fig. 45.7C) and guided generation of new bone over 6 months in vivo in adult pigs (Fig. 45.7D). In contrast, soft issue formed in the condylectomy control (Fig. 45.7E). Custom perfusion bioreactors may be extended to implement multiple chambers for engineering adjacent tissues, such as engineering the articular cartilage surface on bone to form whole joints [63,64].

An important advantage of perfusion bioreactors is the ability to control the media flow throughout engineered bone, not only for mass transport but also to introduce appropriate shear stresses to cells for bone development. Previous reviews reported on the mechanobiology of bone development and the use of bioreactors to recapitulate physiological shear stresses [53,65]. Shear stresses are critical to bone formation and resorption via mechanotransduction in osteocytes, which communicate via paracrine signaling with osteoblasts and osteocytes to regulate matrix turnover [66]. Shear stress was also shown to direct osteogenic differentiation of MSCs [67]. Several studies attempted to recapitulate the physiological stresses seen by cells in native bone using perfusion bioreactors [56].

However, because no method exists for measuring the locally applied shear stress directly at the cellular level in 3D, studies rely on computational simulation of flow rates to determine local stresses. An important study established predictive correlates between the perfusion rate and the local osteogenic behavior of human MSCs in

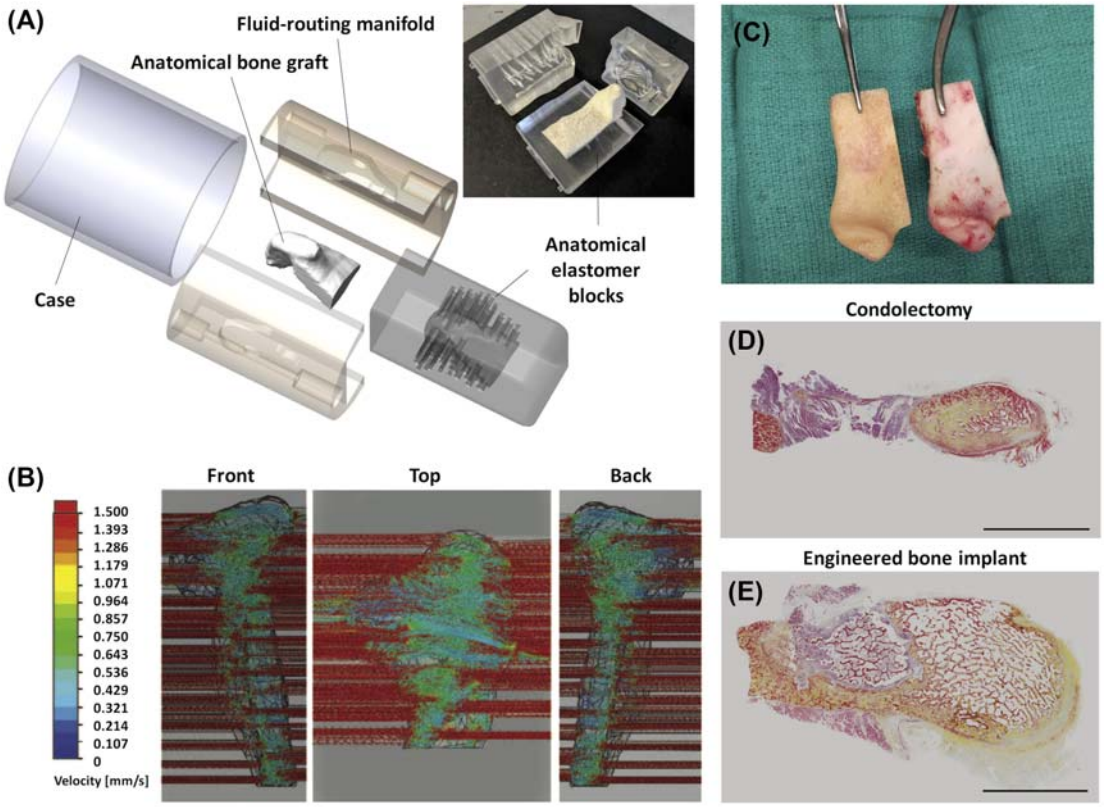

FIGURE 45.7 **Engineering anatomical bone grafts using a perfusion bioreactor.** (A) The bioreactor consists of two polydimethylsiloxane - blocks with incorporated channels, two manifolds, and a casing, providing controlled perfusion through the scaffold. (B) Channel diameters and spacing were designed by flow simulation software to provide a desired interstitial flow velocity for a given shape and size of graft. Simulations revealed a uniform flow velocity throughout the volume. (C) Comparison of resected native bone and engineered graft shows closely matched geometry. (D) Movat pentachrome stain of explants from pigs undergoing condylectomy showed fibrous tissue filling the defect; (E) engineered scaffolds guided development of new calcified tissue in the defect [61].

decellularized bone matrix [57]. Computational simulations yielded the independent contributions of oxygen delivery and shear stress to the resulting osteogenic behavior, including gene expression, matrix deposition, and cell proliferation. A range of flow rates from 400 to 1800 μm/s resulted in stresses of 2−20 mPa, respectively; although this is more than an order of magnitude lower than stress values reported in vivo [53], stresses were expected to increase as more matrix was produced and pore size correspondingly decreased.

Although many perfusion bioreactors introduce steady, continuous flow to engineered bone, there may be advantages to mimicking the oscillatory or pulsatile loading experienced by bone tissue in vivo [55]. External loads are applied to cells via a combination of matrix strain and interstitial fluid flow through lacunar-canalicular spaces [68]. A study examined the direct effects of oscillatory flow on MSCs using a parallel-plate bioreactor setup, in which the pressure is spatially constant throughout the setup, as confirmed by computational fluid dynamics (Fig. 45.8A). By testing various load magnitudes and frequencies, a regime of 2 Pa at 2 Hz was identified to have the greatest upregulation of osteogenic expression in MSCs [69], similar to the loads experienced by human cells in vivo during jogging.

Beyond fluid flow, external intermittent compression may be applied for mechanosignaling for bone development. A compression bioreactor setup, including an array of platens driven by a linear actuator and interfaced with a 24-well plate, was used to introduce periodic strain cycles and investigate mechanical regulation in a bone tumor model [70] (Fig. 45.8B). Computational simulation of the local pressure and flow velocity throughout the porous decellularized bone matrix (modeled as a poroelastic material) allowed the correlation of local pressure and matrix strain with gene expression. A new paradigm for dynamic loading in a bone bioreactor was reported in which nanoscale vibrations were introduced to MSCs via a magnetic plate [71] (Fig. 45.8C). Simulations of the displacement within the constructs revealed a constant force magnitude across the construct surface, and MSCs undergoing nanovibrations generated mineralized matrix despite the absence of physiological matrix stiffness

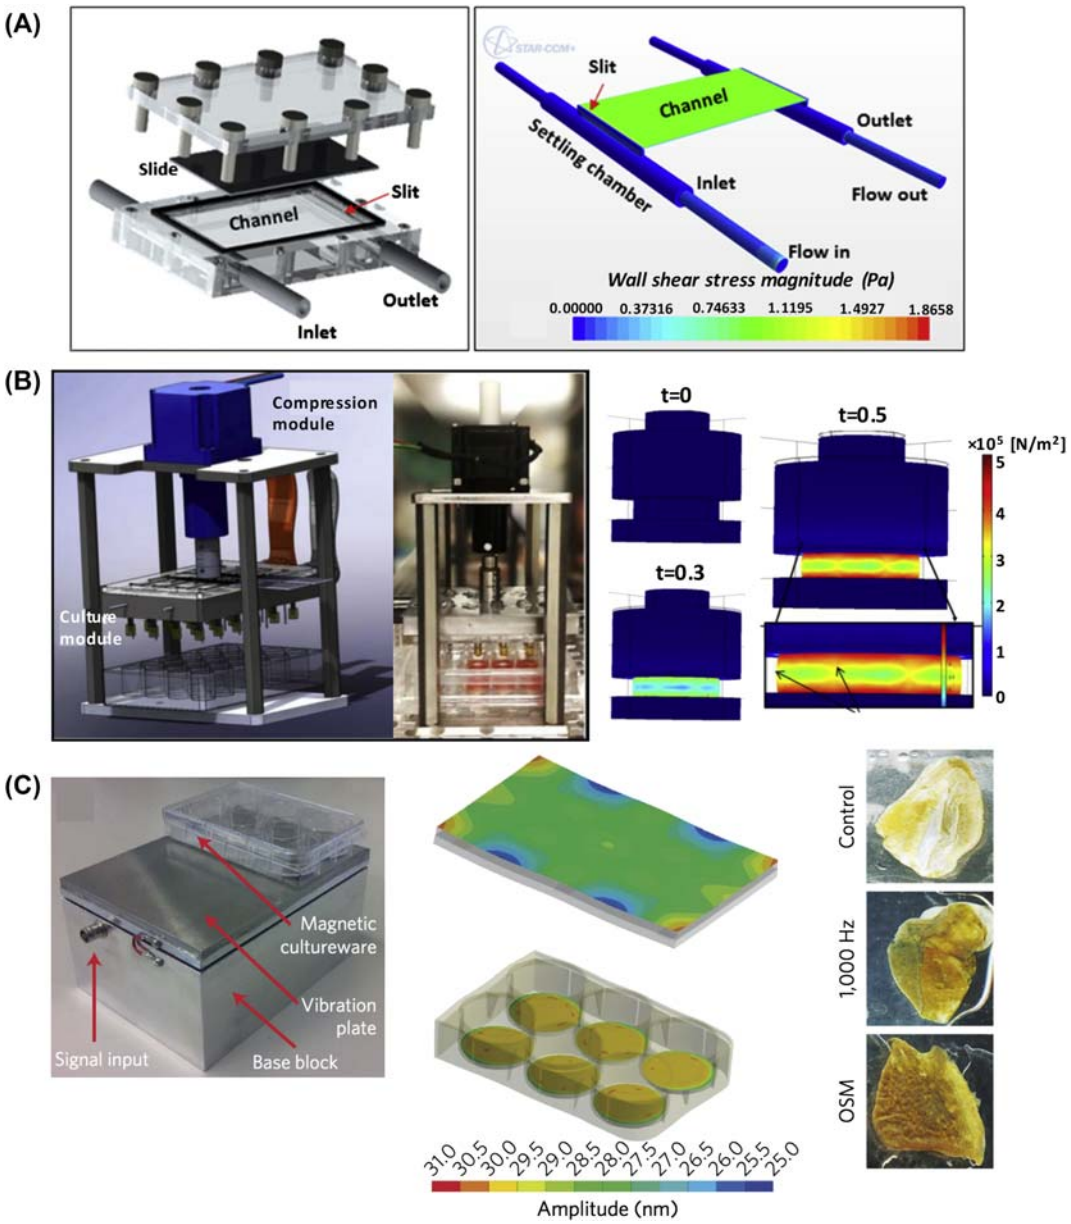

FIGURE 45.8 **Bone bioreactors with advanced loading regimes and corresponding mechanics simulations.** (A) Oscillatory flow bioreactor (*left*) and stress field simulations (*right*) [69]. (B) Compression bioreactor (*left*) and simulated stress field (*right*) [70]. (soft collagen gel served as a matrix material). These diverse approaches to loading bone tissue in bioreactors showed that mechanical effects on bone development must be considered in designing bioreactors.

In Vivo Bone Bioreactors for Solving the Vascularization Problem

One of the greatest challenges in producing viable engineered bone substitutes is the generation and anastomosis of a functioning vascular network. Like lung, bone is a highly vascularized tissue and efforts to incorporate vasculature during in vitro development have fallen short of promoting vascular integration upon implantation. A potential approach to overcome this is to use the body itself as a vascularized bioreactor and develop the bone in an ectopic location before orthotopic implantation [72–74]. This "in vivo bioreactor" principle has the additional advantage that the body provides a further supply of stem cells and growth factors to the construct, avoiding overmanipulating

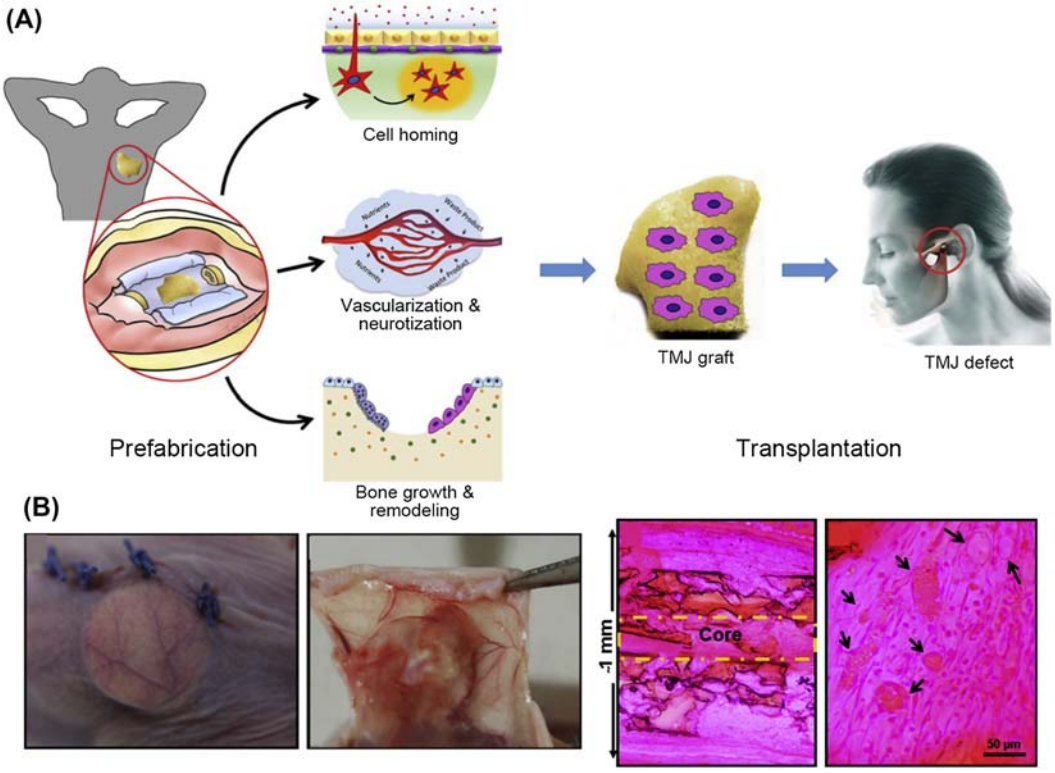

FIGURE 45.9 **In vivo bone bioreactor.** (A) The in vivo bioreactor paradigm: ectopic implantation prepares a construct for successful orthotopic implantation [73]. the tissue ahead of implantation, which could simplify the clinical translation of engineered bone replacements [73] (Fig. 45.9A). Since it was originally introduced, in vivo bioreactor studies have taken advantage of the highly vascularized environment in the periosteum, the connective tissue layer surrounding the bone [69]. The successful formation of mineralized, compact bone was demonstrated by 6 weeks after implantation, in rabbit periosteum. Given the relatively invasive nature of this implantation, subcutaneous implantation has also been explored for its vascularization potential. To promote vascular ingrowth, a layered construct was engineered using MSCs within electrospun polycaprolactone nanofibers, an angiogenic layer composed of collagen–fibronectin gel with endothelial cells, and an osteoconductive layer containing hydroxyapatite particles. After 4 weeks of subcutaneous implantation in nude mice, vasculature was present throughout the core of the scaffold [75] (Fig. 45.9B).

Bioreactors for Studying Bone Development and Disease

Bioreactors for bone were originally introduced to improve mass transport to cells when culturing in large 3D constructs. However, the opportunity to introduce a controlled mechanical and biological environment to realistic 3D bone constructs has allowed sophisticated models of bone development and disease within bioreactors. For instance, advanced mechanobiology studies may be carried out in perfusion bioreactors. A study examined the synergistic effects of matrix stiffness and shear stress on the osteogenic differentiation of progenitor cells. Decellularized bone matrices were coated with various ratios of collagen–hydroxyapatite to vary matrix stiffness and were loaded with MSCs [76]. The authors modeled flow through the constructs to estimate shear stresses and found that oscillatory flow is needed to promote cell viability and osteogenic behavior in long-term culture, whereas matrix stiffness had to be optimized separately for the greatest osteogenic potential. The controlled environment provided by bioreactors could also be used to study fracture repair under different biological regimes. For instance, static culture of hypertrophic chondrocytes improved long bone repair via endochondral ossification in the rat model, in contrast to osteoblast-laden scaffolds cultured in a perfusion bioreactor that promoted intramembranous ossification [77].

Bioreactors have also shown advantages in modeling the bone tumor microenvironment to understand tumorigenesis and drug efficacy better [70,78]. A study that used a dynamic compression bioreactor showed that mechanical loading affects the tumor's drug sensitivity in an engineered model of Ewing sarcoma [79]. Effects of shear stresses on tumor cell homing to bone during metastasis have also been studied. Spinner flask culture upregulated interleukin-24, which was shown to decrease the viability of prostate cells in engineered bone compared with static coculture [80]. The role of compression in inhibiting tumor-mediated osteolysis and metastatic tumor formation in bone by breast cancer cells was observed in a compression bioreactor for bone engineering [81].

Bioreactors also enable the modeling of joint disease for drug screening applications [82]. By scaling down and simplifying the bioreactor design, the osteochondral interface has been studied "on a chip" using microfluidics to introduce appropriate media to the two tissues [83]. A similar dual-compartment design was implemented to grow osteochondral tissues from human MSCs, and interleukin-1β induced tissue degeneration [84]. This platform is suitable for testing disease-modifying osteoarthritis drugs.

Monitoring the Environment and Tissue Development Within Bioreactors

The abilities to sense and visualize the inner workings of bioreactors are crucial for determining their faithfulness in recapitulating the physiologic environment and for evaluating proper tissue development. In the context of bone bioreactors, several structural, mechanical, and biological assessment tools have been proposed to monitor tissues and cells nondestructively.

Microcomputed tomography (μCT) is a nondestructive imaging modality that visualizes tissue structure in 3D. Because of the high absorption of X-rays by mineralized tissue, it may be used to quantify formation of bone longitudinally and has been a primary modality for this application [85]. Some studies have performed μCT imaging directly within perfusion bioreactors [86,87] without the need to remove the construct from its media circuit and sterile environment. Such longitudinal imaging can provide feedback to 3D tissue formation during culture, enabling the adaptation of biophysical stimuli as needed. Direct μCT monitoring within a perfusion bioreactor also allowed the relation of flow rate to the formation of mineralized tissue by human MSCs in a decellularized bone scaffold [88]. Longitudinal μCT has been used to investigate the effects of the degree of matrix curvature on new bone formation in 3D silk fibroin constructs [86] (Fig. 45.10A). Scaffolds with channels of varying degrees of curvature, to mimic the matrix turnover in vivo, were cultivated with cells in perfusion and static bioreactors to study fracture healing.

Optical imaging, including bioluminescent and fluorescent imaging, offers molecular specificity and may be performed nondestructively to investigate cell behavior within bone bioreactors. Bioluminescence has been used to track stem cell behavior in bone defects in vivo in mice (Fig. 45.10B). MSCs were transfected with two variants of luciferase, one used as a constitutive promoter to quantify cell number and another as a cell differentiation reporter for osteoblast lineage [89]. This approach is a promising avenue to understand stem cell fate better in engineered bone. Noninvasive, optical assessment of oxygenation in a bioreactor has also been achieved by measuring the oxygen-dependent phosphorescence lifetime of microprobes within the media of a perfusion bioreactor [91].

The authors found a decrease in oxygen within tissue constructs under static culture conditions, in contrast to stable oxygen levels in the perfusion setup. However, the technique provides no spatially resolved information; it offers a single oxygen measurement at each time point. Another disadvantage of optical modalities is a limited depth penetration, which restricts imaging to thick, opaque constructs.

Owing to both shear stresses and matrix strains, mechanical effects on bone development have received increased attention, but many studies lack a method to visualize the effects of mechanics directly within dynamic bioreactor environments. A bioreactor system was demonstrated that is capable of real-time mechanical conditioning (dynamic, uniaxial strain, and electrical stimulation) of nanofibrous constructs and the simultaneous monitoring of local strains [90]. Fluorescent beads and MSCs were electrospun directly into fibers, and fluorescence microscopy along with digital image correlation techniques were used to map local strains (Fig. 45.10C). Such a system may provide new insights for bone mechanobiology and allow tracking of the mechanical development of bone tissue in future studies. Elastography, which uses medical imaging including ultrasound, magnetic resonance imaging (MRI), and optical coherence tomography, may also have a role in mechanically conditioned engineered tissues [92].

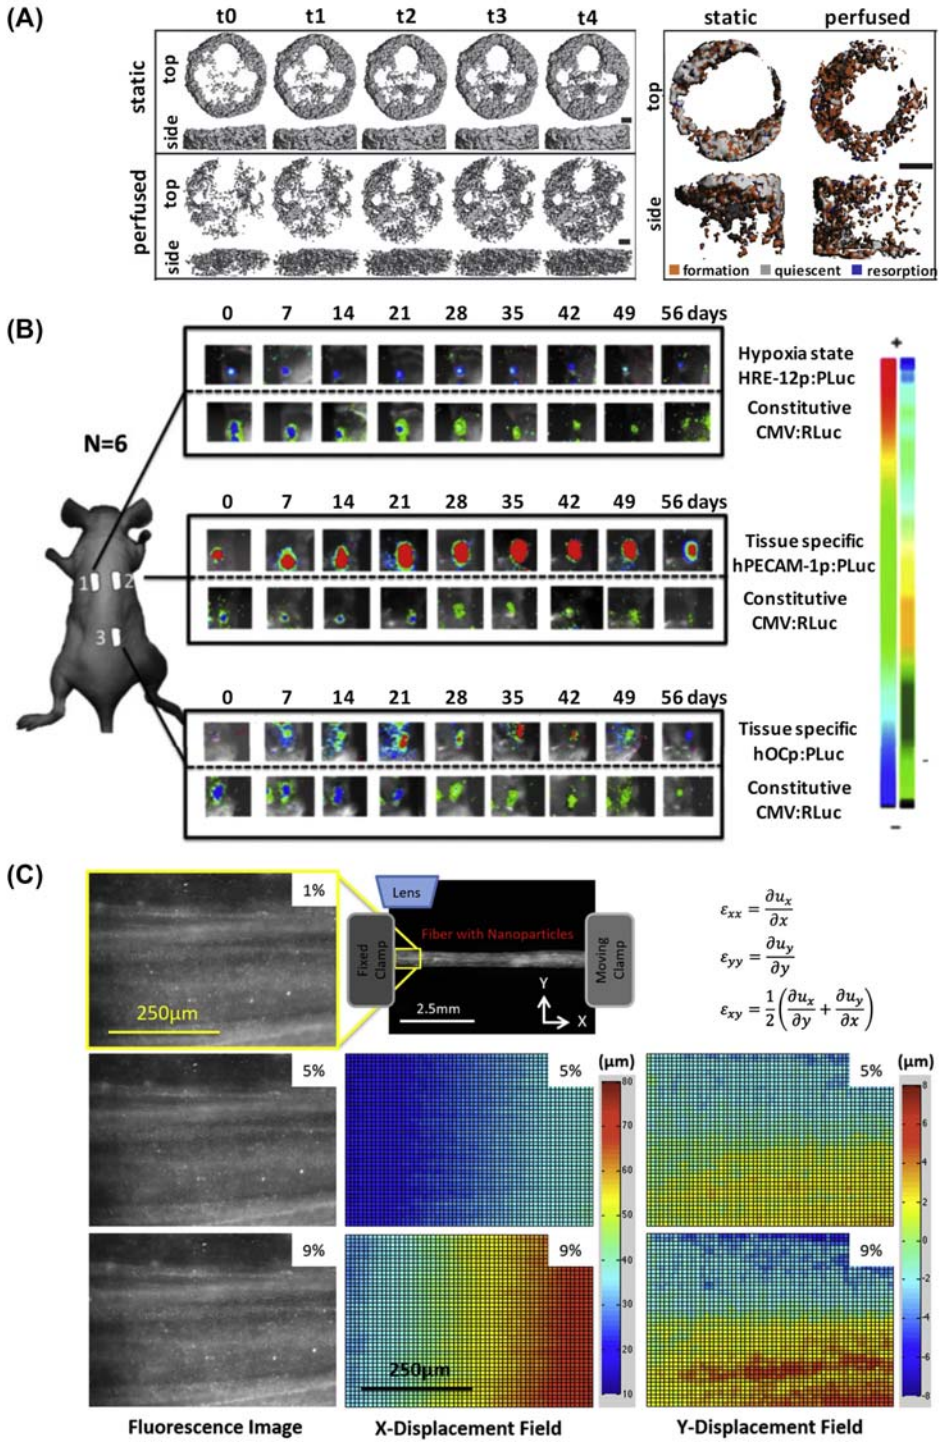

FIGURE 45.10 **Image-based monitoring of tissue and cell behavior in bone models.** (A) microcomputed tomography monitoring of bone deposition in silk fibroin scaffolds with and without perfusion. Color-coded overlays of different time points show areas of new growth and resorption [86]. (B) Bioluminescent imaging of human mesenchymal stem cell (MSC) differentiation in demineralized bone scaffolds implanted in a mouse model. MSCs were transduced with reporters for cell number (renilla luciferase [RLuc]) and/or cell differentiation (photinus luciferase [PLuc]) toward osteoblast lineage (OC), endothelial lineage (human platelet endothelial cell adhesion molecule [hPECAM]), or hypoxic expression (HRE) [89]. (C) Optical monitoring of local strain in nanofibrous constructs in a mechanical bioreactor. Fluorescent beads were incorporated into the fibers to track local displacements [90].

CHALLENGES AND FUTURE DIRECTIONS

Promising advances have been made in designing bioreactors that deliver essential nutrients and environmental cues to drive tissue development. However, several areas require improvement to enable the clinical translation of bioreactor technologies for regenerative medicine. As discussed here for lung and bone tissues, vascularization is critical for graft survival upon implantation. Using ectopic locations in the body as an in vivo bioreactor can mitigate some of the issues, but it may not always be practical. Other bio-inspired strategies should be considered that could be carried out in vitro to prime tissues for vascularization and contribute to success upon implantation. For example, harnessing the inflammatory response to promote angiogenesis has been explored in bone tissue constructs. Biomaterial-directed switching of the macrophage phenotype enabled upregulation of angiogenic factors and improved vascularization in a mouse model. Many bioreactor studies do not account for the inflammatory milieu, but it may be necessary to incorporate these cell types for optimal tissue development in the future.

In this chapter, we have introduced techniques that have been used to monitor the bioreactor environment and tissue development, but much work is needed in this space to interface bioreactors further with advanced imaging and sensing modalities. Although several modalities have been used to monitor cell fate and tissue development in vitro in monolayer culture [93], relatively few have been extended to monitoring the 3D complex environment within a bioreactor. Part of the challenge is the trade-off between the resolution needed to capture cellular-scale events with the field of view needed to monitor large, 3D constructs. MRI-compatible [94] and computed tomography−compatible bioreactors have been developed to monitor media flow and tissue structure, but they cannot track individual cells and have not been widely adopted for laboratory use, likely owing to the cost and size of the systems. Optical techniques including bioluminescence, fluorescence, multiphoton techniques, and optical coherence tomography may have an increasing role in real-time monitoring in future studies [93].

Real-time and nondestructive assessment of tissue and organ regeneration will be essential to the eventual automation of bioreactor control. Imaging and sensing readouts may be used in a feedback loop to signal inputs of environment cues (e.g., mechanical actuation, oxygenation) or delivery of biological factors. Toward this end, a computer-controlled perfusion bioreactor with integrated sensors for oxygen and pH was used to grow bone successfully for implantation in mice [95]. Eventual clinical translation will also require standardization and quality control; here, predictive computational models and automation are expected to contribute. Computational analyses and machine learning techniques may enable further the optimization of culture regimes, resulting in improved reproducibility in engineered construct quality.

INTRODUCTION

The advent of three-dimensional printing (3DP) is revolutionizing approaches to fabricating tissue mimics for therapeutic replacement, drug discovery, and fundamental biological understanding. The potential niche for 3DP in tissue engineering is seemingly infinite, because we have at hand the ability to provide on-demand, fabricated, patient-specific designs rapidly and at a low cost. However, 3DP technology was first intended for industrial settings. The translation to tissue engineering applications is hindered by major hurdles that include technical printing issues and, more important, biocompatibility. Consequently, we are limited by the number of materials available that can satisfy both the 3DP and compatibility requirements. Here we provide a historical perspective of 3DP and summarize the different techniques, consider the important characteristic properties a bioink must have to fit bioprinting criteria, summarize bioink and biomaterial advancement used for 3D bioprinting, and discuss future directions to address current limitations for clinical impact.

Generally, printable biomaterials, or bioinks, are materials that can be used in 3DP techniques that include or will include biological features. The term "bioink" may lead to confusion because some may consider the material a bioink only if it is cell-laden or contains some matrix or matrix-mimicking component. However, we would like to expand its definition to encompass any printable material that (1) will interface with biological components (e.g., tissues, cells, proteins, growth factors) during or after the actual print, or (2) is involved in the structural construction of scaffolds that will interface with biological components.

Bioinks must comply with the 3DP technique as well as provide a biocompatible environment mimicking a desired tissue and ideally degrade controllably with no harmful by-products. Harmful by-products may not originate exclusively in degradation; they may also come from temporary bioinks that have structural roles during the printing process. Unfortunately, to satisfy these criteria, material properties work against each other and require some compromise between desired printability and satisfactory biological features. However, bioengineers have a selection of materials compatible with several different 3DP platforms. Therefore, in our discussion we will cover bioinks in the context of which printing technique is capable of printing with the described material. We will describe the diversity of available bioinks and biomaterials for 3DP under three main categories: (1) matrix or matrix-mimicking, (2) sacrificial, and (3) support [1].

FUNDAMENTALS OF THREE-DIMENSIONAL PRINTING

3DP is an additive manufacturing technique originally applied to plastic and metal manufacturing. It has progressed to adapt to biomedical engineering applications within the past few decades. Over 3 decades ago, Charles

[a] J.N. and G.A.C. contributed equally to the production of this text.

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00046-1

Hull patented a new technology for rapid prototyping, called stereolithography. This described system to fabricate three-dimensional (3D) constructs uses liquid photopolymerization to build desired objects in a stepwise manner and is considered the birth of 3D bioprinting [2,3]. 3DP and bioprinting have revolutionized the ability to create objects with any shape or size on demand. The exciting promise for medicine is that we can customize patient-specific tissue scaffolds, fabricate on-demand medical devices, and reliably reproduce constructs for high-throughput screening.

The key term that defines modern bioprinting is control. Casting approaches have surface resolution defined by the mold itself and no control over the internal structure of the casted sample. Similar salt leaching or electrospinning protocols for porous structures have little to no control over the internal pore size and distribution [4]. Modern technologies allow for control deposition and building; there is control over detailed characteristics such as the location and content of material deposition. This includes microstructures to bear stress, cell encapsulation, and growth factor or other biochemical functionalization. Being able to design the bulk shape and internal microstructure fully has allowed structures to be produced that more closely resemble nature's complexity: controlled internal microstructures (pores, gradients, and layering) [5–10], microchannel and micropatterning for prevascularization [11,12], and the simultaneous deposition of different types of materials [12–14] or different cell lines [6–8,12,15]. The technology allows for control and the mechanics are there to exploit; however, the hurdle to overcome is to define the bioinks that can be adequately used with these systems. An ever-expanding list exists of 3D bioprinting technologies (and bioinks to match) that are differently suited for specific desired materials or applications. These techniques vary based not only according to the materials (e.g., affected by cross-linking mechanisms to determine biocompatibility and/or mechanical properties) but to the resolution of the architecture and the speed of fabrication. Four 3DP methods have been adapted for biomedical application: (1) extrusion-based printing, (2) particle fusion-based printing, (3) inkjet printing, and (4) stereolithography or photopolymerization methods (Fig. 46.1). Technological advances have resulted in novel methods or modifications of these four, including acoustic droplet ejection, direct-write assembly, laser-guided direct writing, and 3D powder printing [3]. Each of these approaches has advantages and limitations. However, given an identified desired application, often one or a combination of technologies proves to match the sought biomaterial and architecture. A 2016 review by the Kaplan Lab [3] summarized the evolution of bioprinting and additive manufacturing technologies.

Extrusion-Based Printing

Extrusion-based printing is the most commonly employed method for 3DP, but it requires thermoplastic materials that are cell compatible only if they are printed at physiological temperatures. The technology forces a viscous ink

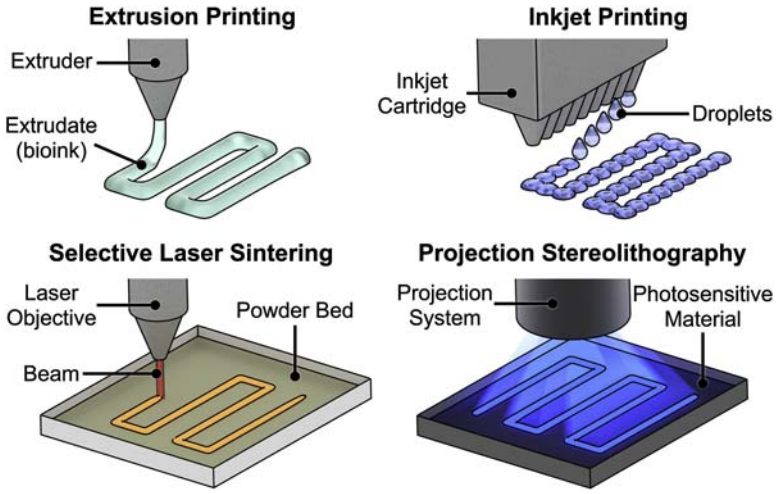

FIGURE 46.1 **Three-dimensional (3D) bioprinting techniques:** Extrusion-based printing deposits continuous filaments on a surface to build constructs layer by layer. Inkjet printing adapts inkjet cartridges to contain bioinks so that liquid droplets are formed on a surface that can quickly solidify. Selective laser sintering uses a laser to melt powder particles together to sinter a 3D object within the powder bed. Finally, projection stereolithography uses photosensitive liquid material that can be cross-linked with light exposure with controllable photomasks. *Reprinted with permission from Miller JS, Burdick JA. Editorial: special issue on 3D printing of biomaterials. ACS Biomater Sci Eng 2016;2:1658–61. Copyright 2017 American Chemical Society.*

through a nozzle that can solidify once deposited onto a build platform. The extruded material is deposited to form individual lines in a predefined path as dictated by a generated computer model to form a 3D object in a layer-by-layer fashion. Typically, each different ink is extruded out of the nozzle at a specific temperature and pressure so that the material can flow through the nozzle (e.g., polycaprolactone PCL] will extrude at 80°C and a pneumatic pressure of 400 kPa, whereas alginate can be deposited at 20°C [7]). Materials that are most commonly used for this technique possess a sharp solid-to-melt transition such that the material can flow and rapidly solidify once passed through the nozzle. Progress has been made in developing thermoplastics that extrude at lower, more physiological temperatures and pressures by exploiting shear thinning properties (i.e., PCL) [17]. Other approaches include using materials that can be extruded at lower temperatures or do not rely on thermal setting but require additional cross-linking mechanisms such as ionic bonding [18], pH alteration [19], or UV photopolymerization, among others. The inclusion of cells, however, can ultimately affect several aspects of the resulting print. Not only do materials need to be able to flow through the nozzle at low temperature, parameters such as high extrusion forces and narrow nozzle diameters, which usually improve the print's resolution for synthetics at high temperatures, affect cell viability. Decreasing the pressure and/or increasing the nozzle diameter may improve cell viability by reducing the cells' experienced shear stress but at the cost of potential nozzle clogging and print resolution. In addition, this technique has difficulty printing overhanging structures without supporting filler structures. The printed filaments can sag or even collapse without underlying support. Although some groups used extrusion printing with PCL or poly(propylene fumarate) (PPF) to create highly controlled porous scaffolds [20–22], others generated structures as a sacrificial template with similar extrusion-based methods to pattern architectures precisely that can be better-suited for some of the biocompatibility issues with this 3DP technique [11,23]. Overall, extrusion-based printing has been applied to many tissue engineering applications and is most widely available.

Selective Laser Sintering

Another printing technique, particle fusion printing methods such as selective laser sintering (SLS), uses a directed laser to raise the temperature of a powder material beyond its melting temperature to fuse or sinter the particles locally. The laser fuses each patterned layer in a repeated process to create 3D structures [24]. The construct's resolution is limited only by the laser resolution and the powder size. This technique has had its most successful applications to bone tissue engineering by sintering composite materials. Examples include ceramics, PCL, and hydroxyapatite [25–28]. Although the tissue engineering field has seen promise with this technique, the printed objects are difficult to incorporate with living cells and instead use a two-step process of first building the volume followed by adding cells. Moreover, there is difficulty in controlling porosity, which can affect the longevity of the biomedical application [3]. However, a major benefit is the technique's capacity to be self-supportive of complex printed structures, as the powder bed enables the printing of overhanging geometries. In addition, similar to extrusion-based printing approaches, groups use the technique of SLS additively [28] and sacrificially [29].

Inkjet Bioprinting

Inkjet bioprinting is considered the cheapest bioprinting technique. It was patented as one of the first strategies for cell printing [30,31]. Originally, inkjet bioprinters were created by replacing traditional 2D ink-based printers' cartridges with biological solutions. Instead of paper used as the recipient of the ink, a moveable stage added a third dimension to build a construct layer by layer [32,33]. Inkjet bioprinters can deposit picoliter droplets with positional accuracy less than 30 μm, allowing high-precision control in positioning different materials and cells into specific microenvironments [34]. To deposit liquid onto a substrate, some inkjet printers electrically heat the print head to a range between 200°C and 300°C. The high heat raises concerns regarding the viability and function of the cells after printing. Still, some studies using this technique show viability for mammalian cells and attribute survival to the short duration of the high-temperature exposure [35,36]. In inkjet printing, a liquid droplet is solidified after deposition onto a substrate, a process that must occur quickly to control the spatial resolution of the printed volume. Important material properties of the ink are the viscosity and the surface tension to determine the final shape, size, resolution, and accuracy of the print. Therefore, an important mechanism to consider to improve the final print is the cross-linkability of the bioink. Effective methods for this application are chemical, pH, or UV cross-linking [37,38]. There is a delicate balance of cross-linking the deposited droplets for rapid structural organization and to limit toxicity introduced to the cells. The chemical modification to achieve the desired cross-linking capability can decrease cell viability and affect the chemical and mechanical properties of the material. These changes can alter

the biomimicry that was relevant before modification [39]. In addition, inkjet printing uses a nozzle head to deposit the bioinks and therefore is limited by the possibility of clogging. Bioinks for inkjet printing should have low viscosities (below 10 cP) because the necessary pressures or heat that would eject higher viscosities would negatively affect cell viability [40].

Stereolithography

The last 3D printing technique to be discussed, stereolithography, brings us to the origins of 3D bioprinting. Stereolithography-based printing uses light as a tool to solidify liquid materials in a photochemical reaction. With a laser often used as the light source, a projection of light is shown onto the liquid material in a specific pattern to solidify the exposed region [41,42]. Using a light source, photosensitive material, and a controlled axis stage, one can print complex 3D structures. Because stereolithography depends on photosensitive material to print constructs, a limited number of biomaterials can be used. Common materials for this application are poly(ethylene glycol) diacrylate (PEGDA)-based materials and gelatin methacrylate (gelMA). Acrylation modification to PEG and gelatin render the material photosensitive for printing [43,44]. Combinations of already self-assembling proteins, such as keratin or decellularized extracellular matrix (ECM), with photoinitiators have allowed the cross-linking of soft hydrogels [45]. This method has the advantage of excellent structural integrity because no artificial interfaces result from droplets (inkjet printing) or lines (extrusion printing). Also, the electromagnetic spectrum and its multiple energy wavelengths allow for a broad range of chemistry alterations; various wavelength lasers, UV sources, and the visible light spectrum are common energy sources used in this technique. The use of light with all available intensities and wavelengths results in very fast and precise builds. Resolution of this technique ranges from 25 to 200 μm for commercially available printers [3,45] down to ~10 μm for two-photon polymerization setups [46]. However, because the material must be photosensitive, many biomaterials cannot be used or they must be chemically modified for photopolymerization [45,47]. A photopolymerizable material such as PEGDA is not in itself good for cell viability. Additional surface modifications are necessary to allow for cell attachment and material degradation by incorporating peptide sequences [48]. In addition, resolution is determined mostly by the laser spot size and therefore has high 3D resolution, but the prints often are warped because the mechanical properties are typically weak [3].

Overall, 3D bioprinting techniques vary in approach and can result in a wide array of medical applications from tissue repair to modeling disease. There has been tremendous progress in the development of the technique as well as the biomaterials synthesized to expand the palette of available 3DP bioinks. 3D bioprinting has exciting translational potential to produce implantable structures for regenerative medicine and high-throughput, reproducible drug screening. However, to realize this medical impact, researchers must continue to explore the architecture, the biocompatible yet printable materials, and the inclusion of proliferating and differentiating cells for fabricated living tissues to reach a desirable function.

BIOINKS

3D bioprinting may offer the potential to fabricate physiological tissue mimics; however, progress toward therapeutic application relies heavily on its integration with bioinks. Therefore, the development of biocompatible yet printable bioinks requires tremendous consideration to match physical and functional aspects of the desired tissue closely. Because 3DP technologies originally were designed for nonbiological applications, some of the materials used as inks for printing, such as thermoplastic polymers, ceramics, and metals, cannot translate to supporting living cells. Hence, one of the greatest challenges of the field is to find materials that are both biocompatible and printable.

As defined previously, printable biomaterials, or bioinks, encompass any printable material that (1) will interface with biological components during or after the actual print, or (2) is involved in the structural construction of scaffolds that will interface with biological components. The key difference between bioinks and other printable inks is cytocompatibility; bioinks cannot be toxic or produce any toxic by-products that could be detrimental to living cells, to the physiological function of the printed tissue, or to surrounding or down-stream native tissues.

Generally, materials used in the field of regenerative medicine are divided between natural and synthetic materials. Natural materials have all of the advantages of being physiological and inherently bioactive. However, natural materials lack tunability, batch-to-batch consistency, and often the physical properties necessary for printing. On the

TABLE 46.1 Bioink Materials Compatible With Associated Printing Techniques

	Material	Extrusion	Stereolithography	Inkjet	Sintering
Natural	Fibrin	[23,51]		[52,53]	
	Collagen	[23,54,55]	Multiphoton cross-linking [9]	[53,56]	
	Alginate	[6,7,14,18,23,57–60]		[61]	
	Hyaluronic acid (HA)	[62], Thiolated HA plus thiolated gelatin [63]	Acrylated HA [3]

	Poly(vinyl alcohol)	[89,90]	[3]		

other hand, synthetic materials benefit from a high degree of tailoring to specific physical property needs with inherent consistency to meet the printing technique's criteria. Still, synthetic materials often fail to match the biocompatibility of natural materials, and sometimes lead to toxic degradation products or the lack of cell-binding sites. Some groups have compromised the divided material set by synthesizing a semisynthetic class of materials such as gelMA or methacrylated hyaluronic acid [49,50]. Of our palette of biomaterials, only a subset is also suitable for bioprinting (Table 46.1).

For a bioink to be biocompatible as well as printable, the material must have the capacity to be accurately and precisely deposited with spatial and temporal control. Each bioprinting technique may require a different subset of material properties. For example, inkjet printing requires bioinks to possess low viscosity to avoid nozzle clogging; extrusion printing benefits from shear thinning properties to fluidize through the nozzle and quickly solidify once deposited; SLS must be able to become a fine powder and have an attainable melting temperature; and stereolithography requires photosensitive bioinks. These material properties to promote printability often come at the cost of compromising biocompatibility. As an example, a photosensitive material that cross-links in the presence of a photoinitiator that can be highly cytotoxic. Therefore, available bioinks are chosen to meet the demands of the particular printing process, but also for its ability to shield encapsulated cells from a possibly harmful printing process.

The requirements for printing depend on a variety of properties, including rheological behavior, the gelation process, or available biological interactions. From a rheology perspective, only specific ranges of viscosities match well with either inkjet or extrusion printing, but shear thinning is an example of a rheological property ideally suited for extrusion. The gelation process, or cross-linking, can greatly influence the geometric integrity of the print. Gelation can occur through ionic, thermal, enzymatic, or photocross-linking mechanisms; these ultimately dictate the printing technique with which the bioink is compatible. Biological interactions might need to be enhanced, especially for synthetic materials, by incorporating cell binding motifs or inclusion of an additional natural material.

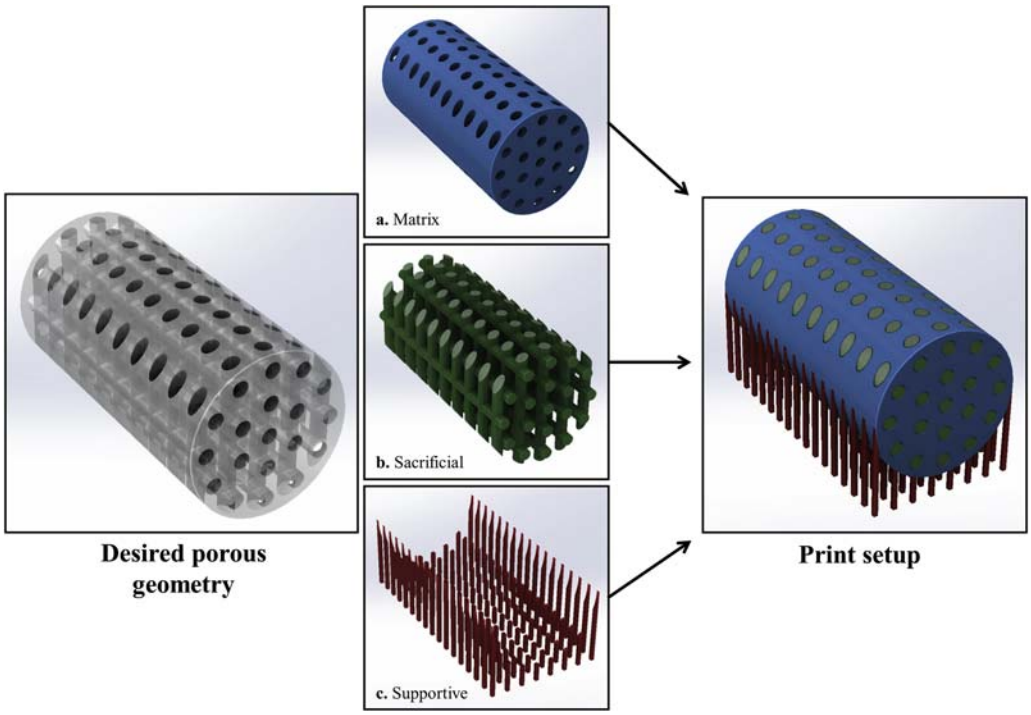

FIGURE 46.2 **Bioink categories** (*from left to right*): A desired final geometry volume can be fabricated with three different bioink approaches to result in the ultimate final print. The print setup shows how different bioinks would be incorporated during the print fabrication.

We categorize the available bioinks into three categories: (1) matrix or matrix-mimicking, (2) sacrificial, and (3) support [1]. As seen in Table 46.1, the same bioink can fall into several bioprinting strategies even if the bioink is used in a different way. Each category requires specific workflows, but they are ultimately brought together in the printing process, as illustrated in Fig. 46.2.

Matrix or Matrix-Mimicking Bioinks

Matrix or matrix-mimicking bioinks are printed and remain part of the scaffold system. A scaffold can be printed and consist of the matrix bioink material only (acellular scaffold), the matrix material with its surface chemically altered during or after the printing process (functionalized acellular scaffold), or the matrix printed with a loaded cell population (cell-laden scaffold). In all cases, the matrix bioink is the material that provides the mechanical structure to which cells adhere, and which will then be used to enhance cellular communication, proliferation, migration, and differentiation, and ultimately determine the function of the system.

As a structural element in a biological environment, there is a delicate balance between achieving the rheological and mechanical properties needed to print a self-supporting structure and the eventual effects that the material may have on the biological development of the cellular component. This balance is specific to the properties and function ultimately desired for the printed sample, anything ranging from soft and porous hydrogels for the in vitro culture and assessment of cells [65,81,91] to very strong and durable scaffolds for in vivo bone regeneration [10,76,92,93]. The desired mechanical and biological properties of the matrices are nevertheless restricted by the capacities of the 3DP technologies and the bioinks associated with each method. As has been reiterated in the literature, synthetic materials can be engineered to provide strong scaffolds with tunable mechanical and chemical properties [76]. Nevertheless, these materials have been traditionally associated with low biocompatibility [91], complex and demanding manufacturing processes (high temperatures, high pressures, strong solvents, etc.) [34,94], very low degradation rates [76,77], and, in some cases, cytotoxicity or harmful by-products [94]. On the other hand, natural materials inherently provide the adequate biological cues that cells need for proper development. The perfect combinations of amino acid sequences, protein ratios, growth factors, and cytokines are found in natural materials from fauna (ECM combinations, collagen, elastin, fibrin, keratin, hyaluronic acid [HA], chitosan, etc.) and flora (alginate, agarose, agar, silk, etc.) [3,91,95,96]. However, natural materials are also associated with weaker mechanical

properties and high batch-to-batch variability [7,46]. Natural variability is unavoidable and perfectly defined manufacturing protocols for natural materials are virtually impossible. Thus, truly tunable properties are difficult to predict and the reason why results in studies using ECM usually differ in a case-to-case scenario. As will be discussed in the next sections, synthetic and natural materials cannot be defined by positive and negative characteristics; researchers have been working on mitigating the weaknesses of both, either by biochemically altering the individual materials or by implementing synthetic—natural hybrids or combined prints that use the strengths of each.

Synthetic Materials

As mentioned, 3D bioprinting is an adapted technology; the original patent filed by Hull in 1986 [2] proposed using the stereolithographic method to optimize prototype manufacturing of plastic parts for industrial applications. Since then, the processes have evolved and revolutionized the industry and have bled into many other manufacturing applications including bioengineering, regenerative medicine, and tissue engineering. The original Hull patent was intended for synthetic materials, named "U- curable materials," which could be processed as a "fluid medium capable of solidification in response to prescribed stimulation" [2]. This definition is technologically viable today and could be applicable to most modern bioprinting methodologies, even if the solidification is not via UV cross-linking. The materials have greatly evolved and new ones have arisen, allowing researchers to incorporate synthetic materials and printing technologies into biomedical and tissue engineering.

The greatest strength of synthetics is that the manufacturing processes are well-known and can be engineered to specific mechanical and biochemical properties [91,94]. Polymer engineering allows control over molecular weights and distributions, as well as cross-linking densities, which can be tailored to control mechanical properties such as yield stress and strain, ultimate stress and strain, and elastic modulus [94]. This tailoring can occur as part of the polymer synthesis process, but it can be further modified in the printing or postprinting processes with curing or cross-linking steps. In the end, robust mechanical properties can be used to sustain high loads or adequately respond to elastic deformation, which is ideal for the structural scaffolding components of biological constructs. The synthesis of tunable mechanical properties also means that synthetic materials can be used in multiple 3DP techniques (Table 46.1) and result in constructs with consistent macroscopic and microscopic definition. The pore distribution in a biological scaffold is an important parameter that will define the presence or absence of vascularization for oxygen, nutrient, and metabolic waste transport in tissue regeneration [93]. The superior print resolution and fidelity of synthetics have been widely explored to produce complex morphologies that may be applied as biomimicking scaffolds in regenerative medicine (Fig. 46.3) or as structural supports in co-printing applications, a concept that will be further detailed in following sections.

In theory, just as the synthetic print resins can be modified to facilitate the manufacturing processes, surface modifications can be implemented to allow better interactions with biologic components. However, the manufacturing and modification processes and variables are usually demanding and work in narrow ranges to achieve specific properties. Often, printing techniques will involve high temperatures, toxic organic solvents, or cross-linking agents, which renders them incompatible with living cells and biological materials such as growth factors and proteins that aid cellular function and survival [94]. Synthetic materials generally do not support cell adhesion without additional surface functionalization for adhesion ligands such as arginine-glycine-aspartic acid, which is widely identified as a binding motif for proteins such as fibronectin, osteopontin, and fibrinogen [45,91,94]. Even with consistent morphology control and compatibility with surface modification strategies, synthetic polymers do not innately mimic ECM, which remains its weakest characteristic for the clinical translation of synthetic bioprinted scaffolds [3]. Still, synthetic materials that are commonly used in bioprinting applications include poly(ethylene glycol) (PEG) and PEGDA, PCL, poly(D,L-lactic-*co*-glycolic acid) (PLGA), poly(L-lactic acid) (PLA), and PPF, among others.

PEG has long been used as a coating on medical devices to control host-immune responses or alter degradation rates in vivo [94]. Furthermore, PEG is commercially available in many physical (linear, branched, molecular weight variation) and chemical variants (diacrylated variant PEGDA) and is approved by the US Food and Drug Administration as a biocompatible material, which makes it a versatile polymer for bioengineering [81]. Here, biocompatibility, a broad term, means the material does not kill cells or induce an aggressive immune reaction, but it does not necessarily mean that it induces cell adhesion or proliferation. As for other synthetic materials, PEG lacks attachment sites that cells need to adhere to a substrate. PEG requires chemical immobilization of binding motifs to support cell adherence and stem cell differentiation [3,94]. These characteristics usually result in PEG being used as a secondary plasticizer component in bioinks: even more so, PEG is often modified with acrylate groups to create photopolymerizable PEGDA, a variation that is commonly used with extrusion or stereolithography approaches, and can be easily coupled with natural biomolecules for cell-laden bioinks [3,81].

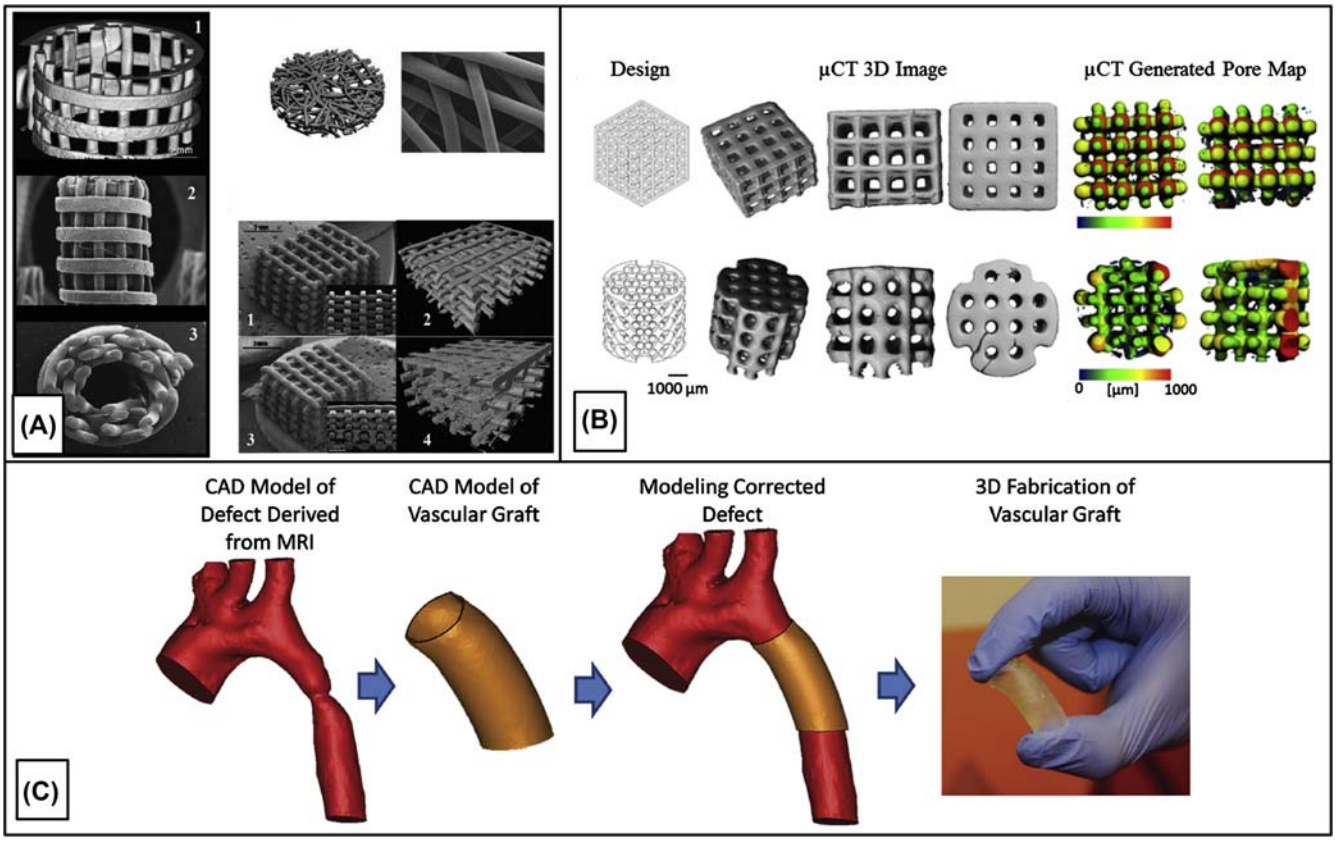

FIGURE 46.3 **Synthetic materials in bioprinting applications:** (A) Morphology of bioprinted starch- poly(ε-caprolactone) (PCL) scaffolds, including tubular scaffolds made by rapid prototyping and fiber-bonded scaffolds [77]. (B) Variations of three-dimensional (3D) printing (3DP) poly(propylene fumarate) (PPF) assessing scaffold and pore geometry to study the effects of pore geometry on cell viability and differentiation [10]. (C) Design and fabrication process of a 3DP PPF graft to treat a coarctation of the aorta [88]. *CAD*, computer-aided design; *MRI*, magnetic resonance imaging; *μCT*, microcomputed tomography.

PCL is synthesized by ring-opening polymerization of ε-caprolactone [77]. PCL is a high−molecular weight semicrystalline polymer that has good solubility, a low melting point, thermoplastic behavior, and an extended hydrolysis-induced degradation profile in vivo. This polymer is stable in the body for over 6 months [97]; then it exhibits nonenzymatic hydrolysis degradation of 2−4 years (depending on the molecular weight) at physiological pH and temperature, leaving no cytotoxic by-products [76,77,96]. Extended degradation is ideal for providing long-term load-bearing support during healing and regeneration processes [7]. PCL has a melting point close to 60°C, a relatively low temperature in the manufacturing industry, which allows easy processing [77,94,96]. Upon heating, PCL has viscoelastic properties ideal for the extrusion printing of constructs with elastic mechanical behavior, a characteristic that improves the brittle properties of polymers such as PLA and polyurethanes [97]. The Hutmacher group printed cylindrical scaffolds of medical-grade PCL−tricalcium phosphate by fused deposition modeling that required added growth factors to increase the osteogenic potential of seeded mesenchymal stem cells (MSCs) [76]. The growth factor−coated PCL scaffolds successfully completed up to 12 months of unrestricted load bearing in vivo within large tibial defects in sheep [76]. The use of additional osteogenic growth factors indicates the biochemical limitations of PCL; other than the hydrophobic nonspecific binding of cells, PCL lacks binding motifs that provide specific binding sites for cells [94]. Combination with natural materials or other functionalized materials is the usual approach to address this limitation. The Atala group, for example, concurrently prints PCL with hydrogels based on gelatin, HA, or fibrin; the hydrogels provide the biochemical cues for cellular adhesion and viability [94]. Starch, a natural polysaccharide, has also been widely used to improve the biocompatibility of PCL [77]. PCL−starch prints can enhance and stimulate osteoblast proliferation for bone regeneration, support hippocampal neurons and glial cells to treat spinal cord injury, or support bovine articular chondrocyte adhesion and proliferation, and glycosaminoglycans for cartilage tissue engineering [77].

PLA is a well-known established aliphatic polymer used in temperature-based extrusion methods [96,97]. It has a melting temperature close to 175°C, so it can be extruded in melt-based systems between 200°C and 230°C [97]. However, PLA glass transition occurs around 60°C and easily interacts with many plasticizers and solvents to change viscosity, a characteristic that allows printing at lower temperatures [96]. The resulting mechanical properties are usually high, with an elastic modulus around 1.5−2.7 GPa, but it tends to be brittle [96,97]. PLA is commonly used in orthopedic implants and drug delivery systems owing to its biocompatibility and biodegradability [96,97]. Nevertheless, its degradation is via the hydrolysis of ester bonds, which releases acidic by-products; in vivo, this may cause the localized decrease of pH through the release of lactic acid, inflammation, and cell death [97].

PLGA is the copolymer of lactide and glycolide, obtained via ring-opening polymerization, synthesized to address individual limitations and uncontrolled degradation of PLA and poly(glycolic acid) (PGA) [96]. Popular polymerization of D- and L-configurations of lactide yield the PLGA variation, which is frequently used owing to its improved toughness and easy manipulation of hydrolysis-driven degradation rates [96]. The Shah group synthesized "hyperelastic bone," a particle−laden 3D bioink that combines hydroxyapatite, a highly bioactive ceramic, and either PCL or PLGA [78]. The extrusion-printed structures exhibited mechanical and physical properties that allow further manipulation (sheets that can be rolled, folded, or cut). The hybrid with PCL showed highly elastic properties capable of reaching a 61.2% ± 6.4% strain and a tensile elastic modulus of 10.3 ± 1.3 MPa, a behavior superior to that of the PLGA combination (36.1% ± 4.3% strain and 4.3 ± 0.4 MPa elastic modulus). In terms of cell interaction, the PLGA combination showed better results; both the hydroxyapatite−PLGA and hydroxyapatite−PCL scaffolds supported human MSC adhesion and proliferation and induced osteogenic differentiation in the absence of engineered growth factors after 28 days [78].

PPF is a biodegradable polymer broadly applied in tissue engineering owing to its ability to form cross-linked networks through its carbon−carbon double bond [10,22]. The Mikos [22] and Fisher [10,88] groups extensively studied PPF and its cross-linking capabilities for 3DP and tissue engineering. Because it is biocompatible and can be photocross-linked, PPF is a prime candidate for 3DP via stereolithography [22,88], but it can also be as a viscous bioink for extrusion and cured using a UV source [22]. In the first case, the printing process is driven by the intensity of the light source and the proportions of photoinitiator and photoinhibitor in the bioink, but the resulting mechanical properties of the constructs heavily depend on the amount of printing or postprinting exposure to UV, which determines the polymer cross-linking density [10,88]. In the case of extrusion, PPF resins exhibit shear thinning behavior and the concentration of PPF drives the viscosity level. Other factors such as fiber spacing during deposition and pressure affect the pore size and fiber diameter, respectively, but interplay among the factors can also alter scaffold architecture [22]. Melchiorri et al. reported that human umbilical vein endothelial cells and human umbilical vein smooth muscle cells were seeded on stereolithography-printed PPF surfaces and proliferated in a 7-day study [88]. Similarly, MSCs were cultured on PPF scaffolds over 7 days and exhibited levels of metabolic activity that were not statistically different from cells cultured on standard tissue culture polystyrene [10]. In vivo, using 3DP PPF grafts to treat a coarctation of the aorta in mice for 6 months, printed PPF experienced a 40.76% ± 8.37% decrease in mass, and full endothelialization of the inner lumen on the grafts was observed even without preceding cell-seeding or surface modifications [88].

Natural Materials

Based on the definition earlier proposed, bioinks will interact with biological components (e.g., tissues, cells, proteins, growth factors) during or after the actual print or will serve as structural components during the printing of scaffolds that will interface with biological components. Without considering the specifics of in vivo or in vitro applications, there is an imminent interaction between cells and tissues with the bioink or its by-products. Natural materials are taken from animal or plant sources; these are materials that naturally developed to sustain cellular life cycles, nutrient and waste transport, and healing processes. They are composed of the perfect combinations of amino acid sequences, protein ratios, growth factors, and cytokines, thus intrinsically providing safe and nurturing interactions with cells. The composition provides the proper biochemical environment for cells to adhere or feel attracted to, subsequently allowing individual cells the healthy completion of the cell cycle and then induce cellular proliferation, migration, and differentiation. This is the basic definition of cytocompatibility, and natural materials provide a high intrinsic level of it [3,91,94]. Just as important, the composition and biochemistry of a natural material are designed to be degraded by physiologically viable processes through natural enzymatic and chemical processes, and to be discarded by natural metabolic activity, leaving behind no significantly harmful by-products [91]. Bioinks

from these materials can be further biochemically enhanced by encapsulating tissue-specific growth factors, genes, and other controlled-release chemical-regulation factors. Similarly, the surfaces of printed hydrogels can be functionalized by adding the same biochemical factors with both approaches, aiming to recreate environments more like those of in vivo tissues [78,91,94,95]. The balance between cytocompatibility and degradation means that these materials naturally go through the proper cycles and rates needed to induce healthy integration with host tissue [3].

Natural materials can be used as isolated, purified proteins (e.g., collagen, fibrin, keratin, or elastin) or as the natural protein combinations already present in the ECM, combinations that are specific to each type of tissue and determine the type of cells present, the bulk mechanical properties, and its function. Methods to obtain and alter natural materials in laboratory mainly consist of enzymatic cleaving, ionic interactions, and variations in temperature and pH [3]. These methods are used to cross-link the bioinks via multiple 3DP techniques (Table 46.1) and produce hydrogels with theoretically fine-tuned biochemical and mechanical properties. As it will be discussed further (see Cell-Laden Bioinks section), encapsulated cells or those that later migrate into the printed scaffolds are greatly affected by the mechanical cues imparted by the surrounding material. Cellular adhesion, morphology, migration, and especially differentiation, have been widely proven to be affected by the stiffness of the substrate [70,94]. In general, 3DP natural materials result in weak hydrogels difficult to manipulate into specific ranges of physical properties; they are limited by the inefficient or low-energy cross-links achieved by the traditional methods mentioned [94]. Weak mechanical properties have been used as an advantage when attempting to model or regenerate soft tissues or substrate for cell culture, but they are a severe disadvantage when the applications relate to load-bearing hard (e.g., bone, cartilage) or elastic tissue (e.g., muscle, skin, vascular and gastrointestinal tissues, ligaments, tendons). This major weakness has led to combinations with strong and elastic synthetic materials by co-printing or as hybrids, as will be detailed later (see Co-printing and Hybrid Bioinks section).

The intrinsic biocompatibility of natural materials is the main reason why these have been used to formulate bioinks for use in a wide range of in vitro and in vivo bioengineering and regenerative medicine applications (Fig. 46.4). The most popular materials are generally proteins from mammalian origin such as collagen, gelatin and gelMA, fibrin, HA, elastin, and keratin; similarly, popular polysaccharides from plant sources include alginate, starch, agarose, and silk, among others.

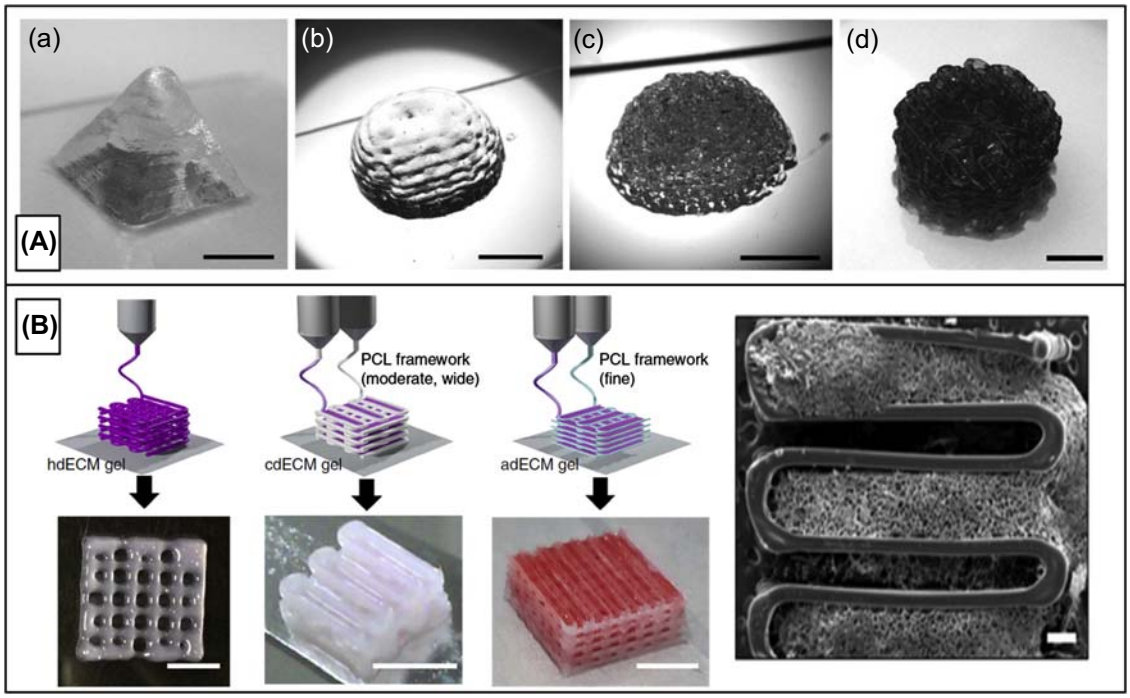

FIGURE 46.4 **Natural materials in bioprinting applications:** (A) Examples of plotted gelatin methacrylate–gellan structures after UV curing: (*clockwise*) solid pyramid, solid hemisphere, porous hollow cylinder, and 30% porous hemisphere (5-mm scale bars) [70]. (B) Examples of decellularized extracellular matrix (dECM) printing in combinations with polycaprolactone (PCL) framework, including heart dECM (hdECM), cartilage dECM (cdECM), and adipose dECM (adECM) (scale bar = 5 mm). Also, scanning electron microscopy of PCL tissue constructs with adipose-derived dECM bioink (scale bar = 400 mm) [100].

Collagen, particularly type I collagen, is the most abundant ECM protein in tissues [9,94,98]. The most common types of collagen are the fibril-forming collagens (e.g., type I, II, III, V, and XI); they are the main component in the ECM of tissues such as bone, tendon, ligament, skin, muscle, or cornea [9,98]. Because of its natural abundance in all types of tissues, collagen has variations that interact with most types of cells and it performs a wide range of mechanical roles in soft, elastic, or hard tissues. For this reason, collagen is arguably the material that most researchers have tried to adapt for bioengineering applications and has been reported as the most commonly used for cell and tissue culture [94]. It has been used in 3DP techniques such as extrusion [23,55], stereolithography [9], and inkjet [51], mostly employing variations of pH-triggered or temperature-triggered gelation [98] that range from hours to minutes [91]. Cross-linking of collagen by altering pH using solubilized sodium bicarbonate solution has been used to construct multilayered cell−hydrogel composites. This method provided a novel approach to printing both fibroblasts and keratinocytes in a single experiment to model dermal−epidermal-like distinctive layers in a 3D hydrogel [15]. Natural material hydrogels have typically been reported to have subpar printing resolution compared with synthetics. Nevertheless, Bell et al. reported printing line widths of about 1 μm using multiphoton cross-linking of type I collagen with a flavin mononucleotide photosensitizer, which confers structural control at a microscale level [9]. Collagen has also been widely used in combinations with other natural and synthetic materials, principally bringing strong biocompatibility to the mixture [13,91,99].

Gelatin is the denatured form of collagen that has undergone partial hydrolysis [9,94]. As collagen, gelatin is characterized by its wide availability, biocompatibility, predictable enzymatic degradation, nontoxic by-products, and inherent cell binding motifs [70]. It has been involved in engineering soft and hard tissues ranging from liver to bone, either by itself or as part as hybrids such as gelatin−alginate, gelatin−fibrin, and gelatin−HA [95,100]. Gelatin is widely regarded as the easiest protein to print, mainly because of thermally responsive behavior that allows extrusion at temperatures below 20°C and hydrophobic cross-linking [64,94]. However, the melting temperature of gelatin (30−35°C) is below physiological temperature, which severely limits its clinical application in vivo [95]. Even with the high resolution obtained by extrusion-based printing [70], gelatin hydrogels are usually soft and limited by temperature, which requires further cross-linking either by postprinting approaches (e.g., using glutaraldehyde or thrombin [95]) or by adding functional groups [94]. Like the acrylate modification on PEG that produces the versatile PEGDA, methacrylamide photoinitiator groups can be used on gelatin to obtain gelMA to produce a photocross-linkable resin. This modification enables irreversible cross-linking, generally by UV irradiation, that preserves printed architectures under physiological conditions [70]. UV exposure time and gelMA concentration regulate printability, whereas the degree of methacrylation determines the mechanical properties and additional acetylation can be used to influence the rheological properties of the bioink further [70,96].

Fibrin is a glycoprotein composed of fibrinogen monomers; it is synthesized in the liver by hepatocytes. In the body, it has important roles in blood clotting and wound healing [94]. The clotting pathway has been replicated as a cross-linking method for 3DP; thrombin is used to polymerize fibrinogen rapidly into cross-linked fibrin [12,94]. As a glue-like gel, fibrin has been used clinically as surgical hemostatic agents and sealants [94]. Enzymatically quick cross-linking rates have been exploited with extrusion and inkjet-based printing [51,52,94], but the mechanical properties of the constructs have been paradoxically described as both robust [94] and weak regardless of the concentration of the reagents [46]. Fibrin-based hybrids materials with natural or synthetic components are usually reported to fine-tune mechanical properties depending on the application, including cross-linking with PEG and adding PGA fibers, PLGA, hydroxyapatite, or demineralized bone matrix [46].

Alginate is a natural polysaccharide derived from algae or seaweed. Sodium alginate is generally cross-linked in calcium chloride ($CaCl_2$) aqueous solution, via an ion exchange reaction between sodium and calcium [3,101]. This chemically efficient reaction results in biocompatible, low−polymer density, high−water content hydrogels [3]. Traditionally, cell encapsulation in calcium alginate hydrogels was the main application of alginate in tissue engineering and bioengineering models, despite the controversial effects of $CaCl_2$, the cross-linking reagent, as well as sodium citrate and ethylenediaminetetraacetic acid (EDTA), commonly used chelators, on cell viability [94]. This ionic cross-linking approach has been implemented in bioprinting. It works particularly well in extrusion-based systems that extrude alginate resin into $CaCl_2$ reservoirs [6,7,14,18,60]. Cells can be suspended in a solution of sodium alginate in cell-specific culture medium, after which cross-linking is induced by incubation in $CaCl_2$ and results in a hydrogel construct laden with cells. This approach has been successful in bioprinting, such as in human cardiac-derived cardiomyocyte progenitor cells (hCMPCs) for an in vitro committed cardiac tissue [18]; heterogeneous scaffolds with MSCs and chondrocytes (in alginate with osteogenic or chondrogenic differentiation medium, respectively) for osteochondral tissue engineering [6]; or encapsulated HepG2 liver cells printed directly on a polydimethylsiloxane chamber for a microfluidic pharmacokinetic liver model [101]. Nevertheless, Carrow et al. stated that there were major challenges for bioprinting alginate: (1) the difficulty of controlling the ionically driven process,

which results in unpredictable microstructures; and (2) the high solubility of alginate, which was a disadvantage when printing thick structures by extruding directly into $CaCl_2$ aqueous solutions [96].

Hyaluronic acid (HA), also called hyaluronan, is a hydrophilic nonsulfated glycosaminoglycan present in the ECM of tissues [94]. The Atala group has regularly used HA in bioprinting processes by adding photocross-linkable methacrylate groups that can undergo free radical polymerization when irradiated with UV light. This modification allows soft hydrogels to be printed via stereolithography or extruded with additional postprinting UV curing [62,63,94]. Although not mechanically robust on their own, HA hydrogels have served in cutaneous and corneal wound healing, prototype vessel structure bioprinting, tumor modeling, and 3DP of cell-laden structures [94].

Other lesser-used natural materials for bioprinting include proteins and polysaccharides such as elastin [98], keratin [45], starch [77], and agarose [3,91]. Despite the success of using isolated natural polymers, there has been growing interest in using the innate combination of proteins in the ECM. The ECM allows structural support and anchoring to cells and also provides a substrate for transport and communication, ultimately affecting the survival and differentiation of cells. Cell−ECM interactions are extremely complex and cannot be fully and precisely replicated in vitro or engineered from isolated proteins. Several groups have presented decellularized ECM (dECM) bioinks derived from adipose, cartilage, heart, bone, or skin tissues. The combination of proteins in the ECM can be understood as a hybrid of multiple natural materials; therefore, available cross-linking methods and bioprinting approaches have been successful in producing 3D dECM scaffolds. Pati et al. developed dECM bioinks that can be extruded as filaments; printed scaffolds can then undergo gelation at physiological temperatures, remaining in the solution below 15°C and cross-linking by incubation at 37°C [100].

Co-printing and Hybrid Bioinks

Approaches attempting to print synthetic and natural materials individually have produced scaffolds with mechanical and biochemical properties that affect cells and tissues differently, and thus can be used in different types of in vitro and in vivo applications. A common generalization in the field is that synthetics are used for their strong, finely tunable mechanical properties; nevertheless, it has been proven that they can provide tunable degradation rates, functionalization capabilities, and various degrees of biocompatibility and print resolution. On the other hand, natural polymers have proven to be highly compatible with a wide variety of cells and biological components, mostly owing to their inherent composition and function. As with synthetics, it is hard to generalize the negative characteristics of natural bioinks, but the properties (mechanical or biochemical) are rarely fine-tunable and usually are presented as ranges and wide error margins commonly associated with batch-to-batch variability. Overall, natural material properties, printing quality, and in vitro or in vivo behavior can be described as unpredictable and difficult to replicate. Combining both types of materials has been an increasingly popular hypothesis that relies on the positive properties of each. In theory, synthetic materials provide structural integrity and printing definition, whereas natural polymers can be used to incorporate cells and other biological components [95,97,100]. Two broad categories for combining synthetics and natural materials as bioinks for 3DP applications are (1) co-printing, the individual but parallel printing of natural and synthetic resins; and (2) hybrid bioinks, in which the resin is a uniform solution of both materials printed as a single construct.

Co-printing approaches rely on printing synthetic scaffold structures with robust mechanical properties onto which natural hydrogels can be printed. This addresses the common limitation of natural materials, the inability to maintain uniform 3D structures in vivo (e.g., to allow tissue load bearing or provide a specific porosity or microstructural pattern) or in vitro (e.g., to be handled robustly in bioreactors, or as cell substrates), by integrating a synthetic scaffolding [14].

The main challenge is that co-printing relies on technologies that dispense more than one material during the printing process, sometimes with radically different deposition necessities and cross-linking mechanisms, as illustrated in Fig. 46.5. In extrusion-based systems, for example, the rheology of the materials is the driving principle, and variables such as viscosity, flow rate, temperature, and pressure determine the extruded line width, fabrication time, or print resolution [7]. Shim et al. used a multihead tissue−organ building system possessing six dispensing heads to dispense thermoplastic PCL and alginate hydrogel individually in the same structure, to produce constructs containing two different cell types for osteochondral tissue regeneration [7]. As they reported, the viscosity of alginate solution was about 10 Pa s and needed low driving forces but high force control to achieve high resolution; on the other hand, viscosity for PCL ranged from 1020 to 2560 Pa s at 80−120°C (a temperature high enough to damage cells) which required high driving forces to extrude [7]. The same PCL−alginate approach was reported using a multihead deposition system, they printed PCL and chondrocyte-laden alginate with and without transforming growth factor β [14]. Here, PCL was extruded at 80 mm/min at 80°C using a 650-kPa pneumatic pressure. Sodium alginate was deposited at room temperature between lines of PCL at 400 mm/min, and then cross-linked in sodium chloride

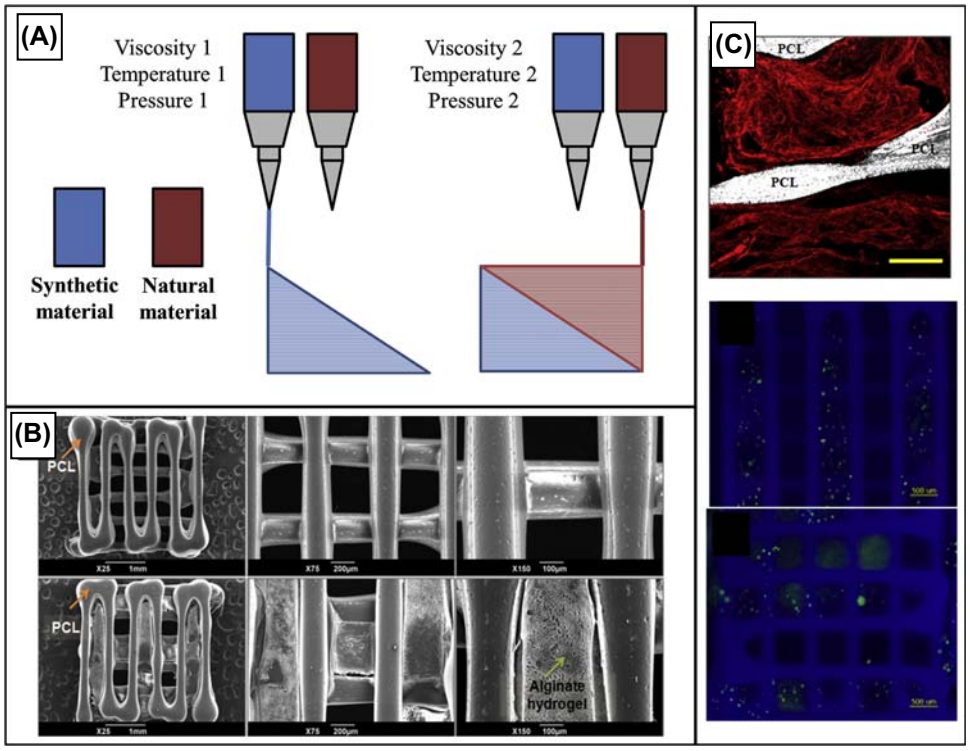

FIGURE 46.5 **Co-printed systems with synthetic and natural bioinks:** (A) Synthetic and natural materials are deposited using independent cartridges and print heads. The different properties of each material can be exploited to print them separately and sequentially, but it is necessary to consider force and temperature shocks that may alter one material when the other is printed in contact with it. (B) Bioprinting of poly(ε-caprolactone) (PCL)-alginate scaffolds. Scanning electron microscopy images comparing PCL and PCL−alginate scaffolds [14]. (C) AlexaFluor 594 red fluorescent dye positively staining type II collagen fibrils deposited by viable chondrocytes encapsulated in the same PCL−alginate scaffolds. Also, live/dead assay of chondrocytes showing cellular viability on the natural material but none on the synthetic component [14].

[14]. These cases illustrate the complexity of printing two different materials in the same structure; as stated before, the key lies in the independent extruding heads, in which the variables of the process (temperature, speed, pneumatic pressure, architectural patterns, etc.) can be controlled independently for each different material.

The ability to control each material separately but still building a single construct has high impact in resolution. In particular, the ability to place cells and materials with different properties into specific patterns confers high control over the resulting mechanical and biochemical behavior of the whole construct. Complex tissue constructs have been achieved via co-printing, such as the muscle−tendon unit (MTU) approach reported by the Atala group [60]. The MTU is the interface between muscle, which is elastic and fibrous in nature, and the tendon, which is stiff and sparsely cellular. In this approach, natural hydrogels were composed of gelatin, HA and fibrinogen. Elastic polyurethane and hydrogel laden with C2C12 myoblasts were chosen for the muscle side, whereas stiffer PCL and National Institutes of Health (NIH)/3T3 fibroblasts gels were selected for the tendon group [60]. The co-printing approach allowed the controlled construction of the interface in which two mechanically different tissues with different cell populations flawlessly met (Fig. 46.5). They reported that the construct was not only able to mimic the complex mechanical behavior of the MTU but successfully retain cell viability in both hydrogel portions (C2C12 cells with 92.7% ± 2.5% viability and NIH/3T3 cells with 89.1% ± 3.3% after 7 days [60]). The PCL-hydrogel co-printing approach has also been used to mimic mandible bone, ear cartilage, and skeletal muscle for tissue engineering [92].

Not restricted to producing tissue scaffolds for eventual in vivo applications, co-printing enables the construction of complex models for in vitro testing, particularly vascularization, microfluidic, and tissue-on-a-chip models. Having multiple heads depositing various materials and cells, under strict spatiotemporal control, has allowed researchers to produce highly complex models that more closely resemble the behavior of biological systems in vitro. These efforts usually require the use of cell-laden hydrogels (see Cell-Laden Bioinks section) and complex types of bioinks such as sacrificial (see Sacrificial Bioinks section) or supportive bioinks (see Supporting Bioinks and Supporting Baths section). An interesting example of such structures can be observed in the work of the Lewis group. Those researchers used the co-printing of natural and synthetic materials to develop in vitro models of tissues

and vascularization [12]. They concomitantly printed natural materials that included cell-laden castable and printable ECM composed of fibrinogen and gelatin, cross-linked via thrombin and transglutaminase enzymatic reactions, whereas the synthetic parts included silicone chip bases and Pluronic sacrificial materials [12]. These materials were deposited and cross-linked independently and sequentially to produce a highly organized vascularized tissue analogue based on the strong characteristics of both natural and synthetic materials.

Hybrid bioinks are the second approach to integrating synthetic and natural materials. In this case, there is a single bioink solution that includes both types of materials as solutes. Generally, hybrid bioinks are composed of a synthetic substrate solution with specific mechanical and rheological properties into which a natural component is mixed to alter biochemical and biocompatibility properties, as illustrated in Fig. 46.6. For synthetic materials, adding natural groups to the bioink usually results in improved compatibility with cellular processes, including binding sites and growth factors or reducing the high hydrophobicity of synthetics [14]. For natural materials, the benefits are usually observed as structural or mechanical, but the inclusion of synthetic polymers to the protein chains also enables natural materials to be processed using the techniques and equipment designed for synthetics. The weak ionic interactions or unpredictable enzymatic processes reserved to process alginate, fibrin, or collagen can be changed for optimized and finely tunable techniques such as photocross-linking or high-resolution extrusion [94].

The hybridization of the materials can be achieved by mechanical entanglement of the materials in solution or by chemically joining the polymer and protein chains. The first is a common approach to improving the mechanical or rheological properties of natural materials. Narayanan et al. used human adipose tissue stem cells loaded in alginate bioink with suspended PLA nanofibers [102]. The cell-laden alginate solution could be prepared separately from the nanofibers but they were vortexed together into a single solution, printed, and cross-linked, trapping the PLA within the hydrogel with no cross-linking interaction between the two. This approach was successful in producing constructs that allowed stem cell differentiation down the chondrogenic pathway; more interestingly, it revealed a

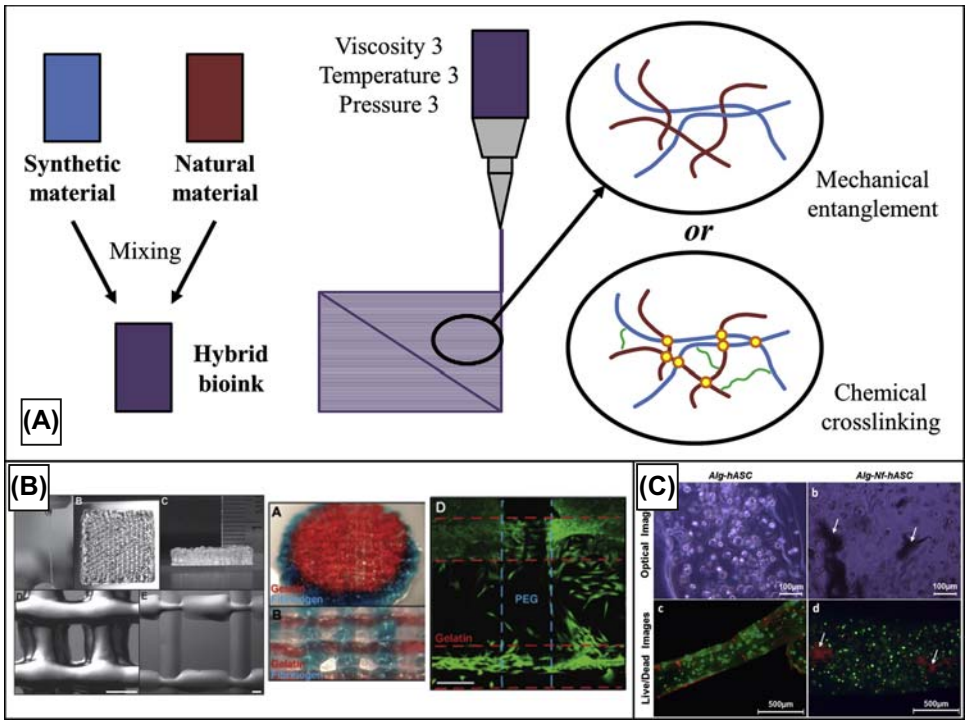

FIGURE 46.6 **Hybrid bioinks combining synthetic and natural biomaterials:** (A) Hybrid bioinks can be three-dimensionally (3D) printed from a single ink containing both the synthetic and natural components. The two materials can be printed into a single construct and structurally held together either by mechanical entanglement of the polymers or by biochemical cross-linking (a process that can occur during resin formulation or after printing). (B) 3D bioprinting of poly(ethylene glycol) with reactive ends (PEGX)—biomolecule hybrids. Extrusion printing of PEGX—gelatin hybrid. Next, PEGX—gelatin (*red*) and PEGX—fibrinogen (*blue*) can be printed in a single cylinder. Finally, PEGX—poly(ethylene glycol) (PEG) and PEGX—gelatin fibers crosshatched, live/dead assay show viable human dermal fibroblasts preferentially adhering to PEGX—gelatin, a synthetic—natural hybrid, but not to the PEGX—PEG, a synthetic mixture [81]. (C) Optical and live/dead fluorescence images (after 16 days) showing cell viability in bioprinted strands of alginate with adipose-derived stem cells (Alg-hASC) and of alginate-poly(L-lactic acid) (PLA) nanofibers with human adipose-derived stem cells (Alg-Nf-hASC) [102].

method to use the distribution and alignment of the PLA nanofibers to stimulate orientations within the ECM-mimicking hydrogels [102]. The second approach relies on chemically altering and cross-linking the synthetic and natural chains. It is commonly used to improve the biocompatibility of the synthetic portion or print the natural material using synthetic methodologies. The chemical modification allows the personalization and optimization of the resulting bioink chain, which means higher specificity of the printed materials to cell or tissue functions. The Shah group, for example, used functionalized PEG to include a variety of proteins in extrudable, tunable, and cell-compatible bioinks [81]. As illustrated in Fig. 46.6, PEG with reactive ends (PEGX) is used to bridge protein and polymer chains in a variety of configurations, producing mixtures such as PEGX−collagen, PEGX−gelatin, PEGX−fibrinogen, and PEGX−PEG, among many others, that can be successfully loaded with cells and printed via extrusion [81].

Cell-Laden Bioinks

Current definitions of bioinks refer to resins that are loaded with cells and printed. As described before, we expanded the definition of bioink to include several categories of printable materials, and do not necessarily consider cells to be the determinant "bio" factor. Nevertheless, the importance of cells for bioengineering and regenerative medicine is undisputable, and cell-laden bioinks are crucial for the development of 3D bioprinting technologies and the goal of printing functional in vivo and in vitro tissues and organs (Fig. 46.7).

Synthetic and natural materials have been proven to have various degrees of success in cell compatibility, tissue integration, and tunable mechanical and biochemical properties, so why incorporate the complex additional factor of cells? It is commonly accepted that the acellular scaffold approaches have poor translation in vivo, mostly owing to the limitation of cells adhering only to the surface of the constructs. The success of this approach is unpredictable, locations and concentrations of growth factors or chemoattractants within the constructs cannot be guaranteed, and cell behavior cannot be controlled [14]. We have mentioned before that the key term that defines modern bioprinting is control. Being able to control where cells, matrix, growth factors, and other biological components are placed results in structures with higher orders of specificity and functionality. If materials and cells can be located and properly stimulated to construct gradients, strata, or clusters, there is a higher chance for success without relying on the unpredictable colonization of native cells. Fedorovich et al. exploited this control feature to reproduce the specific spatiotemporal distribution of cells and ECM in osteochondral tissue [6]. The bioinks consisted of alginate solution in osteogenic or chondrogenic differentiation medium, in which MSC or chondrocytes, respectively, were added. After successful extrusion mimicking the adjacent bone and cartilage portions, ionic cross-linking, and subcutaneous implantation in mice, the dual, heterogeneous scaffolds showed two different cell lineage commitments, with each type of cell remaining in its printed position and depositing lineage-committed ECM [6]. Another multiphase approach to osteochondral tissue engineering was presented by the Demirci group, aiming to study tissue interfaces in the anisotropic composition of fibrocartilage [8]. Human MSCs were encapsulated in gels and printed by droplet deposition in an arrangement with zone-specific biochemical factors and ECM components (transforming growth factor-β1 for fibrocartilage and bone morphogenetic protein-2 for bone regions). Again, cells showed different lineage commitment by upregulating osteogenesis- and chondrogenesis-related genes defined by the position and matrix in which they were printed, yet constructing a single heterogeneous scaffold [8].

Cell-laden bioinks are generally hybrid or natural bioinks that can be 3DP into hydrogels. The materials provide innate cell-binding motifs, hydrophilic surfaces, and low cytotoxicity to promote cell adhesion [94]. The hydrogel structures provide soft, degradable, and swelling networks that mimic ECM and allow cell migration, metabolism, and differentiation with minimal restriction [70,97]. The mechanical properties of 3DP hydrogels can be modified by regulating cross-linking density, the linking chemistry, or polymer concentrations to match properties close to those of native ECM [94]. Structural properties of the microenvironment, such as stiffness or composition, can deliver biochemical cues by mechanotransduction to regulate cell shape, migration, and differentiation lineage selection [81,91,94]. As an example, bioinks used for high-resolution prints generally produce stiffer gels ideal from a 3DP and structural standpoint, but the high elastic modulus will drive stem cell differentiation toward the stronger tissue lineages (bone and cartilage), making it an obsolete approach to produce soft tissues [70].

Hydrogels seem to have the ideal characteristics for cell adhesion and sustenance, but the material−cell tandem must also work with 3DP methods and account for the impact of the processes on cell function after printing. First and foremost, no part of the bioink, printer setup, additional cross-linking mechanisms, or by-products can be cytotoxic; and they have to be sterile-compatible. This seems straightforward, but it considerably reduces the available materials and processes that can be used [3]. 3D bioprinting methods mostly rely on physical forces or temperature to deliver materials. The most popular methods, extrusion-based and inkjet printing, rely on some mechanism of pressure that pushes the bioink through a nozzle. This setup translates pressure on the cells first as a compressive

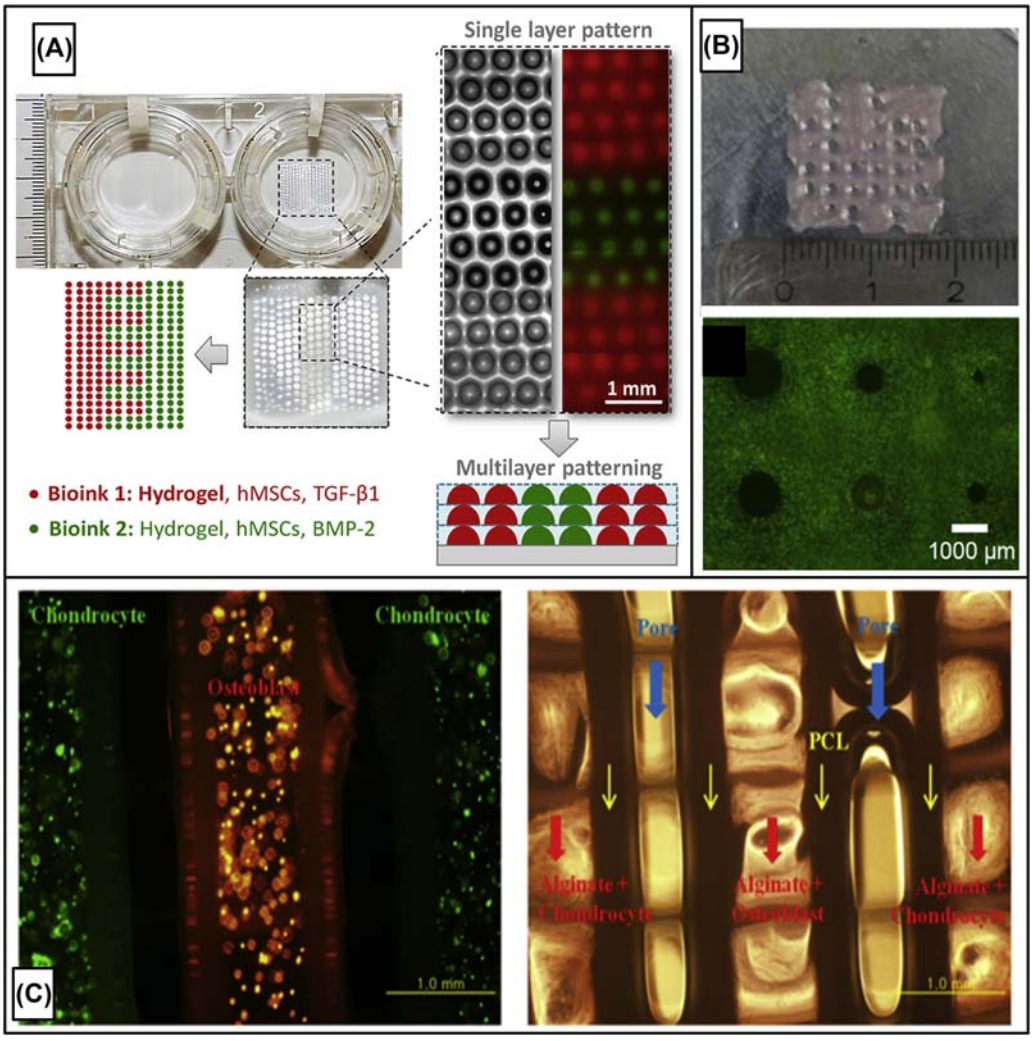

FIGURE 46.7 **Applications of cell-laden bioinks:** (A) Micropatterning and bioprinting the anisotropic three-dimensional (3D) fibrocartilage phase, composed by merging two human mesenchymal stem cell (hMSC)-laden gelatin hydrogels with either tendon or bone growth factors [8]. (B) Macroscopic and live/dead images of printed human cardiac-derived cardiomyocyte progenitor cells in 5% alginate scaffold [18]. (C) Fluorescence image of alginate hydrogels laden with chondrocyte (*green*) and osteoblast (*red*) cells and dispensed into a poly(ε-caprolactone) (PCL) framework. force within the cartridge and then as shear stress while they are moving through the nozzle. Varying the pneumatic pressure, extrusion speed, and nozzle diameter regulates the stress delivered to cells and has been proven to affect cell viability during and after printing [14,94]. A variety of printing protocols have studied these parameters and successfully printed multiple types of cells and materials with a very high viability rate: extrusion of MSCs and chondrocytes in alginate with 89% viability 5 h after print [6] or 97% cell viability after thermal inkjet deposition [34]. High shear rates and shear stress have been proven to harm the cells, but high viability may be explained: (1) Stress causes protein denaturation by damaging the tertiary or quaternary structures of the chains, a process that is reversible with time [34]; or (2) natural or hybrid gels have shear thinning behavior, which decreases stress on the cells even at high shear rates or pressures [6,100]. Bioink viscosity and surface tension can also be modified to reduce shear stress using solvents or surfactants [34,95], although these must comply with minimum cytotoxicity requirements. In the case of stereolithography, the UV intensities required to initiate and sustain photoinitiator and photocross-linking reactions can negatively alter cell morphology and viability [3]. The amount of energy radiated can also cause irreversible damage to the cells as a result of increasing temperatures and dehydration.

Temperatures different from physiological 37°C, both high or low, and drastic changes will alter cell metabolic activity and may cause cell death [94]. This is a critical consideration for co-printing approaches, in which the

temperature required to deposit synthetic materials could easily be above 60−100°C and then solidify on cold surfaces. Both extremes having the potential for irreversible cell damage [4,6,12,14]. Chemically or pH-induced cross-linking by ionic and physical mechanisms can also harm cells. Additional cross-linking or postcuring approaches, such as postprint glutaraldehyde or EDTA chemical cross-linking or additional UV irradiation, which guarantee 3D geometries and mechanical properties, are commonly seen as additional negative factors [4].

A critical element to maintain cells in the bioinks is the permanent need for proper oxygenation and metabolic transport. In vivo, any cell will be located within 100−200 μm of a capillary, the maximum distance for adequate gas and metabolic exchange [4,7,91]. Thick-casted or printed hydrogels without pores do not allow diffusion deep enough to supply oxygen or nutrients and result in necrotic cells encapsulated in the center of the structure. Generally, the design of 3DP architectures is envisioned with pores or channels that provide open transport pathways and open vascularization channels. Interconnected pores, constructed by weaving strands or layered patterns, with dimensions ranging from tens to hundreds of micrometers usually allow transport through the scaffolds and report high cell viability and development [7,10,64,95]. Another common approach is to induce fast vascularization of the constructs, generally by adding endothelial progenitor cells or growth factors and using bioreactors [4,12].

Overall, accounting for the strengths and limitations of printing cell-laden bioinks, numerous approaches regularly report positive effects of this approach on cell behavior for a wide range of applications. As an in vitro example: Gaetani et al. printed a model of undifferentiated but committed cardiac tissue [18]. Here, sodium alginate was dissolved in a culture medium and mixed with hCMPCs. 3D constructs were obtained by printing strands into layers, stacking them to obtain different degrees of porosity, and cross-linking with $CaCl_2$. Compared with regular 2D cultures, bioprinting had no effect on cell viability and proliferation, but it increased cardiac lineage commitment by upregulating early and late cardiac transcription factors and markers [18]. On the other hand, in an in vivo application aiming to produce an implantable bioartificial liver, Wei et al. used a gelatin−fibrinogen matrix loaded with rat hepatic cells to produce 3D porous constructs via extrusion printing and thrombin-induced gelation [51]. After extrusion, about 98% of the hepatic cells were reported to be viable, steadily producing albumin, and dissolving the surrounding gelatin matrix throughout the culture time [51].

Sacrificial Bioinks

Sacrificial bioinks enable the fabrication of complicated structures and open geometries without dealing with many of the difficulties related to satisfying biological requirements. Using a sacrificial bioink for a print material, the print volume is initially created and will subsequently be washed away, as shown in multiple approaches in literature illustrated in Fig. 46.8. The bioink provides space-filling volume and support that will be evacuated. Some groups refer to their sacrificial bioinks as fugitive inks to suggest its temporary role in printing in the scope of the final structure [103]. Therefore, a sacrificial bioink only needs to be nontoxic and will not introduce harmful by-products; however, no further biological features are necessary, such as cell adhesiveness or biodegradability [1]. Here, by nontoxic, we idealize success cases in which the by-products are also noncytotoxic. Still, sacrificial bioinks ideally match these specifications: high print fidelity, ease of removal, and the lack of toxicity (Fig. 46.8).

To enable ease of removal, an important material property is its gelation process: in other words, the conditions under which the printed material will wash away. Some examples of bioinks, such as Pluronic F127 or gelatin, have a thermally reversible gelation process. Therefore, although printing can occur at one temperature, the printed material can evacuate when another temperature is attained. The Lewis laboratory is one of the leaders using Pluronic F127 as a fugitive ink to create perfusable networks in tissue mimics. Pluronic F127, a poloxamer, is solid at 37°C but it can be liquefied when cooled to 4°C. They take advantage of this material property to flush out the fugitive bioink with cold cell media, leaving behind perfusable channels. The resulting print structures resemble thick vascularized tissue mimics with endothelialized lumens viable after 45 days of perfusion [12]. The same group applies this strategy to other tubular tissues; the technique was also applied to fabricating renal proximal tubules [86].

Other common sacrificial bioinks include agarose [67], alginate [57], and gelatin [66]. The Khademosseini laboratory applied sacrificial templating strategies with different materials. For agarose, the geometry was extruded to form a solid network at 4°C. Subsequently, the agarose fibers could be manually removed or lightly vacuumed because the material does not adhere to surrounding photocross-linked hydrogel [67]. With a different material, the Khademosseini cohort used sodium alginate to fabricate a sacrificial network. The gelation of alginate occurred ionically with calcium chloride and could be removed with EDTA treatment [57]. Others applied this strategy to 3DP other tissue mimics such as aortic valves and bone; however, those groups did not print with this bioink sacrificially

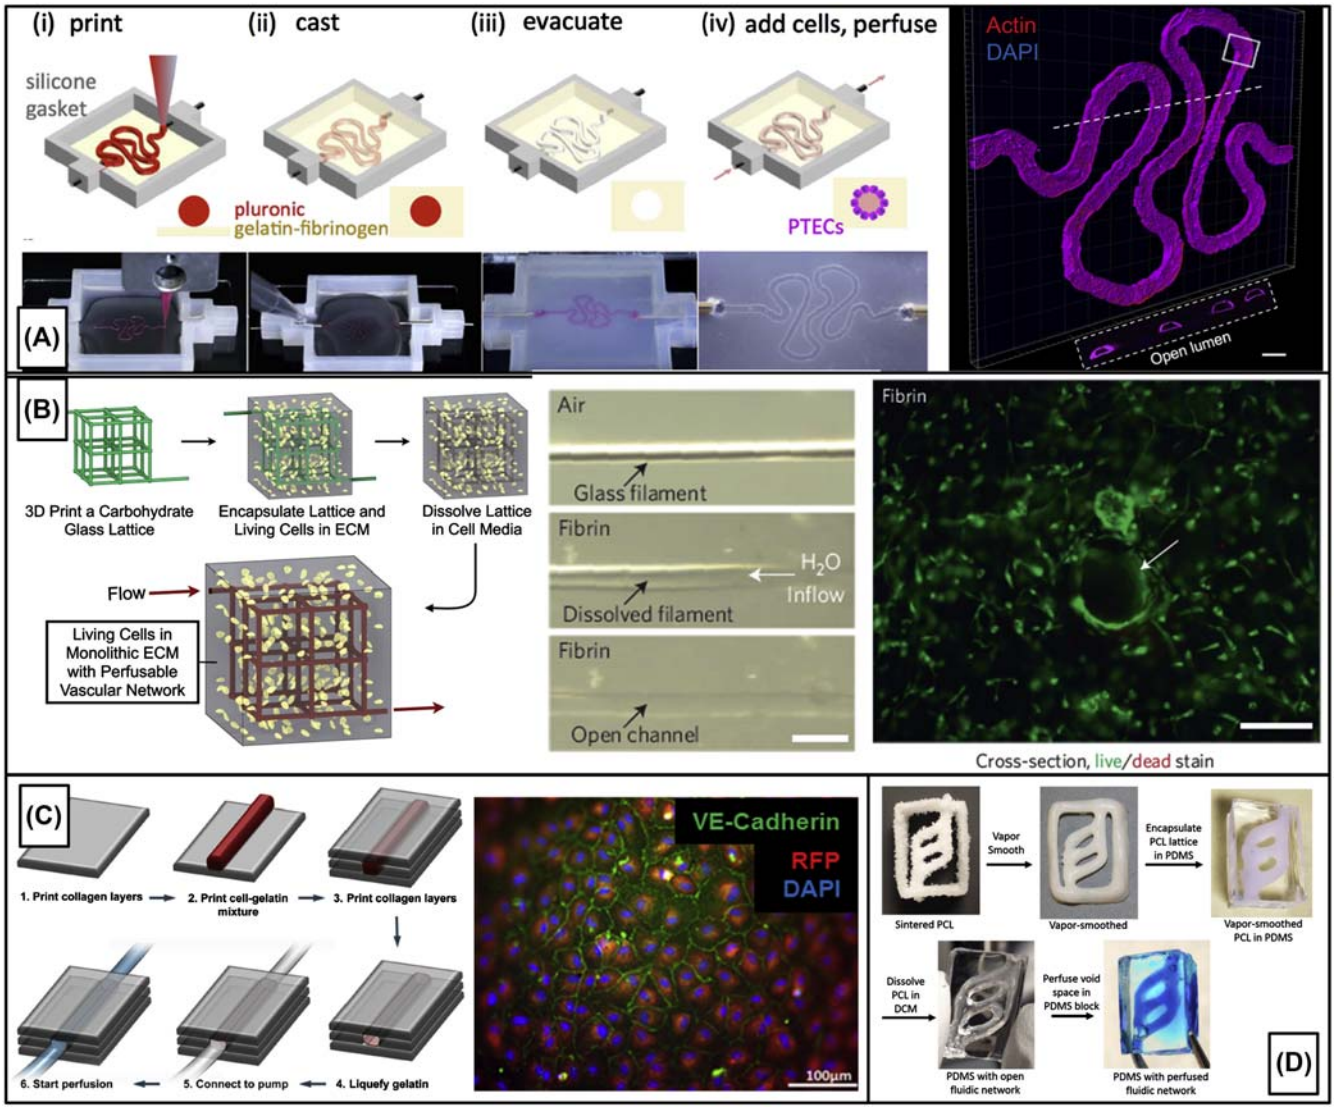

FIGURE 46.8 **Sacrificial templating strategies:** (A) The Lewis laboratory extrudes Pluronic F127 filaments in a renal proximal tubule geometry that is cast with a gelatin–fibrinogen gel. The extruded Pluronic can then be flushed out by cooling to 4°C to leave behind perfusable renal tubules that can be seeded with proximal tubule endothelial cells [86]. (B) Miller and colleagues similarly extrude a lattice structure with carbohydrate sugar glass that can be encapsulated with a number of different extracellular matrix (ECM) or ECM-like materials and later dissolved for a perfusable vasculature. Human umbilical vein endothelial cells are seeded in the casted gel and remain viable owing to the perfusion of cell media through the vascular architecture [11]. (C) Lee et al. print collagen layers with intermittent sacrificial and cell-laden gelatin filaments via inkjet. Gelatin's gelation process relies on thermal transition; therefore, it can be liquified to evacuate open geometries. When seeded with endothelial cells, junctional markers confirm their barrier function after long-term perfusion [66]. (D) Kinstlinger et al. demonstrate that selective laser sintering can also be implemented with a sacrificial templating strategy. Vascular geometries can be formed with poly(ε-caprolactone)(PCL) and casted over with polydimethylsiloxane (PDMS) (shown here) or other materials and leave behind open channels [29]. *3D*, three-dimensional; *DAPI*, 4′,6-diamidino-2-phenylindole; *PTECs*, proximal tubular epithelial cells; *RFP*, red fluorescent protein; *VE-cadherin*, vascular endothelial cadherin.

[58,104]. An additional naturally derived sacrificial bioink, gelatin, is thermally reversible, which proves useful for a sacrificial templating strategy. Lee and colleagues used inkjet printing to form vascularized tissue constructs dropwise and layer by layer with gelatin and collagen. Collagen layers were printed and polymerized at 4°C with a pH-altering cross-linking agent (sodium bicarbonate) so that the thermal responsive nature did not take precedence over the intended material evacuation. Within the collagen layers, gelatin was left uncross-linked and therefore was removed by liquefying the printed structure when the final print structure was raised to room temperature [66]. These natural sacrificial bioinks are all able to be easily evacuated, which fits one of the crucial characteristics of a sacrificial bioink.

So far, the sacrificial bioinks that have been discussed have poor mechanical strength potentially leading to complications in maintaining print fidelity after the print. Some researchers have addressed this complication by using an alternative sugar material that has high mechanical stiffness and is water soluble [11,105]. Miller and colleagues developed an approach to using carbohydrate sugar glass to fabricate complex vascular designs. This strategy circumvented issues related to poor mechanical strength. However, a similar evacuation approach is employed in which the printed perfusable network is evacuated by running cell media through the channels to provide a fluidic network. Although the carbohydrate glass lattices were printed at high temperatures (110°C, a temperature physiologically unviable), the finished print volume could be brought to physiological temperature with complete cell media for 10 min to dissolve the carbohydrate glass [11]. After evacuation, these open channels could be perfused with cell suspensions for long-term cell culture. However, the extrusion-based printing technique used to fabricate structures has limitations. One example of a limitation is that because the build volume relies on depositing material layer by layer, this technique is unable to create overhanging structures without support.

Some in the bioengineering community employ SLS as a different 3D bioprinting technique extending the list of bioinks while addressing the overhang limitation of extrusion-based approaches. SLS-based prints have been commonly used with materials such as PCL and PLA to produce bone-mimicking scaffolds, for example. However, emerging research for this printing strategy falls under the scope of sacrificial bioinks [106,107]. Limited in resolution only by the smallest powder size of the bioink and the laser used, SLS exhibits micron-sized fabricated structures with complicated overhangs with a sacrificial templating workflow [29]. Using PCL, a lattice structure can be selectively laser sintered and dissolved to leave behind a fluidic network. However, to provide perfusable channels, the printed construct requires dissolving in dichloromethane, which may or may not induce toxicity to future seeded cells [29]. More gentle evacuation for future cell encapsulation may be necessary to translate to a cytocompatible workflow. Although others use sacrificial templating strategies with plastics (i.e., acrylonitrile butadiene styrene) to fabricate intricate microfluidic systems and subsequently remove them with acetone, these removal approaches may not lend well to tissue incorporation [108].

Although there is a short list of sacrificial bioinks, these materials share one thing in common: the need to have multimaterial integration for a finalized structure. Inevitably, for the sacrificial ink to be evacuated, a requirement is an encapsulating material in which the flushed material can leave behind a space. The selection of the encapsulation material, the matrix, or matrix-mimicking bioink (see Extrusion-Based Printing section) is crucial to incorporating cells, or otherwise an interface with biological tissue might require cell-adhesive sites or degradation properties. Moreover, the gelation process of the encapsulation should ideally mismatch the sacrificial bioink so that the intended material is the one being sacrificed at the point of dissolving.

Supporting Bioinks and Supporting Baths

Supporting bioinks and supporting baths are used during 3DP to improve the mechanical properties and expand the geometric capacities of the bioprinted scaffold, as shown in Fig. 46.9. High viscosity is commonly a desired material property for supporting baths to provide structural integrity as the print is fabricated. This material property functions to hold the print in place so that the printed material alone (without the support bath) would be unable to be maintained (i.e., overhanging features or ultrathin features). Consistent with requirements for other bioinks, the material should not possess toxicity, to ensure biocompatibility.

The Feinberg laboratory takes an innovative approach to bioprinting by taking advantage of material properties to extrude bioprinted features within a hydrogel support bath. Their approach, coined freeform reversible embedding of suspended hydrogels, uses a gelatin slurry hydrogel bath embodying thermoreversible properties and Bingham viscosity to print soft, fragile constructs within the bath material. With the bath's Bingham plasticity, the material acts as a solid unless a yield shear stress is attained, in which case the material will flow as a viscous fluid locally to the applied shear. In this way, extruded cross-linked printed structures (i.e., fibrin, alginate, and collagen type I via enzymatic, ionic, and pH mechanisms- respectively) within the hydrogel bath will immediately be surrounded by the supporting viscous material- enabling improved complexity in fabrication without collapsing or deforming under the printed structure's own weight. In addition, the gelatin slurry possesses thermoreversible and biocompatible properties. The temporary support bath can be removed by raising the temperature from room temperature maintained during the printing process to a physiological range at 37°C (for gelatin specifically) to release the 3DP object supported within. Because the gelatin slurry is biocompatible, cells can be incorporated in the extruded bioink within the bath without concern regarding its effect on cell viability[23].

Similarly, others have achieved the bioprinting of intricate structures that otherwise cannot be achieved without support baths. Carbopol is another support bath material possessing desirable rheological properties in that the

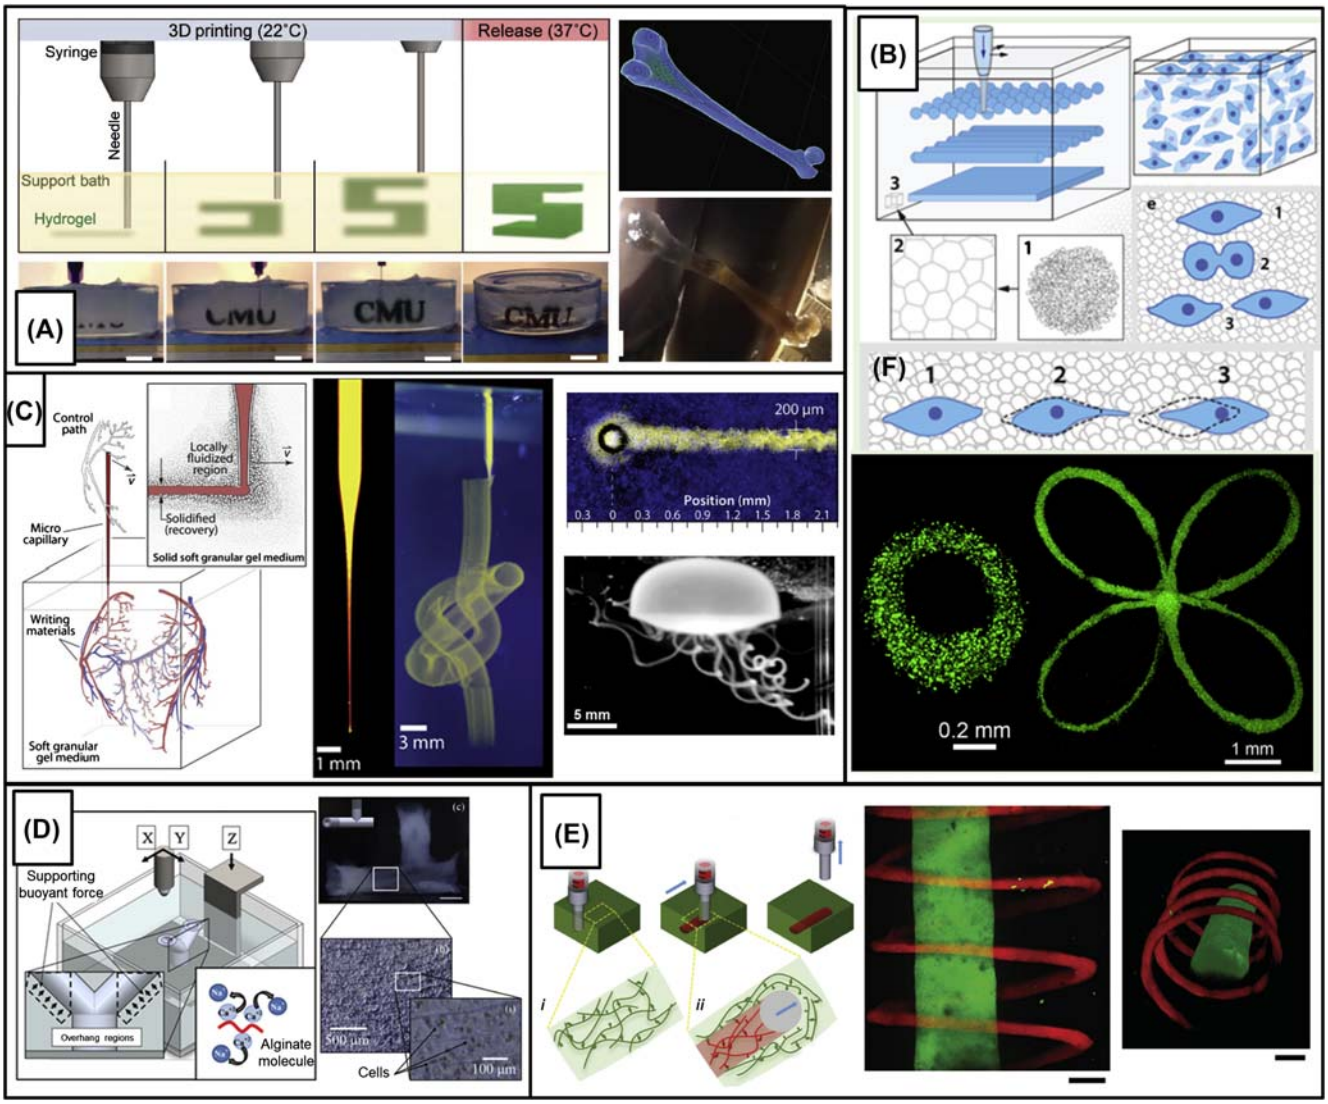

FIGURE 46.9 **Supportive baths used in three-dimensional (3D) bioprinting:** (A) The Feinberg laboratory developed the free-form reversible embedding of suspended hydrogels method to 3D printing (3DP) structures within a support bath. The bath is a Bingham plastic gelatin slurry that provides structural integrity to the print; an example is a human femur computed tomography scan that was downsized to create a printed version composed of alginate (scale = 1 cm, 4 mm) [23]. (B) Angelini's group demonstrates the capacity of cells to remain functional (viable, migrating, and proliferative) with their 3DP method [110] that expanded from their previous work in (C). In (C), a 3D object is printed within another gel support bath. This support bath, based on carbopol, fluidizes locally to the point at which shear is applied (i.e., the needle head extruding print material). The print can be released and form intricate structures such as the fine tentacles of a jellyfish [89]. (D) Christensen et al. use calcium chloride as a supporting and cross-linking bath for sodium alginate bifurcated objects with inkjet printing. This material supports cell encapsulation and allows for overhanging geometries [61]. (E) The Burdick laboratory uses photosensitive hyaluronic acid bioinks printed within a self-healing support hydrogel to form free-standing geometries, as shown by the spiral enveloping a channel [50].

transition from locally fluidized to solidified afforded by its Bingham plastic nature allows for the support of printed structures. Although the writing medium is more permanent (via photocross-linking or other means), the support bath can be dissolved with water [89,109]. The Angelini group has even expanded their carbopol support material to be cytocompatible for a range of cells (i.e., MSCs, human aortic endothelial cells) with enough elasticity to support cell division with the inclusion of cell media adjusted to pH 7.4 [112].

For those using inkjet printing for their bioprinted constructs, a common support bath system employs a $CaCl_2$ solution that can dually function as a cross-linking agent and a support material. In this way, the alginate inkjetted

deposition with or without cells is fabricated with the support bath instantly polymerizing the material to allow for complex structures with overhangs [61].

Yet another extrusion-based bioprinting approach, the Burdick laboratory developed a hydrogel bioink format that is directly written into a self-healing support hydrogel based on guest−host complexes. Their system is based on noncovalent and reversible bonds with the application of shear. By directly writing into this material, the bonds of the support bath are disrupted by the physical stimulus but are quickly reformed after the shear is removed. This enables the capacity of injectable hydrogels and extrusion 3DP. Their writing bioink based on HA was chemically modified for photocross-linking; more important, the support bath possesses shear thinning properties to provide structural support to print freestanding structures [50] (Fig. 46.9).

Support baths must interact with the finalized structure in such a way that the material itself must still provide a minimal baseline of compatibility. Certainly, some approaches have been using the support bath as a reservoir of cells or perhaps cross-linking agents that will ultimately become part of the printed construct; therefore, the level of cytocompatibility is going to increase correspondingly. Regarding toxicity, beyond the baseline of cell compatibility in cell-laden prints, future studies might want to consider long-term effects on cytotoxicity. If residual components of support baths are cytotoxic, a few days after the print is not long enough to prove long-term cell viability and functionality. Finally, in parallel to sacrificial inks, these materials must be easily removable to decouple from the finalized printed construct.

Current Translation of Three-Dimensional Bioprinting

3D bioprinting has opened the door for opportunities in directly translating to the clinic. 3DP provides us with the ability to print tissue analogs by controlling the delivery of living cells and matching the appropriate material in a defined and organized manner. The control is promising because it is beyond defining the exact location as well as the sufficient number of cells in a multimaterial environment. 3DP has applications to tissue-engineering scaffolds, constructing cell-based sensors, physiological screening for drug and toxicity, and modeling tissue disease and tumors [100]. Here we will broadly characterize translation applications using in vitro and in vivo examples.

In Vitro Applications

In general, lab-on-a-chip style models can represent tissue analogs well by incorporating the many fluidic networks of our body (i.e., vasculature, lymphatics). An example of lab-on-a-chip, miniaturized, functional tissue mimics was discussed in the sacrificial section from the Khademhosseini laboratory. In their work, they incorporated embedded vascular networks in their 3DP constructs [67]. Many others have also dedicated their research to incorporating vascular fluidic networks, because vascularization remains a critical challenge in tissue engineering [11,29,86,103]. As discussed, beyond a few hundred microns of the diffusion limit, cells will not remain viable. However, even with many research groups studying vascularization strategies, many challenges remain, such as which vascular geometries to print and how to reach truly multiscale vasculature. By miniaturizing human tissue functional elements, studies can more accurately predict drug toxicity over animal models. Khademhosseini and colleagues delved into more complex in vitro models by developing liver-on-a-chip constructs. By developing a liver model, one can assess drug toxicity more adequately because the liver has the most important role in drug metabolism. Their liver model was biofabricated as a perfusable bioreactor with a direct-write printer to create hepatic spheroid-laden hydrogel structures [65].

In addition to better drug screening, in vitro models fabricated with 3DP approaches can better represent tumor models to help researchers elucidate cancer mechanisms. Efforts are being made to represent tumors 3D in models, because the progression of tumor metastasis is significantly different from that of a 2D counterpart [111]. The West laboratory modeled tumor angiogenesis with layer-by-layer tunable PEG hydrogels [112]. 3DP can provide cancer researchers with control over specific 3D microenvironments influencing nutrient transport and fluid shear stresses. With this kind of physiological mimicry, researchers can identify mechanisms directing tumor metastasis.

A major challenge for 3DP is scale for tissue engineering translation: Printers often have difficulty achieving large, clinical-size organ analogs with the microdetail of the cellular organization necessary to be functional. The Atala laboratory reported an integrated tissue-organ printer that prints cell-laden hydrogels of desired mechanical stiffness with sacrificial hydrogels. Fabricated constructs presented include mandible bone, cartilage, and skeletal muscle. The printed anatomical shapes can be composed of multiple biomaterials and cells resulting in structures that in the future can be vascularized and included in more complex, solid organs [113]. Until then, these constructs may be difficult to incorporate in the clinic because encapsulated cells will quickly necrose without proper vascularization.

For in vitro 3DP, clinical translation is mostly limited to drug screening and disease modeling. These applications can provide important information regarding addressing drug toxicity and to develop drugs.

In Vivo Applications

The promise of 3DP to fabricate tissue parts for implantation in the body is taking shape in in vivo applications. Tissue engineering has the potential to facilitate tissue regeneration by replacing injured parts and encouraging regrowth with the appropriate healing environment (i.e., growth factors, vascularization, stem cells). With 3DP, a diversity of critical-sized defects can be addressed tailored to the needs of the individual. In this section, we discuss studies that use 3DP to fabricate scaffolds applied in vivo.

As mentioned previously, rapid vascularization is a limitation in applying tissue mimics in vivo, because cells will necrose soon after implantation without access to nutrients and oxygen. Several studies achieve rapid vascularization in vivo enabled by prevascularization strategies fabricated with 3DP techniques [114,115]. Using sacrificial templating with a sacrificial carbohydrate bioink, an open microvascular network can anastomose in line with the rat femoral artery with a surgical technique [11,114]. Similarly, others employ 3DP biodegradable scaffolds to anastomose built-in vasculature directly and surgically in an AngioChip to the host vasculature of the rat hind limb femoral vessels [115]. Patency is maintained through the fabricated vessels within the scaffold. These studies demonstrate the potential of prevascularizing tissue analogues with 3DP for rapid vascularization in vivo.

Other tissues have been fabricated and implanted in vivo, such as bone. Bone scaffolds 3DP with MSCs, bone morphogenetic protein growth factor, and PCL as the bioink have been implanted in critical-sized bone defects of sheep. After 3 and 12 months, bone healing progresses with signs of vascularization ingrowth, mineralization, and appropriate mechanical stiffness [76]. By considering important aspects of biocompatibility and degradability, many of the bioink principles described earlier here have resulted in the success of 3DP tissue mimics for in vivo implantation.

The opportunities to apply 3DP to in vivo applications are still being explored. Integration with the host tissue is of utmost importance for all in vivo studies. For researchers, great care is taken to select the most appropriate bioink during fabrication to allow the best possibility for successful integration. Future work is necessary to ensure the functionality of the intended tissue analog taking into consideration the role of the parenchyma.

CONCLUSION AND FUTURE DIRECTIONS

This chapter introduces current 3DP techniques and describes the materials used to enable bioengineering applications. For bioprinting, the materials, or bioinks, used for fabrication must be biocompatible as well as printable. Bioinks are printing materials that will interface with biological components or are part of the fabrication process of a construct that will come into biological contact. We describe three separate categories for bioinks: (1) matrix or matrix-mimicking, (2) sacrificial, and (3) supporting.

Although there has been great progress in synthesizing biocompatible and printable materials, future work is needed to address the greatest limitations in bioengineering. For one, vascularization must be rapidly integrated. Many of the challenges for vascularization strategies involve scale to realize multiscale hierarchical vessels. Reaching capillary-sized vessels requires microscale resolution in printing. However, many printing techniques that can even reach these small levels are not able to print rapidly. Another limitation in current studies is the use of physiologically relevant cell types. Fortunately, induced pluripotent stem cells hold much promise in alleviating this limitation. Materials available as bioinks are limited. Generally, the bioinks used are a compromise between structural strength and biocompatibility. Therefore, current and future work follows a multimaterial approach to achieve the desired properties.

The advent of 3DP applied to bioengineering and tissue engineering has pushed researchers to create complex biological structures with incorporated fluidic networks with multiple cells and materials for the most physiologically mimicking environment. This is an exciting time for the field to realize approaches that have a clinical impact. From rapidly reiterating studies for drug screening to achieving high spatial resolution to fabricate tissue analogs, 3DP holds much promise for therapeutic translation. The choice of bioinks will continue to have a fundamental role in determining ultimate biocompatibility.

List of Acronyms and Abbreviations

2D Two-dimensional
3D Three-dimensional
3DP Three-dimensional printing
$CaCl_2$ Calcium chloride
dECM Decellularized extracellular matrix
ECM Extracellular matrix
EDTA Ethylenediaminetetraacetic acid
gelMA Gelatin methacrylate
HA Hyaluronic acid
hCMPC Human cardiac-derived cardiomyocyte progenitor cell
MSC Mesenchymal stem cells
MTU Muscle–tendon unit
PCL Poly(ε-caprolactone)
PDMS Polydimethylsiloxane
PEG Poly(ethylene glycol)
PEGDA Poly(ethylene glycol) diacrylate
PEGX Poly(ethylene glycol) with reactive ends
PGA Poly(glycolic acid)
PLA Poly(L-lactic acid)
PLGA Poly(D,L-lactic-*co*-glycolic acid)
PPF Poly(propylene fumarate)
SLS Selective laser sintering
UV Ultraviolet

INTRODUCTION

Attempts have been made in tissue engineering to develop biological substitutes to address the high shortage of tissues and organs for transplantation. Although tissue engineering has progressed rapidly over the past 2 decades, conventional fabrication methods are limited in their ability to create clinically applicable tissue constructs with well-interconnected pores, complex architectures, patient-specific geometries, and heterogeneous material distributions. Over the past few years, three-dimensional (3D) bioprinting strategy has been applied to overcome these limitations. It enables the fabrication of tissue constructs with unique spatial control over the deposition of cells, biomaterials, and bioactive molecules such as growth factors, cytokines, peptides, and small molecules, resulting in higher regenerative capability after implantation [1,2]. 3D printing technology was developed in the 1980s and included various approaches to creating objects from a computer-generated file [3]. This technology quickly became a powerful tool in tissue engineering and biomedical research [4]. In structure-based bioprinting, bioinert or bioactive materials such as metals, ceramics, and polymers are used to develop a tissue structure followed by precisely depositing cells and bioactive molecules onto it [5,6]. In cell-based bioprinting, a high density of cells is patterned spatially with a prescribed organization in a layer-by-layer fashion, forming tissue constructs [5].

Thus, additive biomanufacturing or 3D bioprinting allows the creation of tissue-specific architectures with precise geometries that have been limited using conventional fabrication methods. Landers et al. first introduced 3D bioprinting as an extrusion-based method to dispense cells continuously within a hydrogel material (bioink) from a dispensing head to a stage-based patterns predesigned through computer-aided design/computer-aided manufacturing (CAD/CAM) tools [7,8]. Various types of 3D bioprinting methodologies are available to meet specific requirements in tissue engineering applications.

BIOPRINTING STRATEGY: FROM MEDICAL IMAGE TO PRINTED TISSUE

Bioprinting aims to achieve reproducible, complex tissue structures that are well-vascularized and suitable for future clinical use. Human tissues and organs have arbitrary 3D shapes composed of multiple cell types and an extracellular matrix (ECM) with a functional organization. CAD/CAM processes are important technologies necessary for future clinical applications of 3D bioprinting because these processes provide an automated way to replicate the 3D shape of a targeted tissue structure. In general, the process starts by scanning the patient to produce 3D volumetric information about a target object using medical imaging modalities such as computed tomography

A 3D CAD model developed from medical image data generates a visualized motion program, which includes instructions for XYZ stage movements and actuating pneumatic pressure to achieve 3D bioprinting. *CT*, computed tomography; *DICOM*, Digital Imaging and Communications in Medicine; *MRI*, magnetic resonance imaging; *STL*, stereolithography.

(CT) and magnetic resonance imaging. These imaging tools acquire information from cross-sectional slices of the body and the data are stored in the Digital Imaging and Communications in Medicine format, which is a standard format for digital imaging in medicine. This information is transformed into a 3D CAD model by reverse engineering. This process starts by interpolating points within and between image slices to improve the resolution and generate voxels from the measured data. This CAD model is created by extracting localized volumetric data from a targeted tissue structure to generate a surface model. In this step, sophisticated reconstruction of the CAD model is required for bioprinting owing to the complexity of the tissue or organ. A motion program, which is instructional computer codes for the printer to follow designed paths, is generated with a CAM system. This CAM process is divided into three steps: slicing, the tool path, and the generation of the motion program. Slicing obtains information about sliced 2D shapes of an object for the layer-by-layer process. Then, tool path generation creates a path for the tool to follow to fill the cross-sectional space of each layer. The printed tissue-specific structure has the proper inner architecture constructed with multiple cellular components for efficient tissue regeneration. Therefore, a well-organized strategy for tool path generation is required to have high efficient tissue regeneration and is an important process for 3D bioprinting. Fig. 47.1 shows the 3D bioprinting strategy from the medical image to the printed tissue constructs developed by CAD/CAM process and automated printing of a 3D shape imitating a target tissue or organ.

BIOPRINTING MECHANISMS

Researchers have developed a variety of printing mechanisms, all of which aim to accomplish the same goal: printing 3D human tissue or organ structures for reconstruction. The effectiveness of each printing mechanism relies heavily on the choice of biomaterials and the targeted applications. Bioprinters consist of three main components: a three-axis stage, printing cartridges, and the dispenser. Stage controllers are used to move the printer head in the X, Y, and Z directions. Printing cartridges, usually in the form of a syringe, store either the polymeric components of the scaffold or the cellular/hydrogel components. They contain the nozzle, which determines the amount of material dispensed at set printing parameters. The dispenser is the final component; it varies among printing methods, but it is the mechanism that deposits materials (Fig. 47.2).

Jetting-Based Printing

Jetting-based printing, or "inkjet" printing, is the most commonly used printing mechanism for both nonbiological and biological objects [9]. Similar to an inkjet printer used to apply ink to paper, jetting-based bioprinters dispense a controlled volume of liquid to a predefined location through noncontact deposition (Fig. 47.2A). The "ink" in this instance is usually a hydrogel that may or may not contain cells and can be dispensed in

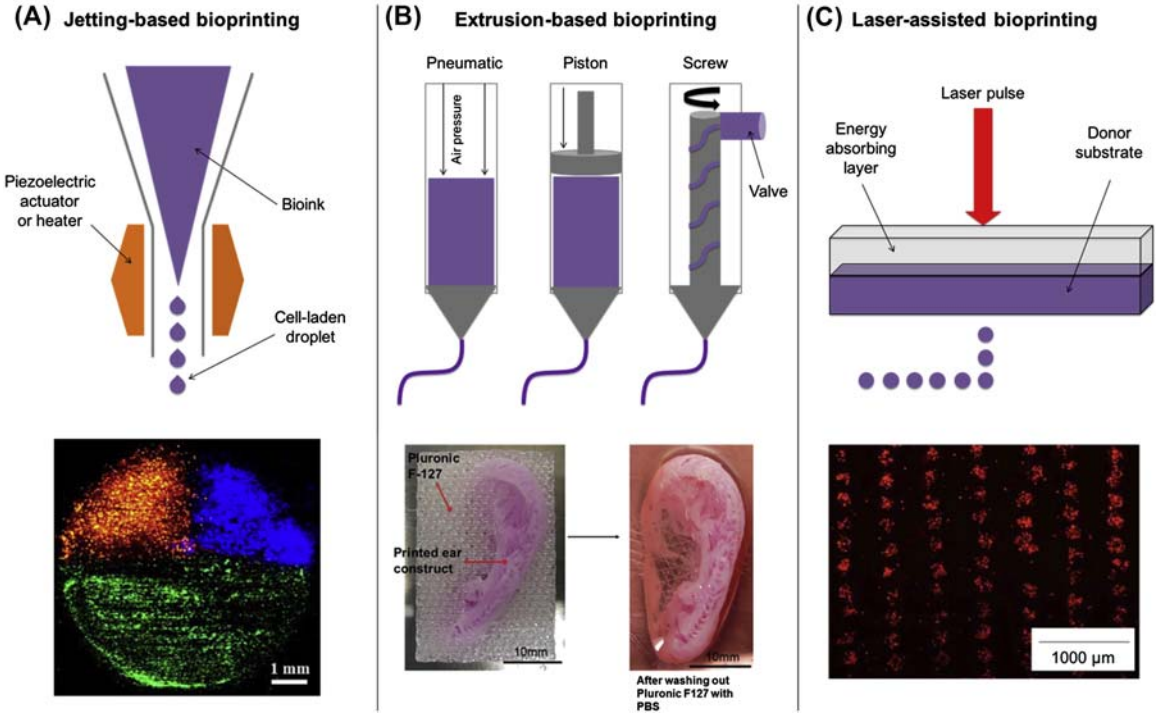

FIGURE 47.2 (A) Microscopic view of a three-dimensional multicell "pie" construct printed by a jetting-based mechanism. Individual cells were printed in predetermined locations and then located by microscopy at those locations after printing [124]. (B) Auricular implant was printed through extrusion-based mechanisms with cell-laden hydrogel, poly(ε-caprolactone), and Pluronic F-12 [47]. (C) Human umbilical vein endothelial cells were printed precisely in straight lines through laser-assisted bioprinting to study cell migration rates [125]. *PBS*, phosphate-buffered saline.

volumes between 10 and 150 pL, depending on the dispensing modules used [10]. The two main dispensing methods for jetting-based printing are thermal and piezoelectric inkjets. Thermal inkjets use an electric heater that generates small bubbles in the printhead. These bubbles collapse to create pressure pulses that force droplets of liquid out of the nozzle. Although thermal inkjets use heat at around 200−300°C, the duration of heating is typically around 2 μs, which studies have found to result in only a 4−10°C rise in hydrogel temperature [9]. Piezoelectric inkjet printers use a polycrystalline piezoelectric ceramic to create the pressure pulse that ejects the droplet [10]. The volume of liquid dispensed depends on the temperature gradient, the frequency of the pressure pulse, and the ink viscosity. To determine where the material will be dispensed, the bioprinter can control the X and Y positions of the nozzle heads to a scale of micrometers, which allows for precise, high-resolution printing.

A major drawback of jetting-based printing is the amount of shear stress induced on the cells as they are forced through the nozzle. Shear stress creates a huge risk to damage cell membranes and causes cell lysis [10]. Another drawback of this printing is that to dispense materials, it has to be in a liquid form, so to form a solid structure, the liquid has to be cross-linked during or very soon after printing. This causes a significant reduction in printing speed, because a time for cross-linking must be determined. It is also considered that high cell concentrations (greater than 10 million cells/mL) often result in nozzle clogging and some instances may even alter the properties of the hydrogel so much that it can no longer be cross-linked [11,12].

Despite these drawbacks, jetting-based printing offers many advantages over laser-assisted and extrusion-based printing methods. Commercial inkjet printers are readily available, and because of this, many laboratories can modify the printers so that they can experiment with bioprinting at a low cost. The printers also offer high printing resolution, which allows concentration gradients of cells, biomaterials, or bioactive molecules to be introduced throughout the structure by altering drop sizes and densities [9]. The droplets can be arranged into patterns such as lines 50 μm wide or single droplet patterns containing one or two cells [13]. The droplet size can be controlled electronically and can range from less than 1 pL to more than >300 pL in volume with deposition rates from 1 to 10,000 droplets per second [14].

Extrusion-Based Printing

Unlike jetting-based printing, extrusion-based printing is an additive manufacturing mechanism that relies on fused deposition modeling and requires direct contact with a surface to print (Fig. 47.2B). These printers mainly include a temperature-controllable dispensing system and a stage, with one or both capable of movement in the X, Y, and Z axes. Some 3D extrusion printers have multiple dispensers that allow them to switch printing material without going through the process of retooling [15]. Extrusion-based printing methods offer improved printing resolution, speed, and spatial control. These printers also differ from inkjet printers in the manner in which they deposit material, because they dispense in a continuous string as opposed to individual droplets. The printer extrudes a 2D pattern designed by CAD/CAM software, and then each layer serves as the foundation for the next layer above it. Three systems can be used to extrude the material: pneumatic, piston, or screw-based dispensing systems [9]. Pneumatic dispensing systems can deposit high viscous materials, but the drawback is that there is a delay in deposition owing to the time it takes to compress the gas in the cartridge. The ultimate force of pneumatic systems is limited only by the air-pressure capabilities of the system. Mechanical systems such as a piston and screw-based dispensers provide more spatial control at the cost of reduced maximum force capabilities [9].

Extrusion-based printing methods have the widest range of biomaterials that can be printed; they vary from hydrogels to polymers and cell aggregates. Materials with viscosities ranging from 30 mPa/s to greater than 6×10^7 mPa/s have been successfully printed with extrusion-based printers, with high viscous materials acting as structural support and low viscous materials providing an adequate environment for cell printing [16]. This printing method is also able to print a high density of cells; however, cell viability may be decreased with smaller nozzle sizes and a high pressure level. The main challenges to extrusion-based printing mechanisms are the low printing resolution and low printing speed: 5- to 200-μm pattern resolution at linear speeds of 10−50 μm/s [17].

Laser-Assisted Printing

Laser-assisted bioprinters operate by focusing a laser pulse toward an absorbing layer, typically gold or titanium, to generate high-pressure bubbles that propel cell-containing bioinks toward a collector substrate [9]. A standard laser-assisted printing system usually consists of a pulsed laser beam, a focusing system, a "ribbon" that has a transport support made from a laser energy−absorbing layer, a layer of hydrogel or cellular material, and a substrate-receiving layer (Fig. 47.2). Laser-assisted printing method has successfully transferred peptides, DNA, and cells [18]. The main advantage of this method is that it is nozzle-free; therefore, it avoids nozzle clogging issues found in other bioprinting systems. Laser-assisted methods can deposit materials with viscosities ranging from 1 to 300 mPa/s and cell densities close to 10^8 cells/mL, with resolutions close to a single cell per drop without significant effects on cell viability or function. In addition, many factors affect the printing resolution. Some of these factors include the energy delivered per unit area owing to the laser, the surface tension, substrate wettability, the gap between ribbon and substrate, and the thickness and viscosity of the biological layer [9].

There are also a lot of disadvantages associated with the laser-assisted printing system. One drawback is that each ribbon must be prepared following a time-consuming process that may become overwhelming if multiple cells or hydrogels must be codeposited [9]. It can also be difficult to target and position the cells accurately because of the nature of the ribbon cell coating. Metallic residues may be present in the final construct owing to vaporization of the laser-absorbing layer, although there have been methods to reduce this contamination, including using nonmetallic absorbing layers and altering the printing process so that an adsorbing layer is not needed [19].

Hybrid and Other Mechanisms

Hybrid fabrication is a combination of technologies that are practiced individually. Despite rapid growth over 2 decades, current 3D bioprinting techniques and systems fall short in integrating rigid and soft multifunctional components. In some instances, the advantages of one technology might not be sufficient to meet the requirements of creating targeted functional tissue constructs. Merging technologies may overcome this limitation and improve the bioprinting process. The combination of technologies can be at the cellular, bioink, or bioprinter level. Tan et al. introduced a 3D bioprinting strategy by integrating conventional scaffold-based fabrication and the cell-based bioprinting approach [20]. They explored the use of hydrogel-encapsulated, cell-laden microspheres as the bioink for 3D bioprinting. The hydrogel lubricates and glues the microspheres during printing and fuses them together

after printing upon gelation. Kucukgul et al. developed computational algorithms to generate support structures for cylindrical cell aggregates to print fully cell-based vascular structures [21]. Xu et al. proposed a combination of electrospinning and inkjet bioprinting techniques to develop layered cartilage constructs [22]. Combining the two principles of electrospinning and bioprinting resulted in the fabrication of a cartilage construct with appropriate cell function and mechanical properties. Shanjani et al. developed a new hybrid 3D bioprinting technology called Hybprinter by integrating soft and rigid components [23]. This technique employs a digital light processing–based stereolithography component and molten material extrusion techniques. Poly(ethylene glycol) diacrylate (PEGDA) was used as soft hydrogel and poly(ε-caprolactone) (PCL) as the scaffold's structural support. Mendoza-Buenrostro et al. reported a hybrid bioprinting technique for the fabrication of scaffolds with topography scales ranging from nanometers to millimeters [24]. Scaffolds were produced by extrusion-printing PCL embedded with nanofibers.

BIOMATERIALS FOR BIOPRINTING: BIOINKS

Printability

When used in bioprinting, hydrogels that can encapsulate and deliver cells and bioactive molecules through printing mechanisms are referred to as bioinks. In extrusion-based bioprinting, bioinks should have strong shear thinning behavior, which means that viscosity decreases under shear strain [25]. They should also have low surface tension so that extrusion is possible without the formation of droplets at the needle tip. In addition, bioinks should have proper viscoelastic properties that allow them to be stable enough to be printed in multiple layers before cross-linking. Traditional hydrogel precursors are low-viscous solutions that are cross-linked either during or after the printing process. Cross-linking before printing increases the shear stress on the cells, resulting in cellular damage and nozzle clogging. Cross-linking after printing affects the resolution because of the spread of bioink in the time between extrusion and cross-linking and can lead to incomplete cross-linking deep in large, multilayered constructs [9]. Fig. 47.3 shows a schematic diagram of variables, including printability, in 3D bioprinting.

There are structural properties that must be satisfied so that the printed construct maintains shape, accuracy, and integrity after printing is finished. The printed construct should maintain its predesigned structure, which includes shape, resolution, orientation, and mechanical properties. Because bioprinting aims to build a 3D tissue construct with cells, cell viability after printing is one of the main criteria for the printability of bioinks. For the cells to survive, a biologically favorable microenvironment is required so that the cells can be well-preserved not only during the printing process but also afterward in culture. In hydrogel-based bioinks, cell density, diffusion coefficient, temperature, and humidity can significantly affect the printability of the bioinks [26–28].

Hydrogel-Based Bioinks for Cell Printing

Hydrogels are naturally derived or synthetically produced. Hydrogel networks consist of polymer chains or peptide chains. They are highly moist and ideal for absorbing high levels of nutrients and oxygen, enabling cells to survive within the construct and diffuse waste. Therefore, hydrogels have been printed by a variety of mechanisms to deliver cells in the printed constructs. In the extrusion-based printing, the required properties of hydrogel-based bioinks during the printing process are (1) high viscosity to provide homogeneous cell suspension and initial structural integrity, (2) strong shear-thinning behavior to minimize cell damage, and (3) rapid gelation mechanism to stabilize a 3D-printed structure. If the gelation time is too long, the spatial resolution is lost and the layer cannot be printed correctly. To control the gelation time, the cross-linking mechanisms can be manipulated by chemically modifying the material, introducing a cross-linking agent or changing the polymer content [29].

Synthetic Hydrogels

Synthetic hydrogels used as bioinks have low cytotoxicity, controlled biodegradability, and good mechanical properties; however, most synthetic hydrogels have low biological properties that interact minimally with cells. Pluronic F127, a thermosensitive hydrogel, undergoes a phase transition at room temperature and becomes a viscous substance [30]. When the concentration of Pluronic F127 is 25% w/v or more, it can be dispensed with high printability. Although high-resolution of the printed structures can be achieved using Pluronic F127, the structure can

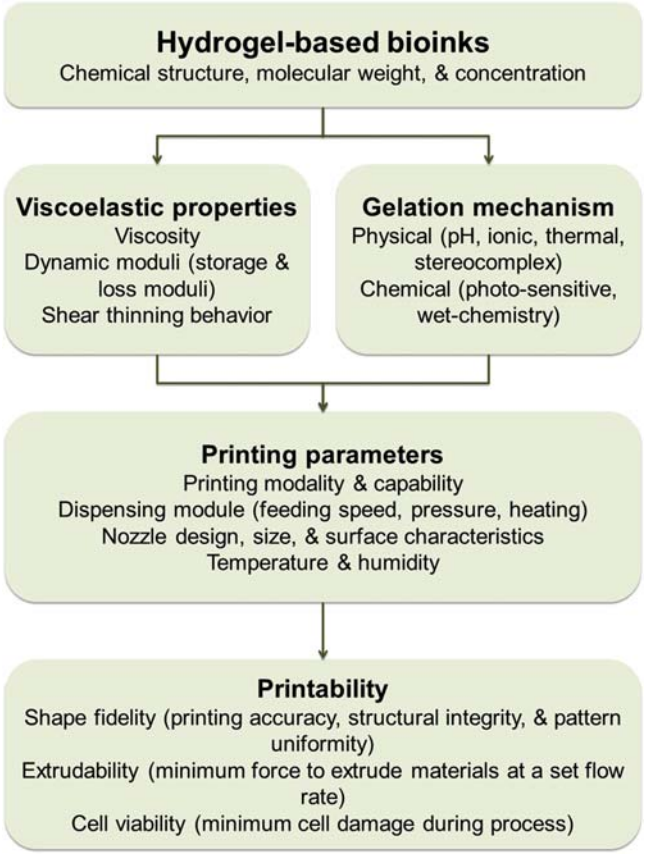

FIGURE 47.3 Schematic diagram of variables critical to three-dimensional bioprinting strategy. The hydrogel-based bioinks determine the viscosity, gelation mechanism, and printing parameters, and eventually the bioprinted tissue structures.

easily be collapsed in the culture condition. To improve its mechanical stability, Pluronic F127 has commonly been used chemically modified as a photocross-linkable hydrogel [31]. Poly(ethylene glycol) (PEG)-based hydrogels can be chemically modified to control their biological and biomechanical properties. Therefore, PEGs have been used as bioink materials in 3D bioprinting by introducing various functional motifs attached to the terminal end of PEG [32] or combining them with other hydrogels [33,34].

Naturally Derived Hydrogels

Natural hydrogels are classified into mainly proteins and polysaccharides. Most of them are present in the body, so they show high biological properties and do not cause a severe immune response. Collagen (type I) is the most abundant component of ECMs; it contains cell-guiding chemical cues such as the cell adhesion peptide sequence arginine-glycine-aspartic acid. Under the appropriate temperature and pH, a pure collagen solution physically forms a gel with properties dependent on the solution concentration. However, collagen itself has rarely been used as a bioink material owing to low viscosity and poor mechanical stability. To overcome these limitations, collagen has been mixed with various other hydrogels such as agarose, chitosan, fibrin, and hyaluronic acid (HA) [22,35–37]. An approach to printing skin cell-containing collagen solution from separate nozzles using an inkjet microvalve dispensing method was reported [38]. In the printing process, the collagen solution remained acidic and cooled. Multiple layers of cell-laden collagen bioink were printed and then treated with aerosolized sodium bicarbonate ($NaHCO_3$) to buffer the pH toward neutral for gelation. The results showed high cell viability at 1 day after printing for keratinocytes and fibroblasts, which indicated the survival of cells and spatial control of the printing approach, which is needed to offer a functional skin replacement.

Gelatin is a substance in which water-insoluble collagen is made soluble by high temperature or acid–base treatment. It forms a thermoreversible hydrogel. Moreover, chemical modification of gelatin with unsaturated methyl methacrylate results in gelatin methacrylate (GelMA), which can form covalently cross-linked hydrogels

under UV exposure [39]. Photocross-linkable GelMA is the most popular bioink material for cell bioprinting because of high printability and tunable mechanical properties. GelMa was used to print a complex architecture that contained various cell types and vasculature [40]. A cell-laden GelMa and sacrificial Pluronic F127 were dispensed and embedded within the GelMa block in a predetermined 3D structure. Afterward, the printed structure was cross-linked by UV exposure. The sacrificial Pluronic F127 was removed at 4°C by phase transition to create open microchannels within the GelMa block. Finally, a suspension of human umbilical vein endothelial cells (HUVECs) was seeded into the open microchannels. This approach allowed for the viable deposition of cells in a 3D structure with a microvessel-like structure that was covered by endothelial cells (ECs) to provide nutrients to surrounding cells.

HA is the most abundant of the glycosaminoglycan (GAG) family; it has the repeating structure of glucuronic acid and *N*-acetyl-glucosamine disaccharide. HA has a high molecular weight and a large amount of branching, which allows for intermolecular hydrogen bonding and high viscosity. Like other polysaccharides, HA can support cell survival but has low cell-binding motifs. Moreover, HA itself has low structural integrity and shape fidelity after printing; therefore, HA has been chemically modified for cross-linking or mixed with other hydrogels [41].

Fibrinogen, which is a glycoprotein, is reacted with thrombin to convert into fibrin network self-assemblies [42]. Fibrin has many cell-binding motifs that enable cell attachment and vulnerability to proteases for remodeling. Fibrin-based bioink has been used by laser-induced forward transfer–based printing for a 3D multicellular array [43]. To improve the gel stability, HA was added to a fibrinogen solution to print the arrays. Endothelial colony-forming cells (ECFCs) were printed along with adipose-derived stem cells (ASCs) in a 3D array to observe cell-cell interactions. These droplet arrays were printed onto a layer of fibrinogen–HA that was spray-treated with a thrombin–calcium chloride solution to induce gelation. The cell-laden droplets were converted into fibrin–HA as they encountered the treated substrate with a residual thrombin solution. Results showed that ASCs initially migrated toward ECFCs with no evidence of ECFC sprouting or migrating. Once ASCs contacted the ECFC aggregates, an explosion of ECFC network sprouts began to extend from the initial droplet position and remained stable networks for several weeks.

Alginate is a naturally derived anionic polysaccharide that exhibits gelation in the presence of bivalent ions such as Ca^{2+} [44]. Alginate hydrogel has served as a cell delivery material for many tissue engineering and drug delivery applications owing to its ease of preparation and relatively good cell compatibility; however, a major drawback is the lack of mammalian enzymatic degradation, which limits tissue remodeling when implanted. Because the solubility of alginate is low, it is often mixed with other materials to increase the printing resolution as a bioink. For example, alginate solution mixed with cellulose nanofibers improved shear fluidization and viscosity, resulting in high printing resolution. In addition, alginate was cross-linked with the divalent cation Ca^{2+} to stability the printed construct.

Tissue-specific, ECM-based bioinks have been developed and tested. Technically, ECMs obtained from various decellularized tissues are pulverized and solubilized as bioinks [45]. The approaches combined with tissue-specific ECM-based bioinks and tissue-specific cell types have been shown to be valuable for recapitulating anticipated tissue features [45,46]. However, the ECM solution inherently has a low viscosity and exhibits low shape fidelity and structural stability. Thus, various attempts have been made to enhance their chemical and physical properties in 3D bioprinting.

Biodegradable Synthetic Polymers for Structural Integrity

Synthetic polymers have some advantages for applications in tissue engineering and 3D bioprinting. These polymers can be synthesized with reproducible quality and fabricated into various structures with predetermined bulk and surface properties. Additional advantages include the ability to tailor their biomechanical properties and biodegradation kinetics for various biomedical applications. In bioprinting, synthetic polymers such as PCL, poly(lactide-*co*-glycolide) (PLGA), and poly(lactic acid) can provide mechanical strength, thereby overcoming limitations of the hydrogel-based constructs regarding size, shape, and structural integrity [47]. For the extrusion method, melted polymers or polymer solutions with proper viscosity are needed. Therefore, PCL is the most commonly available polymer for extrusion-based bioprinting because of its low melting point of 60°C and high printability. Many research groups are exploring the synthesis of polymeric biomaterials for 3D bioprinting.

Scaffold-Free Cell Printing

3D tissue structure can be printed using multicellular aggregates without supporting materials [48]. This method enables cell aggregates to be dispensed from a capillary to form a 3D structure. Norotte et al. reported a scaffold-free cell printing method using multicellular spheroids consisting of smooth muscle cells (SMCs) and fibroblasts and agarose hydrogel for temporary support [49]. After printing, the printed cell aggregates were fused and formed a small-diameter vessel-like tube ranging from 0.9 to 2.5 mm in diameter. Li et al. fabricated vertical channels without using a support material by taking advantage of the gelation behavior of gelatin combined with cross-linking alginate or fibrinogen [50]. Itoh et al. proposed a method to fabricate a scaffold-free vascular tube using cell aggregates [51]. Predesigned 3D tubular structures were constructed with cell aggregates consisting of ECs, SMCs, and fibroblasts. The multicellular aggregates self-organized and fused into a tubular structure that was perfused with a bioreactor. To avoid droplets from forming at the end of the nozzle owing to surface tension, Ozler et al. developed a quantitative model to predict the success of cell aggregate extrusion [48]. This approach can be repeated for different cell types after obtaining their respective rheological properties. In addition, cell viability can depend on the compression ratio applied during printing. Thus, it is necessary first to investigate the impact of compression on their survival rate and cellular functions.

THREE-DIMENSIONAL BIOPRINTING IN REGENERATIVE MEDICINE APPLICATIONS

Three-Dimensional Bioprinted Vascular Structures

A major limitation of bioengineered tissue constructs is the lack of proper vascularization into the implanted constructs. Fully vascularized tissue constructs are required to attain long-term cell survival and tissue functions. 3D tissue constructs packed with metabolically active cells can rapidly form necrotic cores in the absence of a vascular network [52]. The transport of nutrients and other physiologically relevant molecules toward and away from a large tissue construct is still limited [53,54]. When a 3D tissue construct with cells is implanted, efficient mass transfer requires an intact microvasculature to maintain the metabolic functions of cells deep inside the construct. Indeed, the ingrowth of a microvascular system into the implanted bioengineered tissue constructs in a timely manner is the key to success in clinical use [9]. Hence, many attempts have employed 3D bioprinting as a promising technology to fabricate vascularized tissue constructs (Fig. 47.4) [40,49,55].

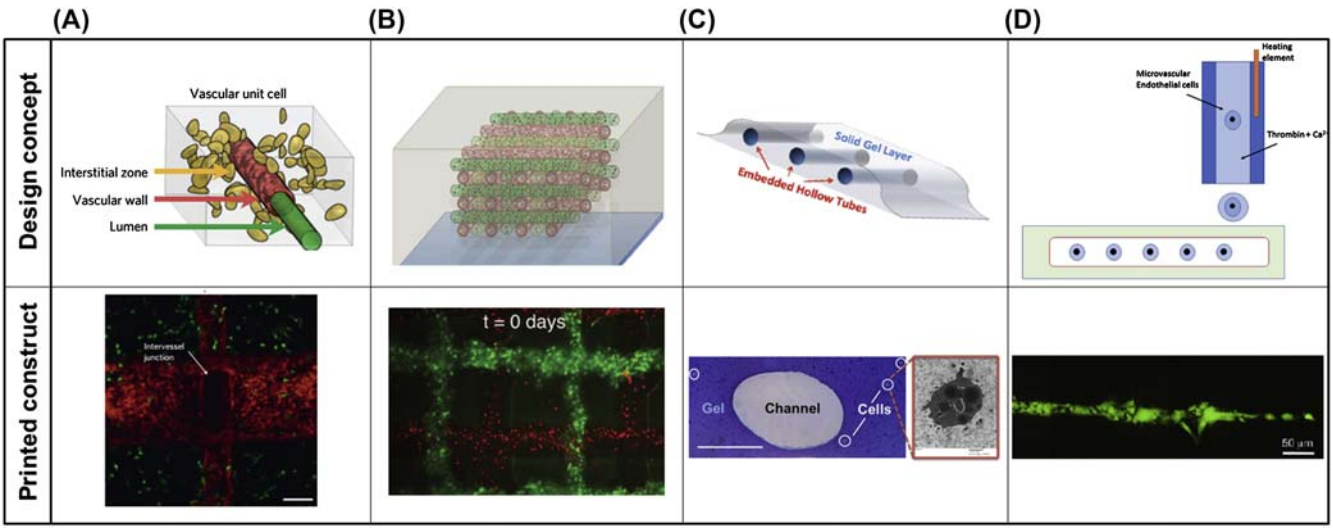

FIGURE 47.4 Examples of the three-dimensional bioprinted vasculature. (A) Vascular unit printed by Miller et al. [56] The construct shows three compartments consisting of the vascular lumen, the endothelial cell (EC) lining, and the matrix-encapsulated cells. Endothelialized channel walls and the intervessel junction surrounded by human fibroblasts. (B) Engineered tissue construct developed by Kolesky et al. [40] showing channels lined with human umbilical vein endothelial cells (HUVEC) (*red*) and human neonatal dermal fibroblast–laden gelatin methacrylate (*green*). (C) Hydrogel construct with embedded, connected hollow channels reported by Attalla et al. [57] and cross-section of hollow channel embedded within HUVEC-laden hydrogel. (D) Deposition of ECs and fibrin channel scaffold using thermal inkjet printer described by Cui and Boland [55]. Fluorescent image shows the printed microvasculature after 21 days.

One of the earliest and simplest approaches to fabricating a vascularized tissue construct is to use a sacrificial component that acts as a structural role during printing and is later removed to create a hollow tunnel. Miller et al. reported a vascular casting approach with carbohydrate glass as the sacrificial template; however, vascular networks developed by carbohydrate glass are limited in size and culture duration because of the practical difficulty of direct perfusion [56]. Kolesky et al. attempted to overcome these limitations by fabricating 3D constructs complete with a vasculature including multiple cell types and ECM proteins [40]. Attalla et al. modified a printhead with a microfluidic unit and generated instantly perfusable vascular networks integrated within a cell-seeded hydrogel [57]. The vascular structures were made from alginate using a coaxial nozzle. Cui and Boland reported an inkjet-based printing method with a precise droplet volume of 130 pL to fabricate microchannels [55]. Human microvascular ECs combined with the printing of biomaterials were found to align themselves inside the microchannels and form a confluent microvascular lining. Although bioprinting technologies have evolved to a level of creating complex vascularized constructs with multiple cell types and ECM proteins, reconnection of the vascular structures to the host circulatory system remains challenging. Lee et al. developed a novel bioprinting approach to creating a network from capillaries to large perfused vascular channels [58]. This was achieved by angiogenic sprouting from the large vessel through a natural maturation process. However, these printed constructs are often thin or hollow structures, so they are nourished by diffusion from the host vasculature but not by anastomosing [59]. When the diffusion limit needed by engineered tissues exceeds 150−200 μm, a precise vascular network must be embedded into fabricated constructs, a feat that has not yet been accomplished [60,61]. Efforts to simplify the complex fabrication methods and find new technologies for bioprinting vascular structures are in great need by tissue engineering as a whole.

In Vitro Tissue Models

Drug discovery is an inefficient process with a high failure rate and an extreme financial burden. Animal studies do not always indicate the results in human trials, and the regulatory environment is becoming stricter as time progresses. In addition, from a moral standpoint, attempts should be made to reduce the number of animal studies conducted. In vitro studies, mostly 2D cell culture methods are also severely limited. Drug response, gene expression, migration, morphology, and viability have all been shown to differ between 2D and 3D environments. Much emphasis has been placed on creating in vitro 3D tissue models to overcome these limitations. Typically, this is done by suspending cells or organoids (or cell aggregates) in a 3D culture within a singular or entire array of microfluidic devices. 3D in vitro assay systems have advanced immensely to a level in which living constructs can closely mimic the native tissue environment in a high-throughput platform. Although several fabrication techniques have been used to develop these models, 3D bioprinting technologies are advantageous owing to their low cost and efficiency, high throughput, excellent reproducibility, and ability to create complex geometries. The two major areas in which 3D printed in vitro tissue models have been applied are cancer research and drug screening systems. Table 47.1 summarizes bioprinting applications for in vitro biological systems.

Tumor Models

3D bioprinting of cells as tumor models are helpful for studying the interaction of immune and tumor cells and for screening new treatments [62]. Xu and Celli et al. introduced a 3D in vitro cancer model using human fibroblasts and ovarian cancer cells on a Matrigel matrix; they showed precise and reproducible control over the cell density and spacing compared with manual ejection by micropipettes [63]. Snyder et al. introduced a similar model in 2011 with human hepatic carcinoma cells and mammary epithelial cells. Cells and the microfluidic device were printed to test the radiation shielding of the prodrug amifostine. Radioprotective benefits for the liver were seen in their in vitro model [64]. Huang et al. examined tumor cell migration in a honeycomb structure with different channel widths (25, 45, and 120 μm) to mirror those of natural blood vessels [65]. HeLa and 10T1/2 cells were seeded within the device and were evaluated in the different channel sizes. HeLa cancer cells showed less morphological changes between channel sizes than did 10T1/2 cells and migrated at higher rates as the channel size decreased. Also looking at bioprinted HeLa cells, Zhao et al. examined the cell response after extrusion in a gelatin−alginate−fibrinogen hydrogel compared with a 2D culture model. Cells in the 3D model showed higher proliferation, matrix metalloproteinase expression, and chemoresistance [28]. Hribar et al. used 3D projection printing to create concave PEG structures that formed and maintained breast cancer spheroids for long-term culture [66]. The breast cancer spheroids exhibited necrotic, hypoxic cores, which are key components of the tumor in vivo microenvironment.

TABLE 47.1 Applications of Bioprinting In Vitro Biological Systems

Tissue/Organ	Bioprinting Method	Cell Type	Encapsulation Material	Testing	Outcomes	References
Tumor/cancer	Pneumatic cell droplet patterning	Fibroblasts and ovarian cancer cells	Matrigel	Reproducibility and precision of cell density and spacing	Bioprinting methods showed improved performance compared with micropipette ejection	[63]
Tumor/cancer	Temperature controlled, pneumatic extrusion	Hepatic carcinoma and mammary epithelial cells	Matrigel	Radiation shielding capabilities of the prodrug amifostine	Amifostine provided radioprotection to cells, with greatest benefit seen in dual-cell model	[64]
Tumor/cancer	Projection stereolithography (UV exposure)	HeLa and 10T1/2	Poly(ethylene glycol) diacrylate	The effect of channel width on tumor cell and 10 T1/2 migration and morphology	Tumor cells showed increased migration speed and less change in morphology with smaller channel sizes compared with 10 T1/2	[65]
Tumor/cancer	Extrusion	HeLa	Gelatin−alginate−fibrinogen	Viability, proliferation, MMP expression, and chemoresistance versus 2D culture	3D cell culture increases cancer cell proliferation, MMP expression, and resistance to chemotherapy	[28]
Tumor/cancer	Continuous 3D projection (with nonlinear exposure)	Breast cancer cells	Poly(ethylene glycol)	Long-term culture and validation of breast cancer spheroids	Spheroids showed hypoxic cores and signs of necrosis, key features of tumor environment	[66]
Liver	Extrusion	Hepatocytes	Alginate	Validation of liver cell activity and metabolic performance	Cells were viable, proliferative, synthesized urea, and metabolized 7-ethoxy-4-trifluoromethyl coumarin to 7-hydroxy-4-trifluoromethyl coumarin	[67,68]
Bacterial Infection	Inkjet	*Escherichia coli*	Alginate	Treatment of *E. coli* with several common antibiotics	Similar results to current low-throughput, less reproducible, and more expensive methodologies	[69]
Brain	Extrusion and subsequent dissolution of sacrificial resin	Mouse brain endothelial cells	Type 1 collagen microchannels	Model validation with transendothelial permeability measurements and hyperosmotic mannitol disruption test	Permeability decreased over 3 weeks of culture and then recovered over 4 days after hyperosmotic mannitol disruption	[70]
Lung	Extrusion	Endothelial and epithelial cells	Matrigel	Cell viability, distribution, morphology, and permeability compared with manually placed cells	Printed constructs resulted in more homogeneous cell distributions, proper cell morphologies, lower permeability, and similar viability	[71]

3D, three-dimensional; *MMP,* matrix metalloproteinase.

Drug Screening Systems

The number of in vitro drug screening systems has increased immensely in both quality and quantity, ranging from hepatic cells suspended in a microfluidic device to integrated, multiple-tissue, body-on-a-chip systems. Chang et al. used direct cell writing bioprinting to create a 3D microorgan housed using soft lithographic micropatterning [67]. Alginate-encapsulated hepatocytes printed in the microfluidic device were viable and proliferated and were capable of synthesizing urea. This work was furthered by infusing a hepatocyte containing a microfluidic device with 7-ethoxy-4-trifluoromethyl coumarin, which was metabolized into 7-hydroxy-4-trifluoromethyl coumarin, mimicking the in vivo behavior of the liver [68]. Rodriguez-Devora et al. developed an inexpensive drug-screening platform via inkjet bioprinting deposition. *Escherichia coli* were printed in an alginate solution with different antibiotic droplets patterned on the cells, resulting in similar bacteria inhibition compared with the current screening process [69]. An in vitro model of the blood–brain barrier was developed by Kim et al. Mouse brain ECs were cultured within an array of type I collagen microchannels fabricated using microneedles on a 3D printed frame [70]. The model was validated by measuring transendothelial permeability and a disruption experiment by hyperosmotic mannitol. In addition to the blood–brain barrier, an air–blood barrier was developed to model the lung. Horváth et al. developed a model by bioprinting epithelial cells and ECs separated by a basal membrane layer [71]. The bioprinted model was more reproducible and had thinner cell layers than that which could be manufactured using traditional manual methods.

In addition to these already successful in vitro models, several areas for future work stand out in this new field. Work is in progress to incorporate an array of tissue types into the same drug screening platform. Bioprinted in vitro models are also in good position to evaluate gene therapy techniques; however, standardized model systems and industry standards are needed to facilitate comparison across studies. The use of these in vitro models show promise in increasing our understanding of biology, disease progression, organ cross-talk, and many other areas as the field progresses.

Tissue Engineering Applications

Bioprinting has been used in the laboratory to fabricate constructs targeting nearly every tissue types in the body. Although clinical implantation is still rare in this relatively new technology, there have been many successes in vitro and in vivo. Highly detailed, anatomically correct, and patient-specific tissue constructs have been fabricated for a number of tissues and organs. A wide range of cells has been shown to maintain viability, gene expression, and functional capabilities after the printing process. Various stem cells have demonstrated the ability to preserve their differentiation potential and also have been directed by various cues applied during the printing process [72,73]. This section will highlight a select few of the many tissue-specific regenerative medicine applications that have been studied with bioprinting technologies.

Bone

Bone regeneration is a natural target application for bioprinting given the importance of anatomical structure to its in vivo function. Conventional 3D printing technologies are in use clinically as patient-specific metal implants [74]. Bioprinting offers a unique and promising alternative to bone grafting because of the wide variety in anatomic location, defect size, and patient-specific morphology for bone pathologies [75,76]. The advantage of bioprinting is especially apparent for bone defects, which also feature a significant cosmetic function such as in craniofacial reconstruction [77]. Fedorovich et al. printed a mixture of Matrigel and alginate hydrogels with endothelial progenitor cells and mesenchymal stem cells (MSCs) [78]. The constructs were implanted subcutaneously in immunodeficient mice. The researchers were able to demonstrate that incorporating biphasic calcium phosphate microparticles caused the MSCs to differentiate into an osteogenic lineage and caused bone formation within 6 weeks after implantation. Phillippi et al. used inkjet bioprinting to pattern bone morphogenetic protein 2 on primary muscle-derived stem cells on fibrin-coated coverslips [79]. The stem cells differentiated into an osteogenic lineage even under myogenic differentiation media conditions. Keriquel et al. demonstrated in situ bioprinting by delivering nanoscale hydroxyapatite and osteoblasts into mouse calvarial defects, with positive outcomes [80]. Using CT scanning, Yao et al. were able to print anatomically accurate PCL–hydroxyapatite mandible scaffolds that supported physiological loads [81]. Wang et al. examined the degradation profile of printed poly(propylene fumarate) scaffolds as it pertained to pore size, porosity, and mechanical properties [82]. They also developed a novel test for cytotoxicity of the degradation products and determined the scaffolds to be suitable for bone tissue engineering applications. To incorporate biological

materials with bioprinting technology, Pati et al. cultured MSCs onto a printed PCL−PLGA−β-tricalcium phosphate (TCP) scaffold [83]. The cells deposited ECM during a brief culture period, after which the scaffold was decellularized. In vivo, the ECM-enriched scaffolds induced greater bone formation than did unadorned scaffolds of the same composition.

Many limitations exist, including for large-sized defects and in high−load bearing applications. Lack of perfusion and neovascularization prevent large defects from being treated with bioprinting strategies; further research is needed in this area [84]. In addition, the discovery of new bioprinting-compatible materials and unique structural designs could increase maximum load-bearing applications for these constructs. More work is also needed to match the degradation profiles of scaffolding materials closely with those of the bone remodeling rate. New bone formation is obstructed if the scaffolding material degrades too slowly, but the defect site is left without a load-bearing material if degradation occurs too quickly, damaging nearby tissue. Altogether, bone tissue is one of the more promising target tissue applications for bioprinting owing to its many advantages relative to other tissue engineering strategies and the natural ability of bone to remodel in vivo (Table 47.2).

Cartilage

Articular cartilage is imperative to reducing friction and absorbing compressive forces in load-bearing joints with little to no capacity for self-regeneration. Current cartilage tissue engineering strategies are insufficient for reproducing tissue that is equivalent to healthy cartilage [85]. However, there has been greater interest in the zonal differences found in cartilage matrix and cellular composition [86]. Bioprinting presents an appealing tool for constructing stratified scaffolds, especially in patient-specific size and shape of individual lesions [87]. Gruene et al. used laser-induced forward transfer to generate MCS grafts, showing good cell viability, density, and functionality [88]. MSCs were able to differentiate into osteoblasts and chondrocytes and the graft maintained good structural integrity in vitro. Cui et al. loaded chondrocytes into poly(ethylene glycol) dimethacrylate hydrogel and inkjet bioprinted them into an osteochondral plug [89]. The implant had mechanical and biochemical properties similar to native cartilage, and Safranin-O staining revealed good integration with surrounding cartilage tissue. The same group also used their experimental setup to investigate the effects of fibroblast growth factor 2 and transforming growth factor β1 on cartilage generation. Samples were cultured up to 4 weeks, and the highest GAG content was found for samples containing both growth factors, suggesting a synergistic effect between increased cell proliferation and increased chondrogenic phenotype expression [90]. To address some of the limitations of bioprinting, Xu et al. alternated between inkjet-bioprinted layers of rabbit elastic chondrocytes suspended in a fibrin-collagen hydrogel and electrospun PCL [22]. The construct formed cartilage-like tissues in vitro and in vivo demonstrated by type II collagen and GAG deposition. In addition, the scaffolds with electrospun layers showed improved mechanical properties compared with those that were only bioprinted.

In particular, engineering the external ear has been a notably successful area of bioprinting cartilage tissue. The ear is almost completely avascular and aneural, it has a complex geometry, and it serves a largely aesthetic function, which places a greater emphasis on individualizing each prosthetic to the specific patient. Mannoor et al. developed a bionic ear that can translate sound waves into an electrical output [91]. The scaffold was extrusion bioprinted with sodium alginate, silver nanoparticles, and chondrocytes in an ear-shaped geometry around the conductive, sound-translating coil. Lee et al. extrusion printed PCL with PEG as a supporting sacrificial layer [92]. Chondrocytes and adipocytes were differentiated from adipose-derived stromal cells, encapsulated in alginate hydrogel, and dispensed into their respective regions. After 7 days in in vitro culture, immunostaining analysis confirmed chondrogenesis and adipogenesis. We also applied the extrusion-based bioprinting to fabricate a complex shape by making human-sized ear cartilage tissue construct (Fig. 47.5A) [47]. After implantation, the printed ear shape was well-maintained, with cartilage tissue formation upon gross examination. Histological analyses showed the tissue formation of cartilage tissue as confirmed by GAG and collagen type II staining. Quantitatively, GAG content increased over time, reaching 20% of that of native ear GAG content at 2 months after implantation.

At this stage, the next challenge for bioprinting as a means for cartilage regeneration is to conduct translational studies. Few in vivo studies have been conducted. The long-term stability of bioprinted cartilage constructs has yet to be demonstrated and no studies have compared these strategies with practices used clinically. However, research in cartilage bioprinting is growing exponentially and exhibits many promising results for the future.

TABLE 47.2 Three-Dimensional Bioprinting Technologies for Tissue Regeneration Applications

Tissue/Organ	Testing Model	Printing Method	Cell Type	Bioink	Outcomes	References
Bone	In vitro viability and differentiation studies	Extrusion	Endothelial progenitor and multipotent stromal cells	Matrigel and alginate hydrogels	Viability and differentiation capability were unaffected by printing process, and the two distinct cell populations were maintained within a single scaffold	[78]
	In vitro differentiation studies	Inkjet	Primary muscle-derived stem cells	Fibrin	Incorporation of bone morphogenetic protein-2 caused spatially controlled osteogenic lineage differentiation even in myogenic media conditions	[79]
	In situ bioprinting	Laser	Osteoblasts	Glycerol and n-Ha slurry	Successful in situ bioprinting into mouse calvarial defects with minimal side effects	[80]
	In vitro	Extrusion	–	Polycaprolactone-hydroxyapatite	Reconstructed from CT scans, anatomically accurate and supportive of physiological loads	[81]
	In vitro degradation, mechanical, and cytotoxicity	Laser	Fibroblasts	Poly(propylene fumarate)	Scaffolds maintained their mechanical stability, and degradation products did not induce significant cell death	[82]
	In vitro and in vivo bone formation	Extrusion	Mesenchymal stromal cells	PCL/PLGA/B-tricalcium phosphate	Scaffolds which were decellularized after brief culture period induced greater bone formation in vivo	[83]
Cardiac Muscle	In vitro	Extrusion	Spheroids of HUVECs and cardiac cells	Type 1 collagen	Viable cells, fusion and beating at 70 h with early signs of vascularization	[98]
	In vitro	Inkjet	Cardiomyocytes	Alginate	Viability in thickness as high as 1 cm and contraction was observed at macroscopic and microscopic levels	[99]
	In vivo cardiac infarct patch	Laser	HUVECs and human MSCs	Polyester urethane urea	Increased function and vessel formation compared with cell-only treatment 8 weeks postinfarction	[100]
	In vitro	Extrusion	Cardiac-derived cardiomyocyte progenitor cells	Alginate	Cells demonstrated viability, phenotypic cardiac expression, and ability to migrate from hydrogel	[101]
Cardiac valve	In vitro	Extrusion	Porcine aortic valve interstitial cells	PEGDA and alginate	Anatomical accuracy was confirmed; a range in mechanical properties was obtainable by varying the concentrations of the hydrogels	[6,103,104]
Cartilage	In vitro	Laser	MSCs	None	Good structural integrity and osteoblast and chondrogenic differentiation	[88]
	In vitro	Inkjet	Articular chondrocytes	PEGDMA	Similar mechanical and biochemical properties of native cartilage and good integration with surrounding tissue; fibroblast growth factor 2 and transforming growth factor β-1 synergistically improved GAG deposition	[89,90]

TABLE 47.2 Three-Dimensional Bioprinting Technologies for Tissue Regeneration Applications—cont'd

Tissue/Organ	Testing Model	Printing Method	Cell Type	Bioink	Outcomes	References
	In vitro and in vivo	Inkjet	Rabbit elastic chondrocytes	Fibrin–collagen	Combined PCL electrospinning and bioprinting technique facilitated type 2 collagen and GAG deposition with improved mechanical properties	[22]
	In vitro	Extrusion	Chondrocytes	Alginate	Biomimetic ear could translate sound waves into an electrical signal and coexist with viable chondrocytes	[91]
	In vitro	Extrusion	Chondrocytes and adipocytes	PCL and PEG (sacrificial) and alginate (encapsulation)	Chondrogenesis and adipogenesis confirmed by immunostaining	[92]
Skin	In situ bioprinting	Extrusion	Amniotic fluid derived stem cells	Fibrin–collagen	Amniotic fluid–derived stem cells outperformed both MSCs and acellular graft	[105]
	In vitro and in vivo	Laser	Fibroblasts and keratinocytes	Collagen	Early indicators of stratum corneum formation and blood vessels after 11 days	[106,107]
	In vivo	Inkjet	Fibroblasts, keratinocytes, and microvascular endothelial cells	Collagen	10% improvement of wound contraction compared to allogeneic skin substitute	[108]
Bone–cartilage	In vitro and in vivo	Extrusion	MSCs and chondrocytes	Alginate	Distinct tissue regions were found after 21 days in culture and 6 weeks after subcutaneous implantation	[113]
	In vitro	Extrusion	Osteoblasts and chondrocytes	Type 1 collagen and hyaluronic acid	Cells showed better proliferation, migration, and function on hydrogels made from their native ECM and performed well in 14-day coculture	[37]
Muscle–tendon	In vitro	Extrusion	Myoblasts and 3T3 fibroblasts	PCL & Polyurethane	Cells were viable after a week in culture and scaffolds showed an appropriate trend in mechanical properties	[96]
Pancreas	In vivo	Extrusion	INS1E β/islets	Alginate and gelatin	Scaffolds were formed and embedded while maintaining cell viability and morphology	[123]
Adipose	In vitro	Laser	Adipose-derived stem cells	Alginate	Cells maintained viability, differentiation potential, and adipogenic gene expression after 10 days	[121]
Neural	In vivo	Extrusion	Bone marrow MSCs and Schwann cells	–	Grafts underperformed autograft controls, but provide a proof-of-concept for future work	[114]
	In vitro	Inkjet	Retinal ganglion cells and glia	–	Good cell viability and growth properties of cells was found after printing	[115]
	In vitro and in vivo	Laser	Neuronal, Schwann, and dorsal root ganglion cells	PEG	After 3 weeks, the nerve guide supported reinnervation across a 3-mm gap equal to that of an autograft	[116]

CT, computed tomography; *FGF-2*, fibroblast growth factor-2; *GAG*, glycosaminoglycan; *HUVECs*, human umbilical vein endothelial cells; *MSCs*, mesenchymal stromal cells; *n-Ha*, nano-hydroxyapatite; *PCL*, polycaprolactone; *PEG*, poly(ethylene glycol); *PEGDA*, poly(ethylene glycol) diacrylate; *PEGDMA*, poly(ethylene glycol) dimethacrylate; *PLGA*, poly(lactide-co-glycolide).

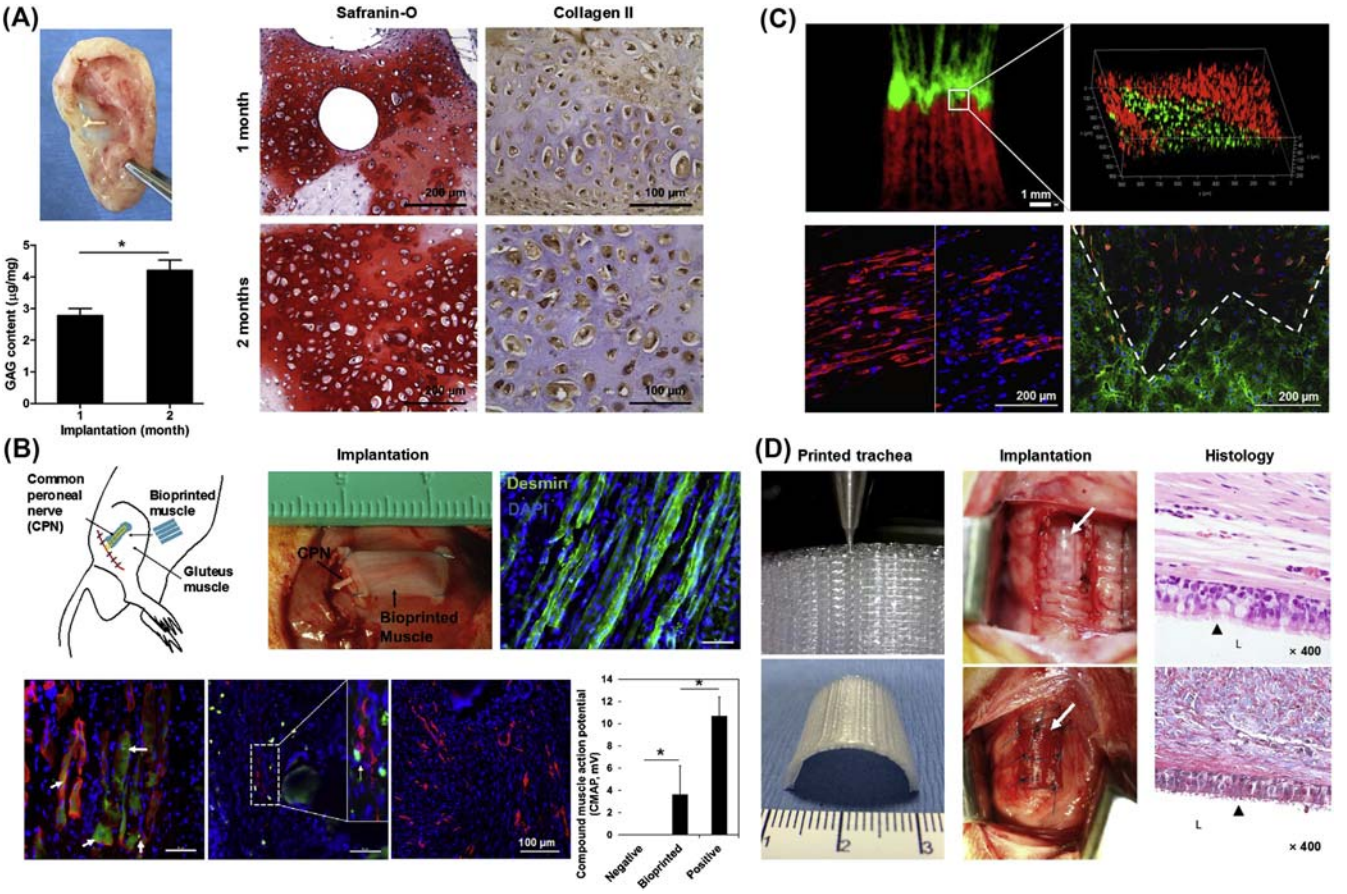

FIGURE 47.5 (A) Bioprinted ear construct: The shape was well-maintained, with substantial cartilage formation upon gross examination. Histological and immunohistochemical analyses showed the typical cartilage tissue formation [47]. (B) Bioprinted organized muscle construct: The retrieved muscle constructs showed well-organized muscle fiber structures, the presence of acetylcholine receptor clusters on the muscle fibers (myosin heavy chain (MHC+) and α-bungarotoxine (α-BTX+)), as well as nerve (neurofilament) contacts with α-BTX+ structures within the implants at 2 weeks after implantation [47]. (C) Bioprinted muscle–tendon unit (MTU): fluorescently labeled dual-cell printed MTU constructs (*green*: DiO-labeled C2C12 cells; *red*: DiI-labeled National Institutes of Health/3T3 cells; *yellow*: interface region between green and red fluorescence) [96]. (D) Bioprinted tracheal construct: Ingrowth of ciliary respiratory epithelium from the normal region was observed in the lumen of the bioprinted construct. Typical morphologies of respiratory mucosa and pseudocolumnar ciliary epithelium with goblet cells were well-developed at 8 weeks after implantation [120]. *DAPI*, 4,6-diamidino-2-phenylindole; *L*, lumen.

Skeletal Muscle and Tendon

The organized ultrastructure of skeletal muscle is required for muscle contraction and force generation [93]. Because 3D bioprinting mechanism enables control of the spatial organization of cell-laden bioinks, we were able to fabricate highly oriented, muscle-like bundles to engineer skeletal muscle construct (Fig. 47.5B) [47]. The printed, aligned cellular construct began stretching along the longitudinal axis at 3 days in culture, and the constructs underwent compaction from polymeric pillars, keeping the fibers taut during differentiation. The aligned muscle fiber-like structures were observed at 7 days in differentiation medium condition. This bioprinted skeletal muscle construct maintained the tissue organization, followed by tissue maturation and host nerve integration in rats. The results demonstrate that the 3D bioprinting is capable of producing promising the structural and functional characteristics of skeletal muscle constructs in vitro and in vivo.

Tendon has a hierarchical architecture, and tenocytes are aligned along with a dense collagen fibrous structure [94]. To mimic these structural characteristics of the tendon, an electrohydrodynamic jetting printing was introduced to generate a tubular-shape, multilayered tendon construct with highly porous, oriented microscale PCL fibers [95]. The cultured human tenocytes on the bioprinted structure showed a highly cellular orientation, metabolism, and type I collagen expression. 3D bioprinting technologies are particularly useful for composite tissue constructs such as muscle–tendon. We used our integrated tissue and organ printing system to print four different components to fabricate a single integrated muscle–tendon unit (MTU) construct (Fig. 47.5C)

[96]. The printed MTU construct was composed of mechanically heterogeneous polymeric materials that were elastic (polyurethane [PU]) on the muscle side and relatively stiff (PCL) on the tendon side, in addition to having a tissue-specific distribution of cells with C2C12 myoblasts on the muscle side and National Institutes of Health/3T3 fibroblasts on the tendon side. Results showed that cells were printed with high cell viability and cellular orientation as well as increased musculotendinous junctional gene expression. It was demonstrated that 3D bioprinting technology enabled a 3D heterogeneous tissue construction with region-specific biological and biomechanical characteristics.

Cardiac Tissue and Heart Valves

The heart is a complex organ in both shape and tissue organization, both of which are difficult to replicate by other fabrication methods. The ability to control the distribution of different cell types and growth factors spatially make bioprinting an attractive option for cardiac engineering, although only proof-of-concept successes have been accomplished thus far [97]. Jakob et al. were able to use extrusion-based bioprinting to pattern spheroids of HUVECs and cardiac cells on collagen [98]. The cells proved viable after the process; they fused at 70 h into a beating tissue and showed early signs of forming vascularization. Using inkjet bioprinting, Xu et al. printed a half heart shape (with two connected ventricles) with cardiomyocytes encapsulated in an alginate hydrogel [99]. Cell viability was preserved in constructs as thick as 1 cm owing to the designed porosity within the structure, and contraction was observed in vitro at both the microscopic and macroscopic levels. Instead of targeting whole-heart reconstruction, Gaebel et al. developed a cardiac patch for regeneration after cardiac infarction [100]. Using laser-induced forward transfer, HUVECs and human MSCs were patterned on polyester urethane urea and transplanted into the infarct zone. After 8 weeks, increased vessel formation and function were found, compared with a control treatment of bioprinted cells alone. A patch by Gaetani et al. used human cardiac-derived cardiomyocyte progenitor cells; they were extrusion-bioprinted in a sodium alginate mesh pattern [101]. They demonstrated cell viability, phenotypic expression of cardiac lineage, and the ability to migrate from the alginate, which suggested that bioprinting can be used to define cardiac cell delivery.

Patients with heart valve failure must receive a replacement valve that can be mechanical requiring a lifetime of anticoagulant treatment, or biological, which typically fails within 10–20 years [102]. Bioprinting has gained momentum as a potential heart valve fabrication strategy to mimic the complex geometry and nonhomogeneous material makeup, mechanical properties, and cell distributions that naturally occur in heart valves [102]. Hockaday et al. used a dual ionic and physical cross-linking hydrogel strategy by using a PEGDA sodium alginate composite [6]. The printing accuracy of the aortic valve root wall and trileaflets was confirmed via microCT scanning. By varying PEGDA and alginate concentrations, elastic moduli were found to range from 1.5 to 5.3 kPa. Porcine aortic valve interstitial cells were seeded and cultured on the scaffold for 21 days with nearly 100% viability. Later studies by the same group printed the cells directly within the hydrogel, as opposed to seeding the scaffolds afterward, also with good geometric accuracy, cell viability, and mechanical properties [103,104]. Although these studies are far removed from use in the clinic, they demonstrate that bioprinting technology is amenable to cardiac tissue regeneration and open the door for many future studies focused on improving the current methodology and outcomes.

Skin

Bioprinting is an excellent technology for depositing distinct layers. It has been used in an attempt to mirror the layers of native skin, and research in this area has increased significantly. Skardal et al. performed direct in situ printing of amniotic fluid–derived stem cells suspended in the fibrin–collagen hydrogel [105]. Compared with an acellular graft and an MSC graft, amniotic fluid–derived stem cells showed increased microvessel density and capillary diameter. Laser-assisted bioprinting has been used to embed fibroblasts and keratinocytes in collagen [106]. Histology revealed a high density of both cell types and the expression of laminin protein. The same group grafted their construct onto mice and reported early indicators of stratum corneum formation and blood vessels after 11 days [107]. Yanez et al. printed keratinocytes and fibroblasts in collagen as well, but they included human microvascular ECs [108]. When implanted onto the backs of mice and compared with allogeneic skin substitute as a control, wound contraction improved by 10% and histological results appeared similar to those of normal skin. Sweat glands and hair follicles remain elusive, as does commercial and regulatory viability [109]. Nonetheless, skin bioprinting has shown many encouraging successes, and the clinical bioprinting of skin appears to be an impending reality [20].

Other Tissue Types

Many other tissue types have been targeted with bioprinting technology, albeit to a lesser extent than those discussed thus far. This could be caused by a lesser clinical need, a higher difficulty of tissue engineering in general, or a poor match between the advantages of bioprinting and the necessary components for regenerating that tissue. Composite tissues are a major challenge facing regenerative medicine. No organ in the body is completely isolated, and many tissues such as tendons have specific and functional interfaces with other tissue types. Bioprinting is uniquely positioned to address this problem by spatially directing the placement of different cell types, growth factors, and biomaterials [110–112]. Fedorovich et al. extrusion bioprinted MSCs with hydroxyapatite, β-TCP, and biphasic calcium phosphate particles in alginate for one section of the scaffold and chondrocytes in alginate for the other [113]. Distinct tissue formation was found after 21 days in a mixture of osteogenic and chondrogenic media culture as well as after 6 weeks of subcutaneous incubation in vivo. Park et al. bioprinted osteoblasts in collagen I hydrogel and chondrocytes in HA hydrogel with good results after 14 days in vitro, in the process showing that the cells performed better on hydrogels made from their native ECM [37]. Finally, Merceron et al. targeted the MTU using PCL and 3T3 fibroblasts for the tendon zone and PU and myoblasts for the muscle zone [96]. Cells were viable after 7 days, and the scaffold showed appropriate trends in mechanical properties.

Neural tissue has also been addressed by bioprinting. Owens et al. extrusion bioprinted a nerve graft containing bone marrow MSCs and Schwann cells [114]. The grafts were implanted for 10 months in a rat sciatic nerve injury model with autograft controls. The researchers concluded that that bioprinting was a promising approach to nerve grafting. Retinal ganglion cells and glia were piezoelectric inkjet bioprinted by Lorber et al., and the results showed good cell viability and growth-promoting properties in vitro [115]. Pateman et al. used a microsterolithographic technique to print PEG-based nerve guides for nerve repair [116]. In a 3-week, common fibular nerve injury mouse model, the nerve guide was capable of supporting reinnervation across a 3-mm injury with results similar to that of an autograft.

Trachea is mainly composed of tightly stacked cartilage rings and respiratory mucosa in the luminal surface. Several synthetic implants have been used to reconstruct tissue defects [117–119]; however, these implants have been limited in their ability to mimic the tracheal functions biologically and biomechanically. We developed a biomimetic tracheal construct using a 3D bioprinting approach that could reconstruct a partial tracheal defect in a rabbit model (Fig. 47.5D) [120]. The printed tracheal PU constructs provided excellent structural characteristics. In the rabbit tracheal defect model, the printed PU constructs maintained the biomechanical function of the trachea, whereas the microscale porous architecture in the construct allowed cellular infiltration for the biological integration with host tracheal tissue. Moreover, the printed PU scaffold provided a proper microenvironment to facilitate the resurfacing of the ciliated respiratory epithelium and the ingrowth of connective tissue with microvasculature.

Adipose tissue is not often targeted by regenerative medicine strategies, but Gruene et al. [121] laser bioprinted adipose-derived stem cells encapsulated in alginate. They proved that the cells maintained their viability, differentiation ability, and adipogenic gene expression after 10 days in vitro culture. Preliminary progress has also been made in several more complicated organs such as the intestine [122] and pancreas [123]. This section briefly examined the application of bioprinting to specific tissue types. Many studies were excluded because of space constraints; several tissue types that have been explored via bioprinting have not been covered here.

CONCLUSIONS AND FUTURE PERSPECTIVES

The ultimate goal of tissue engineering and regenerative medicine is to reduce patient morbidity and mortality while improving quality of life by producing patient-tailored tissue constructs that induce tissue regeneration. 3D bioprinting technologies hold great promise for achieving this goal. The focus on replicating complex and heterogeneous tissue constructs continues to increase as 3D bioprinting technologies progress. Progression from single, simple tissues such as skin, bone, and cartilage, to organized contractile tissues such as skeletal muscle and cardiac tissue, to composite tissues such as osteochondral tissue and MTUs, and finally to robust organs such as the kidney and heart are under way.

A novel bioink system needs to be developed to improve printability with high-resolution capability and structural maintenance. The availability is limited of biomaterials, including hydrogels and polymers, in 3D bioprinting that can serve as cell delivery bioinks and supporting structures, but which also provide biological properties and mechanical and structural support. Advances in biomaterials depending on 3D bioprinting mechanisms

are necessary for long-term success in tissue engineering applications. An approach that uses the decellularized ECM can provide a tissue-specific microenvironment to the cells. Decellularized ECM-based bioinks are still the closest biological microenvironment that mimics in vivo conditions; thus, tissue-specific ECM-based bioinks are capable of providing critical cues for targeted cell engraftment, survival, and tissue formation.

There must be an increase in knowledge about biological, anatomical, and physiological aspects of complex tissues and organs. In particular, the development of in vitro 3D tissue models to study tissue-specific functions in the body will require a better understanding of morphological, structural, and functional units in tissues or organs. Moreover, the well-known limitation to building a large-scale tissue construct is vascularization in the construct. 3D bioprinting may have a unique capability among the various tissue engineering technologies to overcome this limitation. A few groups have made progress toward printing vascular structures; however, integrating functional microvascular structures into tissue or organ-like constructs has not been accomplished. Approaches to using high porosity, angiogenic factors, and highly organized patterns of vascular cells may encourage vasculogenesis.

Bioprinting methods are able to construct 3D free-form shapes containing multiple cell types, biomaterials, and bioactive molecules, resulting in sophisticated tissue constructs that have the potential to replace damaged or diseased human tissues and organs. Although there is much work to be accomplished to advance these technologies toward successful clinical translation, our efforts will constantly contribute to producing clinically applicable tissue constructs until 3D bioprinting is able to improve the lives of patients.

Glossary

Bioprinting The incorporation of biological materials into additive manufacturing techniques, either by directly depositing cells layer by layer or indirectly by three-dimensional printing biologically active materials for later use in cellular applications.
Cross-linking A chemical bond between two polymer chains that changes the overall properties of the material.
Electrospinning A method for producing fibers that uses electrical forces to draw out nanoscale threads of melted polymer material.
Extracellular matrix The environment secreted by cells that biochemically and structurally supports a cellular network.
Extrusion bioprinting Direct contact bioprinting mechanism that relies on pressure or displacement to force material through the syringes.
Fused deposition modeling An additive manufacturing technology that extrudes heated material layer by layer to create three-dimensional structures.
High-throughput screening Drug delivery process in which a lot of drugs or chemicals can be tested at a rapid pace.
Hybrid bioprinting Using multiple bioprinting mechanisms in one system to overcome the limitations of each mechanism.
Hydrogel A polymeric gel material in which the main component is water.
In situ bioprinting Bioprinting directly in vivo such as onto a skin wound or into a bone defect, as opposed to bioprinting separately and then surgically placing a scaffold into a defect.
Jetting bioprinting Originating from inkjet printers, this noncontact bioprinting mechanism uses pressure pulses to apply bioink in predetermined locations.
Laser-assisted bioprinting Bioprinting mechanism that uses a focused laser to generate high-pressure bubbles that propel cell-containing material onto a substrate.
Microfluidic device A device that is able to manipulate and control the flow of fluids on a microliter to picoliter scale.
Scaffold The material which acts in place of the extracellular matrix , providing a physical, three-dimensional environment for cells to attach, migrate, and proliferate.

Micropatterning Precisely controlling the cellular microenvironment on a substrate for the purposes of studying cell behavior.
Perfusion The process of oxygen and other vital nutrients being delivered from the bloodstream to tissues and cells.
Piezoelectric A ceramic crystal that creates an electric charge in response to an applied mechanical stress.
Printability The ability and usefulness of a particular material to be applied as a bioink.
Printing resolution The smallest dimension that can be controlled by a particular bioprinting system.
Spheroid A three-dimensional conglomerate of cells, often organized into a spherical shape.
Stereolithography Three-dimensional printing process in which liquid photopolymer is exposed above a perforated platform and then cross-linked by a UV laser forming the first layer. The platform then lowers exposing a new surface of liquid which the UV laser cross-links to form layer two.
Structural stability The ability of a printed construct to maintain its shape.

DEVELOPMENT AND FRACTURE OF BONE

Bone Development

Normal bone formation takes place by two different processes: endochondral ossification and intramembranous ossification. The endochondral ossification process features a sequential formation and degradation of cartilaginous tissue. By contrast, intramembranous ossification occurs by direct differentiation of precursor cells into mature osteoblasts [1].

Limbs of the body undergo endochondral ossification whereas the flat bones in the skull are formed by intramembranous ossification. Although these two processes are regulated by many of the same signaling molecules, the means by which cells differentiate and form bone are vastly different. In intramembranous ossification, precursor cranial neural crest cells differentiate into osteoblasts, which are bone-forming cells [2,3]. By contrast, mesenchymal stem cells (MSCs) establish a cartilage template, which is subsequently mineralized to form cortical bone during endochondral ossification [4]. During embryonic development, specific embryologic zones are defined for the formation of precisely defined structures of cartilage and bone. These early processes are regulated by several signals including soluble growth and differentiation factors, as well as cell−cell and cell−extracellular matrix (ECM) interactions. During an initial commitment phase, cells that will form bone are committed in a defined time and space. After initial commitment, cells are then differentiated into the terminal and mature cell phenotypes that are needed to construct bone.

Fracture Healing

In some ways, bone fracture healing is similar to the process of initial bone development, as described earlier [5]. It involves the establishment of an environment that drives the differentiation of precursor cells to repair and replenish the tissue at the site of the injury. Fracture healing has several distinct features. After a fracture occurs, there is an immediate inflammatory response that recruits activated macrophages and polymorphonuclear neutrophils to the site of injury. The macrophages release multiple factors that stimulate the formation of a hematoma. Granulation tissue fibroblasts then proliferate to form a blastema. Osteoprogenitor cells are then recruited from the periosteum, surrounding soft tissue, and bone marrow at the site of the fracture. These cells differentiate into chondrocytes and osteoblasts to repair the fracture. Several soluble growth and differentiation factors influence this process. Mitogenic growth factors stimulate proliferation of precursor cells. They include fibroblast growth factors, insulin-like growth factors, and platelet-derived growth factors. Differentiation factors such as bone morphogenetic proteins (BMPs) induce the differentiation of precursors into osteoblasts and chondrocytes. Typically, differentiation follows a proliferative phase, so BMPs are often found in higher concentrations later in the healing process.

Principles of Regenerative Medicine, Third Edition

PRINCIPLES OF BONE TISSUE ENGINEERING

For fractures to be healed successfully, a sufficient number of precursor cells must be present at the site of injury and they must be directed toward osteogenic differentiation. Cells can be recruited in vivo or implanted directly. Expression of signaling factors can be upregulated or they, too, can be applied directly. The signals must be given in appropriate time course and quantity to stimulate cell growth and differentiation in a controlled manner.

Although fractures can heal naturally without intervention, larger defects require clinical interventions to repair or regenerate bone. These are referred to as critical-size defects. The reference standard treatment of these defects is autologous bone grafting, a process by which donor bone tissue removed from the patient's hip is shaped according to the site of injury and surgically implanted into the defect site. These grafts contain viable cells, signaling factors, and a matrix that can support healing. However, the success of these grafts is variable, the surgical intervention has associated risks, and donor site morbidity has been reported as a complication of this treatment.

In this chapter, we provide an updated overview of the state of bone tissue engineering as a means for treating bone defects and disease [6]. Bone tissue engineering provides an alternative method to regenerate bone while eliminating some limitations associated with grafts. In tissue engineering, a precisely engineered scaffold can be combined with an appropriate osteoprogenitor cell type and relevant growth and differentiation factors [7]. Damaged tissue sites that reach critical sizes can have limited self-healing potential in terms of the availability of precursor cells and concentration of growth and differentiation factors, as well as by scarring or inflammation. Thus, delivery of cells and growth factors can boost the efficacy of bioengineered scaffolds for bone regeneration in these cases. Nucleotide and gene delivery [8] and immune modulation [9] are also being pursued in bone and bone regeneration research.

STEM CELLS IN BONE TISSUE ENGINEERING

Stem cells are defined cell populations with the capacity for self-renewal and the potential for differentiation to multiple cell fates [10]. In bone tissue engineering, adult MSCs, which are often derived from bone marrow, are the most common cell type used to regenerate bone. Other cell types frequently used in the field include embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs), and adipose-derived stem cells (ADSCs).

Mesenchymal Stem Cells

MSCs are a common cell source for bone regeneration therapies because they are easily obtained and amplified. They are a multipotent cell type and have low immunogenicity. In vivo, MSCs develop into cells that make up bone, cartilage, and fat. MSCs have been isolated from fetal blood, liver, and umbilical cord, but they are most frequently derived from bone marrow. In culture, they exhibit fibroblastic morphology. They easily adhere to plastic dishes and flasks and can be expanded in culture for several passages without loss of phenotype.

Osteogenic differentiation of MSCs can be stimulated in vitro by an induction media supplemented with dexamethasone, ascorbic acid (vitamin C), and β-glycerophosphate. Exposure to osteogenic media causes upregulation of alkaline phosphatase (ALP) activity and expression of two transcription factors that direct osteogenic differentiation, runt-related transcription factor 2 (Runx2) and osterix in MSCs during early stages of differentiation. During later stages, expression of matrix proteins including osteocalcin, osteopontin, and bone sialoprotein can be observed. Deposition of calcium within the ECM is also observed as osteogenic differentiation progresses (Table 48.1).

Adipose-Derived Stem Cells

Like bone marrow, white adipose tissue is mesodermally derived and contains endothelial cells, smooth muscle cells, and MSCs. The MSCs can be isolated from adipose tissue and expanded in culture. These cells (ADSCs) behave similarly in culture to MSCs obtained from bone marrow. They are multipotent and highly proliferative and can be obtained in large numbers with minimal invasiveness. ADSCs can be directed toward osteogenic differentiation with the same induction media used for MSCs. Given their similarities to bone marrow–derived MSCs, ADSCs are a clinically relevant cell source with potential for use in bone tissue engineering. However, compared with MSCs from other sources, the efficiency of osteogenic differentiation of ADSCs is low in both in vitro and in vivo

TABLE 48.1 Markers of Osteogenic Differentiation

Marker of Osteogenic Differentiation	Highest Expression During Stages of Osteogenic Differentiation	Function
Alkaline phosphatase (ALP)	Early	The function of ALP is not well-described; however, it is thought to have a role in promoting calcification of tissue [133].
Runt-related transcription factor 2 (Runx2)	Early	Runx2 is a transcription factor that activates osteogenic genes and has a role in cell fate determination of mesenchymal stem cell to osteoprogenitor cells [134].
Osterix	Early	Osterix is a transcription factor that acts downstream of Runx2 to direct osteogenic differentiation [135]
Osteocalcin	Late	Osteocalcin is the most abundant noncollagenous protein in bone extracellular matrix. It serves as a metabolic regulator of bone [136].
Bone sialoprotein (BSP)	Late	Extracellular matrix protein of bone that regulates the microenvironment of osteoblasts, hypertrophic chondrocytes, and osteoclasts. Regulates bone formation, mineralization, and turnover [137].
Osteopontin	Late	Similar to BSP, osteopontin is an extracellular matrix protein that regulates mineralization and bone matrix quality [138].

studies [11–13]. Therefore, many researchers have designed studies that aim to increase osteogenic differentiation of ADSCs by treating cells with osteogenic growth factors or introducing osteoconductive scaffolds [13].

Embryonic Stem Cells

ESCs are derived from fertilized embryos, typically donated from embryos that are not used after in vitro fertilization. These cells are grown in a plastic dish on a layer of feeder cells that maintain ESCs in their undifferentiated, pluripotent state. To differentiate ESCs, the cells are allowed to clump, forming embryoid bodies that can then be subjected to distinct culture conditions and develop into all three primordial germ layers. Direct differentiation of ESCs or differentiation of ESCs to an intermediate MSC stage can be used in tissue engineering applications [14]. Culture of committed cells is conducted in monolayer and supplemented with lineage-specific media conditions. Osteogenic differentiation media used to differentiate ESCs are the same combination of exogenous factors used for MSC differentiation. Although ESCs have greater capacity for self-renewal and can result in more tissue types compared with MSCs, ethical issues and complex culture requirements complicate their clinical and research use.

Nonetheless, human ESCs (hESC) or hESC-derived mesenchymal progenitor cells have been seeded onto an osteoconductive nanofibrous scaffold and subsequently treated with osteogenic factors. These culture conditions guide the osteogenic differentiation of hESC-derived cells in three dimension (3D) and demonstrate the potential role of hESCs in bone tissue engineering [14,15].

Induced Pluripotent Stem Cells

As an alternative to the controversial use of ESCs, iPSCs were developed to have the same capacity for self-renewal and pluripotency as ESCs. These cells are adult cells that have been reprogrammed to behave like ESCs. When iPSCs were initially described in 2006, researchers exposed mouse embryonic or adult fibroblasts to four factors under culture conditions used to maintain ESCs. The resulting cells had the same morphology, growth properties, and gene expression as ESCs and formed tumors of all three germ layers [16]. These cells were referred to as iPSCs.

The innovation of iPSCs was revolutionary to the field of stem cell biology, because it opened new areas of research into cell fate determination. It also opened the door to the use of iPSCs in tissue engineering. Several studies combined iPSCs or iPSC-derived cells with tissue engineering constructs to regenerate bone. In tissue engineering, one of the most appealing characteristics of iPSCs is that they originate from a patient with a tissue defect. The ability

to isolate and proliferate a patient-specific cell source would alleviate the risks in tissue engineering of allogenic graft rejection or disease transmission.

Several methods and several adult cell types are being used to generate iPSCs. The most common of these methods is exposure of cells to exogenous factors, genetic modification by viruses, and other methods of genetic alteration [17,18]. Researchers are pursuing methods that increase the efficiency of reprogramming and reduce the risk for tumor formation [17,19–22]. As methods improve to reprogram adult somatic cells, so does the variety of cell types that can be reprogrammed to iPSCs. In humans, dermal fibroblasts are among the most common cells used for iPSC generation. Other cell types that have been reprogrammed include dental and oral cells, cord blood cells, and peripheral blood cells [23].

Human and murine iPSCs show promise for osteogenic differentiation [24,25] and in bone tissue engineering [26–31]. Like other cell types, human iPSCs and cells derived from iPSCs can be seeded onto scaffolds and differentiated bone-forming osteoblasts.

SCAFFOLDS FOR BONE TISSUE ENGINEERING

Scaffolding Design Criteria

Scaffolds engineered for bone regeneration are designed to support cell adhesion, migration, proliferation, and differentiation [7,32–34]. Key features of a supportive architecture for bone tissue engineering scaffold include a controlled porous microstructure, high interconnectivity between pores, mechanical stability, a controlled degradation rate, and osteoconductive interaction with cells. The porous microstructure facilitates the ingrowth of cells and enhances the regeneration of tissue. Interconnectivity of pores allows for uniform cell seeding and nutrient exchange. Scaffolds are designed to degrade at controlled rates to match the rate of formation of new tissue. Finally, the structure and microenvironment of scaffolds are conducive to differentiation of precursor cells into osteoblasts and to support functional activities of osteoblasts in bone regeneration. In addition, it was found that a fibrous nanostructure could enhance osteoconductive characteristics of scaffolds for bone tissue engineering [35]. Nanofibers mimic the native ECM of bone and nanofibrous scaffolds support enhanced osteogenic differentiation compared with non-nanofibrous scaffolds. Nanofibrous scaffolds were shown to enhance osteogenic differentiation in vitro and heal critical size calvarial defects better in a rat model compared with solid-walled scaffolds [36,37].

To fabricate porous 3D scaffolds and microspheres for bone regeneration, a variety of processing techniques have been developed. These include solvent casting/particulate leaching [38,39], gas foaming [40,41], emulsion freeze-drying [42], electrospinning [43,44], rapid prototyping [45,46], and thermally induced phase separation (TIPS) [47–49]. Each of these methods has advantages and disadvantages that are discussed at length in several review articles [7,35,50–52]. This chapter will not provide an exhaustive description of processing techniques. Instead, it will focus on how scaffolding design can be used to improve bone tissue engineering with respect to porosity, interconnectivity, mechanical strength, elastic modulus, morphology, and surface properties.

Porous and Highly Interconnected Scaffolds

The porosity and interconnectivity of pores in scaffolds are important for uniform distribution of cells when seeded on a scaffold. A classical method to obtain porous scaffolds is the solvent casting/salt leaching method [38]. The process involves casting a mixture of polymer solution and salt (NaCl) into a mold. Subsequent drying of the mixture and leaching of the salt with water result in a porous structure. The pore size and porosity of the scaffolds fabricated using this method can be controlled by the particle size of the added salt and the salt-to-polymer ratio. This method produces scaffolds with limited interpore connectivity, which limits its value in tissue engineering.

To create a scaffold with highly interconnected pores and a spherical pore shape, paraffin spheres and sugar spheres were used a porogen [53,54]. The interconnectivity of the scaffold was finely tuned by changing the heat treatment time to bond the paraffin spheres. Meanwhile, changing the concentration of polymer solution, size of paraffin spheres, and number of casting steps controlled the porosity and pore size. Together, this approach allowed for the creation of porous scaffolds with high interconnectivity, which is critical to the uniformity of cell seeding and tissue ingrowth on the scaffold.

Nanofibrous Scaffolds for Bone Tissue Engineering

It is well-established that the ECM has a critical role in regulating cell behavior [55]. As previously noted, one of the key design features in bone tissue engineering has been the development of scaffolds with fibrous nanostructures that mimic native ECM and support cellular attachment, differentiation, and proliferation. Therefore, scaffolds were designed with nanofibrous structures that resembled the collagen fibers present in native ECM [56]. Collagen nanofibers were shown to have an integral role in cell adhesion, proliferation, and differentiation as early as the 1980s. To create poly-L-lactic acid (PLLA) scaffolds with nanofibers that resembled collagen fibers, a liquid–liquid phase separation technique was developed by integrating sugar sphere template leaching with phase separation [57]. The resulting nanofibrous PLLA (NF-PLLA) matrix featured fibers with diameters ranging from 50 to 500 nm, or within the same range of collagen fibers [49,53,58,59]. Fig. 48.1.

The combination of techniques to make porous materials and techniques to make nanofibrous materials produced scaffolds with biomimetic nanostructures and porous microstructures, which incorporate the advantages of both synthetic materials and natural structures for bone tissue engineering.

Nanofibrous materials have been successfully fabricated using electrospinning for applications in bone tissue engineering. Electrospinning uses an electric field to overcome the surface tension of polymer solutions. This causes the polymer to be ejected out of a needle to a conductive collector, resulting in fibers on the nanoscale to submicroscale [35]. Early electrospun scaffolds for bone tissue engineering were made of poly-ε-caprolactone (PCL) as the biodegradable polymer of choice [60–62]. Today, electrospun scaffolds are made from a variety of synthetic and natural polymers and can also be combined into composite scaffolds, as described in the next section. Several different electrospun scaffolds for bone tissue engineering have been described, including one method that used PLLA nanofibrous scaffolds that were produced by both thermally induced phase separation and electrospinning, and enhanced by surface calcium phosphate deposition for bone tissue engineering [63,64].

Composite Materials for Bone Tissue Engineering Scaffolds

The makeup of natural bone ECM is a combination of fibrous proteins, primarily collagen, upon which mineralized calcium is deposited [55]. In bone regeneration, researchers often attempt to replicate the natural ECM by synthesizing polymers from natural or synthetic building blocks. Because of intrinsic limitations of individual polymers, it is challenging to create a tissue engineering scaffold using a single material source that incorporates the fibrous microstructure of native ECM and supports sufficient mineralization. There are key limitations to each individual material, as no "perfect" single material exists for bone tissue engineering. Researchers therefore combine materials in various ways to form composite scaffolds that possess the advantageous qualities of each component material and better support the physical and biochemical requirements of bone regeneration. Integration of a mineral component into a fibrous scaffold can contribute to both the structural integrity and osteoconductive activity of the scaffold [35].

A variety of synthetic materials have been developed for bone tissue engineering, including PLLA, poly(lactic-*co*-glycolic acid) (PLGA), and poly(glycolic acid). Similarly, collagen, hydroxyapatite (HAP), decalcified bone matrix, chitosan, and other natural materials have been used in bone regeneration applications. The goal of composite scaffolds is to have a biocompatible, osteoconductive matrix with suitable mechanical properties to support bone regeneration.

One early composite matrix was made from combining synthetic polymer with ceramic through thermally induced phase separation. These scaffolds, made from highly porous poly(α-hydroxy acids)/HAP, had significantly improved physical properties (compressive modulus and yield strength) compared with pure polymer scaffolds. They also improved cellular ingrowth, increased osteoblast survival rate, and enhanced bone-specific gene expression [59,65,66]. Alternatively, coating a polymeric scaffold with apatite particles can produce a composite scaffold with the improved ability to deposit calcium in bone regeneration [66,67].

Other composites have been developed in an effort to combine the advantageous qualities of different synthetic and natural materials [68–70].

Injectable Scaffolds

Concurrent with the development of implantable 3D scaffolds for tissue engineering, researchers have sought to develop injectable scaffolds in the form of hydrogels, microspheres, or nanospheres.

Microspheres

An effort to fabricate microspheres with the same porosity and interconnectivity of 3D scaffolds yielded two new tissue engineering scaffolds. These particles retain the favorable characteristics of their implantable counterparts while having the potential for noninvasive treatment. The nanofibrous hollow microsphere (single pore) and the nanofibrous spongy microsphere (multiple pores) (NF-SMS) were created to mimic the physical characteristics of a 3D scaffold in an injectable format. Nanofibrous microspheres were made from linear PLLA create solid nanofibrous microspheres. By substituting linear PLLA with star-shaped PLLA in a surfactant-free emulsification technique, a hollow microsphere, with a single pore was developed [71]. By changing the number of arms on the star-shaped PLLA and altering its hydroxyl density, additional pores could be introduced, forming the NF-SMS [72]. These two novel microsphere scaffolds have shown promise for cartilage and dental tissue regeneration [71,73].

Other microsphere-based systems are used as cell carriers and/or drug carriers and are composed of synthetic, natural, or composite polymers [74–78]. These can be porous or nonporous and are used independently as tissue engineering platforms, or in combination with a 3D scaffold or hydrogel [79,80].

Hydrogels

Considerable research has been conducted into using hydrogels for bone regeneration. Hydrogels are polymer networks made of natural or synthetic components that are hydrophilic in nature and form viscous gels owing to 3D interactions between the polymer chains. These interactions can be either physical or chemical cross-linked between polymer chains. In bone tissue engineering, a number of hydrogels have served as a scaffold or used to deliver osteogenic drugs. An ideal hydrogel should be injectable so that it can be used to treat a bone defect noninvasively and fill abnormally shaped tissue defects. It should also be biocompatible and able to release osteogenic drugs over an extended time [81]. Controlled drug release remains a challenge for hydrogels because they are often prone to a burst release of drug within the first 24–48 h of treatment.

Hydrogels are often combined with other materials to form composite scaffolds for bone regeneration. PLLA/PCL nanoyarns were suspended in a collagen hydrogel to make a composite scaffold that showed benefits for in vitro differentiation of human MSCs [82]. In another study, 45S5 Bioglass was introduced into alginate, forming a composite hydrogel that demonstrated enhanced osteogenic potential with MC3T3-E1 osteoblast precursor cells [83]. A third study used a nanohydroxyapatite-reinforced chitosan hydrogel to stimulate osteogenic differentiation in vitro and bone regeneration in vivo [84]. These represent a small sampling of the many composite hydrogels being evaluated for bone tissue engineering.

Surface Modification and Functionalization of Scaffolds for Bone Regeneration

In an effort to increase the effectiveness of tissue engineering scaffolds, biologically active molecules can be attached to the surface or integrated within the scaffold. A specific molecule or peptide can be chosen to promote cell attachment and proliferation or direct cell differentiation [57,85,86]. For example, modification of poly(α-hydroxy acids) scaffold with gelatin enhanced osteoblast attachment, proliferation, and deposition of collagen [87]. Surface modification of a PLLA scaffold with calcium phosphate by electrodeposition enhanced osteogenic differentiation of MC3T3-E1 cells compared with cells attached to a control PLLA scaffold [64]. PEG hydrogels that are functionalized with integrin-specific peptides can enhance bone formation and vascularization when also treated with vascular endothelial growth factor [88]. Scaffolds can also be functionalized by the deposition of diamond nanoparticles. The addition of nanoparticles to a conventional scaffold can change the physical and chemical characteristics of the scaffold and enhance cell attachment and differentiation to support better bone formation [89]. Various additional methods and strategies for surface modification of scaffolds are being pursued [85,90].

Three-Dimensional Printed Scaffolds

3D printing technology is becoming increasingly capable of designing microenvironments and developing novel tissue engineering platforms. Many 3D printed scaffolds for bone regeneration have been developed that use many of the same natural, synthetic, and composite polymers discussed previously [91]. One approach to 3D printing scaffolds for bone tissue engineering is to print scaffolds that can be used to make vascularized bone grafts [92]. By varying the internal porosity of the scaffold or adding osteogenic and angiogenic factors such as zinc and silicon, researchers have attempted to increase the neovascularization of regenerated bone and simultaneously enhance the osteogenic differentiation of progenitor cells [93–95]. The successes and challenges of current strategies, descriptions of 3D printing methodologies, and clinical progress of 3D printing for bone tissue engineering are covered in depth in relevant reviews in the literature [96–98].

GROWTH AND DIFFERENTIATION FACTORS IN BONE TISSUE ENGINEERING

Bioactive molecules, hormones, and nucleic acids can be used to enhance the growth and differentiation of cells. The effective combination of these factors with tissue engineering constructs and drug delivery systems can improve the regeneration of bone both in vitro and in vivo.

Bone Morphogenetic Proteins

A group of proteins within the transforming growth factor-β superfamily, known as BMPs, have various roles in bone development, as well as the development of a multitude of tissues within the human body. Fifteen BMPs have been identified; of those, BMP-2 and BMP-7 show the most robust activity to induce bone formation. Both BMP-2 and BMP-7 have been used clinically in US Food and Drug Administration (FDA)-approved devices to treat a narrow range of severe bone defects.

BMPs act on bone-forming osteoblasts, preosteoblasts, and other precursor cells, including MSCs, ADSCs, iPSCs, and ESCs. Typically, BMPs form homodimers and bind with known BMP receptors to activate a cascade of signaling pathways that initiate differentiation and mineralization of cells and tissue. Some evidence of BMP-2/7 heterodimers having a stronger osteogenic effect than the respective homodimers has been published [99,100]. BMP-2 and BMP-7 act to stimulate osteogenic differentiation through intracellular phosphorylation of the smad

1/5/8 proteins. Upon phosphorylation, p-smad 1/5/8 proteins translocate to the nucleus and upregulates Runx2. BMPs can also activate other pathways in parallel, including Wnt signaling [101]. BMP-related signaling is generally divided into either smad-dependent or smad-independent, depending on which pathway is being described or studied.

The clinical use of BMP-2 began after its approval by the FDA in 2002 for the treatment of anterior lumbar interbody fusion within a threaded titanium tapered cage. The scope of its use expanded in 2004 to include tibial nonunions, and in 2007 for oral maxillofacial reconstruction. After the expanded use of BMP-2 for these clinical and other off-label applications, a number of serious side effects were observed and reported [102]. Inflammatory complications, including swelling of the cervical spine [103], radiculopathy [104], ectopic bone formation [105,106], osteoclast activation [107,108], urogenital events [109], and wound complications were reported [102].

For in vitro bone regeneration, BMP-2 and BMP-7 are applied in concentrations ranging from 50 to 100 ng/mL. For in vivo applications, encapsulation of BMP-2 and BMP-7 in a drug delivery system can provide local, clinically relevant doses for short or long time. This is often accomplished by encapsulating BMPs in a delivery vehicle such as a biocompatible polymer microsphere or hydrogel. Controlled release of recombinant human BMP-7 in a microsphere delivery system enhanced a bone tissue engineering scaffold in a subcutaneous mouse model [110].

Parathyroid Hormone Delivery

Parathyroid hormone (PTH) is secreted by the parathyroid glands and can have both catabolic and anabolic effects on bone [111]. It is well-known that a continuous and sustained treatment of PTH will lead to increased bone resorption or reduction in bone mass [112]. Conversely, an intermittent or pulsatile treatment of PTH can enhance osteogenesis or bone regeneration. PTH is used as an FDA-approved treatment of osteoporosis, which requires daily injections of a sufficient dose to be effective. A novel approach to PTH delivery uses a multilayered scaffold to achieve local pulsatile release of PTH to stimulate bone regeneration. Layers of PTH are separated by layers of polyanhydride (PA) and sealed with PCL. Surface erosion of PA allows the sequential release of PTH from the scaffold in controlled doses. Using this approach, a daily spike in PTH was observed and corresponded to superior healing of a critical-size defect in a calvarial mouse model [113] (Fig. 48.2).

Nucleotide Delivery and Gene Therapy

Nucleic acids (DNA, RNA, small interfering RNA, and microRNA [miRNA]) regulate gene and protein expression in cells. There are several methods to enhance or suppress the expression of specific proteins or genes that are involved in healing or new tissue formation.

The goal of gene therapy is to increase or sustain the local expression of factors related to healing, cell recruitment, cell proliferation, or cell differentiation. This is most frequently accomplished by delivering nonintegrating plasmid DNA or inserting additional copies of the desired genes into the chromosomal DNA. Transfer of genes to cells at the site of injury can be accomplished by viral and nonviral delivery methods [8,114]. Transcription and translation of these additional gene copies can enhance the expression of factors that promote healing.

For bone regeneration, gene therapy often involves modulating the temporal and spatial expression of BMPs [115,116]. The use of adenovirus vectors allows researchers to transfect progenitor or differentiated cells with additional copies of genes that enhance regenerative processes. In one example, adenoviral gene transfer was used to elicit the expression of BMP-7 from muscle cells. These cells were then implanted into femoral defects to evaluate their regenerative potential [117]. Although gene transfer can be effective, improvements are needed in the efficiency, stability, and safety of these methods.

In a nonviral approach, a gene vector that incorporates a plasmid encoding for BMP-2 is protected by a poly(D,L-lactide) (PDLLA) copolymer and delivered to a mandibular defect [118]. In this strategy, the gene vector is delivered on a PDLLA scaffold to induce cells localized at the site of injury to express BMP-2 and improve regeneration of the bone defect. In a similar approach, a BMP-7 plasmid enhanced by a heparin-binding site is transfected into MSCs and applied to regenerate bone defects [119].

Local delivery of nucleic acid molecules is another promising novel approach to bone regeneration. In particular, applications that use miRNA are being developed to enhance pro-osteogenic factors or suppress antiosteogenic factors [120]. Controlled release of miRNA-26a demonstrated a significant regenerative capability in an in vivo osteoporotic mouse model. In this example, miRNA-26a increased bone regeneration and healing by targeting a known inhibitor of osteoblastic activity, glycogen synthase kinase-3β [121]. Polymer−miRNA complexes (polyplexes) were

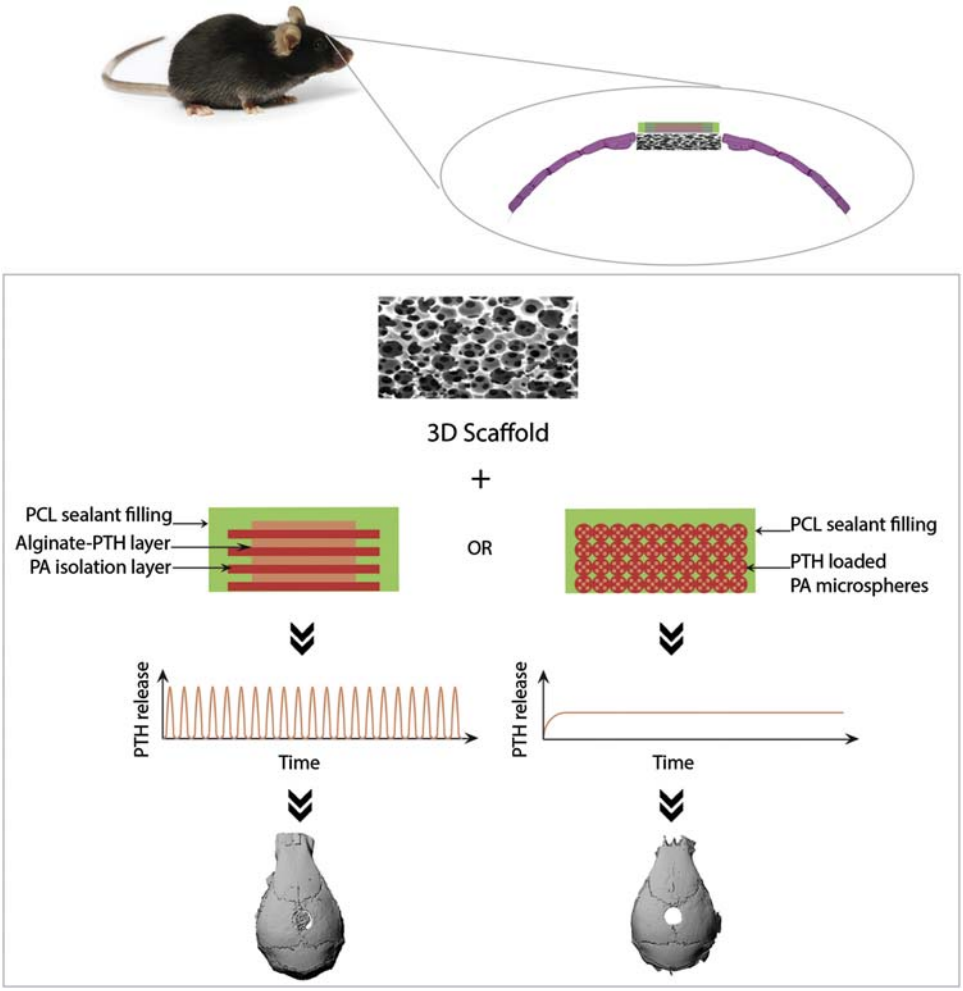

FIGURE 48.2 Experimental design of using a three-dimensional (3D) cell-free scaffold and a parathyroid hormone (PTH) deliver device (pulsatile or continuous) to repair calvarial bone defect in a mouse model. *PA*, polyanhydride.

created by mixing miRNA-26a and hyperbranched polyesters with affinity to miRNA-26a. These polyplexes were encapsulated in PLGA microspheres and were subsequently immobilized on a nanofibrous PLLA scaffold. The polyplex–microsphere–scaffold platform was surgically implanted in critical-size calvarial defects in osteoporotic mice. Efficient intracellular delivery of the miRNA was accomplished in a stepwise manner. As the PLGA microspheres were hydrolyzed, the miRNA-26a–containing polyplexes were released from their interior. These polyplexes were subsequently engulfed by cells via endocytosis. Endosomal escape allowed release of the miRNA into the cytoplasm of the cell. Fig. 48.3 Intracellular release of miRNA-26a in osteoblasts increased bone mass and increased expression of early and late genetic markers of osteogenic differentiation [121].

The advent of Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-9–associated (Cas9) gene editing technology has increased the efficiency by which researchers can manipulate the genome of mammalian cells and establish new cell lines for use in culture. Although CRISPR/Cas9 has increased the ability of researchers to study bone function and regeneration [122–124], no CRISPR-based therapeutic approaches have been developed to date.

IMMUNOMODULATION IN BONE REGENERATION

During the natural process of healing of a bone injury, the inflammatory and immune response activates several distinct cell types that can directly or indirectly interact with progenitor cells, osteoblasts, and osteoclasts [125–127]. Methods to modulate these interactions are being developed to enhance bone regeneration therapies.

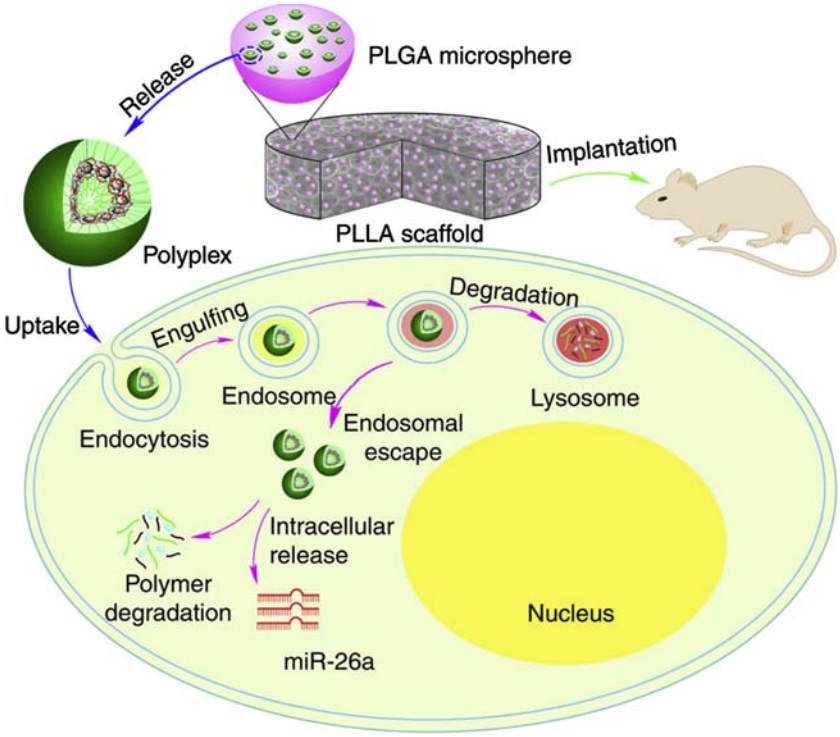

FIGURE 48.3 Hyperbranched polymers (HPs) and microRNA (miRNA) formed polyplexes in water. The HP—miRNA polyplexes were encapsulated into the poly(lactic-*co*-glycolic acid) (PLGA microspheres) via the double-emulsion method, and the PLGA microspheres containing the HP—miRNA polyplexes were then attached on the poly-L-lactic acid (PLLA) nanofibrous scaffold. The PLGA microsphere-incorporated PLLA scaffolds were implanted into mice. The HP—miRNA polyplexes released from the PLGA microspheres (on the PLLA scaffold) could be taken into cells through endocytosis. Intracellular release of miRNA in the cytosol after enzymatic polymer degradation allows its regulation of gene expression.
